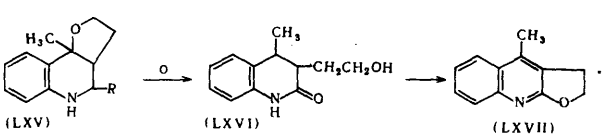
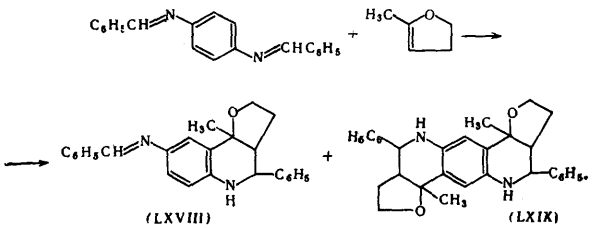
The reactions of unsaturated ethers with Schiff bases proceed stereospecifically with the formation of a single addition product. Only in certain instances were low-melting isomers isolated in an insignificant amount, their infrared spectra being identical with those of the high-melting addition products[104]. The ratio of the isomers depends on the reaction temperature. At an elevated temperature the amount of the low-melting isomer can become predominant as was shown by the example of the reaction of benzylidene-*p*-methoxycarbonylaniline with dihydrosylvan[19]



The anils of cinnamaldehyde and citral gave addition products (LXV) containing a vinyl group in position 2:[101]

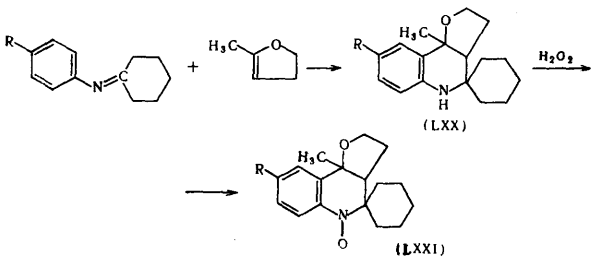
(LXV)

where R = $-CH=CH-C_6H_5$; $-CH=C(CH_3)CH_2CH_2CH=C(CH_3)_2$.



In the oxidation of addition products (LXV) with $KMnO_4$ in both instances 3-(2-hydroxyethyl)-4-methylquinol-2-one (LXVI) was obtained[108], which is readily cyclised under the action of polyphosphoric acid into 4-methyl-2,3:2′,3′-dihydrofuranoquinoline (LXVII):

(LXV) (LXVI) (LXVII)

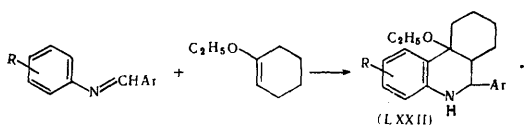


These conversions showed the structure of addition products (LXV), which was also confirmed by infrared spectra.

In the reaction of dihydrosylvan with bis-*N*-benzylidene-*p*-phenylenediamine [19] mono- (LXVIII) or bis- (LXIX) addition products can be obtained, depending on the ratio of the reagents:

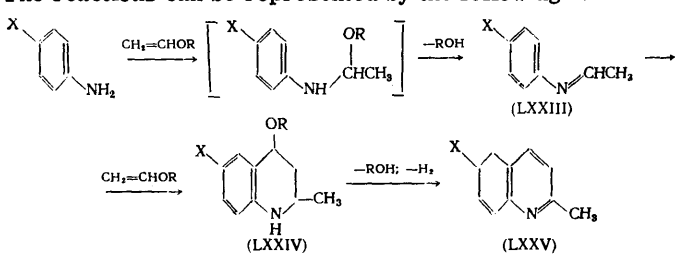
(LXVIII) (LXIX)

The reaction of dihydrosylvan with cyclohexanone anils [101,109,110] leads to addition products (LXX), which contain a spirocyclohexyl substituent in position 2. Their oxidation with hydrogen peroxide in the presence of sodium tungstate gave [109-111] stable nitroxide radicals (LXXI):



(LXX) (LXXI)

where R = H, OCH_3.

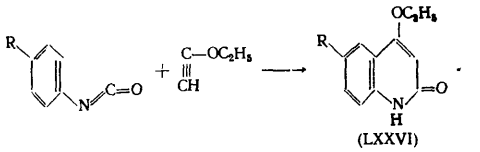


The reaction of cyclohexylidene-1-naphthylamine and cyclohexylidene-2-naphthylamine with dihydrosylvan [109] was used to synthesise 7,8- and 5,6-benzo-derivatives of quinoline of type (LXX), from which stable nitroxide radicals were also obtained.

The reactions of Schiff bases with cyclohex-1-enyl ethyl ether [102] is of special importance since here hydrogenated 9-arylphenanthridines (LXII) are formed:

(LXXII)

Povarov and Mikhailov [105] showed that the anils of aliphatic aldehydes are capable of diene condensations with alkyl vinyl ethers. The reaction conditions were such that the anils of acetaldehyde (LXXIII) reacted with the alkyl vinyl ethers at the moment of formation. This occurred in the reaction of aromatic amines with alkyl vinyl ethers in the presence of boron trifluoride. During this, 4-alkoxy-1,2,3,4-tetrahydroquinaldines (LXXIV) were formed, which under the action of *p*-toluenesulphonic acid were converted into the corresponding quinaldines (LXXV). The reactions can be represented by the following scheme:



(LXXIII) (LXXIV) (LXXV)

where X = H, OCH_3, Br; R = C_2H_5, C_4H_9.

The reaction usually starts at 30–35°C and subsequently proceeds with liberation of heat. The yields of tetrahydroquinaldines (LXXIV) are 30–50%. In the condensation of 2-naphthylamine with butyl vinyl ether, 5,6-benzoquinaldine was obtained directly.

On other reactions of nitrogen heterodienes with unsaturated ethers the literature contains only a few examples of the condensation of ethoxyacetylene with arylisocyanates [112,113], as a result of which 4-ethoxyquinol-2-ones (LXXVI) were obtained:

(LXXVI)

This reaction has been carried out with phenyl, *p*-tolyl, 1-naphthyl, and *p*-nitrophenyl isocyanates. After 6 months at room temperature an addition product of phenyl isocyanate with ethoxyacetylene was obtained in 42% yield. Resinification occurred at high temperatures.

III. Acetylene–allene rearrangement 675
IV. Acetylene–allene–cumulene rearrangement 678
V. Rearrangement of acetoacetates and of acetates of acetylenic alcohols 679
VI. Rearrangement of acetylenic compounds containing other functional groups 679

INTRODUCTION

After the discovery of the isomerisation of acetylenic hydrocarbons, the rearrangement of acetylenic compounds containing the most diverse functional groups became the subject of many investigations. It was found that acetylenic, vinylacetylenic, and diacetylenic compounds which contain a hydroxyl group, halogens, sulphur, nitrogen, phosphorus, etc. smoothly undergo various rearrangements with the formation of isomeric compounds. Most of these rearrangements are unique, and often the only method of making previously inaccessible new classes of unsaturated alcohols, aldehydes, ketones, and other compounds.

A review of rearrangements of acetylenic compounds has not appeared in the literature, with the exception of Jasiobedzki's article [1] dealing only with the acetylene–allene rearrangement.

In the present article we have tried to collect, and as far as possible, systematise the very interesting and abundant material relating to this subject which has now accumulated.

I. PROTOTROPIC REARRANGEMENT OF ACETYLENIC HYDROCARBONS

During the synthesis of acetylenic hydrocarbons from dihalogenoalkyls Favorskii [2] found that instead of the expected monosubstituted acetylenes disubstituted compounds are obtained. He concluded that under the conditions of the experiment isomerisation of the triple bond along the chain occurred. Subsequently he and his coworkers [3-8] found that various alk-1-ynes isomerise into the

corresponding alk-2-ynes when heated with alcoholic potassium hydroxide solution to 170°C:

$$R{-}CH_2C{\equiv}CH \rightarrow R{-}C{\equiv}C{-}CH_3.$$

On heating disubstituted acetylenes with metallic sodium the reverse process takes place, that is, they are converted into monosubstituted acetylenes[9-15]:

$$R{-}C{\equiv}C{-}CH_3 \rightarrow R{-}CH_2C{\equiv}CH.$$

Hence Favorskii discovered the very interesting reversible isomerisation of acetylenic hydrocarbons [alkynes]. Detailed study of the mechanism of this reaction led the authors to conclude that it proceeds through allenic compounds according to the scheme:

$$R{-}CH_2C{\equiv}CH \rightarrow R{-}CH{=}C{=}CH_2 \rightarrow R{-}C{\equiv}C{-}CH_3.$$

Direct confirmation of this is provided by the fact that under analogous conditions[2,10,16-19] allenic hydrocarbons are isomerised into acetylenes.

Subsequently an analogous rearrangement was observed also in the dehydrohalogenation of polyhalogeno-compounds by sodium amide[20-23].

Isomeric conversions of acetylenic hydrocarbons were widely studied[24-47]. Various examples showed that the triple bond can migrate to either the middle[24-42] or the end[42-47] of the chain.

It must be noted that in dehydrohalogenation by solid or molten alkali without a solvent the specified isomerisation proceeds very weakly or is generally not observed[16].

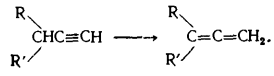
It has been found that in several instances dehydrohalogenation of polyhalogeno-compounds often leads, not to the expected non-conjugated alkadiynes, but to conjugated alkadiynes[16,48-52]:

$$CH_2BrCHBrCH_2CH_2CHBrCH_2Br \rightarrow \begin{cases} HC{\equiv}C{-}CH_2CH_2C{\equiv}CH \\ H_3C{-}C{\equiv}C{-}C{\equiv}C{-}CH_3 \end{cases}.$$

Recently a series of authors[53] have also studied the isomeric conversions of various alkadiynes.

Thus it has been shown that when non-conjugated diacetylenes are heated with alkaline agents (potassium hydroxide, sodium amide, etc.) they are isomerised into conjugated diacetylenes[53-55]. When the reaction is carried out in the presence of potassium t-butoxide, both vinylacetylenic and diacetylenic hydrocarbons are converted into conjugated polyenes and polyenynes respectively[56,57]:

$$\begin{array}{ll} RC{\equiv}CCH_2CH_2C{\equiv}C{-}R' & R{-}C{\equiv}CCH_2CH_2C{\equiv}C{-}R' \\ \downarrow & \downarrow \\ R{-}CH{=}CHCH_2C{\equiv}C{-}R' & R{-}CH{=}C{=}CHCH_2C{\equiv}C{-}R' \\ \downarrow & \downarrow \\ R{-}(CH{=}CH)_3R' & R{-}(CH{=}CH)_2C{\equiv}C{-}R' \end{array}.$$



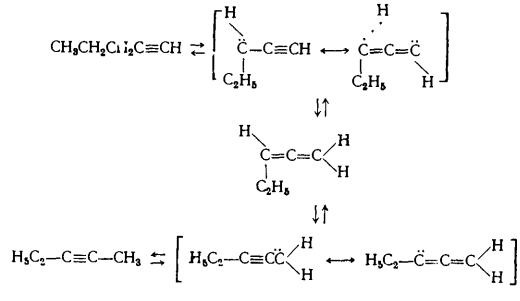
In the presence of potassium t-butoxide various cyclic polyacetylenes are converted into conjugated enynes[58-62] or dienes[63].

As well as the catalysts mentioned, metal oxides, fluorides, and other catalysts have been used for the rearrangement of acetylenic hydrocarbons[64-80]. The isomerisation of acetylenic[7,8,81,82] or vinylacetylenic[83] hydrocarbons was also observed during their alkylation by methyl iodide in the presence of metallic sodium.

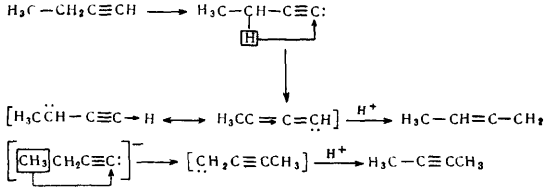
Usually the isomerisation of acetylenic hydrocarbons takes place at 160–250°C. Isomerisation does not occur at lower temperatures[34,84,85]. It has been shown experimentally[86] that isomerisation proceeds readily when in monosubstituted acetylenic compounds there is a primary radical at the acetylenic carbon atom:

$$R{-}CH_2C{\equiv}CH \rightarrow R{-}C{\equiv}C{-}CH_3.$$

With a secondary substituent at the carbon atom the isomerisation proceeds only to the allene compound:



When the substituent in these compounds is a tertiary radical, isomerisation generally does not occur.



After detailed study of the reaction of mutual conversions of acetylenic compounds, Favorskii[86] concluded that the isomerisation of acetylenes in alcoholic solutions takes place not by addition and loss of the alcohol, as he thought earlier[2], but simply by jumping over of the β hydrogen atom with simultaneous migration of a multiple bond:

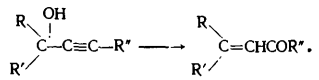
In the opinion of Jacobs and coworkers[75] and of other authors[87,88] under the action of alkali deprotonation of one of the labile α hydrogen atoms of the acetylenic or allenic compound takes place. Subsequently the intermediate carbonium ion which is formed rearranges according to the scheme:

Müller[89] suggests that in the isomerisation of acetylenic compounds the proton is detached not from the methylene but from the methine [presumably methylidyne (Ed. of Translation)] group; the anion formed undergoes cationotropic or prototropic rearrangement according to the scheme:

II. ANIONOTROPIC REARRANGEMENT OF ACETYLENIC ALCOHOLS

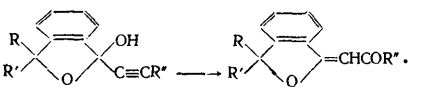
1. Rearrangement of Acetylenic Alcohols into $\alpha\beta$-Unsaturated Ketones. The Meyer–Schuster Rearrangement

In studying the reaction of acetyl chloride with phenylethynyldiphenylcarbinol [1,1,3-triphenylprop-2-yn-1-ol],



Meyer and Schuster[90] isolated phenylbenzalacetophenone [β-phenylchalcone]:

The authors found that this ketone was the only product when acetyl chloride was replaced by thionyl chloride, hydrogen chloride, acetic anhydride, or sulphuric acid. They showed, by the example of phenylethynyldi-(*p*-chlorophenyl)carbinol [1,1-di-(*p*-chlorophenyl)-3-phenylprop-2-yn-1-ol] that in the above rearrangement it is the hydroxyl group, not the aromatic radical, that migrates:

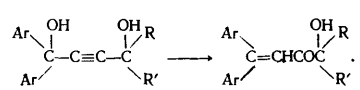


Subsequently various acetylenic alcohols with aliphatic, alicyclic, and aromatic substituents were subjected to rearrangements of this type in the presence of various acid agents[91-106]:

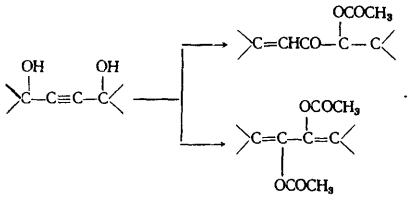
To obtain the best yield it was necessary to carry out the reaction in solvents; often dioxan, acetone, alcohols, and esters of organic acids were used. Acids (sulphuric, formic, sulphonic, etc.) were used as catalysts.

Recently Venus-Danilova and her coworkers have shown that ethynyl derivatives of hydroxyphthaleins undergo the Meyer–Schuster reaction[107,108]:

It has been shown that the rearrangement of secondary acetylenic alcohols proceeds analogously[104]:



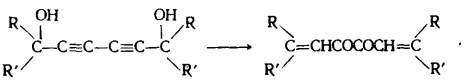
With acetylenic 1,4-glycols the rearrangement leads to the production of α-hydroxy-αβ-unsaturated ketones[109-111]:



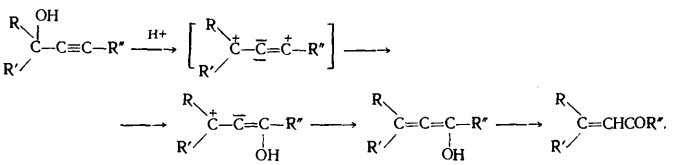
When the reaction is carried out in alcoholic solutions β-alkoxy-α-hydroxyketones or furanidones are formed[110-117].

In the rearrangement of primary-tertiary acetylenic glycols[118,119] under Meyer–Schuster conditions the hydroxyl group which migrates is that connected with the tertiary carbon atom.

In acetylenic glycols with aromatic and aliphatic substituents, on rearrangement it is the hydroxyl group at the carbon connected with the aromatic substituent that migrates[118-122]:



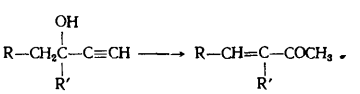
With alicyclic and aromatic symmetrical glycols both hydroxyls migrate, with the formation of acetates of keto-alcohols or diacetates of enols[118,123,124]:



In all instances when the reaction proceeds in the presence of acetyl chloride acetoxy-derivatives of the keto-alcohols produced are obtained.

It was shown recently that on heating diacetylenic glycols in methanol solution in the presence of mercury sulphate they undergo rearrangement with the formation of unsaturated α-diketones[125]:

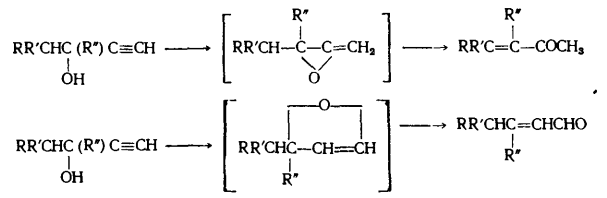
Dornow and Ische[126] suggest that the Meyer–Schuster rearrangement proceeds by a carbonium ion mechanism with formation of an intermediate vinyl alcohol and its subsequent isomerisation into a vinyl ketone:



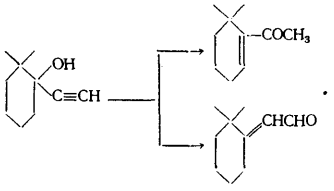
2. Rearrangement of Acetylenic Alcohols into αβ-Unsaturated Aldehydes and Ketones

The rearrangement of acetylenic alcohols with an active acetylenic hydrogen was first studied by Rupe and coworkers. They showed that when acetylenic alcohols react with formic acid they are rearranged into αβ-unsaturated aldehydes[127-135]:

Subsequent studies[136-138] did not confirm the results of Rupe and coworkers. The authors cited reported that αβ-unsaturated ketones, not aldehydes, are obtained in the rearrangement of acetylenic alcohols with active acetylenic hydrogen:



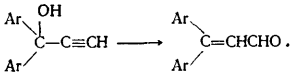
It must be noted that in the work there are no convincing data on the absence of the isomeric aldehydes.



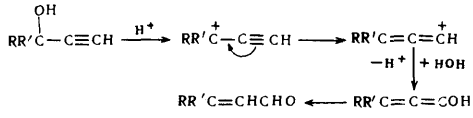
In later communications Rupe and coworkers also mention that ketones are also formed as well as aldehydes[131,134,139].

To explain the chemistry of the formation of aldehydes and ketones, the authors propose a mechanism for the

rearrangement with the intermediate formation of oxidic compounds [134]:

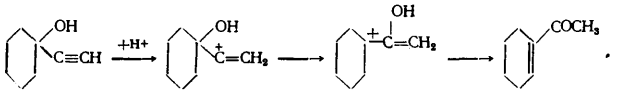


Chanley [140] showed convincingly that in the rearrangement of 1-ethynylcyclohexan-1-ol and its derivatives, in addition to ketones the corresponding $\alpha\beta$-unsaturated aldehydes are formed, in particular 1-ethynylcyclohexan-1-ol gives 50% of the expected ketone and 0.8% aldehyde, and 1-ethynyl-2,2-dimethylcyclohexan-1-ol gives 56% of the ketone and 6% of the aldehyde:

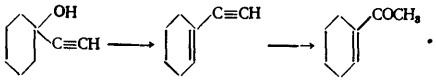


Despite this, in several papers the authors state that in the rearrangement of acetylenic alcohols with aliphatic [141-146], alicyclic [103,141,147-152], and aromatic [153] substituents only the $\alpha\beta$-unsaturated ketones are obtained. Other papers give results showing that in the isomerisation of a series of aliphatic [154-157] and alicyclic [158,159] acetylenic alcohols in addition to the ketones the corresponding $\alpha\beta$-unsaturated aldehydes are isolated.

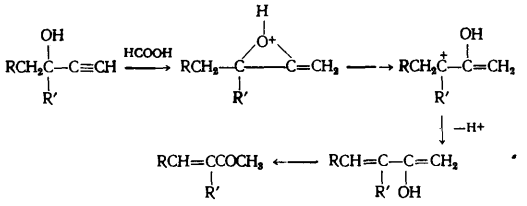
In contrast to the above results the rearrangement of aromatic acetylenic alcohols with an active acetylenic hydrogen leads to the formation mainly of the expected aldehydes [104 160-169]:



According to Bergmann [154], in the catalytic isomerisation of ethynyldimethylmethanol [2-methylbut-3-yn-2-ol] in the vapour phase β-methylcrotonaldehyde is formed in 30% yield. Other results have been published about the rearrangement of various acetylenic alcohols into aldehydes or ketones in the presence of various catalytic agents [170-176].



Hennion and coworkers [144] represent the mechanism of the rearrangement of ethynylcarbinols as an allyl rearrangement:



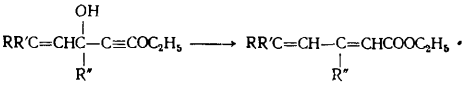
Newman [146,155] suggests that the rearrangement of ethynylcarbinols into $\alpha\beta$-unsaturated ketones proceeds by a carbocation mechanism:

Others think [138,144,177] that under the reaction conditions acetylenic alcohols are dehydrated into enynes and their subsequent hydration leads to the formation of ketones:

Cram and Hammond [178] explain the formation of $\alpha\beta$-unsaturated ketones by the following scheme:

It is evident that the mechanism of the formation of aldehydes and ketones from acetylenic alcohols has not been established and additional studies are needed.

3. Rearrangement of Alkoxyacetylenic Alcohols into the Esters of $\alpha\beta$-Unsaturated Acids

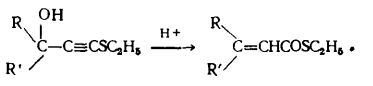


In the presence of sulphuric or hydrochloric acids alkoxyacetylenic alcohols undergo anionotropic rearrangement with the formation of the esters of $\alpha\beta$-unsaturated acids [179-182]:

Arens and coworkers [183] showed that alkoxyacetylenic alcohols are also rearranged in the presence of weakly basic amines, particularly in the presence of nitroaniline.

Heterocyclic [184], aldehydo- [185], and keto- [186] alkoxyacetylenic alcohols undergo this reaction.

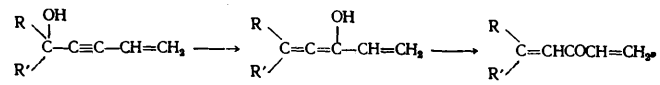
Esters of dienic acids are obtained in the rearrangement of vinyl(alkoxy)acetylenic alcohols [179,180,187]:



Alcohols in which the double bond is in the $\beta\gamma$-position or further removed undergo rearrangement in an analogous manner [187,189].

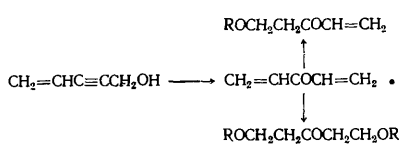
This reaction has been used for the preparation of perfumes [180,190], steroids [191-196], and terpenes [197]. Other studies of the rearrangement of various alkoxyacetylenic alcohols have appeared [198,199].

It has been shown that in the reaction of carbonyl-containing compounds with ethoxyacetylene in the presence of BF_3, esters of $\alpha\beta$-unsaturated acids are formed [200]:

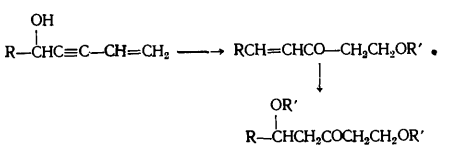


In the presence of acid agents thioacetylenic alcohols are also rearranged in an analogous manner [201,202]:

4. Rearrangement of Vinylacetylenic and Divinylacetylenic Alcohols



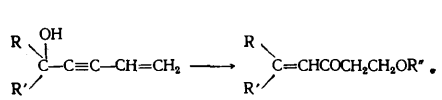
Nazarov and coworkers have shown that in acetone solution in the presence of mercury sulphate vinylacetylenic alcohols are isomerised into divinylketones by the following scheme[203,204]:



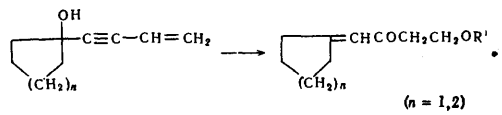
This reaction was carried out with a yield of ketone up to 40% for dimethyl(vinylethynyl)methanol [2-methylhex-5-en-3-yn-2-ol] alone. On increasing the molecular weight of the tertiary alcohol the reaction proceeds with difficulty and the yields of the divinyl ketones do not exceed 5% owing to side-reactions, particularly the dehydration and cyclodehydration of the alcohol.

It was found later that the isomerisation of vinylacetylenic alcohols takes place exceptionally readily in a solution of alcohols capable of adding to divinyl ketones. BF_3.HgO and mercury sulphate are catalysts for isomerisation[204,205]. The ease of isomerisation under these conditions (especially in methanol) is explained by the fact that the divinyl ketones formed are converted by addition of the alcohols into β-alkoxyketones and leave the sphere of reaction.

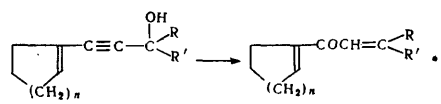
The isomerisation of the primary vinylethynylmethanol under these conditions leads to the formation of a divinyl ketone. Under the conditions of the experiment one or two methanol molecules add to the latter to form 1-methoxypent-4-en-3-one and 1,5-dimethoxypentan-3-one[206]:



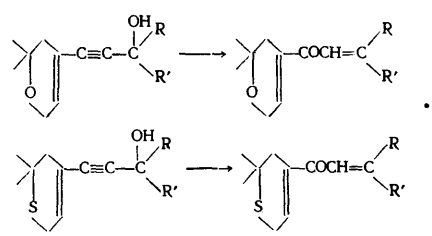
In solution in alcohols in the presence of mercury salts secondary vinylethynylmethanols are isomerised into divinyl ketones, which readily add one molecule of the alcohol at the unsubstituted vinyl group to form unsaturated alkoxy-ketones[207]:



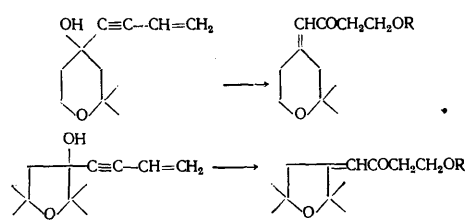
Under the influence of mercury salts a second alcohol molecule can be added to a β-alkoxyvinyl ketone to form dialkoxy-ketones.



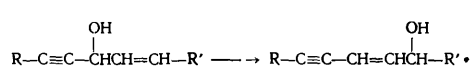
A still greater number of stages is observed in the addition of alcohols to ββ-dialkyldivinyl ketones [bis-(2-alkylvinyl)ketones]. Thus in the isomerisation of tertiary vinylacetylenic alcohols usually only one molecule of alcohol can be added to the divinyl ketones formed at the unsubstituted vinyl group and during this the corresponding unsaturated β-alkoxy-ketones are mainly formed[204,205,208,209]:



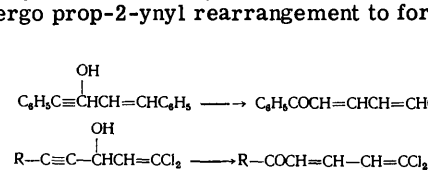
It has been shown that alicyclic vinylacetylenic alcohols are also rearranged with the formation of a mixture of the corresponding divinyl and β-alkoxy-ketones[210,211]:



The isomerisation of Δ′-cyclohexenylethynylmethanols[212] and also of Δ′-cyclopentenylethynylmethanols[213] leads to the formation of divinyl ketones:

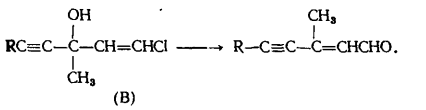


The isomerisation of vinylacetylenic alcohols which contain a vinyl group in the heterocyclic ring undergo isomerisation in an analogous manner[214-216]:



Many results on the rearrangement of vinylacetylenic alcohols containing various substituents have been published[217-226]. It has been found that 4-(vinylethynyl)tetrahydropyran-4-ols[226,227] and also vinylacetylenic furanols[228] undergo isomerisation with the formation of the expected ketones:

It is interesting to note that vinylacetylenic alcohols (A), depending on the nature of the substituent, undergo either allyl or prop-2-ynyl rearrangement. Thus the carbinols (A) undergo the allyl rearrangement[229-248]:

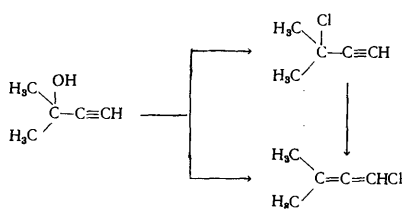


When R and R′ are electron-acceptor atoms or groups, particularly chlorine[102] or phenyl radicals[249], these alcohols undergo prop-2-ynyl rearrangement to form divinyl ketones:

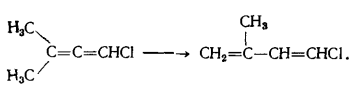
The prop-2-ynyl rearrangement is also observed when in the alcohols (A) R = C_6H_5 and R′ is a methyl[249] group or

hydrogen[169]. It is curious that the monochlorovinylacetylenic alcohols (B) undergo an allyl rearrangement under analogous conditions[250]:

(B)



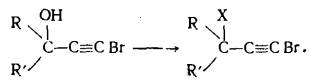
It has been found that diacetylenic methanols also rearrange in a similar manner[104]:



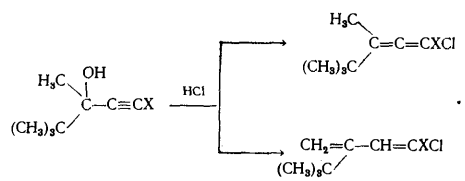
III. ACETYLENE–ALLENE REARRANGEMENT

1. Rearrangement of α-Halogenoacetylenes

Favorskii and Favorskaya found that reaction of dimethylethynylmethanol with hydrogen chloride in the presence of copper(I) chloride and ammonium chloride gives, in addition to the expected chloroalkyne, a derivative of allyl chloride[251]:



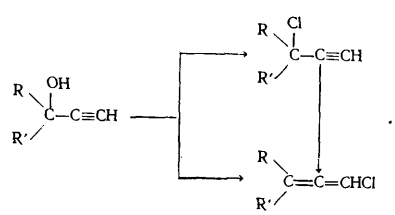
It was shown later that under the specified conditions chloroacetylene is actually rearranged into chloroallene[252]. On prolonged standing over ammonium chloride and copper(I) chloride, the latter is subjected to allene–diene rearrangement with the formation of the diene chloride[252]:



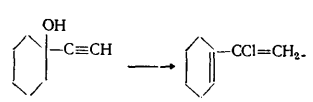
In studying the reaction of hydrogen chloride with dimethylethynylmethanol Hennion and coworkers[253] showed that when the reaction is carried out in the presence of calcium chloride, chloroacetylene is obtained in good yield. However, when the reaction is carried out in the presence of copper(I) chloride and ammonium chloride the main reaction product is allenyl chloride. An analogous picture is also observed with other acetylenic alcohols[143,254,255]. According to the results of Favorskaya[256–258] and others[143,259–261] this reaction proceeds similarly with hydrogen bromide. Campbell and coworkers[262] showed that in the reaction of hydrogen chloride with ethylethynylmethylmethanol the expected isomeric chloro-compounds are obtained. Favorskaya[263] showed that when this reaction is carried out in the presence of copper(I) chloride and ammonium chloride the chloroalkyne which is formed slowly rearranges into both the allenyl chloride [chloroalka-1,2-diene] and the diene chloride. When the reaction is carried out without catalysts[143] a chloroalkyne is mainly obtained.

Isomerisation of 3-chloro-3-ethylpent-1-yne proceeds even more slowly; a chloroalka-αβ-diene is still obtained but does not rearrange into the diene [chloride][264].

In the hydrochlorination of t-butylethynylmethylmethanol [3,4,4-trimethylpent-1-yn-3-ol] the sole product of the reaction is a chloroalka-1,2-dien[265]. Dialkyl(bromoethynyl)methanols react with hydrogen halides to form the corresponding halogenoalkynes[266]:



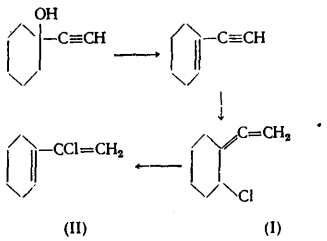
It was found also that t-butyl(halogenoethynyl)methylmethanols react with hydrogen chloride to give chloroalka-1,2-dienes[267] but the corresponding bromo-alcohols give mainly the bromoalka-1,3-dienes:



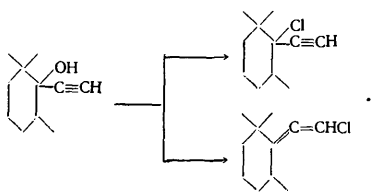
Dialkylethynylcarbinols react with hydrogen chloride[268,269] or phosphorus(III) chloride[270] to form chloroacetylene; however, according to the results of other authors[92], the action of hydrogen bromide on this alcohol gives, in addition to bromoalkynes, halogen derivatives of allene.

All attempts to carry out this reaction with other dialkylethynylcarbinols were unsuccessful[271,272]. The acetylene–allene rearrangement was also observed in the reaction of secondary acetylenic alcohols with hydrogen halides[255,273].

The reaction of aliphatic ethynylcarbinols with thionyl chloride[273,274] or phosphorus(V) chloride[275] in ethereal solution leads to the formation of two isomeric chlorides:



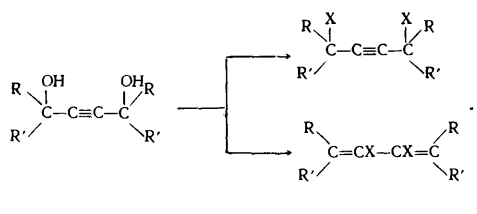
It should be noted that when a bromoallene derivative is formed in the reaction of tertiary acetylenic alcohols with $[(C_6H_5O)_3PBr_2]$, secondary and primary acetylenic alcohols form only bromoalkynes[261]. Jones and coworkers[276] found that thionyl chloride reacts with ethynylcyclohexanol in the presence of pyridine to give 1-chlorovinylhexene:



We think that a diene chloride could be obtained by the dehydration of an acetylenic alcohol followed by the addition of hydrogen chloride to the enyne formed in the 1,4 position to give an allenic chloride (I). The latter isomerises

under the conditions of the experiment into the diene chloride (II):

The formation of chlorides in the work of Bergmann and others[275] can be explained similarly.



In the reaction of ethynylcyclohexanol and other alicyclic ethynylcarbinols with thionyl chloride in the presence of pyridine in various solvents both acetylenic and allenic chlorides are formed[255,272]:

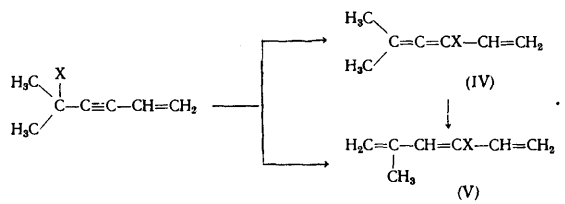
Acetylene–allene rearrangement was also observed in the reaction of thionyl chloride with aromatic acetylenic alcohols[278]. It was shown that when prop-2-ynyl halides are heated in the presence of copper salts they are rearranged into halogenoalka-$\alpha\beta$-dienes[279]; during this, partial isomerisation of the halogenoalka-$\alpha\beta$-dienes was also noted.

Other information on the rearrangement of halogenoacetylenes into halogenoalka-$\alpha\beta$-dienes is available[280-285].

The reaction of acetylenic glycols with hydrogen halides leads to the formation of dichlorodienes (III)[286-302] by the scheme:

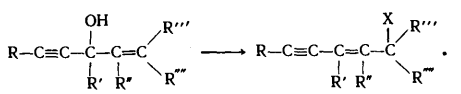
(III)

It was found that in the action of hydrogen halides on acetylenic 1,4-glycols hydroxyl is replaced by halogen and acetylenic dihalogeno-derivatives are obtained. Under the reaction conditions the latter undergo isomerisation into dihalogeno-derivatives of dienes.



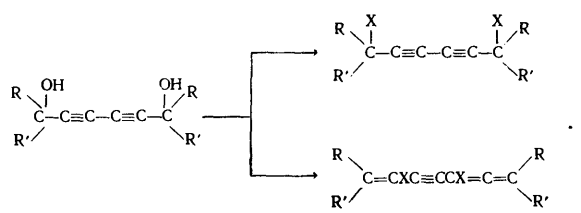
According to Johnson[109] 1,4-dibromo- or 1,4-di-iodobut-2-ynes are converted on standing into 2,3-dihalogenobutadienes:

$$XCH_2C{\equiv}CCH_2X \longrightarrow CH_2{=}CX{-}CX{=}CH_2.$$

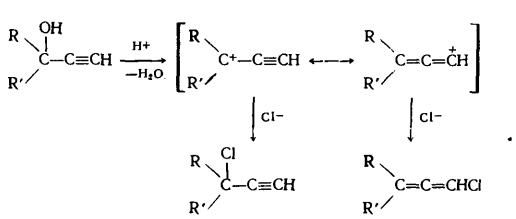


1,4-Dichlorobutynes rearrange similarly in the presence of copper(I) chloride and ammonium chloride[303].

Nazarov and coworkers[304] showed that on shaking chlorodimethyl(vinylethynyl)methane with copper(I) chloride and ammonium chloride at room temperature it undergoes rearrangement with the formation of allenic (IV) and trienic (V) chlorides.

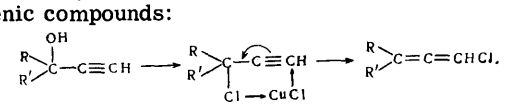


It is interesting to note that in the production of vinylacetylenic bromides only allenic (IV) and trienic (V) bromides are obtained[305]:

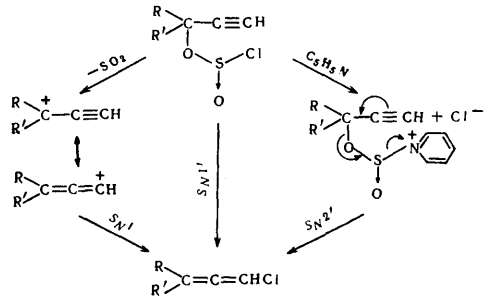


In contrast with this, in the reaction of the vinylacetylenic carbinols mentioned below with hydrogen chloride, thionyl chloride, or phosphorus(III) bromide the reaction passes through an allyl rearrangement[236,249,306-310]:

Diacetylenic glycols react with hydrogen chloride to form diacetylenic and diallenic chlorides[311]:

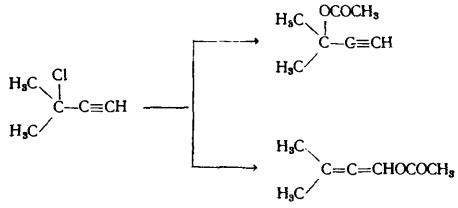


It is interesting that the reaction of hydrogen halides with diethynylquinols also proceeds through a rearrangement[312,313]. Hennion and coworkers[253,314-317] represent the mechanism of the reaction as follows. Under the influence of a proton initially hydroxyl is detached from the alcohol to form a carbonium ion; addition of a chloride anion to the latter leads to the formation of acetylenic and allenic chlorides:

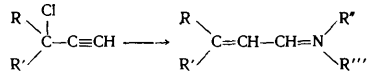


Other authors[302,318,319] regard the isomerisation of chloroalkynes analogously.

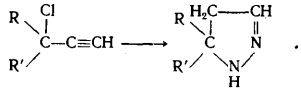
The isomerisation of chloroalkynes under the influence of catalysts is improbable, according to Hennion and coworkers[253,315], taking into account the linear structure of acetylenic compounds:



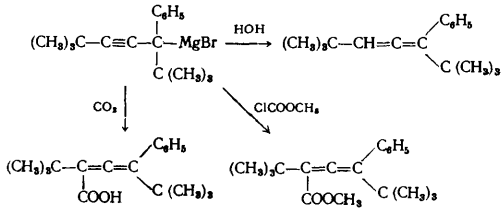
Other authors[259,320] suggest that a chloroalka-1,2-diene can be formed both by an S_N1 and by an S_N2' mechanism:



2. Rearrangement on Replacement of the Halogen in α-Halogenoacetylenes



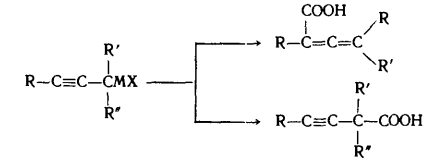
In the nucleophilic replacement of chlorine in α-chloroacetylenes the final product of the reaction is often the corresponding allene compound. Thus in the reaction of sodium acetate with chloroethynyldimethylmethane [3-chloro-3-methylbut-1-yne], in addition to an acetate derivative of acetylene the acetate of allenic alcohol [3-methylbut-1,2-dienyl acetate] is obtained[321]:



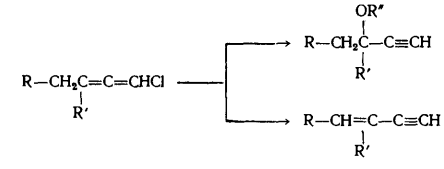
It was found recently that acetylenic chlorides react with substituted hydrazines to form the hydrazones of the isomeric aldehydes[322]:

With unsubstituted hydrazine instead of the acetylenic hydrazines 5,5-dialkyl-Δ^2-pyrazolines are obtained[323]:

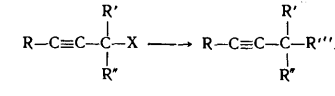
Marvel and coworkers[92] found that during the hydrolysis of an Iotsich complex obtained from an acetylenic chloride instead of the acetylenic hydrocarbon the corresponding allenic hydrocarbon was obtained. The acetylene–allene rearrangement is observed also in the reaction of an Iotsich complex with carbon dioxide or with methyl chloroformate[92]:



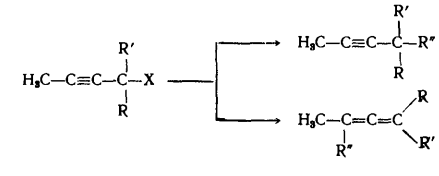
Isomerisation is not observed in the formation of magnesium or sodium derivatives from prop-2-ynyl bromides, but on standing the prop-2-ynylmagnesium complex is isomerised into the prop-1-ynyl complex[324]:



However, in making prop-2-ynylzinc bromide a mixture of acetylenic and allenic derivatives is formed, but with aluminium only a derivative of allene structure is obtained[324,325]:



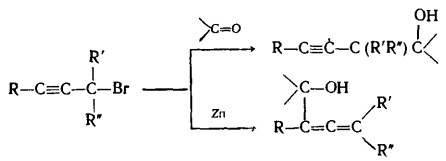
When the prop-2-ynyl Grignard complex reacts with carbon dioxide, a mixture of acetylenic and allenic acids is obtained[324,326-331]:



In halogenoalkynes with a halogen atom in β or other positions isomerisation was not observed[332]. It must be noted that an acetylene–allene rearrangement does not occur in the preparation of ethers from the corresponding alkyne chlorides and alcohols in the presence of alkali[314,333] and also in the replacement of halogen in various prop-2-ynyl halides by a variety of agents (amines, alkoxides, salts of acids, sodioacetoacetic ester and sodiomalonic ester[324]). In contrast to this in the replacement of allenic chlorides by a hydroxyl[252,255,333] or alkoxyl[314] group the reaction proceeds with rearrangement:

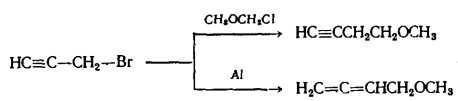
It was shown that when acetylenic chlorides react with Grignard complexes normal substitution products are obtained[334-336]:

However, in a more detailed study of this reaction, Zakharova noted that in addition to the normal substitution product rearrangement products are obtained—allenic hydrocarbons[337-339]:



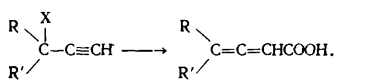
Subsequently the above results were confirmed by other authors[324,340-345] by various examples with primary, secondary, and tertiary acetylenic chlorides. Here allenic hydrocarbons are sometimes the main products of the reaction[346].

The rearrangement also takes place during the reaction of prop-2-ynylmagnesium bromide with dibutyl sulphate[347]:



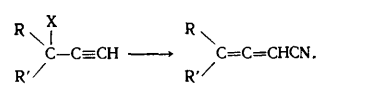
Lithium or sodium acetylides react with benzyl chloride to form allenic compounds[348].

In the presence of zinc acetylenic halides are condensed with aldehydes and ketones with the formation of β-hydroxyacetylenes or -allenes[325,349-351]:

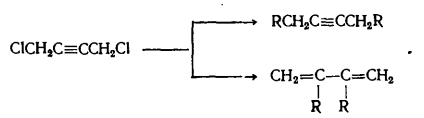


The above halides react similarly with esters[352] and with amides[349] of acids in the presence of metallic magnesium.

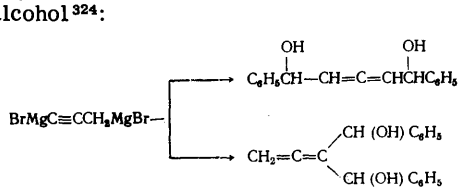
It is interesting to note that allenic Grignard complexes under these conditions form mainly acetylenic alcohols[325, 349,353,354]. The complex of prop-2-ynyl bromide with aluminium reacts with chlorodimethyl ether with the formation of a mixture of acetylenic and allenic esters[325]:



In the reaction of α-halogenoalkynes with tetracarbonylnickel in ethanol or water solution an acetylene–allene rearrangement takes place with the formation of the corresponding allenic acids or their esters[355,356]:

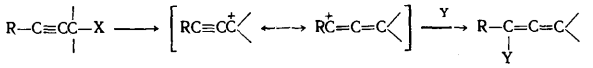


It has been shown that under the same conditions chloroallenes do not react[355], consequently the preliminary rearrangement of chloroacetylenes into chloroallenes and the subsequent course of the reaction is ruled out.

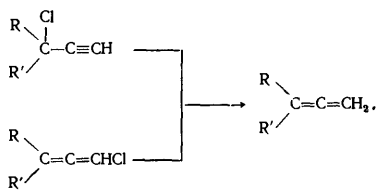


According to patent claims[357] α-halogenoalkynes react with sodium cyanide so that allenic nitriles are obtained:

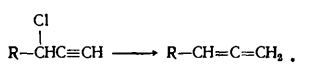
Levina and coworkers[358-360] showed that in the reaction of 1,4-dichlorobutyne with alkylmagnesium bromides a mixture of acetylenic and 1,3-dienic hydrocarbons is obtained:



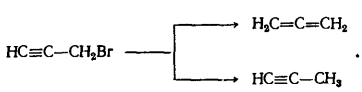
It was also found that the dimagnesium derivative of prop-2-ynyl bromide reacts with benzaldehyde to form an allenic alcohol[324]:



Gaudemar explains the formation of allenic alcohols from acetylenic halides by the prototropic isomerisation of intermediate Grignard complexes[324]:

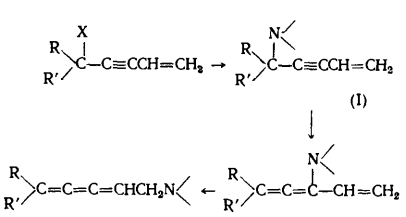


However, in the opinion of many authors the above rearrangements take place through a carbonium ion mechanism according to the scheme[302,324,361]:



Ginzburg[362,363] showed that in the reduction of α-halogenoacetylenes by zinc instead of the expected acetylenic hydrocarbons allenic ones are obtained. The latter are also obtained in the reduction of allenic chlorides:

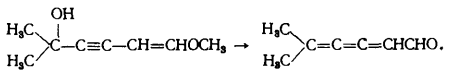
Reactions proceed similarly with secondary acetylenic chlorides[364,365]:



Under these conditions prop-2-ynyl bromide is reduced to a mixture of allene and methylacetylene[273,366,367]:

An analogous reaction is observed in the reduction of chloroacetylenes by metallic zinc, magnesium amalgam and silver, and also by lithium tetrahydroaluminate[75,273, 361,367-369]. Vinylacetylene and diacetylene halides are reduced similarly[370]. Several authors[361,364] have discussed the mechanism of reduction of chloroacetylenes by the above reagents.

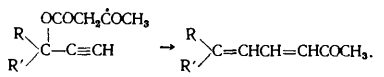
IV. ACETYLENE–ALLENE–CUMULENE REARRANGEMENT



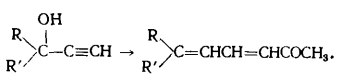
It has recently been found that various vinylacetylenic chlorides smoothly react with amines at room temperature both in the presence of water and also in various solvents: a mixture of vinylacetylenic (I), allenic (II), and cumulenic (III) amines is obtained[371-374]:

It has been found that in the presence of equimolecular amounts of amines the amount of cumulenic amine in the reaction products is increased[372]. The reaction proceeds smoothly at 20–25°C over a few days. It was shown that

under the conditions of the reaction vinylacetylenic and allenic amines undergo rearrangement with the formation of allenic and cumulenic amines.

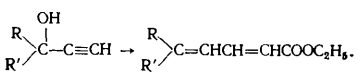


It was found recently that during the slow distillation of a (methoxyvinylethynyl)dimethylcarbinol in the presence of potassium hydrogen sulphate a cumulenic aldehyde is obtained[375,376]:

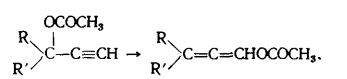


The production of cumulenes from acetylenic and diacetylenic glycols and dihalogen derivatives is another type of rearrangement with participation of the π electrons of the triple bond. There is a review article about this problem[377] so we shall not discuss it.

V. REARRANGEMENT OF ACETOACETATES AND OF ACETATES OF ACETYLENIC ALCOHOLS

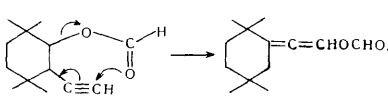


It has been shown that the acetoacetates of acetylenic alcohols are decarboxylated on heating to 160–200°C with the formation of dienic ketones[378,379]:



It was found later that this reaction also occurs on the gradual heating of tertiary acetylenic alcohols with acetoacetic ester[380,381]:

Preobrazhenskii and coworkers[382] showed that malonic ester also reacts with acetylenic alcohols, esters of dienic acids being formed as a result:



It was also shown that in the pyrolysis of acetates or formates[383–386] of ethynylcarbinols in a steam of nitrogen, acetates of allenic carbinols are obtained as a result of a rearrangement:

The mechanism of the above reaction has been discussed in several papers. Some authors think that it proceeds without the formation of intermediate vinyl esters, others[387–398] explain the formation of the final products through a Claisen rearrangement of the vinyl esters.

The mechanism of the rearrangement of acetates of acetylenic alcohols has been presented by Landor and Landor[150] as a cyclic process:

This problem is discussed in greater detail elsewhere[389,390].

VI. REARRANGEMENT OF ACETYLENIC COMPOUNDS CONTAINING OTHER FUNCTIONAL GROUPS

Babayan and coworkers found that 1-dialkylaminobut-2-yne is readily isomerised into 1-dialkylaminobut-3-yne in ethereal solution in the presence of metallic sodium at room temperature[391,392]:

Under these conditions allenic amines also isomerise to form acetylenic amines[393]:

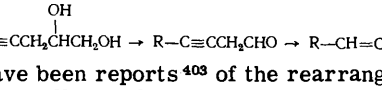
On heating allenic amines in the presence of bases isomerisation proceeds in the reverse direction[394]:

When 3-dialkylaminobut-1-ynes are heated in the presence of aluminium oxide and 1% $Fe(OH)_3$ they are rearranged into the corresponding dienic amines[144,395]:

On passing 1,4-bisdialkylaminobut-2-ynes over Cr_2O_3 catalyst[396] at 320–330°C and also in the presence of metallic sodium[397] they are isomerised with formation of the dienic amines:

It has been shown that acetylenic thioesters also undergo isomerisation[398] in the presence of bases:

1,4-diphenoxybut-2-ynes are rearranged similarly on heating with potassium t-butoxide[399]:



1,1,4,4-Tetraphenylbut-2-yne isomerises in the presence of sodium ethoxide into 1,1,4,4-tetraphenylbuta-2,3-diene[400]:

It has been shown that in the oxidation of acetylenic carbinols or keto-carbinols, instead of the expected acetylenic ketones allenic ketones are obtained[349,401]:

Winter[402] observed similar behaviour in the oxidation of acetylenic glycols with sodium [periodate. (Ed. of Translation)]:

There have been reports[403] of the rearrangement of acetylenic into allenic aldehydes. However, other results[404,405] contradict this.

Johnson and coworkers studied the prototropic conversions of acetylenic acids by many examples. It was shown that prop-2-ynylcarboxylic acid or its esters and also prop-1-ynylcarboxylic acid in the presence of potassium hydroxide is rearranged into an allenecarboxylic acid or its esters[406]:

However, it was found that but-2-yncarboxylic or buta-2,3-diencarboxylic acids are isomerised into but-3-yncarboxylic acid[407]:

$$\left.\begin{matrix} H_3C{-}CH_2C{\equiv}CCOOH \\ H_3C{-}CH{=}C{=}CHCOOH \end{matrix}\right] \rightarrow H_3C{-}C{\equiv}C{-}CH_2COOH.$$

In the presence of amines acetylenic hydroxy-acids are also rearranged into allenic[408]:

$$C_6H_5CHC{\equiv}CCO_2Me \rightarrow \left[C_6H_5C{=}C{=}CHCO_2Me\right] \rightarrow C_6H_5COCH{=}CHCO_2Me.$$

It is curious that in the presence of potassium hydroxide acetylenic alcohols with aromatic substituents are converted into $\alpha\beta$-unsaturated ketones by prototropic rearrangement[409]:

$$(C_6H_5)_2CHC{\equiv}CC_6H_5 \rightarrow \left[C_6H_5C{=}C{=}CHC_6H_5\right]$$
$$C_6H_5COCH_3 + C_6H_5CHO \leftarrow C_6H_5COCH{=}CHC_6H_5$$

It was found that acetylenic acids in which the triple bond is further removed from the carboxyl group undergo rearrangement with formation of the corresponding allenic and dienic acids[407]:

$$R{-}C{\equiv}C{-}CH_2CH_2COOH \rightarrow RCH{=}C{=}CHCH_2COOH \rightarrow RCH{=}CHCH{=}CHCOOH$$

[R = CH_3 (Ed. of Translation)].

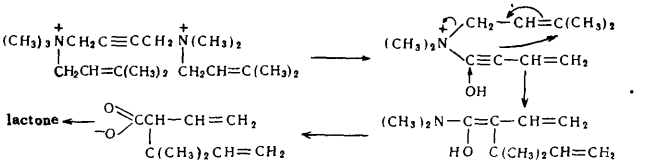
In the oxidation of acetylenic glycols with the aid of Cr_2O_3 Jones and coworkers[410] isolated isomeric allenic acids:

$$HOCH_2(CH_2)_nC{\equiv}CCH_2(CH_2)_nCH_2OH \rightarrow HOOC(CH_2)_nCH{=}C{=}CH(CH_2)_nCOOH.$$
$$\uparrow\downarrow$$
$$HOOCCH_2(CH_2)_nC{\equiv}C(CH_2)_nCOOH$$

In the presence of bases vinylacetylenic[350] and diacetylenic[411] acids are converted by a prototropic rearrangement into the corresponding allenic and dienic acids:

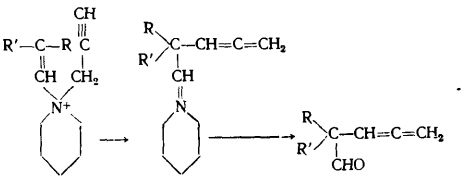
$$RC{\equiv}CCH{=}CHCH_2COOH \rightarrow RCH{=}C{=}CHCH{=}CHCOOH$$
$$\left.\begin{matrix} HOOCCH_2C{\equiv}CC{\equiv}CCH_2COOH \\ HOOCC{\equiv}C(CH_2)_2C{\equiv}CCOOH \end{matrix}\right] \rightarrow HOOCCH{=}CHCH{=}CHC{\equiv}CCOOH.$$

The isomerisation of conjugated diacetylenic acids leads to the production of polyenic acids[411]:



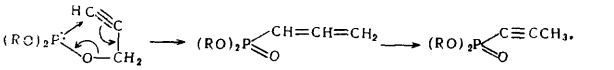
$$HOOC(CH_2)_2(C{\equiv}C)_2(CH_2)_2COOH \rightarrow HOOC(CH{=}CH)_4COOH.$$

It was shown recently that prop-2-ynyl vinyl ethers undergo a Claisen rearrangement as follows[412]:

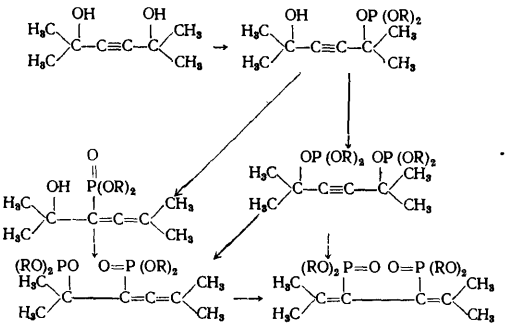


$$CH_2{=}CHOCH_2C{\equiv}CH \xrightarrow[CO_2]{C_2H_5MgBr} HOOCC{\equiv}CCH_2OCH{=}CH_2$$
$$\downarrow$$
$$HOOC{-}\underset{\|}{C}(CH{=}O){-}CH{=}CH_2 \leftarrow HOOC{-}\underset{|}{C}(CH_2CHO){=}C{=}CH_2$$
$$\downarrow\uparrow$$
$$H_2C{=}CH\underset{\|}{C}(CH{-}OH){-}\underset{|}{C}{=}O$$

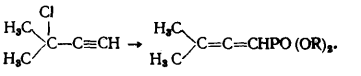
According to some investigators[412,413], other prop-2-ynyl vinyl ethers undergo this reaction, particularly the prop-2-ynyl acetal of isobutyraldehyde. It was also shown that the 1,4-bisdiphenyl esters of but-2-yn-1,4-diol undergo a Claisen rearrangement when heated in diethylaniline[414].



Babayan and coworkers[415] showed that quaternary ammonium bases which contain $\beta\gamma$-acetylenic and allyl radicals form acids or the corresponding lactones under the influence of aqueous alkalis, by the scheme:



According to the result of Opitz[416], prop-2-ynyl vinyl bases undergo a Claisen rearrangement with the formation of intermediate enamines which are hydrolysed into allenic aldehydes:



Pudovik and coworkers[417] showed that dialkyl-$\beta\gamma$-propynyl phosphites isomerise on standing into the dialkyl esters of $\alpha\beta$-propynylphosphinic acids:

It has been shown that phosphoric esters of butyndiols[418,419] also undergo the rearrangement described above:

Analogous results were obtained in the reaction of chloroethynyldimethylmethane [3-chloro-3-methylbut-1-yne] with a trialkyl phosphite[420]:

An acetylene–allene rearrangement was observed in the reaction of acetylenic carbinols with R_1R_2PCl, R_1PCl_2, PCl_3.[421] Allenic and acetylenic esters of phosphonic acids readily undergo prototropic isomerisation on heating in the presence of a catalytic amount of sodium ethoxide[422]:

$$RCH{=}C{=}CHPO(OR)_2 \rightarrow RCH_2C{\equiv}CPO(OR)_2,$$
$$CH{=}CH{-}C{\equiv}CCH_2PO(OC_2H_5)_2 \rightarrow CH_3CH{=}CHC{\equiv}CPO(OR)_2.$$

The authors state that these rearrangements proceed more smoothly than the rearrangement of the corresponding ethylene esters of phosphoric acid[423].

IV. Hydrazino-, thiocyanato-, nitro-, mercapto-, and other deoxy-derivatives of cellulose; preparation and properties. 690

I. INTRODUCTION

From the time it was established that cellulose is a high-molecular-weight polysaccharide, the elementary unit of which contains alcoholic hydroxyls, investigations in the field of cellulose chemistry were directed mainly towards the study of the reactions involving replacement of the hydrogen atoms of the hydroxyl groups by acyl and alkyl radicals, that is, reactions of *O*-acylation and *O*-alkylation. The interest in obtaining cellulose ethers and esters is due to their widespread use in various products. Existing reviews and monographs mainly survey the progress in the field of the preparation and investigation of the properties of *O*-derivatives of cellulose. Even in the reviews which have appeared recently, in addition to such problems of cellulose chemistry as the dependence of the reactivity of cellulose on its physical structure and the comparative reactivity of the hydroxyl groups in alkylation and acylation, only problems arising in connection with the preparation of cross-linked cellulose macromolecules and graft copolymers of cellulose are considered[1,2].

The present review considers the development of the chemistry by the *C*-derivatives of cellulose, in which the hydroxyl groups are replaced by other functional groups. After the publication of the last monographs on cellulose chemistry[3,4] a number of new syntheses of aminodeoxy- and halogenodeoxy-celluloses have been effected. Hydrazino-, thiocyanato-, nitro-, mercapto-, and other new *C*-derivatives of cellulose have now been obtained.

The chemistry of the *C*-derivatives of cellulose is of great theoretical interest for the further study of the structure of cellulose. It allows a large number of reactions to be used for studying the glucopyranose unit. The investigation of the properties of *C*-derivatives of cellulose with a specified position of a substituent in the elementary unit allows information to be obtained about the carbon atom at which a given substituent is located. This will evidently facilitate an understanding of the complex problems of the mutual influence of groups in carbohydrates and the induction effects acting in them.

The practical interest in the chemistry of *C*-derivatives of cellulose consists both in the modification of cellulose materials with the aim of discovering new possibilities for their use, and also in the search for new ways of using cellulose as an organic raw material.

II. AMINO-DERIVATIVES OF CELLULOSE AND OTHER POLYSACCHARIDES

Attempts to replace the hydroxyl groups in cellulose and starch by amino-groups were made about 75 years ago[5], but the interest in this problem has never waned since then. Amination was carried out with the aim of increasing the dyeability of cellulose fibres[6,7], and for the production of

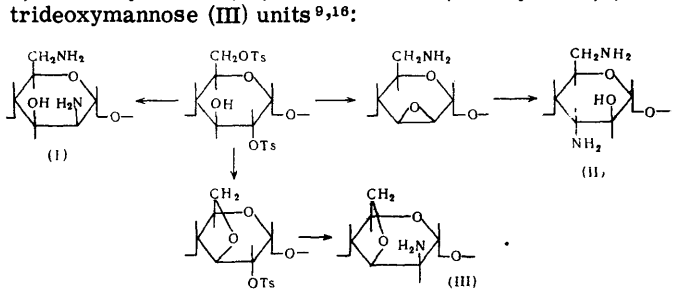
anion-exchange materials[8] or of analogues of chitosan and chitin[9].

1. Reactions Used for Introducing Amino-Groups into Polysaccharides

Several reactions have been used for obtaining amino-derivatives of cellulose and other polysaccharides.

a. The action of ammonia on cellulose- and acetylcellulose-esters of sulphonic acids:

$$C_6H_7O_2(OH)_{3-x}(OSO_2R)_x \xrightarrow{NH_3} C_6H_7O_2(OH)_{3-x}(OSO_2R)_{x-y}(NH_2)_y.$$



On boiling cellulose *p*-toluenesulphonate (tosylcellulose) with a concentrated solution of ammonia for 1 h at 100°C, Karrer and Wehrli[10] introduced 0.7–0.8% nitrogen into cellulose. On investigating the same reaction Sakurada[11,12] concluded that it only takes place to a slight extent. Gardner[13] also did not succeed in introducing an appreciable amount of nitrogen into cellulose by the action of ammonia on its mixed ester containing tosyl and acetyl groups. During the process the cellulose underwent considerable degradation.

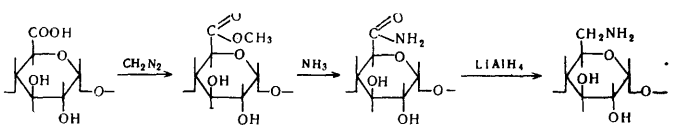
By carrying out the reaction at room temperature or heating cellulose methanesulphonate (mesylcellulose) containing from 0.5 to 1 mesyl group per unit with an aqueous solution of ammonia (28–29%), part of the mesyl groups could be replaced. The products contained 0.5–4% nitrogen and 3–6% sulphur. A change in the reaction conditions did not yield a product free from sulphur[14]. An aminocellulose with 2.5–4.2% nitrogen, 12–14% sulphur, was obtained on treating mesyl cellulose (γ = 150–170) with a solution of ammonia in methanol[15].

b. Reaction of amylose *p*-toluenesulphonate with hydrazine or sodium hydrazide, with subsequent reduction:

$$C_6H_7O_2(OH)_{1.3}(OSO_2C_6H_4CH_3)_{1.7} \xrightarrow{NH_2NH_2} C_6H_7O_2(OH)_{1.6}(NHNH_2)_{1.4} \xrightarrow{NaNO_2} C_6H_7O_2(OH)_{1.6}(N_3)_{1.4} \rightarrow C_6H_7O_2(OH)_{1.6}(NH_2)_{1.4}.$$

The replacement of a considerable proportion of the hydroxyl groups in a polysaccharide by amino-groups was achieved in the reaction of tosylamylose (γ = 170) with hydrazine followed by reduction of the reaction product. To obtain the hydrazinoamylose, ditosylamylose was boiled for 7 days with anhydrous hydrazine under nitrogen. The hydrazinoamylose was reduced to aminoamylose in aqueous solution by Raney nickel for 24 h. The aminoamylose obtained (γ = 140) is an absolutely inhomogeneous product containing, in consequence of the reaction having proceeded in various directions, both 6-amino-6-deoxyglucopyranose and also 2,6-diamino-2,6-dideoxymannose (I), 3,6-diamino-3,6-dideoxyaltrose (II), and 2-amino-3,6-anhydro-2,3,6-trideoxymannose (III) units[9,16]:

6-Amino-6-deoxyamylose with a degree of substitution of 0.1–1 was obtained through the 6-amino-derivative with protected secondary hydroxyl groups by the following scheme[17]:



amylose
↓
6-*O*-tritylamylose
↓
6-*O*-tritylamylose 2,3-di-*O*-phenylcarbamate
↓
amylose 2,3-di-*O*-phenylcarbamate
↓
6-azido-6-deoxyamylose 2,3-di-*O*-phenylcarbamate
↓
6-amino-6-deoxyamylose.

c. Reduction of cellulose nitrate by sodium amide:

$$C_6H_7O_2(OH)(ONO_2)_2 \xrightarrow{NaNH_2} C_6H_7O_2(OH)_2(NH_2).$$

By reducing cellulose nitrate (11.7% nitrogen) with sodium amide in liquid ammonia for 9 h, Scherer and Feild[18] obtained monoaminocellulose, with 8.35% total and 7.94% amine nitrogen, which was evidently extensively degraded, as it was extremely soluble in water.

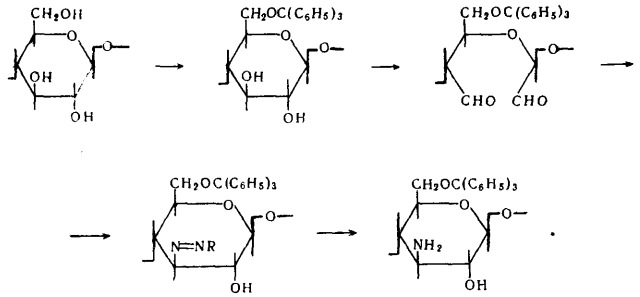
d. Reduction of the amide of an alginic acid:

A new attempt was recently made to introduce an amino-group into a polysaccharide by making use of the reduction of an acid amide. The degree of esterification of the alginic acid and the number of amido-groups introduced were sufficiently high but the product obtained on reducing the amide with lithium tetrahydroaluminate only contained 12 amino-groups per 100 glucose residues[19].

e. Action of ammonia on halogenodeoxycellulose:

$$C_6H_7O_2(OH)_{3-x}(hal)_x \xrightarrow{NH_3} C_6H_7O_2(OH)_{3-y}(NH_2)_y.$$

It has proved impossible to introduce into cellulose an appreciable amount of nitrogen by treating acetyl-6-iodo-6-deoxytosylcellulose with ammonia in organic solvents; a little nitrogen (0.3%) was introduced into it on using sodium amide in liquid ammonia[13]. Recently, Polyakov and Rogovin[8] reinvestigated this reaction. As a result of treating chlorodeoxycellulose with ammonia in alcoholic solution at 160°C they succeeded in introducing 23 amino-groups per 100 glucose residues, which corresponded with 2.25% nitrogen. Under the action of aqueous ammonia saponification of the chlorine occurred in addition to the substitution.



f. Phthalimide synthesis.

An attempt was made to replace a tosyl group in cellulose and acetylcellulose by a phthalimide residue. It was suggested that on saponification of the phthaloyl derivative an aminocellulose and phthalic acid would be obtained.

Only 25% of the tosyl groups in 2,3-di-*O*-acetyl-6-*O*-tosylcellulose could be replaced. In acetyltosylcelluloses with 1.85 acetyl and 0.43 tosyl groups per elementary unit of the cellulose, the tosyl groups were replaced stoichiometrically by the phthalimido-groups. However, it was

found impossible to remove the phthalic acid residues and obtain aminocellulose in this way[20].

g. Condensation of 2,3-dialdehydo-6-*O*-tritylcellulose with *p*-tolylhydrazine and reduction of the condensation product[21,22]:

The condensation of 2,3-dialdehydo-6-*O*-tritylcellulose with *p*-tolylhydrazine in pyridine solution for 24 h gave partially and completely substituted 3-deoxy-3-*p*-tolylazo-6-*O*-tritylcellulose. Reduction of the condensation product in the presence of Raney nickel at a hydrogen pressure of 150 atm and 90°C yielded 3-amino-3-deoxy-6-*O*-tritylcellulose with various amino-group contents, for example:

$$C_6H_7C_2(CH)_{1.46}(NH_2)_{0.62}[CC(C_6H_5)_3]_{0.92}.$$

Hence despite the many stages in the processes, the incompleteness of the reactions, and the great difficulty in proving the structure of the products obtained, the search for new syntheses of aminopolysaccharides is still continuing. The greatest degree of conversion into aminopolysaccharides was reached during the introduction of hydrazido- or azido-groups into tosylamylose and their subsequent reduction. Of all the reactions used, only the condensation of 2,3-aldehydo-6-*O*-tritylcellulose with *p*-tolylhydrazine and subsequent reduction of the product allows an amino-group to be introduced into the glucopyranose chain of cellulose in a definite position: at the third carbon atom.

2. Properties of Aminodeoxypolysaccharides

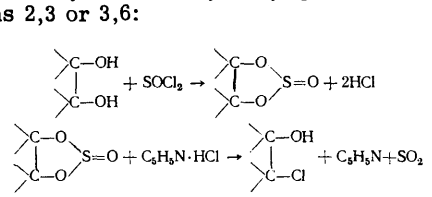
Aminocellulose is soluble in water, capable of being diazotised and of forming dyes on combination with 1-naphthol, 2-naphthol, aniline, resorcinol, phenol, *o*-cresol, 1-naphthylamine, 2-naphthylamine, etc. It is uncertain, however, whether the dyes produced have the diazo-structure since they are stable to reduction and nitration[23].

Deacetylated chitin and desulphated heparin are deaminated under the action of nitrous acid[24,25].

The exchange capacity of aminocellulose with a high concentration of amino-groups is 2.5 mg-equiv. g^{-1}.[8]

The chemical properties of the glucoside bond and of hydroxyl groups when amino-groups are present in the polysaccharide have been studied in detail, by the example of chitosan and chitin[26]. Danilov and Plisko investigated the action of acids and alkalis on chitin and also its reactivity in etherification and alkylation. The chitin is dissolved in dilute organic and mineral acids after swelling in 8–10% sodium hydroxide at −40°C. Glyceryl, hydroxyethyl, ethyl, and carboxymethyl ethers of chitin were obtained[27–30]. Note that chitin is less reactive than cellulose (as was shown earlier[31–33]) in the reactions for the formation of ethers and esters[34].

N-alkyl and *N*-aryl derivatives of aminocellulose were obtained indirectly[6,7,8,20,35–40]. They dissolve in organic solvents[36] and dilute solutions of acetic acid, and are capable of forming fibres with the best dyability with acid dyes. There are indications that it may be possible to use them as finishes, protective coatings, photographic film base, etc.[41]



Aminocellulose exhibits increased affinity for acid dyes[6,7] and it is capable of being formed into threads from solution in acetic acid in an alkaline bath[42]. Aminocellulose and aminostarch are mentioned as basic polysaccharides which can be used for finishing fibres[35].

III. HALOGEN DERIVATIVES OF CELLULOSE

The introduction of halogen into cellulose has two aims: modification of the cellulose and the production of reactive derivatives for further syntheses[43].

1. Reactions Used for Introducing a Halogen into Cellulose

a. The reaction of cellulose with thionyl chloride. As long ago as 1931, Carré[44] obtained a substance of composition $C_6H_9O_4Cl$ by the action of thionyl chloride in pyridine on cotton linter. Recently a more detailed study was made both of the reaction itself and of the products obtained. The influence of time and temperature on the degree of substitution of chlorodeoxycellulose[45] was investigated and it was shown that replacement of pyridine by a more polar solvent, for example, dimethylformamide, accelerates the reaction[8]. Chlorodeoxycellulose obtained in pyridine or dimethylformamide at elevated temperatures is dark cinnamon-brown. Carrying out the reaction in carbon tetrachloride or chloroform at the boiling point of the solvent allows a colourless chlorodeoxycellulose to be obtained[46]. The presence of iron accelerates the reaction, especially in carbon tetrachloride. During the preparation of chlorodeoxycellulose in pyridine, hydrolysis of the cellulose takes place, which becomes apparent in a drop in its tensile strength[44]. Chlorodeoxycellulose obtained in pyridine contains sulphur, possibly as sulphate esters. The sulphur concentration depends on how the chlorodeoxycellulose is treated at the end of the reaction: with dilute alkali, sodium chlorite, sodium hydrogen carbonate, or methanol[45]. The possibility of the formation of elementary units with anhydro-rings on carrying out the reaction either in pyridine[45] or in dimethylformamide[8] is not ruled out. Chlorodeoxycellulose obtained in a medium of chloroform or carbon tetrachloride did not contain sulphur and anhydro-rings; hydrolysis of cellulose did not take place during its preparation[46]. Two mechanisms for the formation of chloro-substituted cellulose using thionyl chloride in pyridine have been suggested. In the first of these it is assumed that there are intermediate cyclic sulphate esters which are formed by the reaction of thionyl with the hydroxyl groups of the cellulose in positions 2,3 or 3,6:

The second mechanism presupposes the formation of an intermediate unstable ester of chlorosulphurous acid:

$$ROH + SOCl_2 \rightarrow ROSOCl + HCl$$
$$ROSOCl \rightarrow RCl + SO_2.$$

The first mechanism is supported by the fact that chlorodeoxycellulose is obtained under the conditions for the tosylation of cellulose where the chlorinating agent can only be pyridinium chloride:

$$C_6H_7O_2(OH)_2(OSO_2C_7H_7) + C_5H_5N\cdot HCl \rightarrow$$
$$\rightarrow C_6H_7O_2(OH)_2(OSO_2C_7H_7)_{1-x}Cl_x + C_5H_5NHSO_2C_7H_7,$$

and also by the fact of the formation of cyclic sulphites from polyhydroxy-compounds[47-49] and by the presence of stably-bound sulphur in chlorodeoxycellulose.

The second mechanism finds support from the results of a detailed investigation of the reaction of simple alcohols with thionyl chloride[50-52].

b. Nucleophilic substitution in the reaction of cellulose sulphonates and nitrates with salts of hydrohalogen acids. An exhaustive review[53] on the reactivity of cellulose sulphonates (particularly in reacting with alkali metal halides) has been published.

The specificity of this reaction, namely, the replacement first of all of the tosyl group at the primary carbon atom, was first shown with galactose[54].

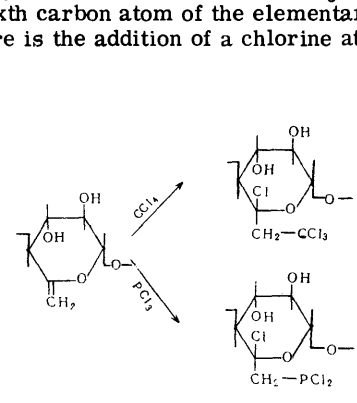
A polysaccharide containing a halogen at $C_{(6)}$, 6-deoxy-6-iodo-2,3-ditosylstarch, was first obtained by the action of sodium iodide on tritosylstarch in acetone at 100°C for 3 days[55-57].

Cramer and Purves[58] were the first to replace a primary tosyl group in cellulose by iodine; they used a preparation of partially saponified triacetylcellulose[58]. Then a series of papers were devoted to the use of this reaction for studying the distribution of tosyl groups between the primary and secondary carbon atoms of the elementary unit of cellulose[59-61]. Despite the fact that tosyl groups at secondary carbon atoms are also replaced by halogen[60,62], as was noted above, this reaction has also repeatedly been used for studying the structure of various derivatives of cellulose[63-69] and other polysaccharides[70]. It was shown recently that on carrying out the reaction in a polar solvent not only tosyl groups at the primary but also those at secondary carbon atoms are replaced by halogen[71]. Halogenocellulose free from sulphur was obtained on replacing a methanesulphonate group in a mixed cellulose ester containing acetyl and mesyl groups by iodine (the cellulose ester was treated with sodium iodide). The product contained 0.4 atom of iodine per elementary unit of the cellulose. The initial content of mesyl groups was 0.9.[13]

A method for the introduction of I, Br, Cl, and F into cellulose by the reaction of alkali metal salts and hydrohalogen acids with mesylcellulose in aqueous medium, not in organic solvents, has been developed[72].

In the nucleophilic replacement of a nitrate group by iodine, on treating partially nitrated cotton cellulose with sodium iodide in ethyl methyl ketone for 12 h at 115°C iodine-containing cellulose nitrate was obtained (33% iodine and 0.7–2.5% nitrogen; initial nitrogen content 2.5–9.0%).

By analogy with the monosaccharides it is thought that the iodine replaces only the primary nitrate groups[73]. This reaction is used for studying the distribution of substituents in the elementary unit of cellulose derivatives[74,75]. An insignificant drop in temperature significantly retards the reaction. On using zinc, calcium, or barium iodide under the same conditions only 0.2–2.8% iodine could be introduced into cellulose[73].



In comparing the reactivity of tosyl, nitrate, and sulphate esters of cellulose in reactions with halides it was found that with lithium chloride or potassium bromide the tosyl ester is most reactive and cellulose sulphate does not react. In reactions with sodium iodide the difference in the reactivity of cellulose *p*-toluenesulphonate and nitrate is less noticeable[76]. It was shown that as a result of side-reactions the ester groups are removed without the introduction of halogen[73,76].

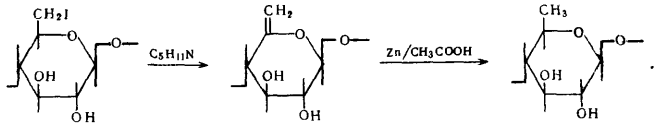
c. Reaction of cellulose phosphinates with alkyl halides:

$$C_6H_7O_2(OH)_3 \xrightarrow{(C_2H_5)_2NP(C_2H_5)_2} C_6H_7O_2(OH)_{3-x}[OP(C_2H_5)_2]_x \xrightarrow{C_6H_5CH_2Cl}$$
$$\rightarrow C_6H_7O_2(OH)_{3-x}Cl_x.$$

A new method of obtaining deoxyhalogenocelluloses by the reaction of cellulose diethylphosphanate with benzyl chloride was recently developed. As a result of a fivefold treatment of a cellulose ester with 4% phosphorus ($\gamma = 30$), with benzyl chloride for 4 h at 120–130°C a chlorodeoxycellulose with 4% chlorine was obtained[77].

d. Addition of CCl_4 and PCl_3 at a double bond. There is a report of the preparation of 5-chloro-6-deoxycellulose starting from cellulose-5,6.[78] Here simultaneously with the addition of the CCl_3 and PCl_2 radicals to the sixth carbon atom of the elementary unit of cellulose there is the addition of a chlorine atom to the fifth carbon atom:

2. Properties of Deoxyhalogenocelluloses



a. Structure and properties. An attempt was made with the aid of paper chromatography of the hydrolysis products to determine the position of chlorine in chlorodeoxycellulose obtained by the action of thionyl chloride in pyridine on cellulose. A specimen of chlorodeoxycellulose containing 6% chlorine was investigated. It was shown that 22% of the chlorine is at $C_{(6)}$. 6-Chloro-6-deoxyglucopyranose was isolated and characterised in this way, but the composition of the other four fractions was not studied. It is suggested that they can contain 2- or 3-monosubstituted glucose, mannose, and allose, and also 2,3- and 3,6-anhydro-derivatives of the same monosaccharides. It was noted that the chlorine in the chlorodeoxycellulose is resistant to saponification under conditions of complete hydrolysis of the latter at the glucoside bonds by 72% sulphuric acid. The introduction of halogen into the cellulose also raises the resistance of the glucoside

bonds to hydrolysis: with increase in the degree of substitution there is an increase in the amount of the unhydrolysable part[45].

On treating the chlorodeoxycellulose with concentrated aqueous solution of ammonia, in addition to the replacement of halogen by an amino-group 50% of the chlorine is saponified. When treated with an alcoholic solution of ammonia, saponification does not take place[8].

Iodine- and bromine-containing mesylcelluloses show enhanced resistance to combustion compared with the initial mesitylcellulose. The introduction of chlorine has no effect on the stability of mesylcellulose to combustion, but the introduction of fluorine impairs it[72].

b. Reactions of deoxyhalogenocelluloses. When pyridine acts on 6-deoxy-6-iodo cellulose (γ = 70), HI is lost and the cellulos-5,6-ene formed. By reduction of an unsaturated derivative of cellulose with zinc in acetic acid, a completely saturated compound is obtained, 6-deoxycellulose[79]:

Cyanodeoxycellulose was obtained by the reaction of chlorodeoxycellulose with potassium cyanide in dimethylformamide or methanol at elevated temperatures. Under the conditions used not more than 65% of the chlorine atoms are replaced. When even a little water (1–1.5%) is present in the reaction mixture, gradual saponification of the nitrile groups takes place[8].

$$C_6H_7O_2(OH)_{2.37}Cl_{0.63} \xrightarrow{KCN} C_6H_7O_2(OH)_{2.59}(CN)_{0.41}.$$

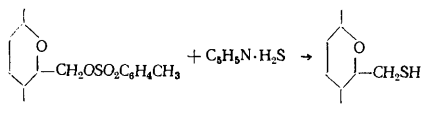
A solution of sodium hydrazide in absolute hydrazine or liquid ammonia (in nitrogen atmosphere) acts on chlorodeoxycellulose to give deoxyhydrazinocellulose. It is possible that there is the parallel formation of anhydrides, since there was some disagreement between the proportion of chlorine atoms removed and the content of hydrazino-groups:

$$C_6H_7O_2(OH)_{2.37}Cl_{0.63} \rightarrow C_6H_7O_2(OH)_{2.37+(0.63-x)}(NHNH_2)_x.$$

IV. HYDRAZINO-, THIOCYANATO-, NITRO-, MERCAPTO-, AND OTHER DEOXY-DERIVATIVES OF CELLULOSE; PREPARATION AND PROPERTIES

Deoxyhydrazinocellulose with a 0.16–0.88 substitution was obtained on the reaction of a solution of sodium hydrazide in absolute hydrazine with tosyl or mesyl esters of cellulose containing 0.44–1.71 sulphonate groups per elementary unit of the cellulose. The reaction was carried out at 20° and –33°C for 15–72 h [80]. Whistler and Shasha[81] obtained 6-deoxy-6-hydrazinocellulose from 6-*O*-tosylcellulose with a degree of replacement of 0.64 by treatment with hydrazine for 30 min at 100°C. Viscosimetric measurements showed that hydrazinolysis took place to an insignificant extent under the conditions of the experiment.

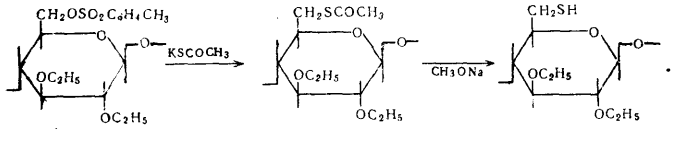
Note that not all the tosyl groups are replaced by hydrazine residues. Since the deoxyhydrazinocellulose did not contain sulphur, evidently part of the tosyl or mesyl groups are saponified under the conditions of the experiment.



Highly substituted deoxyhydrazinocelluloses (γ = 70–80) are soluble in water and dilute acids, but do not dissolve in alcohol or acetone[80]. The hydrochloride of 6-deoxy-6-hydrazinocellulose is stable and dissolves in water to form a transparent, stable solution. Oxygen, hydrogen peroxide, nitrous acid, iodine, and potassium iodide oxidise the free base[81]. Fabric based on deoxyhydrazinocellulose is readily dyed by acid dyes and absorbs from 1.5 to 1.7 moles hydrochloric acid per hydrazino-group[80]. A deoxy(phenylhydrazino)cellulose with degree of substitution 1–1.35 was obtained on the basis of ditosylcellulose. This preparation also contained from 0.61 to 0.96 tosyl groups per elementary unit of the cellulose. Deoxy(phenylhydrazino)cellulose is soluble in dimethylformamide and does not dissolve in acetone, chloroform, or methanol[80].

Deoxynitrocellulose was obtained by the nucleophilic replacement of tosyl groups in tosylcellulose. The tosylcellulose (γ = 100–180) was treated with sodium nitrite in water and in dimethylformamide for different periods at temperatures from 20° to 140°C. All the tosyl groups could not be replaced. The cellulose derivatives obtained contained both tosyl and nitro-groups. The maximal degree of substitution was 0.4 for nitro-groups[82]:

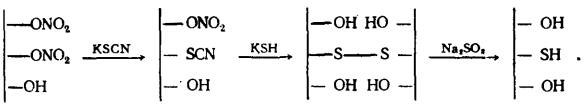
$$[C_6H_7C_2(CH)_{1.96}(OSO_2C_6H_4CH_3)_{0.62}(NC_2)_{0.42}]_n.$$



Thiocyanatocellulose (γ = 100) was obtained by the action of sodium or potassium thiocyanate on ditosylcellulose for 8–10 h [59,71]. Partially substituted deoxythiocyanatocellulose was obtained from cellulose nitrate. The maximal degree of substitution of ester groups by thiocyanato-groups under these conditions was 42%.[83]

Deoxymercaptocellulose was obtained by the action of hydrogen sulphide in pyridine on a mixed ester of cellulose containing acetyl (2.44 per elementary unit) and tosyl (0.35 per elementary unit) groups. 80% of the tosyl groups were replaced by mercapto-groups in 8 hours at 35–40°C. When the reaction product,

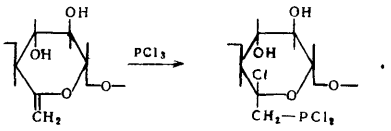
which is soluble in acetone, was held in air or treated with iodine, it lost its solubility, owing to the formation of disulphide bridges between the cellulose macromolecules[84].



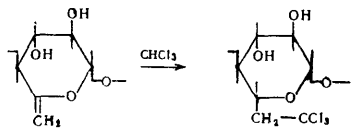
A small number of mercapto groups (0.16 per elementary unit) was introduced into cellulose by the action of potassium thioacetate on a mixed cellulose ester containing ethoxy- and tosyl groups with subsequent deacetylation. The product is soluble in acetone, but in air it oxidises readily, being converted into an insoluble cross-linked polymer[85]:

A cotton cellulose with mercapto-groups was obtained similarly[86].

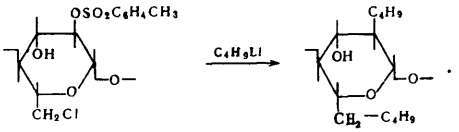
By passing hydrogen sulphide through a solution of ditosylcellulose in dimethylformamide from 0.5 to 1.79 mercapto-groups could be introduced into the cellulose (calculated per elementary unit)[71].



A cellulose derivative containing mercapto-groups was also obtained by the denitration of deoxythiocyanatocellulose nitrate with subsequent reduction[83]:

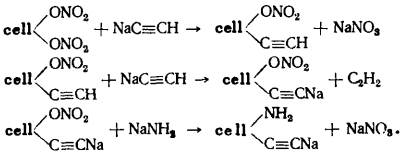


Phosphorus-containing deoxycellulose is formed by the reaction of tosylcellulose with sodium diethyl phosphite[87]:

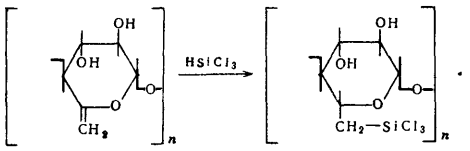


$$\text{cell}-OSO_2C_6H_4CH_3 + NaPO(OC_2H_5)_2 \rightarrow \text{cell}-PO(OC_2H_5)_2 .$$

An original reaction of radical addition of phosphorus trichloride to a cellulose-5,6-ene has been described[78]:



Alkyldeoxycellulose. Papers appeared recently on two methods of introducing alkyl radicals into the glucopyranose unit of cellulose[78,88]:



Ethynyldeoxycellulose. As a result of the reaction of cellulose nitrate (11.9% nitrogen) with sodium acetylide in liquid ammonia, a product is obtained with one acetylene and one amino-group for each elementary unit of cellulose:

The acetylene derivative of cellulose in the preparation is readily soluble in liquid ammonia and is not precipitated by water and alcohol. However, after evaporating off the ammonia the product loses its solubility, both in ammonia and in organic solvents, probably because of polymerisation at the acetylene groups[89].

Silicon-containing deoxycellulose is obtained as a result of the following reaction[78]:

---o0o---

Despite the fact that the chemistry of the *C*-derivatives of cellulose began to develop a long time ago and that interest in it has intensified recently, it is noteworthy that even the most serious investigations have not been pursued to the end. Many authors considered it sufficient to show just the possibility in principle of some particular reaction.

There is a need for further development of the investigations in the field of *C*-derivatives of cellulose, both to seek for new reactions and to find conditions under which these reactions would proceed as completely as possible and not be accompanied, if possible, by various side-processes and by the change in the configuration of the elementary unit of cellulose.

There is special interest in specific reactions which would ensure the production of cellulose derivatives with a definite position of a substituent in its elementary unit. New reactions, for example, the condensation of 2,3-dialdehydo-6-*O*-tritylcellulose with *p*-tolylhydrazine[21,22] and the radical addition of a series of compounds to cellulose-5,6-ene[78], show that possibilities in this direction are far from exhausted.

The study of the properties of *C*-derivatives of cellulose can be considered an almost untouched field of investigation.

THE ELECTRONIC ABSORPTION AND LUMINESCENCE SPECTRA OF *N*-HETERO-AROMATIC COMPOUNDS AND THEIR DERIVATIVES

R. N. Nurmukhametov

CONTENTS

1. General remarks 693
2. Characteristic features of bands due to electronic $n-\pi^*$ and $\pi-\pi^*$ transitions 694
3. Condensed aromatic heterocycles with one nitrogen atom 696
4. Azabenzenes and polycyclic compounds with two or more nitrogen atoms 700
5. Substituted *N*-heterocyclic compounds 702
6. Azomethines and azo-compounds 703
7. Porphyrins and phthalocyanines 706

1. GENERAL REMARKS

In recent years considerable progress has been made towards establishing the relationship between the structure and the spectroscopic-luminescent properties of polyatomic organic molecules. This progress is due to the mutual enrichment of theoretical and experimental studies. The work of a large number of experimentalists, using the results of theory, has revealed comparatively simple and general features, which reflect the relationship between spectra and structure and for which theoretical papers have given further qualititative or semi-quantitative explanations based on an examination of successfully chosen approximations and models. The *N*-hetero-aromatic compounds form one class of compound for which important results have been obtained.

N-Heteroaromatic compounds differ formally from aromatic hydrocarbons in that a =CH– group has been replaced by =N– in the aromatic ring. Since the π-system is preserved, it might be expected that the absorption spectra of *N*-heterocyclic compounds would contain bands similar to chose of the hydrocarbon analogues and due to $\pi-\pi^*$ transitions (excitation of an electron from a filled bonding π-orbital of an unoccupied antibonding π^*-orbital). Such bands are in fact observed, although the intensities and positions are slightly different, because of the inductive effect of the N atom and the decreased symmetry of the molecule. In addition to these bands, the spectra of *N*-heterocycles contain other less intense bands due to $n-\pi^*$ transitions (excitation by promotion of an electron of an unshared pair from the non-bonding orbital of the N atom to an antibonding π^*-orbital). The bands due to $n-\pi^*$ transitions are clearly distinguished in the spectrum only when they are the bands with longest wavelength. The assignment of the bands to $\pi-\pi^*$ and $n-\pi^*$ transitions and the classification of the bands of aza-heterocycles and other organic compounds, based on this assignment, were developed in a paper by Kasha[1].

Goodman made a systematic experimental and theoretical study of the electronic spectra of azines, and summarised the results in a review[2], in which he put forward a theory to explain the energies of the transitions, their intensities, and the singlet-triplet splitting. Mason[3-6] made a systematic study of the position and intensities (oscillator strengths) of the π, π^* and n, π^* absorption bands for various *N*-heterocyclic aromatic compounds. Clementi and Kasha[7] examined the problem of spin-orbital coupling in the n, π^*-state of *N*-heterocycles; this was subsequently developed by El-Sayed[8].

The n, π^*- and π, π^*-states show significantly different luminescent properties, which therefore depend on the relative arrangement of the singlet and triplet n, π^*- and π, π^*-levels. For this reason, the luminescent properties of aza-aromatic compounds differ from those of the corresponding hydrocarbon analogues. Aromatic hydrocarbons exhibit fluorescence and phosphorescence, whereas many *N*-heterocycles are non-fluorescent.

If the spectroscopic-luminescent properties of molecules depend on the relative arrangement of the n, π^*- and π, π^*- levels, this arrangement is determined by the structure of the molecules. The similarity in the π, π^*- bands of *N*-heteroaromatic compounds and their hydrocarbon analogues, demonstrated by Zanker[9], makes it possible to transfer the relationships known for the π, π^*-bands of aromatic hydrocarbons to the corresponding *N*-heterocycles.

The empirical relationships between the structure and spectra of aromatic polynuclear condensed hydrocarbons[10] are found to be applicable for the π, π^*-bands of *N*-heterocyclic compounds. These relationships facilitate the examination of the electronic spectra of these compounds. A general feature of triplet-singlet ($T-S_0$) transitions in aromatic hydrocarbons is that they exhibit polarisation perpendicular to the plane of the molecule. Dorr[11,12], who established this characteristic feature, showed that it also applies to the $T-S_0$ transitions of the π, π^* phosphorescence of *N*-heterocyclic compounds. El-Sayed and Brewer[13] showed for various *N*-heterocycles that the n, π^* phosphorescence exhibits polarisation in the plane of the molecule whereas the π, π^* phosphorescence exhibits polarisation perpendicular to the plane of the molecule. Zimmerman and Joop[14] showed that the polarisation of the π, π^*-bands for the absorption and fluorescence of *N*-heterocycles is the same as that for their hydrocarbon analogues.

The presence of an *N*-hetero-atom produces a marked change in the interaction between the molecule and the solvent, compared with the hydrocarbon analogue. This interaction is responsible for the influence of the solvent

on the electronic spectra of N-heterocyclic compounds and sometimes produces a very marked change in the fluorescent properties. This influence has been described by Mataga and coworkers[15-17], Kasha[18,19], and Ermolaev and coworkers[20-22].

2. CHARACTERISTIC FEATURES OF BANDS DUE TO ELECTRONIC $n-\pi^*$ AND $\pi-\pi^*$ TRANSITIONS

Electronic absorption bands may differ in their position, intensity, behaviour in various solvents, and polarisation. In emission, electronic transitions may give fluorescence and phosphorescence bands differing in intensities (quantum yields), polarisation, behaviour in various solvents, lifetimes, or interval between the phosphorescence band and the fluorescence band or long-wave absorption edge when fluorescence is absent (this interval characterises the magnitude of the singlet-triplet splitting). Both absorption and emission electronic bands may also differ in vibrational structure and the degree of structure of the bands.

Kasha[1] was the first to formulate the characteristic empirical criteria of π, π^*- and n, π^*-bands; these were later refined and supplemented[18]. In a review devoted to the spectra of molecules with $n-\pi^*$ transitions (in particular the results of theoretical examination), Sidman[23] also gives a table of the characteristic features of $n-\pi^*$ and $\pi-\pi^*$ transitions.

It should be noted, however, that no one characteristic by itself is unambiguous, and the assignment of experimentally observed bands to a definite type of transition is possible only by examining all their characteristic features. If the molecule contains an electron-donating group of the type -OR, -SR, or $-NR_2$, the unshared pair of the hetero-atom of this group conjugates with the π-electrons, leading to marked changes in the electronic states and transitions[24,25]. We shall refer to these as $\pi, \pi^*(2p_z)$-states, to distinguish them from pure π, π^*-states. As far as luminescent properties are concerned, however, the levels of the π, π^*- and $\pi, \pi^*(2p_z)$-states are similar, so that for the sake of brevity we shall subsequently refer to them as π, π^*-levels.

The distinguishing characteristics of electronic bands of various types are summarised in Table 1.

Platt[26] examined theoretically the problem of the intensity of n, π^*-bands by analysing the local symmetry of the n, π^*-states, and showed that two types of transition are possible: those permitted and those forbidden by local symmetry.

If the n-orbital is a pure p-orbital, the transition is forbidden by local symmetry. If the n-orbital is a hybridised sp^2-orbital, the transition if permitted, and the intensity of the band is determined by the weight of the s-state:

$$\int n(1)\,\hat{M}\,\pi^*(1)\,d\tau \equiv \langle n(1)\,|\,\hat{M}\,|\,\pi^*(1)\rangle$$
$$\langle (s+p)\,|\,\hat{M}\,|\,\pi^*\rangle = \langle s\,|\,\hat{M}\,|\,\pi^*\rangle + \langle p\,|\,\hat{M}\,|\,\pi^*\rangle.$$

Thus the integral of the one-electron transition moment may be vanishingly small, even if the transition is permitted by the general molecular symmetry.

Calculations on the intensities of $n-\pi^*$ transitions were reviewed by Sidman[23] and Goodman[2].

TABLE 1. Characteristic distinguishing features of electronic bands of various types.

π,π^*-bands	$\pi,\pi^*(2p_z)$-bands	n,π^*-bands
Intensity of absorption bands		
Usually of high intensity (if not forbidden by symmetry) $\epsilon \geqslant 10^3$	Intense $\epsilon \geqslant 10^3$	Of low intensity even when transition permitted by symmetry ϵ from 1 to 10^3
Polarisation of absorption bands		
In the plane of the molecule	In the plane	Perpendicular to the plane of the molecule
Influence of polar solvent		
No change or slight displacement of the band, usually towards longer wavelengths	Marked displacement of band, usually towards longer wavelengths	Usually a short-wave displacement, to different extents for different molecules
Behaviour in acid medium		
Slight displacement, if molecule is preserved	Marked transformation	Disappears
Influence of electron-donating (conjugated) substituent		
$\pi,\pi^*(2p_z)$-bands appear in place of the π,π^*-bands. Occasionally some of the π,π^*-bands are preserved, but the band with longest wavelength is a new $\pi,\pi^*(2p_z)$-band		Band displaced towards shorter wavelengths
Fluorescence band		
Adjoins and partly overlaps the long-wave absorption band and is also polarised $\tau = 10^{-8}$–10^{-6} s	Highly sensitive to the nature of the solvent $\tau = 10^{-10}$–10^{-8} s	Either absent or of low intensity $\tau = 10^{-7}$–10^{-5} s
Phosphorescence band		
Long-lived phosphorescence with polarisation perpendicular to the plane of the molecule. Slight displacement in polar solvents τ = 0.1–10 s	Different displacements for different compounds τ = 0.1–10 s	Short-lived phosphorescence, often with high yield $\tau = 10^{-4}$–10^{-2} s
Magnitude of singlet-triplet interval		
Interval large (S^*,T splitting large) and dependent on the geometry of the π-system. For most known hydrocarbons it lies in the range 12 000–5000 cm^{-1}	Interval much smaller than that for the original hydrocarbon. Decrease greater, the stronger the electron-donating power of the substituent.	Interval relatively small (about 2000–3000 cm^{-1}) for molecules with one heteroatom (C=O, C=N, etc.). With several identical groups containing heteroatoms, the picture is complicated by splitting of the states, with removal of the degeneracy.
Sharpness of vibrational structure		
Diffuse vibrational structure for the vapour of most molecules studied. Often much sharper in frozen solutions, both for absorption and more particularly for luminescence.	Bands with diffuse structure predominate, both in the vapour and in solutions.	Exceptionally sharp structure in some instances in absorption and emission for the vapour. Absorption bands diffuse in solutions. Phosphorescence bands often show marked structure at low temperatures. The domination of the progression of an individual frequency is characteristic (for carbonyl compounds).

The difference in the magnitude of the S^*, T splitting for the n, π^*- and π, π^*-levels can also be explained. Examination of the dependence on structure of this splitting for π, π^*-levels in a series of aromatic hydrocarbons showed that its values lie in the range 12 000–4000 cm^{-1}. The magnitude of the S^*, T splitting for n, π^*-levels is always about 2000–3000 cm^{-1}. The magnitude of the S^*, T splitting depends on the magnitude of the two-electron exchange integral (between the orbital from which the electron is excited and the orbital into which it is transferred). For n, π^*-states it is determined by the integral $\langle n\pi^*\,|_G\,|\pi^* n\rangle$. This exchange integral is the energy of repulsion between two n, π^*-electrons and its value is small, since the functions of n- and π^*-orbitals are mutually orthogonal. The value of the integral will increase with increase in the overlap between the n- and π^*-orbitals.

The short-wave displacement of the n, π^* bands in polar solvents is attributed to binding of the n-electrons, leading to a decrease in the energy of the n-orbital. The binding is particularly effective when hydrogen bonds are formed. The binding of the n-electrons in acidic and alkaline media leads to disappearance of the n, π^*-bands.

The efficiency of fluorescence is limited by non-radiative processes. One of these is singlet-triplet conversion. Kasha attributed the luminescent characteristics of n, π^*-states to the high probability of singlet-triplet conversion. Clementi and Kasha[7] confirmed this theoretically by estimating the spin-orbital coupling in aza-heterocycles. Later, El-Sayed[8] showed that the magnitude of the spin-orbital coupling in aza-heterocycles between states with the same type of electronic configuration is of the same order of magnitude:

$$\frac{\langle S_{n\pi^*} | H_{s.o.} | T_{n\pi^*} \rangle}{\langle S_{\pi\pi^*} | H_{s.o.} | T_{\pi\pi^*} \rangle} \sim 1$$

whereas between states with different electronic configuration it is greater by two to three orders of magnitude:

$$\frac{\langle S_{n\pi^*} | H_{s.o.} | T_{\pi\pi^*} \rangle}{\langle S_{\pi\pi^*} | H_{s.o.} | T_{\pi\pi^*} \rangle} \sim 10^2 - 10^3.$$

These results also explain the absence of fluorescence from n,π^*-levels in aromatic compounds, in which the $T_{\pi\pi^*}$-level usually lies between the $S_{n\pi^*}$- and $T_{n\pi^*}$-levels, and also the absence of fluorescence from the $S_{\pi\pi^*}$-level, when the $T_{n\pi^*}$-level lies between this level and the $T_{\pi\pi^*}$-level.

The luminescent properties of molecules with n,π^*-levels should depend on the relative arrangement of the lower single and triplet levels of different character. There are five possible most characteristic mutual arrangements of excited singlet and triplet levels of the π, π^*- and n, π^*-type (Fig. 1). This classification was published earlier[27].

Type I. In molecules of this type the long-wave absorption band is due to an n–π^* transition and has a low intensity. In view of the relatively low probability of $S_{n\pi^*}$–$T_{n\pi^*}$ conversion, it is possible to have n, π^* fluorescence and weak short-lived n, π^* phosphorescence with a short interval (about 2000–3000 cm^{-1}) between the luminescence bands, or absence of luminescence, when non-radiative transitions have a high probability.

Type II. This corresponds to a long-wave absorption band of the n, π^* type, with low intensity. In these molecules there is a high probability of S^*–T conversion, responsible for extinction of the fluorescence. The spectrum shows a band due to short-lived n, π^* phosphorescence ($\tau \sim 10^{-4}$–10^{-2} s) in the frequency range 2000–3000 cm^{-1} below the long-wave absorption edge.

Type III. The lower triplet level is $T_{\pi\pi^*}$, and the lower singlet level $S_{n\pi^*}$. The weak long-wave n, π^* absorption band in these molecules is usually overlapped considerably by the stronger π, π^*-band and appears either as an inflection or as a weak long-wave "tail" (it is therefore difficult to observe experimentally). Fluorescence is also absent, since it is suppressed by $S_{n\pi^*}$–$T_{\pi\pi^*}$ conversion, for which the probability is high. The emission shows only long-lived phosphorescence, due to the $T_{\pi\pi^*}$–S_0 transition ($\tau \simeq 0.1$–10 s). The spectral interval between the long-wave absorption edge and the phosphorescence band will be greater than the first two types. The phosphorescence yield is expected to be lower than that for molecules of type II.

Type IV. This corresponds to a long-wave absorption band of the π, π^*-type, with high intensity. The luminescent properties of molecules of this type are similar to those of molecules of type III. A characteristic feature of these molecules is that direct experimental observation of the n–π^* transitions is difficult. The $T_{n\pi^*}$-level cannot be observed in emission, and the n, π^* absorption band is hidden by more intense bands. Thus the absence of fluorescence provides an important indirect criterion for estimating the energy of the $T_{n\pi^*}$-levels in molecules for which it is expected that this level lies between the $S_{\pi\pi^*}$- and $T_{\pi\pi^*}$-levels.

Since the excitation energy of the n, π^*-state is to a considerable extent localised on the bonds adjoining the hetero-atom, whereas for the π, π^*-state it is delocalised throughout the π-system, the $T_{n\pi^*}$–$T_{\pi\pi^*}$ conversion, according to Ermolaev and Terenin[28], is a process of intramolecular transfer of energy among triplet levels.

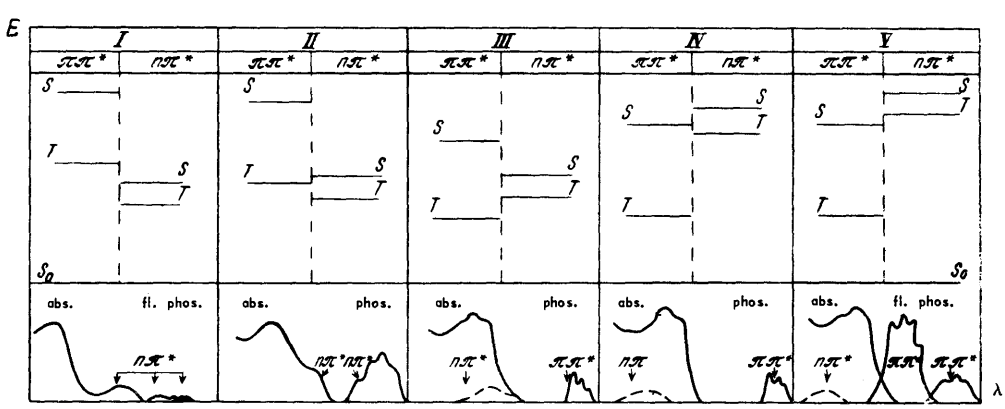

Fig. 1. Various types of arrangement of singlet and triplet π,π^*- and n,π^*-levels and the corresponding qualitative forms of electronic spectra.

Type V. Here the spectroscopic-luminescent properties are similar to those of the corresponding aromatic hydrocarbons. Both fluorescence bands and long-lived phosphorescence bands are observed.

Thus examination of the relative arrangement of the singlet and triplet n, π^*- and π, π^*-levels of molecules containing hetero-atoms and their assignment to one of the above types make it possible to understand the general character of the spectroscopic-luminescent properties of these molecules.

It should be noted, however, that this classification is not absolute, for the influence of various factors in a specific molecule may alter the ratio of the various transition probabilities and hence the luminescent properties.

Let us consider the various structural factors determining the mutual arrangement of the n, π^*- and π, π^*-levels. In systems with one hetero-atom, responsible for the $n-\pi^*$ transition, the energy of the $\pi-\pi^*$ transitions decreases more rapidly with increase in the π-system than the energy of the $n-\pi^*$ transitions. This is illustrated by the levels for the series: pyridine, quinoline, and acridine (Fig. 2). This relationship may provide an additional criterion for distinguishing n, π^*- and π, π^*-bands when the spectra of a series of compounds are compared.

When several identical hetero-atoms determining the n, π^*-levels are present, splitting of the n, π^*-levels takes place, so that the energy of the lower $n-\pi^*$-transition is reduced sharply. The magnitude of the splitting decreases rapidly with increase in the distance between the hetero-atoms. Thus in an aromatic hydrocarbon the replacement of several =CH– groups by an =N– atom leads to appreciable lowering of the $n-\pi^*$ transitions, whereas the $\pi-\pi^*$ transitions change little.

The splitting of the degenerate n, π^*-states in N-heterocycle was examined theoretically by El-Sayed and Robinson[29] on the basis of a localised model, in which it was assumed that the n-electron transferred to the π^*-orbital remains on the N atom, because of the coulombic attraction between this electron and the positive hole produced. El-Bayomi and Kearns[30] showed that the results of calculations based on a delocalised model provide a better explanation of the experimental data than do calculations based on a localised model. Both models predict an increase in splitting with decrease in the distance between the N atoms, and also a difference in the behaviour of the S^* and $T_{n\pi^*}$ states. Thus there should also be a change in the magnitude of the S^*, T interval for the lower n, π^*-levels.

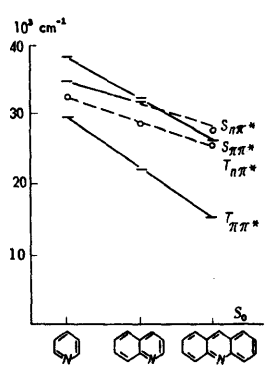

Fig. 2. Relative arrangement of the singlet and triplet π, π^*- and n, π^*-levels in the series: pyridine, quinoline, acridine.

The introduction of electron-donating substituents of the type –OR, –SR, and $-NR_2$ leads to a marked short-wave displacement of the n, π^*-bands (often by 2000–8000 cm^{-1}), whereas the π, π^*-bands are usually displaced towards longer wavelengths.

Finally, certain molecules, for example quinoline[8,18,19], show a change in the relative arrangement of the $S_{\pi\pi^*}$- and $T_{n\pi^*}$-levels under the influence of solvent; this will be illustrated in more detail in Section 3.

3. CONDENSED AROMATIC HETEROCYCLES WITH ONE NITROGEN ATOM

Let us first consider the relationship between structure and the bands due to $n-\pi^*$ and $\pi-\pi^*$ transitions in the series pyridine, quinoline, isoquinoline, acridine, etc., that is, the hetero-analogues of the poly-acene series containing one N atom. The data are given in Table 2.

The n, π^* and π, π^* absorption bands of pyridine (I) were first identified by Kasha[1]. Rush and Sponer[31,50] described the absorption spectrum of pyridine vapour and carried out a vibrational analysis of the structure. In the vapour, the n, π^*-band of pyridine is resolved into a large number of sharp narrow bands with (0, 0)-band at 34 770 cm^{-1}, whereas the π, π^*-band consists of more diffuse bands (ν_{00} = 38 350 cm^{-1}). The intensity of the π, π^*-band ($\epsilon \sim 2000$) is slightly greater than that of the corresponding band of the transition in benzene, where it is forbidden by symmetry. The increase in intensity is related to the decreased symmetry of the pyridine molecule. According to Jaffé and Orchin[51], the fact that the intensity of the band is not as high as might have been expected for an allowed transition indicates that the departure of the distribution of the π-cloud in pyridine from D_{6h} symmetry is slight. Stephenson[52] used the absorption spectra of solutions to estimate the oscillator strengths of the $\pi-\pi^*$ transitions (f = 0.041 in 2,2,4-trimethylpentane) and the $n-\pi^*$ transition (f = 0.003). Kasha first assumed that the low intensity of the $n-\pi^*$ transition is due to the fact that it is forbidden by symmetry, but measurements in the vapour[50] did not confirm this assumption. The low f-value was attributed to the low value of the transition moment integral resulting from the small overlap of the ψ-functions of the ground and excited n, π^*-states[26]. Halverson and Hirt[32] studied the influence of solvents on the absorption spectrum and showed that in polar solvents the n, π^*-band (ν_{00} = 34 000 cm^{-1} in cyclohexane) undergoes short-wave displacement and is overlapped by the π, π^*-band, whose position does not change (ν_{00} = 38 000 cm^{-1}). On going from cyclohexane to alcohol, the displacement is about 2000 cm^{-1}.

The luminescence of pyridine could not be observed, although it might be expected to show phosphorescence of the benzene type[35]. The $T-S_0$ absorption spectrum[35] showed a band at 29 577 cm^{-1}, with frequency close to the frequency of the $T-S_0$ transition for benzene, so that it can reasonably be assigned to the $T_{\pi\pi^*}$-level. Theoretical estimation of the $T_{n\pi^*}$-level predicts a frequency of 32 000–33 000 cm^{-1}.

The absorption spectrum of quinoline (II) is similar to the spectrum of naphthalene (ν_{00} = 31 980 cm^{-1}) for the

* Several errors in the formulae have been corrected in the translation (Ed. of Translation).

long-wave π, π^*-band and does not contain a long-wave n, π^*-band. The long-wave absorption bands are classified as ^1L_b (32 000 cm^{-1}) and ^1L (35 000 cm^{-1}) according to Platt, and this is confirmed by polarisation measurements[13]. From the appearance, in the vapour, of exceptionally sharp $n-\pi^*$ absorption lines in the region of 3130 Å against a background of diffuse bands due to the $\pi-\pi^*$ transition, Mataga and coworkers[15] estimated the frequency of the $n-\pi^*$ transition is quinoline as 32 000 cm^{-1}. That this estimate is reasonable is also confirmed by the absence of fluorescence from quinoline in the vapour and hydrocarbon solutions[15-22]; the extinction of the fluorescence can be attributed to the fact that the $T_{n\pi^*}$ level lies slightly below the $S_{\pi\pi^*}$-level for quinoline. The frequency of the $T_{n\pi^*}-S_0$ transition can be estimated as 30 000 cm^{-1}, with the assumption that the magnitude of the S, T splitting of the n, π^*-level of quinoline is about 2000–3000 cm^{-1}, as in pyridine.

The appearance of a fluorescence band, similar to the band given by naphthalene, in polar solvents[15-22] is attributed to a change in the relative positions of the $S_{\pi\pi^*}$- and $T_{n\pi^*}$-levels: under the influence of a polar solvent, particularly when intermolecular hydrogen bonding results, the energy of the $S_{n\pi^*}$- and $T_{n\pi^*}$-levels is raised and they occupy a position above the $S_{\pi\pi^*}$-level of quinoline. Indirect confirmation that such an increase can occur is provided by the N-heterocycles with clearly defined n, π^*-bands, where these bands are displaced towards higher frequencies by 2000–3000 cm^{-1} on going from hydrocarbon solution to alcoholic solution.

Quinoline gives a long-lived phosphorescence band, whose position, structure, and polarisation are similar to those of the phosphorescence band of naphthalene[11]. Dorr and Gropper[11] showed that the phosphorescence spectrum at 90°K in alcohol consists of two series of bands. The frequencies of the main series of bands, with polarisation perpendicular to the plane of the molecule, are given by the formula $\nu = \nu_{00} - n\times1400$ cm^{-1}, where $\nu_{00} = 21\,800$ cm^{-1} and $n = 0, 1 \ldots 4$. The beginning of the secondary series is displaced by 500 cm^{-1} towards lower frequencies; this corresponds to the frequency of the asymmetric vibration, which alters by 90° the polarisation of the bands of this series relative to the main series.

The absorption[11], fluorescence, and luminescence spectra of isoquinoline (III) differ only slightly from those of quinoline.

The absorption spectrum of acridine (IV) is similar to that of anthracene. The fluorescence is weak in hydrocarbon solutions at room temperature, but it increases considerably in alcoholic solutions[15-17]. There is no information on the phosphorescence of acridine, but it is reasonable to expect it in the near infrared range, as for anthracene. Evans[36] reported $T-S_0$ absorption of acridine in the region of 15 800 cm^{-1}. The extinction of the fluorescence in hydrocarbons indicates that the $T_{n\pi^*}$-level in acridine is close to the $S_{\pi\pi^*}$ level, although slightly above it.

Spectroscopic data have been used to construct a scheme of triplet and singlet π, π^*- and n, π^*-levels for the series pyridine, quinoline, and acridine (Fig. 2); the change in the frequencies of the $\pi-\pi^*$ transitions in this series with increase in the π-system is the same as that in the polyacene series[10]. On linear ring addition, the frequencies of the $S_{\pi\pi^*}-S_0$ and $T_{\pi\pi^*}-S_0$ transitions decrease by 5000 cm^{-1} per benzene ring, whereas the magnitude of the S^*, T splitting of the π, π^*-level remains about 10 000 cm^{-1} (Table 2). The frequencies of the $n-\pi^*$ transitions decrease at less than half this rate. The decrease in the frequencies of the $n-\pi^*$ transitions is determined by the decrease in the energy of the π^*-orbital and provides evidence in support of the delocalised model of n, π^*-states in aza-heterocycles[30].

Since even in the quinoline molecule the energies of the $S_{\pi\pi^*}$- and $S_{n\pi^*}$-levels coincide and the n, π^*-band does not appear as a long-wave band, the band cannot be a long-wave band in more complex mono-aza-aromatic polycycles.

The absorption spectra of benzo[*f*]quinoline (V), benzo[*h*]quinoline (VI), and phenanthridine (VII) are similar to those of phenanthrene[34]. The introduction of the N atom into the phenanthrene ring leads to a slight displacement of the long-wave π, π^*-band and an increase in its intensity, The fluorescence spectrum ($\nu_{00} = 28\,500$) and phosphorescence spectrum ($\nu_{00} = 21\,850$ cm^{-1}) of benzo[*h*]quinoline in alcohol at 100°K [12,33] have discrete vibrational structure and are polarised, like the bands due to $S_1^*-S_0$ and $T-S_0$

transitions in phenanthrene. Analogous fluorescence (ν_{00} = 28700 cm^{-1}) and phosphorescence (ν_{00} = 22050 cm^{-1}) spectra were described for phenanthridine[12]. The frequencies of the $S_1^*-S_0$ and $T-S_0$ transitions of the π,π^*-type for mono-aza-phenanthrenes differ from the frequencies for quinoline in approximately the same way as the frequencies of the phenanthrene transitions differ from the frequencies for naphthalene. They are also characterised by a decrease in the magnitude of the S^*, T splitting of the π,π^*-level to 6500–7000 cm^{-1}.

Similarity between the absorption spectra was established for the following pairs[34]: 1′-aza-3,4-benzophenanthrene (VIII)–3,4-benzophenanthrene; 3,4-benzacridine (IX)–1,2-benzanthracene; 5-aza-1,2-benzanthracene (X)–1,2-benzathracene; 3-aza-chrysene (XI)–chrysene; and 1-aza-triphenylene (XII)–triphenylene.

Thus in every instance the changes in the frequencies of the $S_1^*-S_0$ and $T-S_0$ transitions of the π,π^*-type in catacondensed mono-aza-aromatic polycycles are analogous to those in the corresponding aromatic hydrocarbons[10].

From the established dependence of the frequencies of $\pi-\pi^*$ and $n-\pi^*$ transitions on the magnitude of the π-system of mono-aza-aromatic polycyclic compounds, it is not difficult to obtain a general picture of their spectroscopic-luminescent properties. These molecules have a low T-level of the π,π^*-type (beginning with pyridine) so that they can exhibit only long-lived π,π^*-phosphorescence. In the N-hetero-analogue of naphthalene—quinoline—the energies of the $S_{\pi\pi^*}$- and $S_{n\pi^*}$-levels coincide (in the vapour and hydrocarbon solvents) so that in compounds of this series (apart from pyridine) the n,π^*-band cannot appear as a long-wave band. In the acridine molecule, the energies of the $S_{\pi\pi^*}$- and $T_{n\pi^*}$- levels coincide, so that those N-heterocycles (containing one N atom) whose $\pi-\pi^*$ transitions lie at shorter wavelengths than those of acridine will be non-fluorescent, whereas those whose $S_{\pi\pi^*}-S_0$ transitions lie at longer wavelengths will exhibit fluorescence like their hydrocarbon analogues. In acidic media and polar solvents, however, particularly when an intermolecular hydrogen bond is formed with the N atom, fluorescence may appear (be activated) for those molecules in which the $T_{n\pi^*}$-level lies above the $S_{\pi\pi^*}$-level. This is observed for quinoline, azaphenanthrenes, acridine, and benzacridine in alcoholic and other polar solutions.

4. AZABENZENES AND POLYCYCLIC COMPOUNDS WITH TWO OR MORE NITROGEN ATOMS

The introduction of two or more N atoms leads to more marked changes in the spectrum, influencing the positions and intensities of both the n,π^*- and π,π^*-bands. As a result of the interaction of the n,π^*-states of the N atoms, leading to splitting of the n,π^*-levels, the spectrum may show several n,π^*-bands. The interaction of n,π^*-states has been studied in most detail for the diazene series. It was established that the magnitude of the splitting depends to a marked extent on the mutual arrangement of the N atoms, decreasing rapidly with increase in the distance between them.

Azabenzenes

The spectra of diazines differ significantly from the spectra of pyridine and from one another.

Halverson and Hirt[33] found that the absorption spectrum of pyrazine (XIII) vapour consists of a system of sharp bands in the region of 3200 Å and a system of diffuse bands at 2800 Å, and assigned these to $n-\pi^*$ (ν_{00} = 30879) and $\pi-\pi^*$ (ν_{00} = 38763 cm^{-1}) transitions respectively.

The assignment of the bands was confirmed by a study of the behaviour of the absorption bands in various solvents[32]. In particular, a short-wave displacement of the n,π band was observed on going from cyclohexane to alcohol, although the displacement was much smaller ($\Delta\nu \simeq$ 300 cm^{-1}) than that for pyridine.

A detailed analysis of the vibrational structure of the long-wave absorption of the vapour enabled Japanese authors[40] to separate two overlapping systems of bands—a sharp system with a resolved 0–0 band equal to 30875 cm^{-1}, and a more diffuse system with lower intensity in the range 30500 cm^{-1}, assigned to a second $n-\pi^*$ transition, forbidden by symmetry. The behaviour of the absorption bands of pyrazine in various solutions was also described by Shimada[41], who also confirmed the $n-\pi^*$ character of the absorption band with ν_{00} = 30640 cm^{-1} in cyclohexane. Its frequency increases to 31020 cm^{-1} on mono-protonation, and the band disappears in solutions with salt formation[1]. The lower excited singlet level of pyrazine ($S_{n\pi}$) was assumed to be non-fluorescent[35]. Recently, Logan and Ross[53] reported the existence of two emission bands for pyrazine in the vapour and frozen hydrocarbon solutions. In the vapour, the band with shorter wavelength (in the region of 30000 cm^{-1}) adjoins the n,π^* absorption band, and the start of the long-wave band (at about 26500 cm^{-1}) coincides with the start of weak $T_{n\pi^*}-S_0$ absorption[45]. Innes and Giddings[45] obtained the rotational structure of the band due to the $n-\pi^*$ transition. In hydrocarbon solution at 80°K, pyrazine exhibits strong phosphorescence (with ν_{00} = 26420 cm^{-1}) and weak fluorescence with peaks at 29400, 28700, and 28050 cm^{-1}. Goodman and Kasha[35] studied the phosphorescence spectrum in an ether–isopentane–ethanol mixture at 90°K, and found that $\tau \simeq 0.02$ s and that the fluorescence band exhibits polarisation in the plane of the molecule. The influence of substituents, which led to short-wave displacement, confirmed the assignment of the phosphorescent T-level to the n,π^*-type.

Shimada[41] studied the phosphorescence spectrum of pyrazine in various media at 90°K and obtained good resolution of the vibrational structure, particularly in cyclohexane solution (ν_{00} = 26518–26445 cm^{-1}). It may be noted that in alcohol (ν_{00} = 26250) the fluorescence band does not show the characteristic short-wave displacement, indicating that this characteristic is not unambiguous. The $T-S_0$ transition was identified as an $n-\pi^*$ transition[41] from the behaviour of the phosphorescence band in acidic media, in which it undergoes appreciable extinction and is displaced towards higher frequencies, that is, it shows behaviour completely analogous to that of an n,π^* absorption band. Sidman[23] showed theoretically that the lower T-level is an n,π^*-level. The absorption in the region of the $T-S_0$ transition has also been described, with assignment to an 0–0 band equal to 26553 cm^{-1} in isopentane[35] or 26600 cm^{-1} in cyclohexane[37]. It has been shown theoretically[3] that the n,π^*-level lies at 31000 cm^{-1}. The dipole nature of the transition responsible for emission has been examined[54] and it was shown that the transition polarised in the plane of the molecule is symmetry allowed.

The absorption spectrum of pyrimidine (XIV) vapour, described by Uber and Winters[55,56], consists of a system of more than one hundred sharp narrow bands in the range

30 000–38 000 cm^{-1} and a system of broad diffuse bands in the range 39 000–45 000 cm^{-1}. From the behaviour of these bands in various solvents, Halverson and Hirt[32] assigned them to the $n-\pi^*$ transition (ν_{00} = 31 000 cm^{-1} in cyclohexane) and the $\pi-\pi^*$ transition respectively. Shimada[40] confirmed the assignment of the long-wave band to the $n-\pi^*$ transition, demonstrating that it disappears on salt formation.

It has been assumed that pyrimidine does not fluoresce from the n,π^*-state[18,19], but Börresen[57] had reported the observation of n,π^* fluorescence in liquid solution, and Goodman and coworkers[42] have described the n,π^* fluorescence spectrum at 298°K in 2,2,4-trimethylpentane (ν_{00} = 30 700 cm^{-1}) and found that $\tau = 10^{-9}$ s.

The phosphorescence band of pyrimidine—$\tau \simeq 10^{-2}$ s, ν_{00} = 28 332–28 218 cm^{-1} (cyclohexane), ν_{00} = 28 475 cm^{-1} (alcohol)—was studied in detail by Shimada[46], who obtained good resolution of the structure in various solvents. The phosphorescent level was interpreted as an n,π^*-level. In acid media the short-lived phosphorescence band disappears, with the production of weaker phosphorescence with $\tau \simeq 0.1$ s at shorter wavelengths, assigned to emission from the $T_{\pi\pi^*}$-level. The absorption spectrum of pyridazine (XV) vapour also shows two systems of bands—a diffuse system at 2500 Å and a sharp system with a purely electronic band at 26 656 cm^{-1} (3750 Å). According to Hirt[37], the long-wave band starting at 3700 Å in hexane is displaced towards shorter wavelengths by 300 Å in aqueous solution, whereas the second band—the π,π^*-band (2680 Å or 38 750 cm^{-1}) id displaced by only about 50 Å. Halverson and Hirt[32,33] assigned the first band to the $n-\pi^*$ transition, confirming this by observation of a short-wave displacement in polar solvents and under the influence of halogeno-substituents. Although Kasha assumes the existence of a $T-S_0$ transition of the $n-\pi^*$ type with energy 3.08 eV in pyridazine, Shimada[46] was unable to observe any luminescence, even at low temperatures. Goodman and coworkers[42] described the n,π^* fluorescence spectrum of pyridazine (ν_{00} = 27 000 cm^{-1}) in solution at 298°K with $\tau = 2.6 \times 10^{-9}$ s.

The absorption spectra of the vapour and solutions of *sym*-triazine (XVI) have been described[38]. The long-wave system of bands with initial band at 31 000 cm^{-1}, assigned to the $n-\pi^*$ transition on the basis of its behaviour in solutions, the influence of alkyl substituents, and the sharpness in the vapour, is more intense (ϵ = 880 at 36 780 cm^{-1}) than the diffuse system of bands due to the $\pi-\pi^*$ transition, starting at 44 000 cm^{-1} ($\epsilon \sim 150$ at 45 050 cm^{-1}). Paris and Hirt[47] described the phosphorescence spectrum of *sym*-triazine (ν_{00} = 26 400 cm^{-1} and τ = 0.44 s) and detected $T-S_0$ absorption. The $T-S_0$ transition was identified as an $n-\pi^*$ transition.

Mason[5] described the n,π^* absorption spectrum of *sym*-tetrazine (XVII) in the vapour and in cyclohexane solution at room temperature, and also in a mixture of hydrocarbons at 77°K (ν_{00} = 17 970 cm^{-1}). He obtained a resolved vibrational structure, particularly with the vapour (ν_{00} = 18 135 cm^{-1}). Chowdhury and Goodman[43,44] observed the n,π^* fluorescence of tetrazine with ν_{00} = 17 800 cm^{-1} and dimethyl-*sym*-tetrazine with ν_{00} = 17 100 cm^{-1} and $\tau \simeq 10^{-5}$ s. The existence of n,π^* fluorescence, observed for the first time for azines, is related to the absence of a $T_{\pi\pi^*}$-level between the $S_{n\pi^*}$- and $T_{n\pi^*}$-levels, between which there is no direct spin-orbital coupling.

Thus the n,π^*-bands in diazines, triazine, and tetrazine lie at lower frequencies than those in pyridine, whereas their π,π^*-bands are approximately the same. The first theoretical examination of the spectra of azines was made by Orgel[58], who showed that the simple molecular orbital method, used to describe the orbitals of the ground state, is inadequate for a description of the excited states. The changes in the $n-\pi^*$ transitions and to some extent in the $\pi-\pi^*$ transitions were attributed to the electronegativity of the N atoms, leading to a lowering of all the n,π^*- and π,π^*-levels relative to the levels in pyridine. The greater changes in the frequencies of the $n-\pi^*$ transitions were related to the fact that two $n-\pi^*$ transitions are possible in diazines. Although these levels belong to different symmetry classes, there may be approximate degeneracy, because the overlap is small, so that the interaction between the atomic orbitals of the two atoms is small. This degeneracy is removed for excited n,π^*-states. Thus diazines are convenient materials for studying the interaction between excited chromophoric groups in n,π^*-states[29]. Splitting of the n,π^*-levels should lead to the appearance of two n,π^*-bands in the spectra. In accordance with this picture, detailed analysis of the spectra of pyrazine[40] and other diazines established two systems of bands due to $n-\pi^*$ transitions, one symmetry allowed and the other symmetry forbidden, as predicted by theory. The theoretical examination was carried out by Mason[3]. The relationship between the frequencies of the $n-\pi^*$-transitions in the diazone series has not been elucidated completely, however.

Diazanaphthalenes

Although the spectra of quinoline do not show the n,π^*-bands directly, and reveal only the $T_{n\pi^*}$-level in the extinction of the fluorescence, we may expect their appearance in diazanaphthalenes with the displacement of the $n-\pi^*$ transitions to lower frequencies as a result of splitting, as in the diazines. The spectra of the diazanaphthalenes differ significantly from one another. The chief difference is in the position of the n,π^*-bands. As already noted, the extent to which the frequency of the n,π^*-band is lowered increases with decrease in the distance between the N atoms.

The absorption spectra of 1,5-naphthyridine (XVIII) and 1,8-naphthyridine are similar to the spectrum of quinoline, and have n,π^*-bands at shorter wavelengths than the π,π^*-bands[6]. This is readily understood: the N atoms are fairly widely separated, and the effect of splitting is almost absent. 1,5-Naphthyridine apparently does not fluoresce in hydrocarbons but it exhibits fluorescence in alcohol and other polar solvents[12]. The long-lived phosphorescence band (ν_{00} = 22 000 cm^{-1}) is similar to the naphthalene band, but has less structure.

In quinoxaline (XIX), however, the n,π^*-band (26 670 cm^{-1}) appears as a long-wave band[6], and the π,π^*-band (31 630 cm^{-1}) coincides with the naphthalene band, like the prolonged phosphorescence band (21 250 cm^{-1}).

In quinazoline (XX) the n,π^*-band lies at even lower frequencies (27 330 cm^{-1}), and in phthalazine (XXIII) it lies at 25 820 cm^{-1},[6] whereas the π,π^* absorption and phosphorescence bands are similar to those of naphthalene, although the frequencies are slightly higher for phthalazine[39].

The electronic bands due to $\pi-\pi^*$ transitions in all the diazanaphthalenes are similar to the naphthalene bands; in particular, the characteristic magnitude of the S^*, T splitting of the π,π^*-level is preserved. The luminescent properties can be explained on the basis of the theories of

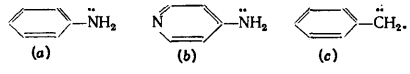
the n, π^*- and π, π^*-states, with allowance for the relative arrangement of their singlet and triplet levels.

Phthalazine has the most symmetrical molecule, and its spectrum is similar to that of naphthalene.

Cinnoline (XXI) gives three strong bands in the range 3100–3200 Å, whereas the other azanaphthalenes do not give bands in this range. The decrease in the energies of the $n-\pi^*$ transitions in diazanaphthalenes as the N atoms approach can be explained by arguments analogous to those for azabenzenes. As a result of this decrease, the long-wave absorption bands in the spectra of diazanaphthalenes are the n, π^*-bands, but the lower T-levels remain the $T_{\pi\pi^*}$-levels.

Diazaphenanthrenes

It is convenient to analyse the spectra of diazaphenanthrenes by comparing them with the spectra of phenanthrene. The absorption, fluorescence, and phosphorescence spectra of p-, m-, and o-phenanthrolines in alcohol solution are similar to the spectra of the original hydrocarbon, as already noted for the monoazaphenanthrenes. Thus the interaction of the n, π^*-states of the N atoms in the phenanthrolines does not produce such a marked decrease in the energy of the $n-\pi^*$ transitions, and they are found to be greater than the energy of the long-wave $\pi-\pi^*$ transition. The differences in the positions of the N atoms lead only to slight spectroscopic changes: the frequencies of the $\pi-\pi^*$ transitions are slightly higher for 4,7-phenanthroline (XXIV) ($S_1^*-S_0 = 29\,800$ cm^{-1}, $T-S_0 = 22\,200$ cm^{-1}) than for the 1,7-isomer (XXV) (29 700 cm^{-1} and 22 150 cm^{-1} respectively) and the 1,10-isomer (XXVI) (29 500 cm^{-1} and 22 100 cm^{-1})[12]. In the molecule of benzoquinoxaline (XXVII) the lower $S_1^*-S_0$ and $T-S_0$ transitions are also the $\pi-\pi^*$ transitions with lower frequencies (27 500 cm^{-1} and 21 000 cm^{-1} respectively in alcohol solution[38]). For diazaphenanthrenes, the magnitude of the S^*, T splitting of the π, π^*-levels remains at about 7500 cm^{-1}, as in phenanthrene; this is a characteristic feature of the geometry of a π-system with bent coupling of the rings[10]. The fluorescence of these compounds in alcoholic solutions is much weaker than that for phenanthrene, and is almost absent in hydrocarbon solvents; this can be attributed to the similarity in the energies of the $T_{n\pi^*}$- and $S_{\pi\pi^*}$-levels in these molecules.



In the molecule of 9,10-diazaphenanthrene (benzocinnoline) (XXXI) with two neighbouring N atoms, the $n-\pi^*$ transitions lie at much longer wavelengths (the n, π^* absorption and fluorescence[48v] have $\nu_{00} = 20\,300$ cm^{-1}, and the n, π^* phosphorescence has $\nu_{00} = 13\,500$ cm^{-1}). Solutions of benzocinnoline give an n, π^* fluorescence band.

Other polycyclic aza-heterocycles whose spectra have been described include phenazine (XXVIII), dibenzoquinoxaline (XXIX), and dibenzo[a, c]phenazine (XXX); in the molecules of these compounds the N atoms are fairly far from one another, and the n, π^*-bands are masked by the π, π^*-bands, so that their spectra are similar to the spectra of the corresponding hydrocarbon analogues.

The spectra of bipyridyls do not show n, π^*-bands, and are similar to the spectra of biphenyl[49].

5. SUBSTITUTED N-HETEROCYCLIC COMPOUNDS

The introduction of substituents leads to various changes in both the absorption spectra and the luminescent properties. A particularly marked influence is shown by electron-donating substituents, which are so-called strong auxochromes. We shall not deal in detail with problems of the interpretation of the influence of substituents, and we refer the reader to the appropriate literature[24,25,59]. We would merely point out that substituents of the type NR_2, OR, and SR produce marked changes in the spectrum as a result of the conjugation of the electrons of the unshared pair with the π-electrons. A common feature of these substituted molecules is that the substituents increase the number of atomic orbitals by one unit and the number of π-electrons by two units. If the N-heterocycle forms an even alternant π-system, its derivative forms an odd alternant system, and this leads to the production of an upper filled π-orbital which is higher than that in the unsubstituted molecule. This is responsible for the appearance of an absorption band with longer wavelength and a decrease in the ionisation potential[59]. This can be illustrated more clearly by comparing the molecules of aniline (a) and aminopyridine (b) with the benzyl anion (c):

(a) (b) (c)

These systems are π-isoelectronic, and the benzyl anion has an upper filled π-orbital of non-bonding character[25].

Thus electron-donating substituents reduce the energy of the lower $\pi-\pi^*$ transitions. Experiment shows, however, that when these substituents are introduced the energy of the $n-\pi^*$ transitions is usually increased, so that these substituents displace the π, π^*- and n, π^*-bands in opposite directions. This characteristic feature of the behaviour of the bands with different character provides an additional criterion for their identification by studying the spectra of a series of substituted molecules.

The short-wave displacement of the n, π^*-bands can be explained qualitatively[39,58], by assuming that the substituents, by acting as electron donors, create a slight negative charge at the C atoms, which hinders the promotion of the n-electron of the N atom to the π^*-orbital. This transition requires even more energy, and the corresponding band lies at shorter wavelengths. A detailed semi-quantitative quantum-mechanical description of this displacement due to electron-donating substituents has not yet been made, however.

Different changes in the energies of the $\pi-\pi^*$ and $n-\pi^*$ transitions due to substituents may lead to changes in the relative positions of the singlet and triplet π, π^*- and n, π^*-levels, and hence in the luminescent properties of the molecules.

Let us examine spectroscopic data on the influence of substituents on the spectra of individual N-heterocyclic compounds.

Stephenson[52] studied the absorption spectra of the three isomers of picoline and 2- and 3-halogeno-substituted pyridines in a hydrocarbon solvent and in alcohol, and showed that in the 2- and 3-picolines, and also in the 3-fluoro, 3-chloro-, and 3-bromo-pyridines the n, π^*-band lies at the same position as that for pyridine, and is displaced in alcohol to higher frequencies by not less than 2000 cm^{-1}. In the spectrum of 4-picoline, the n, π^*-band is found at 35 200 cm^{-1}, but for 2-fluoro-, 2-chloro-, and 2-bromopyridines this band is hidden by the π, π^*-band. The spectra have been used to estimate the oscillator strengths of the $\pi-\pi^*$ and $n-\pi^*$ transitions. Rush and Sponer[50] published

the vibrational absorption spectra of picoline vapours (γ-picoline has $\nu_{n\pi^*} = 35\,165$ cm^{-1} and $\nu_{\pi\pi^*} = 38\,320$ cm^{-1}; for β-picoline the corresponding frequencies are 34 684 cm^{-1} and 37 380 cm^{-1}, and for α-picoline the corresponding frequencies are 34 753 cm^{-1} and 37 620 cm^{-1}). Misra[60] described the absorption spectra of 2-bromo- and 3-bromopyridine in all phase states, and also showed that the $n-\pi^*$ transition is observed for the 3-bromo-isomer ($\nu_{n\pi^*} = 35\,080$ cm^{-1}, $\nu_{\pi\pi^*} = 36\,300$ cm^{-1}) but is not observed for the 2-bromo-isomer; this is due to the inductive effect of the Br atom on the sp^2-electrons of the N atom.

The introduction of substituents of the type OR and NR_2 leads to more marked changes in the spectra; intense π, π^* absorption appears at longer wavelengths, whereas the n, π^*-bands cannot be distinguished. Mason[4] described the absorption spectra of hydroxy- and methoxypyridines in various media, put forward an interpretation of the bands, and discussed problems of tautomerism.

The presence of halogeno-substituents in pyrazine leads to a marked increase in the frequencies of the $n-\pi^*$ transitions. Halverson and Hirt[32] showed that the frequency is increased by 1700 cm^{-1} in 2-chloro-pyrazine and by 3200 cm^{-1} in 2,3-dichloropyrazine, relative to pyrazine. Hirt[37] described the $S_{n\pi^*}-S_0$ (32 068 cm^{-1}) and $T_{n\pi^*}-S_0$ absorption (28 100 cm^{-1}, $\epsilon \sim 0.05$) of pyrazine. The S_1^*, $T-n\pi^*$ splitting is about 4000 cm^{-1}.

Uber and Winters[55] described the absorption spectra of the vapours of dichloro-, trichloro-, and tetrachloropyrimidines, which have a system of bands with low intensity at long wavelengths, together with a more intense second system of bands. Halverson and Hirt[32] described the absorption spectra of chloropyridazine solutions. An n, π^* fluorescence band was observed for 3,6-dichloropyridazine[42]; the frequency of the 0–0 transition for this compound is higher than that for pyridazine, by 1800 cm^{-1}. Trimethyltriazine gives an absorption spectrum[38] with $\nu_{00} = 37\,880$ cm^{-1} for the $n-\pi^*$ transition and $\nu_{00} = 43\,960$ cm^{-1} for the $\pi-\pi^*$ transition, and also bands due to $T-S_0$ absorption and $T-S_0$ emission phosphorescence with $\tau = 0.65$ s), assigned to the $n-\pi^*$ transitions (ν_{00} for the $T_{n\pi^*}-S_0$ transition $\sim 27\,000$ cm^{-1}). Chowdhury and Goodman[44] studied the absorption spectrum and n, π^* fluorescence (with $\nu_{00} = 17\,000$ cm^{-1}) of dimethyltetrazine.

There are some unsystematic data on the spectra of substituted azanaphthalenes. The absorption spectrum of 4-methylquinoline at low temperature[61] and the spectra of dichloroquinazoline and 4-methylcinnoline [(XXII) (Ed. of Translation)][39] have been published.

Kosta and coworkers[62] studied the extinction of the fluorescence of dimethylquinoline solutions by halide, $C_6H_5NH_3^+$, SCN^-, and Cu^{2+} ions. Topolats and coworkers[63] described the extinction of the fluorescence of quinoline derivatives by gallic acid, hydroquinone, resorcinol, phloroglucinol, orcinol, and pyrocatechol. Witwer and Zanker[54] measured the polarisation absorption and fluorescence spectra of mono-and di-aminoacridines at low temperature.

Aromatic N-Oxides

The N-oxides are unique derivatives of aromatic N-heterocycles. Ziolkowsky and Dorr[64] studied the absorption, fluorescence, and phosphorescence spectra, and also the polarisation spectra, of the N-oxides of pyrazine, quinoline, 2-chloroquinoline, isoquinoline, and quinoxaline in various solvents at 90°K, and showed that the electronic absorption and luminescence bands are similar to the bands of the corresponding aromatic hydrocarbons and are very sensitive to change in the solvent; the spectra do not show n, π^*-bands. Thus the attachment of an O atom to the N atom in the hetero-ring leads to a marked change in the state of the n-electrons but has little influence on the π-system.

6. AZOMETHINES AND AZO-COMPOUNDS

A wide range of compounds of practical importance are included among the aromatic azomethines (A) and azo-compounds (B):

Ar—CH=N—Ar′ (A) Ar—N=N—Ar′ (B)

which formally have a π-system isoelectronic with the π-system of the corresponding arylethylenes. If the n-electrons of the N atom are localised on an atomic orbital, two types of transition are possible: $\pi-\pi^*$ and $n-\pi^*$; the π, π^*-bands can be expected to be similar to the bands for the corresponding arylethylenes. This is in fact observed for the molecules of azo-compounds with a planar structure, but is not observed for aromatic azomethines. The sharp difference between the absorption spectrum of benzylideneaniline and the spectrum of stilbene, and also a number of characteristic features of the absorption spectra of benzylideneaniline and its derivatives were attributed by Izmail'skii and Smirnov[65], and later by others[66,67], to the non-coplanar structure of these molecules. The conclusion that the benzylideneaniline molecule is not coplanar was confirmed by the quantum-chemical calculations of Minkin and coworkers[68,69]. The non-planar structure of benzylideneaniline is more stable than the planar structure because of the interaction of the unshared pair of electrons (the n-electrons) of the N atom with the π-electrons of the N-phenyl ring. This complicates the possibility of separating the electron transitions in benzylideneaniline into n, π^*- and π, π^*-types. Nevertheless, its long-wave absorption band has been assigned[66,70] to the $n-\pi^*$ transition.

Conjugation of the n-electrons and simultaneously a p-electron of the nitrogen atom with the π-electrons complicates considerably the interpretation of the spectra of molecules of type (A) with non-planar structure.

Let us consider the simpler case of planar molecules of type (A). The relative energies of the n, π^*-bands in a series of planar molecules (A) can be estimated by selecting a molecule with a shortened π-system. It is known that with increase in size of the π-system, the π, π^*-bands are displaced towards longer wavelengths much more rapidly than the n, π^*-bands, so that by shortening the π-system it is possible to achieve better separation of the π, π^*- and n, π^*-bands. In the absorption spectrum of N-benzylidenebenzylamine $C_6H_5CH{=}N{-}CH_2C_6H_5$, the n, π^*-band does not appear as a long-wave band (the estimated lower boundary $\nu_{n\pi^*} \geqslant 32\,000$ cm^{-1}). Thus the n, π^*-band cannot be the long-wave band in the spectrum of planar models of the molecules of benzylideneaniline $C_6H_5CH{=}N{-}C_6H_5$ and other aryl-substituted compounds with general formula (A), so that their spectra should be similar to the spectra of arylethylenes. This is in fact observed, when a planar structure is forced on molecules of type (A), for example, by enclosing the –CH=N– group in a benzoxazoline

ring. The spectroscopic-luminescent properties of arylbenzoxazoles and arylethylenes have been shown to be similar [65,72,73].

What then is the nature of the absorption spectrum of benzylideneaniline? It extends to much longer wavelengths than the spectrum of stilbene (Fig. 3). This displacement cannot be attributed merely to destruction of the coplanarity of the π-system, which should lead to a short-wave displacement. The benzylideneaniline molecule represents essentially a symbiosis of two molecules: aniline and nonplanar stilbene. Conjugation of the n-electrons with the π-electrons of the N-phenyl ring leads to the production of a system of "aniline" levels, whereas the participation of a p-electron of the N atom in π-conjugation defines a system of "stilbene" levels (Fig. 3). The chief factor [59] responsible for the long-wave displacement of the spectra of aromatic compounds when electron-donating substituents are introduced is the production of higher-lying upper-filled π-orbitals. Thus the long-wave absorption band of benzylideneaniline can be interpreted qualitatively by relating it to the transition of an electron from the upper filled "aniline" π-orbital to the lower vacant "stilbene" π-orbital. Since the electron of the "aniline" orbital is situated chiefly on the N atom and the probability of its transition is determined to a considerable extent by the overlap of the n- and p-orbitals of the N atom, which are mutually orthogonal, it is natural to expect that this transition will have a low probability, and this explains the low intensity of the long-wave band. The bands at shorter wavelengths probably result from the superposition of several transitions. It is reasonable to assume that the range 300–350 nm corresponds to superposition of the "aniline" and "stilbene" bands. Although quantum-chemical calculations have been carried out for the spectra of benzylideneaniline [67-69,74], a more rigorous and detailed theoretical examination of this unique molecule is desirable. The qualitative picture, which makes it possible to understand to some extent the differences between the spectra of benzylideneaniline and stilbene, can be extended to other aromatic azomethines whose spectra have been described [75].

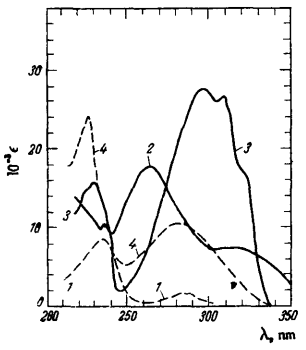


Fig. 3. Absorption spectra of aniline (1), benzylideneaniline (2), *trans*-stilbene (3), and *cis*-stilbene (4).

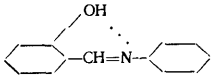
As expected, the absorption spectra of compounds of the type



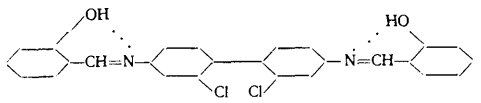
$$C_6H_5CH=N—C_6H_4—X—C_6H_4—CH=N—C_6H_5,$$

whose molecules consist of two benzylideneaniline molecules joined by a bridge X = $-CH_2-$ or $-CH_2-CH_2-$ which does not transmit π-conjugation, are similar to the spectra of benzylideneaniline [76]. The introduction of bridges X formed by –O–, –S–, or –NH– groups, which are electron donors, produces changes in the spectrum which are the same as the changes in the spectrum of benzylideneaniline resulting from the introduction of the substituents OH, SH, or NH_2 into the *para*-position of the aldehyde ring. The absorption spectra of compounds of this series were described by Krasovitskii and Mal'tseva [77]. Increase in the number of benzene rings between the azomethine groups in $C_6H_5CH=N-(C_6H_4)_n-N=CH-C_6H_5$ from $n = 1$ to $n = 3$ does not alter the absorption spectrum [76].

Azomethine compounds of the above types do not show luminescence. The absence of luminescence is apparently due to the non-coplanar structure, which is characterised by an extinguishing effect resulting from the excitation of torsional vibrations.

The introduction of substituents leads to complicated changes in the electronic structure of the molecules, and also influences their degree of non-coplanarity. This complicates the spectra and may alter the luminescent properties of the molecules. The interpretation of the spectra of these derivatives is very difficult. It is clear, however, that the introduction of substituents cannot lead to the appearance of $n-\pi^*$ transitions as long-wave transitions.

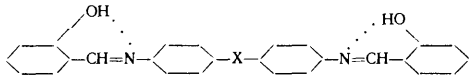
With Kozlov, Shigorin, and Puchkov [78-80], we showed that a particularly marked change in spectroscopic-luminescent properties is produced by the introduction of an OH substituent into the *o*-position of the aldehyde ring. *o*-Hydroxybenzylideneaniline (I)



(I)

exhibits bright green fluorescence at 77°K and reversible phototropic properties. The absorption spectrum of *o*-hydroxybenzylideneaniline contains a weak long-wave band, previously assumed to be the n, π^*-band. This band shows an anomalous increase in intensity on going from a non-polar solvent to a polar solvent [81]. Studies of the spectra of *o*-hydroxybenzylideneaniline under various conditions and of the phenomenon of phototropy established [79,80,82] that the long-wave band belongs to another tautomeric form of the *o*-hydroxybenzylideneaniline molecule, whose relative concentration depends on the nature of the solvent and temperature. No explanation has yet been given, however, for the anomalously large Stokes displacement between the long-wave absorption and the fluorescence band [82,83].

The absorption and luminescence spectra of various hydroxyazomethine compounds have been studied [84]. It was shown that doubling of the *o*-hydroxybenzylideneaniline molecule displaces the intense band by about 2500 cm^{-1}, that is, the displacement is not as great as that observed on going from stilbene to bistilbene, and the displacement of the long-wave band (assigned to the other form) is even smaller. A remarkable feature is that the absorption spectrum does not depend on the number of phenyl rings



between the N atoms, although there is undoubtedly a conjugation effect, as indicated by the short-wave displacement of the band for (II):

(II)

compared with the molecule which does not contain substituents causing steric hindrance.

It was also shown[77] that the bridge X = –O–, –S–, or –NH– in the molecules (III):

(III)

influences the spectra as an electron-donating substituent, but it does not exhibit the properties of a conjugation transmitter.

Arylazo-Compounds Ar–N=N–Ar′

These have molecules with planar structures. Their intense absorption bands, due to $\pi-\pi^*$ transitions, are similar to the bands of the corresponding arylethylenes[75,85] and the long-wave range (20 000–24 000 cm^{-1}) shows a weak band due to the $n-\pi^*$ transition, which has been most extensively studied for azobenzene. Jaffé and coworkers[70] carried out a detailed study and theoretical examination of the spectra of azobenzene and related compounds. On the basis of the small short-wave displacement in polar solvents and under the influence of substituents, they assigned the long-wave band at 420 nm to an $n-\pi^*$ transition, assuming that it is formed by the superposition of two bands due to $n_a-\pi^*$ and $n_s-\pi^*$ transitions. It should be noted, however, that their method of graphical resolution of the bands has no real basis and can hardly be correct. Dyck and McClure[86] described the structure of the band due to the $\pi-\pi^*$ transition (ν_{00} = 27 662 cm^{-1}), resolved in a mixed azobenzene–bibenzyl crystal at 20°K, using the frequencies 220, 378, and 1342 cm^{-1}. The last frequency was assigned to the stretching vibration of the –N=N– group in the excited π, π^*-state. Hochstrasser and Lower[87] showed that the n, π^*-band exhibits polarisation in the plane of the molecule and that the transition is forbidden by symmetry, in agreement with theoretical calculations of the splitting of the n, π^*-states of the two nitrogen atoms. The magnitude of the splitting was estimated as 8900 cm^{-1}. This estimate agrees with experiment. As noted above, for one N atom the band due to the $n-\pi^*$ transition is expected in the region of 32 000 cm^{-1} (planar benzylideneaniline model) and for azobenzene the $n-\pi^*$ transition lies at about 22 000 cm^{-1}. The molecules of arylazo-compounds may exhibit two configurations: *cis* and *trans*[75,85,86]. The *trans*-configuration is the more stable. The absorption spectra of the *trans*-isomers of various arylazo-compounds Ar–N=N–Ar′ (where Ar = phenyl, α-naphthyl, or β-naphthyl) have been described[85]. The *trans*-isomers may be converted into the *cis*-isomers under the influence of light. The study of the photo-*trans*-*cis*-isomerisation of azo-compounds has been the subject of a number of papers[88]. The spectra of the pure form of *cis*-azobenzene have been isolated and studied[89], and the absorption spectra of the *cis*-isomers of more complex azo-compounds have been described[90,91].

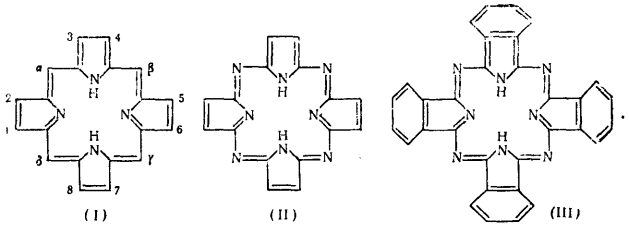
Azo-compounds form one of the most extensive classes of non-fluorescent compound. The absence of fluorescence is apparently due to the high probability of S^*-T conversion from a lower $S_{n\pi^*}$-state into the $T_{\pi\pi^*}$-state, and is also related to the photochemical instability of azo-compounds.

Derivatives of azo-compounds form a large class of organic dyes, so that a large number of their spectra have been studied. Brode and Wyman and coworkers[92–96] studied the absorption spectra of a large number of azo-compounds and azo-dyes in order to establish the relationship between the spectra and chemical structures of the dyes. The phenomenon of phototropy and the *cis*-*trans*-isomerisation of aromatic azo-compounds have been described[92], and the influence of dissolution and temperature on the *cis*-*trans*-isomerisation of the amino-, hydroxy-, alkyl-, and halogeno-derivatives of azobenzene, benzeneazonaphthol, and benzeneazonaphthylamine has been described[51]. The appearance of a new absorption band in the spectrum of azo-dyes as a result of the hydration of the dye molecules when water is added to the organic solvent has been described[94]. The change in the spectra accompanying the interaction of the molecules of binary mixtures of dyes in aqueous solutions[95] and the phenomenon of phototropy in solutions of complex diazo methoxyazo-dyes[96] have also been studied.

A series of papers by Heilbronner, Gerson, Schulze, and coworkers[75,97–106] described the study of the electronic structure and properties of azo-compounds. The ultraviolet absorption spectra of arylazoazulenes have been studied[97,98] and it has been established that the displacement of the band shows a simple dependence on the Hammett constant; the dipole moments of phenylazoazulene derivatives have been studied[99] and the spatial structure of the molecules has been established. The π-electronic structure of phenylazoazulene has been examined theoretically by the MO LCAO method[100], and the energies of transitions and the oscillator strengths have been calculated. A special study has been made[101] of the problem of the influence of a substituent in the benzene ring on the position of the absorption band in the range 16 500–17 000 cm^{-1}, and a study has been made[41] of the bathochromic shifts of the bands accompanying the protonation of the molecules of arylazoazulene derivatives in ethanol–hydrochloric acid systems. Study of the spectra of *trans*- and *cis*-azobenzenes[103] in acid solutions showed that their conjugate acids have different structures; the *cis*-isomer of the acid is gradually converted into the *trans*-form. The spectra and structure of the *p*,*p*′-bis(dimethylamino)azobenzene azonium cation have been studied[105] and the influence of protonation on the spectra of *p*′- and *m*′-derivatives of *p*-dimethylaminoazobenzene[97,98] *p*-dimethylaminophenylazoazulenes[106] has been described.

Robin and Simpson[107] studied the absorption spectra of polyphenyl azo-dyes $C_6H_5-N=N-(C_6H_4-N=N-)_n-C_6H_5$ (n = 0–5); the spectra were interpreted on the basis of a model with transfer of the electronic excitation along the chain of the molecule, the polarisation of the transitions was established, and the $n-\pi^*$ transitions were isolated.

Skulski and Urbanski described the absorption spectra of azo-dyes based on 4-hydroxy- and 4-acetoxyazobenzenes[108], 4-formyl-, 4-nitro-, and 4-(2-nitrovinyl)azobenzenes[109], and acetoxy- and acetylamino-derivatives of 1-phenylazonaphthalene[110]. It has been established[108] that electron-accepting groups in the *o*-position relative to the phenol groups in the dyes $X-C_6H_4-N=N-C_6H_3YOH$ produce a hypsochromic shift of the adsorption band. The absorp-



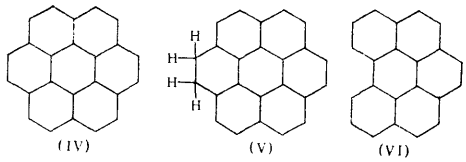
spectra of *o*- and *p*-azo-dyes based on 1-phenylazonaphthalene have also been described[111,112].

Si-Jung and Jaffé[113] studied the transfer of the electronic effects of the $-N=NC_6H_4-$ group in the compounds p-$HO-C_6H_4N=NC_6H_4-X$, where X = OCH_3, CH_3, or Br. Baba[114] studied the influence of intermolecular hydrogen bonding on the absorption spectrum of *p*-hydroxyazobenzene, and showed that the n, π^*-band is displaced towards shorter wavelengths, and the π, π^*-band towards longer wavelengths. It was shown that the displacement of the frequencies is greater for the O–H...N < bond than for the O–H...O < bond.

It is pointed out in Pringsheim's monograph[115] that among more than 700 azo-dyes there is no example of fluorescence in solutions. With Shigorin, Kozlov, and Puchkov[116,117], we investigated structural factors leading to activation of the fluorescence of azo-compounds, and showed that this activation is facilitated by the introduction of an *o*-hydroxy-substituent, which leads to the formation of an intramolecular six-membered quasi-aromatic ring with hydrogen-bonding, and that this ring stabilises the structure of the molecule. The *o*-hydroxyazo-compounds exhibit bright fluorescence in powders and frozen solutions. The substance becomes non-fluorescent when the OH group is methylated. The fluorescent S_1^*-state in the *o*-hydroxyazo-compounds is the π, π^*-state. It is lower because of the decrease in frequency caused by the electron-donating OH substituent, whereas the OH...N interaction removes the degeneracy of the n, π^*-states (the N atoms are not equivalent) and leads to marked displacement of the frequency of the $n-\pi^*$ transition towards higher values.

7. PORPHYRINS AND PHTHALOCYANINES

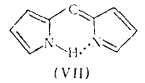
Without examining in detail the relationship between the spectra and structures of the molecules of porphyrins and phthalocyanines (although this problem deserves attention, despite the existence of a number of reviews[118-120] and theoretical calculations[121-123]) let us examine the extent to which the spectra of these complex systems show general regular features characteristic of heterocyclic compounds. It is of interest to determine the range of the spectrum in which we can expect $n-\pi^*$ transitions for these molecules and to find whether they exhibit luminescence.



(I) (II) (III)

Porphine (I), the parent compound of the porphyrins, has a lower $S_1^*-S_0$ transition in the region of 6130 Å (16 300 cm^{-1}), active in absorption and fluorescence. Solov'ev, Sevchenko, and coworkers[124] obtained a quasi-line multiplet structure for the fluorescence and absorption bands of porphine in octane at 77°K. There is no information on the phosphorescence of porphine. To understand the relationship between the spectrum and the structure, let us consider the characteristic features of the structure of the porphine molecule. Formally, it is obtained by forming a ring of four pyrrole groups by means of methine bridges. In the process, only two pyrrole rings are preserved; the N atoms of these rings each bring one atomic orbital and two electrons into the π-system. The N atoms of the other two rings each bring one atomic orbital and one electron, and also carry n-electrons, capable of giving $n-\pi^*$ transitions. These could be the lowest frequency transitions, as with the previously examined *N*-heterocycles, only if the entire absorption spectrum lay above 32 000 cm^{-1}. Since the absorption of porphine begins at much lower frequencies, due to the extensive π-system, the $S_{n\pi^*}$- and $T_{n\pi^*}$-levels in molecules of this type will lie above the $S_{\pi\pi^*_n}$-level and will not influence the luminescence of the molecules. The cyclisation of four pyrrole rings to give one large ring should produce properties characteristic of the angular cyclisation of aromatic nuclei. It is convenient to compare the skeletons of porphine and coronene (IV), whose outer perimeters have approximately the same number of π-electrons. As already noted, on angular cyclisation the long-wave bands are α-bands of low intensity (in coronene this band is further forbidden by symmetry). The greater lowering of the frequency of the $S_1^*-S_0$ transition in porphine compared with coronene is due to the presence of the NH group, which produces the strong bathochromic shift of the bands, discussed in Section 5. The angular cyclisation itself does not lead to marked lowering of the frequency of the $\pi-\pi^*$ transition. This is effectively confirmed for porphyrins on going from porphine to tetrabenzoporphyrin, which gives a frequency in the region of 15 200 cm^{-1}, that is, only 1100 cm^{-1} below the $\nu_{S_1^*-S_0}$ frequency of porphine (or only 270 cm^{-1}, calculated for one benzene ring). Shkirman and Solov'ev[125] also obtained a quasi-line structure for the fluorescence and absorption bands of tetrabenzoporphine in octane at 77°K. An important characteristic feature of angular cyclisation is the decrease in the magnitude of the S^*, T splitting, which can also be expected for porphine. Although phosphorescence is not known for porphine, its T-level can be determined from data on metalloporphyrins. The intrdouction of a metal, producing little change in the frequency of the $S_1^*-S_0$ transition, leads to an increase in the relative phosphorescence yield with increased atomic weight of the metal. In various metallomesoporphyrins, the magnitude of the S^*, T splitting is about 3000–3500 cm^{-1},[126] which is even slightly less than that in coronene. It is reasonable to attribute the additional decrease to the electron-donating effect of the NH and N–metal groups. Thus it is also possible, for the complex porphyrin molecules, to distinguish those characteristic features of the spectra which are determined by the topology of their π-electronic structure or the topology of the molecular framework over which the π-electrons are distributed.

This conclusion is further confirmed by examining molecules which are related to porphine but which have a smaller π-system, and this in turn makes it possible to understand various spectroscopic-luminescent characteristics of these molecules.



In the molecule of chlorin (which differs from porphine in that it contains a hydrogenated 1–2 bond), the frequency of the $S_1^*-S_0$ transition is displaced towards lower frequencies (ν_{00} = 15 780 cm^{-1})[125]. Rabinowitch tried to attribute this displacement and the increase in the intensity of the long-wave absorption band to the production of a new lower-lying excited level; the band associated with transition to this level is assumed to mask the "porphine" bands of low intensity. It is not at all clear how decrease in the π-system leads to an increase in the number of electron

levels (preservation of the former levels and the production of a new level). Sevchenko and coworkers[124] consider than this explanation is without foundation, but they in turn assume a correlation between the levels of chlorin and porphine. It is not rational, however, to look for such a correlation. When one double bond is eliminated in the coronene ring:

(IV) (V) (VI)

there is also a long-wave displacement of the $\pi-\pi^*$ transition. The spectroscopic properties of dihydrocoronene (V) are similar to those of 1,12-benzoperylene (VI), whose molecule can reasonably be regarded as a doubled phenanthrene molecule[10]. Thus the hydrogenated bond in the chlorin molecule produces the long-wave displacement as a result of the sharp decrease in the circular symmetry, that is, the change in the topology of the π-system. This also explains the difference in the intensity of the band and the absence of phosphorescence. The magnitude of the S^*, T-splitting in 1,12-benzoperylene is approximately double that in coronene. If this also applies on going from porphine to chlorin, the frequency of the $T-S_0$ transition of the latter will lie in the region of 10 000 cm^{-1}. The probability of $T-S_0$ emission in this range would be expected to be very low, because of the strong non-radiative deactivation. This is apparently related to the absence of phosphorescence in metallochlorins[127], although metals such as Cu have a marked ability to increase the phosphorescence yield. Increase in the magnitude of the S^*, T splitting (up to 7000 cm^{-1}) takes place in the molecule of bipyrrole (VII), which is as it were half a porphine molecule:

(VII)

The absorption band for this compound lies in the region of 20 000 cm^{-1}, that is, 3700 cm^{-1} higher than that for porphine. However, the displacement is very slight in relation to the position of the pyrrole band at about 220 nm.

Although bipyrrole exhibits fluorescence, replacement of the methine group by –N= leads to extinction of the fluorescence. The extinction is apparently due to the fact that the π-electrons of the pyrrole ring are conjugated with the n-electrons of the N atom. This leads to breakdown of the planar structure of the π-system, as in benzylideneaniline.

In tetra-azaporphine (II), the =CH– methine bridges are replaced by =N–. This replacement produces almost no displacement of the π, π^*-band (16 350 cm^{-1})[125]. In phthalocyanine (tetrabenzotetra-azoporphine) (III), the frequency is lowered by only 1900 cm^{-1} relative to that for tetra-azaporphine[128].

Evstigneev and coworkers[129-131] and Livingston, and coworkers[132,133] observed "activation" of the fluorescence of chlorophyll: the absence of fluorescence in non-polar solvents and the production of fluorescence when polar solvents were added. The first authors[129-131] attribute this "activation" to breakdown of chlorophyll associates, whereas the second authors[132-135] attribute it, by analogy with quinoline, to a change in the relative position of the $S_{\pi\pi^*}$ and $T_{n\pi^*}$-levels under the influence of the polar solvent. Simple analysis of the structural characteristics of the chlorophyll molecules shows, however, that the $n-\pi^*$ transitions in these molecules cannot be as low as this. In actual fact, as noted for porphine, the energy of the n, π^*-levels in this molecule is much greater than that of the π, π^*-levels. The same is true for tetra-azaporphyrin, since increase in the number of N atoms cannot lower the n, π^*-levels because of their splitting; the latter should be small, because of the relatively short distance between the N atoms. The presence of C=O groups in the chlorophyll molecule may lead to the appearance of n, π^*-bands in the range 27 000–26 000 cm^{-1}, that is, again at higher frequencies than the lower π, π^* transitions of the π-system of the porphine ring. This provides further confirmation of the interpretation given by Evstigneev and coworkers[129-131].

In conclusion it may be noted that the above general features, relating the spectra to the molecular structure, make it possible to obtain an overall picture of the spectroscopic-luminescent properties of a wide range of organic compounds. Many of these regular features require theoretical examination.

---o0o---

NOTE ADDED IN PROOF

The following reviews appeared after the present paper had been submitted for publication: one by Lower and El-Sayed[136], devoted to the triplet state in intramolecular electronic processes, one by Innes[137] on the spectroscopic properties and geometry of the excited electronic states in azines, and their theoretical interpretation, and a Russian translation[138] of Mason's review on the electronic absorption spectra of heterocyclic compounds.

I. INTRODUCTION

Compounds of fluorine with all the elements are known. Until recently the noble gases constituted an exception, but advances in the chemistry of inorganic fluorides in recent years led to the synthesis of the fluorides of these elements too in a pure state [1,2]. The interest in fluorine is largely due to its unusual "extreme" position in the Periodic System—its unusual chemical reactivity. The extremely high oxidising power of fluorine led to its wide application in the preparation of compounds of many elements in their highest valence states [3-7]. These compounds are in turn important in practice, being used in many branches of the new engineering, in the first place in the technology of the processing of nuclear fuel [8-10].

Certain highest fluorides, which are solids, are also powerful fluorinating agents, but considerably inferior to elemental fluorine. As an example, one may mention the difluorides of silver and mercury [11-13], the trifluorides of cobalt and manganese [11, 14-16], lead tetrafluoride [17], and others [18-22].

The compounds of fluorine with the other halogens constitute the most interesting class of inorganic fluorides because they are unusual and highly reactive compounds. They can be synthesised relatively easily, many of them are liquids under normal conditions, and they all behave as very powerful fluorinating agents. Halogen fluorides can be arranged in the following series in terms of their reactivity:

$$ClF_5 > ClF_3 > BrF_5 > IF_7 > ClF > BrF_3 > IF_5 > IF_3 > IF$$

The reactivity of chlorine trifluoride approaches almost that of elemental fluorine, and with certain inorganic and organic substances ClF_3 actually reacts more vigorously [23]. For example, even before the discovery of halogen fluorides, it was noted that the addition of small amounts of chlorine to fluorine enhances the activity of the latter [24]. There is no doubt that this is associated with the formation of chlorine fluorides.

Chlorine pentafluoride ClF_5 was not obtained in a pure form until 1966, [25] its chemical properties have not been investigated, and, in view of the lack of experimental data, its oxidising power can only be inferred from general relations governing the activity series of halogen fluorides. However, it is quite evident that ClF_5 is a most powerful oxidising agent and an extremely active fluorinating agent, approaching elemental fluorine in these properties.

Chlorine trifluoride, like fluorine itself, can oxidise many metals to their highest valence, but it has an important advantage over elemental fluorine in that it is easy to

handle, can be relatively readily stored, can be transported, and can be used in the liquid state. Chlorine trifluoride converts silver chloride and fluoride into the difluoride and cobalt difluoride into the trifluoride[26,27], and as mentioned above, these compounds are some of the most powerful solid fluorinating agents used. Not only many transition metals, but also oxides are fully converted into the highest fluoride when acted upon by chlorine or bromine trifluoride[28-32].

The above remarks account for the great interest in the chemistry of halogen fluorides. The methods for their synthesis and their physical and chemical properties are being investigated very vigorously and a number of extensive reviews have been published on these topics[20-23,33-37]. There is no doubt that inorganic fluorides, which may be somewhat inferior in their oxidising power to elemental fluorine and halogen fluorides but are solid under normal conditions, are of great practical interest and can find wide application as powerful fluorinating agents. From this point of view, alkali metal fluorohalogenates, the most active of which have been synthesised literally in the last 2–3 years and whose chemistry has developed enormously at the present time, are the most promising.

Table 1 lists all the alkali metal fluorohalogenates known at present and includes for comparison the data for halogen fluorides and elemental fluorine. It is noteworthy that alkali metal fluorofluorates, i.e. compounds of the type $M[F(F_2)]$, where M is an alkali metal, would be most promising from the point of view of their employment as highly active fluorinating agents, but repeated attempts to synthesise such compounds have been unsuccessful so far[38-45]. Nevertheless, similar compounds of chlorine, bromine, and iodine are known, have been isolated in a pure state, and have been investigated in fair detail; their stability increases in the series Cl–Br–I.[46-50]

Evidently the analogous fluorine compounds also exist but, in conformity with the general tendency of halogens, alkali metal fluorofluorates must be very unstable; in all probability this is why their synthesis and isolation present considerable experimental difficulties, which unfortunately have not been overcome as yet.

The advantages of alkali metal fluorohalogenates as fluorinating agents are as follows: (a) high oxidising power of the compounds, greatly exceeding that of all known solid fluorinating agents; (b) the possibility of carrying out reactions at elevated temperatures without the development of a high pressure in a closed system, which means that fluorination can be performed in relatively simple apparatus; (c) the use of purer fluorinating agents than is the case when elemental fluorine or halogen fluoride are used for this purpose; (d) ease of handling of the solid substances; (e) the achievement of complete fluorination (by virtue of the higher temperatures used) of the compounds for which this is impossible in the presence of halogen fluorides, for example.

The last finding is confirmed by the data of Table 2, where compounds which are only partially fluorinated by bromine trifluoride even under severe conditions are listed. On the other hand, when potassium tetrafluorobromate(III) $KBrF_4$ is used, the reaction goes to completion after a relatively short time[51].

Apart from the possibility of using alkali metal fluorohalogenates as fluorinating agents, it is interesting to note that their application for analytical purposes to determine oxygen, and also in isotopic geology, for the removal of oxygen from minerals[51], is also promising.

Alkali metal fluorohalogenates are not only of great practical value but they also constitute a class of inorganic compounds which is of considerable theoretical interest. It has been established[52,53] that halogen fluorides are ionisable solvents, which dissociate according to the equation

$$2XF_n \rightleftarrows XF^+_{n-1} + XF^-_{n+1}.$$

Consequently these substances are amphoteric solvents and their behaviour can be most readily understood on the basis of the acid–base theory of non-aqueous solvents[33,52-59]. The fluoride ion plays a role analogous to that of the proton, namely the addition of a fluoride ion is equivalent to the loss of a proton [sic (Ed. of Translation)].

TABLE 1. Conditions of synthesis and certain physical properties of alkali metal fluorohalogenates, halogen fluorides, and elemental fluorine.

Compound	Fluorine content, wt. %	Synthetic reaction	Temperature of synthesis, °C	M.p., °C	Decomposition temperature, °C

TABLE 2. Fluorination of certain oxides with potassium tetrafluorobromate(III).

Compound	Fluorination temperature, °C	Time required for complete fluorination, h	Compound	Fluorination temperature, °C	Time required for complete fluorination, h	Compound	Fluorination temperature, °C	Time required for complete fluorination, h
Nd_2O_3	350	1	ZrO_2	350	1	NiO	500	2
CeO_2	350	1	MnO_2	500	1	Fe_2O_3	500	5
ThO_2	400	2	Al_2O_3	400	1	CaO	500	16

By considering halogen fluorides as ionisable solvents, it is easy to show that certain groups of compounds will react in them as acids and bases, and therefore it is possible to have compounds both with the cation XF_{n-1}^{+} and with the anion XF_{n+1}^{-}. The former are acids and the latter bases. The synthesis of such complex compounds is a direct demonstration of the mechanism of the self-ionisation of halogen fluorides and comprehensive study of the compounds extends greatly our knowledge of the chemistry of complex compounds involving a complex ion consisting entirely of halogens.

A large number of acids with the complex cation XF_{n-1}^{+} are known[60-72]. Among compounds with the complex anion, bases of Group I and Group II elements are known; compounds with alkali metals, in the first place potassium, rubidium, and caesium and, to a lesser extent sodium and ammonium, are most widely represented. So far lithium fluorohalogenates have not been isolated in a pure form, although hypotheses have been put forward concerning the possibility of their existence, at least in an unstable state; this can be fully accounted for by the low radius of the cation which sets up in its vicinity a powerful electric field coordinating the most electronegative ligands of the complex anions and thereby disrupting the latter.

Among alkaline earth metals, compounds with calcium, strontium, and barium are known. The bases with beryllium and magnesium have not been synthesised so far. This is probably also to be accounted for by steric factors. Complex compounds where Ag^{+}, NO^{+}, and NO_2^{+} serve as the cations are also known[33,72-75].

The relative ease of preparation of the complex compounds of KF, RbF, and CsF, compared with other alkali metal and alkaline earth metal fluorides, should be noted. It is interesting that similar behaviour is also characteristic of the anion ClF_3O^{-}.[76]

Among the compounds of alkali metals of small dimensions, the more stable are fluorohalogenates containing a larger halogen. This conforms to the general rule which determines the stability of polyhalogenates[77]: symmetry, the presence of a cation with a large molar volume, and the location of a large electropositive atom in the centre of the anion with all other atoms electronegative.

From this standpoint, it is clear why rubidium and caesium fluorides are more readily converted into the hexafluorobromates(V) $MBrF_6$ (M = Rb, Cs) than into the tetrafluorochlorates(III) $MClF_4$ (M = Rb, Cs) and why sodium tetrafluorochlorate(III) $NaClF_4$ does not exist while small amounts of sodium tetrafluorobromate(III) $NaBrF_4$ have been detected.

Many problems involving alkali metal fluorohalogenates have remained unsolved so far and the available information is usually restricted to purely experimental data. The first serious and successful attempt to give a systematic account of alkali metal fluorohalogenates was the review of Stepin et al.[75], but these authors, who examined alkali metal anionohalogenates in general, were of course unable to systematise sufficiently widely and completely the results of studies of fluorohalogenates in particular. Furthermore, as a result of the vigorous development of precisely this branch of inorganic chemistry, many most interesting and important data were obtained in very recent investigations and were therefore of course not included in the review of Stepin et al.[75]

The present review deals with the methods of synthesis and physicochemical properties of alkali metal fluorohalogenates—compounds which are very interesting theoretically and very important in practice in view of the possibility of their employment as highly effective solid fluorinating agents.

II. ALKALI METAL FLUOROCHLORATES

The first information about the preparation of alkali metal fluorochlorates was obtained in 1950, when Bode[39,40] established that, in the interaction of elemental fluorine with potassium, rubidium, and caesium chlorides or fluorides, powerful fluorinating agents are formed, to which the author assigned the formula MF_x (M = K, Rb, Cs; $x \simeq 3$). It was suggested[78] that compounds of this type can have the formula $M^{I}[M^{III}F_4]$. None of these data were confirmed subsequently. Evidently in this case the tetrafluorochlorates(III) of potassium, rubidium, and caesium ($MClF_4$), markedly contaminated by the initial fluorides, were obtained for the first time. Chemical analysis of the synthesised compounds did not reveal the presence of chlorine, which can be explained by the fact that tetrafluorochlorates(III) form chlorate and not chloride ions on interaction with water. This was demonstrated experimentally more than ten years later[79,80] and therefore reliable data on alkali metal fluorochlorates, the methods of their synthesis and their properties, derive from publications of the last 3–5 years.

1. Alkali Metal Difluorochlorates(I)

Chlorine monofluoride is only very slightly ionised in solution, according to the equation

$$2\,ClF \rightleftarrows Cl^{+} + ClF_2^{-},$$

which is confirmed by the very low electrical conductivity of liquid ClF.[52] However, at the present time compounds have been synthesised which contain both the cation Cl^{+} [65] and the anion ClF_2^{-}.[81,82]

In 1965 it proved possible to obtain for the first time a complex compound with the anion ClF_2^{-} by the reaction of nitrosyl fluoride with chlorine monofluoride[81]:

$$NOF + ClF = NO^{+}ClF_2^{-}.$$

Nitrosyl difluorochlorate(I) $NOClF_2$ is stable in the solid state only at low temperatures. Similar salts, stable at room temperature, were synthesised by the same worker with the cation NO^{+} replaced by potassium, rubidium, and caesium[82]. The preparation of potassium, rubidium, and caesium difluorochlorates(I) was achieved by two possible reactions:

$$NO^{+}ClF_2^{-} + MF = M^{+}ClF_2 + NOF \quad \text{or}$$
$$ClF + MF = M^{+}ClF_2^{-}.$$

In the synthesis of alkali metal difluorochlorates(I) various conditions (temperature, reaction time, pressure) were used. The starting materials were the corresponding fluorides, chlorine monofluoride, and nitrosyl fluoride. The latter behaved, strictly speaking, as a catalyst for the reaction, ensuring the synthesis of $NO^{+}ClF_2^{-}$ and its further interaction with the alkali metal fluoride; the latter process liberated NOF in a free state again and it was therefore not consumed in the reaction. In some experiments caesium fluoride was subjected to a preliminary

treatment with CF_3COCH_3, which, however, did not improve the reaction and the treatment was subsequently abandoned.

The best method for the synthesis of potassium, rubidium, and caesium difluorochlorides(I) proved to consist in the direct interaction of chlorine monofluoride with the corresponding fluorides. It is noteworthy that the higher the pressure and temperature the more complete is the conversion of the fluoride into the difluorochlorate(I), but in none of the cases described was 100% conversion achieved, with synthesis of a pure substance (Table 3). On the other hand, further increase in temperature, which, it would seem, should reduce the reaction time and should ensure that the reaction goes to completion, is restricted to 230°C (the temperature limit of the thermal stability of the substances synthesised).

Attempts to prepare lithium and sodium difluorochlorates(I) by a similar method at temperatures between 25° and 150°C and pressures of the order of 140 atm were unsuccessful. Chlorine was not detected in the reaction products and X-ray diffraction studies failed to reveal the presence of substances other than the initial fluoride.

Ammonium fluoride does not react with gaseous chlorine monofluoride[83] and the use of high temperatures and pressures was not undertaken; however, even this would probably not lead to success, since ammonium difluorochlorate(I) should exist only at low temperatures, if at all.

Potassium, rubidium, and caesium difluorochlorates(I) are solid white salts with relatively high thermal stability (the decomposition temperatures of $KClF_2$, $RbClF_2$, and $CsClF_2$ are respectively 237°, 248°, and 262°C). The decrease of the size of the cation and the increase of polarisation on going from Cs^+ to Li^+ are consistent with the stability of alkali metal fluorochlorates(I). As oxidising and fluorinating agents, these compounds are somewhat inferior to the corresponding tetrafluorochlorates(III).

Infrared spectroscopic studies on caesium difluorochlorate(I)[82] revealed the presence of an absorption band at 636 cm^{-1}, which is consistent with the data obtained earlier for $NO^+ClF_2^-$ (635 cm^{-1}) and corresponds to the asymmetric vibration to the ClF_2^- anion. It is suggested that in nitrosyl difluorochlorate(I) this anion has a linear structure. A similar structure is probably typical for ClF_2^- also in alkali metal difluorochlorates(I).

X-Ray diffraction studies on potassium, rubidium, and caesium difluorochlorates(I) showed the presence of very intense lines corresponding to the α-modification of the bifluoride impurity[84], while the difluorochlorate(I) itself gives rise only to lines of low intensity or is altogether amorphous to X-rays[82].

The infrared spectroscopic data, confirming the linear configuration of the ClF_2^- anion, can be accounted for by one of the following models: (a) the hybridisation model[85], permitted mainly by the sp^3d hybridisation of the atomic orbitals of chlorine, which leads to a trigonal bipyramid with two fluorine atoms at the apex, the chlorine atom in the centre, and three free electron pairs in the remaining corners; (b) the more probable molecular orbital model[85], incorporating mainly the $p\sigma$-atomic orbitals which are used to form semi-ionic bonds.

In conclusion it should be noted that at the present time no alkali metal difluorochlorate(I) has been obtained in a pure form. The results of chemical analysis (Table 3) have been calculated from the increase in the weight of the starting material and on the assumption that the final product is a mixture of only two substances— the alkali metal fluoride and the corresponding difluorochlorate(I). However, X-ray diffraction data fail to confirm this, showing the presence of the bifluoride; furthermore, there is a possibility of a definite amount of impurities due to reaction with the walls of the vessel. Therefore the above chemical identification cannot be regarded as sufficiently reliable. On the other hand, the thermal data, the fluorinating properties of the synthesised mixtures, and also the infrared spectroscopic data (which have been obtained unfortunately only for $CsClF_2$) definitely characterise the new compounds as the difluorochlorates(I) of potassium, rubidium, and caesium.

There is no doubt that the next problem to be solved involves the finding of ways to separate the difluorochlorate(I) from the unreacted fluoride or conditions in which the reaction is successfully taken to completion with formation of a pure product. Only then will it be possible to consider further reliable and comprehensive chemical and physicochemical studies of alkali metal difluorochlorates(I).

2. Alkali Metal Tetrafluorochlorates(III)

In 1961 Asprey et al.[79] showed, having repeated the experiments of Bode[39,40], that the reaction of elemental fluorine with potassium, rubidium, and caesium chlorides does not result in the formation of polyfluorides MF_x ($x \simeq 3$) but tetrafluorochlorates(III), according to the following equation:

$$MCl + 2F_2 = MClF_4.$$

Since the reaction is strongly exothermic, a temperature exceeding the thermal stability of the synthesised tetrafluorochlorate(III) is readily attained and the decomposition is accompanied by the formation of the fluoride:

$$MClF_4 = MF + ClF_3.$$

For this reason, tetrafluorochlorates(III) are very difficult to obtain in a pure form, and the substances synthesised usually contain a certain amount of the corresponding fluoride as a impurity. On the other hand, when the temperature of the synthesis is reduced, the reaction does not go to completion and the impurity is then the initial chloride.

Potassium, rubidium, and caesium tetrafluorochlorates(III) were synthesised in the temperature range 90–250°C.[79] It is noteworthy that Bode and Klesper[43], having

repeated, simultaneously with Asprey et al.[79], their earlier experiments on the fluorination of rubidium chloride with elemental fluorine and having carried out a more comprehensive identification of the substances synthesised, virtually abandoned their earlier findings concerning the formation of polyfluorides[39,40] and arrived at a conclusion analogous to that of Asprey et al.[79] They isolated[43] a substance with the composition Rb_3ClF_6 which was shown by X-ray diffraction to contain no rubidium fluoride. This compound is the double salt $2RbF.RbClF_4$.

Kelly et al.[80] investigated the reaction of alkali metal chlorides with elemental fluorine as a function of temperature (up to 300°C) and pressure (up to 4000 atm). The reaction between potassium chloride and fluorine leads to the formation of potassium tetrafluorochlorate(III) $KClF_4$ only at elevated temperatures and pressures (Table 4). At room temperature only part of the initial potassium chloride is converted into KF even at a pressure of 4000 atm, and potassium tetrafluorochlorate(III) does not form (Table 4, experiment 1).

An increase of temperature leads to the formation of $KClF_4$, the yield being higher the higher is the temperature and pressure. At 300°C and 3400 atm the starting material is completely absent from the final product, but up to 10% of potassium fluoride remains as an impurity and pure $KClF_4$ cannot be obtained (Table 4, experiment 4). Potassium tetrafluorochlorate(III) was identified chemically and by X-ray diffraction. Total chlorine, total fluorine, and potassium were determined for the chemical identification. The calculations were based on the equations

$$\%\ KF = \left(\frac{\%\ K}{39.1} - \frac{\%\ Cl}{35.5}\right) \times 58.1$$

$$\%\ KClF_4 = \frac{1}{4}\left(\frac{\%\ F}{19.0} - \frac{\%\ KF}{58.1}\right) \times 150.6$$

$$\%\ KCl = \left(\frac{\%\ Cl}{35.5} - \frac{\%\ KClF_4}{150.6}\right) \times 74.6\ .$$

Such chemical identification is undoubtedly not free from disadvantages and of course the next problem is to obtain pure potassium tetrafluorochlorate(III). X-Ray diffraction study of the substances synthesised (Table 4, experiments 3 and 4) showed the absence of potassium chloride and the presence of potassium fluoride together with a new phase—potassium tetrafluorochlorate(III).

When elemental fluorine was allowed to react with rubidium chloride (300°C, 1500 atm), a white powder containing 56.7% Rb, 30.9% F, and 11.3% Cl formed. These data and also the results of X-ray diffraction analysis show that under the conditions indicated a mixture with the composition 62.5% $RbClF_4$ + 36.2% RbF was synthesised.

The reaction of elemental fluorine with caesium chloride (300°C, 1250 atm) yielded a powder, amorphous to X-rays, the chemical analysis of which showed the presence of 61.3% Cs, 28.3% F, and 10.0% Cl (calculated for $CsClF_4$: 54.4% Cs, 31.1% F, 14.5% Cl), i.e. evidently in this case a mixture of caesium tetrafluorochlorate(III) and caesium fluoride was obtained.

TABLE 4. Synthesis of potassium tetrafluorochlorate(III) $KClF_4$ by the reaction $KCl + 2F_2 = KClF_4$.

No. of experiment	Maximum temperature, °C	Maximum pressure, atm	Results of chemical analysis, wt. %			Compounds present, wt. %		
			K	F	Cl	KCl	KF	$KClF_4$
1	25	4000	56.8	9.8	33.8	70.0	30.0	—
2	175	3600	42.9	39.8	17.3	8.7	35.4	55.9
3	300	2800	30.2	47.9	21.9	1.9	9.0	89.1
4	300	3400	28.4	50.3	21.3	—	9.6	90.4

The attempts to prepare sodium and lithium tetrafluorochlorates(III), even in a mixture with the corresponding fluoride, by the reaction of elemental fluorine with the corresponding chlorides were unsuccessful. In all cases (even at high temperatures and pressures) only the fluorides of these metals formed. The attempt to carry out the reaction of potassium fluoride with elemental fluorine (300°C, 3000 atm) to prepare potassium polyfluoride KF_n ($n > 1$) also failed.

The method of preparation of alkali metal tetrafluorochlorates(III) based on the reaction of elemental fluorine with the corresponding alkali metal chlorides at high temperatures and pressures is experimentally very difficult and leads to the formation of substances with a large amount of impurities. A more promising procedure is based on the use of chlorine trifluoride[86]. The solvolysis of alkali metal fluorides in liquid chlorine trifluoride yields the corresponding tetrafluorochlorates(III). The reaction can be described by the equations

$$2\,ClF_3 \rightleftarrows ClF_2^+ + ClF_4^-,$$

$$MF + ClF_3 = M^+ + ClF_4^-.$$

The self-ionisation of chlorine trifluoride results in the formation of the complex anion ClF_4^- which gives rise to the base $M^+ClF_4^-$ on interaction with the alkali metal.

Chlorine trifluoride free from the F_2, Cl_2, and ClF impurities and also alkali metal fluorides of high purity, which had been subjected to preliminary heat treatment to remove traces of moisture, were used in the reaction. The syntheses were achieved in a vacuum system made from Monel and nickel. The degree of conversion of the fluoride into the tetrafluorochlorate(III) was determined from the increase in weight after complete removal of excess ClF_3. Chemical analysis involved the determination of total chlorine and total fluorine. The results of the study on the behaviour of alkali metal fluorides in chlorine trifluoride are compiled in Table 5.

The data in Table 5 are completely consistent with the results of earlier work[79,80] and show that lithium and sodium tetrafluorochlorates(III) are not formed even when chlorine trifluoride is used. The conversion of potassium, rubidium, and caesium fluorides into the corresponding tetrafluorochlorates(III) with the aid of chlorine trifluoride is more complete and takes place at lower temperatures than in the reaction between elemental fluorine and the corresponding chlorides. The degree of conversion depends on the nature of the cation and is higher the greater is the size of the alkali metal cation, which is consistent with the general rule governing the stability of polyhalides[77]. The stability series for alkali metal tetrafluorochlorates(III) should evidently be as follows: Cs > Rb > K. The size of the cations NH_4^+ and K^+ (1.48 Å for NH_4^+ and 1.33 Å for K^+)[87] suggests that the conversion of NH_4F into NH_4ClF_4 in the reaction with chlorine trifluoride should be possible. However, the substance formed is unstable and decomposes with explosion when an attempt is made to isolate it in a pure form[86]. N_2, Cl_2, and NF_2Cl in various proportions were found in the explosion products[83].

It is interesting to examine the interaction in ternary systems of the type HF–MF–ClF_3 (M is an alkali metal)[86]

TABLE 5. Synthesis of alkali metal tetrafluorochlorates(III) using chlorine trifluoride*.

Fluoride	Molar ratio ClF_3:MF	Results of chemical analysis, wt. %		Results of analysis
		Cl	F	
LiF	8	–	–	Does not react
NaF	8	–	–	Does not react
KF	8	14.7	46.7	A white crystalline substance forms, 56.5% of the initial KF being converted into $KClF_4$. Calculated for the composition $KClF_4.0.8KF$: 18.2% Cl; 46.5% F.
RbF	7	15.4	37.3	A crystalline solid substance forms, 85.2% of the initial RbF being converted into $RbClF_4$. Calculated for the composition $RbClF_4.0.2RbF$: 16.5% Cl; 36.9% F.
CsF	8	14.4	30.8	A solid crystalline substance forms, 91% of the initial CsF being converted into $CsClF_4$. Calculated for the composition $CsClF_4.0.1CsF$: 13.7% Cl; 30.0% F.
NH_4F	–	–	–	$NH_4F + ClF_3$ mixture explodes on heating above 0°C. The unstable ammonium tetrafluorochlorate(III) NH_4ClF_4 probably forms.

* The reactions were carried out at 100°C.

in order to test the possibility of synthesising alkali metal tetrafluorochlorates(III) in this way. Chlorine trifluoride was added to solutions of the alkali metal fluoride in liquid hydrogen fluoride, the molar ratio MF : HF being chosen so that the alkali metal fluoride was completely dissolved. With lithium fluoride and sodium fluoride, only the bifluorides were obtained. On the other hand, when potassium fluoride, rubidium fluoride, and caesium fluoride were used, the products were solvated bifluorides. Thus in all cases the compounds obtained were the same as those synthesised earlier in the binary systems HF–MF;[88-92] there was no addition of ClF_3, and chlorine was completely absent from the products. These results contradict the data concerning the existence of complexes of HF and ClF_3 [93,94] but are consistent with later data, according to which chlorine trifluoride behaves in hydrofluoric acid as a strong base[95], which favours the formation of stable bifluoride ions[96]:

$$2\,HF + ClF_3 \rightleftarrows ClF_2^+ + 2\,HF_2^-,$$

i.e. its behaviour is analogous to that of alkali metal fluorides in liquid hydrogen fluoride:

$$MF + HF \rightleftarrows M^+ + HF_2^-.$$

It now becomes quite clear why tetrafluorochlorates(III) were not obtained under these conditions. The concentrations of the alkali metal fluorides in liquid hydrogen fluoride solutions correspond to their solubilities[97,98]:

$$CsF > RbF > KF > NaF > LiF.$$

Potassium, rubidium, and caesium tetrafluorochlorates(III) are white crystalline substances which melt at about 100–200°C and decompose into the alkali metal fluoride and gaseous products on heating in a vacuum or in an inert medium at 350–400°C.[86] According to infrared spectroscopic data, the gaseous products are ClF_3 and ClF. The infrared spectrum of solid potassium tetrafluorochlorate(III) showed the presence of the 1970, 1830, 1225, and 970 cm^{-1} frequencies. Caesium tetrafluorochlorate(III) is diamagnetic.

X-Ray diffraction study of potassium tetrafluorochlorate(III) led to its assignment to the tetragonal system with the lattice constants $a = 6.18$ and $c = 10.94$ Å. The type of the unit cell is evidently that of potassium perchlorate, but the crystallisation of alkali metal tetrafluorochlorates(III) is not entirely similar to that of the corresponding perchlorates. Rubidium tetrafluorochlorate(III) crystallises in the cubic system with $a = 4.30$ Å and the unit cell is tentatively assumed to be of the caesium chloride type. As mentioned above, caesium tetrafluorochlorate(III) is amorphous to X-rays.

Potassium tetrafluorochlorate(III) decomposes at about 200°C, while caesium tetrafluorochlorate(III) can be heated for several hours at 300°C without decomposition. As regards thermal stability, rubidium tetrafluorochlorate(III) is intermediate between the tetrafluorochlorates(III) of potassium and caesium.

The densities of potassium and caesium tetrafluorochlorates(III), containing a certain amount of the fluorides as impurities, are as follows[86]:

$$d_4^{25} = 2.58 \text{ for } KClF_4.0.8KF,$$

$$d_4^{24} = 3.40 \text{ for } CsClF_4.0.1CsF.$$

The densities of pure potassium and caesium tetrafluorochlorates(III) can be calculated on the basis of additivity (assuming that the specimens are $MClF_4 + MF$ mechanical mixtures)—the corresponding values are 2.61 and 3.39.

The high oxidising power of alkali metal tetrafluorochlorates(III) must be regarded as their main chemical property[86]. They react vigorously with water, the reaction resulting in the evolution of oxygen and the formation of chlorate ions.

Iodates are oxidised by tetrafluorochlorates(III) to iodine. The chemical reactivity of the compounds is inversely proportional to their stability, which can be represented by the following general scheme:

$$\xrightarrow{\text{increase of stability}}$$
$$K—Rb—Cs$$
$$\xleftarrow{\text{increase of chemical reactivity}}$$

It is known that Pyrex glass does not react with chlorine trifluoride free from hydrogen fluoride, but a solution of an alkali metal fluoride in ClF_3 breaks down Pyrex glass very vigorously, which is evidently due to the increased self-ionisation of chlorine trifluoride as a result of the shift of the equilibrium

$$2\,ClF_3 \rightleftarrows ClF_2^+ + ClF_4^-.$$

Thus it may be suggested that solutions of alkali metal fluorides in chlorine trifluoride can serve as fluorinating agents more powerful than liquid chlorine trifluoride.

Alkali metal tetrafluorochlorates(III) char wood and paper on contact and react explosively with many organic substances.

As a result of their low vapour pressure, alkali metal tetrafluorochlorates(III) can be used in fluorination reactions at temperatures up to 500°C without the development of a high pressure in a closed system, i.e. these compounds find application as convenient sources of fluorine in those reactions where it is difficult to use liquid or gaseous chlorine trifluoride and other halogen fluorides.

In view of their unusual nature, high oxidising power, and high fluorine content, alkali metal tetrafluorochlorates(III) are the most interesting compounds among all the fluorohalogenates known at the present time. It is interesting to examine the behaviour of these compounds as bases and

their interaction with various acids and to investigate the mechanism of the hydrolysis, fluorination processes, etc. However, it should be noted that the chemistry of alkali metal tetrafluorochlorates(III) has been investigated very little and that all the problems enumerated above remain unresolved so far. Information about the physical properties is also very limited. Furthermore, alkali metal tetrafluorochlorates(III) free from the fluorides as impurities have not been synthesised and the nature of the impurities has not been established (i.e. whether these substances are present as mechanical mixtures or whether they are compounds of the double salt type). All these are the most interesting and promising problems awaiting solution in the further study of alkali metal tetrafluorochlorates(III).

As regards alkali metal fluorochlorates in general, it should be noted that the most promising and important task at the present time is the synthesis of hexafluorochlorates(V) with the general formula $MClF_6$, where M is the alkali metal. The information about chlorine pentafluoride is limited to three brief communications[25,99,100] and the reliable synthesis of chlorine pentafluoride was developed as late as 1966.[25] Evidently, as for other fluorochlorates[52,53], the phenomenon of self-ionisation in solution is characteristic of chlorine pentafluoride:

$$2\,ClF_5 \rightleftarrows ClF_4^+ + ClF_6^-$$

which means that there is a possibility of the formation of acids and bases containing the corresponding complex ions. Bases of this type should be the most powerful solid fluorinating agents among those known at the present time.

III. ALKALI METAL FLUOROBROMATES

The reaction leading to the formation of alkali metal fluorobromates was first achieved by Moissan[101], who observed the formation of a compound of fluorine and bromine on fluorination of potassium bromide with gaseous fluorine. Potassium tetrafluorobromate(III) $KBrF_4$ was probably obtained but the compound was not isolated in a pure state; under the experimental conditions used $KBrF_4$ decomposed into potassium fluoride and bromine trifluoride, which was in fact the new, hitherto unknown compound of fluorine and bromine.

The following compounds of bromine and fluorine are known[102-105]: bromine monofluoride BrF, bromine trifluoride BrF_3, and bromine pentafluoride BrF_5. Bromine monofluoride has not yet been isolated in a pure form: it is the least stable compound of the three enumerated above, which is why it has not been well characterised physicochemically. Its chemical properties have not been much investigated either, since it is difficult to separate it from BrF_3, BrF_5, and Br_2 which are in equilibrium with it. Evidently this is the reason why alkali metal difluorobromates(I) have not been isolated so far. Analogous derivatives of BrF_3 and BrF_5 have been successfully synthe- and their properties have been vigorously investigated in recent years.

Banks et al.[52] observed experimentally a considerable difference (by a factor of about 100) between the electrical conductivities of bromine trifluoride in the solid and liquid state; they believe that this is evidence of the ionic character of the conductivity of bromine trifluoride. In view of this and also a number of chemical properties of bromine trifluoride, self-ionisation according to the following equation has been suggested:

$$2\,CrF_3 \rightleftarrows BrF_2^+ + BrF_4^- .$$

The analogous behaviour of bromine pentafluoride is also quite evident:

$$2\,BrF_5 \rightleftarrows BrF_4^+ + BrF_6^- .$$

Thus successful synthesis of two types of alkali metal fluorobromates, containing the anions BrF_4^- and BrF_6^-, was to be expected. Representatives of both classes are in fact known: alkali metal tetrafluorobromates(III) and hexafluorobromates(V).

1. Alkali Metal Tetrafluorobromates(III)

The determination of the nature of liquid bromine trifluoride and its solutions served as a basis for the successful synthesis of alkali metal tetrafluorobromates(III).[52,53,106-109] Bromine trifluoride can behave both as a donor and acceptor of electrons. The data on the solubility of alkali metal halides in bromine trifluoride are very important for the elucidation of the conditions in which alkali metal tetrafluorobromates(III) can be synthesised. The solubility is of the ionic type. On dissolution in bromine trifluoride, alkali metal fluorides are almost completely dissociated into ions, the solubility increasing sharply with the atomic weight of the metal[110]. When an alkali metal fluoride dissolves, the anion BrF_4^- forms in accordance with the equation

$$MF + BrF_3 = M^+[BrF_4^-] .$$

Thus bromine fluoride behaves in this case as an acceptor of fluoride ions. It is interesting that similar behaviour is also characteristic of hydrogen fluoride:

$$MF + HF = M^+[HF_2^-] .$$

Sharpe and Emeléus[107] investigated the reactions of bromine trifluoride with alkali metal halides. With lithium chloride, double decomposition results in the formation of lithium fluoride, which is sparingly soluble in an excess of bromine trifluoride. When sodium fluoride is dissolved in bromine trifluoride and when the excess of the latter is removed in a vacuum, a compound with the composition $NaF.0.97BrF_3$ forms. Evidently sodium tetrafluorobromate(III) with an admixture of sodium fluoride is obtained in this case. Potassium chloride is appreciably soluble in bromine trifluoride, the dissolution involving more profound transformations than is the case with lithium fluoride; this is confirmed by the isolation of the reaction product in a pure state. When the excess solvent is removed (vacuum 130°C), a white crystalline substance remains, whose composition corresponds to the formula $KBrF_4$. Sharpe and Emeléus[107] also point out the possibility of preparing the analogous rubidium and caesium salts; however, it was not possible to isolated these compounds in a pure state.

The data for ammonium fluoride show that the compound NH_4BrF_4 is unstable and decomposes explosively. However, ammonium tetrafluorobromate(III) NH_4BrF_4 should be much more stable than ammonium tetrafluorochlorate(III) NH_4ClF_4, and it is quite evident that its isolation in a pure form is possible. So far this compound has not been isolated and investigated. There are only data showing that the interaction of ammonium fluoride with bromine trifluoride yields a white solid product with the tentative composition NH_4BrF_4.[86] Apart from the reaction between alkali metal fluorides or chlorides with liquid bromine trifluoride, alkali metal tetrafluorobromates(III) can be prepared by a "dry" method involving the reaction

$$MBr + 2\,F_2 = MBrF_4 .$$

The tetrafluorobromates(III) of potassium, rubidium, and caesium were obtained in this way[79]. This method was first used by Bode[39,40], but the latter incorrectly identified the reaction products, as in the case of the chloride.

Thus potassium, rubidium, and caesium tetrafluorobromates(III) have so far been isolated in a pure form, sodium tetrafluorobromate(III) has been obtained together with impurities, and it has been suggested that ammonium tetrafluorobromate(III) may be obtained.

Alkali metal tetrafluorobromates(III) are white crystalline involatile substances. For example, when potassium tetrafluorobromate(III) was placed in a quartz tube and evacuated at room temperature for 6 h, the weight loss was only 0.5%. At 158°C the vapour pressure of $KBrF_4$ is 20 mmHg and at 356°C it is only 90 mmHg. In the above temperature range the vapour pressure is described by the equation

$$\lg P_{mm} = 3.38 - \frac{890}{T}.$$

When potassium tetrafluorobromate(III) is heated at 200°C for 5 min, the weight loss is 30%, while sodium tetrafluorobromate(III) decomposes completely under these conditions; furthermore, rapid decomposition of $NaBrF_4$ is observed even at 80°C. This is one of the reasons for the difficulty of synthesising pure sodium tetrafluorobromate(III).

The melting point of $KBrF_4$ has been determined approximately–it is near 330°C. When the substance is heated above 330°C, the vapour pressure rises sharply, which can be explained by the decomposition of $KBrF_4$ with evolution of gaseous BrF_3.

Thermal decomposition of potassium tetrafluorobromate(III) is accompanied by the evolution of BrF_3 and the formation of potassium fluoride. Similar thermal decomposition is in general characteristic of analogous compounds, i.e. the more electronegative halogen remains in a compound with the alkali metal. This rule is also evident in the thermal decomposition of $KICl_4$ and $RbICl_3F$. The thermal decomposition of these compounds is accompained by the evolution of ICl_3 and the formation of potassium chloride and rubidium fluoride respectively[111,112].

This general tendency in the decomposition of polyhalogenates is explained by the fact that the lattice energy of the alkali metal halides decreases on going from the fluorides to iodides and therefore the formation of the halides involving the most electronegative halogen is favoured by the energy change.

There are no data on the thermal stability of rubidium and caesium tetrafluorobromates(III). The stability series should however be the same as for the tetrafluorochlorates(III), i.e. Cs > Rb > K > Na > Li. The data for $KBrF_4$ and $NaBrF_4$ fully confirm this hypothesis. The first views concerning the structure of potassium tetrafluorobromate(III) were put forward by Sharpe and Emeléus[107]. It was suggested that $KBrF_4$ has a structure analogous to that of $KICl_4$, which was found to consist of the cation K^+ and a planar anion $[ICl_4^-]$.[113] Potassium fluoride lines are absent from the powder diffraction pattern. If the $[BrF_4^-]$ anion has a configuration analogous to that of $[ICl_4^-]$, then the first is much smaller than the second, because the Br–F distance should be 1.78 Å and the I–Cl distance 2.34 Å. Subsequently a complete investigation of the crystal structure of $KBrF_4$ was made[51,114] and it was shown that the compound crystallises with a tetragonal unit cell ($a = 6.174$, $c = 11.103$ Å), the space group being $I4/mcm$. Experimental determination of the density (3.06) showed that 4 molecules are present in the unit cell, which is in good agreement with the density calculated from the X-ray diffraction data. The fluorine atoms are disposed tetrahedrally with respect to each bromine atom, with a Br–F distance of 1.81 Å. The F–F distances in the $[BrF_4^-]$ anion are 2.81 and 3.03 Å. Each potassium atom is linked to eight fluorine atoms, the K–F distances being 2.84 Å. These results were obtained from powder diffraction patterns of potassium tetrafluorobromate(III).

Sly and Marsch[115] believe that the more likely configuration is a square $[BrF_4^-]$ anion. The fluorine atoms give rise to approximately square symmetry with respect to potassium atoms. The interatomic distances in this case are as follows: Br–F 3.30, K–F 2.74, and F–F 2.70 Å. However, the authors themselves note[115] that, on the basis of the available experimental data, it is difficult to establish reliably the validity of one of the two proposed structures. The experimental results correspond with approximately the same precision to both the tetrahedral and the square configuration of the $[BrF_4^-]$ anion. The final determination of the structure of $KBrF_4$ will evidently be possible after studies on single crystals. There have been no investigations of the structures of other alkali metal tetrafluorobromates(III).

Potassium tetrafluorobromate(III) is a very reactive substance which reacts vigorously with water. The reaction products are bromine, hydrobromic and hydrofluoric acids, oxygen, and potassium fluoride. The first stage of the reaction can be represented by the equation

$$K^+BrF_4^- + 2H_2O = K^+ + HBrO_2 + 3H^+ + 4F^-\,\dagger$$

with subsequent decomposition of $HBrO_2$ into Br_2, HBr, and O_2.

$KBrF_4$ does not react with carbon tetrachloride, acetone, and dioxan and does not dissolve in them, whereas BrF_3 reacts very vigorously, usually explosively. On the other hand, even boiling BrF_3 does not react with platinum, while $KBrF_4$ does react with platinum on heating, with formation of K_2PtF_6.

$AgBrF_4$ and $Ba(BrF_4)_2$ are known to be more reactive than $KBrF_4$, due to their lower stability and the greater ease of evolution of BrF_3, which is the active principle in the reaction of these compounds. Consequently sodium tetrafluorobromate(III) should be more reactive and rubidium and caesium tetrafluorobromates(III) less reactive than potassium tetrafluorobromate(III), but no experimental data are available for these compounds.

It must be emphasised that the available experimental data refer in the first place to $KBrF_4$. The information about the tetrafluorobromates(III) of other alkali metals is restricted virtually only to the method of synthesis. All other properties can be considered only on the basis of analogies in the series Li–Na–K–Rb–Cs. Therefore so far there has been no reliable and comprehensive physicochemical study of alkali metal tetrafluorobromates(III).

† It is interesting to compare this reaction with the reaction $BrF_3 + H_2O = HBrO_2 + 3H^+ + 3F^-$.

2. Alkali Metal Hexafluorobromates(V)

The hexafluorobromates(V) of potassium ($KBrF_6$), rubidium ($RbBrF_6$), and caesium ($CsBrF_6$) were first obtained in 1964 by Whitney et al.[86] in a detailed study of the solvolysis of BrF_5. The mechanism of the interaction of alkali metal fluorides with BrF_5 involves the reactions

$$2\,BrF_5 \rightleftarrows BrF_4^+ + BrF_6^+,$$

$$MF + BrF_5 = M^+ + BrF_6^-,$$

where M is the alkali metal. The ease of reaction depends on the nature of the cation. Table 6 gives the conditions for the synthesis of alkali metal hexafluorobromates(V).

It is evident from Table 6 that the general rule common to all the alkali metal fluorohalogenates applies to hexafluorobromates(V) as well, i.e. the ease of the reaction $MF \rightarrow MBrF_6$ increases in the series Li–Na–K–Rb–Cs. The pure hexafluorobromate(V) has been obtained only for caesium, while lithium hexafluorobromate(V) does not form and sodium hexafluorobromate(V) has been obtained only as a small amount of impurity in the bulk of sodium fluoride which has not reacted.

Alkali metal hexafluorobromates(V) are white crystalline substances. They are unusually stable to heat, compared with alkali metal polyhalides without fluorine. For example, it has been shown that $CsBrF_6$ can be heated to 300°C for several hours without appreciable decomposition. The density of $CsBrF_6$ is 3.68, the density of the composition $RbBrF_6 . 0.1RbF$ is 3.59, and the value calculated for pure $RbBrF_6$ on the basis of additivity is 3.58.

Alkali metal hexafluorobromates(V) are very reactive, their hydrolysis involving the formation of bromate ions predominantly. These compounds are very powerful fluorinating agents, and since they are stable on heating to at least 300°C, their employment in high-temperature fluorination processes appears to be highly desirable.

The most important problems involving fluorobromates are those that have already been noted for fluorochlorates, i.e. they include the search for methods of synthesis of these compounds in a pure form, the determination of the nature of the mixtures synthesised, containing a definite amount of the initial alkali metal fluoride, a comprehensive physicochemical investigation of the compounds, and also the development of methods for the synthesis of alkali difluorobromates(I), which have not been obtained so far.

TABLE 6. Synthesis of alkali metal hexafluorobromates(V) using bromine pentafluoride*.

Fluoride	Molar ratio BrF_5 : MF	Results of analysis, wt. %		Results of synthesis
		Br	F	
LiF	10	–	–	Does not react.
NaF	10	–	–	No reaction observed; sodium hexafluorobromate(V) probably forms at 140°C but the degree of conversion is less than 5%.
KF	10	25.2	43.5	A white crystalline substance forms; 49.4% of the initial KF is converted into $KBrF_6$. Calculated for $KBrF_6 . KF$: 27.3% Br; 45.4% F.
RbF	10	27.3	39.8	A white crystalline substance forms; 90% of the initial RbF is converted into $RbBrF_6$. Calculated for the composition $RbBrF_6 . 0.1RbF$: 27.6% Br; 40.8% F.
CsF	10	24.4	34.8	A white crystalline substance forms; 100% conversion of CsF into $CsBrF_6$. Calculated for $CsBrF_6$: 24.4% Br; 34.8% F.
NH_4F	–	–	–	A white crystalline substance forms, but breaks down on heating above 0°C. Probably NH_4BrF_6.

* The reaction was carried out at 100°C.

IV. ALKALI METAL FLUOROIODATES

Iodine fluorides constitute the most extensive class of halogen fluorides. Iodine monofluoride IF, trifluoride IF_3, pentafluoride IF_5, and heptafluoride IF_7 are known[116–120]. Iodine heptafluoride is the only compound, not only among halogen fluorides but among interhalogen compounds in general, which contains seven atoms of one halogen in the molecule. Iodine is the only halogen which in its reaction with fluorine exhibits the highest valence characteristic of the Group. The capacity to form higher molecular species can be explained by the position of the elements in the Periodic System: the wide separation of the halogens facilitates the preparation of higher interhalogen compounds. The reason is the enhanced difference between the properties of the elements which facilitates their mutual saturation on interaction. The geometrical factor is also important: the large atomic radius of iodine and the small atomic radius of fluorine favour the maximum saturation of iodine by fluorine.

Despite the very wide variety of iodine fluorides, alkali metal fluoroiodates have been investigated least completely, which in the first place is evidently due to the low fluorinating activity of iodine fluorides, compared with chlorine and bromine fluorides.

1. Alkali Metal Tetrafluoroiodates(III)

Alkali metal tetrafluoroiodates(III) were first synthesised in 1960 by Hargreaves and Peacock[121]. The authors used IF_5 for the synthesis instead of iodine trifluoride (evidently because of the low fluorinating capacity of the latter and the low solubility of alkali metal fluoride in it). The use of IF_5 became possible after it had been established that a solution of an alkali metal fluoride in iodine pentafluoride behaves as a reducing agent, capable of reducing, for example, MoF_6 to MoF_6^- and ReF_6 to ReF_6^-.[122,123] Since the I^- ion does not exist in the solution, it is evident that the reducing agent in this case is a new complex, i.e. the tetrafluoroiodate(III) ion $[IF_4^-]$.

In the synthesis of alkali metal tetrafluoroiodates(III) with iodine pentafluoride a large excess of the latter was condensed on to the iodide of the corresponding alkali metal. The interaction was accompained by the evolution of free iodine:

$$5MI + 4F_5 = 5MIF_4 + 2I_2 .$$

After the complete dissolution in the cold of the initial solid, the excess solvent was removed in a vacuum and the reaction product was heated in the vacuum to 50°C to remove the residual iodine. Tetrafluoroiodates(III) with the general formula MIF_4 were obtained in this way for potassium, rubidium, and caesium, and also a soluble compound of caesium with the composition $CsIF_4 . IF_5$ (CsI_2F_9) (Table 7).

Alkali metal tetrafluoroiodates(III) were also synthesised using iodine trifluoride[124]. The alkali metal fluoride dissolved in acetonitrile was treated with iodine trifluoride for a long period at −45°C. Chemical analysis of

TABLE 7. Synthesis of alkali metal tetrafluoroiodates(III) using iodine pentafluoride.

Starting materials	Temperature of synthesis, °C	Products	Results of chemical analysis			
			calc., %		found, %	
			F	I	F	I
NaI+IF_5	20	—	—	—	—	—
KI+IF_5	20	KIF_4	31.4	52.5	33.0	45.3
RbI+IF_5	20	$RbIF_4$	26.3	44.1	26.2	43.3
CsI+IF_5	20	CsI_2F_9	30.7	45.5	30.7	46.6
CsI_2F_9	100 (vacuum)	$CsIF_4$	22.6	37.8	24.8	37.9

* Erroneous values were quoted by Hargreaves and Peacock [121] for the calculated iodine content of the tetrafluoroiodates(III): 48.4% for KIF_4, 44.6% for $RbIF_4$, 46.3% for CsI_2F_9, and 38.7% for $CsIF_4$. The corrected results are given in this table. It should be noted that they do not alter fundamentally the experimental data obtained for the tetrafluoroiodates(III) of rubidium and caesium and confirm the successful synthesis of these compounds. Hargreaves and Peacock [121] evidently also obtained potassium tetrafluoroiodate(III) but with considerable admixtures of the hexafluoroiodate(V), which is confirmed by the results of chemical analysis—the low iodine content and the high fluorine content of the substance synthesised.

the resulting colourless finely crystalline powders confirmed the formation of compounds with the composition MIF_4 (Table 8).

It has been stated, without the description of the conditions of synthesis, that the tetrafluoroiodates(III) of potassium, rubidium, and caesium can also be obtained using elemental fluorine to fluorinate the corresponding iodates [79]. It is surprising that the authors [79] obtained under these conditions tetrafluoroiodates(III) and not hexafluoroiodates(V). The latter is the more likely, but, in view of the brevity of the information given and the lack of identification of the products, it is impossible to assess the conclusions with sufficient reliability [79].

The tetrafluoroiodates(III) of lithium, sodium, and ammonium have not been obtained. The known alkali metal tetrafluoroiodates(III) are readily decomposed by atmospheric moisture and water. Their stability depends, as with other fluorohalogenates, on the size of the cation, which is confirmed by data derived from thermal studies. The tetrafluoroiodates(III) of potassium, rubidium, and caesium readily decompose on heating. Potassium tetrafluoroiodate(III) decomposes slowly even at room temperature with evolution of iodine, but caesium tetrafluoroiodate(III) is much more stable to heat and does not undergo appreciable changes on heating in a vacuum to 120°C. Vigorous decomposition is observed on heating below 70°C for KIF_4, below 70°C for $RbIF_4$, below 60°C for CsI_2F_9, and above 120°C for $CsIF_4$. [124] The powder diffraction patterns of potassium, rubidium, and caesium tetrafluoroiodates(III) did not permit the determination of the structures of these compounds, but they confirmed unambiguously that they do not have the same structures as the corresponding tetrafluorobromates(III). [51,114,115]

TABLE 8. Synthesis of alkali metal tetrafluoroiodates(III) using iodine trifluoride.

Compound	Results of chemical analysis					
	calc., %			found, %		
	metal	F	I	metal	F	I
KIF_4	16.1	31.4	52.5	17.3	30.5	52.0
$RbIF_4$	29.6	26.3	44.1	28.8	26.9	44.3
$CsIF_4$	39.6	22.6	37.8	39.8	23.6	36.5

2. Alkali Metal Hexafluoroiodates(V)

Iodine pentafluoride is appreciably inferior as a fluorinating agent to chlorine and bromine trifluorides. However, it too is capable of self-ionisation in solution [52,53,66,125]:

$$2\,IF_5 \rightleftarrows IF_4^+ + IF_6^-,$$

which means that the formation of acids and bases containing the corresponding complex ions is probable.

Sharpe and Emeléus [107] first showed in 1948 that potassium fluoride dissolves in IF_5 (about 1% KF) with the probable formation of potassium hexafluoroiodate(V) KIF_6. Subsequently the same workers [126] successfully achieved the synthesis of KIF_6 and examined the behaviour of other fluorides on dissolution in iodine pentafluoride.

Boiling IF_5 dissolves up to 1% of KF and on cooling white crystals are deposited from the solution. The attempt to remove the solvent at a reduced pressure (< 1 mmHg) did not result in the isolation of potassium hexafluoroiodate(V) in a pure form; phases of variable composition were produced (KF. $0.61IF_5$, KF. $0.91IF_5$). A product of constant composition was obtained by removing the excess IF_5 at 15–20°C and a pressure of 2–5 mmHg. Under these conditions the substance synthesised does not decompose and has the composition KIF_6. Potassium hexafluoroiodate(V) can also be obtained on prolonged boiling of potassium nitrate in iodine pentafluoride with subsequent removal of the excess of the latter in a vacuum at 20°C. [127]

When equimolar amounts of IF_5 and KF.HF are dissolved in anhydrous hydrogen fluoride, a deposit forms, whose composition has not been established accurately, but chemical analysis suggests that in this case too the product is KIF_6, contaminated with the initial KF.HF. [66] It is interesting to note 40% hydrofluoric acid converts KIO_3 into KIO_2F_2. [128] This compound may be regarded as the product of the partial replacement of fluorine by oxygen in potassium hexafluoroiodate(V). Caesium hexafluoroiodate(I) was obtained, like KIF_6, by crystallisation from solution in iodine tetrafluoride [126,129]. Furthermore, it has been stated that this compound can be obtained by fluorinating caesium iodide with elemental fluorine [79].

As already mentioned, when an alkali metal iodide reacts with cold IF_5, the tetrafluoroiodate(III) forms. On the other hand, the corresponding hexafluoroiodate(V) is produced in hot iodine tetrafluoride [121]. The alkali metal iodide is treated with an excess of IF_5, the solution is boiled for 5 min and then rapidly cooled, and the excess of the solvent is pumped off in a vacuum. The hexafluoroiodates(V) of potassium, rubidium, and caesium have been obtained in this way.

When NH_4F is dissolved in IF_5, a white solid is formed, which probably has the composition NH_4IF_6. In view of its extreme instability, the compound was not isolated in a pure form [85]. From the point of view of finding new ways of synthesising alkali metal fluorohalogenates, it is interesting to examine the interaction of alkali metal fluorides in

TABLE 9. Synthesis of alkali metal hexafluoroiodates(V) using copper pentafluoride.

Compound	Composition			
	calc., %		found, %	
	I	F	I	F
KIF_6	45.3	40.7	45.7	40.2
$RbIF_6$	38.3	34.9	38.3	35.5
$CsIF_6$	33.0	30.5	33.9	30.5

mixtures of halogen fluorides. It is known [130] that ClF_3 dissolves in IF_5 and BrF_5 and is not evolved on heating the mixture appreciably above its boiling point (60–70°C). This is undoubtedly due to interaction in solution. The effect of such complex self-ionisation in solution and the nature of the interaction between the alkali metal fluoride and the mixture of halogen fluorides can be explained on the basis of data for the relative acidities of the pair of halogen fluorides under consideration. In the stronger acids fluoride ions are coordinated to form complex anions of the type XF_n^-. It follows from the data in Table 10 that BrF_5 and IF_5 are stronger acids than ClF_3; the following reactions are involved:

$$\text{(a)}\ ClF_3 + BrF_5 \rightleftarrows ClF_2^+ + BrF_6^-,$$

$$MF + ClF_2^+ + BrF_6^- \rightleftarrows MBrF_6 + ClF_3,$$

$$\text{(b)}\ ClF_3 + IF_5 \rightleftarrows ClF_2^+ + IF_6^-,$$

$$MF + ClF_2^+ + IF_6^- \rightleftarrows MIF_6 + ClF_3.$$

The interaction of potassium fluoride with the ClF_3–BrF_5 mixture is an exception. In this case the tetrafluorochlorate(III) forms instead of the expected potassium hexafluorobromate(V). No explanation has so far been found for this phenomenon. When alkali metal fluorides are dissolved in ClF_3–BrF_3 mixtures, the reaction products should be the hexafluorobromate(III), and this is confirmed by the study of fluorine isotope exchange between ClF_3 and BrF_3 [93] which has shown that in this case chlorine trifluoride is a base and bromine trifluoride an acid:

$$ClF_3 + BrF_3 \rightleftarrows ClF_2^- + BrF_4^-.$$

Thus one of the methods of synthesising alkali metal fluorohalogenates is based on the use of mixtures of halogen fluorides as solvents. This is particularly important in the synthesis of fluoroiodates, in view of the lower fluorinating activity of iodine fluorides compared with chlorine and bromine fluorides.

TABLE 10. Interaction of alkali metal fluorides with ClF_3–BrF_5 and ClF_3–IF_5 mixtures.

Fluoride	Solvent	Temperature of synthesis, °C	Reaction products
KF	ClF_3+BrF_5	25	$KClF_4 \cdot KF$
KF	ClF_3+BrF_5	100	$KClF_4 \cdot 0{,}7\ KF$
RbF	ClF_3+BrF_5	25	$RbBrF_6 \cdot 0{,}5\ RbF$
CsF	ClF_3+BrF_5	25	$CsBrF_6 \cdot 0{,}1\ CsF$
KF	ClF_3+IF_5	100	KIF_6

Potassium hexafluoroiodate(V) KIF_6 is the first fluorohalogenate containing seven halogen atoms in the complex anion whose existence has been reliably established. There are no structural data for potassium hexafluoroiodate(V), but its properties are known and, by analogy with other similar compounds, one can reliably suggest the formula $K^+IF_6^-$. This is also quite evident for the hexafluoroiodates(V) of rubidium and caesium.

The iodine atoms in the complex anion $[IF_6^-]$ should have a valence shell of 14 electrons but only six coordination sites. This distinguishes the $[IF_6^-]$ anion from IF_7. Since $[IF_6^-]$ resembles $[SeF_6]^{2-}$ and $[TeF_6]^{2-}$, [131,132] it is possible that it has an octahedral structure. The configuration of iodine atoms in $[IF_6^-]$ is $5s^25p^25d^46s^2$ and therefore it can be suggested that $[IF_6^-]$ does not resemble other polyhalide anions, where the bond length is the sum of the corresponding radii [133], and that in this case the distance between the halogen atoms should be anomalously large [126].

Structural studies on KIO_2F_2 [128] have shown that the $IO_2F_2^-$ ion is an octahedron or a trigonal bipyramid. The iodine and oxygen atoms lie in one plane, the O–I–O angle is 100°±10°, and two fluorine atoms, forming an angle of 180°, are located in a direction perpendicular to the plane containing the iodine and oxygen atoms. The interatomic distances are 1.93±0.05 Å for I–O and 2.00±0.05 Å for I–F.

Potassium hexafluoroiodate(V) is moderately soluble in cold IF_5 and appreciably soluble in hot IF_5. It is decomposed by water with evolution of heat according to the equation

$$IF_6^- + 3H_2O = 6F^- + IO_3^- + 6H^+.$$

Thermal decomposition is accompanied by the evolution of IF_5 and the formation of KF. The melting point of KIF_6 is about 200°C. The fusion of KIF_6 is accompained by decomposition, since vigorous evolution of iodine pentafluoride is observed. Carbon tetrachloride does not affect KIF_6, while dioxan decomposes it only slightly [126]. All these findings are evidence of the relative stability of potassium hexafluoroiodate(V).

There are no data on the chemical behaviour of rubidium and caesium hexafluoroiodates(V). One can, however, speak of the similarity of their chemical and thermal properties and their greater stability compared with potassium hexafluoroiodate(V).

The question of the existence of alkali metal octafluoroiodates(VII) so far remains open. It is known [134] that, on interaction with iodine heptafluoride and subsequent evaporation of the latter at room temperature, rubidium chloride is only partially converted into rubidium fluoride. Under these conditions sodium, potassium, and rubidium fluorides do not dissolve in IF_7. Schumb and Lynch [134] concluded that compounds of the type MIF_8 cannot form under these conditions. However, this conclusion does not disprove the possibility of achieving the synthesis of similar compounds under other conditions; the compounds are the first representatives of bases containing nine halogen atoms in the complex anion. The synthesis of alkali metal octafluoroiodates(VIII), the search for new methods of synthesising and purifying tetrafluoroiodates(III) and hexafluoroiodates(V), the study of the physical and chemical properties of fluoroiodates, and the determination of their fluorinating capacity are the most important problems which must be solved first in further studies on alkali metal fluoroiodates.

V. ALKALI METAL FLUOROPOLYHALOGENATES

The first note concerning alkali metal fluorohalogenates containing two halogens in addition to fluorine dates back to 1931, when Cremer and Duncan[77] published an extensive paper on alkali metal polyhalogenates. It is interesting that a stability series for polyhalogenates is quoted in this paper, but the series was established only qualitatively. For the same anion the stabilities can be arranged in the following sequence: $Na < K < NH_4 < Rb < Cs$. Cremer and Duncan[77] do not indicate the position of lithium in this series, but there is no doubt that its compounds, if they exist at all, are the least stable. Only one compound containing fluorine is quoted in the paper, namely caesium fluorobromoiodate CsIBrF, which was obtained, by the adsorption of IBr on CsF, in the form of a yellow crystalline compound. The authors do not quote the results of chemical analysis and do not prove that it is indeed a chemically individual compound which, as far as one can judge from the very brief description, was evidently not isolated in a pure form. Later communications describe the syntheses of alkali metal fluorotrichloroiodates $MICl_3F$,[112,135] which have been obtained with potassium, ammonium, rubidium, and caesium in the form of orange-yellow needle-shaped crystals. The authors state that the caesium salt is the most stable and the potassium salt the least stable. In these papers the results of chemical analyses of polyhalogenates containing fluorine are quoted for the first time but fluorine was not determined directly (it was found by difference); the methods chosen by the authors for the determination of the remaining components are not the most reliable and therefore there are not sufficient grounds to believe that these compounds exist at room temperature in a free form. It should be noted that the information about alkali metal fluoropolyhalogenates is limited to the above communications, which are more than thirty years old and the experimental data of which give rise to considerable doubt. Thus at the present time there is no reliable information about this extremely interesting class of inorganic fluorides, although the existence of similar compounds of other halogens has been reliably established and they have been investigated in detail[49,136-140].

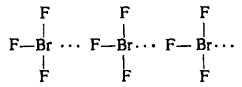
---o0o---

Fluorine compounds have a number of specific properties which make them very interesting objects of study in different branches of chemistry, such as the chemistry of volatile compounds, non-aqueous solvents, complex compounds, etc., in the theory of the chemical bond, and in the study of the structure of matter. Furthermore, fluorine compounds have found considerable application in industry. The range of their application is extremely wide, in the first place because the most active and the most inert substances are to be found among one or other class of fluorine compound. However, these substances are not usually encountered in nature: they are synthesised artificially, and therefore the preparation of fluorinating agents whereby the initial compounds can be converted into fluorides always constitutes a very important problem. Evidently it is essential to have an extensive set of fluorinating agents permitting the synthesis of fluorine compounds in a predetermined manner. Powerful oxidising agents, whereby exhaustive fluorination can be readily carried out, occupy an important place here. Such substances are, in the first place, elemental fluorine, halogen fluorides, and the alkali metal fluorohalogenates examined in the present review.

There is no doubt about the advantages of alkali metal fluorohalogenates in fluorination processes. However, these compounds have not found wide practical application at the present time, which the present author believes is primarily due to the fact that they have not been adequately investigated and that reliable methods of synthesis are altogether lacking for some alkali metal fluorohalogenates, while for others they have been developed only recently. Furthermore, many methods proposed yield the required compounds only with an admixture of the initial fluoride, which is larger the lighter is the alkali metal in the fluorohalogenate synthesised.

The most promising method for the synthesis of alkali metal fluorohalogenates is the one based on the reaction of the corresponding halogen fluorides with alkali metal fluorides. It is in fact this method which yields the purest products. It is based on a reaction in a non-aqueous medium.

At an early stage of the development of inorganic chemistry water was used almost exclusively as the reaction medium, while in modern synthetic inorganic chemistry non-aqueous media are used to an increasing extent[141-144]. Reactions in non-aqueous media can be divided into two types: (a) reactions involving the self-ionisation of the solvent (i.e. solvolysis reactions) or with direct participation of the solvent and (b) reactions which are independent of the solvent. Reactions of the first type are used in the synthesis of alkali metal fluorohalogenates—the solvent itself takes part in the reaction. In this case the correct choice of the solvent and the reaction conditions is of primary importance. The task in further studies on alkali metal fluorohalogenates on these lines consists in a comprehensive investigation of binary systems of the type alkali metal fluoride–halogen fluoride which will lead to the discovery of the most rational methods of synthesising alkali metal fluorohalogenates and will permit the investigation of their most important property—their fluorinating capacity.



While in the initial period water was used as the sole medium in synthetic inorganic chemistry and then non-aqueous solvents, nowadays there is a tendency to use mixed non-aqueous solvents[145,146]. The most interesting results under these conditions are in fact to be expected for alkali metal fluorohalogenates; the most complete information about the conditions of the synthesis and the properties of the compounds obtained can be derived from studies of the corresponding multicomponent non-aqueous systems by methods of physicochemical analysis; this is one of the most important tasks in the further development of methods for the synthesis of alkali metal fluorohalogenates.

In the reactions considered, where aprotic solvents such as halogen fluorides are used, one may apply Gutmann and Lundqvist's definition of acids and bases[147]. Alkali metal fluorides are donors of fluoride ions and behave as bases in halogen fluorides:

$$\overset{F^-}{\overbrace{KF + ClF_3}} \rightleftarrows K^+ + ClF_4^- .$$

The possibility of fluoride ion transfers is determined by the structure of the compounds: for example, the BrF_3 molecule has a T-shaped configuration[148-151] while the BrF_4^- ion has a planar square structure[115,152]. The formation of fluoride bridges in pure solvents with corresponding fluoride ion transfers takes place without appre-

ciable structural changes; probably association takes place via fluoride bridges [153]:

Further structural studies should show whether the BrF_4^- ions or fluoride bridges exist in this case.

It has been shown by ^{19}F nuclear magnetic resonance that continuous fluorine exchange takes place in the KF–AsF_3 system [154]:

The ^{19}F nuclear magnetic resonance of SbF_5 solutions in AsF_3 also reveals the exchange of fluoride ions bound in fluoride bridges [154]. Consequently the presence of fluoride ions and fluoride ion coordination are characteristic of covalent solvents, which include halogen fluorides. The processes occurring in the synthesis of alkali metal fluorohalogenates using halogen fluorides should in fact be examined from these standpoints.

Thus comprehensive investigation of the reactions between halogen fluorides and alkali metal fluorides will greatly extend our knowledge about reactions in non-aqueous media, will lead to the development of reliable methods for the synthesis of alkali metal fluorohalogenates, will enable the investigation of their behaviour as oxidising agents, and will place at the disposal of theoretical and applied science new highly effective fluorinating agents.

In view of their practical value and the advances in the chemistry of alkali metal fluorohalogenates, a considerable future can be forecast for this class of inorganic fluorides.

THE REACTIONS OF ACTIVE NITROGEN WITH ORGANIC MOLECULES

O.K.Fomin

CONTENTS

1. Introduction 725
2. Reactions of nitrogen atoms 725
3. Reactions of excited nitrogen molecules 731
4. Reactions of nitrogen ions 732

1. INTRODUCTION

The fixation of nitrogen continues to be the subject of extensive studies in organic chemistry, biochemistry, photochemistry, electrochemistry, and radiation chemistry. This problem is vitally important, and at the same time difficult to solve. Molecular nitrogen is characterised by an unusual chemical inertness, which makes it impossible for nitrogen to react chemically with the great majority of chemical substances under ordinary conditions. The dissociation energy of nitrogen is 225.96 kcal mole^{-1} (at 298°K), the greater part of this energy (~ 125 kcal mole^{-1}) being required for the rupture of the first bond. These values are so large that they generally cannot be compensated by the liberation of energy on formation of new bonds. For example, the energies of the bonds formed by the nitrogen atom with a number of other elements have the following values (kcal mole^{-1})[1]:

N—H	N—C	N—Si	N—O	N—S	N—P	N—Sb	N—F	N—Cl	N—Br
84	195	105	152.3	116	164.9	111	61	62	70

It is clear that most fundamental reactions involving the rupture of the bonds (or even one bond) in the nitrogen molecule cannot take place spontaneously, without preliminary excitation of the molecular nitrogen. This last requirement is not simple either, however, since all the first excitation levels of molecular nitrogen are relatively high. For example, the excitation of molecular nitrogen to the first vibrational level requires an energy quantum of 0.43 eV. Thus this process will take place to a significant extent only at temperatures of the order of several thousand degrees. The energy required for the electronic excitation of N_2 amounts to not less than 6.167 eV, and that required for photochemical excitation is 8.546 eV.[2] The ionisation potential of N_2 is 15.6 eV.[1] Thus electronic excitation of nitrogen is difficult and requires extremely severe conditions. The central problem in the fixation of nitrogen is therefore the conversion of molecular nitrogen into a chemically active state. There are in principle two possibilities: (1) transfer to the nitrogen molecule of sufficient energy to bring about its electronic or vibrational excitation, dissociation, or even ionisation; (2) mild activation of molecular nitrogen; the mechanism of this process has not been elucidated, but it takes place in the fixation of nitrogen in biological systems. The second possibility has led to search for chemical systems providing models of these biological systems, and encouraging results have already been obtained[3-7]. Possible routes to chemical activation of N_2 in these systems have been examined[3,5]. Significant excitation of molecular nitrogen is achieved in the photochemical and radiation-chemical fixation of nitrogen, and also in discharge reactions. Here we are dealing with energy-rich nitrogen species such as atoms, electronically excited molecules, ions, etc. Routes to the fixation of nitrogen by organic molecules by the irradiation of these systems with hard radiation have recently been indicated[8]. In order to understand the mechanism of these complex reactions, it is important to know how the various active nitrogen species react with organic molecules. A considerable amount of factual material on these problems (particularly concerning nitrogen atoms) has accumulated, and we have tried to summarise this material in the present paper. Generally speaking, the reactions of energy-rich nitrogen species with organic molecules lead to the formation of a wide range of products. Since the present paper is concerned with the problem of nitrogen fixation, however, we shall consider here only the nitrogen-containing products of these reactions.

2. REACTIONS OF NITROGEN ATOMS

The reactions of nitrogen atoms with organic molecules will be examined chiefly on the basis of data obtained in the study of active nitrogen, that is nitrogen withdrawn from an electric discharge. The composition of active nitrogen has been the subject of detailed study since its discovery[9]. Up to the present, the following species have been identified, in addition to non-excited nitrogen molecules: $N(^4S)$, $N(^2P)$, $N(^2D)$, vibrationally excited $N_2(X^1\Sigma_g^+)$, $N_2(A^3\Sigma_u^+)$, $N_2(B^3\Pi_g)$, $N_2(C^3\Pi_u)$, and $N_2(a^1\Pi g)$.

The presence of nitrogen atoms in active nitrogen has been proved by a number of direct physical methods. The ultraviolet range of the absorption spectrum of active nitrogen shows the transitions $NI(^4S \rightarrow 2p^4P)$, $(^4S \rightarrow 3s^4P)$, $(2p^32D \rightarrow 3s^2P)$, and $(2p^32P \rightarrow 3s^2P)$[10].

The forbidden $NI(^2P)$ line ($\lambda = 3466$ Å) can be observed in the emission spectrum of active nitrogen at pressures

close to atmospheric [11-13]. The presence of $N(^4S)$ atoms has also been confirmed by the ESR method [14,15]. The presence of excited $N(^2P)$ and $N(^2D)$ nitrogen atoms could not be detected by this method, however (the sensitivity of the method required concentrations of paramagnetic species in active nitrogen of about 1%) [14]. Much information on the composition of active nitrogen has been obtained using mass spectrometers. The presence of both non-excited [16-23] and excited (metastable) $N(^2P)$ and $N(^2D)$ atoms in active nitrogen has been proved by this method [20,21]. The presence of nitrogen atoms in active nitrogen is very effectively demonstrated by adding nitric oxide. With increase in the rate of supply of NO to a stream of active nitrogen, the colour of the latter changes from yellow-orange through blue to greenish white, with a sharp change in colour at the moment when the N atoms are used up completely. The following reactions take place:

$$NO + N \rightarrow N_2 + O\,, \quad (1)$$

$$N + O + M \rightarrow NO\,(B^3\Pi, A^2\Sigma) + M\,, \quad (2)$$

$$NO\,(B^3\Pi, A^2\Sigma) \rightarrow NO\,(X^2\Pi) + h\nu \text{ (pale-blue luminescence)}, \quad (3)$$

$$NO + O \rightarrow NO_2 + h\nu \text{ (greenish-white luminescence)}. \quad (4)$$

Because of the high rate of reaction (1) ($k \simeq 10^{-11}$ cm^3 molecule^{-1} s^{-1}) almost all the N atoms are used up in this reaction even in the presence of a considerable excess of NO. Kistiakowsky and Volpi [24] suggested this reaction for the determination of the concentration of nitrogen atoms in active nitrogen. The correctness of this procedure was subsequently confirmed by a number of workers: (a) by comparison of the concentration of nitrogen atoms determined by titration with nitric oxide with the value found from the decrease in pressure in an abruptly isolated volume containing active nitrogen [25]; (b) by determination of the equivalence point using the ESR method [15]; and (c) by comparison of the heat liberated in the deactivation of the active species on a cobalt surface with the expected value, calculated on the assumption that only the N atoms whose concentration was determined by titration with nitric oxide are removed on the surface [26].

The concentration of nitrogen atoms in active nitrogen depends on the type of discharge used for the excitation. The active nitrogen withdrawn from a microwave or ultra-high frequency discharge contains $\sim 1\%$ of nitrogen atoms, whereas that withdrawn from a condensed discharge contains up to 100% of nitrogen atoms [27]. Most of the atoms are in the ground (^4S) state. Estimation of the relative concentrations of nitrogen atoms in various excitation states, carried out by spectroscopic [10] and mass-spectrometric [20,21] methods, gave results showing satisfactory agreement and indicated that the concentration of $N(^4S)$ is greater than the concentration of $N(^2P)$ and $N(^2D)$ by 2-3 orders of magnitude. These data relate to the composition of active nitrogen about 1×10^{-3} s after it has left the discharge tube. At later stages of the afterglow, metastable nitrogen atoms cannot be detected at all [20,21]. This is apparently due to the rapid deactivation of the excited atoms on the walls.

Vibrationally excited nitrogen molecules in the ground electronic state ($X^1\Sigma_g^+$) have been observed in active nitrogen by spectroscopic methods. Dressler [28] recorded in the absorption spectrum nine bands from the Lyman-Birge-Hopfield (L-B-H) system ranging from (0,0) to (0,8). In a number of studies of the absorption spectra of the so-called pink afterglow of active nitrogen which lasts about 1×10^{-3} s, it was shown that this nitrogen contains a large quantity of $N_2(X^1\Sigma_g^+)$, excited to high vibrational levels (up to $v = 29$) [29,32]. On the basis of an analysis of ionisation curves for N_2^+, obtained by the mass-spectrometric method, Foner and Hudson [20,21,33] concluded that in the early stages active nitrogen contains $N_2(X^1\Sigma_g^+)$ molecules, whose vibrational energy reaches 7.5 eV. Kaufman and Kelso [34] detected appreciable liberation of heat when N_2O and CO_2 were added to active nitrogen; this can be interpreted as transfer of the vibrational energy of the nitrogen molecules to translational degrees of freedom, sensitised by these additives. According to their estimate, the heat liberated amounted to ~ 2 kcal mole^{-1}, which corresponded to a vibrational energy distribution with 30% of the $N_2(X^1\Sigma_g^+)$ molecules in the vibrational level with $v = 1$. Thermochemical studies of the deactivation of active nitrogen on the surface of a cobalt catalyst confirmed the existence, in active nitrogen, of a large quantity of nitrogen molecules excited to the first vibrational level [26]. It is now assumed that the active nitrogen with which chemical reactions are usually carried out (~ 0.1 s after removal from the discharge tube) does not contain the highly excited vibrational states of $N_2(X^1\Sigma_g^+)$ molecules [35]. As with metastable nitrogen atoms, this is apparently due to the fact that N_2 molecules excited to high vibrational levels are formed only in the discharge, and before they are observed in the chemical reaction vessel they are able to redistribute their energy in collisions with non-excited nitrogen molecules. For example, 1×10^{-4} s after leaving the discharge, active nitrogen contains $N_2(X^1\Sigma_g^+)$ molecules with vibrational energy up to 7.5 eV; [33] the corresponding figures after 1×10^{-3} s and 1×10^{-2} s are 7.16 eV [29-32] and 2.36 eV [28] respectively, and after 5×10^{-2} s active nitrogen contains only N_2 in the first vibrational level ($E_{v=1} = 0.43$ eV) [26]. Estimates of the concentrations of vibrationally-excited nitrogen molecules, carried out in the early stages of the afterglow, give values which showed good agreement: 10% according to the absorption spectra [28,29] and 8% from mass-spectrometric data [33]. Study of the deactivation of vibrationally-excited nitrogen molecules in the later stages of the afterglow with the aid of N_2O has given estimated values for the concentration of $N_2(X^1\Sigma_g^+, v = 1)$ of 30% [34] and more [26].

The intense emission by bands of the first positive system of nitrogen ($B^3\Pi_g \rightarrow A^3\Sigma_u^+$) suggests that active nitrogen contains considerable concentrations of metastable $N_2(A^3\Sigma_u^+)$ molecules, since the radiative lifetime of this state, according to recent estimates, is of the order of 10 s, and its deactivation by collision with N_2 is hindered [13,36]. Nevertheless, optical transitions from this state in active nitrogen (pressure about 1 mmHg) have not been observed, either in the absorption spectra under ordinary conditions [37] or in the emission spectra [Vegard-Kaplan bands (V-K bands)] [35,38-40]. Corresponding transitions were observed in the discharge [41,42], and its was established that, in order to observe the V-K bands, it is necessary to have very pure nitrogen; traces of Hg and O_2 are particularly harmful [32]. It may be assumed that the $N_2(A^3\Sigma_u^+)$ molecules in active nitrogen are rapidly deactivated in collisions with the walls or impurities. Working with pure nitrogen, Noxon [11,13] observed fairly intense luminescence of V-K bands in active nitrogen at high pressure (up to 1 atm), when deactivation on the walls was hindered. After thorough purification of nitrogen, Zipf [36] was also able to observe V-K bands in the afterglow of nitrogen in the pressure range 0.1-10 mmHg. Young [40] concluded that nitrogen atoms can play the same role as an impurity in the deactivation of $N_2(A^3\Sigma_u^+)$ molecules. On collision, exchange by atoms takes place according to the reaction:

$$N + N_2(A^3\Sigma_u^+, v=0) \rightarrow N_2(X^1\Sigma, v=25) + N\,. \quad (5)$$

According to his estimates, this reaction takes place very rapidly ($k = 2 \times 10^{-10}$ cm^3 s^{-1}). This might have explained the decrease in the intensity of the V–K bands with increase in the concentration of nitrogen atoms [13,36]. If Young is correct, however, it is difficult to understand why $N_2(X^1\Sigma_g^+)$ molecules, excited to high vibrational levels, cannot be detected in the afterglow after 5×10^{-2} s. The greater intensity of the V–K bands compared with the first positive system of nitrogen, observed by Noxon and Zipf, suggests that there exist other sources of $N_2(A^3\Sigma_u^+)$ molecules in addition to recombination of atoms. One such source is undoubtedly the discharge. This is indicated by the results of mass-spectrometric studies [20,33], in which it was established that $N_2(A^3\Sigma_u^+)$ molecules are present in active nitrogen in significant concentrations only 100 μs after leaving the discharge (100 μs was the lower limit in these experiments) and are observed throughout the entire time interval studied (up to 2×10^{-3} s). It is possible that $N_2(A^3\Sigma_u^+)$ molecules were detected in active nitrogen by the ESR method [43]: the authors cited observed the ESR spectrum of paramagnetic species but the spectrum could not be assigned to nitrogen atoms or free electrons. The rate of deactivation of these species was described by a first-order kinetic equation with a half-life of 0.07 s at a pressure of 4.4 mmHg.

The presence of $N_2(B^3\Pi_g)$ in active nitrogen is evident, since the long-lived yellow afterglow, characteristic of active nitrogen, consists of first positive bands of nitrogen. The bands with $v' > 12$ are usually not observed, but it is possible to observe the band ($B^3\Pi_g$, $v' = 26 \rightarrow A^3\Sigma_u^+$, $v = 20$) by immersing the tube in liquid nitrogen [44]. The Y system ($^3\Sigma_u^- \leftarrow B^3\Pi_g$) has also been observed in the emission spectra at low temperatures [45]. The concentration of $N_2(B^3\Pi_g)$ in active nitrogen should be low, since the emission lifetime of this state is small, of the order of 10^{-6} s. [46]

The second positive system of nitrogen ($C^3\Pi_u \rightarrow B^3\Pi_g$), which proves the presence of electronically excited $N_2(C^3\Pi_u)$ molecules in active nitrogen, can be observed only in the early stages of the afterglow, and its intensity is very low [30]. In this instance $N_2(C^3\Pi_u)$ is apparently formed in the discharge. The authors cited consider that formation of these molecules in the afterglow by $N(^4S) + N(^2D)$ collisions was observed when active nitrogen was cooled to liquid nitrogen temperature [47].

The emission of L–B–H bands ($a^1\Pi_g \rightarrow X^1\Sigma_g^+$), whose intensity is much less than that of the first positive system, was observed in the far ultraviolet [10]. Thus $N_2(a^1\Pi_g)$ molecules are present in active nitrogen in very small quantities. Mass-spectrometric methods have confirmed that active nitrogen contains highly excited electronic states of molecular nitrogen (probably $a^1\Pi_g$ or $a'^1\Sigma_u^-$, with energies of 8.548 eV and 8.398 eV respectively), but these states could be observed in quantities comparable with the concentrations of $N_2(A^3\Sigma_u^+)$ only within time intervals less than 1×10^{-3} s after the active nitrogen had left the discharge [20,33].

The presence of excited molecules in active nitrogen is revealed chemically: (1) in the decomposition of NH_3 [22,35,48–59] (nitrogen atoms doe not react with NH_3 [52,55]); (2) in the decomposition of nitric oxide to an extent greater than that corresponding to reaction (1) [51,60]; and (3) in the existence of a low-temperature (< 150°C) mechanism of the reaction of hydrocarbons with active nitrogen, differing from the high-temperature mechanism (> 150°C) [57,59]. The states of the excited nitrogen molecules responsible for these effects have not yet been identified. It has merely been established that NH_3 and hydrocarbons apparently react with the same excited nitrogen molecules, since the addition of NH_3 decreases the yield of HCN in the reaction of active nitrogen with hydrocarbons [57]. It has also been shown that NH_3 and NO react with N_2^* species in different excited states, since competition between them is not observed in their reaction with active nitrogen [51]. Herron [22] confirmed this conclusion and showed that NH_3 reacts with electronically excited metastable N_2 molecules, which can be observed by mass-spectrometric methods. Since the emission lifetime of the N_2^* species reacting with NH_3 is large (apparently much greater than 0.1 s [35,51,56]), it may be assumed that these are $N_2(A^3\Sigma_u^+)$ molecules.

To summarise, it may be concluded that active nitrogen, 0.1 s after its removal from the discharge, contains appreciable quantities of $N(^4S)$ atoms and vibrationally-excited $N_2(X^1\Sigma_g^+, v = 1)$ molecules, together with a small quantity of electronically-excited molecules, apparently in the $A^3\Sigma_u^+$ state. It is usually this active nitrogen which is used to study its chemical reactions with organic molecules. It has now been established that atomic nitrogen is the chief chemical reagent in active nitrogen [51,61–63].

The reactions of active nitrogen with organic molecules have now been studied for a long time, beginning with the work of Strutt (1911). The general features of the procedures used in these studies can be described as follows. Active nitrogen is prepared in a discharge at a nitrogen pressure of several mmHg, produced in a discharge tube by various methods. A condensed discharge, microwave discharge, or ultrahigh frequency discharge is usually employed. At atmospheric pressure active nitrogen is obtained by means of ozonisers. A current of nitrogen activated in this way is withdrawn from the discharge tube and passed into the reaction vessel. The organic compound is introduced into the same reaction vessel and reacts with the active nitrogen. The products formed are frozen out in traps and studied by chemical and physicochemical methods. The most extensive studies of the reactions of active nitrogen with organic molecules have been carried out by Winkler and coworkers. In 1956 they summarised the result of approximately ten years of work in this field [63]. The main conclusions can be summarised as follows: in the majority of reactions of active nitrogen with saturated and unsaturated hydrocarbons, alkyl chlorides, alkyl cyanides, and alkylamines, the chief and sometimes the only nitrogen-containing product is HCN; a characteristic feature of the reaction with unsaturated hydrocarbons is the formation of a nitrogen-containing polymer and a small quantity of C_2N_2; under certain conditions, all the N atoms are used up in reactions with the organic molecules. The range of studies of the chemical reactions of organic compounds with active nitrogen has now broadened considerably. A number of qualitatively new results have been obtained (some of these have been examined in a review by Mannella [64]); the most important of these results is the production of new nitrogen-containing compounds—NH_3 and various nitriles—in appreciable yield. Table 1 gives all the organic compounds whose reactions with active nitrogen have been studied, together with the reaction products. The plus sign indicates the products observed in the reaction between active nitrogen and the organic molecules listed on the left-hand side of the Table. As before, a common feature of these reactions is the formation of HCN, usually in highest yield. The preferential formation of CH_3CN in the reaction of active nitrogen with propene, observed by Lichtin [65], has not yet been confirmed [66]. Other charac-

teristic products are cyanogen and a nitrogen-containing polymer. Here, to supplement the earlier summary[63], it may be noted that the formation of a nitrogen-containing polymer and a certain amount of cyanogen is characteristic not only of unsaturated compounds, but also of halogenated hydrocarbons. The formation of a solid polymer is often observed with other organic compounds. Up to 65% of the nitrogen reacting goes into this deposit, depending on the specific system. The composition of the deposit depends on the nature of the organic compound reacting with active nitrogen: the concentration of nitrogen in the deposits obtained by various workers[77,78,82,84,87,96] varied from 16% to 37%. The polymer formed in the reaction with acetylene has been shown to have a formula of the type[90]:

$$\begin{matrix} -CH- \\ | \\ CN \end{matrix} (CH=CH)_n \begin{matrix} -CH- \\ | \\ CN \end{matrix} .$$

In the reaction with buta-1,3-diene, the deposit has the formula $(C_4H_6N)_x$,[84] and the reaction with isoprene gives the polymer $(C_3H_5N)_x$.[88] The deposit formed in the reactions with halogen-substituted hydrocarbons contains the halogen[99], and the products of the reactions with silanes have been found to contain Si–N and Si–C bonds[75]. Some experimental results indicate that the deposit is not an individual chemical compound, but a mixture[84,88,97]. Aronovich and Mikhailov[77,78] reported that the nitrogen in the deposit which they obtained is almost completely hydrolysed to NH_3. The ease of hydrolysis suggested to them that the deposit contained nitrile or even imino-groups. The chemical inertness of these deposits makes their study difficult.

* The following products have also been found in reactions of atomic nitrogen: with buta-1,3-diene—1-cyanobuta-1,3-diene, 3-cyanobutadiene, 3-cyanobut-1-ene, 1-cyanopent-3-ene, crotonitrile, and pyrrole; with isoprene—crotonitrile, pyrrole, and β-methylpyrrole; with benzene—benzonitrile, phenyl isocyanide, and pyridine; with naphthalene—quinoline and isoquinoline; and with cyclohexanone—cyanohydrins.

It can be seen from Table 1 that there are a large number of compounds which react with active nitrogen to give ammonia and nitriles; the formation of NH_3 is characteristic of alkanes, methyl-substituted silanes, and polymers containing methyl groups, and the formation of nitriles is characteristic of alkenes and halogenated methanes. A distinctive feature of the reactions of the latter is the formation of ClCN. Ammonia is extremely convenient both for direct use and for subsequent conversion into valuable nitrogen-containing products, so that its formation in the reactions of active nitrogen with organic compounds is of particular interest. Unfortunately, the absolute yield of NH_3 is generally low: for hydrocarbons[70] and siloxane[79], it does not exceed 10 mole %, calculated on the organic reagent decomposed. The yield of NH_3 for methylsilanes is much greater, but the reaction rate is smaller by one order of magnitude than that for hydrocarbons[75]. In all instances the yield of NH_3 is lower than the yield of HCN. The appropriate data (Table 2) show that in the reactions of active nitrogen with hydrocarbons, the yield of NH_3 is usually 10–20% of the yield of HCN. Winkler and coworkers[57] showed, however, that this figure can be increased to 50% by increasing the flow rate of the organic reagent. It should be noted that the latter reaction was carried out below 150°C. There are thus grounds for assuming that excited nitrogen molecules play an important part in altering the mode of the reaction. For organosilicon compounds, a change in the NH_3/HCN ratio with change in temperature was not observed[79,100]. The

absolute and relative yields of NH_3 increase with increase in the concentration of methyl groups in the original molecule[88,100,101].

Despite extensive study of the reactions of active nitrogen with organic compounds, few results have indicated the possibility of forming products corresponding to the mild degradation of the original organic molecules in appreciable yield in these reactions. It is these data, however, which throw light on the mechanism of the reaction of active nitrogen with organic molecules. The formation of benzonitrile[77,78,87] and pyridine[77,78] in the reaction of active nitrogen with benzene, and the formation of quinoline and isoquinoline in the reaction with naphthalene[77,78] are of interest in this connection. Work by Lichtin and coworkers[84-86], specially undertaken to find conditions for obtaining products of the mild degradation of the original molecules, showed that a large number of nitriles and pyrrole are formed in the reactions of buta-1,3-diene and isoprene with active nitrogen.

The reactions of active nitrogen with organic molecules are usually very rapid. The kinetic characteristics of a number of reactions are given in Table 3. Most of the kinetic data relate to the overall reactions of HCN formation. In some instances it has been assumed[23,58,95,103,105] that the initial attack by the N atom on the organic molecule is the rate-determining step in the complex reaction of HCN formation, and the kinetic constants obtained by the authors cited relate to the corresponding fundamental reaction. This assumption is based on the view that the subsequent stages leading to the formation of HCN involve organic radicals, and therefore should take place very rapidly. The problem of assigning the experimentally determined effective rate constants to given fundamental reactions can be resolved, however, only after the complete reaction mechanism has been established. Such studies have not yet been carried out for any reaction of active nitrogen with an organic molecule. In the reactions studied the systems always contain atomic hydrogen[23,63], which produces radicals by reacting with the organic molecules; from the kinetic viewpoint this may lead to appreciable "masking" of the initial step in the formation of HCN from atomic nitrogen and the organic molecule. Most kinetic studies of the reactions of active nitrogen with organic molecules have been carried out in low-pressure flow systems. The dependence of the yield of HCN on the concentration of the reagents and temperature, or on the duration of the reaction and temperature, has been studied. The results have been analysed on the assumption that the

* Symbols used in the table: A is the pre-exponential term in the expression for the reaction rate constant $k = A\exp(-E/RT)$, P the steric factor, E the activation energy, and k the reaction rate constant.

only chemically active species in the active nitrogen are nitrogen atoms, and that their reactions with organic molecules are bimolecular. For comparatively slow reactions, the calculations of the kinetic constants in a number of instances were carried out assuming both laminar flow and turbulent flow of active nitrogen in the reaction vessel. The methods generally used to determine the concentration of nitrogen atoms are as follows: (a) titration of the stream of active nitrogen with nitric oxide, based on reaction (1); and (b) determination of the maximal yield of HCN in the reaction of active nitrogen with ethylene. The values obtained for the concentration of nitrogen atoms by the first method are on the average one and a half times those obtained by the second method. Until recently it was not clear which method ought to be given preference, so that both were used. Only recently it was shown convincingly[23] that the reaction with ethylene involves recombination of nitrogen atoms, catalysed by intermediate products, so that preference must be given to the reaction with nitric oxide. The kinetic constants obtained by using NO to determine the concentration of nitrogen atoms can therefore be regarded as more reliable.

A second serious source of errors lies in the determination of the reaction time. It is necessary to be able to stop the reaction sharply at a given moment of time, and this is a difficult task in reactions of active nitrogen with organic molecules, particularly reactions with unsaturated compounds, which take place extremely rapidly. Comparison of a number of methods [104] has shown that two are most suitable for this purpose: (1) a method based on the introduction into the reaction zone of NO, which stops the reaction by reacting rapidly with the remaining nitrogen atoms; and (2) the removal of nitrogen atoms from the reaction by rapid surface recombination on a cobalt catalyst. The mean values of the reaction rate constants obtained using the two methods show good agreement [104].

There are a number of other sources of systematic errors in the flow method for studying the kinetics of the reactions of active nitrogen with organic molecules. For example, allowance is not always made for the following factors: deactivation of N atoms within and on the surface of the reaction vessel (flow tube), the influence of the reaction on the pressure gradient in the flow tube and on the rate of flow, the influence of impurities formed by erosion of the electrodes in the discharge tube, and the influence of hydrogen atoms. Thus the kinetic constants obtained in early work must be regarded merely as estimates of the appropriate quantities, to within one order of magnitude. It must also be borne in mind that the data given in Table 3 are influenced by errors associated with imprecise knowledge of the reaction mechanisms. To estimate the magnitude of these errors, it may be noted that the individual values of the rate constants for the reactions of active nitrogen, determined using improved methods, deviate from their arithmetic mean by 10–25% within the ranges of reagent concentration and duration of reaction studied. A regular increase in the rate constants with decrease in the duration of the reaction is observed, indicating the complexity of the process and hence the relative value of the arithmetic-mean rate constants for the reaction of active nitrogen. The reactions of active nitrogen with ethylene have been the subject of the greatest number of kinetic studies, because of the unique part played by this reaction in the study of active nitrogen. The method of diffusion flames [81,103] has been used to obtain approximate values of the rate constant for this reaction. More reliable values were obtained in work [23,104] in which the results were analysed by various methods, and the values obtained for the constants showed good agreement. The most reliable value of the rate constant for the first fundamental step in the reaction of active nitrogen with ethylene,

$$N + C_2H_4 \rightarrow HCN + CH_3 . \qquad (6)$$

is that obtained by Herron [23]. This determination was based on a precise knowledge of the reaction mechanism. Other rate constants [80,100] assigned to stage (6) are slightly higher than those given by Herron. These constants [80,100] apparently cannot be assigned to this fundamental reaction step, and they should rather be regarded as more accurate values of the rate constant for the overall reaction of HCN formation.

The mechanism of the reaction of active nitrogen with organic molecules has not yet been elucidated. In accordance with the unified mechanism proposed by Winkler for these reactions, it is assumed that the nitrogen atoms attack directly one of the carbon atoms in the organic molecule, and that the resulting complex decomposes according to a unimolecular law with the formation of HCN as the product of the primary stage of the reaction, together with organic radicals, which subsequently react rapidly with atoms, again with the formation of HCN. For example, the formation of HCN from propane, propene, propyl chloride, and ethanol can be represented as follows:

$$N + C_3H_8 \rightarrow [NC_3H_8] + H_2 \rightarrow HCN + C_2H_5 + H_2 \qquad (7)$$

$$N + C_3H_6 \rightarrow [NC_3H_6] \rightarrow HCN + C_2H_5 \qquad (8)$$

$$N + C_3H_7Cl \rightarrow [NC_3H_6] + HCl \rightarrow HCN + C_2H_5 + HCl \qquad (9)$$

$$N + C_2H_5OH \rightarrow [NC_2H_5] + OH \rightarrow HCN + CH_3 + OH . \qquad (10)$$

Winkler's mechanism provides a satisfactory explanation for the formation of not only HCN but also new hydrocarbons and other compounds which do not contain nitrogen. In the selection of probable reactions it is necessary only to make allowance for energy and spin restrictions [63]. For reasons related to the energetics of the process, however, it is doubtful if this mechanism is applicable to the reactions of lower hydrocarbons. It has also been shown that that hydrocarbon radicals play an important part in the reactions of hydrocarbons with active nitrogen [106]. Safraniy et al. [106] consider that the lower alkanes must first form radicals, which then react rapidly with N atoms to form HCN. The initial formation of radicals from alkanes is an unresolved problem. It is possible that the excited nitrogen molecules which are present in active nitrogen may act as initiators in these reactions. All that has been said above relates to the mechanism of HCN formation. The formation of NH_3 and the various products obtained by mild degradation of the organic molecules also requires explanation. For example, the pyrrole and *trans*-crotonitrile obtained by the reaction of active nitrogen with buta-1,3-diene can be regarded as the products of the attachment of an N atom to the original molecule and the removal of an H atom. The mechanism of this substitution is not yet clear. Ammonia may be formed by the reactions of N atoms with molecular or atomic hydrogen, produced by the decomposition of the organic reagents with active nitrogen. This was used, in particular, to explain the formation of NH_3 in the reactions of active nitrogen with ethane and ethylene frozen at −196°C. [70] In general, however, this explanation cannot be regarded as satisfactory, as there are a number of serious objections. The formation of NH_3 in a reaction with atomic hydrogen should pass through a stage involving the formation of an NH radical, which decomposes very readily:

$$NH + NH \rightarrow N_2 + H_2 \qquad (11)$$

$$NH + N \rightarrow N_2 + H . \qquad (12)$$

The NH_2 radical, which is the intermediate species in the formation of NH_3 by the reaction of atomic nitrogen with molecular hydrogen, decomposes in analogous fashion:

$$NH_2 + N \rightarrow N_2 + H_2 . \qquad (13)$$

Thus the intermediate species produced in the formation of ammonia not only disappear themselves in side reactions which take place readily, but also lead to the irreversible removal of the original reagent—N atoms—from the reaction. The decomposition of NH and NH_2 radicals should evidently be particularly efficient in an excess of nitrogen atoms, and this is usually the situation in the reactions of active nitrogen with organic compounds. Moreover, the reaction of N with H_2 is termolecular [107]:

$$N + H_2 + N_2 \rightarrow NH_2 + N_2 \qquad (14)$$

and its rate is therefore low ($k = 0.85 \times 10^{-32}$ cm^6 molecule^{-2} s^{-1}). It can be observed only at pressures of molecular nitrogen greater than 6 mmHg. [107] The formation of NH_3 is always observed, however, at pressures below

6 mmHg. Thus the formation of NH_3 under the conditions of the reactions of active nitrogen with organic molecules apparently does not take place in secondary reactions of the N atoms with hydrogen liberated by the decomposition of the original organic molecules. The correlation between the formation of NH_3 and the number of methyl groups in the original organic molecule suggests that NH_3 is formed in a single stage in some process in which the N atom displaces two or three H atoms from the CH_3 group[75,89,100].

The reactions of hot N atoms, formed in the process $^{12}C(d, n)^{13}N$, with organic molecules also leads to the formation of chiefly HCN with a small quantity of nitriles[68,69,89,98]. Thermalisation of the ^{13}N atoms does not alter significantly the composition and yield of the products[69]. As in the reactions of active nitrogen, CN radicals do not play a significant part in the formation of the products[69]. Thus the reactions of hot N atoms with organic molecules resemble the reactions of active nitrogen. The mechanism of these reactions is identified with Winkler's unified mechanism, which in this instance is applicable even to the lower alkanes, if it is postulated that the reacting species are excited $N(^2D)$ atoms[69]. An interesting feature is that it has been proved that in systems of this type organic radicals do not influence the reaction rate[68] and that the addition of nitric oxide had little influence on the yield of HCN[69].

3. REACTIONS OF EXCITED NITROGEN MOLECULES

The electronic excitation of a molecule generally makes it more reactive. This is due to a number of factors[108]: (1) on excitation, unpairing of one of the electron pairs of the molecule takes place, facilitating the attachment of another molecule with an unpaired electron; (2) the excited electron is less firmly held by the molecule, so that the reaction of the excited molecule with an electrophilic reagent is facilitated; and (3) the excited electrons sometimes play little part in chemical bonding, so that the energy required for dissociation of the molecule is decreased. It is known[109], however, that simple excited molecules are very rarely the initial centres of chemical reactions. We should therefore not expect reactions of excited nitrogen molecules with organic molecules to be very widespread. This problem has been insufficiently studied by experiment. Photochemical study of nitrogen is difficult, since N_2 absorbs light only with $\lambda < 1450$ Å (8.546 eV) and its absorption cross-section in the $X^1\Sigma_g^+ \rightarrow a^1\Pi_g$ bands is less than 4×10^{-21} cm^2.[110] Thus information on the reactions of excited nitrogen molecules is very limited and is conjectural in character, since it has been obtained indirectly, chiefly in the study of the reactions of active nitrogen. Direct photo-activation of a mixture of nitrogen and methane at a pressure of 5–8 mmHg was achieved by Dodonova[111]. Light from a hydrogen lamp with $\lambda > 1250$ Å and intensity 10^{15}–10^{16} photon s^{-1} was used for the photo-activation. The formation of HCN was detected under these conditions.

Study of the reactions of active nitrogen with hydrocarbons has revealed facts whose explanation required the assumption that active nitrogen contains excited N_2^* molecules, which react with organic molecules[34,38,52,112]. It has been proved that the N_2^* molecules react with CH_4,[57] C_2H_6,[51,57,59] $C(CH_3)_4$,[59] C_2H_4,[51] and CCl_4.[49] Since the conditions under which the reactions take place with the participation of N_2^* give the same products as the conditions under which the chief reagent is atomic nitrogen, it is assumed that second-order collisions with N_2^* molecules excite organic molecules; these subsequently dissociate to form radicals, which react with atomic nitrogen in the usual way[51,59]. The reaction mechanism can then be represented as follows:

$$N_2^* + RH \rightarrow N_2 + RH^* \quad (15)$$

$$RH^* \rightarrow R + H \quad (16)$$

$$R + N \rightarrow HCN \text{ and other products} . \quad (17)$$

It is apparently possible that in a number of instances the participation of N_2^* in reactions with organic molecules may alter the mode of these reactions. Thus in the reaction of active nitrogen with CH_4, C_2H_6, and C_2H_4 below 150°C a considerable increase in the yield of NH_3 compared with the yield of HCN has been observed[51,57]. This was attributed to the participation of nitrogen in excited-molecule reactions[51]. The excited state of N_2^* reacting with hydrocarbons has not been reliably identified. It is usually assumed, however, that long-lived excited states of the molecules are most important in chemical reactions. Table 4, taken from a paper by Phillips[113], gives the long-lived states of molecular nitrogen. Of these, $A^3\Sigma_u^+$, $^3\Delta_u$, and $a^1\Pi_g$ have been detected in the afterglow of nitrogen, and the $^5\Sigma_g^+$ state has been postulated[64]. No definite proof has been obtained for the presence of the $^3\Delta_u$ state in active nitrogen; it was selected as the upper state of the so-called Y series recently discovered in the afterglow of nitrogen[45,114]. Here a choice was made between the $^3\Delta_u$ and $^3\Sigma_u^-$ states. Later results[115] indicated that the upper state in this series is more likely to be $^3\Sigma_u^-$ than $^3\Delta_u$. If $N_2(^3\Delta_u)$ molecules are present in active nitrogen, their concentration should be very low, since this state is apparently readily deactivated in collisions with nitrogen molecules in the ground state[116]. Thus the part played by $N_2(^3\Delta_u)$ in the reactions of active nitrogen with organic molecules cannot be important.

Nothing definite can be said regarding the part played by the excited $^5\Sigma_g^+$ state, since there are no experimental data. Estimates of the lifetime of N_2^* molecules reacting with organic molecules[35,51] gave values slightly greater than $\tau_{emission}$ for the $a^1\Pi_g$ state, excluding the possibility that this state takes part in the reactions with hydrocarbons. The properties of $N_2(A^3\Sigma_u^+)$ molecules, however (the long lifetime, the difficulties associated with the transfer of energy to nitrogen molecules in the ground

state [13], and their ready deactivation in collisions with impurities [81,117], make their participation in the reactions of active nitrogen with organic molecules extremely probable, as suggested by Winkler and coworkers [57]. This is confirmed by the competition between the reactions of hydrocarbons and ammonia with active nitrogen [49,51,57], since we now have a considerable amount of evidence that the $A^3\Sigma_u^+$ state of molecular nitrogen is responsible for the decomposition of ammonia in active nitrogen [35]. Safrany et al. [106,118] cast doubt on the initiating role of $N_2(A^3\Sigma_u^+)$ molecules in the reactions of active nitrogen both with organic molecules and with NH_3. They showed, in particular, that an increase of the concentration of $N_2(A^3\Sigma_u^+)$ in active nitrogen as a result of the recombination of N atoms catalysed by a metal surface does not alter the rate of decomposition of hydrocarbons and NH_3. [106,118] The decomposition of ammonia by paramagnetic non-atomic species present in active nitrogen has been confirmed, however [35]. The authors cited consider that these species are $N_2(A^3\Sigma_u^+)$ molecules. There are thus a number of indications that it is the $N_2(A^3\Sigma_u^+)$ species which reacts with organic molecules.

4. REACTIONS OF NITROGEN IONS

a. Positively charged ions. The ion-molecule reactions of compounds of various classes are now being studied extremely intensively. Data on the ion-molecule reactions of nitrogen with organic molecules are still limited, however. There is published information on the reactions of N_2^+, N_2^{2+}, and N^+ ions with organic compounds of various classes: alkanes (CH_4, C_2H_6), alkenes (C_2H_4), aromatic compounds [C_6H_6, $C_6H_5CH_3$, $C_6H_5CH(CH_3)_2$], ketones (CH_3COCH_3), and halogen-substituted alkanes (CCl_4, CF_4, CF_3Cl). All these studies have been carried out in mass-spectrometer ion sources. All the above reactions, except the reaction with CD_4, [129] were studied by bombarding the organic molecules in the gaseous phase with nitrogen ions obtained in a separate ion source: the reaction with deuteriomethane, however, was carried out in an ionisation chamber, in which a mixture of deuteriomethane and nitrogen was ionised with fast electrons, and the reactions of the ions formed were studied. In other words, the methods used were those of external and internal ionisation, using the nomenclature proposed by Tal'roze [126].

Dissociative charge transfer or ion dissociation processes, induced by collision, are most characteristic of the reactions of positive nitrogen ions with organic molecules in the ranges of ion energies studied (see Table 5). Dissociative charge transfer gives a spectrum of organic fragment ions, and there is a tendency for the ions formed in greatest yield to be those which best satisfy the requirements of the resonance principle, that is the ion whose formation is most intensive is the one for which the absolute magnitude of the heat of formation Q is minimal [$Q \simeq$ (energy of recombination of the primary ion with an electron) – (appearance potential of the fragment ion)] [128]. Superimposed on this tendency, however, is the requirement that the corresponding fundamental reaction be exothermic [128]. Both of these requirements reflect the general laws governing ion – molecule reactions of this type [138].

Transfer of heavy species has been observed only in three instances (reactions 2, 7, and 10 in Table 5), where formation of the ions N_2D^+, NCl^+, $NCCl^+$, and NC^+ was observed; it may also be assumed that in reaction 6 some ions also contain nitrogen. In the last instance, however, not all the ions in the resultant mass spectrum were identified, and insufficient justification was obtained for the suggestion put forward. Evidence in support of the suggestion is provided by the following considerations: some of the fragments do not fit into the scheme proposed by the authors cited to explain the mass spectrum, and the molecular weights of these fragments suggest that they contain nitrogen; for example, the value $m/e = 29$ may correspond to the N_2H^+ ion. A small quantity of N_2H^+ ions was also observed in reactions 5. The intensity of the nitrogen-containing ions in this instance, however, was low compared with the ions resulting from charge transfer. The kinetics of the reactions of nitrogen ions with organic molecules have not been studied. The single exception is the reaction

$$N_2^+ + CD_4 \rightarrow N_2D^+ + CD_3 \qquad (18)$$

for which the cross-section is found to be about 4×10^{-16} cm^2 molecule^{-1} ($k \simeq 1 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}) [88]. The studies which have been carried out are as yet insufficient to enable any conclusions to be reached regarding the part played by ion-molecule reactions in the formation of nitrogen-containing organic products during radiolysis. The available data indicate, however, that the formation of nitrogen-containing fragment ions depends both on the energy of the ions and on the chemical nature of the molecules and ions. It may therefore be expected that there exist systems or conditions, in which ion-molecule exchange reactions between nitrogen and organic molecules take place to a significant extent. The absence of such processes in most of the reactions studied can be attributed, for example, to the fact that the studies were carried out using ions whose kinetic energies were too large, whereas the transfer of heavy species in ion-molecule reactions most probably takes place at low energies [138].

b. Negatively charged nitrogen ions. The negative nitrogen ions N^- and N_2^- have not been detected in the ground state, due to the very low electron affinity of both atomic and molecular nitrogen. The formation of an N^- ion in the excited state by the attachment of an electron to an excited nitrogen atom is possible [134-136]. The excited

$N^-(^1D)$ and $N^-(^1S)$ states are metastable, but their possible breakdown as a result of self-ionisation often hinders even the experimental detection of these ions[95]. Accordingly, ion-molecule reactions with the participation of negative nitrogen ions are unknown.

The azide ion N_3^-, formed by the dissociation of NaN_3, exists in solutions. If undergoes photochemical reactions fairly readily; for example, it reacts with water with the formation of N_2, NH_2OH, N_2H_4, and NH_3 on irradiation by light with $\lambda = 2540$ Å,[137] but as yet nothing is known of its reactions with organic molecules.

III. Reactions with transfer of electrons to the tropylium ion 738

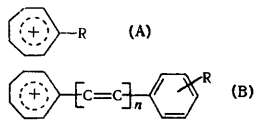
IV. Sandwich compounds of the tropylium ion 742

V. Formation of the tropylium ion and its properties 745

I. INTRODUCTION

The tropylium cation, predicted in 1931 by Hückel[1] and obtained in 1954 by Doering and Knox[2], constitutes a non-benzenoid aromatic system. According to Vol'pin's definition, "those unsaturated cyclic compounds are aromatic in which all the atoms in the ring are involved in the formation of a single conjugated system, the π-electrons of the system forming a closed† electron shell"[3].

In fact, the seven-membered tropylium ring has a sextet of π-electrons, like benzene and the cyclopentadienyl anion, i.e. it obeys Hückel's rule. Calculation shows that the six π-electrons of the tropylium ion are distributed among the bonding molecular orbitals and form a closed electron shell; the removal and addition of electrons increase the total energy of the system, lowering its stability. The planar structure of the ions follows from X-ray diffraction data[4]. The identity of all seven carbon atoms in the tropylium ion and hence the equality of all the carbon–carbon bonds in the ring have been demonstrated by the radioactive tracer method[5]. The high degree of symmetry of the tropylium cation is also reflected in a small number of infrared and Raman absorption bands[2,6].



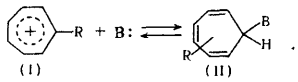
From the chemical point of view, the aromaticity of the tropylium ion is shown in the ease of its formation. The tropylium ion forms under the action of oxidising agents, including hydride ion acceptors (see p. 746), on cycloheptatriene, in the degradation of cycloheptatriene derivatives under the action of electrophilic agents (see p. 747), and when isomeric C_7H_8 hydrocarbons are subjected to electron impact in a mass spectrometer (see p. 748).

The tropylium cation is extremely stable to the action of electrophilic agents[7], exhibiting at the same time high reactivity towards nucleophilic agents[3,8]. Many examples confirming the high electrophilicity of the tropylium cation are known at the present time. Thus the cation combines with many nucleophilic agents[9]. In particular, the tropylium ion is used for the investigation of hydride migration reactions as a hydride ion acceptor[10]. It readily alkylates double bonds activated by electron donor substituents and compounds with "labile" hydrogen (see p. 749). Reactions involving nucleophilic substitution of one group by another are characteristic of the tropylium system[8,11,12]. These properties of the tropylium ion make it a splendid model for the investigation of the properties of carbonium ions, in most cases unstable, which are formed in many chemical reactions as transient intermediates.

The advances achieved in the chemistry of the tropylium ion up to 1960 have been described in Vol'pin's review[3]. In recent years the number of papers on the chemistry of the tropylium ion has increased greatly and in many of them new problems have been posed. We thought it timely to describe in detail problems which were not discussed or discussed superficially in Vol'pin's review. Chapters II, III, and IV of our review deal with these new problems in the chemistry of the tropylium ion. In Chapter V we attempted to describe briefly the papers in which the problems posed in the previous reviews have been developed and new evidence concerning them has been obtained.

II. ACIDITY OF SUBSTITUTED TROPYLIUM IONS

The stability of the tropylium ring changes on introduction of a substituent. Let us consider the effect of substituents on the stability of cations of three types:



benzotropylium derivatives (C)

The pK_a values for the acid–base equilibrium

$$R^+ + 2H_2O \rightleftarrows ROH + H_3O^+$$

can serve as quantitative characteristics of the stability of carbonium ions. The higher is the pK_a of the carbonium ion the lower is its acidity and, as a rule, the higher its stability in relation to nucleophilic agents. Table 1 lists the pK_a values for the most stable carbonium ions[2,13,14].

In the study of the effect of the substituent on the acidity of the tropylium cation it is necessary to take into account the energy of the conjugation of the substituent both with the tropylium system (I) and the cycloheptatriene system (II):

(I) (II)

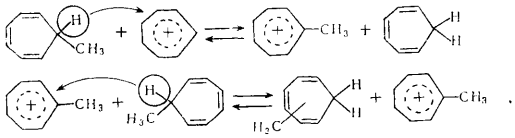
If the difference between the conjugation energies of the unsubstituted and substituted tropylium ion (I) is higher than the difference between the conjugation energies of the

TABLE 1.

Cation	pK_a	Cation	pK_a
Tropylium	+4.75*	Triphenylmethyl	−6.63**
Tri-p-anisylmethyl	+0.82**	Diphenylmethyl	−13.3**
Tri-p-tolylmethyl	−3.56**	Fluorenyl	−14.0**

* Measurements in water.

** Measurements in sulphuric acid.

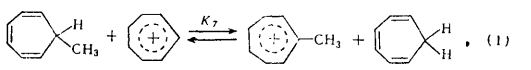


† In the sense given to this term by Hückel.

unsubstituted and substituted cycloheptatriene (II), then, other conditions being equal (change in hybridisation, entropy and solvation effects), electron-donor substituents which delocalise the positive charge of the tropylium ion will reduce its acidity, i.e. its pK_a value will increase. Electron-acceptor substituents should increase the acidity of the tropylium ion. This relation between the acidity and the electron-acceptor or electron-donor properties of substituents has been observed for cations of types (A) and (B), a larger pK_a value indicating in this case a higher stability of the substituted tropylium ion.

If the substituent has a greater effect on the cycloheptatriene system than on the tropylium system, then on introduction of electron-donor substituents delocalising the positive charge of the tropylium ion the acidity of the latter will increase, i.e. the pK_a value will fall. The introduction of electron-acceptor substituents should in this case lead to an increase of the pK_a value. An example of this type of effect of substituents on the acidity of the tropylium ion is the acidity of benzotropylium cations[15-19].

At present there are few data concerning the acidity of substituted tropylium ions of type (A). Johnson et al.[20] showed that the introduction of the electron-acceptor carboxy-group into the tropylium ring lowers the pK_a value from +4.75 for the unsubstituted tropylium ion to +3.3 for the carboxytropylium ion, i.e. reduces the stability of the cation. On the other hand, the introduction of the electron-donor methyl group enhances the stability of the tropylium ion. The acidity constant of the methyltropylium ion has not been measured. However, the stability of tropylium ions can be inferred from the free energy responsible for their reactivity.

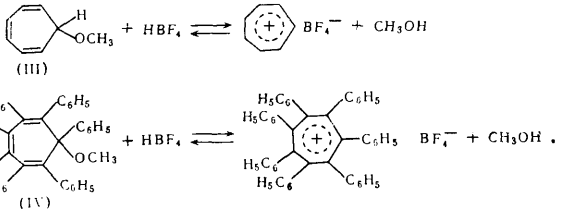


Conrow[21] showed that the free energy of the methyltropylium ion is smaller by 3.7 kcal mole^{-1} than that of the unsubstituted tropylium ion. He investigated the isomerisation of 7-methylcycloheptatriene under the action of the tropylium ion and showed that under these conditions unsubstituted cycloheptatriene forms in addition to the isomeric methylcycloheptatrienes. During a certain period the amount of cycloheptatriene remains constant and no longer changes, while the amount of 7-methylcycloheptatriene continues to decrease. These results enabled Conrow to propose the following reaction mechanism:

The tropylium ion removes a hydride ion from the 7-methylcycloheptatriene molecule with formation of cycloheptatriene and a methyltropylium ion. The latter enters into a further reversible hydride transfer reaction with methylcycloheptatriene.

To confirm this mechanism, Conrow investigated the reduction of the methyltropylium ion with lithium aluminium hydride, sodium borohydride, and calcium hydride. It was found that the relative amounts of methylcycloheptatrienes obtained in this case, where hydride transfer undoubtedly takes place, are approximately the same as in the isomerisation of 7-methylcycloheptatriene.

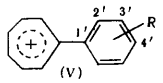
Knowing the relative amounts of the isomeric methylcycloheptatrienes in the reaction of the methyltropylium ion with lithium aluminium hydride, and also having determined chromatographically the yield of each isomeric methylcycloheptatriene in the isomerisation reaction, Conrow calculated the free energy of the equilibrium reaction (1),



i.e. $\Delta F_7 = -3.72$ kcal mole^{-1}.

Conrow suggested that the resonance energies of 7-methylcycloheptatriene and cycloheptatriene are equal (to within not more than 0.3 kcal mole^{-1}) and their solvation conditions are the same, so that the free energy of reaction (1) can be attributed only to the difference between the free energies of the tropylium and methyltropylium ions. This difference is 3.7 kcal mole^{-1}. Having obtained this quantity, Conrow calculated the free energy differences between the isomeric methylcycloheptatrienes. It follows from his calculations that the methyl group stabilises the tropylium ion much more (by 3.7 kcal mole^{-1}) than the cycloheptatriene molecule (by 1.61 kcal mole^{-1} for 7-methylcycloheptatriene) and therefore the tropylium ion is a better hydride ion acceptor (and in general an acceptor of nucleophilic species) than the methyltropylium ion and 7-methylcycloheptatriene is a better hydride ion donor than cycloheptatriene.

Thus Conrow demonstrated, for the methyl group as an example, that a substituent in cations of type (A) has a greater effect on the tropylium ring than on the cycloheptatriene system. The phenyl substituent is known to have an electron-donor effect in some cases[22] and an electron-acceptor effect in others[23]. It has been found that the phenyl group behaves as a weak electron-acceptor substituent in relation to the tropylium ion. The acidity constant pK_S of the phenyltropylium ion[24], measured by Jutz‡, is +3.87. The acidity constant of the tropylium ion in the 1 : 1 acetonitrile–water mixture is $pK_S = 4.01$. Thus the phenyl group destabilises the tropylium ion. Jutz explains this finding by the fact, shown by calculations, that the benzene and tropylium rings are inclined at an angle 45–50°. Such disposition of the rings results in a decrease of the conjugation between the benzene and tropylium systems and the negative inductive effect of the phenyl substituent may be increased thereby.

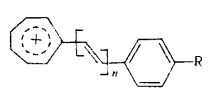


The introduction of seven phenyl substituents destabilises the tropylium ion even more. Due to the very low solubility of heptaphenyltropylium salts, the pK_a value for this ion could not be measured. However, Battiste[25] showed that in a 1 : 1 methanol–acetonitrile mixture methoxycycloheptatriene (III) is fully ionised, with formation of the tropylium ion, under the action of 0.01 N fluoroboric acid, while heptaphenylmethoxycycloheptatriene (IV) is ionised to an extent less than 10% under the action of 1 N acid in the same solution:

‡ Here and henceforth pK_S denotes pK values for carbonium ions measured in a 1 : 1 acetonitrile–water mixture, as was done by Jutz.

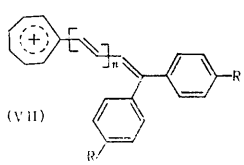
Consequently the pK_a value for the heptaphenyltropylium ion is lower by 3 pK units for the tropylium ion, i.e. the heptaphenyltropylium ion is less stable than the tropylium ion in a 1 : 1 methanol–acetonitrile solution by a factor of at least one thousand. It follows from what has been said above that very little is known about the effect of substituents in tropylium ions of type (A) and the quantitative data which have been obtained can be compared only qualitatively.

The effect of substituents bound to the tropylium ring via a benzene ring and a conjugated system of double bonds [cations of type (B)] has been investigated in fair detail. Jutz[24,26] measured the pK_S values for phenyltropylium (V) salts with substituents in the benzene ring.



(V)

It was found that these pK_S values are linearly related to Jaffe's σ constants for the substituents [apart from $N(CH_3)_2$], i.e. Hammett's equation holds (see Fig. 1):

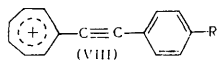


$$pK_s = pK_0 - \sigma\rho;\ \rho = +2.4\ .$$

The positive value of ρ shows that electron-donor substituents reduce the acidity of the phenyltropylium ion, i.e. increase its pK_S value, while electron-acceptor substituents increase its acidity, i.e. lower the pK_S value.

Bearing in mind the disposition of the benzene and tropylium rings at an angle of 45–50°, it may be supposed that in this case the effect of substituents is transmitted as follows: the effect of the substituent R is transmitted by conjugation and inductive mechanisms to position 1′ of the benzene ring in compound (V) and from position 1′ it is further transmitted by an inductive mechanism to the tropylium ring. The introduction of 1, 2, 3, and 4 double bonds between the tropylium and benzene rings in the phenyltropylium ion reduces the acidity of the latter. The pK_S values obtained by Jutz[27,28] for compounds (VI) and (VII) are given below:

(VI)



(VII)

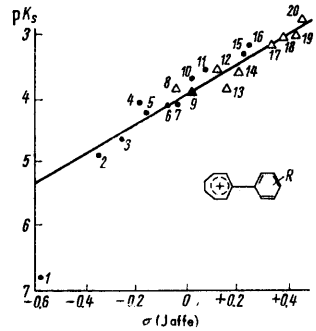
for (VI)	R=H	for (VII)	R=H
n	pK_s	n	pK_s
0	3.87	0	4.23
1	4.13	1	4.35
2	4.70	2	4.56

The stabilising effect of conjugated double bonds can be understood if account is taken of their capacity to distribute the positive charge over a large number of centres.

In contrast to the double bond, a triple bond between the tropylium and benzene rings in the phenyltropylium ion greatly increases the acidity of the latter, i.e. decreases the pK_S value: pK_S = +2.40 for the phenylethynyltropylium ion (VIII, R = H)[27], while for the phenyltropylium ion pK_S = +3.87

(VIII)

Consequently the triple bond acts as a powerful electron-acceptor group. It has a similar effect on the ionisation



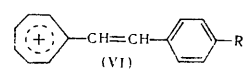


Fig. 1. Variation of the acidity constants pK_S of phenyltropylium cations with Jaffe's σ constants; the substituent R:
1) p-$N(CH_3)_2$; 2) p-OH; 3) p-OCH_3; 4) p-$C(CH_3)_3$; 5) p-CH_3; 6) p-$NHCOC_6H_5$; 7) p-SCH_3; 8) m-CH_3; 9) H; 10) p-C_6H_5; 11) p-F; 12) m-OCH_3; 13) β-naphthyl instead of C_6H_4R; 14) m-C_6H_5; 15) p-Cl; 16) p-Br; 17) m-F; 18) m-Cl; 19) m-Br; 20) m-CF_3.

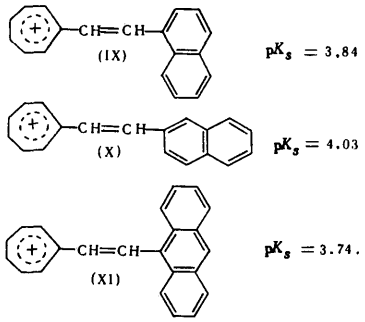
of acids, for example. Thus phenylpropiolic acid is one hundred times stronger than benzoic acid, while cinnamic acid is somewhat weaker than benzoic acid (see Table 2).

The substituents R in the series of compounds (VI), (VII), and (VIII) have qualitatively the same effect on the stability of the tropylium ion as in the series of compounds (V), namely electron-donor substituents decrease the acidity of the cation, while electron-acceptor substituents increase it. The following pK_S values may be quoted as an example for the styryltropylium series (VI, n = 1):

(VI)

R	H	CH_3	OCH_3	Br	C_6H_5
pK_s	4.13	4.25	4.89	3.82	3.78

However, in contrast to series (V), Hammett's equation does not hold in these cases.



Thus one may conclude that the acidity of tropylium ions of type (B), like that of ions of type (A), increases and decreases respectively in the presence of more powerful electron-acceptor and electron-donor substituents.

The enhanced acidity of (β-arylvinyl)tropylium ions, namely β-(1-naphthyl)- (IX), β-(2-naphthyl)- (X), and β-(9-anthryl), vinyltropylium (XI), ions[29], consitutes an exception. Although these ions have a longer conjugated π-electron system, their acidity is enhanced (the pK_S values are lower) compared with the stability of the styryl-

TABLE 2.

Acid	K_{diss} (in water)
Benzoic	$6 \cdot 10^{-5}$
Cinnamic	$4 \cdot 10^{-5}$
Phenylpropiolic	$6 \cdot 10^{-3}$

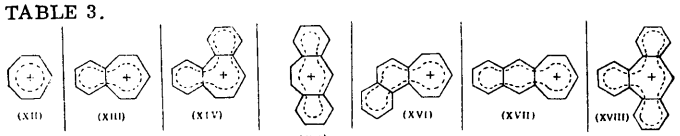
tropylium ion (pK_S = 4.13) and even the unsbustituted tropylium ion (pK_S = 4.01):

The acidity of tropylium ions of type (C) changes with the nature of the condensed rings, their number, and position. All six benzotropylium ions known at the present time exhibit greater acidity than the tropylium ion. The pK_a values for benzotropylium ions measured in sulphuric acid are listed in Table 3.

The increase of the acidity (decrease of pK_a) of the tropylium cation condensed with benzene rings is surprising at first sight, since it might have been supposed that in such compounds the positive charge would be more delocalised than in the unsubstituted tropylium ion. However, as already mentioned on p. 735, in the examination of the effect of the substituent on the acidity of the carbonium ion account must be taken of the effect of the substituent both on the cation R^+ and on the pseudobase ROH conjugated with it:

$$R^+ + 2\,H_2O \rightleftarrows ROH + H_3O^+ .$$

Probably the benzene rings condensed with the tropylium ion stabilise the uncharged cycloheptatriene system to a greater extent than the positively charged tropylium ring. This results in a decrease of pK_a. Heilbronner and coworkers[18] calculated the difference between the delocalisation energies of the cation E_{R^+} and the pseudobase E_{ROH}, denoted by A^+_{opt} (the energy of atomic delocalisation), for compounds (XII)–(XVIII):



$$A^+_{opt} = E_{R^+} - E_{ROH} .$$

They believe that the entropy and solvation effects and the change in hybridisation are the same for these compounds, i.e. on going from compound (XII) to (XIII), etc. only A^+_{opt} changes. On this basis, it is to be expected that the values of A^+_{opt} are related linearly to the pK_a. The authors showed that such a relation does indeed exist for the cations (XII), (XIII), (XV), (XVI), and (XVII) (see Fig. 2).

The breakdown of coplanarity in the cations (XIV) and (XVIII) leads to a higher acidity of the cation, compared with the values calculated from the plot in Fig. 2.[30]

In contrast to tropylium cations with condensed benzene rings, the tropylium ion condensed with a thiophen ring (XIX) is much more stable than the unsubstituted tropylium

TABLE 3.

+4.7[2] | +1.7±0.1[15] | −2.9±0.3[16] | −1.9±0.1[17] | +2.2±0.1[18] | +0.3±0.1[16] | −7.4[19]

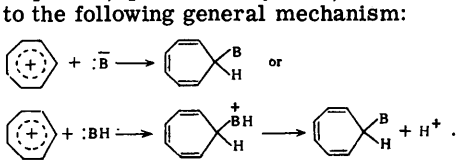
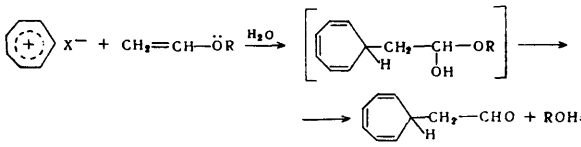
ion[31]: the pK_a value for this cation is +6.05 (pK_a = +4.75 for the tropylium ion).



(XIX)

Thus the introduction of the substituent linked to the tropylium ring by a single σ-bond [ions of types (A) and (B)] alters the acidity of the cation in a manner depending on the electron-donor or electron-acceptor properties of the substituent. Electron-donor substituents reduce the acidity of the tropylium ion and electron-acceptor substituents increase it. The explanation of this is probably that such substituents have a much greater effect on the positively charged seven-membered tropylium ring than on the uncharged cycloheptatriene system. On the other hand, in cations of type (C), for example the benzotropylium ion, the condensed benzene rings stabilise the cycloheptatriene system to a greater extent than the tropylium system, and this has been confirmed by calculations. This leads to an increase of the acidity of the benzotropylium ions, i.e. a decrease of their pK_a values, compared with the unsubstituted tropylium ion.



III. REACTIONS WITH TRANSFER OF ELECTRONS TO THE TROPYLIUM ION

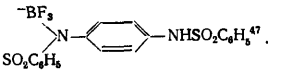
1. The Tropylium Ion as the Acceptor in Charge-Transfer Complexes

As already mentioned, the tropylium cation is one of the most stable carbonium ions and it therefore constitutes an excellent model for the investigation of the properties of carbonium ions. The positive charge of the tropylium ion is responsible for its intense electron-acceptor properties, as in other carbonium ions. Thus the tropylium ion readily reacts with nucleophilic agents, for example with complex alkali metal hydrides[32], alkoxides, organometallic compounds, potassium cyanide, ammonia[2,9], etc. according to the following general mechanism:

The tropylium ion reacts readily also with compounds containing a double bond activated by electron-donor substituents, for example with vinyl ethers[33]:

The electron-acceptor properties of the tropylium ion are not shown only in their capacity to add to reaction centres at which there is an enhanced electron density, with formation of a covalent bond. In some cases the tropylium ion can form charge-transfer complexes, playing the role of the acceptor.

Usually the formation of a charge-transfer complex is detected from the appearance in the absorption spectra of new bands which are not characteristic either of the donor or the acceptor separately in the same solvent; this is accompanied by a deepening of the colour. McConnel[34] showed that the charge-transfer energy $E_{ct} = h\nu$ is linearly related to the ionisation potential of the donor and the electron affinity of the acceptor. The ionisation potentials or the electron affinities can be measured, for example by polarography; if there is a linear relation between the observed wavelengths of the maxima in the absorption spectra and the ionisation potentials, the formation of charge-transfer complexes is demonstrated. Such a linear relation has been obtained experimentally in a number of cases[35].



Charge-transfer complexes with the tropylium ion as the acceptor were observed for the first time by Feldman and Winstein[36]. They found that, when aromatic hydrocarbons are added to solutions of tropylium perchlorate and fluoroborate in dichloroethane and acetonitrile, new absorption bands, which are not characteristic either of the hydrocarbons or of the tropylium ion, appear in the ultraviolet and visible spectra (Table 4).

The observed wavelengths of the absorption bands are linearly related to the wavelengths of the absorption maxima of the charge-transfer complexes formed by the same donors with other acceptors, for example trinitrobenzene, iodine, or tetracyanoethylene. The energies of charge transfer from benzene, naphthalene, and anthracene to the tropylium ion have been calculated by the molecular orbital method as $E = h\nu = 1.445\beta$, 1.063β, and 0.859β respectively[1], whence λ_{max} = 322, 438, and 540 nm. The calculated data are in good agreement with those found experimentally (Table 4). On the basis of these results, the authors attributed the new absorption bands to charge transfer complexes of the tropylium ion and the aromatic hydrocarbons.

The tropylium ion forms charge-transfer complexes also with other donors, for example with certain anions.

As already stated above, the tropylium ion combines with certain nucleophilic species, in particular anions, with formation of a covalent bond. Highly nucleophilic ions give rise to a covalent bond, while weakly nucleophilic anions form ionic bonds with the tropylium ion. Vol'pin et al.[37] showed that the transitions from ionic tropylium compounds $C_7H_7^+X^-$ to covalent cycloheptatriene derivatives C_7H_7X occurs in the range of the K_a values of the corresponding acids between 1.2×10^{-4} (HNCO) and $(6.3-7.75) \times 10^{-5}$ (C_6H_5COOH and CH_3COOH), i.e. acids with $K_a > 1.2 \times 10^{-4}$ form ionic compounds with the tropylium ion, while those with $K_a < 6.3 \times 10^{-5}$ form covalent compounds.

A large number of ionic tropylium compounds are known at the present time, namely salts with the following anions: Br^-, Cl^-, I^-, BF_4^-,[38] SiF_6^-, ClO_4^-, $PtCl_6^{2-}$, $B(C_6H_5)_4^-$, HgI_4^{2-}, $HgBr_4^{2-}$,[3] BCl_4^-, BBr_4^-, BI_4^-,[39-43] HCl_2^-, HBr_2^-,[44] $SnCl_6^{2-}$,[45] $SnBr_6^{2-}$, $AlCl_4^-$, $FeCl_4^-$,[46]

Their ultraviolet spectra, polarographic behaviour, and magnetic properties as well as X-ray diffraction studies show[3] that all these compounds contain the same cation $C_7H_7^+$. Thus there is now no doubt about the capacity of the tropylium ion to form ionic bonds with certain anions. However, some anions are capable of forming charge-transfer complexes with the tropylium cation under certain conditions.

Doering[8] explained the colour of tropylium halides by the formation of charge-transfer complexes. Kitaigorodskii et al.[4] pointed out the possible presence of a weak charge-transfer bond between the seven-membered ring and the iodide anion in crystalline tropylium iodide. Harmon and coworkers showed[48,49] that the absorption spectra of tropylium halides in methylene chloride (a solvent with a low dissociation capacity and a dielectric constant ϵ = 9.08) contain new bands, compared with the spectra of tropylium halides in sulphuric acid, for example (Table 5).

In contrast to the halides, the solutions of tropylium perchlorate and fluoroborate are not coloured and do not show absorption bands in the long-wavelength region. The halide solutions retain their colour only when fresh and therefore the colour is not due to decomposition products or polarisation, as sometimes happens. The wavelengths of the maxima in the absorption spectra are linearly related to the ionisation potentials of the anions.

On the basis of the results obtained, Harmon et al.[48,49] concluded that in solution in methylene chloride the tropylium ion forms charge-transfer complexes (CTC) with halide anions. Such complexes are not formed with the anions BF_4^- and ClO_4^-. In more polar solvents the absorption bands due to charge transfer disappear. This is consistent with the properties of other charge-transfer complexes, the positions of the absorption maxima of which depend on the polarity of the solvent. Kosower showed

TABLE 4.

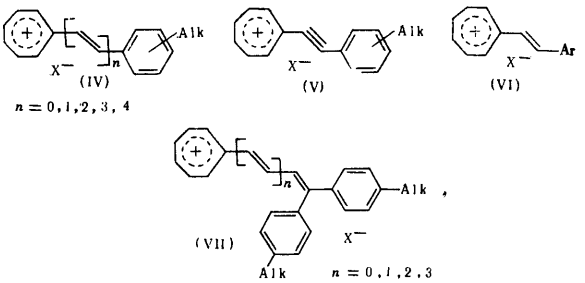
that the dependence of the position of the maxima in the absorption spectra of charge-transfer complexes on the nature of the solvent is represented by a straight line when a special quantity Z characterising the polarity is introduced[50]. It was found that the energy of charge transfer for tropylium iodide in various solvents is also linearly related to Z (Fig. 3)[51].

Thus halide anions occupy a middle position among other anions as regards their nucleophilic properties: they form ionic compounds with the tropylium ion but they are sufficiently nucleophilic to give rise also to a charge-transfer complex. It is reasonable to expect that certain organic anions forming a covalent bond with the tropylium ion may form charge-transfer complexes with the tropylium ion when electron-acceptor substituents are introduced into the anions. In fact, on interaction with the tropylium ion, lithium cyclopentadienide forms a covalent compound—(1-cyclopentadienyl)cycloheptatriene[37]:

(I)



In contrast, LeGoff and La Caunt[52] showed that with potassium 1,2,3,4,5-pentamethoxycarbonylcyclopentadienide the tropylium ion forms a salt-like compound (III), with an absorption maximum in the region of 470 nm, which is not characteristic of the individual ions, i.e. a charge-transfer complex forms:

(II) (III)

where R = $COOCH_3$.

In the cases described the tropylium ion is the acceptor, while the donors are either hydrocarbon molecules or anions. However, Jutz showed that substituted tropylium cations (IV)–(VII), with substituents having a mobile π-electron system, also exhibit certain properties characteristic of charge-transfer complexes[24,27-29]. Jutz calls these cations "internal" charge-transfer complexes, in which the tropylium ring is the acceptor and the substituent is the donor:

(IV) (V) (VI)

$n = 0, 1, 2, 3, 4$

(VII)

$n = 0, 1, 2, 3$

where Ar = phenyl, 1-naphthyl, 2-naphthyl, 9-phenanthryl, 3-pyrenyl, and 9-anthryl and X = ClO_4 and BF_4. In fact all these salts are coloured (they absorb in the long-wavelength region of the spectrum). All the cations (IV)–(VII) are characterised by negative solvatochromism (displacement of the absorption maxima into the long-wavelength region on going to less polar solvents), which is shown mainly in the long-wavelength absorption maxima. Electron-donor substituents have a powerful effect on the positions of these absorption maxima, displacing them towards longer wavelengths. Furthermore, Jutz showed that for the cations (VI) there is a linear relation between the energies $E = h\nu$ (for the long-wavelength maxima) and the ionisation potentials $E_{1/2}$ of methyl-substituted hydrocarbons corresponding to the substituents[24,27-29,53]. Consequently interaction of the donor–acceptor type takes place in charge-transfer complexes between the tropylium ring and the substituents in the cations (IV)–(VI).

Thus the tropylium ion can form ionic and covalent bonds and also donor–acceptor bonds in charge-transfer complexes. The latter are of great theoretical interest, since they are logical intermediates in reactions involving nucleophilic addition to carbonium ions, both stable and transient, which are formed in many reactions.

2. Electron Transfers to the Tropylium Ion

In the discussion of charge-transfer complexes as intermediates in reactions it is assumed that the first stage of the reaction is displacement of electron density, while the interchange of nuclei and their fixation in new positions constitute a secondary process[54]. However, one could imagine that in some cases the displacement of electron density may be followed by electron transfer without displacement of the nucleus. In the case of the tropylium ion the tropyl radical C_7H_7 or its dimerisation product (ditropyl) should then form. The possibility of such chemical reactions with the tropylium ion is confirmed by the high conjugation energy of the tropyl radical, which, according to Streitwieser's calculations[55], is -2.54β, and also by the low potential of the one-electron electrochemical reduction of the tropylium ion, which is 1.2 V§.[56]

In fact, Doering[9] showed that ditropyl forms in the interaction between a tropylium salt and zinc dust in aqueous solution. According to Vol'pin's data[58], the

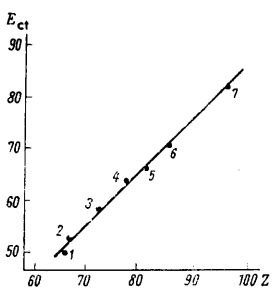


Fig. 3. Variation of the charge transfer energy E_{ct} of tropylium iodide in various solvents with the quantity Z characterising the polarity of the solvent:
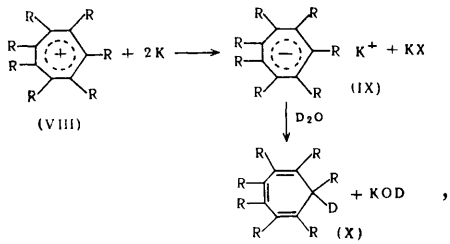
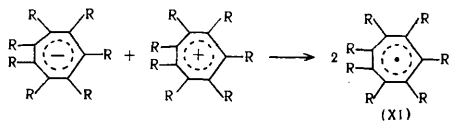
1) methylene chloride; 2) acetone; 3) acetonitrile; 4) isopropyl alcohol; 5) ethyl alcohol; 6) methyl alcohol; 7) water.

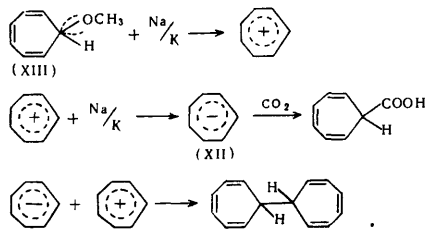


§ It is interesting to note that the tropylium ion forms in the electrochemical oxidation of cycloheptatriene, i.e. two-electron oxidation takes place[57]:

tropylium ion reacts similarly with other metals, even noble metals, i.e. tropyl behaves as a metal located on the right-hand side in the potential series. Probably tropyl radicals are formed in the reaction, and their dimerisation leads to the formation of ditropyl:



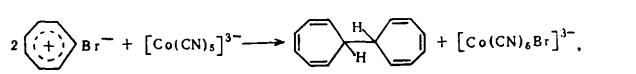
Indeed, under special conditions, namely when freshly sublimed tropylium bromide reacts with a sodium–potassium alloy in dimethoxyethane solution at −80°C, dos Santos-Veiga[59] succeeded in measuring the ESR spectrum of the tropyl radical. In some cases there is a possibility of the transfer of two electrons to the tropylium ring with the formation of a seven-membered anion. Thus Breslow and Chang[60,61] showed that the reaction of the heptaphenyltropylium ion (VIII) with metallic potassium leads to the formation of potassium heptaphenylcycloheptatrienide (IX), which is soluble in dimethoxyethane but insoluble in ethyl ether. In the reaction with D_2O there forms potassium hydroxide and deuterioheptaphenylcycloheptatriene (X), whose structure has been demonstrated by NMR spectroscopy:



where R = C_6H_5.

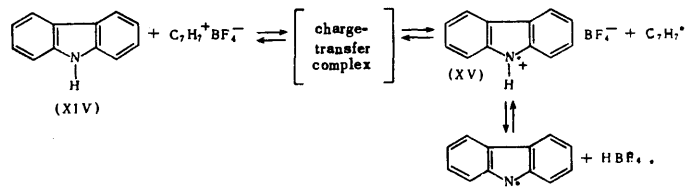
When the anion (IX) reacts with an excess of a tropylium salt, there forms a radical (XI), which gives rise to an ESR signal (the anion does not exhibit paramagnetic properties):

where R = C_6H_5.



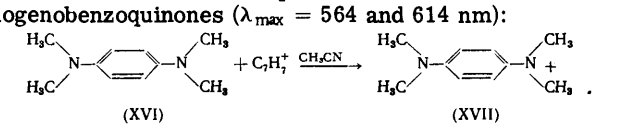
Dauben explained by a two-electron transfer the formation of the unsubstituted cycloheptatrienide anion (XII).[62] He showed that, when methoxycycloheptatriene (XIII) is added slowly to a solution of the sodium–potassium alloy in tetrahydrofuran at −20°C, a blue solution forms, whose subsequent carboxylation yields ditropyl and cycloheptatriene-7-carboxylic acid, which is evidence of the formation of the anion as an intermediate. Dauben suggests the following reaction mechanism:

The C–O bond in methoxycycloheptatriene undergoes ionic dissociation with formation of the tropylium ion, which is further reduced by the alkali metal to the anion, yielding on carboxylation cycloheptatrienecarboxylic acid¶. One-electron transfer from the anion to the tropylium ion yields ditropyl.



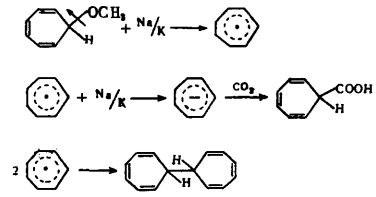
It is noteworthy that Bauld and Brown[63] succeeded in demonstrating with the aid of ESR spectroscopy that during this reaction there is a possibility of the transfer of yet another electron to the cycloheptatrienide anion with the formation of a radical-dianion.

The tropylium ion may be reduced to ditropyl by transition metal complexes, for example[64]:



$NaMn(CO)_5$, $KFe(CO)_nH$, $HgFe(CO)_n$,[65] $V(CO)_6$, and $Na[C_5H_5Cr(CO)_3]$[66] have a similar effect on the tropylium ion.

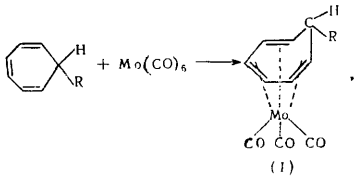
Ledwith and coworkers[67,68] showed that the tropylium ion can remove electrons from certain heterocyclic compounds containing a double bond or an aromatic ring. The latter form radical cations on giving up an electron. Thus carbazole (XIV) is oxidised by the tropylium ion to the radical-cation (XV), whose structure has been demonstrated by NMR, infrared, and ESR ($g \simeq 2$) spectroscopy.



The radical-cation (XV) contains a labile hydrogen atom, as a result of which it is unstable. When *N*-methylcarbazole was used, a radical-cation stable in neutral solution was obtained. To confirm the occurrence of one-electron transfer to the tropylium ion, *NN*-tetramethyl-*p*-phenylenediamine (XVI), which is known to form radical-cations with other acceptors, for example halogenobenzoquinones[69], was used as the reducing agent. It was found that in the reaction with the tropylium ion it forms a radical-cation (XVII) which is identical with that produced in the reaction with halogenobenzoquinones (λ_{max} = 564 and 614 nm):

Unfortunately, in none of their experiments did the authors isolate ditropyl, whose formation would constitute important evidence of the occurrence of one-electron transfer to the tropylium ion.

¶ Although heterolytic dissociation of the C–O bond in cycloheptatriene derivatives under the action of electrophilic agents is widely known in the chemistry of the tropylium ion, we believe that in this case one cannot entirely exclude the possibility of homolytic dissociation:



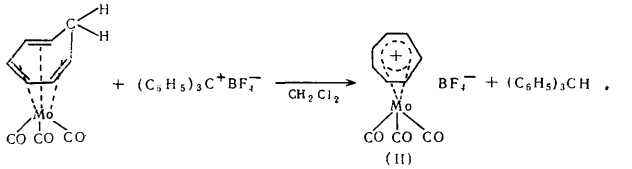
Thus the electron-acceptor properties of the tropylium ion, which is a carbonium ion, are shown not only in its capacity to combine with a species having an electron pair, but also in its capacity to combine with electrons. One-electron transfer to the tropylium ion leads to the formation of the tropyl radical or its dimer and two-electron transfer leads to the formation of the cycloheptatrienide anion. Systems with less mobile electrons can form charge-transfer complexes with the tropylium ion.

IV. SANDWICH COMPOUNDS OF THE TROPYLIUM ION

Sandwich compounds of transition metals with cyclopentatrienyl and arene ligands are widely known at the present time. Many studies have been made on their synthesis and properties. The sandwich compounds of transition metals in which the ligands are C_7H_7 rings have been almost not investigated.

Like the cyclopentadienyl and benzyl rings, the cycloheptatrienyl ring has six π-electrons which can form a bond with a central metal atom. Physical measurements, namely X-ray diffraction analysis and NMR and infrared spectra, have shown that, as a rule, all the carbon atoms of the cycloheptatrienyl ring are identical and lie in one plane. On this basis, one can postulate that the seven-membered ring in such complexes has the structure of the tropylium ion and the complexes may be regarded as tropylium complexes of transition metals.

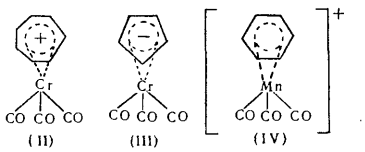
Attempts to obtain transition metal complexes with the tropylium cation were made soon after its synthesis by Doering[2]. Wilkinson[65,70] was the first to attempt the preparation of a tropylium complex of this kind. In the reaction of a metal carbonyl with cyclopentadiene or benzene three carbonyl groups are capable of being replaced by the cyclopentadienide or benzene system, hydrogen being removed from cyclopentadiene in the reaction with the latter. Wilkinson hoped that in the reaction between cycloheptatriene and molybdenum hexacarbonyl the carbonyl group would also be replaced by the tropylium aromatic system with simultaneous removal of the hydrogen atom. However, the latter did not occur and Wilkinson obtained cycloheptatrienemolybdenum tricarbonyl (I). The reaction with cycloheptatriene derivatives took place similarly:



(I)

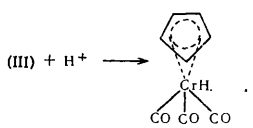
where R = H, C_6H_5, C_7H_7, OC_7H_7.

The attempts to prepare the desired complex by introducing tropylium bromide directly into the reaction were also unsuccessful.



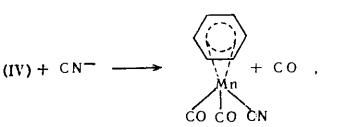
Dauben succeeded in preparing a tropylium complex[71]. Before this he established that, when salts of the triphenylmethyl cation are allowed to act on cycloheptatriene and its derivatives, a hydride ion migrates from cycloheptatriene to the carbonium ion with formation of a tropylium salt and triphenylmethane[38]. An analogous reaction with the cycloheptatrienemolybdenum tricarbonyl obtained by Wilkinson would yield tropylium-molybdenum tricarbonyl (II). The reaction did indeed take place, and the required complex (II) was obtained in quantitative yield:

(II)



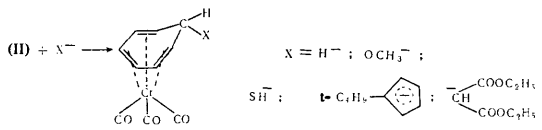
Compound (II) is more symmetrical than the cycloheptatriene complex (I). The greater symmetry of compound (II) is shown in the fact that the infrared spectra have only two carbonyl maxima, analogous to the absorption maxima of cyclopentadienylmanganese tricarbonyl and benzenechromium tricarbonyl, while three carbonyl maxima are observed in the spectrum of the cycloheptatriene complex. NMR spectra reveal the presence of protons of only one type, which confirms the highly symmetrical structure of the complex, with the metal atom bound to all seven carbon atoms of the seven-membered ligand. Complexes with chromium and tungsten were obtained similarly[72,73].

Pauson compared the sandwich cations obtained by Dauben with charged complexes of the type of cyclopentadienylchromium tricarbonyl (III) and benzenemanganese tricarbonyl (IV):[74]

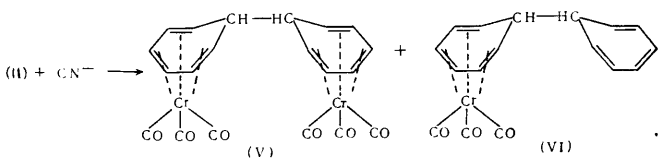


(II) (III) (IV)

Pauson believes that the negative charge in complex (III) is mainly localised in the ring although it is reduced by the action of the electron-acceptor group $M(CO)_3$. However, the addition of a positively charged species to the ring† would lead to the breakdown of the inert-gas electron shell of the system as a whole. Therefore the addition of an electrophilic agent, for example a proton, to the metal atom with formation of a carbonyl hydride is energetically more favourable:

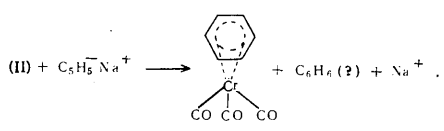


As a result of the same factors as those postulated for compound (III), the positive charge in complex (IV) is distributed between the benzene ring and the metal and again there is no addition of a nucleophilic species to the ring. However, in contrast to compound (III), a nucleophilic species does not add to the metal atom either, since manganese does not have vacant orbitals and therefore reaction, with a cyanide ion for example, can take place only with displacement of a carbonyl group:



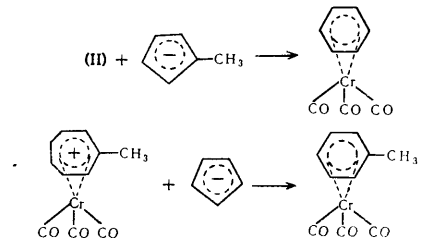
† In this and other cases where a species adds to a ligand or a metal atom only the final products are considered and not the reaction mechanism.

Pauson believes that, in contrast to these compounds, the tropylium complex (II) has a positive charge on the ring, the charge being enhanced further by the electron-acceptor effect of the $M(CO)_3$ group. The addition of nucleophilic species to the ring can result in this case in stable final products, due to the formation of a cycloheptatriene ring linked to the metal atom via six π-electrons, i.e. the inert-gas shell does not break down. In fact the cation (II) does react with certain nucleophilic agents, cycloheptatriene complexes being formed[75]:



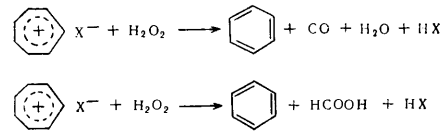
This reaction is analogous to the reactions of the free tropylium ion. Pauson called it the "normal" reaction of tropyliumchromium tricarbonyl salts with anions.

Apart from the "normal" reaction characteristic of the free tropylium ion, reactions characteristic of the system as a whole, with some similarities to those of other carbonyl complexes, were to be expected for complex (II). Pauson and Munro hoped to replace the carbonyl group by a cyanide ion, as happens in benzenemanganese tricarbonyl, already mentioned, and other complexes. However, the reaction of tropyliumchromium tricarbonyl with sodium cyanide takes place in a different manner. Apart from a small amount of the product of the "normal" addition, the authors isolated substances with structures (V) and (VI):[76]



The reaction with $NaHCO_3$, CH_3COONa, $NaNH_2$, C_6H_5Li, $C_6H_5\overset{O}{\overset{\|}{C}}NH_2$, and HCl (2 *N*) takes place similarly. This process was called the "anomalous" reaction of complex (II) with anions.

Attempting nevertheless to replace the carbonyl groups in tropylium chromium tricarbonyl by a nucleophilic species, Pauson and Munro allowed the cyclopentadienide anion, which has a considerable affinity for the metal, to react with the complex. To their surprise, they failed to isolate after the reaction the products of either the "normal" or the "anomalous" addition. Instead they obtained benzenechromium tricarbonyl[73,77]:

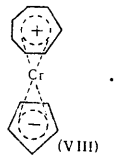


Benzenechromium tricarbonyl is also obtained in the reaction between tropyliumchromium tricarbonyl and sodium methylcyclopentadienide. On the other hand, the reaction between methyltropyliumchromium tricarbonyl and sodium cyclopentadienide results in the formation of toluenechromium tricarbonyl:

Thus benzene bound to chromium is obtained as a result of the contraction of the seven-membered ring of complex (II). To confirm this finding completely, the authors used in the reaction a tropylium complex labelled with tritium and indeed they observed the expected activity in the benzenechromium tricarbonyl. The contraction of the tropylium ring to the benzene ring in compound (II) was also found to occur in the reaction with sodiomalonic ester in the presence of an excess of the complex (in the presence of an excess of the sodiomalonic ester the reaction takes place with formation of "normal" addition products). Hence the authors concluded that the "normal" product forms first and then ring contraction takes place.

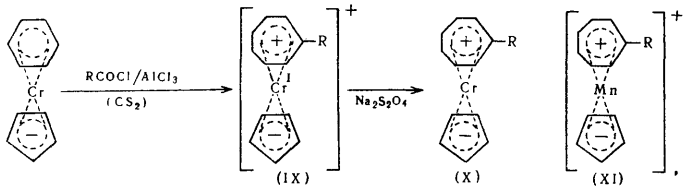
The rearrangement of the seven-membered ring to a six-membered ring with simultaneous elimination of one carbon atom is also known in the chemistry of free tropylium ions. Vol'pin et al. showed[78] that, when a dilute aqueous solution of hydrogen peroxide is allowed to act on the tropylium ion at room temperature, benzene in 80% yield, carbon monoxide, and formic acid are formed:

The "anomalous" addition reaction and the reactions involving the contraction of the seven-membered ring showed that the tropylium complexes obtained for the first time by Dauben are new systems, whose study is of great interest.



Apart from these complex cations, uncharged sandwich compounds of the tropylium ion have been described. If the three carbonyl groups in cycloheptatrienylchromium tricarbonyl are replaced by the cyclopentadienyl residue, the molecule will be uncharged as a whole. Such a complex (VIII) was obtained by Fischer from cyclopentadienylbenzenechromium and cycloheptatriene in the presence of aluminium chloride, with subsequent hydrolysis of the reaction mixture and the reduction with sodium hydrosulphite of the cation (VII) formed initially[79]:

Somewhat later King and Bisnette[80] obtained the same complex (VIII) by a more convenient method, involving the reaction of isopropylmagnesium bromide with a mixture of chromium trichloride, cyclopentadiene, and cycloheptatriene in ethereal solution at −78°C with subsequent alcoholysis of the reaction mixture:



The NMR spectra of compound (VIII) revealed the presence of two types of protons in a ratio of 5 : 7. The infrared spectra also correspond to conjugated five- and seven-membered rings. The dipole moment is 0.79 D in benzene. On the basis of these data, and also in view of the tendency of the C_7H_7 and C_5H_5 systems to undergo conversion into the ions $C_7H_7^+$ and $C_5H_5^-$, a structure with partial positive and negative charges on the seven-membered and five-membered rings respectively may be put forward for compound (VIII):

(VIII)

Similar complexes with an unsubstituted tropylium ring were unexpectedly obtained by Fischer (in 10% yield) in attempts to acylate cyclopentadienylbenzenechromium by the Friedel–Crafts method[81]:

(IX) (X) (XI)

where R = CH_3 or C_6H_5. The cation (IX) formed initially yields on reduction the uncharged complex (X), which has an inert-gas electron shell. With manganese, which has in its shell one electron more than chromium, the tropylium cation (XI), with 18 π-electrons, forms immediately.

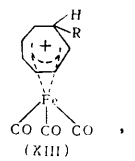
Both complexes have similar infrared spectra and the NMR spectra reveal three types of protons in ratios of 6 : 5 : 3 (for R = CH_3), which is consistent with structures (X) and (XI). To confirm the tropylium structure of the ligand, the authors, using Dauben's method, obtained from the cycloheptatriene complex a compound identical with compound (X).

The paramagnetic cycloheptatrienylcyclopentadienylvanadium, obtained by King and Stone[82] in the reaction between cycloheptatriene and cycloheptadienylvanadium tetracarbonyl:

$$C_5H_5V(CO)_4 + C_7H_8 \rightarrow C_5H_5VC_7H_7 ,$$

and also the diamagnetic cycloheptatrienylvanadium tricarbonyl[65] have structures similar to that of complex (X). The planarity of the seven-membered ring and its high symmetry have been demonstrated by X-ray diffraction measurements[83] and also by NMR and infrared spectroscopy[65,84].

The platinum complex (XII), obtained by Fischer and Fritz[85], is somewhat exceptional. The infrared spectra of this complex are very similar to those of tropylium bromide and differ markedly from the spectra of cycloheptatriene. On the basis of these data, the authors assert that the seven-membered ligand has the tropylium structure:

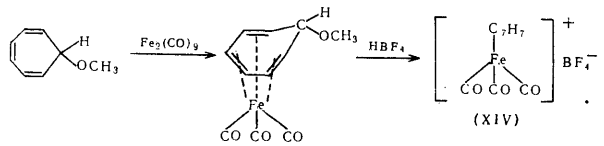


$$PtBr_4 + C_7H_8 \rightarrow (C_7H_7PtBr_2)_2 .$$

(XII)

Thus at the present time only synthetic methods and certain physical properties, which suggest a tropylium structure of the seven-membered ring, have been described for uncharged complexes with the seven-membered ligand.

So far tropylium complexes of transition metals in which an inert-gas electron shell was achieved (the paramagnetic cycloheptatrienylcyclopentadienylvanadium, which has one unpaired electron, is an exception) were considered. Metals of Group VIB then remain zerovalent, vanadium in tropylium vanadium tricarbonyl[65] has a valence of –1, and the cyclopentadienyltropylium-manganese complex[81] is a cation. Analogous complexes of iron, i.e. complexes with a tropylium ligand, for example $[C_7H_7Fe(CO)_3]^+$, would have two electrons more than the corresponding inert gas, or, if Sidgwick's rule holds, would be triply charged cations. Attempts have been made to synthesise such complexes and to determine their structure.



Dauben[72] tried to prepare a complex of iron and the C_7H_7 ligand in the reaction between the triphenylmethyl cation and cycloheptatrieneiron tricarbonyl. However, instead of the removal of a hydride ion, the carbonium ion added to the double bond of the cycloheptatriene ring with formation of the cation (XIII):

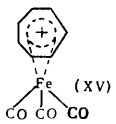
(XIII)

where R = $(C_6H_5)_3C$.

It appears that Pettit and coworkers[86] succeeded in obtaining the desired complex $[C_7H_7Fe(CO)_3]^+BF_4^-$ (XIV) by the action of methoxycycloheptatriene on iron carbonyl with subsequent decomposition with acid of the methoxycycloheptatrieneiron tricarbonyl produced:

(XIV)

However, the study of the chemical properties of compound (XIV) suggests that the ligand C_7H_7 is more likely to have the tropylium structure. Indeed hydrolysis of complex (XIV) yields a complex of tropyl alcohol $C_7H_7OHFe(CO)_3$. Acid decomposition of the latter again results in the formation of compound (XIV). A similar reaction also occurs in the chemistry of the free tropylium ion:

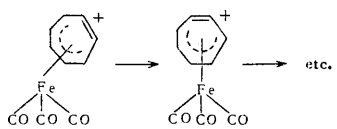


$$C_7H_7^+ + H_2O \rightleftarrows C_7H_7OH + H^+ .$$

Only one signal is observed in the NMR spectra of complex (XIV), i.e. there is only one type of proton. This confirms the symmetrical tropylium structure of the ligand C_7H_7. However, the authors observed in the infrared spectra three absorption bands in the region of C–H vibrations instead of one, as would be expected for the symmetrical C_7H_7 ligand. Comparison of the acidity constants of complex (XIV) and the free tropylium ion (Table 6) shows that the cation (XIV) is less stable than the tropylium cation, while the tropylium complexes of Group VIB metals are more stable than the tropylium cation itself.

TABLE 6.

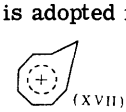
	pK_a in water		pK_a in water
(1) C_7H_7	+4.7	(4) $C_7H_7W(CO)_3$	+6
(2) $C_7H_7Cr(CO)_3$	+6.3	(5) $C_7H_7Fe(CO)_3$	+4.5
(3) $C_7H_7Mo(CO)_3$	+6.2	(6) $C_7H_9Fe(CO_3)$	+4.7



Therefore the structure of the tropylium complex (XIV) cannot be that of compound (XV):

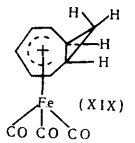
(XV)

It follows from Table 6 that the pK_a values for the cations of cycloheptatrienyliron tricarbonyl (5) and cycloheptadienyliron tricarbonyl (6) are approximately equal. The study of the infrared spectra of the cation (XIV) showed that the vibrations of the carbonyl groups in this complex occur in the same region as the vibrations of the carbonyl groups in dienyliron tricarbonyl complexes (2070 cm^{-1} and 2120 cm^{-1}). Furthermore, the presence of an absorption band in the region of 731 cm^{-1} enabled the authors to suggest the presence of a *cis*-double bond.



On the basis of these results, Pettit and coworkers concluded that the cation (XIV) has the structure (XVI), analogous to that of cationic cyclopentadienyliron tricarbonyl, the inert-gas electron shell being achieved in complex (XVI):

(XVIa) (XVIb)



The identity of the protons revealed in the NMR spectra is explained by the rotation of the $Fe(CO)_3$ group about the seven-membered ring, which leads to the tautomers (XVIa), (XVIb), etc.

In conclusion we shall consider transition metal complexes with protonated cyclo-octatetraene as the ligand. Rosenberg et al.[87] showed that the NMR spectrum of free protonated cyclo-octatetraene $C_8H_9^+$ has four peaks with relative areas of 5 : 2 : 1 : 1. On this basis, the authors suggested that seven carbon atoms lie in one plane, forming a tropylium ring (this accounts for the stability of the cation), while the methylene group lies outside this plane. Thus the structure (XVII) is adopted for the cation $C_8H_9^+$.

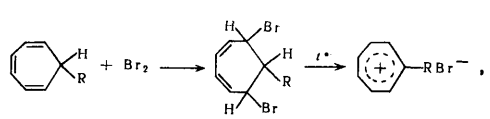
(XVII)

Winstein and coworkers[88] found that the NMR spectra of the complex cation $[C_8H_9Mo(CO)_3]^+$ also reveal the presence of four types of proton in the ratios 5 : 2 : 1 : 1. Consequently the structure of the cation $C_8H_9^+$ [structure (XVII)] persists also in the complex (XVIII), which leads to the participation of six π-electrons in the formation of a metal–ligand bond and a stable common 18 π-electron shell. Thus the structure of protonated cyclo-octatetraenemolybdenum tricarbonyl (XVIII) resembles closely that of tropyliummolybdenum tricarbonyl.

Different workers have attributed different structures to the analogous iron complex[89,90]. Very recently Winstein and coworkers[88] showed, on the basis of a thorough study of the NMR spectra of protonated cyclo-octatetraeneiron tricarbonyl, that this complex has the structure (XIX), similar to the structure of dienylirion tricarbonyl, as for the complex $[C_7H_7Fe(CO)_3]^+$ [complex (XVI)]:

(XIX)

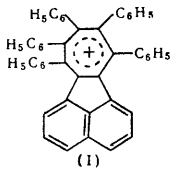
Complexes with the ligand C_7H_7 are now known for metals of Groups VB, VIB, VIIB, and VIII, examples being vanadium (Group V), chromium and molybdenum (Group VI), manganese (Group VII), and iron and platinum (Group VIII). In all these complexes, except for the iron complex, the seven-membered ligand has the tropylium structure and almost all the complexes obey Sidgwick's rule. Exceptions are the paramagnetic cycloheptatrienylcyclopentadienylvanadium $C_7H_7VC_5H_5$, the electron shell of which consists of 17 π-electrons, and the platinum complex $(C_7H_7PtBr_2)_2$, which probably has a shell consisting of 20 π-electrons. In the iron complex (XVI) four π-electrons form a metal–ligand bond of the type which exists in diene complexes and a shell of 18 π-electrons is formed.



There are virtually no data at the moment concerning the reactivity of these complexes. Only certain reactions of the tropyliumchromium tricarbonyl cation are known[75-77]. The chemical properties of the uncharged complexes have not been investigated at all. It is not possible as yet to predict their behaviour in reactions, since the distribution of electron density, which is primarily responsible for chemical reactions, cannot be measured by methods available at the present time, and calculations yield very ambiguous answers (as shown by the calculation for the ferrocene molecule).[91,92] Nevertheless, there is no doubt that further studies will lead to interesting and unexpected reactions of these complexes, a feature which is characteristic of the chemistry of the sandwich compounds of transition metals in general.

V. FORMATION OF THE TROPYLIUM ION AND ITS PROPERTIES

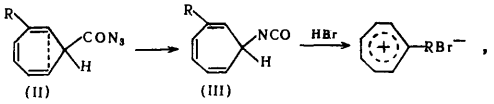
1. Formation of the Salts of Substituted and Unsubstituted Tropylium Ions



One of the characteristic properties of aromatic systems is known to be the ease of their formation. This applies also to the tropylium cation. The ways in which substituted and unsubstituted tropylium ions are formed are presented below.

1. Doering's method[2] consists in the bromination of cycloheptatriene and its derivatives with subsequent dehydrobromination under conditions of mild pyrolysis:

where R = H, COOH, C_6H_5, t-C_4H_9, and Br. Salts of carboxytropylium[20,93,94], phenyl-, t-butyl-, and bromotropylium[8], and also heptaphenyltropylium[25], and

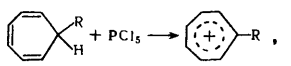


7,8,9,10,11-pentaphenylcyclohepta-acenaphthenylium[95] ions (I):

(I)

were obtained by this method.

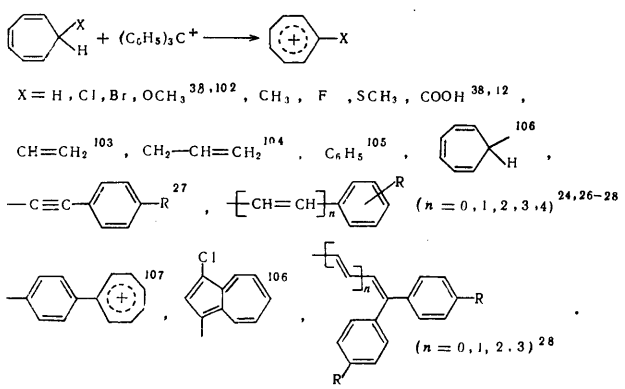
2. The method of Dewar and Pettit[96,97] consists in heating the azides of norcaradienecarboxylic acid (II) in benzene with subsequent treatment of the resulting isocyanate (III) with hydrogen bromide:



(II) (III)

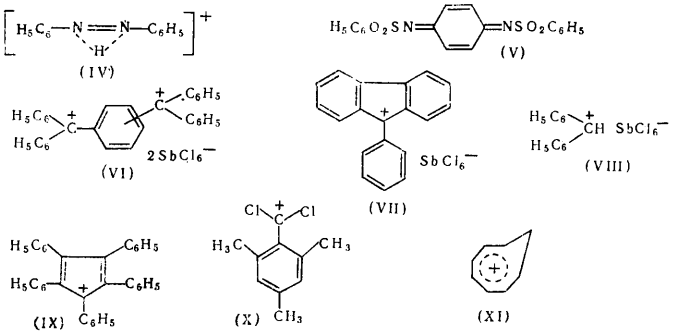
where R = H and CH_3.

3. The removal of a hydride ion from cycloheptatriene derivatives.



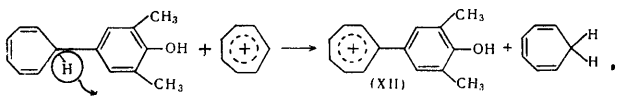
a. In the method of Kursanov and Vol'pin[98] the hydride ion is removed from cycloheptatriene and its derivatives with phosphorus pentachloride in an inert solvent. Salts of methyltropylium[98,99], and ethyl- and benzyl-tropylium[99]‡ ions have been obtained by this method from the 7-substituted cycloheptatrienes:

where R = H, CH_3, C_2H_5, and $CH_2C_6H_5$.



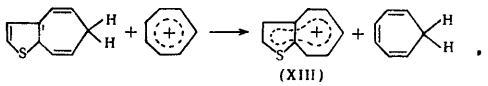
Salts of methoxy- and ethoxy-tropylium ions were obtained in the reaction of phosphorus pentachloride with 1-, 2-, and 3-alkoxycycloheptatriene[100]. When phosphorus pentachloride acts on 7-alkoxycycloheptatriene, the latter decomposes with formation of salts of the unsubstituted tropylium ion (cf. the results of Vol'pin and Akhrem[101]).

b. In Dauben's method[38] the hydride ion is removed from cycloheptatriene and its derivatives by the triphenylmethyl cation which results in the formation of triphenylmethane and an unsubstituted or substituted tropylium ion, which is a more stable carbonium ion than the triphenylmethyl cation:



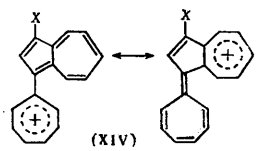
‡ The salts of ethyl- and benzyl-tropylium ions were not isolated in a pure form; a suspension of these salts in methylene-chloride was introduced directly into further reactions.

The following new acceptors have been used in recent years for the removal of the hydride ion from cycloheptatriene: protonated azobenzene (IV)[108,109], benzoquinones[110] and their derivatives, for example *p*-benzoquinone-dibenzenesulphonimide (V) in the presence of boron trifluoride-ether[47] and a number of stable carbonium ions synthesised for the first time, i.e. (VI)[111], (VII)[112], (VIII)[113], (IX)[114], (X)[115], and (XI)[87]:



(IV) (V) (VI) (VII) (VIII) (IX) (X) (XI)

c. The removal of the hydride ions from cycloheptatriene derivatives under the action of the tropylium ion. In this case salts of a substituted tropylium ion more stable than those of the unsubstituted tropylium ion are formed. The 3,5-dimethyl-4-hydroxyphenyltropylium cation (XII)[116]:

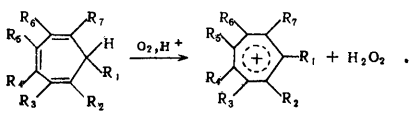


(XII)

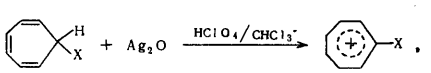
the thenotropylium cation (XIII)[31]:

(XIII)

and the salts (XIV*a*) and (XIV*b*)[117]:



(XIV)

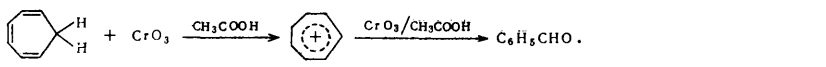


(X = H in *a* and X = C_7H_7 in *b*) were obtained in this way.

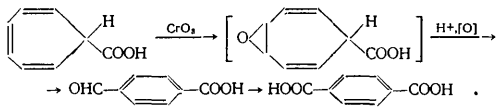
4. The oxidation of cycloheptatriene and its derivatives.

a. ter Borg et al.[118] showed that the oxidation of cycloheptatriene with atmospheric oxygen in acetic acid in the presence of perchloric or fluoroboric acids results in the formation of the tropylium ion in 30–70% yield. They suggest that substituted tropylium salts be obtained in a similar way[119]:

b. Nozoe[120] described the preparation of the tropylium and hydroxyphenyltropylium ions in the oxidation of cycloheptatriene and 4-cycloheptatrienylphenol respectively with silver oxide in chloroform solution in the presence of perchloric acid:

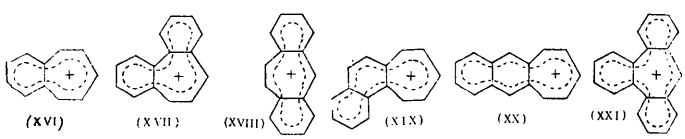


where



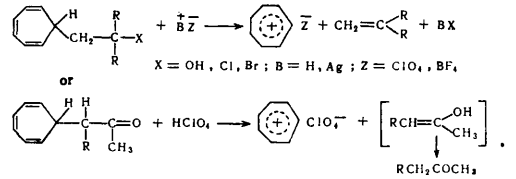
c. The oxidation of 7-cycloheptatrienecarboxylic acid (XV) with lead tetra-acetate, acid potassium permanganate, $Na_2S_2O_8$, $(NH_4)_2Ce(NO_3)_6$, and periodic acid also leads to the formation of the tropylium ion; in some cases benzaldehyde, benzyl alcohol, and terephthalic acid are formed at the same time[121].

In neutral and alkaline media potassium permanganate oxidises the acid (XV) to benzaldehyde and terephthalic acid. Doering showed that benzaldehyde forms in the oxidation of cycloheptatriene with chromic acid[9]. It also forms in the oxidation of the tropylium ion with chromic acid. On the basis of these data, Doering suggested that the oxidation of cycloheptatriene to benaldehyde takes place with the intermediate formation of the tropylium ion:



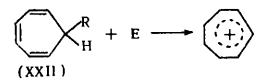
Juppé and Wolf[122] confirmed this reaction mechanism, by oxidising with chromic acid cycloheptatriene labelled with carbon-14 in the methylene group. They found that the benzaldehyde produced contains 6/7 of the label in the benzene ring. Dewar's ideas about the mechanism of the oxidation of cycloheptatriene-7-carboxylic acid to benzyl alcohol and benzaldehyde are consistent with Doering's hypotheses, but he proposes a different mechanism for the oxidation of the acid (XV) to terephthalic acid[121]:

By oxidising cycloheptatriene with chromic anhydride in pyridine, Nozoe and coworkers obtained tropone[123]. The latter also forms in the interaction of the tropylium ion with the same oxidising agent. Using his own data and also the oxidation data described above, Nozoe was able to elucidate the mechanism of the oxidation of cycloheptatriene with intermediate formation of the tropylium cation.



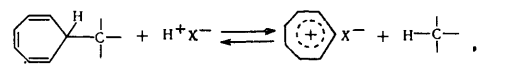
5. Heterolytic dissociation of the bonds C–O, C–C, C–N, and C–S.

a. The C–O bond in tropylium ethers[2] and tropylium-carbinols is readily ruptured under the action of acids with formation of unsubstituted tropylium salts. When acids were allowed to act on the corresponding carbinols, benzotropylium (XVI)[15], dibenzo[*a*, *c*]tropylium (XVII)[16], dibenzo[*a*, *e*]tropylium (XVIII)[17], naphtho[2,1-*a*]tropylium (XIX)[18], naphtho[2,3-*a*]tropylium (XX)[16], and tribenzo[*a*, *c*, *e*]tropylium (XXI)[19] cations were obtained. The carbinols were produced by the reduction of the corresponding tropones with lithium aluminium hydride.

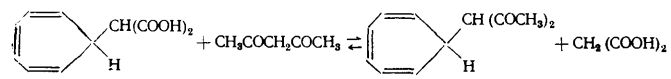


(XVI) (XVII) (XVIII) (XIX) (XX) (XXI)

b. Under the action of electrophilic agents, the C–C bond in compounds with a carbonium centre in the β-position with respect to the cycloheptatrienyl residue may dissociate[3,124]:

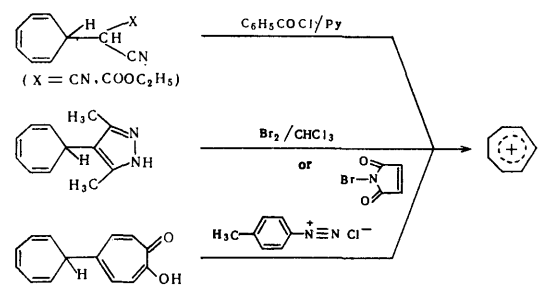


Recently Vol'pin and Akhrem showed[101] that this reaction is more general and is characteristic of cycloheptatriene derivatives with electron-acceptor substituents in the side-chain. Thus cycloheptatrienylmalonic acid (XXII*a*), cycloheptatrienylacetylacetone (XXII*b*), cycloheptatrienylacetaldehyde (XXII*c*) and cycloheptatrienylacetoacetic ester (XXII*d*) are cleaved by a wide variety of electrophilic agents E with formation of the tropylium ion:

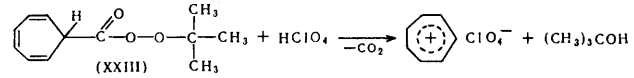


(XXII)

R = $CH(COOH)_2$ (*a*), $CH(COCH_3)_2$ (*b*), CH_2CHO (*c*), and $CH_2COOC_2H_5$ (*d*); E = Br_2, HCl(gas), HBr(gas), H_2SO_4, CH_3COOH, H_3PO_4, PCl_5, $(CH_3CO)_2O$, $(C_6H_5)_3C^+$, t-C_4H_9Br, $ZnCl_2$, and $FeCl_3$.

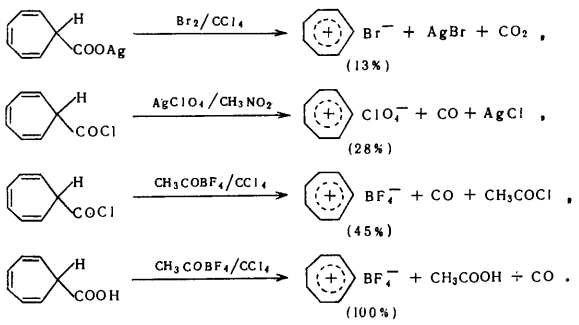


The authors suggested that this cleavage reaction is the reverse of the "tropylation" process[125]:

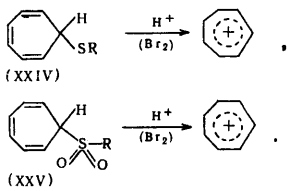


and confirmed this by the "transtropylation" reaction, which consists in the migration of the cycloheptatrienyl residue from one compound with a mobile hydrogen atom to another, for example,

Other examples of the dissociation of the C–C bond in cycloheptatriene derivatives with formation of the tropylium ion may be quoted[126–128]:

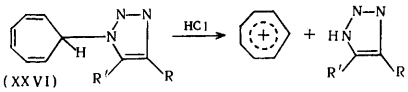


The tendency of cycloheptatriene to form the aromatic tropylium system is so great that under the action of a strong acid the C–C bond dissociates heterolytically even in the peroxide (XXIII)[129]:



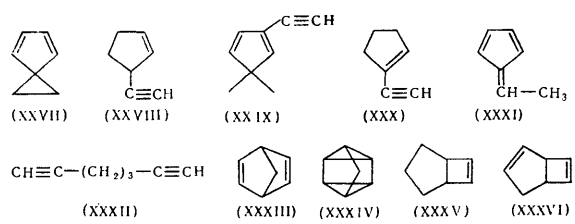
The following reactions of cycloheptatriene-7-carboxylic acid and its derivatives, proposed by Dewar and Ganellin[94]

for the preparation of tropylium salts, may be included among processes involving the dissociation of the C–C bond in cycloheptatriene derivatives:

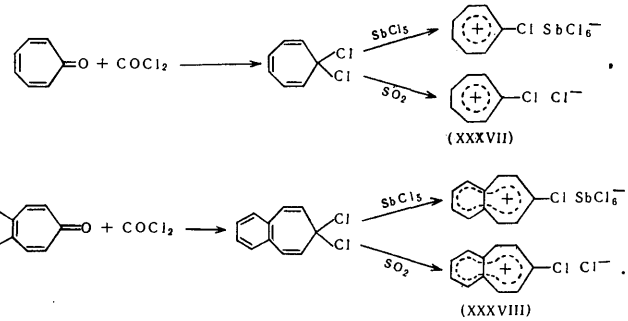


c. The C–S bond in thioethers (XXIV) and sulphones (XXV) of cycloheptatriene readily dissociates with formation of the tropylium ion under the action of acids, for example hydrobromic and perchloric acids or bromine in acetic acid[130,131]:

d. Doering showed, using ditropylurea as an example, that the C–N bond can also dissociate heterolytically with formation of the tropylium ion under the action of an acid[132]:

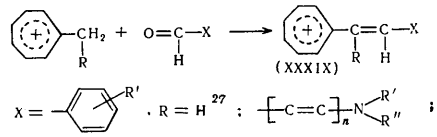


Recently Looker[133] described yet another case of the heterolysis of the C–N bond in cycloheptatriene derivatives (XXVI)[133]:



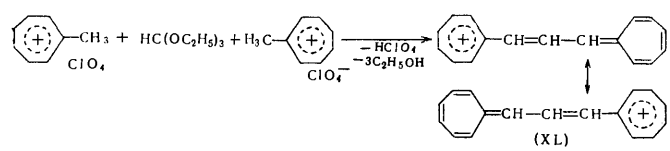
where R = R′ = $COOCH_3$, R = R′ = COC_6H_5 and R = CHO and R′ = H.

6. The formation of the tropylium ion in the mass spectrometer. Earlier it was shown that various alkylbenzenes form the tropylium ion on collision with electrons in the mass spectrometer[134]. In recent years a number of investigators have shown that benzyl chloride, benzyl alcohol[135], the isomeric C_7H_8 hydrocarbons (XXVII)–(XXXIV), cycloheptadiene, Δ^6-bicyclo[3,2,0]heptene (XXXV), and $\Delta^{2,6}$-bicyclo[3,2,0]heptadiene (XXXVI)[136–139] also have identical mass spectra:

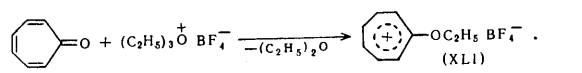


7. Other methods.

a. Föhlisch et al.[140] obtained the chlorotropylium (XXXVII) and 5-chloro-1,2-benzotropylium (XXXVIII) ions by the action of phosgene on tropone in sulphur dioxide or by further treatment with antimony pentachloride of the covalent dichloro-derivatives formed:



b. When methyl-, ethyl-, and benzyl-tropylium salts were condensed with aromatic aldehydes and their derivatives in acetic acid solution containing a small amount of perchloric acid, the following substituted tropylium compounds (XXXIX) were obtained:



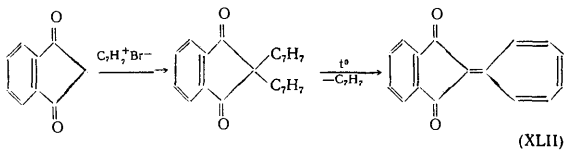
R = H, CH_3, and C_6H_5§ [38]; n = 0 and 1; X = 1-naphthyl, 2-naphthyl, 9-phenanthryl, 9-anthryl, and 3-pyrenyl; R = H.[29]

Hafner and coworkers obtained the salt (XL) by the condensation of the methyltropylium ion with orthoformic ester[141]:

By allowing tropone to react with triethyloxonium fluoroborate, they obtained ethoxytropylium fluoroborate (XLI):

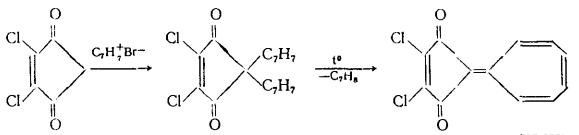
2. The Properties of the Tropylium Ion

The studies on the reactivity of the tropylium ion have continued in recent years. The most important property of the tropylium ion, as a carbonium ion, is its electrophilicity (see Section II). The tropylation reaction discovered by Vol'pin et al.,[142] i.e. the replacement of a mobile



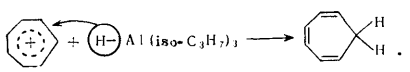
§ The interaction of methyl-, ethyl-, and benzyl-tropylium salts with N-substituted formamides and β-(dialkylamino) acrolein derivatives with formation of immonium salts takes place in the presence of phosphorus oxychloride.

hydrogen atom by the cycloheptatrienyl residue, is associated with the electrophilic properties of the tropylium ion:

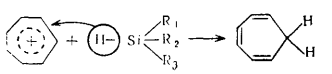


This reaction has found extensive application in the synthesis of cycloheptatriene derivatives.

Thus Jordan and Elliott [143] introduced the seven-membered ring into the molecules of 2-ethoxycarbonylcyclopentanone, potassium phthalimide, and indane-1,3-dione; Nozoe and coworkers introduced the seven-membered ring into β-naphthol [144] and tropolone [128], and Hafner [117] and later Anderson [106] "tropylated" azulene. Kitahara and coworkers obtained quinones of the sesquifulvalene series, (XLII) and (XLIII), with the aid of the tropylation reaction [145]:

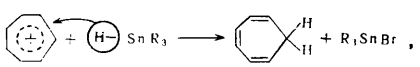


(XLII)



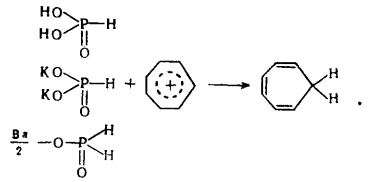
(XLIII)

Further examples of the reaction of tropylium ions in which a double bond is activated by electron-donor substituents, first observed by Vol'pin et al. [142,146], have been discovered [28,147].



The tropylium ion as an acceptor of hydride ions has been used for the further study of hydride migrations. It has been shown that the tropylium ion can remove a hydride ion not only from complex alkali metal hydrides but also from simple aulminium hydrides [32]:

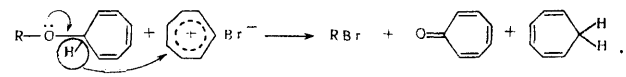
It has been found that the Si–H and Sn–H bonds can also dissociate heterolytically under the action of the tropylium ion [32,148]:



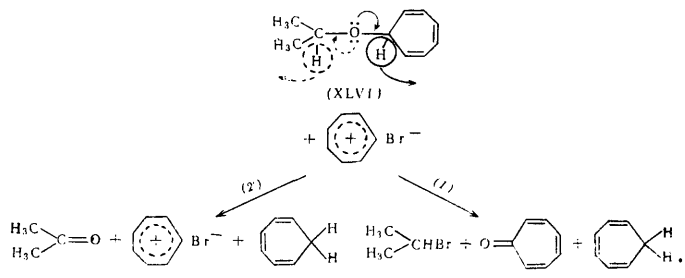
where $R_1 = R_2 = R_3 = C_2H_5$ and $R_1 = H$, $R_2 = CH_3$, and $R_3 = C_2H_5$.

where $R = C_2H_5$ and C_6H_5.

The study of the dissociation of the P–H bond under the action of the tropylium ion proved to be particularly interesting. Examples of both homolytic [149] dissociation of the P–H bond and ionic dissociation with the removal of a proton were known earlier [150]. Recently it has been shown that phosphorous acid, potassium phosphite, and barium hypophosphite in aqueous solution reduce the tropylium ion with formation of cycloheptatriene [10]:

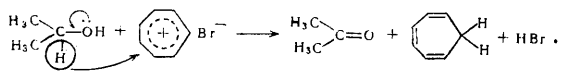


Thus it has now been demonstrated that heterolysis of an E–H bond with removal of a hydride ion under the action of the tropylium ion is in principle possible for elements of Groups I, III, IV, and V:



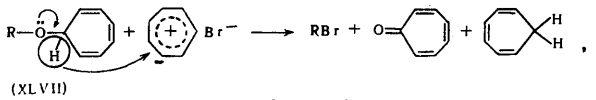
Systematic study of the interaction of the tropylium ion with alcohols has shown that the ion reacts with primary, secondary, and tertiary alcohols [151]. In the reaction with primary and tertiary aliphatic alcohols the first step is the formation of the hydroxonium compound (XLIV), which readily loses a proton with formation of the alkyl tropyl ether (XLV). The alkyl tropyl ether interacts with a second molecule of the tropylium salt. The tropylium ion then removes a hydride ion from the cycloheptatriene ring with formation of cycloheptatriene, tropone, and the alkyl halide:

(XLIV) (XLV)



In the reaction with a secondary aliphatic alcohol, in particular isopropyl alcohol, acetone forms in addition to cycloheptatriene, tropone, and isopropyl bromide. The formation of acetone can be explained by the fact that in the reaction of the intermediate isopropyl tropyl ether (XLVI) with the tropylium ion a hydride ion may be removed not only from the cycloheptatriene ring (1) but also from the isopropyl group (2):

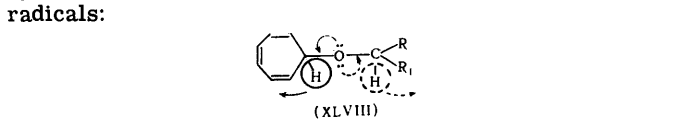
(XLVI)



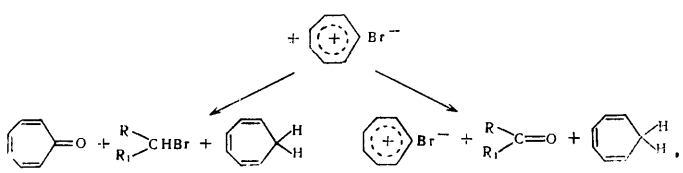
The authors showed that in the reaction between isopropyl ether and tropylium bromide a hydride ion is indeed removed both from the isopropyl group and from the cycloheptatrienyl ring. However, one cannot exclude the possibility of the direct removal of the hydride ion by the tropylium ion from the isopropyl alcohol molecule:

The occurrence of this process in the overall reaction can also be expected on the basis of the relatively large hydride mobility of the hydrogen atom in the CH group of isopropyl alcohol[152-156]. Similar considerations can also be used to explain the reaction between benzyl alcohol and the tropylium ion[32], as a result of which tropone is formed together with benzaldehyde and cycloheptatriene.

The high hydride mobility in alkyl tropyl ethers was suggested by the authors by analogy with the high hydride mobility of the hydrogen atom in ditropyl ether. Ter Borg and coworkers[157] and Nozoe and coworkers[158] showed that ditropyl ether is capable of interacting with the tropylium ion to form cycloheptatriene and tropone, catalytic amounts of the tropylium ion being sufficient for the reaction to occur[159].



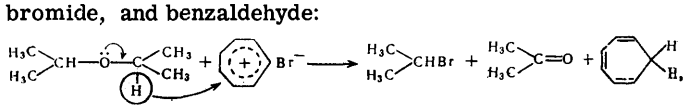
Alkyl tropyl ethers also react with the tropylium ion. In the reaction of methyl tropyl, n-propyl tropyl, and t-butyl tropyl ethers (XLVII) with the tropylium ion cycloheptatriene, tropone, and alkyl halides are formed. This is consistent with the hypothesis of the removal of a hydride ion from the seven-membered ring:

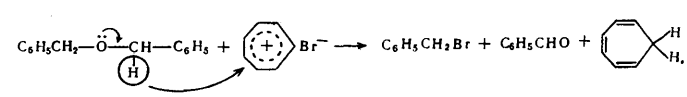


(XLVII)

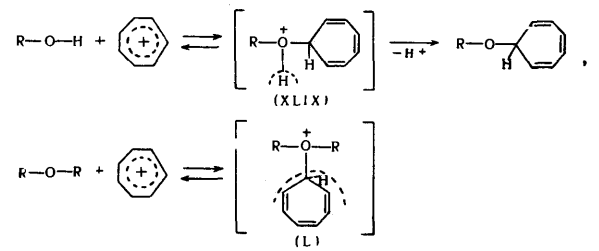
where R = CH_3, n-C_3H_7, and t-C_4H_9.

The reaction of isopropyl tropyl and benzyl tropyl ethers (XLVIII) with the tropylium ion results in the formation of acetone and benzaldehyde in addition to cycloheptatriene, tropone, and isopropyl and benzyl bromides. Thus in these processes a hydride ion is removed both from the cycloheptatriene ring and from the isopropyl and benzyl radicals:



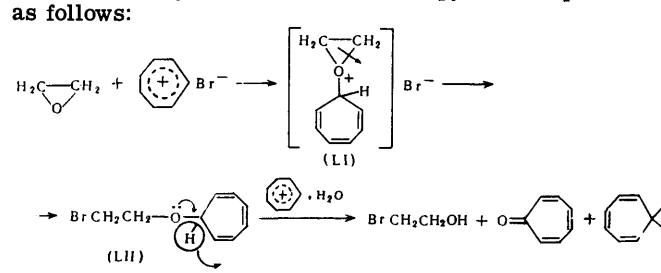


(XLVIII)



where R = R_1 = CH_3 and R = H and R_1 = C_6H_5.

In the study of the interaction of the tropylium ion with ethers the same workers found that bisprimary aliphatic ethers are incapable of interacting with the tropylium ion[160]. Di-isopropyl and dibenzyl ethers do react with the tropylium ion. A hydride ion is then removed directly from the ether molecule. The reaction with di-isopropyl ether yields cycloheptatriene, isopropyl bromide, and acetone and that with dibenzyl ether yields cycloheptatriene, benzyl bromide, and benzaldehyde:

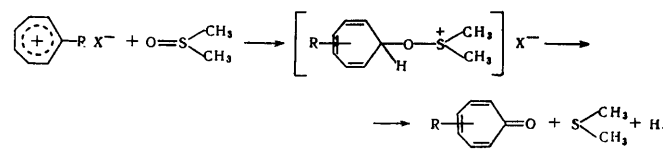


Thus the mechanism of the interaction between the tropylium ion and ether is different from that of its interaction with alcohols. The explanation is probably that in the interaction between alcohols and the tropylium ion hydroxonium compounds (XLIX) are formed, which, on losing a proton, are converted into alkyl tropyl ethers. In their reaction with the tropylium ion ethers can form the oxonium salts (L), which on decomposition most readily split off the tropylium ion, as the most stable carbonium ion, the initial ether being regenerated:

(XLIX)

(L)

However, the same workers found an example of the reaction[161] in which the ether interacts with the tropylium ion with the intermediate formation of an alkyl tropyl ether. The ether involved in this process is ethylene oxide. The reaction of ethylene oxide with the tropylium ion proceeds as follows:



(LI)

(LII)

The C–O bond in the intermediate oxonium compound (LI) readily dissociates as a result of the high strain in the three-membered ring. The β-bromoethyl tropyl ether (LII) was isolated and identified and it was shown that cycloheptatriene, tropone, and ethylene bromohydrin are formed in its reaction with tropylium bromide.

In conclusion one more reaction, which we believe to be of interest, should be mentioned. Kitahara and Funamizu found[162] that tropone is formed in the reaction between the tropylium ion and dimethyl sulphoxide:

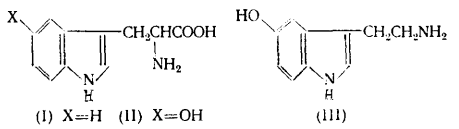
SYNTHESIS OF SUBSTITUTED INDOLES VIA INDOLINES

M. N. Preobrazhenskaya

CONTENTS

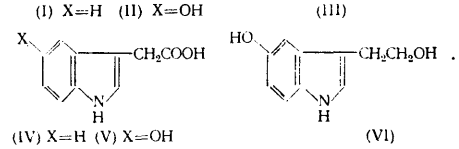
I. Introduction 753

II. Methods of preparation of indolines 754



III. Introduction of substituents into the benzene ring of the indoline molecule 758

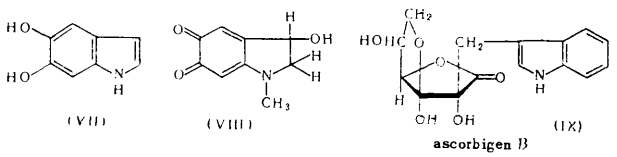
IV. Introduction of substituents into the pyrrole ring of the indoline molecule 763



V. Conversion of indoline derivatives into indoles 764

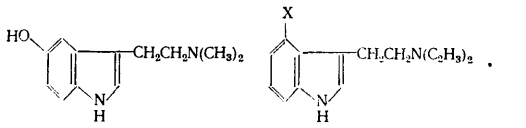
I. INTRODUCTION

Indole derivatives play an important role in vital processes [1,2]. Of special importance are the essential amino-acid tryptophan (I) and the products of its metabolism, for example, 5-hydroxytryptophan (II), serotonin (III), 3-indolylacetic (IV) and 5-hydroxy-3-indolylacetic (V) acids, 5-hydroxytryptophol (VI) and a number of other substances:



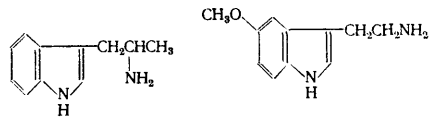
(I) X=H (II) X=OH (III)

(IV) X=H (V) X=OH (VI)



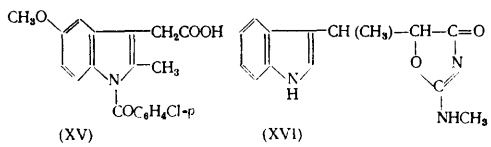
The structure of 5,6-dihydroxyindole (VII) is the basis of the animal pigment melanin [3]. The processes involved in the biosynthesis of melanin are closely related to the metabolism of aminocatechols, including adrenalin and tyrosine. One of the products of adrenalin metabolism is adrenochrome (VIII) [4]. It has been shown recently [5] that ascorbic acid in plants exists in a bound form as two diastereoisomeric ascorbigens A and B (IX):

(VII) (VIII) (IX)



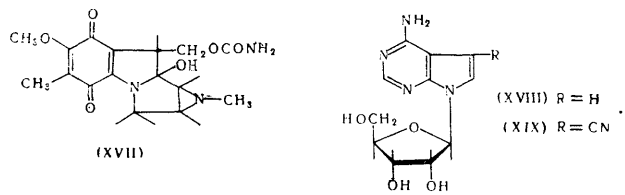
ascorbigen B

Many compounds containing the indole ring exhibit high pharmacological activity. It is sufficient to recall reserpine and other Rauwolfia alkaloids, lysergic acid, brucine, yohimbine, eserine, and other alkaloids, and also halucinogenic compounds such as bufotenin (X) (a component of frog venom), psilocin (XI), psilocybin (XII), and others [1].



(X) (XI) X=OH (XII) X=OPO_3H_2

The synthetic research on pharmacologically active compounds in the indole series has proved extremely fruitful. In particular, valuable medicinal substances have been found—indopane [6] (3-indolylisopropylamine) (XIII), used as a stimulating antidepressant in psychiatry and mexamine (5-methoxytryptamine) (XIV) [7], used in the prophylaxis of radiation damage:

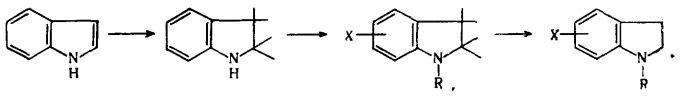


(XIII) (XIV)

Considerable interest was aroused by the discovery of indole derivatives with high anti-inflammatory activity, among which the most important is indomethacin—1-(*p*-chlorobenzoyl)-5-methoxy-2-methylindole-3-acetic acid (XV) [8]:

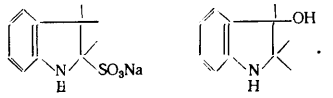
(XV) (XVI)

Until recently indole derivatives with high antimicrobial activity were unknown. However, the first communication dealing with the antibiotic indolmycin (XVI), which inhibits the development of strains of *Staphylococcus aureus*, a micro-organism resistant to the most widely used antibiotics, appeared in 1961. [9,10] Vigorous studies are being made on the synthesis of the antibiotic mitomycin (XVII) and related compounds which exhibit high cytostatic, bacteriostatic, and fungicidal activity [11,12]:



(XVII) (XVIII) R = H (XIX) R = CN

The reports of the discovery of a new group of antibiotics, tubercidin (XVIII) and toyokamycin (XIX) [13], are extremely interesting. These compounds are based on the 5,7-diazaindole (pyrimidinopyrrole) structure.



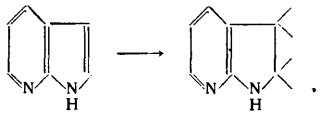
The structure of many indole compounds is based on tryptophan, indole-3-acetic acid, or tryptamine (3-indolylethylamine). In this connection methods of synthesising the side-chain in position 3 of the indole ring have been developed in special detail. The method of introducing substituents in position 1 have been investigated much less,

although many 1-substituted indoles are of great interest—for example, indomethacin (XV), tubercidin (XVIII), and others. The reason for the difficulty of introducing substituents in position 1 of the indole system is that the NH group exhibits acid rather than basic properties, as a result of which direct *N*-alkylation or *N*-acylation of indole frequently cannot be achieved. Mercury or silver salts (with one organic anion) of the type N–M, which are widely used for synthetic purposes, for example in the purine series, have not been described for indoles. Magnesium, sodium, and lithium derivatives of indole usually react with the formation of C_2 or C_3 derivatives. Serious difficulties are also encountered in attempts to introduce substituents into the benzene ring of the indole system. Under the conditions of an electrophilic substitution reaction, most indole derivatives decompose or react in different ways simultaneously. The classical methods of synthesis (the Fischer, Reissert, and other syntheses), in which the molecule is synthesised from components already containing definite substituents, frequently prove cumbersome or altogether inapplicable to indoles with substituents in the benzene ring.

A method based on temporary exclusion of the pyrrole ring has been proposed for the introduction of substituents into the indole ring[14–16]. Indole is converted into 2,3-dihydroindole (indoline), which is an aromatic amine and can be made to undergo various electrophilic reactions with formation of indoline derivatives substituted both in the benzene ring and at the nitrogen atom. Dehydrogenation of these derivatives yields the substituted indole. Thus instead of using unstable, readily decomposed, and difficult to isolate indole derivatives, the experiments are performed with indolines, which are aliphatic-aromatic amines:

Instead of dihydroindole, one can use in this reaction also the unstable adduct of indole and sodium bisulphite, the sodium salt of indoline-2-sulphonic acid (XX), which also exhibits the properties of an aromatic amine[17]. Conversion into indole derivatives is achieved by treatment with alkali:

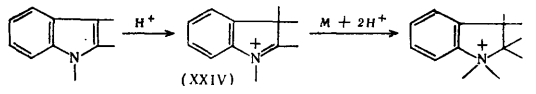
(XX) (XXI)



In many cases indolines cannot be obtained from the corresponding indole derivatives and they are synthesised in other ways. This applies, for example, to 2,3-dihydro-3-hydroxyindole, 3-indolinol (XXI), which is readily substituted and forms indole derivatives on dehydration[18]. In this connection, intensive studies have been made in recent years on the methods of synthesis of various indoline derivatives from hydroxyindoles, isatins, and various aromatic compounds.

This review deals with the methods of synthesis of indolines, the substitution reactions in the indoline series, and methods of conversion into the corresponding substituted indoles.

II. METHODS OF PREPARATION OF INDOLINES†

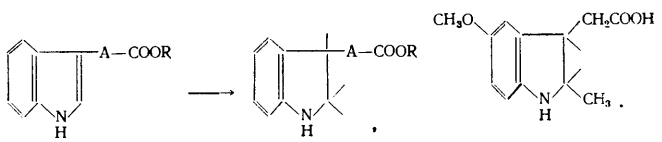


1. Preparation of Indolines by the Reduction of the Corresponding Indoles

The most convenient method for the preparation of indoline is hydrogenation of indole over Raney nickel at 80–100 atm and 75–150°C in an alcoholic or dioxan solution[19]. Further temperature rise leads to the formation of octahydroindole; in alcoholic solution the process is accompanied by *N*-alkylation[20,21]. The method is suitable for the preparation of substituted indolines[22,23]. A series of indolines were obtained by hydrogenation over copper chromite at 250–300 atm and 170–190°C.[24–26] The hydrogenation of indole derivatives over PtO_2 in an alcohol–HBF_4 mixture at 1 atm and room temperature has also been described[27]. The hydrogenation of pyridinopyrrole, 7-azaindole (XXII), to the 2,3-dihydro-derivative (XXIII) is carried out over a nickel catalyst at 200°C and 100 atm. An increase of temperature results in cleavage of the pyrrole ring[28,29]:

(XXII) (XXIII)

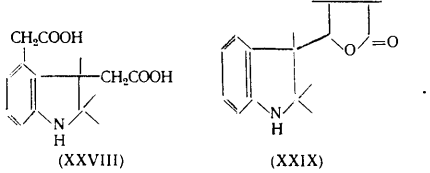
1-, 2-, or 3-alkylindoles can be reduced to the corresponding dihydro-derivatives under the action of zinc or tin in hydrochloric acid[30–35]. The ease of reduction of indoles to 2,3-dihydro-derivatives in an acid medium, associated with the formation of the indolenine structure (XXIV) as a result of the protonation of indoles in position 3, is striking[36,37].



(XXIV)

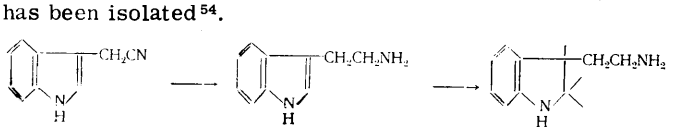
However, in the reduction of unsubstituted indole in hydrochloric acid it is impossible to isolate indoline, because dimerisation and trimerisation products form under these conditions. In the reduction of indole with zinc in 85% phosphoric acid at 70–80°C in a stream of nitrogen it is possible to avoid the polymerisation of indole and to obtain indoline in 64–69% yield[38]. 2,3-Dimethylindole, 1,2,3,4-tetrahydrocarbazole, and its *N*-methyl derivatives have been synthesised under the same conditions. It has been shown that in the reduction of 2,3-dimethylindole with tin in hydrochloric acid the *cis*- and *trans*-isomers‡ are formed in proportions of 3 : 2,[25] and in the reduction with zinc in 85% phosphoric acid the proportions are 65 : 35.[38] In hydrogenation over copper chromite only the *trans*-isomer is formed[25]. In many cases it is possible to reduce the 1-substituted indoles to indolines under the action of lithium aluminium hydride in tetrahydrofuran[40,41]. Electrochemical reduction of indole[42] and reduction of indole with diborane[43] have been described.

† The synthesis and properties of 2,2- or 3,3-disubstituted indolines, which cannot be converted into the corresponding indoles without the rupture of a C–C bond, will not be considered.



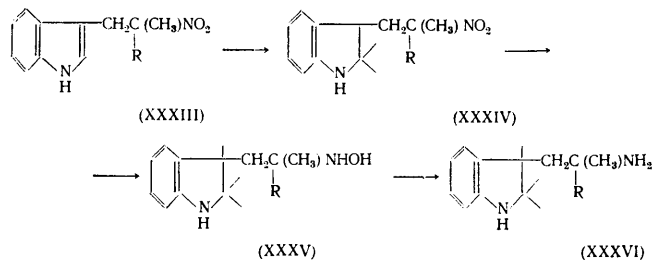
‡ Studies on the *cis-trans*-isomers of 2,3-dimethylindoline have been described by Anet and Muchowski[39].

It is of very great interest to carry out the conversion indole → indoline → substituted indoline → substituted indole using compounds containing the $CH_2CH_2NR_2$ or $(CH_2)_nCOOH$ residue in position 3 of the indole ring. Such conversions have been achieved for indole-3-alkanoic acids[44,45]. 2,3-Dihydroindole-3-propionic (XXVI, A = CH_2CH_2) acid was obtained by dehydrogenation of a salt of indole-3-propionic acid (XXV, A = CH_2CH_2) over Raney nickel at room temperature and 250 atm.[14] Esters of 2,3-dihydroindole-3-propionic [and -3-butyric? (Ed. of Translation)] acids (XXVI, A = CH_2CH_2 or CH_2CHCH_3) have also been obtained under these conditions[46]. The potassium salt of indole-3-acetic acid (XXV, A = CH_2) has been hydrogenated over Raney nickel at 100°C and 70 atm in order to obtain the dihydro-derivative[44]. 5-Methoxy-2-methylindole-3-acetic acid (XXVII), the starting material for the synthesis of indomethacin (XV), has been obtained under the same conditions[47]:



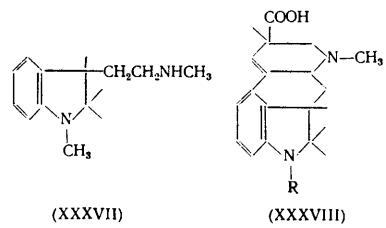
(XXV) (XXVI) (XXVII)

The disodium salt of indole-3,4-diacetic acid has been hydrogenated over Raney nickel at 80°C and 100 atm and the corresponding indoline diacid (XXVIII) has been obtained[48]:



(XXVIII) (XXIX)

The conversion of esters of indole-3-alkanoic acids into the 2,3-dihydro-derivatives by hydrogenation over platinum oxide at the normal pressure and room temperature has been described[49,50]. The ester of 5-methoxy-2-methylindoline-3-acetic acid (XXVII) has been obtained under the action of tin in hydrochloric acid[51]. There is no information about the reduction of amino- and hydroxy-acids of the indole series, with the exception of the reduction of γ-(indol-3-yl)-γ-oxobutyric acid into indolinylbutyrolactone (XXIX)[52]. The data on 2,3-dihydro-5-hydroxytryptophan as well as the information on 2,3-dihydro-5-hydroxytryptamine (dihydroserotonin) appears to be unreliable[53]. The reduction of tryptamines to 2,3-dihydrotryptamines has been almost not investigated. Tryptamine (XXXI) forms in the hydrogenation of indole-3-acetonitrile (XXX) over Raney nickel at room temperature and 90 atm, an increase of temperature to 100°C resulting in partial conversion of tryptamine into dihydrotryptamine (XXXII), whose dipicrate has been isolated[54].

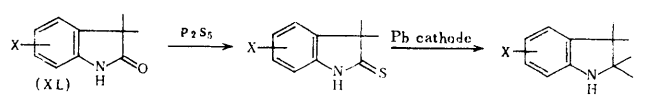


(XXX) (XXXI) (XXXII)

In the hydrogenation of 3-nitroisopropylindole (XXXIII, R = H) over PtO_2 in alcoholic hydrochloric acid it proved possible to obtain the dihydro-derivatives (XXXIV, R = H) and (XXXV, R = H) and on further hydrogenation 3-amino-isopropyl-2,3-dihydroindole (XXXVI, R = H)[55]:

(XXXIII) (XXXIV) (XXXV) (XXXVI)

3-Nitroisobutylindoline (XXXIV, R = CH_3) has been obtained similarly from 3-nitroisobutylindole (XXXIII, R = CH_3). Octahydroindole derivatives are formed together with these substances[55]. The pyrrole ring is reduced more readily than the nitro-group as a result of the easier reduction of the corresponding indolenine structure formed in an acid medium. The introduction of a methyl group into the pyrrole ring of the tryptamine molecule facilitates, as for indolealkanoic acids, the reduction of the double bond in the pyrrole ring. *NN'*-dimethyltryptamine can be converted into the dihydro-derivative (XXXVII) by zinc in hydrochloric acid[56]:

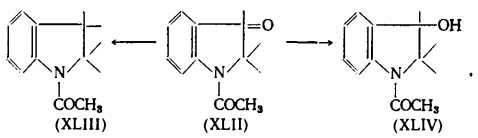


(XXXVII) (XXXVIII)

The conversion of lysergic acid derivatives into dihydrolysergic acid derivatives (XXXVIII) has been achieved similarly[57].

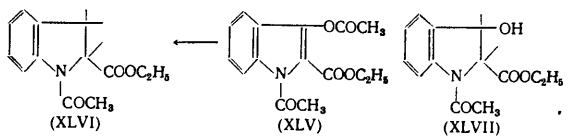
2. Syntheses of Indoline Derivatives Based on Isatins, Indoxyls, and Hydroxyindoles

The direct electrolytic reduction of isatin and hydroxyindole into indoline has been described[58]. It is more convenient to obtain indoline (XXXIX) from hydroxyindoles (XL) via mercaptoindoles (XLI)[59,60]:



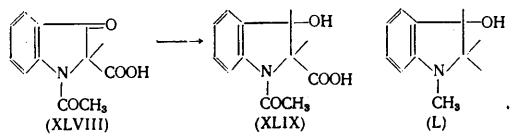
(XL)

where X = H, 4-CH_3O, and 6-CH_3O.



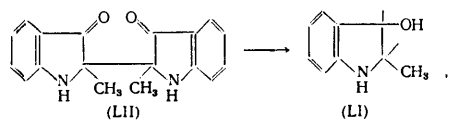
A mixture of indoles and indolines (with the indoles predominating) is usually formed in the reduction of *N*-substituted hydroxyindoles with lithium aluminium hydride[40,61-65]. The hydroxyindole unsubstituted at the nitrogen atom cannot be converted either into indole or indoline by the action of lithium aluminium hydride[40]. The formation of a certain amount of 1-alkylindolines in the reduction of 1-alkylhydroxyindoles with lithium aluminium hydride can probably be accounted for by further reduction of the 1-alkylindoles formed. The reduction of hydroxyindole derivatives with diborane leads to a mixture of the corresponding indoles and indolines[43], but this reaction does not appear to be of preparative value.

Depending on the reaction conditions, 1-acetylindoline (XLIII) or 1-acetyl-3-hydroxyindoline (XLIV) are formed in the catalytic reduction of 1-acetylindoxyl (XLII)[66,67]:



(XLIII) (XLII) (XLIV)

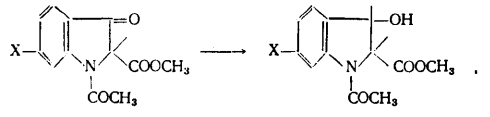
The hydrogenation of *ON*-diacetylindoxyl at 100 atm and 90°C over a nickel catalyst results in the formation of 1-acetylindoline in 90% yield, and from the reaction performed under milder conditions it is possible to isolate 1-acetyl-3-hydroxyindoline (10% yield). In the hydrogenation of 3-acetoxy-1-acetyl-2-ethoxycarbonyl indole (XLV) over Raney nickel at 85 atm and 110°C the product was an ester of 1-acetylindoline-2-carboxylic acid (XLVI) and at 60 atm and 60°C an ester of 1-acetyl-3-hydroxyindoline-2-carboxylic acid (XLVII)[68]:



(XLVI) (XLV) (XLVII)

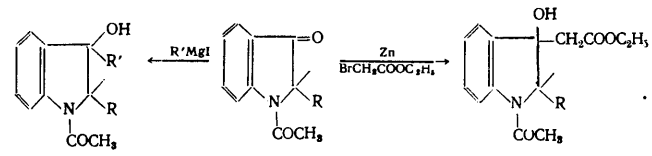
It proved possible to achieve the same reaction in the hydrogenation of an ester of 1-acetylindoxyl-2-carboxylic acid (XLVIII) over nickel chromite at room temperature and a lower pressure[68]:

(XLVIII) (XLIX) (L)



The most convenient method for the preparation of 3-hydroxyindoline is the reduction of isatin with lithium aluminium hydride (yields of 21%[70] and 14%[18]). 3-Hydroxy-1-methylindoline cannot be obtained by the reduction of 1-methylisatin. 3-Hydroxy-1-methylindoline (L) has been obtained by the methylation of 3-hydroxyindoline[71]. In the reduction of dihydroxyindole 3-hydroxyindoline is formed in 15% yield and in the reduction of indoxyl in 5% yield[72]. 3-Hydroxy-2-methylindoline (LI) has been obtained in good yield by the reduction of 2,2′-dimethyl-2,2′-di-indoxyl (LII) with $NaBH_4$ in methanol[73]:

(LII) (LI)

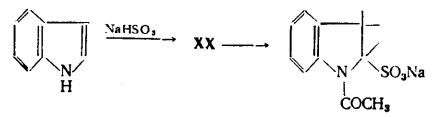


Analysis of the NMR spectrum showed that compound (LI) is a mixture of the *cis*- and *trans*-isomers in proportions of 1:4.[73]

Another example of the conversion of indoxyl derivatives (LIII) into 3-hydroxyindoline derivatives (LIV) with the aid of metal borohydrides has been described[74]:

(LIII) (LIV)

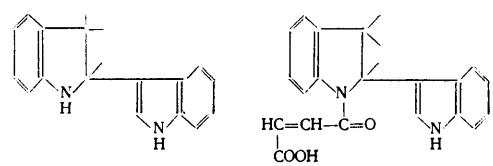
Hydroxyindoline derivatives (LVI) and (LV) have also been obtained from 1-acetyl-2-alkylindoxyls (LVII) by the Grignard and Reformatskii reactions[75]:



(LVI) (LVII) (LV)

In the synthesis of various indole derivatives from indoxyl, compounds whose structure is based on 3-hydroxyindoline (see, for example, Nenitzescu and Dan Raileanu[76]) are often formed as intermediates. Here only those cases are considered where these compounds have been isolated and identified.

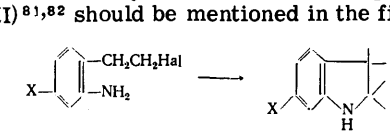
3. Adducts of Indoles and Sodium Bisulphite and Indole Dimers



The "exclusion of the pyrrole ring" of indole can also be achieved by the conversion of indole into the sodium salt of indoline-2-sulphonic acid (XX)[17,77]:

(LVIII)

The product of the acetylation of a salt of indoline-2-sulphonic acid (LVIII) is used in electrophilic substitution reactions. The advantage of this method is the ease of preparation of the adduct (the yields are quantitative) and the ease of reconversion into indole derivatives. However, the instability of the reaction products and the impossibility of purifying and identifying the intermediates greatly reduce the value of this method.

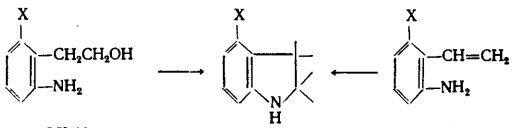


Indole dimers, which have the structure of indolinylindoles (LIX)[78,79] and the adduct of indole and maleic anhydride (LX)[80] should also be mentioned.

(LIX) (LX)

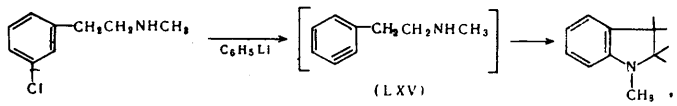
4. Synthesis of Indolines by the Closure of the Pyrroline Ring

The studies on the cyclisation of *o*-aminophenylethyl halides (LXI)[81,82] should be mentioned in the first place:



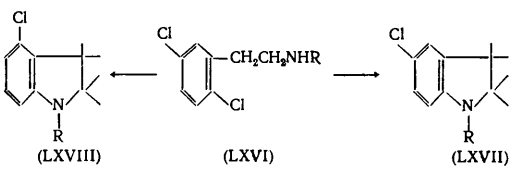
(LXI) (LXII)

where X = H, $RHNSO_2$.



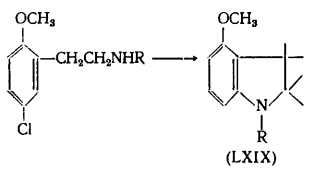
The mechanism of this reaction has not been investigated. The method has been used to prepare indoline-6-sulphonamides (LXII, X = $RHNSO_2$)[83,84]. It is particularly

valuable, since direct sulphonyl chlorination of indolines leads to 5-derivatives (see Section III). The cyclisation is achieved under the action of aqueous alkali. Indoline and its derivatives have also been obtained from *o*-aminostyrene (LXIII)[85] or *o*-aminophenylethanol (LXIV)[65,86,87]:



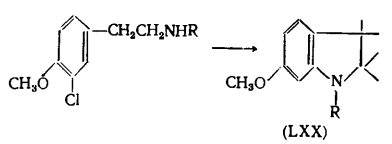
(LXIV) (LXIII)

Indolines are formed when halogeno-derivatives of β-phenylethylamine are acted upon by reagents such as C_6H_5Li, $(C_2H_5)_2NLi$, $NaNH_2$, and others. The intermediate aryne structure (LXV) is formed, this being followed by intramolecular nucleophilic addition to the triple bond of the dehydrobenzene ring[65,88,89].



(LXV)

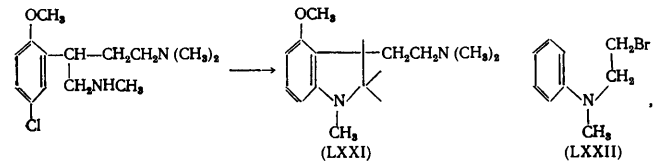
A halogen in a position *meta* to the side-chain forms the aryne more readily than the halogen in the *ortho*-position, which leads to higher yields of indolines when *meta*-derivatives are used. However, it proved possible to obtain 1-methylindoline from β-(*o*-chlorobenzyl)ethylmethylamine in 50% yield[90]. When the benzene ring contains halogens in positions *ortho* and *meta* to the side-chain (LXVI), a mixture of 4- and 5-halogeno-derivatives (LXVIII) and (LXVII) is formed, 4-chloroindoline (the product of the cyclisation of *m*-chlorophenylethylamine) (LXVIII) predominating considerably:



(LXVIII) (LXVI) (LXVII)

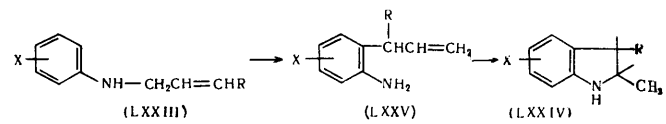
This method has been used to prepare 4-methoxyindolines (LXIX) and 6-methoxyindolines (LXX)[91]:

(LXIX)



where R = H, CH_3, and $CH_2C_6H_5$;

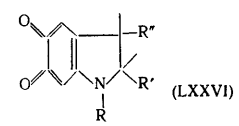
(LXX)



where R = H, CH_3, and C_2H_5.

4- and 6-methoxyindolines have been converted into 4- and 6-hydroxyindolines. 3-(β-Dimethylaminoethyl)-4-methoxy-1-methyl-2,3-dihydroindoline (LXXI) has also been obtained[91]:

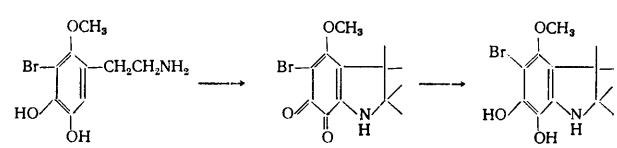
(LXXI) (LXXII)



1-Methylindoline has been isolated after the reaction between aluminium chloride and (β-bromoethyl)methylaniline (LXXII)[92]. 2-Methylindolines (LXXIV) are formed (together with small amounts of 2-methylindoles) when *N*-allylanilines (LXXIII) are cyclised under the action of acid reagents[25,93]:

(LXXIII) (LXXV) (LXXIV)

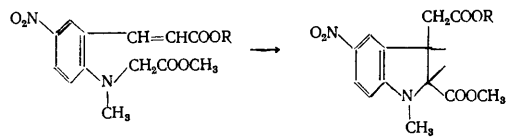
where R = H and CH_3 and X = H, 7-CH_3, 5-CH_3, and 5-F. *o*-Allylaniline (LXXV) is an intermediate in this reaction[25].



The possibility of obtaining indoline systems by the oxidation of aminocatechols should be recalled. Adrenochrome (VIII), which was isolated after adrenalin had been subjected to the action of catechol oxidase, silver oxide, and other agents[94], has already been mentioned. Aminochromes (LXXVI), analogues and derivatives of adrenochromes, have also been prepared:

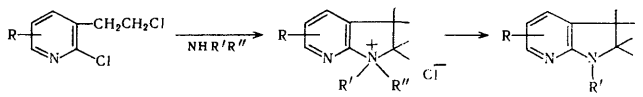
(LXXVI)

Among the ether derivatives of adrenalin, the aminochromes (LXXVI, R = CH_3, R′ = H, R″ = alkoxy-group) have been obtained[95].



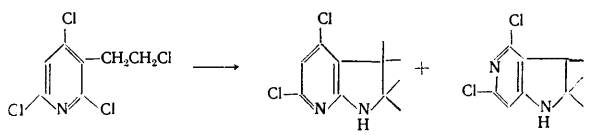
Adrenalin analogues have been prepared from 3-hydroxyindolinequinones (LXXVI, R = R′ = alkyl residues and R″ = OH)[96]. By oxidising dihydroxyphenylalanine derivatives, indolinequinonecarboxylic acids (LXXVI, R = CH_3, C_2H_5, etc., R′ = COOH, and R″ = H) were synthesised[96]. Among the phenylethylamine derivatives, the indolinequinones (LXXVI, R = CH_3, C_2H_5, etc. and R′ = R″ = H) were prepared[96]. Other compounds synthesised are aminochromes, which are indoline-6,7-*o*-quinones (LXXVII), some of which have been used in the synthesis of polyhydroxylated indolines (LXXVIII)[97]:

(LXXVII) (LXXVIII)



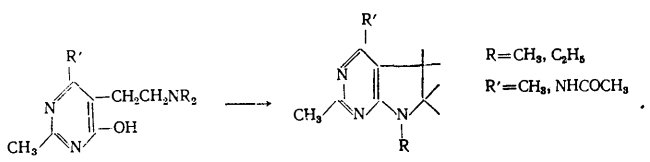
It has been shown that the action of potassiun iodate and other halogen-containing oxidising agents on adrenalin and its analogues leads to the preparation of 7-halogeno-derivatives of adrenochrome[98-100]. Adrenochrome derivatives have been used as the starting materials in the synthesis of certain indole systems.

It proved possible to close the indoline ring (LXXIX) by cyclisation under the conditions of the Michael reaction[101]:



(LXXIX)

In recent years an increasing number of studies have been devoted to the methods of synthesis of pyridino- or pyrimidino-pyrroles (aza- or diaza-indolines)§. These investigations were stimulated by the discovery of the high biological activity of the aza-analogues of nucleosides and nucleotides and the discovery of new antibiotics of the type of tubercidin and toyokamycin. An especially large number of studies are concerned with the development of methods of synthesis of pyridinopyrrolines (azaindolines). It has been established that, when 3-(β-chloroethyl)pyridines containing halogen atoms in positions 2 or 4 (LXXX) are condensed at a high temperature with ammonia and primary or secondary amines, indolines (LXXXI) are formed. Using various chloropyridines and amines, it proved possible to prepare by this method more than 30 substituted 7- and 5-azaindolines[102-114]. The first stage of the reaction[105,109] is the replacement of the aromatic chlorine by the NH_2 residue, this being followed by the formation of the quaternary salt (LXXXII) and the removal of an alkyl halide:

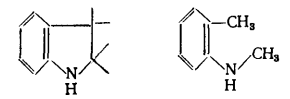


(LXXX) (LXXXII) (LXXXI)

The reaction of 2,4,6-trichloro-3-(β-chloroethyl)pyridine (LXXXIII) with amines takes place with the formation of a mixture of 5- and 7-azaindolines, (LXXXIV) and (LXXXV) respectively, in proportions of 34.6 : 42.2.[109,112] 5- and 7-indolines were obtained by the dechlorination of these compounds.

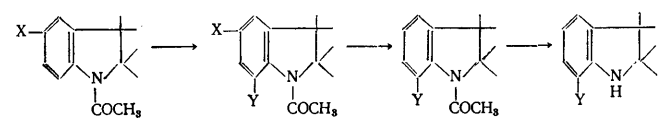
(LXXXIII) (LXXXV) (LXXXIV)

The formation of pyrimidinopyrrolines (5,7-diazaindolines) (LXXXVI) by the action of phosphorus pentachloride and then alkali on pyrimidines containing β-dialkylamino- and hydroxy-groups in the *ortho*-position (LXXXVII) has been described[115,116]:



(LXXXVII) (LXXXVI)

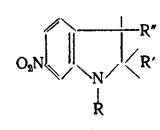
§ The present review deals only with pyridino- and pyrimidino-pyrroles and -pyrrolines, which can be regarded as 4-, 5-, 6-, or 7-aza-analogues of indole or indoline.



III. INTRODUCTION OF SUBSTITUENTS INTO THE BENZENE RING OF THE INDOLINE MOLECULE

The behaviour of indolines in electrophilic substitution reactions has been investigated with the aim of introducing substituents into the benzene ring of the indoline molecule. The question of the site of substitution in these reactions could not be solved by analogy between indoline (LXXXVIII) and *N*-methyl-*o*-toluidine (LXXXIX):

(LXXXVIII) (LXXXIX)

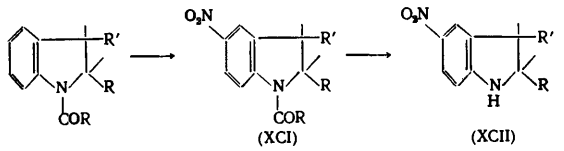


It has been established that these compounds and their *N*-acyl and *N*-alkyl derivatives behave in different ways in electrophilic substitution reactions[117]. The different behaviour of these systems was accounted for by the fact that in *NN*-disubstituted *o*-toluidine the CH_3 and NR_2 groups cannot lie in the plane of the benzene ring due to steric hindrance[117]. This leads to weakening of the conjugation between the NR_2 group and the benzene ring. In disubstituted *o*-toluidine electrophilic substitution takes place in the *para*-position with respect to the methyl group. As a result of the formation of the ring, the indoline molecule is coplanar and there is no weakening of the conjugation between the *p*-electrons of the nitrogen and the π-electrons of the benzene ring. Therefore electrophilic substitution takes place in the *para*-position with respect to the amino- (or acetamido-) group (i.e. position 5), since these groups have a more powerful directing effect. When reactions are carried out in a strongly acid medium, indoline is converted into the indolinium cation, as a result of which the substituents enter the *meta*-position with respect to the ammonium group, i.e. position 6. In the synthesis of 7-substituted indolines, position 5 is blocked by substituents which are readily eliminated and 1-acetylindoline is used as the starting material[118]:

The introduction of substituents into position 4 of the indoline ring, after protection of position 6, was not investigated.

1. Nitration, Nitrosation, and Azo-Coupling of Indolines

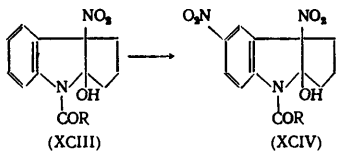
When indolines are nitrated with the nitrating mixture in sulphuric acid, the nitro-group enters into position 6. A number of 6-nitroindolines (XC) have been obtained in high yields[15,16,119-122]:



(XC)

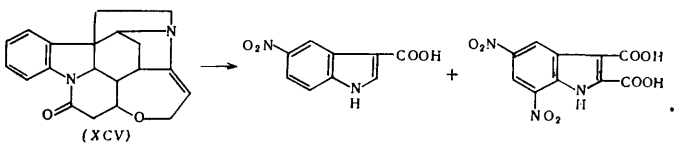
R=R′=R″=H R=R′=H; R″=CH_3.
R=CH_3; R′=R″=H. R=C_2H_5; R′, R″=$(CH_2)_4$.
R=R″=H; R′=CH_3. R=R′=CH_3; R″=H.

A 6-nitro derivative of 2,3-dimethyl-1,7-trimethyleneindoline, which is in all probability a mixture of *cis*- and *trans*-isomers, has also been obtained[123,124]. The nitration of



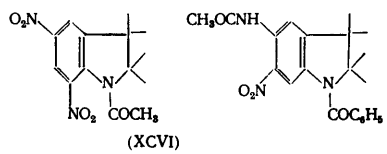
1-acylindolines gave a series of 1-acyl-5-nitroindolines (XCI), which were then converted into 5-nitroindolines (XCII)[16,44,45,119,125-127]:

(XCI) (XCII)



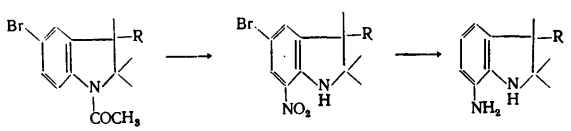
R=R'=H. R=CH_3; R'=H. R, R'=$(CH_2)_4$. R=H; R'=$(CH_2)_nCOOH$.

The nitration of *N*-acylindolines of complex structure (XCIII) has been described[128]:



(XCIII) (XCIV)

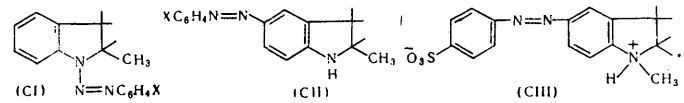
Strychnine (XCV), which is a complex acylindoline, is nitrated in position 2 which corresponds to position 5 in the indole ring (oxidation and hydrolysis take place simultaneously)[129]:



(XCV)

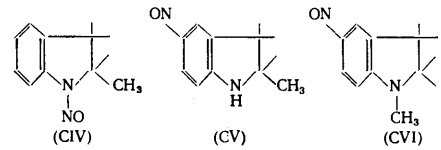
It is interesting to note that 5-nitro-derivatives are formed exclusively; the formation of 7-isomers has not been observed. However, after nitration of 1-acetylindoline, a certain amount of the 5,7-dinitro-derivative (XCVI) was isolated[119]. By further nitration of 1-acetyl-5-nitroindoline, the derivative was obtained in 42% yield[125]:

(XCVI) (XCVII)



The nitration of 5-acetamido-1-benzoylindoline gave probably the 6-nitro-derivative (XCVII), while the product of the nitration of 1-benzoyl-6-diacetamidoindoline was probably the 4-nitro-derivative. The structure of the products obtained was not proved[16]. 5-Bromo-7-nitroindolines (XCIX), the key substances in the synthesis of 7-aminoindolines (C) and indoles, have been synthesised by the action of nitric acid on 1-acetyl-5-bromoindolines (XCVIII)[44,45,118,126,130]:

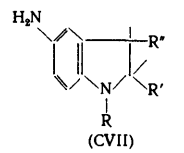
(XCVIII) (XCIX) (C)



where R = H, CH_2COOH, and CH_2CH_2COOH.

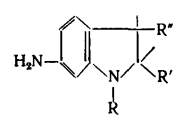
In contrast to 2,3-dihydroindoles, the *N*-acetylated adduct of indole with sodium bisulphite (LVIII) forms on nitration a mixture of 5- and 7-derivatives, which on treatment with alkali yield a readily separated mixture of 5- and 7-nitroindoles[17,77]. On azo-coupling with phenyldiazonium salts in the presence of sodium acetate, 2-methylindoline forms diazoamino-compounds (CI); in a strongly acid medium the products are the diazo compounds (CII)[31]:

(CI) (CII) (CIII)



On coupling with diazotised sulphanilic acid, 1-methylindoline also forms the azo-dye (CIII). It proved possible to isolate the sodium salt of the dye from a strongly alkaline medium[131]. The nitrosation of indoline and 2-methylindoline yields *N*-nitroso-derivatives[30,122,132]. 2-Methyl-1-nitrosoindoline (CIV) undergoes the Fischer–Hepp rearrangement with formation of 2-methyl-5-nitrosoindoline (CV). 1-Methyl-5-nitrosoindoline (CVI) was obtained in the reaction between butyl nitrite and 1-methylindoline[122].

(CIV) (CV) (CVI)

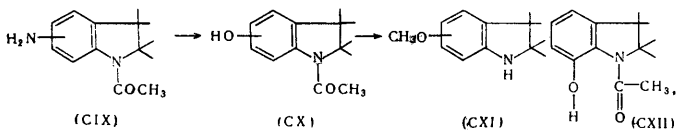


2. Aminoindolines

Aminoindolines have been investigated very thoroughly because, apart from their possible conversion into aminoindoles, they may serve as the starting materials for the preparation of alkoxy-, fluoro-, and other substituted indolines. Elimination of the nitro-group protecting position 5 or 6 also proceeds via the aminoindoline state. 5- and 6-aminoindolines, (CVII) and (CVIII) respectively, have been obtained by the reduction of the corresponding readily available nitroindolines[15,16,44,119,122,133-135]:

(CVII)

R=R'=R"=H;
R=R"=H; R'=CH_3;
R=COC_6H_5; R'=R"=H;
R=R'=H; R"=CH_2COOH.

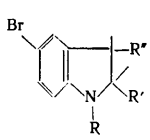


(CVIII)

R=R'=R"=H.
R=R'=H; R"=CH_3.
R=$COCH_3$; R'=R"=H.
R=R"=H; R'=CH_3.
R'=R"=H; R=CH_3.
R'=R"=H; R=COC_6H_5.

Hydrazine hydrate in the presence of Raney nickel[119] and also stannous chloride[15,133] have been used as the reducing agents. Nitroindolines have been hydrogenated over palladium on charcoal[134,135], over the Adams catalyst[16], and over Raney nickel[44]. Certain 5-aminoindolines have been obtained by the reduction of 5-nitroso- or 5-sulphophenylazo-derivatives[31,122]. This method of synthesis is particularly valuable for 5-amino-1-methylindoline, because a method of preparation of 1-methyl-5-nitroindoline has not been described[131]. When bromonitroindolines are

hydrogenated over palladium on charcoal, the bromine atom is eliminated and aminoindolines are produced. The method is suitable for the preparation of 7-aminoindolines.

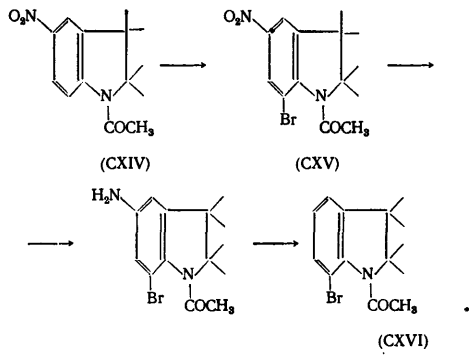


5-Bromo-1-methylindoline [131], 1-acetyl-7-iodoindoline[125], 1-acetyl-6-fluoroindoline [134], 1-acetyl-5-fluoroindoline [134], 1-acetyl-6-chloroindoline [134], and 1-acetyl-5-chloroindoline [134] have been obtained from the corresponding aminoindolines by the Sandmeyer reaction. The replacement of the amino-group by fluorine and chlorine takes place in high yields, the corresponding halogenoindolines being obtained on deacetylation. The conversion of 1-acetyl-5-amino-, 1-acetyl-6-amino-, and 1-acetyl-7-amino-indolines (CIX) into the corresponding hydroxy-derivatives (CX) (in yields of 77, 82, and 42% respectively) has been achieved [133,135]. 5-, 6-, and 7-methoxyindolines (CXI) have been obtained by the methylation of the hydroxy-group. The methylation yield is low in the case of 7-hydroxyindoline (CXII); the authors attribute this to the presence of a hydrogen bond in this compound [135].

(CIX) (CX) (CXI) (CXII)

3. Halogenation of Indolines

5-Bromo-derivatives (CXIII) are formed when indolines are brominated in acetic acid or in the bromination of 1-acetylindolines [44,45,118,119,126,127,131,136,137].

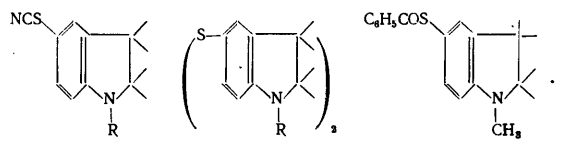


(CXIII)

R=R′=R″=H. R=COC$_6$H$_5$; R′=H; R″=CH$_2$COOH.
R=R″=H; R′=CH$_3$. R=H; R′, R″=(CH$_2$)$_4$.
R=CH$_3$; R′=R″=H. R=H; R′R″=(CH$_2$)$_3$.
R=H; R′=R″=CH$_3$.

The non-protonated indoline species appear to react in the bromination of indolines in a mixture of sulphuric and acetic acids. 6-Bromo-2,3-dimethylindoline has been obtained by the bromination of 2,3-dimethylindoline in a strongly acid medium [137]. The paper describing the synthesis was the first communication about the possibility of a direct synthesis of 6-bromoindolines. It was not stated whether the 5- and 6-bromo-2,3-dimethylindolines were pure substances or mixtures of *cis*- and *trans*-forms [137].

The bromination of the sodium salt of 1-acetylindoline-2-sulphonic acid (LVIII) followed by treatment with alkali gave 5-bromoindole in 70% yield [17,77]. When ICl is allowed to act on compound (LVIII), the 5-iodo-derivative is produced and from the latter 5-iodoindole can be obtained by the action of alkali [17,77]. 5-Iodoindoline has been obtained by the action of ICl on 1-acetylindoline with subsequent hydrolysis of the acetyl group [138]. The attempt to prepare 5-chloroindole by the action of chlorine on the adduct of indole and sodium bisulphite (LVIII) was unsuccessful [17,77]. Chloro- and fluoro-indolines have been obtained, as stated above, from the corresponding 1-acetamidoindolines [134]. The attempt to prepare fluoroindolines from bromoindolines was unsuccessful [134]. The 7-bromo-derivative (CXV) has been obtained by the bromination of 1-acetyl-5-nitroindoline (CXIV). The reduction of the nitro-group and the elimination of the amino-group gave 1-acetyl-7-bromoindoline (CXVI) [126]:

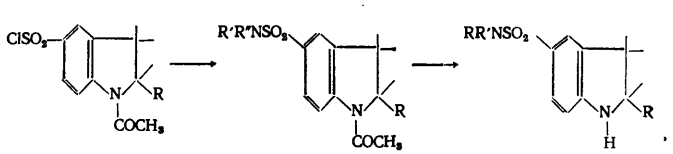


(CXIV) (CXV) (CXVI)

There are data indicating high physiological activity of 1-acyl-5-halogenoindolines [139].

4. Thiocyanato- and Mercapto-Derivatives of Indoline

5-Mercapto-derivatives of indoles and indolines, the thio-analogues of hydroxyindole derivatives which exhibit high pharmacological activity, have been investigated very little so far. 5-Thiocyanato-derivatives (CXVII), which are both of intrinsic interest and are important as key substances for the synthesis of 5-mercaptoindoline or 5-mercaptoindole derivatives, have been obtained by the thiocyanation of indoline derivatives [140]:



(CXVII, R=H, CH$_3$) (CXVIII, R=H, CH$_3$) (CXIX)

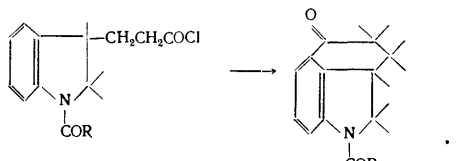
The treatment of 5-thiocyanatoindolines (CXVII) with alkali gave the corresponding disulphides (CXVIII) and the reduction of 1-methyl-5-thiocyanatoindoline with tin in hydrochloric acid led to 5-mercapto-1-methylindoline, which was isolated as the *S*-benzoyl derivative (CXIX) [140].

5. Chlorosulphonation of Indolines and Sulphonamides of the Indoline Series

By the chlorosulphonation of 1-acetylindoline, 1-acetylindoline-5-sulphonyl chlorides (CXX) were obtained, from which a number of indoline-5-sulphonamides (CXXI) [117,138, 141-143] and indoline-5-sulphonic acids were synthesised [117]:

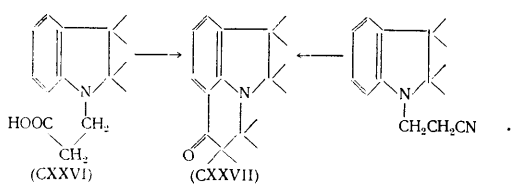
(CXX) (CXXI, R=H, CH$_3$)

As stated above, indoline-6-sulphonamides (LXII) have been obtained by the cyclisation of the indoline ring. The sulphoureides (CXXII) and (CXXIII) have been prepared



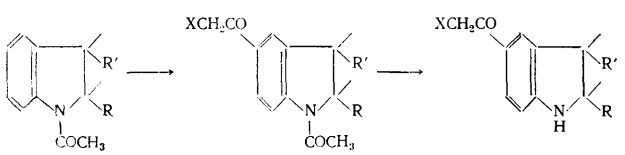
from indoline-5-sulphonamides and indoline-6-sulphonamides [141,143]:

(CXXII) (CXXIII)



6. Acylation and Alkylation of Indolines

Intramolecular *C*-acylation of derivatives of indolinealkanoic acids has been investigated in connection with studies on the synthesis of indole alkaloids. The first stage in the synthesis of lysergic acid consists in the conversion of 1-acylindoline-3-propionic acid into the acid chloride (CXXIV) which is cyclised under the conditions of the Friedel–Crafts reaction with the formation of the corresponding tricyclic derivative [14,144,145] (CXXV):

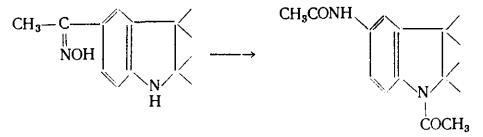


(CXXIV) (CXXV)

The intramolecular cyclisation of indoline-1-propionic acid (CXXVI) by heating with perfluoroacetic anhydride led to the corresponding tricyclic ketone (CXXVII) [146]. The same oxo-derivative (CXXVII) was obtained from *N*-(β-cyanoethyl)indoline (CXXVIII) [147]:

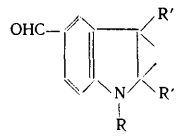
(CXXVI) (CXXVII)

The syntheses of alkyl *C*-indolyl ketones and especially methyl 5-indolyl ketone has been attracting attention in recent years in connection with the discovery of the pharmacological activity of 5-acetyltryptamine and its derivatives [148]. A series of 5-acetyl- and 5-chloroacetyl-indolines (CXXIX) have been obtained by the Friedel–Crafts acylation of 1-acetylindolines [149,150]:



(CXXIX)

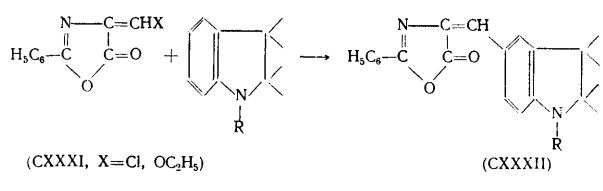
R=R′=H; X=H.
R=R′=H; X=Cl.
R=CH$_3$; R″=X=H.
R=CH$_3$; X=Cl; R′=H.
R, R′=(CH$_2$)$_4$; X=H.



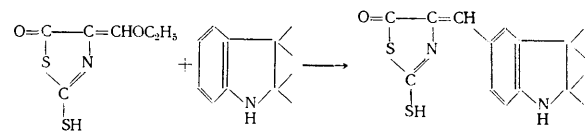
The acylation yields mainly the 5-derivative, but in the chloroacetylation of 1-acetylindoline 3% of a product, which was probably 1-acetyl-7-chloroacetylindoline, was isolated in addition to 83% of the 5-chloroacetyl derivative [149].

Acetamidoindolines have been obtained from the oximes of indolinyl ketones by the Beckmann reaction [149]. For example:

Clemmensen reduction of 5-acetyl- and 5-chloroacetylindolines gives 5-ethylindolines [149].



The Vilsmeier reaction has been used to prepare indoline-5-aldehydes. Indoline-5- and indole-5-aldehydes are of interest as key substances in the synthesis of various 5-analogues of tryptamine and tryptophan. A series of 1-alkyl-5-formylindolines (CXXX) have been obtained by the formylation of *N*-alkylindolines with methylformanilide and phosphorus oxychloride [151]:

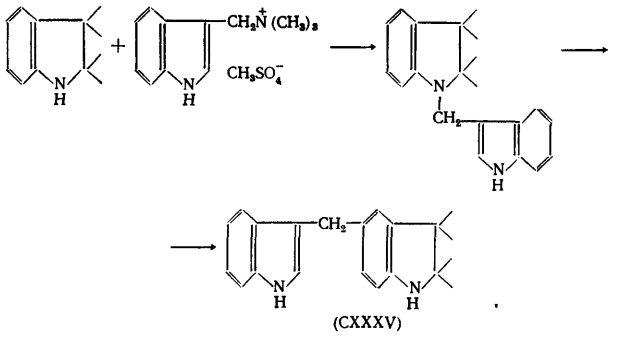


R=n-C$_4$H$_9$; R′=CH$_3$; R″=H. R=CH$_2$CH$_2$CN; R′=CH$_3$; R″=H.
R=R′=CH$_3$; R″=H. R=CH$_2$C$_6$H$_5$; R′=C$_6$H$_5$; R″=H.
R=C$_2$H$_5$; R′=CR$_3$; R″=H. R=H; R′R″=(CH$_2$)$_4$.

(CXXX)

The formylation of indoline and 1-methylindoline with dimethylformamide gives the corresponding 5-formyl derivatives (CXXX, R = R″ = H, R = H or CH$_3$) [152,153]. 1-Methylindoline yields also a certain amount of the 5,7-diformyl derivative [153]. The antitubercular activity of the thiosemicarbazone of 1-methylindoline-5-aldehyde has been described [154]. When phosphorus oxychloride or phosgene are allowed to act on 1-formylindolines, the latter are converted into 5-formylindolines. The authors call this reaction the migration of the formyl group to position 5, although it can be supposed that intermolecular formylation actually takes place. A number of aldehydes [CXXX, R = R″ = H, R′ = CH$_3$; R = R″ = H, R′ = C$_6$H$_5$; R = H and R′, R″ = (CH$_2$)$_4$] have been obtained by this method [155]. 4-(Indolin-5′-ylmethylene)-2-phenyl-5-oxazolone (CXXXII) has been obtained in the reaction of chloro- or ethoxy-methylene-2-phenyl-5-oxazolone (CXXXI) while the reaction of indoline with 4-ethoxymethylene-2-mercapto-1,3-thiazol-5-one (CXXXIII) gave the corresponding derivative of indoline and thiazolone (CXXXIV) [152]:

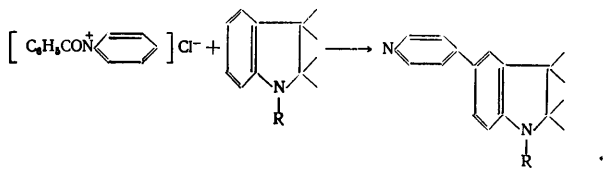
(CXXXI, X=Cl, OC$_2$H$_5$) (CXXXII)



(CXXXIII) (CXXXIV)

Similar *C*-substitution of indoline takes place with high yield on heating in a neutral medium. Indolinylmethylenephenylazlactone (CXXXII, R = H) has been used as the starting material for the synthesis of 5-isotryptophan (5-indolylalanine) [152].

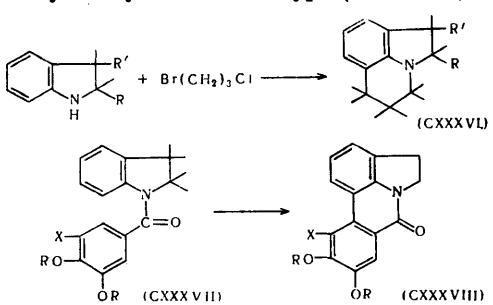
The *C*-alkylation of indolines has been almost not investigated. It has been shown that the reaction of the



quaternary salt of gramine with indoline yields 5-scatylindoline (CXXXV)[156,157]:

(CXXXV)

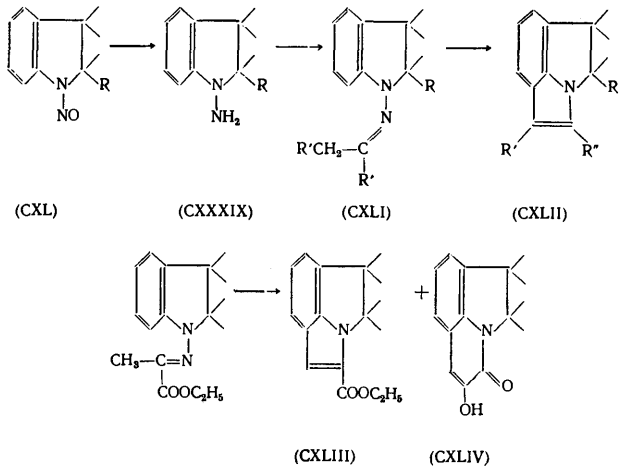
Indoline can probably be alkylated also by other ammonium derivatives.



The reaction of 1-alkylindolines with 1-acylpyridinium salts in the presence of Lewis acids leads to 1-alkyl-5-(pyrid-4′-yl)indolines. 1-Alkyl-5-benzoylindolines are formed as side-products[158]:

1-Acylquinolinium salts react with 1-alkylindolines without catalysts with formation of 1-alkyl-5-(1′-benzoyl-1′,2′-dihydroquinolin-2′-yl)indolines, which are converted by alkaline hydrolysis into 1-alkyl-5-(quinolin-2′-yl)indolines[159].

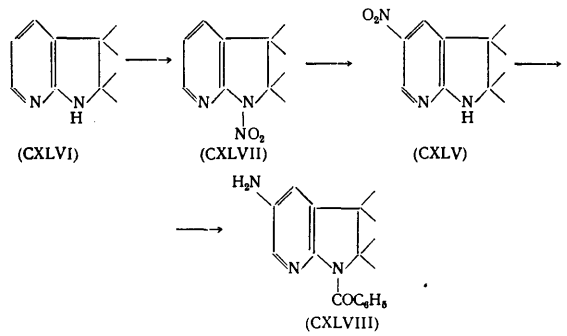
7. Synthesis of Tricyclic Systems Based on Indolines



In connection with studies on the structure of indole alkaloids, the possibility of synthesising condensed indole and indoline systems has been investigated. When 1-bromo-3-chloropropane was allowed to react with indoline, lilolidine and its derivatives (CXXXVI) were obtained[160]. Similarly 9,10-dimethyl-lilolidine (CXXXVI, R = R′ = CH_3) is formed from 2,3-dimethylindoline[161]. It is not clear whether the authors dealt with pure substances or with mixtures of *cis*- and *trans*-isomers. The decomposition of diazotised derivatives of *o*-aminobenzoylindoline (CXXXVII) under the conditions of the Pschorr reaction leads to tricyclic systems of the type (CXXXVIII)[118,162]:

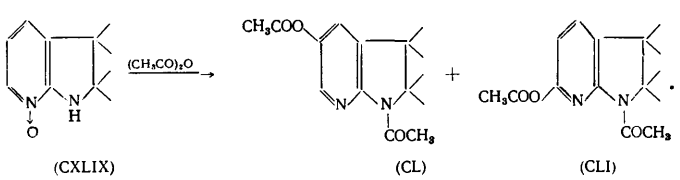
(CXXXVI) (CXXXVII) (CXXXVIII)

A similar cyclic system could not be obtained from 7-amino-1-benzoylindoline. The cyclisation can only be achieved in the presence of several alkoxy-groups in the benzene residue.



The use of indoline derivatives for the synthesis of cyclic systems by the Fischer reaction has also been described. 1-Aminoindolines (CXXXIX), prepared by the reduction of 1-nitrosoindolines (CXL), form with carbonyl compounds the hydrazones (CXLI), from which the tricyclic indole derivatives (CXLII), (CXLIII), and (CXLIV) were obtained[163-166]:

(CXL) (CXXXIX) (CXLI) (CXLII) (CXLIII) (CXLIV)

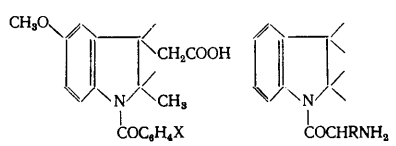


8. Substitution Reactions of Azaindolines

The substitution reactions in the series of pyridinopyrrolines (7-azaindolines) have been investigated with the aim of synthesising 7-azaindole derivatives[167]. 5-Nitro-7-azaindoline (CXLV) has been obtained by the nitration of 7-azaindoline (CXLVI). 1-Nitro-7-azaindoline (CXLVII) forms as an intermediate. 5-Amino-1-benzoyl-7-azaindoline (CXLVIII) has been prepared[167]:

(CXLVI) (CXLVII) (CXLV) (CXLVIII)

By allowing peracetic acid to react with 7-azaindoline, the corresponding *N*-oxide (CXLIX) was obtained and under the action of acetic anhydride the oxide was converted into a readily separated mixture of 5-acetoxy-1-acetyl-7-azaindoline (CL) and 6-acetoxy-1-acetyl-7-azaindoline (CLI). On hydrolysis, these compounds gave 5- and 6-hydroxy-7-azaindolines:

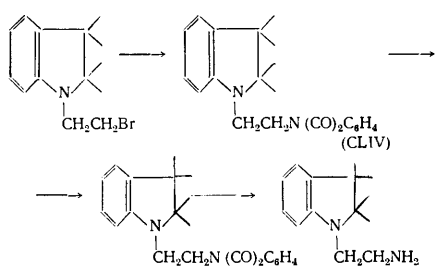


(CXLIX) (CL) (CLI)

It has been shown that 4-methyl-7-azaindoline derivatives are capable of forming 4-styryl derivatives [105]. The halogen in halogeno-7-azaindolines has been replaced by a methoxy-group and iodine [105]. The conditions of the dehalogenation of 6-chloro-7-azaindoline, 2,4-dichloro-7-azaindoline, and 4,6-dichloro-5-azaindoline have been investigated [113].

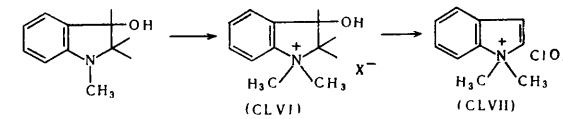
IV. INTRODUCTION OF SUBSTITUENTS INTO THE PYRROLE RING OF THE INDOLINE MOLECULE

The capacity of indolines to form *N*-derivatives, a property characteristic of all aromatic amines, was used to produce *N*-acyl- and *N*-alkyl-indoles, *N*-glycosylindoles, and also a quaternary indole salt, dimethylindolium perchlorate, which are difficult to obtain.



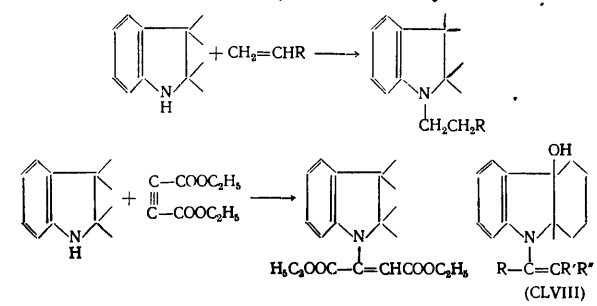
1-Acylindolines. When acted upon by acylating agents, indoline, sodium indoline-2-sulphonate, and 3-hydroxy-indoline form *N*-acyl derivatives. An enormous number of a wide variety of indoline derivatives, obtained by the action of acid anhydrides, arenesulphonyl chlorides, diketen [139], etc., have been described. We shall examine only those *N*-acylindolines which have been converted into the corresponding indole derivatives. In recent years much work has been done on the study of 1-benzoylindoline-3-alkanoic acids [for example, compound (CLII)]. These compounds have been converted into indomethacin (XV) and its analogues. The Merck Co. has published a number of patents dealing with the synthesis of compounds of this type [46,47]:

(CLII) (CLIII)



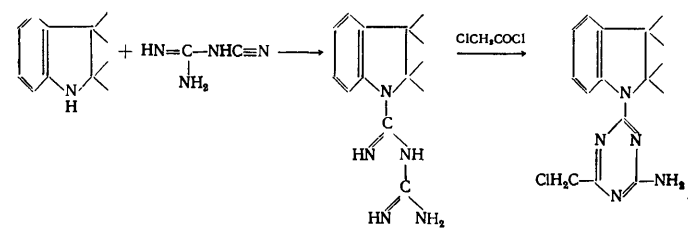
N-Aminoacyl derivatives of indoline (CLIII) have been investigated with the aim of converting them into the amino-acid derivatives of indole [168]. The principal difficulties arising in the preparation of *N*-acylindoles from *N*-acylindolines are encountered in the dehydrogenation stage. Probably the study of the *N*-acylation of the readily dehydrated 3-hydroxyindoline derivatives would prove very useful.

1-Alkylindolines and quaternary indolinium salts. *N*-alkylation of indolines and 3-hydroxyindolines has been investigated in great detail. Particular attention has been devoted to the preparation of derivatives of 1-(β-aminoethyl)indolines (CLIV), used for the synthesis of 1-isotryptamines (CLV) [169-172]:



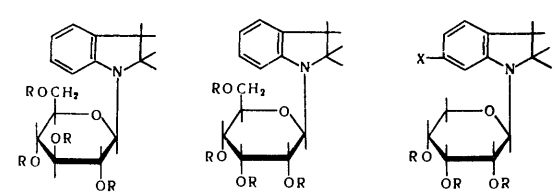
(CLV)

The quaternary 3-hydroxyindolinium salt (CLVI) has served as the starting material for the preparation of the quaternary indolium salt (CLVII) [18]:



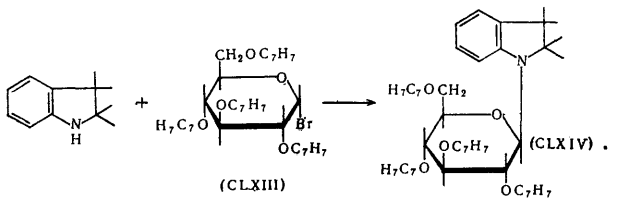
(CLVI) (CLVII)

Like other aromatic amines, indoline is capable of adding to the activated double bond of acrylonitrile [146,173], vinylpyridines [174], and also acetylenedicarboxylic acids [175]:



(CLVIII)

However, in the conversion to indole derivatives difficulties are encountered in this case in the dehydrogenation stage. When the corresponding hydroxyindoline derivative (CLVIII) is used, the conversion into indoles presents no difficulties [175]. The addition of indoline to the −C≡N bond has been described [176]:

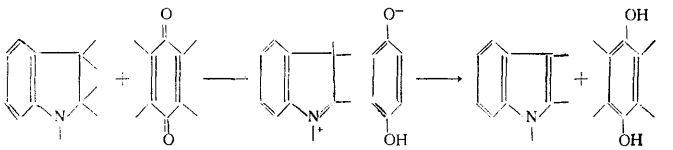


1-Glycosylindolines. In connection with the discovery of the antiviral activity of nucleoside and nucleotide analogues, the study of the properties of 1-glycosylindoles is of great interest. The investigations have acquired special importance after the discovery of the antibiotics tubercidin and toyokamycin. 1-Glycosylindolines have been used as the starting materials for the synthesis of 1-glycosylindoles [177-182]. 1-Glycosylindolines belong to the class of arylaminoglycosides, which have been little investigated. They are formed when indoline reacts with a hexose or pentose. 1-(D-β-Glucopyranosyl)indoline (CLIX, R = H) [177,178], 1-(D-β-galactopyranosyl)indoline (CLX, R = H) [179], 1(D-β-ribopyranosyl)indoline (CLXI, R = H) [180], 1-(D-β-ribopyranosyl)-6-nitroindoline (CLXII, R = H) [181], and their *O*-acetyl derivatives (CLIX, CLX, CLXI, CLXII, R = $COCH_3$) have been obtained.

(CLIX) (CLX)

(CLXI, X = H); (CLXII, X = NO_2).

The pyranoside structure of the products obtained has been confirmed by the fact that they have also been isolated in the reaction between *O*-acetylated pyranosyl acetates or acetohalogenopyranoses and indoline. Furthermore, in the hydrolysis of *O*-acetylated glycosylindolines it proved possible to isolate the corresponding *O*-acetylated pyranoses. The conclusion that 1-glycosylindolines and their derivatives have the β-configuration is based on the analysis of the molecular rotation and the infrared spectra. The formation of α-anomers could not be observed. Tetra-*O*-benzylglucopyranosyl bromide (CLXIII) has also been allowed to react with indoline, the tetra-*O*-benzyl derivative of glucopyranosylindoline (CLXIV) being obtained[182]:



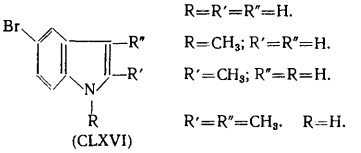
(CLXIII) (CLXIV).

V. CONVERSION OF INDOLINE DERIVATIVES INTO INDOLES

1. Dehydrogenation of Indolines

A wide variety of dehydrogenating agents are used to convert indolines into indoles—quinones with high oxidation potentials (chloranil, 2,3-dichloro-4,5-dicyano-*p*-benzoquinone), the pyridine complex of $CuCl_2$, $Hg(OCOCH_3)_2$, NiO_2, MnO_2, and others. The oxidation of indolines with atmospheric oxygen under various conditions and also catalytic dehydrogenation in the presence of Raney nickel, the Adams catalyst, palladium black or palladium on charcoal, nickel chromite, and other catalysts has also been described. The specific properties of the indole ring preclude the use of dehydrogenating agents such as sulphur and selenium, since indoles react with these substances[183].

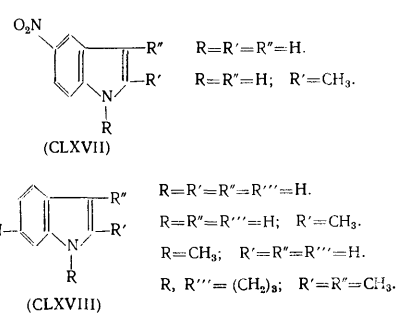
The mechanism of the effect of quinones and other dehydrogenating agents on indoline has not been investigated. However, on the basis of general hypotheses[184], one can assume that at the beginning of the dehydrogenation process a hydride ion is removed, this being facilitated by the high-electron-donor capacity of the >NR group. The transition complex (CLXV) thus produced is then converted into indole and hydroquinone.



(CLXV)

It can be assumed that in other cases too, for example in heterogeneous catalysis, the initial dehydrogenation step is the removal of a hydride ion and the overall dehydrogenation mechanism is as follows:

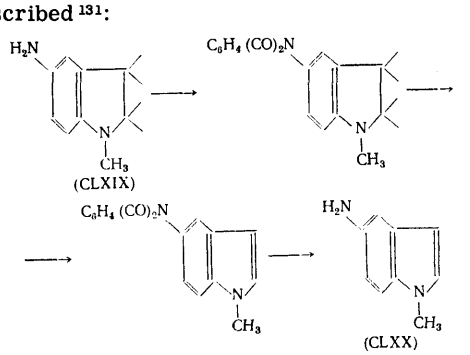
$$\text{indoline} + A \rightleftharpoons \text{indole}.\ H^+.AH^- \rightarrow \text{indole} + AH_2,$$



A being the dehydrogenating agent. In the dehydrogenation with chloranil and in catalytic dehydrogenation electron-donor substituents, which favour the removal of a hydride ion, also facilitate the dehydrogenation. In the dehydrogenation with quinones the *trans*-configuration of the hydrogen ion eliminated is not obligatory, since *cis*-2,3-dimethylindoline forms 2,3-dimethylindole in 38% yield[93], which is consistent with the proposed mechanism of dehydrogenation by quinones. In dehydrogenation with palladium on charcoal selective *trans*-dehydrogenation is also not observed[25].

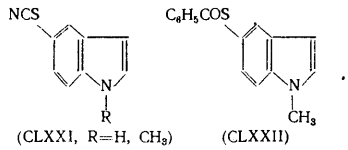
The most widely used dehydrogenating agent is chloranil. Dichlorodicyanoquinone, which has a higher redox potential, is finding increasing application in organic synthesis. Yet another property makes it a valuable dehydrogenating agent—dichlorodicyanohydroquinone formed in the reaction is sparingly soluble in benzene and xylene, which facilitates the isolation of the reaction products. As already mentioned, chloranil has been used to dehydrogenate 2,3-dimethylindoline[93], unsubstituted indoline and other alkylindolines[40], and also 5-ethoxy-1-methylindoline[35]. This agent has been used in the dehydrogenation of halogenoindolines. The following 5-bromoindoles (CLXVI) have been obtained[119,121,127]:

(CLXVI)



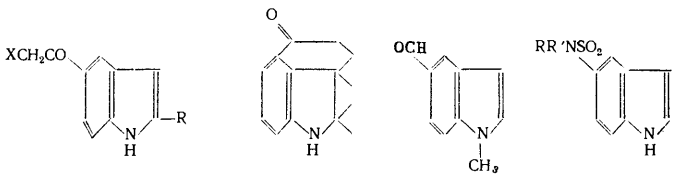
6-Bromo-2,3-dimethylindole has also been prepared[137]. The dehydrogenation of 5-iodoindoline[138], 5- and 6-chloroindolines, and fluoroindolines[134] has been described. A number of nitroindoles (CLXVII and CLXVIII) have been synthesised by boiling with chloranil in xylene[15,119,123,124]:

(CLXVII) (CLXVIII)



When a second nitro-group is introduced into the indoline molecule, the redox potential of chloranil proves insufficient and dinitroindoline cannot be dehydrogenated by boiling with chloranil in xylene[125].

In the dehydrogenation of aminoindolines with quinones it is necessary to protect the amino-group in order to avoid its undesirable interaction with chloranil. The following method for the conversion of 5-amino-1-methylindoline (CLXIX) into the corresponding indole (CLXX) has been described[131]:

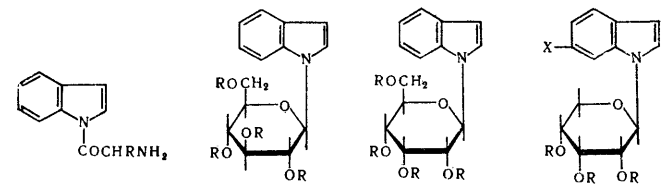


(CLXIX) (CLXX)

5-Thiocyanatoindoles (CLXXI) have been obtained by boiling 5-thiocyanatoindolines with chloranil in xylene. 5-Benzoylmercapto-1-methylindole (CLXXII) has been obtained similarly [140]:

(CLXXI, R=H, CH_3) (CLXXII)

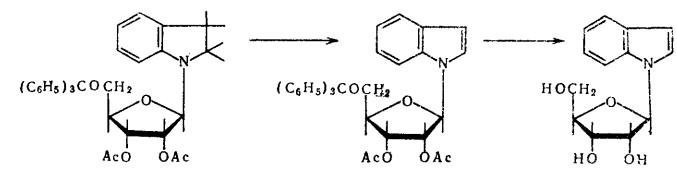
The 5,5′-disulphide of 1-methylindole has been described [140]. Indoles containing an acyl group in the benzene ring have also been synthesised by dehydrogenating the corresponding indolines with chloranil. Chloranil has been used in the synthesis of the ketones (CLXXIII) [149]:



(CLXXIII, R=H; X=H·R=CH_3; X=H. R=H; X=Cl·R=CH_3; X=Cl) (CLXXIV) (CLXXV) (CLXXVI)

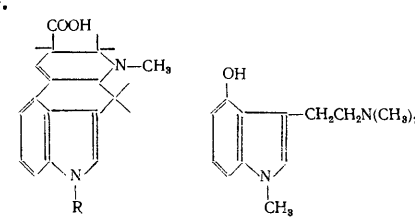
Heat is used in the dehydrogenation with quinones. At room temperature the ketone (CLXXIV) could not be dehydrogenated with chloranil and dichlorodicyanoquinone gave the corresponding indole in 5% yield only [185]. In contrast to 4-(indolin-5′-yl)methylene-5-oxo-2-phenyloxazole (CXXXII, R = H), 1-methylindoline-5-aldehyde was converted into 1-methylindole-5-aldehyde (CLXXV) on boiling with chloranil in xylene. The dehydrogenation of indoline-5-sulphonamides yielded a series of indole-5-sulphonamides (CLXXVI) [117,138,141]. Convenient solvents for the dehydrogenation of indolinesulphonamides and other indoline derivatives which are sparingly soluble in xylene are 1,2-dimethoxyethane [141], diglyme, and dimethylformamide [181].

The reaction with chloranil or dichlorodicyanoquinone also constitutes a general method for the dehydrogenation of 1-alkyl(aryl)-7-azaindolines [103,105,106]. A large number of 7-azaindole derivatives have been obtained. As with indolines, the introduction of electron-acceptor substituents into the azaindoline molecule hinders dehydrogenation, while electron-donor substituents facilitate it [111]. It is noteworthy that, as a result of the lower electron density of the pyridine ring compared with the benzene ring, azaindolines are dehydrogenated under more severe conditions than indolines. In their capacity for dehydrogenation azaindolines are similar to nitroindolines. *N*-Acylation of indolines also hinders dehydrogenation, since the electron density of the pyrrole ring is thereby reduced. However, it has proved possible to obtain a number of *N*-acylindoles from the corresponding indolines. *N*-Aminoacyl derivatives of indole (CLXXVII) have been synthesised from the *N*-aminoacyl derivatives of indoline (CLIII) by boiling with chloranil in xylene [168]. The last stage in the synthesis of indomethacin (XV) consists in the dehydrogenation with chloranil of 1-(*p*-chlorobenzoyl)-2,3-dehydro-5-methoxy-2-methylindole-3-acetic acid (CLII) [47]. Probably the presence of the methoxy-group in position 5 facilitates the dehydrogenation despite the opposed effect of the *p*-chlorobenzoyl residue. 1-Acetyl-5-bromoindoline-3-acetic and 1-acetyl-5-nitroindoline-3-acetic acids could not be dehydrogenated with chloranil [44].



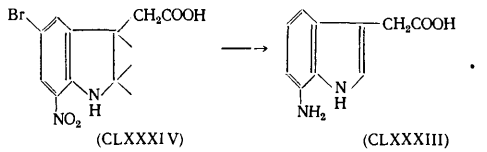
The dehydrogenation of *N*-glycosylindolines has been investigated in detail. The dehydrogenation of 1-(D-β-tetra-*O*-acetylglucopyranosyl)indoline (CLIX, R = $COCH_3$) by boiling with chloranil in xylene gives the corresponding indole in 32% yield (CLXXVIII, R = $COCH_3$) [177,178]. When dichlorodicyanoquinone is used in the synthesis, the yield is quantitative [182]. Dichlorodicyanoquinone has also been used to synthesise 1-(D-β-tetra-*O*-benzylglucopyranosyl)-indole (CLXXVIII, R = $CH_2C_6H_5$) [182].

(CLXXVII) (CLXXVIII) (CLXXIX) (CLXXX)



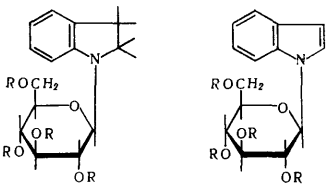
This reagent has also been employed in the synthesis of 1-(D-β-tetra-*O*-acetylgalactopyranosyl)indole (CLXXIX, R = $COCH_3$) [179] and 1-(D-β-tri-*O*-acetylribopyranosyl)indole (CLXXX, X = H, R = $COCH_3$) [180]. In the dehydrogenation of 6-nitro-1-(D-β-tri-*O*-acetylribopyranosyl)indoline (CLXII, R = $COCH_3$) even boiling with chloranil in xylene is insufficient to complete the reaction. The reaction mixture consists of the indoline (CLXII, R = $COCH_3$) and the indole (CLXXX, X = NO_2, R = $COCH_3$), which can be separated after deacetylation. The yield of indole (CLXXX, X = NO_2, R = H) is 19%. [181]

Dichlorodicyanoquinone has been used as the dehydrogenating agent in the conversion of 1-(D-β-5′-*O*-trityl-2′,3′-di-*O*-acetylribofuranosyl)indoline into the corresponding indole derivative which is a key substance in the synthesis of 1-(D-β-ribofuranosyl)indole, an indole analogue of nucleosides [186]:



9,10-Phenanthroquinone has also been used as a dehydrogenating agent for indolines [185].

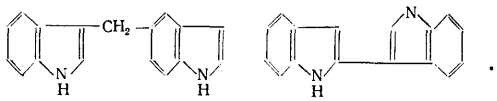
The catalytic dehydrogenation of indoline derivatives has been extensively studied. There is great scope for synthesis using Raney nickel as the catalyst. In the conversion of dehydrolysergic acid (XXXVIII, R = H) into lysergic acid (CLXXXI, R = H) the former was boiled in water with Raney nickel and sodium arsenate [14]. In contrast to this catalyst, which aromatises the pyrrole ring, the use of palladium on charcoal leads to the aromatisation of the naphthalene ring. 4-Hydroxy-3-(β-dimethylaminoethyl)-1-methylindole (CLXXXII) has been obtained by the dehydrogenation of the corresponding indoline over Raney nickel in water [91].



(CLXXXI) (CLXXXII)

In those cases where the indoline molecule contains a group capable of being reduced, Raney nickel causes simultaneous dehydrogenation of the pyrroline ring and reduction of this group. Thus on being boiled with Raney nickel or with the Raney alloy, nitroindolines are converted into aminoindoles. 5- and 6-Aminoindoles, 5-aminoindole-3-acetic acid and 5-aminoidnole-3-propionic acid have been obtained by this method[44,45]. In the presence of a halogen in the indoline molecule, dehydrogenation is accompanied by the elimination of the halogen. By boiling bromonitroindoline with Raney nickel, 7-aminoindole and 7-aminoindole-3-acetic acid (CLXXXIII) have been obtained in one stage from 1-acetyl-5-bromo-7-nitroindoline and 5-bromo-7-nitroindole-3-acetic acid (CLXXXIV) respectively[44,45]:

(CLXXXIV) (CLXXXIII)

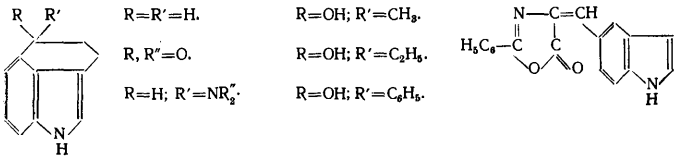


It is interesting that, using Raney nickel, it is difficult to reduce the substituent without the simultaneous dehydrogenation of the pyrroline ring. Thus neither aminoindoline nor nitroindole can be obtained from nitroindoline in the presence of Raney nickel. The nitro-group is reduced even when the reaction is carried out in nitrobenzene or in the presence of added maleic acid. The same phenomenon has been observed in the dehydrogenation of 1-(D-β-tetra-*O*-benzylglucopyranosyl)indoline (CLXXXV, R = $CH_2C_6H_5$)[181]. Dehydrogenation and debenzylation take place simultaneously. The indole (CLXXXVI, R = H) forms in 39% yield. Chromatographic analysis of the reaction mixture showed the absence of the corresponding debenzylated glucosylindoline (CLXXXV, R = H).

(CLXXXV) (CLXXXVI)

Even hydrogenation of compound (CLXXXV, R = $CH_2C_6H_5$) over Raney nickel at 50°C and 50 atm is accompanied by the formation of the indole derivative (CLXXXVI, R = H). In contrast to the *O*-benzyl derivative, the acetylated glucopyranosylindoline (CLXXXV, R = $COCH_3$) and also the unprotected glucopyranosylindoline (CLXXXV, R = H) are not completely dehydrogenated on boiling with Raney nickel. Thus the presence in the molecule of a reducible group greatly facilitates the dehydrogenation. Probably intramolecular transfer of a hydride ion to the reducible group takes place very readily in the complex indole.H^+.AH^- formed in the heterogeneous catalytic dehydrogenation.

Palladium black and palladium on charcoal are also widely used in the dehydrogenation. Hydrogen acceptors—nitrobenzene, cinnamic acid, and maleic anhydride—are frequently added in such reactions. Thus indoline has been converted into indole by heating with palladium black and cinnamic acid[57]. 5- and 6-nitroindoles[16], 6-benzamido-1-methylindole[15], 1-methyl-6-phthalimidoindole[15], and a series of indole-5-sulphonamides (CLXXXVI)[42] have been obtained under the same conditions:



(CLXXXVII) (CLXXXVIII)

The dehydrogenation of indoline derivatives in the presence of catalysts without using hydrogen acceptors has also been described. The following products have been obtained: 5-scatylindole (CLXXXVII)[156] from 5-scatylindoline (CXXXV)[156], 2,3′-di-indolyl (CLXXXVIII) from the indole dimer (LIX)[79], 5-, 6-, and 7-methoxyindoles from the corresponding methoxyindolines[135], and the ketone (CLXXXIX, R, R′ = O) from the ketone (CLXXIV)[184]. 5-Aminoindoline has been converted into 5-aminoindole by heating with palladium on charcoal in the absence of solvent at 190°C.[44] Alkylindolines have also been dehydrogenated by heating with palladium on charcoal up to 200°C.[25] 4-(Indolin-5′-yl)methylene-5-oxo-2-phenyloxazole (CXXXII, R = H), which could not be dehydrogenated with chloranil, gave the corresponding indole derivative (CXC) after boiling for two days with palladium black in xylene[152]. 5,7-Dinitroindoline could not be converted into dinitroindole by boiling with palladium black in mesitylene[125]. The attempt to dehydrogenate 1,1-dimethylindolinium chloride by boiling with palladium black in xylene did not yield the corresponding quaternary indolium salt[18].

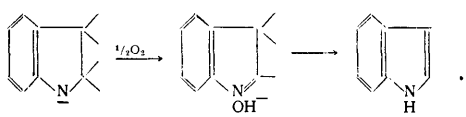
The dehydrogenation of indoline on the $Ni/NiCrO_2$ catalyst at 200°C has been described[187]. The pyridine complex of $CuCl_2$ has also been used as the oxidising agent for indolines[91,142]. The yields of indole and 1-methylindole when the corresponding indolines were heated with cupric chloride in pyridine were 55–60%.[142] Similarly a number of 4- and 6-methoxyindolines have been converted into the corresponding indoles[91]. So far, it has not proved possible to use this reagent in the synthesis of indoles containing electron-acceptor groups.

Oxidation with manganese dioxide in benzene[188] or methylene chloride[185] has also been described. The yield of indoline was 56–59%. The following compounds (CLXXXIX) have been obtained by shaking the corresponding indolines with manganese dioxide in methylene chloride[185]:

(CLXXXIX) (CXC)

Indole-3-propionic acid has also been synthesised by the oxidation of indoline-3-propionic acid[185]. 2-Methylindoline, 2,3-dimethylindoline, and 1-acyl derivatives of indoline could not be dehydrogenated by this method[185]. Attempts have been made to oxidise indolines with nickel peroxide[185]. The dehydrogenation of 2- and 3-methylindolines by distillation from silver sulphate has been described[189].

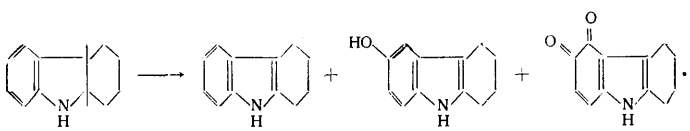
The classical dehydrogenating agent $Hg(OCOCH_3)_2$ is relatively unsuitable for the indoline series, since indole compounds are mercurated by mercury salts, probably with formation of 1,3-dimercuri-derivatives[190]. However, in



some cases dehydrogenation has been achieved. The dehydrogenation of dihydrolysergic acid derivatives (XXXVIII) with $Hg(OCOCH_3)_2$ has been described[57].

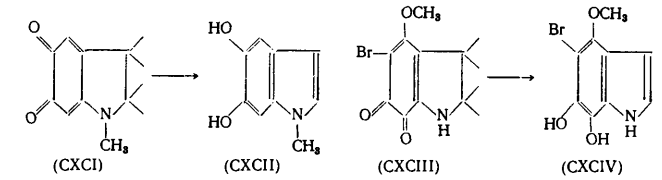
Dinitroindolines can be oxidised to indoles with nitric acid, the oxidation being accompanied by the nitration of the pyrrole ring of indole. 3,5,7-Trinitroindole has been obtained from 5,7-dinitroindoline[125] and 5-nitro and 5,7-dinitroindolecarboxylic acid (XCV) (see p. 756) have been obtained from strychnine.

When 2-methylindoline was heated with concentrated hydrochloric acid at 240°C, 2-methylindole was formed in 28% yield[25]. The mechanism of the process has not been established. Probably atmospheric oxygen is involved. Very interesting data have been obtained on dehydrogenation with atmospheric oxygen in the study of the sodium salts of indolines and azaindolines[22,113]. It has been found that the formation of the *N*-sodio-derivative of indoline in liquid ammonia, toluene, or other solvents is accompanied by the oxidation of this derivative with atmospheric oxygen. Indole, 6-methoxyindole, and 5- and 7-azaindoles and their derivatives have been obtained in high yields from the corresponding indolines[22,113]. *N*-Acyl and *N*-benzyl substituents and halogen atoms are eliminated under the conditions of the reaction. *N*-Metallated secondary amines, for example $(C_2H_5)_2NLi$ or $C_6H_5N(CH_2C_6H_5)Li$, are known to be the most powerful donors of hydride ions and can react as reducing agents for the carbonyl group[191,192]:



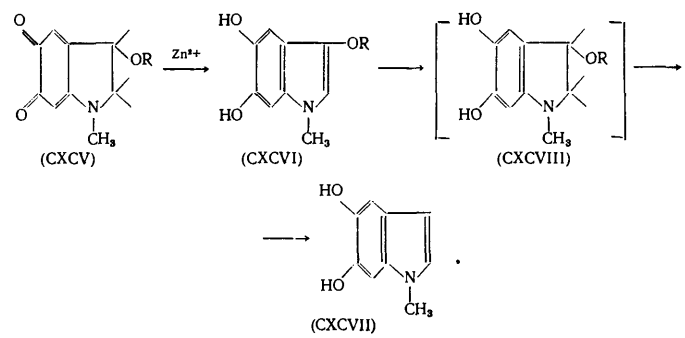
$$(C_6H_5)_2CO + C_2H_5N(Li)CH_2CH_3 \rightleftarrows (C_6H_5)_2CHOLi + C_2H_5N{=}CHCH_3$$
$$(C_6H_5)_2CO + C_6H_5N(Li)CH_2C_6H_5 \rightleftarrows (C_6H_5)_2CHOLi + C_6H_5N{=}CHC_6H_5$$

Evidently, like other *N*-metallated derivatives of secondary amines, the *N*-sodio-derivative of indoline is also a very powerful hydride ion donor, particularly since the removal of a hydride ion leads in this case to indolenine, which is converted into the more stable aromatic indole system:



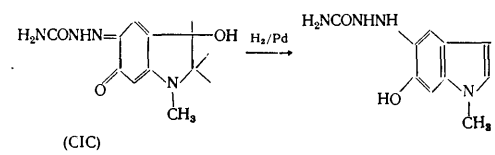
In this case atmospheric oxygen is the hydride ion acceptor[193]. 2,3-Dimethyl-7-ethylindole forms in the reaction of 2,3-dimethylindoline with aluminium anilide and ethylene in aniline at 300°C and 250 atm. It is difficult to say whether dehydrogenation or *C*-alkylation takes place first. Probably the indoline derivative is dehydrogenated as a result of the formation of an $N{-}Al_{1/3}$ derivative which tends to split off a hydride ion like N–Na derivatives[194]. The oxidation of indoline with air in the presence of heavy metal oxides yields indole[195].

When potassium nitrosodisulphonate $(NO)(SO_3K)_2$ is allowed to react with indolines, 5-hydroxyindoles and *o*-quinones of the indole series are formed together with indole derivatives; for example[196]:

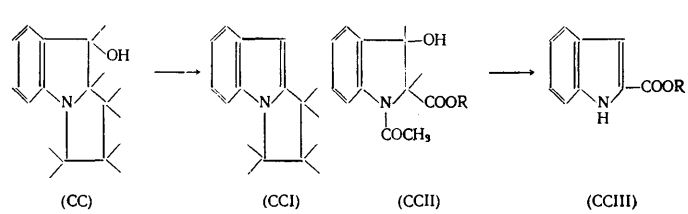


Similar reactions have been achieved with 2-phenylindoline, 2,3-dimethylindoline, and 3-methylindoline[197].

The isomerisation of aminochromes (CXCI) into 5,6-dihydroxyindole derivatives (CXCII) constitutes an unusual reaction involving intramolecular oxidation–reduction[96,198]:

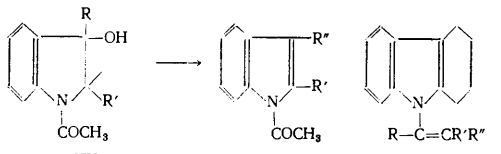


The reaction takes place under the action of Zn^{2+} and Al^{3+} ions. 6,7-Indolinequinones (CXCIII) have been isomerised to 6,7-dihydroxyindoles (CXCIV)[97]. Adrenochrome derivatives (CXCV) give rise to 3,5,6-trihydroxyindoles (CXCVI),[196,199] whose reduction with the Raney nickel alloy yields 5,6-dihydroxyindoles (CXCVII)[96]:



3-Hydroxyindoline derivatives (CXCVIII) probably act as intermediates. The work of Mattlock and Heacock[200] can also be quoted.

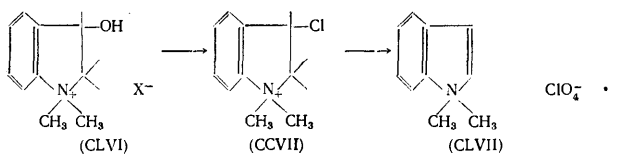
Analogous series of conversions have been described for the semicarbazone of adrenochrome (CIC)[201]:



2. Dehydration of 3-Hydroxyindolines

The use of 3-hydroxyindolines for the synthesis of substituted indoles is extremely promising. Unsubstituted 3-hydroxyindoline is relatively stable in the cold to the action of acids and alkalis but on heating to 70°C it is converted into indole[71]. 3-Hydroxy-1-methylindoline is somewhat more stable to heat[71]. 3-Hydroxy-1,2-trimethylindoline (CC) has been converted into the corresponding indole (CCI) by boiling with acetic anhydride[202]:

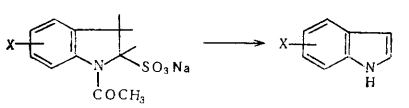
Derivatives of 1-acetyl-3-hydroxyindoline-2-carboxylic acid (CCII) are converted into derivatives of indole-2-carboxylic acid (CCIII) under the action of mineral acids in



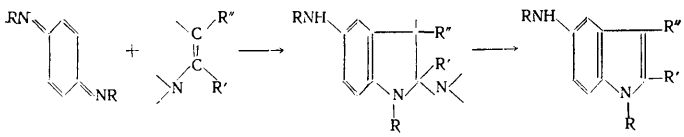
the cold[69] and on heating with alkalis[69]. Under acylation conditions compounds (CCII) give rise to *O*-acyl derivatives. A number of 2,3-disubstituted 1-acetyl-3-hydroxyindolines (CCIV) have been converted into indoles (CCV) by heating with phosphorus pentoxide in benzene[75]:

(CCIV) (CCV) (CCVI)

It has been possible to prepare indole derivatives of the type (CCVI) by heating the corresponding 3-hydroxyindolines (CLVIII) with picric acid in methanol[175].

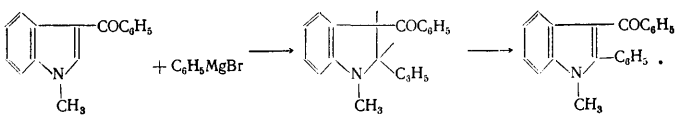


1,1-Dimethylindolium perchlorate (CLVII) has also been synthesised using the corresponding 3-hydroxyindoline derivative (CLVI)[18]:



(CLVI) (CCVII) (CLVII)

However, compound (CLVI) could not be dehydrated. The 3-hydroxyindoline (CLVI) was converted into 3-chloro-1,1-dimethylindolinium chloride (CCVII), which was then further converted into the indole derivative (CLVII) by being passed through a column with Amberlite IRA-400. Evidently, the use of 3-hydroxyindolines for the synthesis of substituted indoles requires study of the method of preparation and reactivity of the *trans*- and *cis*-isomers of 2-substituted 3-hydroxyindolines.



As stated above, derivatives of the sodium salts of indoline-2-sulphonic acid are converted into indoles in an alkaline medium[17]:

The range of substances which can be used for the preparation of compounds of the indole series is not restricted to derivatives of indoline, indoline-2-sulphonic acid, and 3-hydroxyindolines. There are also methods, which have been virtually not investigated, for the synthesis of 2-hydroxy- and 2-amino-indolines and for their conversion into indoles. For example, in the condensation of quinone-imines with enamines, the intermediates are 2-amino-indoline derivatives, which are converted into indoles under very mild conditions[203]:

The conversion of indoles into dihydro-derivatives with the aim of altering the reactivity of substituents in positions 2 and 3 or in order to introduce substituents in position 2 may prove very valuable. Thus 3-benzoyl-1-methyl-2-phenylindoline (CCIX) has been obtained by the reaction of 3-benzoyl-1-methylindole (CCVIII) with phenylmagnesium bromide. Its dehydrogenation over Pd/C gave 3-benzoyl-1-methyl-2-phenylindole (CCX)[204]:

(CCVIII) (CCIX) (CCX)

THE ROLE OF THE STATIONARY PHASE IN GAS-LIQUID CHROMATOGRAPHY AND METHODS OF SORBENT SELECTION

M.S.Vigdergauz

CONTENTS

1. Selectivity of the stationary phase and its relation to the degree of separation and the error of the analysis 771
2. Intermolecular interactions in the column and retention characteristics 772
3. Relation between molecular structure and sorption properties 775
4. Classification of stationary phases 776
5. Methods of selection of stationary phases 777
6. Binary sorbents 782
7. Effect of temperature on the selectivity of the phases; temperature limits of their application 783
8. Effect of the stationary phase on the spreading of chromatographic zones 784

The possibility of controlling the selectivity of the column is one of the principal advantages of chromatography (in the first place gas-liquid chromatography) over other methods for the separation of substances, the nature of the stationary phase constituting the main factor which determines the sequence of the elution of the components from the column and the relative elution times of the peak maxima [1-3]. Furthermore, the effect of the stationary phase extends also to the mode of spreading of the zones.

1. SELECTIVITY OF THE STATIONARY PHASE AND ITS RELATION TO THE DEGREE OF SEPARATION AND THE ERROR OF THE ANALYSIS

An investigator using gas chromatography is able to solve the following groups of problems: (a) qualitative analysis of the mixture; (b) quantitative analysis of the mixture; (c) isolation of a certain amount of pure substances or fractions; (d) determination of certain physicochemical characteristics of the test system.

In qualitative analysis the degree of separation must be sufficient to obtain in the chromatogram separate peak maxima of the individual components and the displacement of these maxima under the influence of the neighbouring components should be fairly small. In quantitative analysis it is important that the analytical error associated with the quality of the separation should be within the permissible limits.

In preparative chromatography the main requirement is to ensure the necessary purity of the fraction for a sufficiently large sample volume, which is also related to the degree of separation. Finally, in the determination of physicochemical characteristics the requirements are determined by the actual problem. Regardless of the aim of the chromatographic analysis, it is desirable that the separation should be attained in a short time.

The ratio of the distance between the ordinates of the maxima to the sum of the peak widths may serve as a measure of the separation of two components. Thus the degree of separation K is defined by the formula [1]:

$$K = \frac{\Delta l}{\mu_{0.5(1)} + \mu_{0.5(2)}},$$

where Δl is the distance between the ordinates of the maxima and $\mu_{0.5(1)}$ and $\mu_{0.5(2)}$ are the peak half-widths [1,4]. K can be found from the expression

$$K = \frac{V_{R_2} - V_{R_1}}{\omega_{0.5(1)} + \omega_{0.5(2)}} = 0.212 K_c \sqrt{n}, \quad (2)$$

where V_{R_1} and V_{R_2} are the retention volumes of the components, $\omega_{0.5(1)}$ and $\omega_{0.5(2)}$ the zone widths expressed in volume units, $K_c = 2(V_{R_2} - V_{R_1})/(V_{R_2} + V_{R_1})$ is the selectivity coefficient of the column, and $n = 5.55(V_R/\omega_{0.5})^2$ the number of theoretical plates characterising the efficiency of the column. The coefficient K_c depends not only on the nature of the stationary phase but also on the fraction of the column volume occupied by this phase. This follows from the equation

$$\frac{1}{K_c} = \frac{1}{k_c} + \frac{V_0}{V_{R_2} - V_{R_1}},$$

where $k_c = 2(V'_{R_2} - V'_{R_1})/(V'_{R_2} + V'_{R_1})$ is the selectivity coefficient of the stationary phase, V'_{R_1} and V'_{R_2} are the reduced retention volumes of the components, and V_0 is the gas volume (the retention volume of the non-sorbed substance).

Thus in order to achieve a satisfactory degree of separation of a two-component mixture, it is necessary that the zone spreading should be small and that the difference between the retention volumes, which is determined by the selectivity, should be large. By selectivity one should understand the property of the sorbent which gives rise to the relative displacement of the chromatographic peaks of the components.

The relation between the selectivity of the stationary phase and the degree of separation follows from Eqns. (2) and (3). However, K cannot be a complete characteristic of the conditions of analysis (determining whether or not they are satisfactory), since it does not determine unambiguously the magnitude of the analytical error (in quantitative analysis), the purity of the fraction (in the isolation of the components for preparative purposes), etc. Yet another important factor is the composition of the binary mixture to be separated. Furthermore, when the peaks are not separated completely, significant differences arise also in the calculation of K. Indeed, as a result of the mutual overlapping of the zones of neighbouring components, the peak width and sometimes also the value of Δl change (this has a particularly pronounced effect on the results of qualitative analysis) and therefore K determined from the general elution curve will differ from the value calculated from the individual curves for the components (the latter value will be called the effective separation factor K_{eff})[5]. It is frequently impossible to determine the peak width at the height necessary for the calculation of K.

Therefore, in order to estimate this degree of separation of overlapping peaks, it is desirable to employ the degree of separation defined by[5,6]

$$\psi = \frac{h_2 - h_{\min}}{h_2},$$

where h_2 is the height of the smaller peak and $h_{\min}$ the ordinate of the minimum between the peaks (Fig. 1). It has been shown[5-7] that the factor ψ, which varies steadily from 0 to 1 with K_{eff} and the ratio m of the heights of the neighbouring peaks, has important advantages over the previously employed factor $\theta = f/g$ (Fig. 1)[4,8,9], where f is the distance along the normal to the base line from the minimum to the point of intersection with the straight line joining the maxima and $g = f + h_{\min}$.

The relation between the degree of separation and the error of quantitative analysis (or the purity of the fraction in preparative chromatography) has been examined[5,10,11,12].

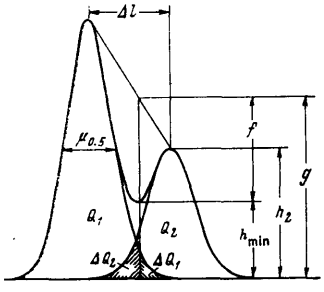

Fig. 1. Partial separation of peaks.

The column selectivity necessary to attain the required accuracy of the analysis (for specified column efficiency and peak ratio m) can be found from a nomogram[7].

Thus the selectivity of the stationary phase, which is the principal chromatographic characteristic of the latter, determines directly (other conditions being equal) the degree of separation and the error of the analysis of a two-component mixture.

2. INTERMOLECULAR INTERACTIONS IN THE COLUMN AND RETENTION CHARACTERISTICS

Raoult's law holds for an ideal dilute solution of a volatile substance:

$$p = xp^0, \tag{5}$$

where p^0 is the vapour pressure of the pure solute, p the vapour pressure of the solute over the solution, and x its mole fraction in the solution. In order to take into account positive and negative deviations from Raoult's law, the activity coefficient γ is introduced into the right-hand side of Eqn. (5). Then the combined Dalton–Raoult law can be represented by the formula

$$yP = \gamma xp^0, \tag{6}$$

where P is the total pressure in the system and y the mole fraction of the given substance in the gas phase.

According to Henry's law,

$$a = \Gamma c, \tag{7}$$

where a is the concentration of the solute in the liquid phase, c the concentration in the gas phase, and Γ Henry's constant; one can write

$$\Gamma = \frac{a}{c} = \frac{N_L + a}{N_G + c} \cdot \frac{x}{y} \simeq \frac{N_L}{N_G} \cdot \frac{x}{y}, \tag{8}$$

where N_L is the number of moles of the stationary liquid per unit volume of the liquid phase and N_G the number of moles of the carrier gas per unit volume of the gas phase. Since

$$P = N_G RT,$$

where R is the gas constant and T the absolute temperature, it follows from Eqns. (6)–(9) that

$$\Gamma = \frac{N_L RT}{\gamma p^0} = \frac{\rho RT}{\gamma p^0 M}, \tag{10}$$

where ρ and M are the density and molecular weight of the stationary liquid.

Thus the following expression can be obtained from Eqn. (10) for the specific retention volume V_g^T at a temperature T:

$$V_g^T = \frac{\Gamma}{\rho} = \frac{RT}{\gamma p^0 M}. \tag{11}$$

The specific (absolute) retention volume V_g is

$$V_g = \frac{273\,R}{\gamma p^0 M}. \tag{11a}$$

Next we establish the relation between Henry's constant and the principal thermodynamic characteristics of the system. The equilibrium between the gas and the liquid presupposes the equality of the corresponding free energies, $F_G = F_L$, where

$$F_G = F_G^0 + RT \ln c \quad \text{and} \quad F_L = F_L^0 + RT \ln a \tag{12}$$

(F_G^0 and F_L^0 are the standard free energies in the gas and liquid phases corresponding to a concentration of one mole per unit volume)†. Hence we have [14] the following equation:

$$\Delta F^0 = RT \ln \Gamma \tag{13}$$

or

$$\Gamma = e^{\Delta F^0/RT} = e^{-\Delta S^0/R}\, e^{\Delta H^0/RT} = \Gamma_S\, \Gamma_H, \tag{14}$$

where ΔS^0 is the entropy change per mole of substance on transition from the gas to the liquid phase and ΔH^0 the corresponding enthalpy change.

It follows from Eqn. (14) that the heat of solution Q, numerically equal to ΔH^0, can be determined from the following equation:

$$\frac{d \ln \Gamma}{d(1/T)} = \frac{\Delta H^0}{R}, \tag{15}$$

using a $\lg \Gamma$ (or $\lg V_R'$, $\lg V_N$, or $\lg V_g$)[4] plot. Evidently the following equation holds for the relative retention volume V^{rel}:

$$\frac{d \ln V^{rel.}}{d(1/T)} = \frac{\Delta Q}{R}, \tag{16}$$

where ΔQ is the difference between the heats of sorption of the component being analysed and a standard. If the enthalpy change is determined on the basis of the relation between the logarithm of the specific retention volume and the reciprocal of the absolute temperature [$d \ln V_g/d(1/T) = \Delta H'/R$], the following equation can be obtained [15,16]:

$$\Delta H' = \Delta H^0 + RT - \frac{RT^2}{\rho}\frac{d\rho}{dT} = 2{,}303R\, b \left(\frac{T}{T+C}\right)^2 + R\, T \left(1 - \frac{\beta T}{\rho}\right), \tag{17}$$

where b is the slope of the plot of $\lg \Gamma$ against $1/(T + C)$, C a constant, ρ the density of the stationary phase (g ml^{-1}), and β the constant in the relation $\rho = \alpha - \beta T$.

The contribution which the activity coefficient makes to the thermodynamic characteristics can be estimated for Eqns. (10) and (13). It has been shown [16-18] that

$$\frac{d \ln V_g}{dT} = -\frac{d \ln \gamma}{dT} - \frac{d \ln p^0}{dT} = -\frac{\lambda - \Delta h}{RT^2}$$

and

$$\frac{d \ln V_g}{d(1/T)} = \frac{\lambda - \Delta h}{R} = \frac{\Delta H'}{R}, \tag{18}$$

where λ is the latent heat of evaporation and Δh the excess enthalpy of solution (numerically equal to the heat of mixing) due to the deviation of γ from unity.

Adlard [19] showed that in the determination of the activity coefficient at infinite dilution γ^∞ from chromatographic data account must be taken of the non-ideality of the gas phase (by the method of Ashworth and Everett):

$$\lg \gamma^\infty = \lg \gamma + \frac{(B - v)(P - p^0)}{2.303\, RT}, \tag{19}$$

where B is the second virial coefficient in the equation of state of the gas and v the molar volume of the liquid solute.

By analogy with the derivation of Eqns. (13) and (14), one can write:

$$\lg \gamma^\infty = \frac{\Delta h}{RT} - \frac{\Delta s}{R}, \tag{20}$$

where Δs is the excess entropy of solution [17] and

$$\Delta h = R \frac{d \ln \gamma^\infty}{d(1/T)}. \tag{21}$$

The activity coefficient and hence the thermodynamic potentials are determined by the sum of the attraction and repulsion forces acting between the molecules in the chromatographic column. The total energy of the interaction of molecules in the liquid phase [1,14,20-23] consists of the energy of dispersion, induction, and orientation forces, the energy of specific interaction, and also the work expended to pull apart the solvent molecules‡.

As a result of the low concentration of the solute, the interaction between its molecules is usually disregarded although it has been shown in some studies [25] that in a number of cases the concentration effect does influence the results of the chromatographic process. Dispersion forces are of decisive importance in the interaction between the molecules of a non-polar solvent and a non-polar solute. They are due to the presence of virtual dipoles which give rise to an electric field inducing dipole moments in other molecules. Orientation forces arise between molecules with permanent dipoles due to their tendency to attain the orientation with the lowest energy. For example, orientation interaction occurs between sulphides and tricresyl phosphate molecules.

Induction forces act between the permanent dipole of one substance and the induced dipole of another. In particular, dipoles are induced in unsaturated and aromatic hydrocarbons. Although the energy of induction interaction is low, amounting to only 5–10% of the energy of dispersion interaction, it can nevertheless be sufficient to ensure the required chromatographic separation.

Specific forces include the hydrogen bond formed between a hydrogen atom and fluorine, oxygen, nitrogen, or chlorine atoms, donor–acceptor interaction, and complex formation.

The overall energy of interaction E between solvent and solute molecules can be represented by the following relation [22] when account is taken of dispersion, orientation, and induction forces:

$$E = -\frac{1}{r^6}\left(\frac{2}{3}\frac{\mu_1^2\mu_2^2}{kT} + \mu_1^2\alpha_2 + \mu_2^2\alpha_1 + 3\pi h \alpha_1\alpha_2 \frac{\nu_1\nu_2}{\nu_1 + \nu_2}\right), \tag{22}$$

where r is the distance between the molecules, μ_1 and μ_2 are the dipole moments, k is the Boltzmann constant, α_1 and α_2 are the polarisabilities of the solvent and solute molecules, h is the Planck constant, and ν_1 and ν_2 are the frequencies. The first term on the right-hand side of the equation characterises the orientation forces, the second and third terms the induction forces, and the fourth term the dispersion forces.

In his analysis of aliphatic acid esters on a column with an Apiezon grease, James [26] found that the dispersion forces decrease with increase in the branching and decrease of the molecular weight of the substances to be separated, because the esters of branched and unsaturated acids move in the column at a higher rate than those of saturated acids. It was shown that the dispersion forces are also influenced by the position of the double bond and the configuration of the molecule, in particular *trans*-isomers have somewhat higher retention volumes than *cis*-isomers

† The questions involved in the selection of the standard state have been examined in detail by James et al. [13]

‡ Kovats and Weiss [24] determined the contribution of these terms on the basis of retention indices [see Eqn. (46)].

and can be separated from the former when the efficiency of the column is equivalent to 4000 theoretical plates.

An example of the effect of induction forces is provided by separation using poly(ethylene glycol) and poly(propylene glycol) adipates as the stationary phases, described in James's paper quoted above. These liquids polarise the double bonds of unsaturated acid esters and increase the retention volumes of the latter, the positions of the double bonds and stereoisomerism being unimportant.

A very interesting example of the separation of components under the influence of induction forces is the chromatographic analysis of a mixture of thiophen and diethyl sulphide, using tricresyl phosphate as the stationary phase[27]. The boiling point and the dipole moment of diethyl sulphide are larger than those of thiophen, but, as a result of the high polarisation of thiophen which has aromatic properties, the latter is eluted after diethyl sulphide (here, as in the preceding example, donor–acceptor interaction evidently also takes place). On a column with a non-polar phase the components are of course eluted in the reverse order.

Hydrogen bonds are formed, in particular, between water and glycerol molecules, which permits the use of glycerol for the analysis of mixtures containing water[28]. When polyethylene oxide is used in the presence of amines, primary amines are strongly retarded and secondary amines less so. Tertiary amines have the smallest retention volumes due to the absence of the hydrogen bond with the stationary phase[29]. Evidently the role of the hydrogen bond in the overall energy of interaction between substances decreases with their molecular weight. Therefore the use of diglycerol or a polyester resin[21,30] as the stationary liquid in the analysis of alcohols makes it possible to elute ethanol first and methanol second.

Chromatographic separation can be achieved also with the aid of stationary phases which form complexes of varying stabilities with the components to be separated. Thus solutions of silver nitrate are widely used in the analysis of unsaturated hydrocarbons[31–35] and salts of aliphatic acids in the separation of amines[29]. The chromatogram obtained in the separation of gases on a column with a solution of silver nitrate in glycol shows that saturated hydrocarbons are eluted as a single peak, which is followed by the elution of the unsaturated compounds.

A novel method for the analysis of light gases has been described by Zhukhovitskii et al.,[36] who used blood as the stationary liquid for the selective retention of oxygen.

The theory of gas chromatography on columns with complex-forming phases (using silver nitrate solutions as an example) has been examined by a number of investigators[33,34]. In particular, Genkin showed[33] that Henry's constant can be determined from the equation

$$\Gamma = \Gamma^0 + \varkappa\Gamma^0 \; c_b \; , \qquad (23)$$

where $\varkappa = c_{ab}/c_a c_b$ is the stability constant of the complex, Γ^0 Henry's constant for the solvent containing the complex-forming agent, c_b the concentration of the complex-forming agent, and c_{ab} the concentration of the complex.

The work expended to pull apart the solvent molecules merits special examination. It has been shown[14] that, when a number of simplifying assumptions are made, this work A can be defined thus:

$$A = 4\pi r^2 \qquad (24)$$

where r is the radius of the solute molecule and σ the surface tension of the solvent. A increases with the size of the molecule in experiments with polar stationary phases and also with the polarity of the phases. Since A and E vary in the opposite sense, it has been concluded[37] that in the dissolution of non-polar substances the total interaction energy E decreases with increasing polarity of the solvent due to an increase of the work A; on the other hand, when polar substances are dissolved, the total energy increases with the polarity of the solvent. In this connection it is evident that for certain weakly polar substances the above effects can cancel out, resulting in an invariant Henry's constant (in the work quoted ethyl ether served as an example of such a weakly polar substance).

The role of the work A has been investigated in detail by Burrows and Preece[15]. If ΔE_A is the energy required to remove (at a constant temperature) the solute molecules from "holes" in the solvent and ΔE_C the energy liberated when the "holes" are filled up by solvent molecules (consequently ΔE_C is the energy of formation of the "holes"), the heat of sorption can be determined from the relation

$$\Delta H' = \Delta E_A - \Delta E_C + RT \; , \qquad (25)$$

where the last term characterises the excess work which must be performed.

The following expression holds for ΔE_A:

$$\Delta E_A = \frac{N(\epsilon_b - \epsilon_i)}{J} \; , \qquad (26)$$

where N is the Avogadro number, $\epsilon_b = \frac{1}{2}mv^2 \simeq \frac{1}{2}m(2\pi\nu r)^2$ the vibration energy of the solute molecule (when its mass is m and velocity v), r the radius of the "hole", ϵ_i the internal potential energy of the solvent molecule, and J the mechanical equivalent of heat (erg cal^{-1}). The radius of the "hole" can be determined as a function of Henry's constant in the following form:

$$r = 5.66 \times 10^7 \Gamma \, (\Delta E_A/2T)^{1/2} \cdot \exp(-\Delta E_A/RT) \qquad (27)$$

and

$$\Delta E_C = \Delta E_A - (\Delta H' - RT) = 18.1 r^2 (n+1)\sigma \; , \qquad (28)$$

where σ is the surface tension and n the constant in the relation between σ and temperature T; $18.1 = \pi N/J$.

An empirical relation derived by Burrows and Preece[15] for dinonyl phthalate (at 80°C) is of the form

$$\lg \Gamma = 0.62\,\Delta E_A - 7.93 \; ,$$

where ΔE_A is expressed in kcal mole^{-1}. The radius of the "hole" was found to be about 3.4 Å.

The effect of the entropy factor on the chromatographic process has been investigated in a number of studies[15,17,37,38]. It has been shown that very often the separation of the sample components is in fact due to the differences in their entropies of solution. Korol'[38] obtained the following formula for the determination of the excess entropy of solution Δs:

$$\Delta s = \beta C_1 \ln\frac{1}{M} + C_2 \; , \qquad (30)$$

where β is a function of the heat of solution and the rigidity of the solvent and solute molecules ($\beta = 0$ corresponds to complete filling of the "holes" while maintaining the structure of the stationary phase), M the number of "holes" per mole of substance, and C_1 and C_2 are constants. Zhukhovitskii et al.[36] also examined the components of the excess entropies: the entropy of migration of the centre of mass

of the molecule and the entropy of rotation of the molecule and its individual parts, the first term being calculated from the excess entropy of a non-polar spherical molecule (carbon tetrachloride) in solution in a saturated hydrocarbon.

In concluding this section, the possibility of rapid chromatographic separation of high-boiling polar compounds may be pointed out. Since the low vapour pressure of such substances in the pure state is due to molecular association, the retention time is sharply reduced in chromatographic analysis on a column with a non-polar phase, where the interactions between solute molecules may be neglected and only dispersion forces act between solvent and solute molecules[5,38]. For example, in experiments on a column with n-heptadecane (at 22°C) the peak of ethylene glycol, which has a boiling point of 197.2°C, is recorded between the peaks due to hexane and heptane, which boil at 68.7° and 98.4°C respectively. Here of course particular attention must be paid to the selection of a carrier with low adsorption activity§. This procedure is also used in the analysis of polar substances by gas-adsorption chromatography[39].

Finally yet another peculiarity, which occurs in the analysis of polar substances on columns with polar stationary phases, may be noted. It has been shown[40-42] that here the absorption of the components being separated is accompanied by their adsorption on the surface of the liquid. Here the retention volume should be defined as the sum of two terms, one of which is the function of Henry's absorption constant and depends on the amount of the liquid phase and the other is a function of the surface excess Γ and depends on the area.

3. RELATION BETWEEN MOLECULAR STRUCTURE AND SORPTION PROPERTIES

One of the first attempts to establish the relation between the activity coefficient and the structure of solvent and solute molecules was made by Pierotti et al.,[43] who proposed the so-called "structural block" method. According to their concept, in which the interactions between the functional groups and alkyl radicals of both molecules are considered, the following relation should hold:

$$\lg \gamma = A + \frac{B - n_C}{n'_C} + \frac{C}{n_C + C'} + D\,(n_C - n'_C)^2 + \frac{F}{n'_C + F'} \quad , \qquad (31)$$

where n_C is the number of methyl and methylene groups in the solute molecule, n'_C the number of the corresponding groups in the solvent molecule, and A, B, C, D, F, C', and F' are constants[20]. A linear relation between $\lg \gamma$ and the number of carbon atoms in the solute molecule follows from Eqn. (31) for the analysis of homologues on a column with a definite phase. In the choice of stationary phases and also in the identification of the components of the mixtures being analysed, relations between retention volumes and the number of carbon atoms in the molecule, the boiling point T_b, or the vapour pressure p^0, which are valid within the limits of a single homologous series of solutes, are widely used. Herington[44] showed that, for the logarithm of the retention volume defined by

$$\lg V^{rel} = \lg \frac{p_1^0}{p_2^0} + \lg \frac{\gamma_1}{\gamma_2} \quad , \qquad (32)$$

where subscript 1 refers to the component being analysed and subscript 2 to a standard, the following relations hold,

$$\begin{aligned} \lg V^{rel} &= a + b\ n_C, \\ \lg V^{rel} &= a_T + b_T\ T_b \quad , \\ \lg V^{rel} &= a_s - b_s \lg p^0 \quad , \end{aligned} \qquad (33)$$

where a, b, a_T, a_s, and b_s are constants whose values depend on the nature of the stationary phase, the working temperature, and the homologous series of the substances being separated.

There is a linear relation also between the retention volumes of the components of a given homologous series on two columns with different stationary phases[45]. Fig. 2 shows that in separation on a column with a non-polar phase the straight lines corresponding to different homologous series are significantly closer to one another than in separation on a polar phase[46].

The selectivity coefficient k'_s for adjacent components of the same homologous series is of course constant, since the heat of solution Q is an additive quantity:

$$Q = Q_0 + Q_{CH_2}\ n_C \quad , \qquad (34)$$

where Q_0 and Q_{CH_2} are constants.

Zhukhovitskii and coworkers[1,47] proposed a more general relation than Eqn. (33):

$$\lg V^{rel} = a' + b' \frac{T_b}{T} \quad , \qquad (35)$$

which holds over a definite range of working temperatures T. Relations between the retention volumes and other physicochemical characteristics of the substances to be separated,

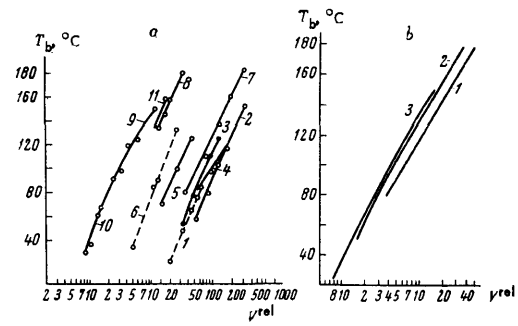

Fig. 2. Variation of the relative retention volumes with the boiling points[44]:
a) column with di(β-cyanoethyl) ether; temperature 67°C: 1) aldehydes; 2) ketones; 3) acetates and formates; 4) alcohols; 5) acetylenes; 6) ethers; 7) alkylbenzenes; 8) alkylcyclohexanes; 9) straight-chain saturated hydrocarbons; 10) olefine; 11) alkylcyclopentanes;
b) column with Fluorolube; temperature 100°C: 1) alkylbenzenes; 2) cycloalkanes; 3) straight-chain saturated hydrocarbons, methylparaffins, and olefins.

§ Without considering in detail the questions associated with the choice of the solid carrier, it may be noted that the interfering effect of the latter on the retention characteristic is often very considerable.

for example refraction[48], the parachor[49], dipole moment[50], etc., are also used in practice. Anvaer et al.[14] showed that, when the work expended to remove equal volumes of the solvent and solute (saturated hydrocarbons) is the same the heat of solution Q should be related to the heat of evaporation λ_v as follows:

$$Q = \frac{\lambda_v}{V_1} V_2 \ , \qquad (36)$$

where V_1 and V_2 are the molar volumes of the solvent and solute. Consequently a linear relation between the logarithm of the reduced retention characteristic and V_2 should hold within the limits of each homologous series.

A method for the calculation of retention parameters, based on the physicochemical characteristics of the solvent and solute, has been proposed by Martire[51], who started with Hildebrand's equation:

$$\ln \gamma = \frac{V_2}{R \cdot T} \Phi_1^2 (\delta_1 - \delta_2)^2 \ , \qquad (37)$$

where V is the molar volume, Φ_1 the volume fraction of the solvent in the solution, $\delta = \sqrt{\lambda_v / V}$ is a solubility parameter, subscript 1 refers to the solvent and subscript 2 to the solute. Since Eqn. (37) holds only for non-polar molecules and for positive deviations from Raoult's law, Martire added appropriate terms and obtained the relation

$$\ln \gamma = \frac{V_2}{R \cdot T} \Phi_1^2 [(\delta_1 - \delta_2)^2 + (\omega_1 - \omega_2)^2 - C] \ , \qquad (38)$$

where $\omega \simeq \mu^2/V$, μ is the dipole moment, and C characterises the negative deviation from Raoult's law, $C = k(V_2/\delta_2)$ and k depending only on the nature of the solvent.

Anvaer[52] based his treatment on a familiar model, according to which the transfer of a molecule with radius r and dipole moment μ from the vacuum into a dielectric with dielectric constant ϵ involves an energy gain:

$$\Delta E = \frac{2}{9} \frac{\mu^2}{r^3} \left(1 - \frac{1}{\varepsilon}\right) \ . \qquad (39)$$

If it is assumed that the work ΔE corresponds to the free energy change, there is a linear relation between the logarithm of Henry's constant (or the logarithm of the relative retention volume) of any component and $1/\epsilon$. This hypothesis has been used[52] to classify stationary phases.

It is interesting to examine the variation of sorption characteristics within a homologous series of stationary liquids. According to the Clausius–Mosotti equation, the molecular polarisation P_{mol} is

$$P_{mol} = \frac{\varepsilon - 1}{\varepsilon + 2} V_1 = \frac{4}{3} \pi N \left(\alpha + \frac{\mu^2}{3kT}\right) \ , \qquad (40)$$

where $\alpha = \alpha_{at} + \alpha_{el}$, α_{at} is the atomic polarisability, α_{el} the electronic polarisability, $\alpha_{or} = \mu^2/3kT$ the orientation polarisability, and k is the Boltzmann constant. Using the equation $\frac{4}{3}\pi N \alpha_{el} = M_R$, where M_R is the molecular refraction, Sakharov[53] obtained the relation

$$\frac{\varepsilon - 1}{\varepsilon + 2} = \frac{M_R}{V_1} + \frac{4}{9} \frac{\pi N}{kT} \frac{\mu^2}{V_1} \ . \qquad (41)$$

The ratio M_R/V_1 and the dipole moment are almost constant within a homologous series and therefore, in accordance with Onsager's equation, we have

$$\Delta E = \frac{\mu^2}{r^3} \frac{\varepsilon - 1}{2\varepsilon + 1} \ , \qquad (42)$$

which is more accurate than Eqn. (39), since the mutual polarisation of molecules is taken into account. Sakharov showed that the following equation holds for a particular component:

$$\lg \Gamma \simeq A \frac{1}{V_1} + B \ . \qquad (43)$$

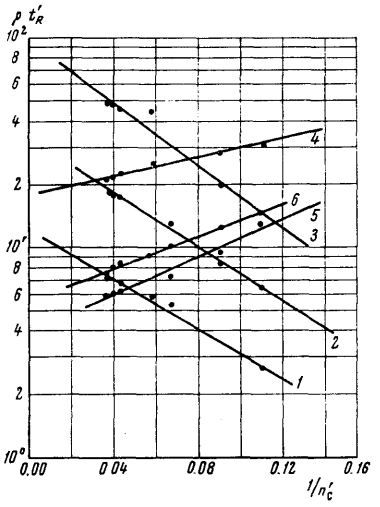

Fig. 3. Variation of the product of the reduced retention time t'_R and the density of the stationary phase ρ with the reciprocal of the number of carbon atoms in the molecule of the stationary phase (dialkyl phthalates); temperature 50°C:
1) n-hexane; 2) n-heptane; 3) n-octane; 4) benzene; 5) methanol; 6) ethanol.

Indeed it has been shown in the work of Chovin and Ducros[54], Petsev and Dimitrov[55], and the author of the present review[56,57] that the relation between $\lg\Gamma$ and the number of carbon atoms n'_C in the stationary phase molecule is non-linear, although it does approach linearity for fairly high values of n'_C. However, the plot in Fig. 3 shows that the relation between $\lg\Gamma$ and $1/n'_C$ is in fact linear.

4. CLASSIFICATION OF STATIONARY PHASES

A number of investigators have based the classification of stationary phases on the relation between the polarity and the retention characteristics of specified substances. Rohrschneider[58] placed the stationary phases along the abscissa axis (Fig. 4) so as to obtain a linear variation of the logarithm of the retention volume of divinyl relative to butane on transition from one phase to another. A polarity of zero was attributed to squalane and a polarity of 100 to di(β-cyanoethyl) ether. This made it possible to characterise stationary phases by the corresponding polarity indices.

In other investigations[59–62] almost the same method of classification was used but with the difference that acetylene and ethane, methanol and butane, two straight-chain saturated hydrocarbons, etc. were used as standards. Sakharov[53,63] showed that all these methods follow from the general relation

$$\lg V^{rel} = B_1 \lg V_{st}^{rel} + B_2 \ , \qquad (44)$$

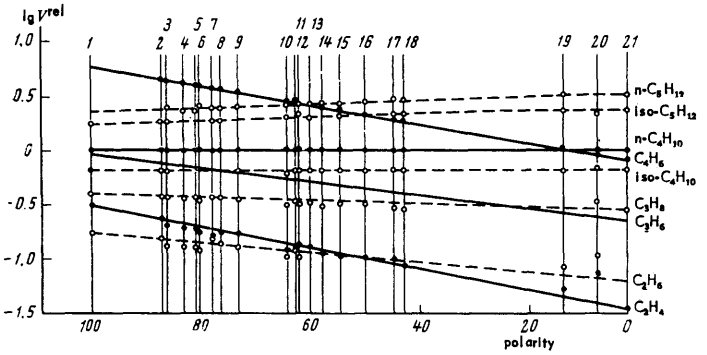

Fig. 4. Relation between the retention volume of a substance (relative to n-butane) and the polarity of the stationary phase[53]:
1) di(β-cyanoethyl) ether; 2) *N*-methylacetyl-β-aminopropionitrile; 3) *N*-formylmorpholine; 4) propylene glycol carbonate; 5) ethyl cyanoacetate; 6) dimethylformamide; 7) poly(ethylene glycol) 600; 8) glycol sulphite; 9) acetonylacetone; 10) benzyl cyanide; 11) diethylformamide; 12) diethylcyanamide; 13) propylene glycol sulphite; 14) epoxypropylmorpholine; 15) 1,3-butylene glycol sulphite; 16) *N*-β-hydroxypropylmorpholine; 17) dibenzyl ether; 18) dibutylformamide; 19) 1-chlorooctadecane; 20) silicone oil; 21) squalane.

where V^{rel} is the relative retention volume of a particular component, V_{st}^{rel} the relative retention volume of the standard, and B_1 and B_2 are constants; B_1 characterises the polarity of the substance being analysed and lg V_{st}^{rel} serves as the characteristic of the polarity of the solvent (for the latter one can use not only the logarithm of the retention volume of the standard but also some other suitable quantity in particular $1/\epsilon$). Sakharov pointed out that the correct choice of the standard can significantly reduce the error in the determination of retention characteristics; it is recommended that a substance belonging to the same class of compounds as the component being analysed should be selected as the standard.

The above method of classification has important advantages because it greatly simplifies the choice of stationary liquids for the separation of particular mixtures and also for the identification of unknown components. However, it also has a number of disadvantages, associated with failure to take into account the entire wide variety of intermolecular interactions between stationary phases and the substances being separated.

Plots of the retention index [see Eqn. (46)] against the polarity of the stationary phase have been quoted by Chovin[54]. Lazarse and Roumazielles[65] showed that the relation between the polarity and the ratio of the reduced retention volumes of straight-chain saturated hydrocarbons (with $z + 1$ and z carbon atoms in the molecules) multiplied by the absolute temperature of the column is of the same type.

The method proposed by Brown[66] is based on a characteristic of only the donor–acceptor properties of stationary phases. On a triangular graph, each phase has a point with the coordinates

$$\frac{V_n}{V_n+V_a+V_d}, \frac{V_a}{V_n+V_a+V_d}, \text{and} \frac{V_d}{V_n+V_a+V_d},$$

where V_n, V_a, and V_d are respectively the retention volumes of a non-polar substance and an electron acceptor and donor on a column with the given phase. n-Hexane, ethanol, and 2-butanone and also n-decane, 1,1,2-trichloroethylene, and dioxan have been used as the standard substances for the determination of the properties of the phases. The position of the point relative to the vertices of the triangle can serve as a characteristic of the phase.

5. METHODS OF SELECTION OF STATIONARY PHASES

In selecting the stationary phase to solve a particular analytical problem the greatest attention is of course given to the selectivity of the phase. Furthermore, there are additional requirements, which include: (1) the absence of chemical interaction with the substance to be separated, the solid carrier, the column wall, and the carrier gas; (2) chemical stability under operating conditions; (3) low vapour pressure under operating conditions; (4) low viscosity. It is desirable that the phase should be readily available and that it should contain the minimum amount of impurities.

Depending on the composition of the mixture to be analysed, the following aspects of selectivity should be considered; (1) selectivity as the capacity to separate any two components; (2) selectivity as the capacity to separate the components of a single homologous series; (3) selectivity as the capacity to separate the components of two (or several) homologous series[67].

The selection of the stationary phase for the separation of two components must be based in the general case on the retention characteristics of the substances taken from the literature[1,9,68–74] or determined experimentally. In the analysis of homologues the principal criterion in the selection of the stationary phase is the coefficient b in the equa-

tion relating the logarithm of the reduced retention characteristic and the number of carbon atoms in the molecule [see Eqn. (33)]. For adjacent homologues, the selectivity coefficient k_s of the stationary phase is

$$k_s = 2\frac{10^b - 1}{10^b + 1} \quad (45)$$

i.e. the selectivity is greater the larger is b.

If instead of the retention volume one uses[75-78] as the retention characteristic the retention index I, defined by

$$I = r\frac{\lg V'_{R_x} - \lg V'_{R_z}}{\lg V'_{R_{(z+r)}} - \lg V'_{R_z}} + z \quad (46)$$

(a quantity larger by a factor of 100 was used by Kovats and coworkers[75-78]), where V'_{R_x}, V'_{R_z}, and $V'_{R_{z+r}}$ are the reduced retention volumes of the substance analysed and straight-chain saturated hydrocarbons with z and $z + r$ carbon atoms in the molecules, then the selectivity, considered as the capacity to separate homologues, can be estimated as the difference between the retention indices of adjacent homologues:

$$\Delta I = b/b_p \ , \quad (47)$$

where the coefficient b_p refers to the homologous series of straight-chain saturated hydrocarbons (paraffins).

If the problem is to separate the components of two homologous series, it is necessary to use a stationary phase which causes a shift of the $\lg V^{rel} - n_C$ linear plot for one series relative to that for another, and the shift can serve as a measure of the selectivity of the phase.

Bayer and Rock[79] introduced a selectivity factor δ, which is equal to the ratio of the reduced retention characteristics of two substances belonging to different homologous series and having different boiling points (or more precisely substances which have the same vapour pressures at the working temperature):

$$\delta = \frac{V'_{R_2}}{V'_{R_1}} = \frac{p_1^0\gamma_1}{p_2^0\gamma_2} = \frac{\gamma_1}{\gamma_2} \ . \quad (48)$$

The values of δ for various sorbents and classes of substances to be separated, determined by graphical interpolation, have been widely used[68,80].

It can be shown that the relation between the factor δ and the selectivity coefficient k_s is

$$k_s = 2\frac{10^b - 1}{10^b + 1} = 2\frac{\delta\left(\frac{p_1^0}{p_2^0}\right)^{b_s} - 1}{\delta\left(\frac{p_1^0}{p_2^0}\right)^{b_s} + 1} \quad (49)$$

when $\delta(p_1^0/p_2^0)^{b_s} > 1$, which corresponds to the elution of the components in the sequence 1–2, and

$$k_s = 2\frac{\frac{1}{\delta}\left(\frac{p_2^0}{p_1^0}\right)^{b_s} - 1}{\frac{1}{\delta}\left(\frac{p_2^0}{p_1^0}\right)^{b_s} + 1} \quad (50)$$

when $\delta(p_1^0/p_2^0)^{b_s} < 1$, which corresponds to the reverse sequence. Instead of $(p_2^0/p_1^0)^{b_s}$, one can use the expression $10^{b\Delta T_b}$, where ΔT_b is the difference between the boiling points of the components to be separated.

Thus the phase with the greatest or smallest factor δ (i.e. the phase which ensures the highest value of the coefficient k_s) is the most effective for the separation of a pair of substances belonging to different homologous series.

Suppose, for example that such pairs are heptane–hept-1-ene and decane–benzene. Fig. 5 shows the relation between the logarithms of the reduced retention volumes and the boiling points of straight-chain saturated hydrocarbons, straight-chain olefins, and alkylbenzenes in analysis on columns with squalane and adiponitrile[67]. It is evident from the graph that δ for olefins and saturated hydrocarbons is 1.90–1.95 on adiponitrile and 1.0 on squalane.

Adiponitrile is one of the most selective phases for the separation of the above classes of compounds. Calculation of the coefficient k_s shows that it is 0.15 for the non-polar phase and 0.53 for the polar phase and thus the latter is preferable. On the other hand, because of the considerable difference between the boiling points of benzene and decane, in their separation the non-polar phase with δ = 1.2 is preferable to the polar phase with δ = 16.0, since in the first case we have k_s = 1.8 and in the second 0.3.

It follows from the above example that the choice of the best phase for the separation of any pair of substances can be based on the tabulated values of δ.

Similarly it is possible to select optimum phases for the analysis of 3- and 4-component mixtures of substances belonging to two homologous series[67]. Thus if substances 1 and 2 belong to one series and substance 3 to another,

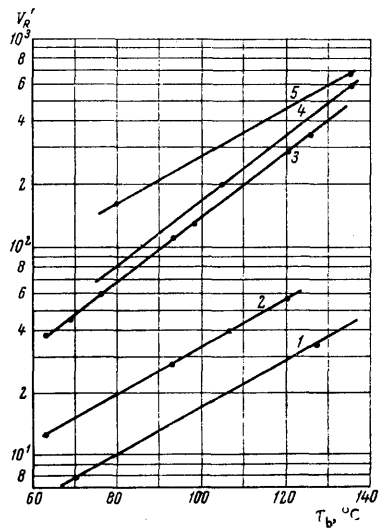

Fig. 5. Relation between the reduced retention volumes and the boiling points of hydrocarbons on columns with squalane and adiponitrile at 40°C:
1) straight-chain saturated hydrocarbons, adiponitrile; 2) straight-chain olefins, adiponitrile; 3) straight-chain saturated hydrocarbons and straight-chain olefins, squalane; 4) aromatic compounds, squalane; 5) aromatic compounds, adiponitrile.

the optimum value of δ for a phase which would ensure elution in the sequence 1–3–2 is

$$\delta = \frac{(p_3^0)^{b_s}}{(p_1^0\ p_2^0)^{0.5 b_s}} \quad \text{or}$$

$$\lg \delta = 0.5\, b_\tau (T_{b_1} + T_{b_2} - 2T_{b_3}) \qquad (51)$$

it being assumed that the values of b_s are similar for both series.

Since the order of elution is influenced both by the selectivity of the phase and the vapour pressures of the components, evidently by itself a certain degree of selectivity of the phase in relation to one of two homologous series does not ensure the separation of these components. Thus mixtures of straight-chain saturated hydrocarbons and alkylbenzenes have been separated on columns with technical fractions of aliphatic acids as the stationary phases[81]. The corresponding chromatograms are shown in Fig. 6. Whereas on the column with the light acid fraction the benzene peak is superimposed on the heptane peak, when the vat residue is used the retention volume of benzene increases and the latter is eluted after heptane. Even greater selectivity in relation to aromatic hydrocarbons is shown by the middle acid fraction on a column in which benzene is eluted together with octane.

Thus it is evident from the chromatograms that, although the middle acid fraction is in fact more selective, the vat residue or even the non-polar liquid paraffin are more suitable for a clear separation of saturated hydrocarbons and alkylbenzenes (Fig. 7).

In the separation of components belonging to two homologous series approximately equal separation factors for all pairs of peaks can be achieved in two ways[82]:

a. By using a selective sorbent characterised by

$$k_{s1,2} = \frac{10^{b_s(m+1)} - 1}{10^{b_s} - 1} k_{s1} \text{ and } k_{s1} \simeq k_{s2}\ , \qquad (52)$$

where $k_{s1,2}$ is the selectivity coefficient with respect to the lightest of the components to be separated in both series, m the difference between the numbers of carbon atoms in the molecules of the last and first component of the first homologous series, and k_{s1} and k_{s2} are the selectivity coefficients for adjacent components of the first and second homologous series. An example of such separation is the analysis of a mixture of straight-chain saturated hydrocarbons and alkylbenzenes on a column with di(β-cyanoethyl) sulphide, where benzene is eluted after nonane. The fraction width Δn, defined as the number of components of the first series which can be separated from the components of the second series, is $\Delta n = m + 1 = 4$. In the examples quoted above with aliphatic acid fractions as stationary phases (Fig. 6) $\Delta n = 1$ for the column with the light fraction and $\Delta n = 2$ for the column with the middle fraction.

b. By using a sorbent of moderate selectivity, characterised by

$$k_{s1,2} \simeq 0.5\, k_{s1} \text{ and } k_{s1} \simeq k_{s2}\ , \qquad (53)$$

i.e. a sorbent which ensures the alternation of the components of both series on elution.

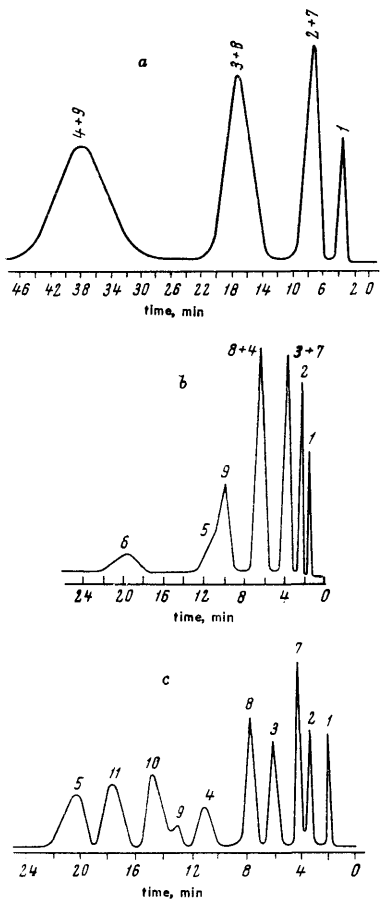

Fig. 6. Chromatograms of mixtures of straight-chain saturated hydrocarbons and alkylbenzenes on columns with different aliphatic acid fractions:
a) light fraction; *b*) middle fraction; *c*) vat residue;
1) hexane; 2) heptane; 3) octane; 4) nonane;
5) decane; 6) undecane; 7) benzene; 8) toluene;
9) ethylbenzene; 10) *m*- and *p*-xylenes; 11) *o*-xylene.

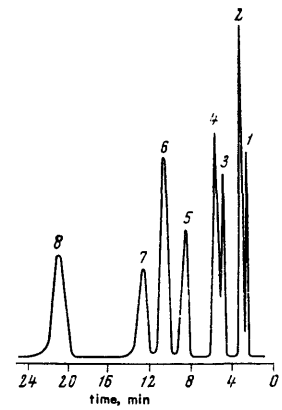

Fig. 7. Chromatogram of hydrocarbons on a column with liquid paraffin:
1) benzene; 2) heptane; 3) toluene; 4) octane;
5) ethylbenzene; 6) nonane; 7) isopropylbenzene; 8) decane.

Relations (53) can hold within wide limits only when the coefficients b_1 and b_2 are identical for both series. Therefore the maximum width of the fraction to be separated should be defined by the formula

$$\Delta n = m + 1 = \frac{0.5\, b_1}{b_2 - b_1} + 1 \quad . \qquad (54)$$

The last condition corresponds to the relation $k_{s1,2} \geq 0.25\, k_{s1}$, i.e. the light component of one series is located midway between two components of the second series and is somewhat displaced towards one of them.

The choice of individual sorbents satisfying the specified conditions is very difficult in many cases, particularly when one deals with the separation not of two but of a large number of homologous series. The search for such sorbents to solve each concrete problem would result in an excessive number of phases used, which is already fairly large. Therefore considerable importance attaches to the use of binary sorbents permitting fine regulation of the selectivity and enabling the peaks on the chromatogram to be displaced relative to one another. A separate section deals with this question.

The procedure involved in the selection of the stationary phase can be significantly simplified by using the relation between the molecular structure of the substance to be separated and its absorption capacity. Recently a number of communications have appeared, dealing with the possibility of calculating the retention volumes assuming additivity, by adding together the increments corresponding to the functional groups[83-87] or different subtypes of the bonds between carbon atoms[88,89]. It is then assumed that

$$\lg V^{rel} = \Sigma n_{ij} A_{ij} \quad , \qquad (55)$$

where n_{ij} is the number of bonds of the given subtype in the molecule of the substance being analysed (or functional groups of the given type) and A_{ij} is the corresponding increment. Eqn. (55) follows from the additivity of the free energy change[90,91], becoming more accurate when a constant term A_0 is introduced on the right-hand side. Special cases of Eqn. (55) are Eqn. (33) and also the method of calculation by the interpolation procedure proposed by Evans and Smith[92].

The authors who calculated retention volumes by the additive procedure used this method only for substances of one class. Indeed when many sorbents are used, the increment per CH_2 group (or bond between secondary carbon atoms) can vary from one homologous series to another. This follows, in particular, from the fact that the $\lg V^{rel}$–n_C lines are not parallel[20,93]. The corresponding lines for various classes of hydrocarbons and their derivatives are parallel only when non-polar solvents are used. Then the method of calculation of retention characteristics by this procedure becomes universal. Evidently the magnitude of the increment is an indication of the selectivity of the phase in relation to the components whose molecules contain the corresponding group or bond[94].

The retention index[75] has significant advantages as a retention characteristic, the additivity of the reduced characteristics entailing the additivity of the index:

$$I = \Sigma n_{ij} B_{ij} + B_0 \quad , \qquad (56)$$

where B_{ij} is the increment per bond (or structural group) and B_0 is a constant.

One of the consequences of Eqn. (56) is the constancy, noted by Evans and Smith[95], within the limits of a homologous series, of the quantity $M_e - M = \Delta M_e$, where M is the molecular weight of the substance and M_e an effective molecular weight equal to the product of the retention index and the sum of the atomic weights of one carbon and two hydrogen atoms (14.026), and also the constancy of "the retention characteristics of the functional group" noted by Swoboda[96].

The difference between the retention indices of two components belonging to different homologous series but containing the same number of carbon atoms in their molecules is a characteristic whereby it is possible to estimate rapidly the suitability of a particular phase for the separation of concrete mixtures. This quantity (δI), which is the difference between the increments per group (or per bond subtype) in the molecules of the series to be separated, is readily tabulated, and does not require a correction for the vapour pressure, which is essential when the factor δ is used. When the coefficients b for homologous series are different, it is necessary to use either average values (as is done in the tabulation of δ values) or values of c and d from Eqn. (57) are tabulated:

$$\delta I = c + d n_C \quad . \qquad (57)$$

The relation between δ and δI is given by equation[97]:

$$\lg \delta + b_T \Delta T_b = b\, \delta I$$

or

$$\lg \delta + b_s \lg \frac{p_1^0}{p_2^0} = b\, \delta I \quad , \qquad (58)$$

where p_1^0 and p_2^0 are the vapour pressures of the substances to be separated, ΔT_b the difference between their boiling points, and b, b_T, and b_s are the coefficients of Eqn. (33).

The difference between the retention indices of a standard substance on squalane and the test phase has also been used as a characteristic of the polarity of the stationary phase[98]. Finally, Rohrschneider[99,100] suggested that the retention indices be calculated from the formula

$$I = I_0 + ax + by + cz + du + es \quad , \qquad (59)$$

where I_0 is the retention index on a column with squalane, a, b, c, d, and e are characteristics of the substance being analysed, and x, y, z, and s are characteristics of the stationary phase.

So far the problem of the selection of stationary phases has been examined only from the standpoint of achieving a definite selectivity without taking into account additional limiting factors, for example the duration of analysis, the column length, the hydraulic resistance of the column[1] etc. It is desirable to select the optimum separation conditions: (a) for a specified accuracy of the analysis (degree of separation of the least readily separated pair of components) on a column of given length with the aim of achieving the fastest possible separation; (b) on a column of given length with the aim of achieving the highest degree of separation; (c) for a specified accuracy with the aim of achieving the most rapid analysis. Therefore, apart from selectivity, it is necessary to consider as the principal properties of the stationary phase its sorption capacity in relation to the most strongly sorbed component and the diffusion characteristics, which are determined by the viscosity.

If the problem is to select a sorbent to attain the most rapid analysis for a specified accuracy on a column of given length, a modified equation for the height equivalent

to the theoretical plate must be resorted to. It can be shown that

$$\frac{H}{L} = A' + B't + C'/t \quad , \tag{60}$$

where H is the height equivalent to the theoretical plate, t the duration of analysis, $A' = A/L$, $B' = B/L^2\Gamma_0$, $C' = C/\Gamma_0$, L is the column length, Γ_0 the overall Henry's constant for the most strongly sorbed component (the ratio of the amount of substance analysed in 1 ml of column volume to its concentration in the gas phase), and A, B, and C are constants of van Deemter's equation[20]. Hence, taking into account Eqn. (2), we have the expression

$$K^2 = \frac{0{,}045\,K_s^2}{A' + B't + C'/t} \quad . \tag{61}$$

Thus the choice of the phase is determined by the specified value of K, the selectivity, and the values of the terms A', B', and C', which depend on the efficiency, column length, and the sorption capacity. Fig. 8 shows different versions of K^2–t plots for two phases under comparison. It is evident that, depending on the specified degree of separation, either one or other phase may be preferable for a more rapid analysis. The time required to separate a two-component mixture for $K = 1$, can be calculated from the relation

$$\frac{t}{K_2} = 22{,}2\,\frac{\Gamma_0 H}{K_s^2 \bar{\alpha}} \quad , \tag{62}$$

where $\bar{\alpha}$ is the average linear flow rate of the carrier gas.

In the analysis of mixtures containing three and more components in the absolute majority of cases the separation factors for neighbouring peaks have different values. Thus, when $K = 1$ is selected for the pair least readily separated, there are "superfluous" sections of the zero line between other pairs corresponding to the excess time expended. The time from the instant of the introduction of the sample to the beginning of the elution of the first peak should be included in this also. If, other conditions being equal, the sorption capacity of the stationary phase is altered in such a way that all the components are separated with equal values of K, the duration of analysis becomes significantly smaller. In other words, on going from a two-component to a multicomponent mixture, the problem of selecting the optimum separation conditions becomes significantly more complex, because a new variable appears, which can be roughly represented by the change of the sorption capacity as a function of the sequential number of the peak on the chromatogram.

The problem of a quantitative estimate of the uniformity of separation was first examined by Peterson and Lundberg[101].

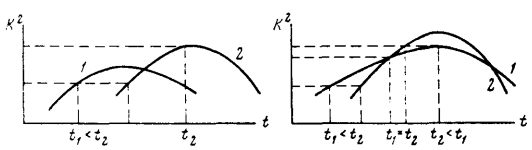

Fig. 8. Various versions on the graphical relation between the degree of separation K and the duration of analysis on a column of specified length with sorbents 1 and 2.

Criteria of the uniformity of separation and the "rapidity" of separation have also been recommended[5,102], whereby it is possible to take into account not only the characteristics determining the separation of two-component mixtures (selectivity, efficiency, sorption capacity) but also those which were previously estimated only qualitatively (uniformity of peak distribution in the chromatogram, desirability of using multistage systems, etc.).

The reduced criterion of uniformity $\bar{\Delta}$ is

$$\bar{\Delta} = \frac{n_k \tau K}{t} \quad , \tag{63}$$

where n_k is the number of peaks, τ the width of the least diffuse peak (in units of time) measured at the height corresponding to the required degree of separation (for example, when almost complete separation is necessary, this is the base of the peak), and K the degree of separation of the pair least readily separated.

The coefficient defining the rate of separation (the "rapid action" coefficient) can be formulated thus:

$$\lambda = \frac{n_k K^2}{t} = \frac{\bar{\Delta} K}{\tau} \quad . \tag{64}$$

The separation of a mixture of C_7–C_{10} straight-chain saturated hydrocarbons on columns containing phases of different polarity [squalane and di(β-cyanoethyl) sulphide] may be examined as an example of the use of λ for the selection of the stationary phase[67]. The corresponding chromatograms and plots of lg V^{rel} against n_C are shown in Fig. 9. The chromatograms were obtained under identical working conditions and for the same efficiency. Evidently best separation on columns of given length is attained with the nonpolar sorbent for which $b = 0.40$ and $k_s = 0.86$ (for the polar sorbent $b = 0.34$ and $k_s = 0.75$). However, if the duration of analysis is the decisive parameter, it is necessary to compare the coefficient defining the rate of separation. Then it was found that the separation of the mixture with the specified degree of separation can be carried out

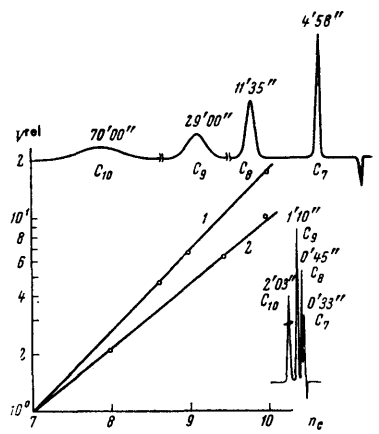

Fig. 9. Variation of the relative retention volumes of straight-chain saturated hydrocarbons with the number of carbon atoms in the molecule; stationary phases:
1) squalane; 2) di(β-cyanoethyl) sulphide; chromatograms obtained on a column 1.2 m long at 60°C and a carrier gas flow rate of 60 ml min^{-1}.

approximately 27 times faster on a column with the non-polar phase, since the "rapid action" coefficient λ is in this case 27 times larger.

If it is necessary to select a phase ensuring the most rapid analysis with a specified accuracy on a column of given length, then the choice depends on the corresponding value of K. If the value of K achieved on the polar phase for the least readily separated pair (heptane–octane) corresponds to the specified value, the polar phase is to be preferred; otherwise the non-polar phase must be chosen.

An estimate of the conditions of chromatographic analysis and, in particular, the suitability of a particular stationary phase for the solution of a concrete problem can be achieved using certain elements of information theory [103]. Thus a method has been proposed [105] on the basis of the concept of useful information [104], whereby it is possible to compare different versions of the analytical procedure. The information defect is the difference between the indeterminacy N_x obtained in the analysis and the entropy S, where

$$N_x = -\sum_{i=1}^{n_k-1} \frac{\psi_i}{\sum_{i=1}^{n_k-1}\psi_i} \mathrm{ld}\,\frac{\psi_{ie}}{\Sigma\psi_{i_e}}$$

and

$$S = \Sigma \frac{\psi_i}{\Sigma\psi_i} \mathrm{ld}\frac{\psi_i}{\Sigma\psi_i} \quad , \qquad (65)$$

ψ_i is the degree of separation of the ith pair of peaks required for the attainment of the specified accuracy, ψ_{ie} the experimental value of ψ, ld denotes a double logarithm, and n_k is the number of peaks. A decrease of the information defect is evidence that the conditions of analysis have become more satisfactory. Instead of ψ one can use other separation factors and also differences between the retention indices of neighbouring components.

6. BINARY SORBENTS

For an optimum separation of complex mixtures, sorbents with a rigorously defined selectivity are required. The problems in the selection of such sorbents can be successfully solved by using binary sorbents of controllable composition. Thus, in the separation of gaseous saturated and unsaturated hydrocarbons a column with a silver nitrate solution is used, but saturated hydrocarbons are eluted as a single peak. On the other hand, a column with the non-polar liquid paraffin does not always lead to a satisfactory separation of ethane from ethylene and of propane from propene, particularly when the detector exhibits significant inertia and the number of theoretical plates in the column is low¶. To achieve a clear separation of all the peaks it is desirable to connect the two columns in series [35].

Columns containing two (or several) individual sorbents can be prepared as follows: (a) sections with individual sorbents are joined in series (compound column); (b) individual stationary liquids are deposited on a solid carrier, the sorbents are mixed, and loaded into the column (column with a mixed sorbent); (c) a mixture of stationary liquids is deposited on a solid carrier (sorbent with a mixed phase).

The dependence of the elution characteristics of substances on columns with binary sorbents on the relative amounts of the individual stationary phases has been investigated by a number of workers [2,35,58,62,106–115]. In those cases where the pressure gradients are low the separation achieved on a compound column is almost identical with that on a column with a mixed sorbent. If the gradients are considerable, they influence the overall sorption characteristics. Thus the effective retention volume [4] of a component on a compound column is

$$V_N = V_{N_1}\frac{j}{j_1}\,\frac{p_{01}}{p_0} + V_{N_2}\frac{j}{j_2} \quad , \qquad (66)$$

where V_{N_1} and V_{N_2} are the effective retention volumes of the component on sections with the first and second sorbent, j the column pressure gradient factor [116], j_1 and j_2 are the pressure gradient factors in the first and second section, p_0 the pressure at the outlet from the column, and p_{01} the pressure at the boundary between the sections. Analogous relations hold also for other retention characteristics [113]. As a result of the influence of pressure gradients, a very interesting effect, first noted by Zhukhovitskii et al., [114] occurs in experiments with compound columns. A change in the sequence of the sections can result in a change of the degree of separation of the components and even in the elution sequence. This effect has been used, in particular, in the development of a method for the determination of the allene and methylacetylene impurities in the propane–propene fraction [117]. Indeed Figs. 10*b* and 10*c* show that with one sequence of the sections the allene and methylacetylene peaks merge into one, which is necessary to obtain a signal to be fed into the control system of the purification process of the propane–propene fraction, while with the reverse sequence the peaks are separated, which is desirable in laboratory analysis.

Graphical relations are used in the selection of the optimum composition of the sorbents; in the general case it is desirable to use for compound columns relations of the type shown in Fig. 10*a*. Here the retention characteristics (reduced retention time, reduced, effective, or specific retention volume) are plotted against the ratio of the reduced lengths of the sections [122], the reduced length of a section being defined thus:

$$L_{\mathrm{red}\,i} = L_i\frac{p_{oi}}{j_i} \qquad (67)$$

where L_i is the length of the section, p_{oi} the pressure at the outlet from the section, and j_i the pressure gradient factor in the given section.

When the effect of the pressure gradient is neglected, the ratio of the true lengths of the sections can be plotted along the abscissa axis. Thus by plotting along the ordinate axis the ratio (t_R/t_0) of the retention time of the given component to that of a non-sorbed substance, Rohrschneider [58] determined the optimum ratio of the lengths of the sections with diethylcyanamide and di(β-cyanoethyl) ether for the analysis of a mixture of C_1–C_5 hydrocarbons.

The corrected peak width on a compound column (ω, ml) can be determined from the following formula:

$$\omega^2 = \omega_1^2\frac{p_{01}^2}{p_0^2}\frac{j^2}{j_1^2} + \omega_2^2\frac{j^2}{j_2^2} \qquad (68)$$

where ω_1 and ω_2 are the corrected peak widths in the first and second sections. Similarly it is possible to calculate

¶ When a high-efficiency column with a non-polar sorbent is used, completely satisfactory, albeit non-uniform, separation of C_1–C_3 hydrocarbons is achieved [102].

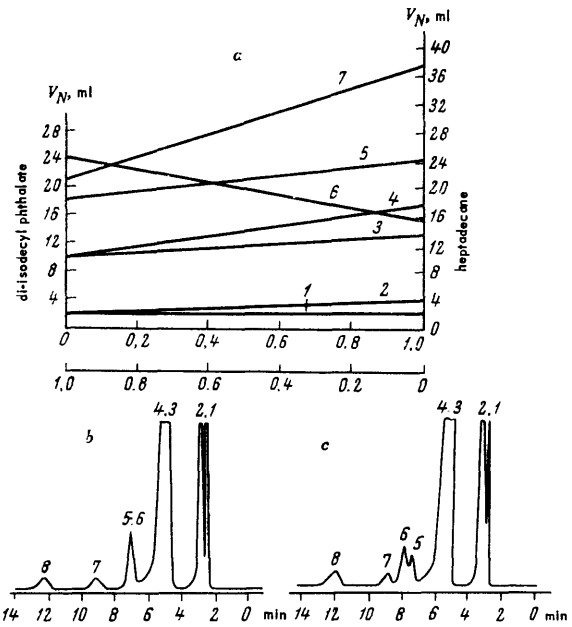

Fig. 10. *a*) Variation of the effective retention volume with the ratio of the effective lengths of sections with heptadecane and di-isodecyl phthalate; chromatograms of the propane–propene fraction on a compound column 7.1 m long;
b) order of sections: 2.4 m with heptadecane and 4.7 m with di-isodecyl phthalate;
c) reverse order; temperature 25°C: 1) ethylene; 2) ethane; 3) propene; 4) propane; 5) allene; 6) methylacetylene; 7) isobutane; 8) n-butane.

the number of theoretical plates, the selectivity coefficient, and the separation factor on compound columns [113]. Thus the degree of separation is defined by the equation:

$$F = \frac{\Delta V_R^2}{\omega_1^2 + \omega_2^2} = \frac{\left(\Delta V_{R_1}^0 \frac{p_{01}j}{p_{0j_1}} + \Delta V_{R_2}^0 \frac{j}{j_2}\right)^2}{\frac{\left(\Delta V_{R_1}^0 \frac{p_{01}j}{p_{0j_1}}\right)^2}{F_1} + \frac{\left(\Delta V_{R_2}^0 \frac{j}{j_2}\right)^2}{F_2}} , \quad (69)$$

where ΔV_R is the difference between the retention volumes of the components on the compound column, ω_1 and ω_2 are the peak widths, $\Delta V_{R_1}^0$ and $\Delta V_{R_2}^0$ are the differences between the corrected retention volumes in the first and second section, and F_1 and F_2 are the separation factors in these sections.

Calculations for columns with mixed sorbents are of course much simpler than for compound columns, because here the optimum ratio of the amounts of the individual sorbents is independent of the pressure gradient. Thus the specific retention volume on a column with a mixed sorbent is

$$V_g = \frac{g_1}{g} V_{g_1} + \frac{g_2}{g} V_{g_2} , \quad (70)$$

where V_{g_1} and V_{g_2} are specific retention volumes (ml g^{-1}) on columns with individual sorbents, $g = g_1 + g_2$, and g_1 and g_2 are the amounts (grammes) of the first and secondary stationary liquid.

The elution characteristics of columns with mixed phases are determined by logarithmic and not linear interpolation. Indeed the following equation follows from the equality of the free energies:

$$\lg V_g = \frac{g_1}{g} \lg V_{g_1} + \frac{g_2}{g} \lg V_{g_2} , \quad (71)$$

This relation is valid only when the excess entropy of the mixture of the two phases is zero [118]. Under the same condition the expression for the retention index is

$$I = I_1 \frac{g_1 b_1}{g_1 b_1 + g_2 b_2} + I_2 \frac{g_2 b_2}{g_1 b_1 + g_2 b_2} , \quad (72)$$

where b_1 and b_2 are the slopes of the plots of $\lg V^{rel}$ against n_C for the first and second phase and I_1 and I_2 are the retention indices on columns with the individual phases.

In conclusion of this section, the work of Porter et al., [119] in which the optimisation of the composition of the mixed phase is achieved with the aid of a computer, may be mentioned.

7. EFFECT OF TEMPERATURE ON THE SELECTIVITY OF THE PHASES; TEMPERATURE LIMITS OF THEIR APPLICATION

Since Henry's constants and also diffusion coefficients depend to a great extent on temperature, the latter is one of the principal factors which determine the duration of analysis, column selectivity, and the degree of spreading of chromatographic zones. Henry's constant (Γ) is known to be exponentially related to the reciprocal of the absolute temperature $1/T$ and therefore an increase of temperature greatly reduces the sorption capacity of the stationary phase.

Fig. 11 shows as an example a plot of the logarithm of the relative retention volume against the reciprocal of temperature† for certain saturated hydrocarbons and cycloalkanes on a column with 12 wt.% of tricresyl phosphate on Chromosorb [120]. Usually, when the temperature is increased, the straight lines corresponding to the individual components approach one another, which leads to a decrease of the selectivity coefficients. This is shown to a particularly high extent when polar forces operate.

However, certain anomalies are also encountered. Thus when a sorbent prepared by solidifying a polyester resin directly on the surface of a solid carrier is used, rapid analysis of a mixture of C_6–C_{10} hydrocarbons can be achieved at 25–30°C. [30] Under these conditions the sorbent exhibits moderate selectivity in the separation of saturated hydrocarbons and alkylbenzenes. When the temperature is raised, the selectivity increases significantly [121]. This is obviously because the sorbent exhibits both adsorption and absorption properties, the latter becoming enhanced at a higher temperature as a result of the decrease of viscosity.

Several papers [122–124] describe chromatographic separation on columns with phases having anisotropic properties and forming liquid crystals in certain temperature ranges. When the temperature is raised above a certain limit, the retention volume decreases sharply, because the phase passes into an isotropic state. The capacity of certain

† A relation of the type of the Antoine equation is more accurate in many cases: $\lg V^{rel} = A + B/(C + T)$, where A, B, and C are constants.

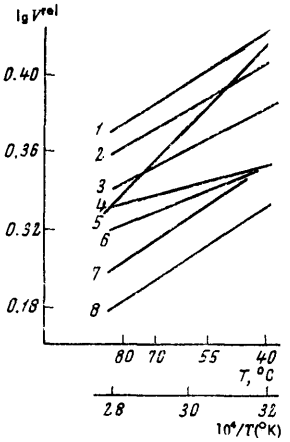

Fig. 11. Variation of the relative retention volume with the operating temperature of a column with tricresyl phosphate: 1) *trans*-1,2-dimethylcyclopentane; 2) *trans*-1,3-dimethylcyclopentane; 3) *cis*-1,3-dimethylcyclopentane; 4) cyclohexane; 5) heptane; 6) 1,1-dimethylcyclopentane; 7) 3-ethylpentane; 8) 2,2,4-trimethylpentane.

substances (in particular *pp*-azoxyphenetole) to form liquid crystals and exhibit selectivity at the same time have been used for the separation of the isomeric xylenes. It is also interesting to note that in many cases it is possible to alter the elution sequence of various substances by altering the temperature. Thus Fig. 11 shows that the position of the heptane peak alters relative to the peaks of the other substances as a function of the operating temperature.

If the values of Γ_S [see Eqn. (14)] for the components being separated are equal, the selectivity coefficient for the column is

$$K_c = \frac{2\varkappa_1\Gamma_S\left(e^{Q_2/RT} - e^{Q_1/RT}\right)}{2\varkappa + \varkappa_1\Gamma_S\left(e^{Q_2/RT} + e^{Q_1/RT}\right)}, \qquad (73)$$

where $\varkappa$ is the fraction of the column volume occupied by the gas phase, $\varkappa_1$ the fraction of the volume occupied by the stationary phase, Q_1 and Q_2 are the heats of solution, and R is the gas constant.

The following relation holds for diffusion in the liquid phase:

$$D_L = D_0 e^{-\beta Q/RT}, \qquad (74)$$

where D_0 is a constant and β the coefficient which can be assumed to be approximately 0.35.[125]

Analysis of theoretical and practical data shows that usually the degree of separation increases as the temperature is reduced, but this involves an increase in the duration of analysis. Evidently it is desirable to reduce simultaneously the operating temperature and the degree of impregnation[126,127], if the overall temperature dependence of the selectivity, sorption capacity, and efficiency indicates an increase of λ.

For a specified duration analysis, there exists an optimum temperature in each system corresponding to the maximum degree of separation. With decrease of the sorption capacity, the optimum temperature falls[82].

The range of operating column temperatures is known to be limited by the requirement that the stationary phase should be almost involatile. But it is recommended that the vapour pressure of the phase at the operating temperature should be not more than 0.5 mmHg (in certain cases a vapour pressure up to 10 mmHg is permitted). The ranges of the operating temperatures for columns with different phases have been tabulated[3,12], their limits being determined not only by the nature of the phase but also by the type of detector and other conditions[129-131]. Since the vapour pressure is related logarithmically to temperature, the "life time" of the column τ_k also decreases logarithmically with temperature. According to Kaiser[9], $\lg \tau_k = k/T$, where k is a constant.

The maximum operating temperature of sorbents with the stationary phases usually employed is such that losses during the first hour of the experiment do not exceed 1% of the total amount of the phase and in the "steady state" they do not exceed 0.1% (the larger losses during the first hour are due to the evolution of volatile impurities)[132]. Only in rare cases are more considerable losses permitted; for example, dimethylformamide, which exhibits high selectivity in the separation of saturated hydrocarbons and olefins, is highly volatile and even at 20°C the losses amount to about 3% per hour.

The method for the determination of the volatility of stationary phases is as follows[132]: 2.0 g of the stationary phase is mixed with 8.0 g of ignited refractory brick and placed in a weighed glass tube. The sorbent layer is compacted somewhat by tapping the tube, after which the tube is reweighed and closed on top by a layer of glass wool. It is then connected to a nitrogen supply and placed in a thermostat set at the required temperature. The flow rate of nitrogen is maintained at 15 ml min^{-1}. After an hour the tube is removed from the thermostat, the nitrogen supply is disconnected, and after being cooled in a desiccator the tube is weighed again. The losses during the first hour and the average losses in the course of the next three hours are recorded.

8. EFFECT OF THE STATIONARY PHASE ON THE SPREADING OF CHROMATOGRAPHIC ZONES

Since the peak width depends both on the sorption characteristic and on the diffusion coefficient in the liquid phase, it is evident that the nature of the stationary liquid phase and its operating conditions have a significant effect on the spreading of the chromatographic zones. Indeed the peak width of the elution curve is related to the width on the sorbent layer σ (cm) by the expression

$$\omega = \Gamma_0\sigma \simeq \Gamma_0\sqrt{LH}, \qquad (75)$$

where Γ_0 is the overall Henry's constant, H the height equivalent to the theoretical plate, and L the column length.

The effect of the stationary phase on the spreading of peaks within the limits of a homologous series has been examined by Turkel'taub[133], who established a linear relation between the logarithm of the peak width and the ratio of the boiling point of the substance to the column temperature. As a result of the proportionality between the peak width and the overall Henry's constant, a linear relation holds between the reduced peak width (the difference between the peak width of the component being analysed and the peak width of a non-sorbable substance) and the number

of carbon atoms in the molecule. This relation obtains also when the column efficiency changes significantly on going from one homologue to another.

If mass transfer by internal diffusion plays a decisive role in zone spreading, the degree of separation is $K' = (\frac{1}{2}\Delta V_R)/\omega_{0.5(1)}$, where ΔV_R is the difference between the retention volumes of adjacent homologues and $\omega_{0.5(1)}$ is the peak half-width of the first homologue, which is related as follows to the number of carbon atoms in the molecule:

$$\lg K' = a' + 0{,}5\, b \cdot n_c \quad . \qquad (76)$$

Here the constant b is the same as in Eqn. (33) and therefore the slope of the $\lg K'-n_C$ line is smaller by a factor of two than the slope of the $\lg V^{rel}-n_C$ line[5].

One of the requirements which must be met by the stationary liquid is that its viscosity should be low. This is quite reasonable when it is remembered that the viscosity is inversely proportional to the diffusion coefficient in the liquid phase. Thus Duffield and Rogers[134] showed that the efficiency of a column with Carbowax 400, whose viscosity is 102 cP (at 25°C), is significantly lower than that of a column with phenylacetonitrile, whose viscosity is 1.98 cP. Quantitative relations characterising the effect of viscosity on efficiency have been given in a number of papers[5,130,135].

If it is assumed that column efficiency is determined solely by internal-diffusion mass transfer, the ratio of the "rapid action" coefficients for two stationary liquids is

$$\frac{\lambda_2}{\lambda_1} = \left(\frac{K_{s2}}{K_{s1}}\right)^2 \left(\frac{\Gamma_{02}}{\Gamma_{01}}\right)^2 \frac{\Gamma_1}{\Gamma_2}\frac{\zeta_1}{\zeta_2}\left(\frac{M_2}{M_1}\right)^{0.5} \frac{\Gamma_{n.1\,(n)}}{\Gamma_{02\,(n)}} \quad , \qquad (77)$$

where the subscripts 1 and 2 refer to the stationary phases, K_s are the selectivity coefficients for the least readily separated pairs, the subscript n refers to the last component, ζ is the dynamic viscosity, and M the molecular weight of the phase. This relation makes it possible to estimate the gain as regards duration of analysis, associated with the selection of a phase having a low viscosity. Examples of the employment of such phases are the rapid analyses on columns with adiponitrile and straight-chain saturated hydrocarbons[5,102].

The data reviewed thus show that, by taking into account the physicochemical characteristics of stationary phases and various relations between them and the retention and spreading parameters, it is possible to solve successfully the problems involved in the selection of the optimum conditions for chromatographic separation.

I. INTRODUCTION

Various properties of solid polymers depend decisively on the nature of the motion of the individual groups and segments of the molecular chains from which they are built up. Therefore it is both of practical and theoretical importance to know the type of molecular motion occurring in the given polymer and the dependence of the type of motion on the composition, structure, molecular weight, temperature, and other factors. One of the most useful physical methods for the investigation of the internal motion of polymeric chains is the internal friction method, the essential features of which are as follows.

When a body is deformed, internal forces (or stresses) arise, due to the change in the distribution of molecules or atoms in it. If the stresses and the relative deformations throughout the period of operation of external forces remain constant and fall to zero instantaneously when the operation of such forces ceases, then we are dealing with a perfectly elastic substance. The isothermal state of such a substance, if the latter is isotropic, is known to be described by the generalised Hooke's law [1]:

$$\sigma_{ik} = 2G\left(u_{ik} - \frac{1}{3}\delta_{ik}u_{ll}\right) + K \cdot u_{ll} \cdot \delta_{ik}\,, \qquad (1)$$

where $\dot{u}_{ik} = 0$ when the external forces are constant. Here σ_{ik} is the elastic stress tensor, u_{ik} the deformation tensor, and G and K are the moduli of shear and bulk elasticity respectively.

It is possible also to imagine another ideal case, where the relative deformations of the substance are not constant under the action of constant external forces, but increase continuously at a particular constant rate which is proportional to the stress. The behaviour of such an ideally viscous isotropic material is described [1] by the generalised Newton equation:

$$\sigma'_{ik} = 2\eta\left(\dot{u}_{ik} + \frac{1}{3}\delta_{ik}\dot{u}_{ll}\right) + \zeta\dot{u}_{ll} \cdot \delta_{ik}\,, \qquad (2)$$

where σ'_{ik} is the dissipative stress tensor, $\dot{u}_{ik}$ the derivative of the deformation tensor with respect to time, and η and ζ are the shear and bulk viscosities.

However, in no real substance with a definite structure can stresses exist indefinitely or decrease instantaneously, since during deformation the structure of the substance changes continuously (and in a complex manner) at a certain finite velocity, determined by the nature of the substance. Therefore the behaviour of a real material is in fact described by more complex relations than Eqns. (1) and (2).

The nature of these relations is most readily elucidated using the state of idealised linear stress as an example. Since shear deformations are of the greatest importance in mechanical problems associated with polymers and plastics, we shall consider homogeneous shear deformation. For this case,

$$u = u_y \text{ and } u_{yz} = \frac{1}{2}\frac{\partial u_y}{\partial z} .$$

For non-zero components of the stress tensor, we find from Eqns. (1) and (2)

$$\sigma_{yz} = G\frac{\partial u_y}{\partial z},\ \sigma'_{yz} = \eta\frac{\partial u_y}{\partial z} . \qquad (3)$$

The behaviour of an ideally viscous material described by Newton's equation [Eqn. (3)] can be represented schematically by a section of a $\partial\dot{u}_y/\partial z - \sigma_{yz}$ straight line passing through the coordinate origin (Fig. 1, curve I). The direct proportionality of the flow rate gradient $\partial\dot{u}_y/\partial z$ to the stress σ_{yz} implies that the shape and state of the structural elements of the object do not undergo any changes and that the shear stress increases and decreases instantaneously.

The flow of high polymers and plastics does not usually[2] obey Newton's equation [Eqn. (3)]. Their flow rate gradient can increase with shear stress either faster (Fig. 1, curve II) or more slowly (Fig. 1, curve III). Apart from fluidity, polymers and plastics exhibit a certain elasticity and therefore the onset of non-elastic deformation (flow) does not as a rule coincide with the origin of the coordinates (Fig. 1, curves IV–VI) of the $\partial\dot{u}_y/\partial z - \sigma_{yz}$ curve. Therefore the total deformation in a solid under the influence of a mechanical load can be represented by the sum of two terms: the reversible† (elastic) deformation u'_y propagated at the velocity of sound and the irreversible (plastic) deformation u''_y. The latter type of deformation in a real substance is not established instantaneously but increases gradually when an external constant load is applied. Its experimental time dependence $u''_y = \Phi(t)$ is very complex and is related to the previous history of the specimen. As a result, when the external load is changed periodically there is a phase lag between the total deformation and the stress, which entails energy dissipation by vibrations. The capacity of a substance to transform the energy of mechanical vibrations into heat is known as mechanical losses or internal friction‡. The following quantity can serve as a measure of internal friction:

$$\delta = \Delta E/E , \qquad (4)$$

where ΔE is the energy dissipated during the cycle and E the vibrational energy. The physical cause of internal friction is the rearrangement in the solid occurring at a finite rate under the influence of mechanical stresses. Five types of this kind of rearrangement are known: thermal rearrangement (thermoelastic effects), electrical rearrangement (electron redistribution, ion migration, rotation of electrical dipoles, and other effects), magnetic rearrangement (magnetomechanical hysteresis, relaxation of the magnetic flux as a result of the appearance of macro- or micro-fluxes, rotation of magnetic dipoles, and other effects), atomic rearrangement (ordering of the atoms under the influence of the stress, the appearance, redistribution, and migration of dislocations, etc.), and molecular rearrangement (relative displacement of groups, segments, and the entire molecules).

In the present review special attention is given mainly to the last type of rearrangement which has been least investigated§. The first four types of internal rearrangement and the mechanisms of internal friction associated with them have been fairly thoroughly examined at various times by numerous investigators (see the review articles [7–11]).

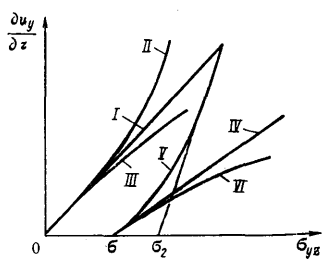

Fig. 1. Principal types of flow curves: I) viscous Newton substance; II) and III) "quasi-viscous" substance; IV) Bingham's "plastic" substance; V) and VI) "quasi-plastic" substance; σ_2—conventional limit of fluidity.

† If the substance exhibits rubberlike elasticity, it is essential to take into account also the rubberlike deformation.

II. METHODS OF MEASUREMENT OF INTERNAL FRICTION

Internal friction can be measured by different methods: (1) from the temperature variation of the substance during deformation; (2) from the variation of the phase shift angle between the stress and the deformation; (3) from the amplitudes of free and forced vibrations at various frequencies; (4) from the decay of elastic waves. The first [12,13] and the second [14–16] methods have not been widely used. The third and fourth methods are the most extensively applied and therefore we shall in fact consider them, leaving aside methods developed for rubberlike materials (see, for example, the review by Bartenev et al. [17]).

1. Methods of Free and Forced Vibrations

The third group of methods is usually divided into two parts. The first part includes all the low-frequency methods and the second all the high-frequency methods. We shall consider briefly the methods in each subsection of this group separately.

a. Low-frequency methods. The low-frequency methods include all known methods based on torsional, bending, longitudinal, and transverse vibrations in the range between 10^{-3} and 10^2 c/s. At vibration frequencies above 2 c/s the variation of the amplitude with vibration frequency is usually recorded automatically. At lower frequencies it is possible (and very convenient) to make visual observations.

‡ In earlier studies [3] internal friction was erroneously identified with the viscosity.

§ It has been partially described by Kolsky [4] and Ferry [5]. Molecular motion in polymers has been described by Mikhailov and Borisova [6].

The oldest and the simplest of all the low-frequency methods for the measurement of internal friction is that of the torsional pendulum. As early as 1837, Weber[18] used the torsional pendulum to solve the problem of the non-elastic behaviour of silk threads, whereby he initiated the studies of internal friction by this method. The torsional pendulum method received general recognition in subsequent years. The method has been used particularly extensively during recent years after its very successful application[19-21] in the study of the viscous behaviour of grain boundaries in metals.

The principal disadvantages of the method of low-amplitude torsional vibrations, which otherwise has many advantages[21], are the inhomogeneity of the deformation of the specimen (the relative amplitude of deformation varies from a maximum of 10^{-5}–10^{-4} on the surface of the specimen to zero at its axis) and the presence of a constant extensive load due to the weight (of the order of 30–50 g) of the inertial system attached to the lower end of the specimen. A torsional pendulum free of the last defect was proposed in 1954 by Ang and Wert[22] and in the same year by Jenckel[23]. It is known as the "reversible torsional pendulum". Its most successful version was developed and constructed in 1960 by Piguzov[24]. This apparatus permits the measurement of internal friction and the modulus of shear in the temperature range between 80° and 770°K. In its design provision is made for the irradiation of the specimen with ultraviolet and X-rays and for the deformation of the specimen directly during the measurement.

Other versions of the torsional pendulum with different design features are also known[25-31]. A novel apparatus, permitting the measurements of the internal friction in polymers and plastics in the frequency range between 10^{-3} and 10^{2} c/s during bending vibrations has been described by Maxwell[33] and apparatus for the measurement of internal friction during torsional vibrations in the infrared frequency range has been described by Illers and Breuer[34] (see also Refs. 35 and 36). Illers[35] described a novel method for the measurement of mechanical losses at a frequency of about 1 c/s.

A simple shear pendulum has been proposed by Rorden and Grieco[37]. Methods in which longitudinal vibrations are used[38,39] have been developed predominantly for materials with rubberlike elasticity. A very interesting method, for materials of the same type, using longitudinal vibrations excited electrically has been described by Hutton and Nolle[40]. The logarithmic decay decrement θ, or the quantity Q^{-1}, which is smaller by a factor of π, serve as measures of the internal friction in this method. The last symbol was introduced by analogy with the decay of electromagnetic oscillations in electrical circuits[9]; Q is the Q-factor of the system in which the mechanical vibrations are excited.

We may note that materials with a very small internal friction (of the order of 10^{-5}) cannot be investigated with the aid of a torsional pendulum (of whatever design), for example, since under these conditions the decay resulting from the losses in the apparatus has an effect.

b. High-frequency methods. These methods are characterised by the absence of a special inertial system linked with the specimen. The specimen in the form of a rod executes torsional, longitudinal, transverse, or bending vibrations at one of its natural frequencies. Steady forced vibrations (resonance method) and the decay of natural vibrations (the method of free vibrations) can be used for the measurements. In the first case the internal friction is measured by the quantity

$$B=\frac{\Delta\nu}{\nu_0}\ , \qquad (5)$$

where $\Delta\nu$ is the half-width of the resonance peak. In the second method the internal friction is measured, as in the low-frequency methods, by the logarithmic decay decrement θ or Q^{-1}.

The frequency range depends on the type of vibrations excited and the size and shape of the specimens. For example, in torsional, longitudinal, and transverse vibrations the frequency is usually between about 10^2 and 10^6 c/s. In bending vibrations the frequency is in the range approx. 10^2–10^4 c/s.

High-frequency vibrations can be excited and recorded in different ways. However, most investigators use the same methods for both purposes. Depending on the way in which the forced vibrations are excited, all the high-frequency methods can be divided into electrical, piezoelectric, electromechanical, and electromagnetic.

In the electrostatic method (Fig. 2*a*) mechanical vibrations are excited by applying an alternating potential to a condenser, one plate of which is the end of the specimen (covered by a conducting layer in the case of polymer) and the end is a stationary plate. To record the vibrations, it is possible to use the same type of condenser at the other end of the specimen, operating as a capacitive microphone. The electrical method is suitable for longitudinal, bending, and torsional vibrations. The method was used for the first time by Bancroft and Jacobs[41] to excite longitudinal and bending vibrations in metallic rods. It was then used by Parfitt[42] for polymers. A description of the subsequent use and development of this method can be found in Refs. 14, 43–49, etc.

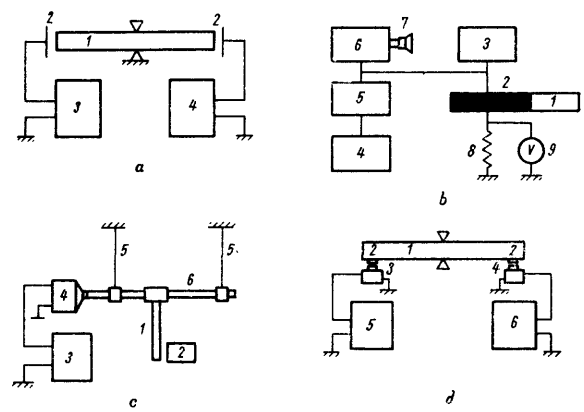

Fig. 2. Schematic representation of high-frequency methods for the measurement of internal friction:
a): 1) specimen; 2) condenser plates; 3) oscillator; 4) detector;
b): 1) specimen; 2) quartz; 3) constant amplitude and alternating frequency generator; 4) constant frequency generator; 5) multivibrator; 6) amplifier; 7) reproducer (beat detector); 8) resistance; 9) valve voltmeter;
c): 1) specimen; 2) "detector"; 3) oscillator; 4) electromechanical transducer; 5) flat springs; 6) connecting rod;
d): 1) specimen; 2) pole pieces; 3) and 4) electromagnetic transducer and receiver; 5) oscillator; 6) detector.

In the piezoelectric method (Fig. 2*b*) the specimen of the test material in the form of a rod is attached by a cement to the end-face of the piezo-quartz rod. When an alternating potential is applied to the piezo-quartz rod, the specimen and the quartz begin to vibrate as a single body (compound vibrator), executing longitudinal or torsional vibrations. From the variation of the current flowing through the quartz, measured by means of a valve voltmeter *9* (or determined from the changes in the resonance curve), it is possible to determine the internal damping of the system, which yields the overall internal friction of quartz and the specimen. The internal friction of quartz can be determined separately and allowed for. The vibration frequencies of the compound vibrator are measured by the method of beats.

Quimby[50,51] and then Zacharias[52] were the first to use this method to measure the internal friction in solids. The compound vibrator method has been applied to the investigation of polymers in Refs. 53–56 and other investigatons. It has been found[57] that, as a resutl of the differences between the coefficients of linear expansion of quartz and the specimen, the internal friction is greatly influenced by the deformations in the cementing layer. This effect is small if the specimen and the quartz rod are selected to ensure that they have similar natural vibrations so that a vibration node is located at the point of attachment. This requirement cannot always be satisfied and therefore the method is not suitable for the investigation of internal friction as a function of temperature. Using a number of precautions, Mikhailov and Solov'ev[54,56] and Wada and Yamamoto[55] nevertheless succeeded in investigating the temperature vibration (in the range between 100° and 360°K) of the internal friction of certain polymers by the compound vibrator method.

In the electromechanical method the vibrations of the specimen are excited by an electromechanical transducer of special design[14,58,59] or simply with the aid of a loudspeaker[60,61], as shown in Fig. 2*c*. In the earliest studies[60,62] the amplitude of the vibrations of the specimen was measured visually using a microscope.

A photoelectric method has been employed for recording the vibrations of specimens[14,58]. Robinson's work[58] is particularly interesting, since he developed a method whereby it is possible to measure the internal friction in the temperature range between 20° and 600°K at vibration frequencies between 10^2 and 10^3 c/s.

Capacitive and inductive methods have been employed for the recording of vibrations[63,64]. An improved capacitive method has also been described[61] for the measurement of the vibration amplitudes in the frequency range between 6 and 6000 c/s. The temperature during the measurements could vary between −50° and +300°C.

In the electromagnetic method (Fig. 2*d*) a disc of a ferromagnetic material is attached to each end of the specimen by means of a special cement. A coil (supplied with power from an oscillator) located near one of the ends of the specimen sets up an alternating magnetic field which interacts with the ferromagnetic disc and gives rise to the vibration of the specimen. In a second coil (near the second disc) an e.m.f. is induced and then amplified and recorded. The relative positions of the coils and discs determine the type of vibration: depending on the relative positions, the vibrations can be longitudinal[65,66], bending[22,67,68], and torsional[69]. The method is not very suitable for the measurement of low internal frictions, since the discs can move at their points of attachment causing additional energy losses. Forster[70] eliminated this defect by modifying the method. In his procedure the vibrations of the specimen are transmitted via a wire suspension. They are then transmitted through another wire suspension to the recording device. This method is suitable for the measurement of internal friction at high temperatures: the wires emerge from the furnace and the entire electrical section is at room temperature. After some design modifications; Kline[71] used Forster's method to investigate the internal friction in polymers at temperatures between 4° and 600°K and frequencies between 50 and 5000 c/s.

Borovitskaya[72] used an optical interference-modulation method[73] to investigate the internal friction in rubberlike materials at frequencies between 10^2 and 10^5 c/s.

2. Method of Wave Propagation

This method for the investigation of internal friction consists in the measurement of the decay of the stress wave during its propagation in the solid. Under certain conditions[4] it is possible to compare this decay with the internal friction determined by the methods examined above. It can be shown that the absorption coefficient α and the quantity δ are related to the wavelength λ as follows:

$$\alpha = \frac{1}{2\lambda}\delta \ . \qquad (6)$$

Using the case where only one relaxation process, characterised by one relaxation time τ, takes place in the solid, Zener[74,75] showed that the parameters (examined above) defining internal friction are simply related¶, regardless of the exact mechanism of energy dissipation, provided that the internal friction is low (for example, $\tan\varphi \leqslant 0.1$). This relation is as follows:

$$\tan\varphi = \frac{\theta}{\pi} = \frac{\delta}{2\pi} = \frac{B}{\sqrt{3}} = \frac{\lambda}{\pi}\frac{\alpha}{\pi} \ . \qquad (7)$$

Bearing in mind the above relation, it is possible to express the absorption coefficient in terms of any parameter used as a measure of internal friction. However, one must not forget that in fact the decay of the pulse is not due solely to absorption but also to a large extent to dissipation at inhomogeneities. The decay of the stress waves is particularly pronounced when the average size of an individual inhomogeneity is comparable to the wavelength. Under these conditions the decay of stress waves is caused not so much by absorption, whose mechanism is similar to that of internal friction, as by diffusive scattering of stress waves by the inhomogeneities.

The method of wave propagation can be subdivided into two separate procedures: the method of "travelling waves" and the pulse method. The method of travelling waves was first used by Ballow and Silverman[79] and then by Nolle[80],

¶ Eqn. (7) breaks down when $\tan\varphi > 0.1$; it depends on the mechanism of energy dissipation[76]. In the region of very high internal friction the logarithmic decay decrement cannot serve as a reliable characteristic and in the region of aperiodic motion the concept of a logarithmic decrement loses all significance. Therefore in the aperiodic region and in the adjacent regions (see Figs. 7, 8, and 10) of rapid decay of the vibrations, it is necessary to use other quantities as characteristics of internal friction, for example the absorption coefficient[77] α or the coefficient of mechanical losses, which in this case is related to $\tan\delta$ in a different way[78].

Kuznetsov[81], and others. The theory of this method and the calculation of the dynamic characteristics of the material have been discussed[82-84]. The method has been developed most completely (Fig. 3*a*) by Volodin[85].

This method for the measurement of α can be used only in a restricted frequency range (approx. 10^3-10^5 c/s) and for materials with values of α which are neither unduly large nor unduly small[81,85].

The pulse method (Fig. 3*b*) consists in the excitation of a short high-frequency vibration pulse ($\nu \simeq 10^5-5\times10^8$ c/s) and the measurement of its propagation and decay times during passage through the specimen. In the earliest studies[86-88] the pulses lasted between 1 and 15 μs with vibration frequencies of the order of 10^8 c/s. The pulse passes back and forth through a liquid (transmitting medium) and along the specimen *1* and is detected by the receiving crystal *3*. The relative amplitudes of the successive pulses determined with a valve voltmeter *8* provide a measure of the decay and the time intervals between them, determined by an oscilloscope *7*, give the rate of propagation.

The method was developed further by other workers[89-94]. In their study of the intrinsic piezo-effect of quartz, Merkulov and Yakovlev[94] measured the absorption coefficient of quartz (for shear and longitudinal waves) by the pulse method up to hypersonic frequencies ($\nu \simeq 10^9$) in the temperature range between −200° and +200°C.

As shown above, the results obtained by the pulse method must be interpreted with some caution. It is necessary to take into account the "spreading" of the pulse during its propagation in the absorbing medium (due to the dispersion of the velocity of sound) and also the fact that the overall weakening of the pulse is due not only to absorption but also to a large extent to scatter by inhomogeneities.

A pulse method for hypersonic frequencies (approx. 10^9-10^{10} c/s) has been described[95,96]. This method, which is a development of Baranskii's method[97], is based on hypersonic excitation in a quartz rod with the aid of an electromagnetic cavity resonator. The quartz rod is the test specimen. Hypersonic vibrations of higher frequencies ($\nu \simeq 10^{12}-10^{13}$ c/s) cannot be excited artificially. We may note that the limit of natural thermal hypersonic frequencies is of the order of $10^{12}-10^{13}$ c/s even in crystalline materials. The study of the rate of propagation and absorption of natural hypersonic vibrations in crystals is possible only by indirect methods, namely optical[98] and X-ray[99-103] methods.

III. EXPERIMENTAL RESULTS

The solid polymers and plastics which have been investigated are listed in the Table which indicates the range of conditions investigated, the method of investigation, and the literature sources available to the author of the review. It is evident from the Table that technically important polymers such as polyethylene, polystyrene, poly(vinyl chloride), polyamides, and acrylic acid polymers have been most completely investigated. Few studies have been made on plastics.

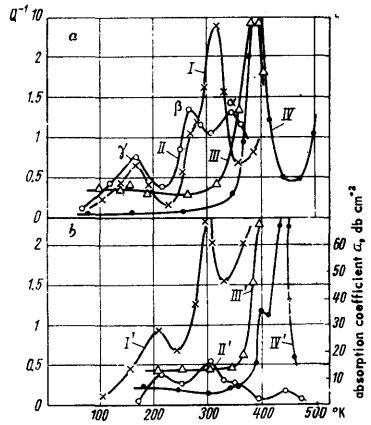
We shall consider briefly the principal results of studies on the temperature and frequency dependence† of the internal friction in polymers and plastics on various factors: structure, impurity content, thermal and mechanical treatment, irradiation, etc., using as examples the macromolecular compounds which are technically the most important.

1. Temperature Dependence

Figs. 4*a*, 4*b*, and 5 show the temperature variation of the internal friction of polyethylene, polystyrene, and poly(methyl methacrylate) of technical purity at various frequencies. The results demonstrate that the Q^{-1}–T curves for all the polymers examined have one or several maxima whose positions along the temperature axis may depend on the vibration frequency (as can be seen in Fig. 5). Fig. 5 shows that, with increasing frequency, the internal friction peak is displaced towards higher temperatures, degenerates into a point of inflection, and finally disappears altogether. However, the peaks on the polyethylene Q^{-1}–T curve, for example, do not disappear when the frequency is increased from 1 to 10^6 c/s and their position along the temperature axis changes little, although their shape does alter appreciably. The shape is very sensitive to the number of methyl groups in the polyethylene macromolecule [117].



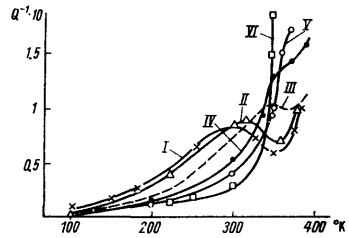


Fig. 4. Temperature variation of the internal friction and of the absorption coefficient α of polyethylene (curves I and II) and polystyrene (curves III and IV):
a) frequencies: 1 c/s for curves I and III and about 10^3 c/s for curves II and IV;
b) frequencies: about 10^4 c/s for curves I and II and about 2×10^6 c/s for curves III and IV.

† For low deformation amplitudes, which usually obtain in measurements of internal friction, the variation of internal friction with the experimental temperature and vibration frequencies is of fundamental importance (see the theory). Various factors (preceding treatment, impurities, irradiation, etc.) alter $Q^{-1}(T)$ and $Q^{-1}(\nu)$. By studying these changes, we are able to assess the nature of molecular motion in solid polymers.

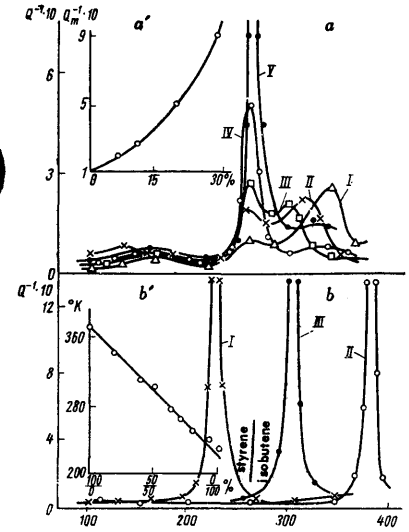

Fig. 6. Effect of chlorine on the shape of the $Q^{-1}-T$ curve for polyethylene:
a) frequency $\nu \sim 1$ c/s:[104] I) 0 wt.% Cl; II) 5.8 wt.% Cl; III) 10.4 wt.% Cl; IV) 12.3 wt.% Cl; V) 28.2 wt.% Cl;
a') variation of the height of the 270°K peak on the $Q^{-1}-T$ curve with the chlorine content;
b) temperature variation of the internal friction of a mixture of polyisobutylene and polystyrene at $\nu \sim 1$ c/s:[104]
I) polyisobutylene; II) polystyrene; III) 50% polystyrene–50% polyisobutylene mixture;
b') temperature variation of the Q_m^{-1} maximum with the ratio of styrene and isobutene in the mixture.

The shape of the peaks depends significantly also on other factors, in the first place on the relative amounts of the amorphous and crystalline phases in the solid polymer. Thus the low-temperature peak on the $Q^{-1}-T$ curve for Teflon decreases in height with increasing degree of crystallinity, while the height of the peak in the region of 300°K actually increases with increasing crystallinity[31,165]. The high-temperature peak on the Teflon $Q^{-1}-T$ curve (at about 400°K) varies with the degree of crystallinity in a more complex manner.

Another factor which influences significantly the shape of the peak is impurities. Fig. 6*a* shows this effect in polyethylene containing various amounts of chlorine atoms. It is seen that for technically pure polyethylene there is a point of inflection near 270°K instead of the peak. With increasing percentage content of chlorine atoms in polyethylene, the peak not only becomes distinct but also increases rapidly in height (Fig. 6*a'*). The high-temperature peak (340°K) also varies appreciably on introduction of chlorine atoms into polyethylene but the variation of its height and position is more complex. The effect of chlorine atoms on the position and height of the low-temperature peak (at about 170°K) is slight.

The position of the maximum in the $Q^{-1}-T$ curve can also depend on the molecular weight of the polymer. For example, increase of the molecular weight of polystyrene[104] from 80 000 to 120 000 causes a displacement of the peak (without significant change in its height) towards higher temperatures by about 16 deg, but effects of this kind are not always observed. For example, a change of the molecular weight of polyisobutylene from 500 000 to 1 750 000 changes neither the position nor the height of the peak on the curve[104].

According to Fig. 6*b*, the $Q^{-1}-T$ curves for polyisobutylene and polystyrene have distinct maxima. A mixture‡ of these polymers also gives rise to a peak (Fig. 6*b*, curve III) on the $Q^{-1}-T$ curve, whose position on the temperature axis (Fig. 6*b'*) depends on the relative amounts of styrene and isobutene in the mixture.

It has been shown[104] that heat treatment influences the form of the $Q^{-1}-T$ curve for a mixture of poly(vinyl chloride) and poly(vinylidene chloride). In the first place the authors draw attention to the fact that, in contrast to pure amorphous polymers which have no peaks on the $Q^{-1}-T$ curve, the curve for a mixture of amorphous homogeneous polymers has an internal friction peak at approximately 300°K. Crystallisation of the mixture (as a result of the heat treatment) leads to the appearance of a second peak on the $Q^{-1}-T$ curve, whose height increases slightly with increasing amount of the crystalline phase, while the peak characteristic of the amorphous phase decreases sharply.

Irradiation has a significant effect on the shape of the $Q^{-1}-T$ curve. Irradiation with γ-rays emitted in the decomposition of radioactive cobalt-60 nuclei at a selected dose (about 100 mr) does not give rise to an appreciable change[111] of the shape of the $Q^{-1}-T$ curve for non-irradiated polyethylene. The situation changes markedly when polyethylene is irradiated with a neutron beam of the order of 10^{18} neutron cm^{-2} s^{-1}.[111,115,118] With increasing intensity of the neutron beam, the low-temperature γ-peak initially broadens and increases in height and then begins to be displaced towards higher temperatures with a simultaneous decrease in height. At the same time the β and α peaks merge into a single, broad peak, which then vanishes altogether.

Summarising, one may say that the $Q^{-1}-T$ curve characterises a given polymer under concrete conditions. Each change in the specimen, be it a change in molecular weight, composition, degree of crystallinity, etc., is reflected in

‡ For more detailed information on the composition of the polymers see, for example, Bartenev et al.[35]

a characteristic change in the shape of the internal friction–temperature curve. We shall see below that theoretical and experimental studies of these changes provide information about the characteristic features of the mechanism of certain processes in polymers.

2. Frequency Dependence

The variation of the internal friction of polymers over a wide range of frequencies has not been investigated. This is due to the experimental difficulties involved in such experiments. Fig. 7*a* shows the frequency dependence of the internal friction of polyethylene and poly(methyl methacrylate) at 30°C based on the results of several investigators [28,55,119,125,128,142,153,176].

Examination of Fig. 7 shows that in the frequency range between 10^{-3} and 10^{6} c/s poly(methyl methacrylate) has a single maximum and polyethylene two maxima in the $Q^{-1}-\nu$ curve. The origin and nature of these maxima will be discussed below. Here attention is drawn to the possible dependence of the positions of the maxima along the frequency axis and their shape on various factors. The results of the investigations presented in Fig. 7*b* make it possible to follow the effect of temperature on the shape of the $Q^{-1}-\nu$ curve. It is readily evident that an increase of temperature entails a displacement of the maximum towards higher frequencies (see also Fig. 5) and an increase in its height.

It has been shown [28] that the introduction of a plasticiser into the polymer [28] almost does not alter the position of the maximum in the $Q^{-1}-\nu$ curve for poly(methyl methacrylate) but does increase somewhat its height. However, if the molecular structure of the polymer is altered, for example by copolymerisation, the shape of the $Q^{-1}-\nu$ curve can change significantly [28]. Comparison of the $Q^{-1}-\nu$ and $Q^{-1}-T$ curves shows that in the first case the frequency must be varied within very wide limits (at least by 5–6 powers of ten, see Fig. 1) in order to detect the required maxima, while in the second case it is sufficient to vary the temperature by less than 1–2 powers of ten (see Fig. 4).

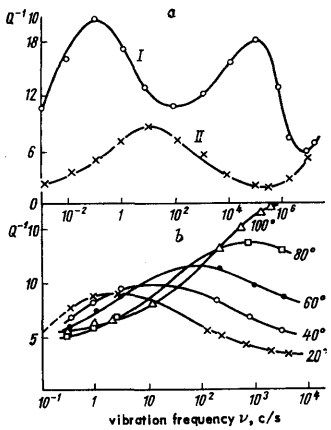

Fig. 7. *a*) Frequency dependence of the internal friction of polyethylene (curve I) and poly(methyl methacrylate) (curve II) at 30°C;
b) frequency and temperature dependence of the internal friction of poly(methyl methacrylate).

IV. THEORY OF INTERNAL FRICTION

It was noted above that in a real solid deformation does not follow exactly the stress applied to the substance from outside but lags behind it by a certain angle φ. As a result, in a periodic deformation of such a substance at a frequency ν, elastic vibration energy is dissipated. Investigations show (see Figs. 4–7) that the relative amount of energy dissipated in one cycle (or internal friction) depends on the vibration frequency and the experimental temperature. The nature of the temperature and frequency dependence of internal friction depends in turn on a multiplicity of various factors, some of which have been examined above.

The theory of internal friction should provide an answer to three questions at least: (1) why there are maxima in the $Q^{-1}-\nu$ and $Q^{-1}-T$ curves and what is their nature; (2) why certain amorphous substances do not have maxima in the $Q^{-1}-T$ curve; (3) how various factors affect the nature of the $Q^{-1}-\nu$ and $Q^{-1}-T$ curves. The modern theory of internal friction cannot yet provide an exhaustive answer to these questions but many of aspects are now fairly clear.

The theory has developed in two main directions: one involving the phenomenological description of the principal laws governing internal friction and one involving the development of its various mechanisms on the basis of the molecular-kinetic theory. We shall examine briefly the principal results of the theory obtained in these two ways.

1. Phenomenological Theory

The phenomenological approach to the solution of the problem of the dissipation of the elastic energy of a real vibrating solid may be twofold. It is possible to solve the problem within the framework of the thermodynamics of irreversible processes after making certain simplifying assumptions about the properties of real substances. Another approach (purely formal) is based on the replacement of the real substance by a model, which reflects some definite property of the real substance. The mechanical properties of real solids, including internal friction, can be described more or less fully by a set of models. We shall begin with the latter procedure, since it has had some success [177] because of the clear-cut nature of the results obtained.

a. The model theory. We shall examine a substance which undergoes elastic deformation under stress and which can also flow. The total deformation of such a substance under the influence of a shear stress, for example, is equal to its elastic deformation and degree of flow, i.e.

$$\varepsilon = \varepsilon_1 + \varepsilon_2 \text{ or } \dot{\varepsilon} = \dot{\varepsilon}_1 + \dot{\varepsilon}_2 \qquad (8)$$

where a dot over a symbol denotes differentiation with respect to time. The rate of elastic displacement is determined from Hooke's law and the rate of viscous flow from Newton's law [see Eqn. (3)].

Hence we have from Eqn. (8)

$$\dot{\varepsilon} = \frac{\sigma}{\eta} + \frac{\dot{\sigma}}{G} . \qquad (9)$$

Let the specimen, the material of which obeys the Maxwell equation [Eqn. (9)] undergo a deformation ϵ_0 and then remain in this state. Then $\dot{\epsilon}_0 = 0$ and Eqn. (9) reduces to the following relation:

$$\frac{\dot{\sigma}}{G} + \frac{\sigma}{\eta} = 0 .$$

The solution of this differential equation has the form

$$\sigma = \sigma_0 \, e^{-\frac{G}{\eta}t} . \qquad (10)$$

Thus the decrease (relaxation) of stress in the specimen with time is exponential and is characterised by the relaxation time

$$\tau = \eta/G . \qquad (11)$$

As will be shown later, the relaxation time is a very convenient characteristic of the rate of relaxation processes in both simple and complex systems.

The behaviour of a substance which obeys the Maxwell equation can be represented by the mechanical model shown in Fig. 8. When stress is applied at a certain instant t_1, the spring is instantly extended by an amount σ/G and the piston begins to be uniformly displaced at a rate σ/η. When at another instant t_2 the stress is discontinued, the spring instantly contracts but the piston remains in the displaced state. As a result, the motion of the lower end of the model [or the deformation $\epsilon(t)$] is of the form shown in Fig. 8.

When a stress $\sigma(t) = \sigma_0 e^{i\omega t}$, which varies periodically, is applied to a Maxwell substance, dissipation of vibration energy is observed. Indeed, on substituting $\sigma(t)$ in the Maxwell equation [Eqn. (9)] and integrating the latter, we find

$$\varepsilon = I^* \sigma ,$$

$$I^* = \frac{1}{i\omega\eta} + \frac{1}{G} , \qquad (12)$$

where I^* is the reciprocal of the complex shear modulus G^* or the pliability. The following quantity is adopted as a measure of internal friction:

$$Q^{-1} = \tan\varphi = \frac{\mathrm{Im}\,(G^*)}{\mathrm{Re}\,(G^*)} = \frac{\mathrm{Im}\,(I^*)}{\mathrm{Re}\,(I^*)} . \qquad (13)$$

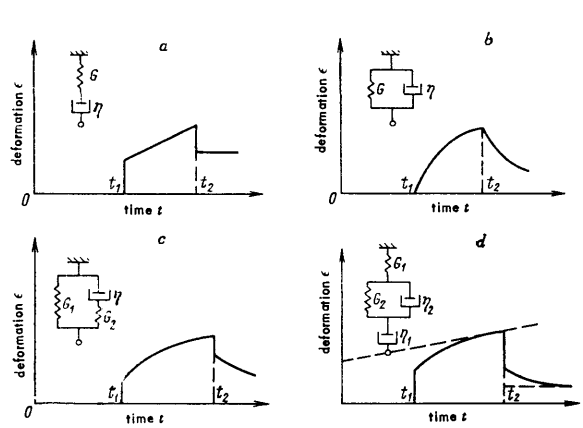

Fig. 8. Variation of the deformation with time for different types of substance (model):
a) Maxwell substance; *b*) Voigt substance; *c*) "standard linear substance"; *d*) Alfrey–Kobeko substance.

Bearing in mind Eqn. (13), we find

$$Q^{-1} = \frac{1}{\omega\tau} . \qquad (14)$$

Since the viscosity of amorphous objects is known [2,177] to decrease rapidly with temperature [in accordance with Eqn. (14)], the internal friction of a Maxwell substance should increase steadily with the temperature of the measurements. The low-frequency internal friction of certain amorphous polymers (K-18-2 resin), polypropylene, etc., does indeed increase steadily with experimental temperature, but this by no means implies that the properties of a Maxwell substance describe a real polymer satisfactorily. It was assumed above that elastic deformation takes place instantly, i.e. that the substance exhibits ideal elasticity (as well as ideal viscosity). A real substance may show a lagging elastic response, which can be represented by the mechanical model in Fig. 8*b*. This device differs from that in Fig. 8*a* in that the spring and the piston are linked in parallel and not in series. There is a significant difference between Voigt and Maxwell elements. In contrast to a Maxwell substance, the behaviour of a Voigt substance is described by the following differential equation:

$$\sigma = G \cdot \varepsilon + \eta \cdot \dot{\varepsilon} . \qquad (15)$$

It can be readily shown that the lag time (retardation) is defined by the same equation [Eqn. (11)] as the relaxation time.

In a cyclic deformation of a Voigt substance the deformation is a periodic function of time, which can be written thus:

$$\varepsilon = \varepsilon_0^* \cdot e^{i\omega t} , \qquad (16)$$

where ϵ_0^* is the complex amplitude. When Eqn. (16) is substituted in Eqn. (15), we obtain $\sigma = G^*\epsilon$, where $G^* = G + i\omega\eta$ is the complex shear modulus. We find from Eqn. (13)

$$Q^{-1} = \omega\tau . \qquad (17)$$

Comparison of Eqns. (14) and (17) shows that the variation of the internal friction of a Voigt substance with temperature [$\tau = \tau(T)$] and frequency is precisely the opposite type and therefore it does not correspond in the least to the experimental variation Q^{-1} with T and ω.

We shall now assume that the solid is a mixture of two phases, one of which is viscous [obeying Eqn. (9)] and the other is purely elastic. The mechanical model representing such an object is shown in Fig. 8*c*. If we put $G_1 = 0$ in the model, the latter becomes a Maxwell model, and if we put $G_2 = \infty$, the Voigt model is obtained.

It is not difficult to show that the differential equation corresponding to the mechanical model in Fig. 8*c* is of the form

$$\sigma + \frac{\eta}{G}\dot{\sigma} = G_1 \cdot \varepsilon + \eta\dot{\varepsilon} . \qquad (18)$$

Since this is the most general linear homogeneous equation, relating the stress, deformation, and their first derivatives with respect to time, the solids which obey Eqn. (18) are called "standard linear substances". If it is assumed that $\dot{\epsilon}$ is zero, Eqn. (18) is converted into the equation $\sigma + (\eta/G_2)\dot{\sigma} = G_1\epsilon_0$, which has a solution of the form

$$\sigma(t) = G_1 \cdot \varepsilon_0 + (\sigma_0 - G_1 \cdot \varepsilon_0)\, e^{-t/\tau_\varepsilon} ,$$

where $\tau_\epsilon = \eta/G_2$ is the relaxation time of the stress under conditions of constant deformation.

If it is assumed that $\dot{\sigma}$ is zero, then, on the basis of similar considerations, we obtain from Eqn. (18) the solution

$$\varepsilon(t) = G_1^{-1}\sigma_0 + (\varepsilon_0 - G_1^{-1}\ \sigma_0)\ e^{-t/\tau_\sigma},$$

where $\tau_\sigma = \eta/G$ is the retardation time.

Introducing the new constants τ_ϵ and $\tau_{\dot{\sigma}}$ into Eqn. (18), we obtain

$$\sigma + \tau_\varepsilon\ \dot{\sigma} = G_1(\varepsilon + \tau_\sigma\ \dot{\varepsilon}) . \qquad (19)$$

We now find the relation between the stress and deformation in standard linear substances when these quantities vary periodically with time. For this purpose, we substitute in Eqn. (19)

$$\sigma = \sigma_0\ e^{i\omega t} \text{ and } \varepsilon = \varepsilon_0^*\ e^{i\omega t}.$$

As a result we have $\sigma = G^*\epsilon$, where the complex modulus G^* is represented by the expression

$$G^* = \frac{1 + i\omega\tau_\sigma}{1 + i\omega\tau_\varepsilon}\ G_1 . \qquad (20)$$

The internal friction is now found thus:

$$Q^{-1} = \frac{\omega(\tau_\sigma - \tau_\varepsilon)}{1 + \omega^2\tau_\varepsilon\ \tau_\sigma} \qquad (21)$$

The last expression loses its significance only when $\tau_{\dot{\sigma}} - \tau_\epsilon > 0$, i.e. when the retardation time is greater than the relaxation time, As will be shown below, this does happen in real solids.

In order to represent the variation of the internal friction of a standard linear substance with angular frequency as clearly as possible, we introduce the geometrical mean§ of the times τ_ϵ and τ_σ: i.e. $\bar{\tau} = (\tau_\epsilon\tau_\sigma)^{1/2}$, and the geometrical mean of the moduli G_1 and G_2, i.e. $\bar{G} = (G_1G_2)^{1/2}$.

Then, using the equation

$$\frac{\tau_\sigma}{\tau_\varepsilon} = \frac{G_2}{G_1} , \qquad (22)$$

it is possible to transform Eqn. (21) into the following form:

$$Q^{-1} = \frac{G_2 - G_1}{\bar{G}}\ \frac{\omega\bar{\tau}}{1 + (\omega\bar{\tau})^2} . \qquad (23)$$

Eqn. (23) agrees fully with the familiar expression for Q^{-1} obtained by Zener[75] by a formal generalisation of Hooke's law, provided that we put $G_2 = M_n$ and $G_1 = M_r$, where M_n and M_r are the non-relaxation and relaxation moduli¶ respectively.

For an isotropic substance, M is understood as one of three quantities: the modulus of elasticity E, the modulus of shear G, and the modulus of bulk compressibility K. In this case the first multiplier on the right-hand side of Eqn. (23) defined the degree of relaxation of the modulus M. However, as will be shown below, for simple exponential relaxation it is more convenient to estimate the degree of relaxation of the modulus M by the quantity

$$\Delta = \frac{M_n - M_r}{M_r} , \qquad (24)$$

which is called the defect of the modulus.

§ This artificial procedure was introduced by Zener[75]. As will be seen later, $\bar{\tau}$ is in fact the really significant time, since in many cases a single average retardation time is sufficient to describe the frequency (or temperature) dependence of the decay.

¶ The final value of the stress/deformation ratio which is attained at the end of the relaxation process for the chosen mechanism with a single relaxation time.

The internal friction defined by Eqn. (23) has a maximum given by

$$Q^{-1}_{max} = \frac{1}{2}\frac{G_n - G_r}{\bar{G}} \qquad (25)$$

when

$$\omega\bar{\tau} = 1 , \qquad (26)$$

i.e. when the vibration frequency ω is equal to the reciprocal of the relaxation time $\bar{\tau}$. On either side of this maximum the internal friction decreases asymptotically to zero.

Thus a standard linear substance, i.e. a substance consisting of an elastic matrix in which viscous regions are embedded, dissipates elastic energy during periodic deformation to an appreciable extent only when Eqn. (26) holds. The relaxation time τ depends on the physical nature of the viscous region and also on its size and shape. If different amorphous regions are embedded in the elastic matrix (the basic material of the solid), then each region will have its own relaxation time τ_i and the behaviour of such a solid will be determined by the complete set of relaxation times τ_i, which leads to some "spreading" of the maximum (if the relaxation times are fairly close to one another).

Numerous experiments have shown that the relaxation time for relaxation phenomena associated with atomic and molecular rearrangement (in the field of internal forces) induced by periodic external forces varies with temperature largely according to the law

$$\tau = \tau_0 \cdot e^{H/RT} , \qquad (27)$$

where H is the heat of activation for the process, R the gas constant, and T the absolute temperature.

Since according to Eqn. (23) the internal friction Q^{-1} varies with frequency and the relaxation time in terms of the parameter $\omega\tau$, it is possible to keep the frequency ω constant and vary τ by varying the temperature. At a certain temperature T Eqn. (26) is satisfied and an internal friction maximum due to the occurrence of the relaxation phenomenon discussed above will be observed in the $Q^{-1}\omega - T$ curve.

Thus the rheological model examined makes it possible to explain the peak on the $Q^{-1} - T$ curve but it does not account for the appearance of an internal friction background, i.e. the increase of the internal friction beyond (with continuous increase of temperature) the high-temperature maximum (Fig. 4). An attempt will be made to describe the relaxation peak and the background by a model based on a series combination of Maxwell and Voigt materials, i.e. an Alfrey–Kobeko substance† (Fig. 6*d*).

The differential equation relating ϵ and σ can be obtained in this case from the following considerations. The overall deformation of an Alfrey–Kobeko substance, under the influence of shear stress for example, is equal to the sum of the deformations of the Maxwell and Voigt elements, i.e. $\epsilon = \epsilon_M + \epsilon_V$ or $\dot{\epsilon} = \dot{\epsilon}_M + \dot{\epsilon}_V$, where according to Eqn. (9) the rate of change of the deformation $\dot{\epsilon}_M$ is

$$\dot{\varepsilon}_M = \frac{\dot{\sigma}}{G_1} + \frac{\sigma}{\eta_1}$$

and according to Eqn. (15) that of $\dot{\epsilon}$ is

$$\dot{\varepsilon}_V = \frac{\sigma}{\eta_2} - \frac{G_2}{\eta_2}\ \varepsilon_V . \qquad (28)$$

† This model is sometimes called the four-element model.

On adding together ϵ_M and $\dot{\epsilon}_V$, differentiating the resulting equation once more with respect to time, and eliminating ϵ_V and $\dot{\epsilon}_V$ from these two equations, we obtain with the aid of Eqn. (33) the required differential equation in the following form:

$$\ddot{\sigma}+\left(\frac{1}{\tau_1}+\frac{G_2+G_1}{G_2}\cdot\frac{1}{\tau_2}\right)\dot{\sigma}+\frac{\sigma}{\tau_1\tau_2}=G_1\ddot{\varepsilon}+\frac{G_1\dot{\varepsilon}}{\tau_2} \quad , \qquad (29)$$

where the relaxation times are

$$\tau_1=\eta_1/G_1; \quad \tau_2=\eta_2/G_2 \quad . \qquad (30)$$

On substituting in Eqn. (29)

$$\sigma=\sigma_0\, e^{i\omega t} \text{ and } \varepsilon=\varepsilon_0^*\, e^{i\omega t} \quad ,$$

we obtain

$$\sigma=G^*\,\varepsilon,$$

where

$$G^*=\frac{-G_1\omega^2+i\omega G_1/G_2}{-\omega^2+i\omega\left(\frac{1}{\tau_1}+\frac{G_2+G_1}{G_2}\,\frac{1}{\tau_2}\right)+\frac{1}{\tau_1\tau_2}} \quad . \qquad (31)$$

According to Eqn. (13),

$$Q^{-1}=\frac{1+\omega^2\tau_2^2+\frac{G_1}{G_2}\omega^2\tau_1\tau_2}{\omega\tau_1\left(\frac{G_2+G_1}{G_2}+\omega^2\tau_2^2\right)} \quad . \qquad (32)$$

Internal friction at a constant frequency depends significantly on the relation between η_1 and G_1 on the one hand and η_2 and G_2 on the other. If, for example, $G_2 \gg G_1$, then the deformation of an Alfrey–Kobeko substance will be determined mainly by the deformation of the Maxwell element and therefore the internal friction must be calculated in this case from a formula analogous to Eqn. (14). Indeed, if $G_2=\infty$, it follows from Eqn. (32) that $Q^{-1}=1/\omega\tau_1$, i.e. Eqn. (14) obtains. If, on the other hand, $G_1 \gg G_2$ and $\eta_1 \gg \eta_2$, the deformation of an Alfrey–Kobeko substance is determined almost entirely by the deformation of the Voigt element. In the limit, when $G_1=\infty$ and $\eta_1=\infty$, we obtain from Eqn. (32) $Q^{-1}=\omega\tau_2$, i.e. Eqn (17), which applies to a Voigt substance.

For other relations between G_1 and G_2 and between η_1 and η_2, a maximum and a background can appear on the Q^{-1}_{ω}–T curve. Fig. 8*a* confirms this. The average relaxation time τ_2 was found from the data of Nolle et al. [178] (Fig. 5). The ratio $G_1/G_2=0.16$ was obtained from Eqn. (32) on the assumption that the maxima on the theoretical and experimental Q^{-1}–T curves are of the same magnitude. We now find that an Alfrey–Kobeko substance does indeed reflect the properties of real solids more fully than a standard linear substance. With its aid, it is possible to explain qualitatively‡ the temperature variation for certain polymers. However, many polymers have not one but several broad and narrow maxima on the Q^{-1}–T curve (Fig. 4).

‡ No model with a single relaxation time can describe satisfactorily a real Q^{-1}–T curve whatever the relations between the moduli G_i and the viscosities η_i, since only absolutely rigid molecules can have a single relaxation time. The molecules of a real polymer are flexible. As a result of their flexibility, the relaxation processes in polymers can be described only with the aid of an extensive set or a continuous spectrum of relaxation times. However, when the maxima on the Q^{-1}–T curve are fairly narrow, they can be described satisfactorily also with a single average (or most probable) relaxation time. See also Refs. 6 and 179.

The introduction of a large number of elastic and viscous elements makes it possible to set up complex rheological models, which are consistent with many relaxation times and which provide the best approximation to various properties of a real polymer [2,5,177,180–183]. A one-dimensional complex rheological model characterised by n relaxation times with a zero equilibrium stress leads to $n-1$ maxima and an internal friction background curve. However, while it is still possible to attribute some definite physical significance to the elements of an Alfrey–Kobeko substance [177], this cannot be done for the elements of a complex rheological model§. Furthermore, a linear rheological model cannot be used to find the temperature variation of the square of the frequency, from which the temperature variation of the modulus of shear is estimated and therefore it cannot yield the correct temperature variation of internal friction, since the latter depends on the frequency.

A less formal approach, which is to some extent free of the above defects, whereby it is possible to solve from the very beginning the three-dimensional problem of the dissipation of the energy of elastic vibrations, is provided by the thermodynamics of irreversible processes.

b. Thermodynamic theory. The principle of the thermodynamic theory of relaxation phenomena in solids (isothermal case) was put forward by Finkel'shtein and Fastov [184]. Later this theory was extended to the case of non-isothermal deformations [185–189]. The following expression has been obtained for the stress tensor for a homogeneous isotropic body [188]:

$$\sigma_{ik}=K\cdot e_{ll}\cdot\sigma_{ik}+2G\left(e_{ik}-\frac{1}{3}e_{ll}\cdot\delta_{ik}\right)+\eta_2/\tau_2\int_{-\infty}^{t}\dot{e}_{ll}(t')\,e^{\frac{t'-t}{\tau_3}}dt'+\frac{2\eta_1}{\tau_1}\int_{-\infty}^{t}\left[\dot{e}_{ik}(t')-\frac{1}{3}\dot{e}_{ll}(t')\,\delta_{ik}\right]e^{\frac{t'-t}{\tau_1}}dt'-C\cdot\delta_{ik}\cdot C_v\int_{-\infty}^{t}\dot{T}(t')\,e^{\frac{t'-t}{\tau_3}}dt'-K\cdot\alpha\cdot\delta_{ik}\int_{-\infty}^{t}\dot{T}(t')\,e^{\frac{t'-t}{\tau_3}}dt' \quad . \qquad (33)$$

Here K is the isothermal modulus of all-sided compression, G the modulus of shear, η_2 the bulk viscosity, η_1 the coefficient of the shear relaxation of the viscosity, τ_2 and τ_1 are the relaxation times of the bulk and shear viscosities C is a constant, C_v the heat capacity per unit volume of the substance at constant volume, α the thermal conductivity, and τ_3 the thermal relaxation time defined by the expression

$$\tau_3\simeq\frac{C_l^2}{\varkappa'\omega^2} \quad , \qquad (34)$$

where $\varkappa'$ is the thermal diffusivity, C_l the velocity of longitudinal sound waves, and ω the angular frequency. The variation of τ_3 with frequency can be accounted for by the fact that an increase of the frequency entails an increase in the size of the regions between which the relaxation of the thermal flux takes place. For polymers (as for metals), temperature relaxation need be taken into account only in the hypersonic region [as is readily evident from Eqn. (34)]. In the region of sonic and ultrasonic frequencies $\omega\tau_3 \gg 1$.

For adiabatic deformation in this frequency range we have [188]

$$\sigma_{ik}=K^{ad}\cdot e_{ll}\sigma_{ik}+2G\left(e_{ik}-\frac{1}{3}e_{ll}\cdot\delta_{ik}\right)+\eta_2^{ad}/\tau_3\cdot\delta_{ik}\int_{-\infty}^{t}\dot{e}_{ll}(t')\,e^{\frac{t'-t}{\tau_3}}dt'+\frac{2\eta_1}{\tau_1}\int_{-\infty}^{t}\left[e_{ik}(t')-\frac{1}{3}e_{ll}(t')\,\delta_{ik}\right]e^{\frac{t'-t}{\tau_1}}dt', \qquad (35)$$

§ For a physical justification of rheological models, see Zelenev and Molotkov [181,182].

where

$$K^{ad} \equiv K + T_0\alpha^2\frac{K^2}{C_v} \qquad (36)$$

$$\eta_2^{ad} = \eta_2 + CT_0\alpha K\cdot\tau_2 \quad . \qquad (36')$$

We now use Eqn. (35) for the stress tensor to calculate the internal friction and the absorption coefficient of longitudinal and transverse elastic waves.

For a pure shear, for example low-amplitude torsional vibrations, $\epsilon_{ll} = 0$, and therefore

$$\sigma_{ik} = 2G\cdot\varepsilon_{ik} + \frac{2\eta_1}{\tau_1}\int_{-\infty}^{t}\varepsilon_{ik}(t')e^{\frac{t'-t}{\tau_1}}dt' \quad .$$

If the deformation is a periodic function of time, then

$$\varepsilon_{ik} = \varepsilon_{ik}^{(0)}\cdot e^{i\omega t} \quad ,$$

and the generalised Hooke's law is written in the following form:

$$\sigma_{ik} = G^*\cdot\varepsilon_{ik} \quad ,$$

where the complex modulus of shear is

$$G^* = G + \frac{i\omega\eta_1}{1+i\omega\tau_1}$$

or

$$G^* = G + \frac{(\omega\tau_1)^2}{1+\omega^2\tau_1^2}\cdot\frac{\eta_1}{\tau_1} + \frac{i\omega\tau_1}{1+\omega^2\tau_1^2}\cdot\frac{\eta_1}{\tau_1} \quad . \qquad (37)$$

The real component of the complex modulus is usually employed as the dynamic modulus, i.e.

$$G_\omega = G + \frac{(\omega\tau_1)^2}{1+\omega^2\tau_1^2}\cdot\frac{\eta_1}{\tau_1} \quad . \qquad (38)$$

We find from the last expression (if the temperature relaxation at hypersonic frequencies is disregarded, as was done above)

$$G_\infty = G + \eta_1/\tau_1 \quad G_0 = G \quad . \qquad (39)$$

Taking into account Eqns. (38) and (39), we obtain the modulus of shear which determines the degree of relaxation:

$$\Delta'_\omega = \frac{G_\infty - G_\omega}{G_0} = \frac{\Delta'_0}{1+\omega^2\tau_1^2} \quad , \qquad (40)$$

where

$$\Delta'_\omega = \frac{G_\infty - G_\omega}{G_0}$$

is the maximum defect of the shear modulus. Bearing in mind Eqn. (13), we find from Eqn. (37)

$$Q^{-1} = \frac{\Delta'_0\,\omega\tau_1}{1+\frac{G_\infty}{G_0}\omega^2\tau_1^2} \quad . \qquad (41)$$

Eqn. (41) is identical, to within the multiplier G_∞/G_0 in its denominator, with Eqn. (23) obtained above from model hypotheses for a standard linear body, if G_2 is identified with G_∞ and G_1 with the modulus G_0. Therefore all that has been said above about Eqn. (23) applies also to Eqn. (41). Furthermore, one may say that the moduli G_2 and G_1 now acquire a completely definite physical significance, defined by Eqn. (39).

Repeating the above reasoning and operations, we find for bulk compression

$$Q^{-1} = \frac{\Delta''_0\,\omega\,\tau_2}{1+\frac{K^{ad}}{K_0^{ad}}\omega^2\tau_2^2} \quad , \qquad (42)$$

where

$$\Delta'' = \frac{K_\infty^{ad} - K_0^{ad}}{K_0^{ad}} \quad . \qquad (43)$$

Evidently the nature of the variation of Q^{-1} with the parameter $\omega\tau$ does not change.

We now find the absorption coefficient α. Suppose that a transverse wave with frequency ω has the wave vector $\vec{k}$ ($k_x = k$, $k_y = 0$, $k_z = 0$), i.e. it is planar and is propagated along the x axis. It will be assumed that the wave is propagated in an infinite relaxing medium, described by the stress tensor (35). On substituting the non-zero components σ_{xy} and σ_{xz} is the equation of motion

$$\rho\frac{\partial^2\varepsilon_i}{\partial t^2} = \frac{\partial\sigma_{ik}}{\partial x_k} \quad , \qquad (44)$$

we find

$$\left.\begin{aligned} -\rho\omega^2A_y &= -k^2GA_y + i\frac{k^2A_y\,\omega\eta_1}{1-i\omega\tau_1} \\ -\rho\omega^2A_z &= -k^2GA_z + i\frac{k^2A_z\omega\eta_1}{1-i\omega\tau_1} \end{aligned}\right\} \quad . \qquad (45)$$

The square of the wave vector, obtained with the aid of Eqns. (45), is

$$k^2 = \frac{\rho\omega^2}{G}\frac{1+2\omega^2\tau_1^2+i\omega\tau_1}{1+4\omega^2\tau_1^2} \quad . \qquad (46)$$

In the limiting case of low frequencies ($\omega\tau_1 \ll 1$), i.e. when the period of the sound wave is large compared with the relaxation time, Eqn. (46) yields the following result:

$$k = \omega\sqrt{\rho/G} + i\frac{\omega^2\tau_1}{2}\sqrt{\rho/G} \quad , \qquad (47)$$

i.e. decay takes place, due to the presence of shear viscosity with the coefficient

$$\alpha'_t = \frac{\omega^2\tau_1}{2}\sqrt{\rho/G} \quad , \qquad (48)$$

which is proportional to the square of the frequency, in agreement with the familiar expression for the absorption coefficient[1]: $\alpha_t = \omega^2\eta_1/2\rho C_t^3$, provided that one puts $\eta_1 = G\tau_1$.

As was to be expected, the rate of propagation of the wave

$$C'_t = \frac{\omega}{\mathrm{Re}\,(k)} = \sqrt{G/\rho} \qquad (49)$$

is independent of frequency. In the opposite limiting case of high frequencies ($\omega\tau_1 \gg 1$), we find from Eqn. (46) for the absorption coefficient

$$\alpha''_t = \frac{1}{4\tau_1}\sqrt{\rho/2G} = \frac{1}{4\tau_1 C''_t} \quad , \qquad (50)$$

where the velocity of sound C''_t is

$$C''_t = \sqrt{\frac{2G}{\rho}} \quad . \qquad (51)$$

Both the absorption coefficient and the velocity of sound are to a first approximation independent of frequency at

high frequencies. In a more accurate expression the frequency dependence of both quantities is taken into account by the multiplier $1 - 1/8\omega^2\tau_1^2$, and the first expression in Eqn. (50) should be used for α_t''.

We shall now consider the propagation of a longitudinal sonic wave in an infinite relaxing medium. The only non-zero terms, the component of the displacement vector ϵ_x and the component of the deformation tensor $\epsilon_{xx} = ik\epsilon_x$, yield the following expression for the corresponding component of the stress tensor (33):

$$\sigma_{xx} = ik\varepsilon_x \cdot K + {}^4/_3 iG \cdot K \cdot \varepsilon_x + \frac{k\omega\eta_2^{ad}}{1-i\omega\tau_2}\varepsilon_x + {}^4/_3\frac{k\omega\eta_1}{1-i\omega\tau_1}\varepsilon_x + \frac{k\omega\chi}{1-i\omega\tau_3}\varepsilon_x, \quad (52)$$

where the conversion from the temperature function to the deformation function is performed with the aid of Eqn. (1), with χ defined thus:

$$\chi \equiv \tau_3\ \alpha^2 K T_0/C_v\,. \quad (53)$$

On substituting Eqn. (52) in the equation of motion (44), we find the square of the wave number:

$$k^2 = \rho\omega^2\left[K + {}^4/_3 G - i\left(\frac{\omega\eta_2^{ad}}{1-i\omega\tau_2} + {}^4/_3\frac{\omega\eta_1}{1-i\omega\tau_1} + \frac{\omega\chi}{1-i\omega\tau_3}\right)\right]. \quad (54)$$

At low frequencies $\omega\tau_1$ and $\omega\tau_2$ are both much less than 1 and, as pointed out earlier, $\omega\tau_3 \gg 1$. Bearing this in mind, we obtain the following expression for the wave number:

$$k \simeq \sqrt{\frac{\rho\omega^2}{K^{ad}+{}^4/_3 G}}\left(1 + \frac{i\omega}{2}\frac{{}^4/_3\eta_1 + \eta_2^{ad} + \chi/\omega^2\tau_3^2}{{}^4/_3 G + K^{ad}}\right). \quad (55)$$

The rate of propagation of longitudinal waves is found from the real part of this expression:

$$C_l' = \sqrt{\frac{K^{ad}+{}^4/_3 G}{\rho}}\,. \quad (56)$$

The imaginary part of Eqn. (55) yields the absorption coefficient for longitudinal waves:

$$\alpha_l' = \frac{\omega^2}{2}\frac{\sqrt{\rho}}{(K^{ad}+{}^4/_3 G)^{3/2}}\left({}^4/_3\eta_1 + \eta_2^{ad} + \frac{\chi}{\omega^2\tau_3^2}\right). \quad (57)$$

In the region of high but not hypersonic frequencies the condition $\omega\tau_1 \gg 1$ holds for all relaxation times. In this case we obtain from Eqn. (54)

$$k \simeq \frac{\omega\sqrt{\rho} + \frac{i\sqrt{\rho}}{2}(\eta_2^{ad}/\tau_2^2 + {}^4/_3\eta_1/\tau_1 + \chi/\tau_3^2)}{[K^{ad} + \eta_2^{ad}/\tau_2 + {}^4/_3(G + \eta_1/\tau_1)]^{1/2}}\,, \quad (58)$$

whence

$$C_l'' = \frac{1}{\sqrt{\rho}}[K^{ad} + \eta_2^{ad}/\tau_2 + {}^4/_3(G + \eta_1/\tau_1)]^{1/2} \quad (59)$$

and

$$\alpha_l'' = \frac{1}{2(C_l'')^3}\left(\eta_2^{ad}/\tau_2^2 + {}^4/_3\eta_1/\tau_2 + \frac{\alpha^2 K^2 T_0 \varkappa'}{C_v (C_l'')^2}\omega^2\right). \quad (60)$$

Thus the viscosity component of the absorption coefficient yields a constant term to a first approximation and the component due to the principal thermal conductivity yields a quadratic relation in frequency which does not differ from the corresponding additional term in the expression for α_l', as in both cases the condition $\omega\tau_3 \gg 1$ holds.

Summarising, one may say that at frequencies between 10^{-3} and 10^8 c/s, which we examined above (Figs. 4 and 5), the important factor is viscous relaxation (shear or bulk), which in the case of homogeneous isotropic solids is characterised by a single relaxation time. Consequently, according to Eqns. (41) and (42), a homogeneous isotropic body is characterised by a peak on the Q^{-1}–$\omega\tau$ curve and the absence of background. The Q^{-1} background can appear only if the body is inhomogeneous, i.e. has two (or more) relaxation times. An example of such a body is a mixture of amorphous polymers, partially crystalline polymers, cross-liked polymers, polymers containing impurities, etc.

A thermodynamic examination of the problem for the case of an inhomogeneous body with two relaxation times has been made by Shermergor and Meshkov[190]. The results of the theory have been examined using polycrystalline aluminium as an example. The form of the Q^{-1}–T curve is similar to that of the analogous curve which the present author obtained for poly(methyl methacrylate) on the basis of model hypotheses (Fig. 9*a*).

Under conditions of cyclic deformation, relaxation processes occur at different rates and at different sites of an inhomogeneous polymer and therefore its behaviour is described by a whole spectrum (discrete or continuous) of relaxation times. However, the spectrum of relaxation times in a solid polymer can be due not only to different rates of the relaxation process in different regions of the inhomogenous body but can also be caused by the presence of various relaxation mechanisms resulting from the flexibility of the molecules[2,7–11,75]. If several independent relaxation processes, each characterised by its own relaxation time τ_i, take place simultaneously in the polymer, the internal friction of the latter, for example in the presence of shear vibrations, is defined by the expression[8,9,75]

$$Q^{-1} = \sum_{i=1}^{n}\frac{\Delta_i^{(0)}\cdot\omega\tau_i}{1 + \left(\frac{G_\infty}{G_0}\right)_i(\omega\tau_i)^2}\,. \quad (61)$$

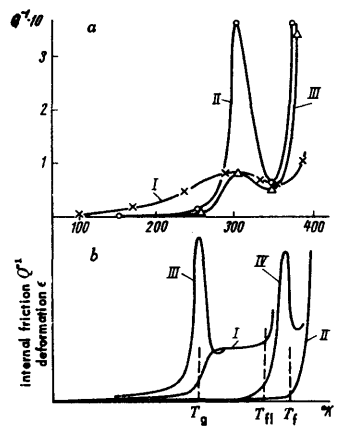

Fig. 9. *a*) Temperature dependence of the internal friction of poly(methyl methacrylate): I) experimental curve[18] for $\nu = 0.4$ c/s; II) and III) theoretical curves [II) $G_1/G_2 = 1$; III) $G_1/G_2 = 0.16$; $\tau_1 = 100\tau_2$; $\nu = 0.4$ c/s];
b) schematic representation of the temperature dependence of the deformation (curves I and II) and internal friction (curves III and IV) of polymers: I) and III) amorphous polymers; II) and IV) crystalline polymers.

Finally, for a continuous distribution of the relaxation constants, which frequently obtains in inhomogeneous materials, the internal friction is defined by the expression[9,75]

$$Q^{-1}=\int_{-\infty}^{+\infty}\frac{\psi(\tau)\,\omega\tau}{1+\left(\frac{G_\infty}{G_0}\right)_{cp}\omega^2\tau^2}\,d(\ln\tau)\ , \qquad (62)$$

where $\Psi(\tau)$ is an unknown distribution function difficult to determine experimentally. It can be found from the condition

$$(\Delta_0)_{cp}=\int_{-\infty}^{+\infty}\psi(\tau)\,d(\ln\tau)\ , \qquad (63)$$

where $(\Delta_0)_{av}$ is the average defect of the modulus found experimentally; this requires the inversion of the integral, which introduces a considerable inaccuracy into the final result.

It is evident from all that has been said above that the phenomenological theory describes fairly completely the frequency and temperature dependence of internal friction in homogeneous and inhomogeneous isotropic solids. The theory of internal friction in anisotropic materials has only just begun to be developed. For example, an expression has been obtained[191] for the stress tensor in a homogeneous anisotropic crystal and it has been shown that the stress tensor components σ_{ik} undergo relaxation to their equilibrium values $\bar{\sigma}_{ik}$, but the relaxation does not involve a simple exponential decay to the equilibrium value, as happens for an isotropic medium, but is determined by the entire set of relaxation times τ_{ik}. In the general case (crystals of the triclinic system) the relaxation of stresses in an isotropic medium is determined by six relaxation times τ_{ik} corresponding to six independent components of the stress tensor.

2. Molecular-Kinetic Description

In contrast to the phenomenological theory, in which the processes responsible for the dissipation of energy by the vibrating body are not considered in detail, the molecular-kinetic theory of internal friction should account for the principal features of the temperature and frequency dependence of the internal friction of solids (and the effect of various factors on the variation of Q^{-1} with T and ν) by a detailed analysis of the molecular processes which constitute its basis. However, the extremely complex structure of polymer molecules, the wide variety of possible types of polymers with the same chemical composition and molecular weight, and other distinctive features, compared with low-molecular compounds and metals, led to considerable difficulties in the development of a molecular-kinetic theory of internal friction.

The starting point of the molecular-kinetic description of the relaxation phenomena consists of hypotheses about the structure of the molecule and about the existence of polymers in various physical states—three amorphous and one crystalline. A clear idea about these physical states is obtained by plotting the deformation of the polymer (developing in a definite period at a given temperature and with specified stress) against temperature. For an amorphous substance, this plot[2], which has been called the thermomechanical curve, should have the form shown schematically by curve I in Fig. 9*b*. The two vertical dashed lines corresponding to temperatures T_g and T_{fl} divide curve I into three regions. The first (from 0°K to T_g) corresponds to the solid vitreous state of the substance, the second to the rubberlike state, and the third to the viscous state.

Since on cooling the polymers solidify (are converted into a glass) in the temperature range arbitrarily denoted by the temperature T_g, the latter has been called the glass point. At temperatures much lower than T_g the polymer molecules cannot change their shape and relative positions. The conformation of the molecular chain is "frozen". However, below T_g individual groups of atoms, which usually form part of the side-chain but can be linked also to the main chain, retain their mobility[192-195].

Near the temperature T_g and above it (but below T_{fl}) a change in the shape of the molecules is observed but not their mutual displacement, the latter being possible near the flow temperature T_{fl} and above it. The temperature range between T_g and T_{fl}, in which the polymer is a rubberlike material, is greater with higher molecular weights. We may note that the same amorphous polymer at the same temperature is capable of exhibiting the properties of vitreous, rubberlike, and viscous-fluid materials, depending on the rate of deformation. Therefore the temperatures T_g and T_{fl} are not physical constants but depend on the rate of deformation or the frequency of the changes in deformation. For example, at a low rate of deformation ($\nu \simeq 1$ c/s) $T_g \simeq 315$°K for poly(methyl methacrylate)[177]. The maximum in the internal friction of poly(methyl methacrylate) occurs at approximately the same temperature (Fig. 9*a*). This relation (schematically shown by curve III in Fig. 9*b*) is observed also for other amorphous polymers. This finding led to the hypothesis[104,107,117,119] that the high-temperature maximum (α-peak) in the internal friction of amorphous polymers is due to a change in the segmental mobility¶ of the molecule.

Similarly the first internal friction peak (or the sharp rise of the Q^{-1}–T curve near the melting point) of crystalline polymers (Fig. 4 and the schematic curve IV in Fig. 9*b*) is attributed[104,117,145] to the increase in the segmental mobility of the polymer molecule on fusion of the individual crystallites.

The nature of the remaining Q^{-1}–T peaks located below the first along the temperature axis may be extremely varied. For example, the second peak (the β-peak) on the Q^{-1}–T curve for poly(methyl methacrylate) is thought to be caused[152,158] by the rotation of the O=C–OCH_3 side-groups between positions of relative stability via an energy barrier, which reflects the steric hindrance due to the methyl groups attached to the same chain atoms. The study of copolymers of variable composition[158] shows that the elimination of the steric hindrance on replacing methacrylate by acrylate results in the disappearance of the loss mechanism; the replacement of the methyl ester group by any rigid and bulky ester group leads to the same effect, which can be explained by the hindrance to the rotation of these groups. On the other hand, the substitution of a more flexible ester group displaced the effect of this mechanism towards higher frequencies and raises the slope of the curves. Although the steric hindrance associated with the existence of two substituted chain atoms is probably responsible for the second peak on the curve for polymethacrylates, secondary loss mechanisms are also observed for polymers whose chains contain monosubstituted atoms

¶ In some cases it can consist of the sum of the contributions Q_α^{-1} and Q_β^{-1} due to the motion of side-groups[196].

but these are usually shown at higher frequencies or at lower temperatures and have smaller maxima. For example, the second peak on the Teflon and poly(vinyl chloride) curves is attributed to an amorphous phase [31]—to conformational changes in the amorphous phase relative to short polar chains [111]. The nature of such local motion is obscure.

The second peak (β-peak) on the polyethylene curve is associated either with the presence of an amorphous phase or with branching of the polyethylene molecules [107,117,126]. The third polyethylene peak (γ-peak) is attributed to the rearrangement of adjacent CH_2 groups [5].

The motion of methyl groups gives rise to the peak on the $Q^{-1}-T$ curve for polypropylene (at about 13°K). [197] Other cases are also known where the side-groups can be involved in motion at low temperatures, while the main skeleton of the molecules shows little mobility, which gives rise to peaks on the $Q^{-1}-T$ curve [104,192,198].

The cases examined above suggest that the observed maxima on the $Q^{-1}-T$ curves for solid polymers can be divided into two groups: the group of the so called principal maximum (α-peak in polyethylene and other substances) and the group of secondary maxima (β-, γ-, etc., peaks)†. The principal maximum is due to change in the mobility of the side-groups or individual small atomic groups of the main chain or the side-chains, which take part in thermal motion as independent elements. The position of the principal maximum is significantly influenced by the size of the side-groups. It has been shown [104] that, as the volume of the side-groups increases, the mobility of the main molecular chain falls and therefore at a constant frequency the principal maximum is displaced towards higher temperatures. At a constant temperature the maximum occurs at lower frequencies.

All these findings demonstrate that the temperature and frequency dependence of internal friction is indeed determined by the type of molecular motion. The type of molecular motion in turn depends on the composition and structure of the polymer and also on external factors (temperature, pressure, radiation, the medium surrounding the polymer, etc). Therefore, in their studies of the effect of composition, structure, and the factors indicated above on the nature of the temperature and frequency dependence of internal friction, various investigators [31,104,107,111,117,119,197,198] were able to arrive at the conclusions discussed above. However, even for a relatively simple molecular system such as polyethylene, it is impossible to make a unique interpretation of the results obtained. This also applies to other polymers which have been investigated [31,104,111]. This ambiguity can be eliminated to some extent by comparing the results of studies of mechanical and dielectric losses with those obtained by the nuclear magnetic resonance method.

V. COMPARISON OF THE RESULTS OF STUDIES ON MOLECULAR MOTION IN POLYMERS, OBTAINED BY DIFFERENT METHODS

1. Mechanical and Dielectric Losses

The first study in which mechanical properties were investigated in order to compare them with dielectric properties is that of Mikhailov and Kirilina [200] more than 25 years ago. They established that at a frequency of about 500 c/s the temperature maxima in Q^{-1} and tan φ_e for ebonite approximately coincide. A similar result was obtained by other investigators [175,201], for ebonite, rubber, and polyisobutylene. Comparison of these results, obtained at low deformation amplitudes, reveals a direct relation between mechanical and electric relaxation (see also Refs. 164, 202, 203).

Fig. 10 presents the results of a study of the temperature variation of the mechanical and dielectric losses for polyethylene [131] and poly(vinyl chloride) [204]. Evidently the $Q^{-1}-T$ and tan φ_e-T curves are of similar form. The form is similar but not identical, since even at the same frequencies (Fig. 10*b*) there is a perceptible difference in the positions of the maxima in Q^{-1} and tan φ_e along the temperature axis [164]. At a frequency of 2×10^6 c/s the tan φ_e maximum (not shown in Fig. 10*b*) is 27 deg below [204] the maximum in Q^{-1}. At a frequency of 3×10^5 c/s the temperature difference is 11 deg and at a frequency of 10^3 c/s only 8 deg. The difference for ebonite at 500 c/s is 3 deg. Such a slight difference suggests that at low deformation amplitudes (when we deal mainly with orientation relaxation), dielectric and mechanical relaxations have a common mechanism. The mechanical and dielectric losses are probably associated with the same form of thermal motion in the polymer [6]. This is shown by the agreement between the activation energies and between the relaxation times [175,200,201,204,205].

It is readily seen (Fig. 10*b*) that at high frequencies (above 10^4 c/s) the maximum in dielectric losses is higher than the maximum in mechanical losses, while at low frequencies (below 10^4 c/s) the opposite relation holds. The opposite variation of the heights of the maxima in Q^{-1} and tan φ_e with frequency is due to the fact that the maximum in dielectric losses is determined by the polarity of the vibrating side-groups or radicals while the maximum in mechanical losses is due to their mass.

The polarity of the side-groups determines not only the frequency but also the position of the maximum along the

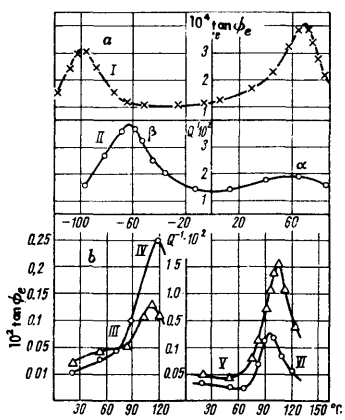

Fig. 10. Temperature dependence of the dielectric loss factor (curves I, IV, and VI) and internal friction (curves II, III, and V) of low-pressure polyethylene (*a*) and poly(vinyl chloride) (*b*):
I) $\nu \sim 5 \times 10^3$ c/s; II) $\nu = 2 \times 10^6$ c/s; III) and IV) $\nu = 3 \times 10^5$ c/s; V) and VI) $\nu = 10^3$ c/s.

† The same subdivision obtains also for rubberlike polymers [59,199].

temperature axis. With increasing dipole moments of the groups, the maximum in tan φ_e is displaced towards higher temperatures, which corresponds to a decrease of mobility with polarity [205]. An increase of the length of the racicals bound chemically to the main chain, while leaving the dipole moment virtually unaltered, causes a diplacement of the tan φ_e maximum towards lower temperatures [206].

Molecular relaxation observed by the dielectric loss method can be divided (like the mechanical relaxation examined above) into two main types: the relaxation of polar groups and the relaxation of the same polar groups together with sections of the main chain, i.e. the relaxation of segments [6,193,207,208]. This has been established for polymers with a wide variety of structures (linear and branched, polymers containing rings in the chain, partially crystallised polymers, and fully amorphous polymers [6,193,208,208]). The losses due to the first type of relaxation are called dipole-radical losses and those due to the second type are called dipole-elastic losses. Usually losses of the first type are observed in a definite temperature range corresponding to the vitreous state of the polymer, while losses of the second type occur above the glass point T_g‡. However, the dipole-radical losses are not a feature of the relaxation of the vitreous state of polymers but can be observed in the rubberlike state, if the period of application of the electric field is comparable with the relaxation time for losses of this type at the chosen temperature [193].

Thus dipole-radical losses reflect the molecular relaxation process which is due to the motion of polar side-groups, while the main chain remains stationary during a period comparable to the vibration period of the applied electric field. If the period of the applied field is sufficiently high, then at certain temperatures it is possible to observe the dipole-elastic losses caused by the displacement of segments together with the polar side-groups. In linear polymers a segment may consist of 2–4 methylene groups [209,210].

The characteristics of losses of the first and second types are also determined by the factors described above. For example, the positions of the temperature and frequency maxima in tan φ_e for dipole-radical losses are independent of the presence of low-molecular impurities [211], but the positions for dipole-elastic losses do depend considerably on such impurities. The relaxation times of the corresponding process decrease under these conditions. The cross-linking of the macromolecules, which impedes their motion and increases the relaxation time of the dipole-elastic losses, has the opposite effect [212,213]. According to the few data available in the literature, the extension of polymer specimens, leading to the orientation of the main chain, increases the relaxation time of dipole-elastic losses but does not affect the relaxation time of dipole-radical losses [214]. Losses of both kinds are considerably influenced by a change in the chemical structure of the monomer unit of the polymer chain. Both polar and non-polar groups, which can be attached either directly to the main chain or to a side-radical, have an effect. For example in a comparative study of mechanical and dielectric losses it has been shown [152] (see Table, entries 13 and 17) that the replacement of the methyl group in the α-position in poly(methyl methacrylate) by a polar group such as CCl, which occupies approximately the same volume, greatly inhibits the segmental motion of the macromolecules. The effects of polarity are enhanced when CH_3 groups are replaced by CN. Comparative study of the temperature variation of Q^{-1} and tan φ_e for low-pressure polyethylene (Fig. 9*a*) [56,131,193] permits the preliminary conclusion that the low temperature β-maximum is due to the "unfreezing" of segmental motion and the high-temperature α-maximum is due to the incipient fusion of poorly formed crystals. The nature of the maxima in Fig. 10*b*, which have been described in detail [204], is not sufficiently clear. The maximum in tan φ_e is due to dipole-elastic losses, i.e. the motion of segments. However, the number of molecular units in the segment remains unknown. The situation is the same as regards the explanation of the γ-maximum on the Q^{-1}–T curve for high-pressure polyethylene, the macromolecules of which are much more branched than for low-pressure polyethylene. The dielectric method does not yield the required information concerning the nature of this maximum. Some workers have simply attributed this maximum to the thermal motion of the parts of macromolecules constituting the amorphous regions of the polymer [215-217].

As mentioned above, the NMR method is very suitable for the investigation of molecular motion. Using this method, one of the first direct demonstrations of rotation of groups about bonds in polymer chains has been achieved [248]. Bearing this in mind, an attempt will be made to resolve, with the aid of the NMR method, the obscure problems concerning the nature of the Q^{-1} maxima, for example on the curves for high-pressure polyethylene and poly(vinyl chloride).

2. Mechanical Losses and Nuclear Magnetic Resonance

The application of nuclear magnetic resonance in the study of molecular motion is based on the observation of changes in the width of the absorption line, which becomes narrower with increasing rate of molecular motion [219-222]. Using nuclear magnetic resonance [223], it is possible to determine both the nature of the mobile group in the polymer and the mode and rate of its motion.

The first comparison of NMR data with results obtained by the internal friction method was made for rubber [224] soon after the discovery of NMR. Some investigators [225-229] have examined the relation between NMR data and the internal friction of polyisobutylene, poly(methyl methacrylate), poly(vinyl chloride), polyethylene, and other polymers. Much work has been done on the relation between mechanical, dielectric, and nuclear resonance absorption in many polymers (see, for example, Refs. 224, 225).

Fig. 11 presents the results of studies on the temperature variation of the internal friction [104,117,119,230] and the nuclear resonance absorption line width [231,232] of high-pressure polyethylene and poly(vinyl chloride) [104,231]. It is seen (Fig. 11*b*) that the absorption line width ΔH varies with temperature similarly to the shear modulus G. In the range 350–360°K, corresponding to the glass point of poly(vinyl chloride), a sharp change in G and ΔH and a distinct maximum in Q^{-1} are observed. The sharp change in ΔH takes place near the transition temperatures which are observed refractometrically [233,234] and by heat capacity measurements [235]. The correlation between the transitions observed by the NMR method and the conversion to the vitreous state observed by other methods makes it possible to relate these transitions to the onset of motion of main-chain segments [194]. However, the number of monomer units in a segment has not been determined with adequate precision. We may note

‡ Sometimes "degeneracy" of the dipole-elastic processes is observed at high temperatures [6].

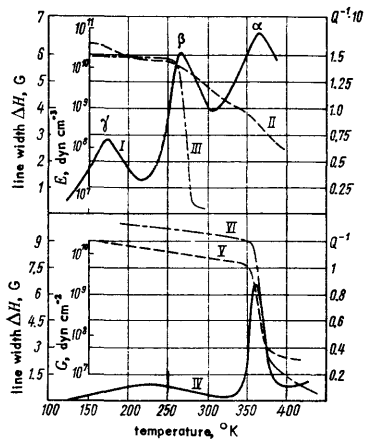

Fig. 11. Temperature dependence of the internal friction (curves I and IV), modulus of elasticity E (curve II), absorption line width (curves III and VI), and modulus of shear G (curve V) of high-pressure polyethylene (a) and poly(vinyl chloride) (b): I) and II) $\nu \sim 10^3$ c/s; IV) and V) $\nu \sim 1$ c/s.

that the agreement between the transition temperatures measured by the NMR and internal friction methods probably cannot be regarded as proof that the same molecular mechanism operates in both cases. It is difficult to imagine the existence of any close relation between molecular motions responsible for the Q^{-1} maximum, which occurs in poly(vinyl chloride) at 330°K and frequencies of the order of 1 c/s, and the motion responsible for the narrowing of the NMR line, which occurs in the same temperature range but at magnetic field frequencies of the order of 10^5 c/s §. Nevertheless the above correspondence between the transitions is observed very frequently [194,195] and therefore there is no reason to believe that this correlation is fortuitous.

A second broad maximum is clearly seen on the Q^{-1}–T curve for poly(vinyl chloride) at about 240°K. It also exists on the tan φ_e curve [237]. However, in the region of this temperature there are no significant changes in the NMR line width. This second Q^{-1} maximum is probably due to slight vibration of methylene groups in the main chain [194].

Fig. 11a shows that the appearance of the low-temperature internal friction maximum (γ-peak) is not accompanied by a sharp change in the width of the NMR resonance line. But the second maximum (β-peak) is satisfactorily correlated with the change in the width of the absorption line. The transition at about 265°K was first observed by the internal friction method [104,114,117,230], but its nature was elucidated by the NMR method. It is due to the rotation of CH_2 side-groups.

Comparison of the second moment of the absorption line with internal friction data suggests that the γ-peak is due to a reorientation of CH_2 groups [108,194]. It has also been suggested [238] that the γ-peak is due to a change in the nature of stereoregularity as a result of cooperative *trans–cis* transitions in polymeric chains. The high-temperature Q^{-1} maximum (α-peak) was discussed above. It is associated with the transition from the state where the main chain is "frozen" to one where its deformation is possible. The corresponding narrowing of the NMR line is almost imperceptible [194]. The study of molecular motion in polymers at these temperatures is best made with the aid of the internal friction and dielectric loss methods. The internal friction method is also preferable in the observation of secondary transitions in the amorphous regions, associated with the motion of individual atomic groups, for example low-temperature transitions in polymers [49,55,104,106,111,125,128,169-171,202].

Voronezh Polytechnic Institute

All this puts great responsibility on chemists, who are armed with modern methods of investigation and the resolve to make a worthwhile contribution to the common task of building a communist society.

Extensive development of theoretical research in all areas of chemistry and a strengthening of the links with industry—these are the most important aims put before Soviet scientists by the XXIIIth Congress of the Communist Party of the Soviet Union, goals which will doubtless be achieved. The remarkable achievements of Soviet chemistry during the fifty years of Soviet rule are a guarantee of this.

U.D.C. 546

FIFTY YEARS OF DEVELOPMENT OF INORGANIC CHEMISTRY IN THE SOVIET UNION

V.I.Spitsyn

The Great October Socialist Revolution opened up unprecedented possibilities for the development of science in the Soviet Union. In fifty years, an extensive network of research centres has been created, and large numbers of teams of highly qualified specialists have been educated and trained for these centres. Considerable success has been achieved in the planned development of science and in the coordination of its various branches.

The intensive growth of theoretical and applied studies, together with the general sharp increase in the industrial potential of the country, has created favourable conditions for the development of strong Soviet research schools, many of which have now obtained world recognition.

It was the creation of a strong science-backed industrial basis for the new technology in the Soviet Union that enabled the country to withstand the severe trials of the Great Patriotic War against German fascism. The same factors in the post-war years made it possible in a short time to resolve such complex problems as the creation of an atomic industry and nuclear energy, the construction of powerful rockets and the development of propellants for them, the organisation of the production of semiconductor and laser materials, etc. Here an important part has been played by the chemical sciences, and by inorganic chemistry in particular.

Inorganic chemistry originated in Russia two hundred years ago when M. V. Lomonosov carried out studies of the oxidation of metals, of outstanding scientific importance, and for the first time on the basis of experimental data formulated the law of conservation of matter. In 1869, D. I. Mendeleev made an outstanding contribution to the development of world science by his discovery of the Periodic Law governing the chemical elements; this law represents the greatest generalisation of our knowledge in the field of inorganic chemistry. The Periodic Law formed the basis for the development of subsequent work involving the study of atomic structure, the phenomena of radioactivity, and the synthesis of new chemical elements.

Scientists in Russia developed the theory of solutions and carried out studies of the platinum metals, one result of which was the discovery of the element ruthenium. Silicates, peroxides, salt ammines, crystal hydrates, and the radioactive elements were studied. The foundations were laid for the development of the method of physicochemical analysis, which has given particularly valuable results in the study of alloys and intermetallic compounds.

Despite the high scientific level of this work, however, the total volume of research on inorganic chemistry in Russia before the revolution was clearly inadequate and the studies were carried out in only a few places: the chemical laboratory of the Academy of Sciences and the inorganic chemistry departments of the universities and certain higher educational establishments of other types. The grants made by the Tsarist government to the maintenance of these laboratories were negligible. There were no specialised research institutes. The number of inorganic chemists carrying out scientific research work throughout the whole of Russia did not exceed several dozen.

Decisive changes in the development of inorganic chemistry and the whole of science took place after the Great October Socialist Revolution. In Soviet Russia, among other measures designed to strengthen science, a start was made in the organisation of chemical scientific research institutes. In 1918 the Institute of Physicochemical Analysis and Institute for the Study of Platinum and Other Noble Metals were founded in the Academy of Sciences. The Central Laboratory founded by the Higher National Economic Council subsequently became the Karpov Physicochemical Institute. The Scientific Institute for Fertilisers, State Applied Chemistry Institute, the Institute for Pure Reagents, the Radium Institute, and a whole series of other research establishments were organised. Scientific research work was extended in the inorganic chemistry departments of Moscow and Leningrad universities and many other higher educational establishments. An important centre for the development of Soviet inorganic chemistry was provided by the Institute of General and Inorganic Chemistry of the Academy of Sciences of the USSR, formed in 1934.

On the instructions of the government, the scientific research institutes and the departments of the higher educational establishments carried out extensive studies of native raw materials and methods for processing them, and helped industry to organise various new production systems, ensuring the economic independence of the young Soviet republic. The rare chemical elements were studied, and on the basis of the scientific research work which was carried out, industry organised the production of many rare metals and their compounds. Scientific research establishments were provided with pure chemical reagents, prepared in Soviet factories.

Since the time of the first five-year plans for the development of the national economy of the USSR (the years 1929–1932 and 1933–1937), the work of Soviet research chemists has been directed chiefly towards the provision of direct assistance in the task of socialist construction. In this period, inorganic chemists have developed the scientific basis for many technological processes in the chemical industry, metallurgy, and the production of binding agents.

Under the direction of N. S. Kurnakov, the salt reserves of the Soviet Union were explored, salt deposits and salt lakes were studied, and methods of natural salt technology were developed. Of particular importance was the study of the Kara-Bogaz-Gol bay in the Caspian Sea, leading to the

organisation of the industrial utilisation of its vast reserves of mirabilite. At the same time, studies were carried out on the dehydration of Glauber's salt and methods for converting it into other compounds.

Thanks to the work of N. S. Kurnakov and his coworkers, vast deposits of potassium minerals were discovered in the USSR, first around Solikamsk, and later in the Ural-Emba region of Western Kazakhstan. Studies were carried out to develop the technology of the natural potassium salts carnallite and sylvinite. In recent years the discovery of vast reserves of potassium salts in Belorussia and the construction of factories for the processing of these salts has strengthened even further the raw-material and technical basis of the Soviet potash industry.

As a result of this scientific research work and the detailed study of natural raw materials containing sodium and potassium, the Soviet Union is assured of a complete supply of compounds of these elements. Instead of importing potassium fertilisers from abroad, as was done before the revolution, the Soviet Union is now able to export these materials. At the same time the country has been provided with magnesium compounds, which have served as raw material for the production of metallic magnesium and various magnesium-containing constructional materials.

The electrochemical preparation of magnesium was studied by V. P. Il'inskii and P. F. Antipin. Studies were made of the dehydration of magnesium chloride hexahydrate, used as electrolyte for the isolation of metallic magnesium. The results of these studies provided information for the construction of magnesium factories.

In the period of industrialisation in the USSR, one of the most important technical problems was the organisation of the production of metallic aluminium from native raw material. Before the discovery of the high-grade Urals bauxites on the eve of the Second World War, the Soviet aluminium industry was based on the comparatively poor Tikhvin bauxites.

In the period 1926–1932, under the direction of A. A. Yakovkin, a large group of research workers developed methods of bauxite technology involving sintering with chalk and soda. The concentrated material was subjected to hydrometallurgical processing. As a result, the problem of the industrial utilisation of high-silica bauxites was solved successfully for the first time. Yakovkin's method was applied in the first factories of the Soviet aluminium industry—the Volkhov Aluminium Combine.

A. N. Kuznetsov and E. N. Zhukovskii put forward another method for the processing of low-grade aluminium ores, involving the high-temperature treatment of a mixture of bauxite, scrap iron, anthracite, and barium compounds. The resulting barium aluminate slag was used for the isolation of alumina. The ferrosilicon formed during the smelting is used in ferrous metallurgy. This method was introduced in the Dnepr aluminium factory.

Under the direction of P. P. Fedot'ev, the electrolysis of cryolite–alumina melts was studied, a new theory of the electrolysis of alumina was developed, and methods for the electrolytic production of aluminium under industrial conditions were devised. On the basis of this work, starting in 1932, Soviet aluminium production was organised, rapidly reaching considerable dimensions, and providing qualified personnel for the further development of this extremely important branch of industry.

Considerable work was done on the search for new forms of cement. P. P. Budnikov studied important problems related to the phenomena of dehydration, hydration, dissolution, and recrystallisation of calcium sulphate. He suggested the use of additives which could "vitalise" insoluble natural anhydrite or gypsum which had been heated at 600–750°C. On the basis of these studies, Budnikov developed a new form of binding agent—anhydrite cement—which has been widely used in constructional work. Budnikov also studied the reactions taking place during the setting of alumina cement and put forward a new form of this material—alumina cement containing added gypsum. This cement is of considerable practical importance.

Later, P. A. Rebinder, N. V. Mikhailov, and others, on the basis of the application of the methods of physicochemical mechanics to the processes involved in the setting and hardening of cements, proposed new forms of constructional materials—sand concrete and colloidal cement binding agent.

Extensive work was carried out in the Soviet Union on the chemistry and technology of phosphorus compounds. The vast deposits of apatite discovered in 1926 in the Kola peninsula were received with mistrust by Soviet industry, since the usual methods for the conversion of natural phosphates into phosphorus fertilisers proved to be inapplicable to these materials. Foreign firms, to whom specimens of the apatite ore were sent for experimental processing, rejected this form of raw material. Studies carried out under the direction of S. I. Vol'fkovich in the Scientific Institute for Fertilisers, however, established the optimal conditions for the conversion of the apatites into phosphorus fertilisers, and the Soviet Union is now assured of an unlimited supply of raw material for the production of these fertilisers, which are of the greatest importance for agriculture.

Studies were also carried out on the chemistry and technology of the rare elements.

One of the first tasks with which the Academy of Sciences was faced was the development of a method for the extraction of radium from native uranium–vanadium ores. This difficult task was successfully resolved under the direction of V. G. Khlopin, and in 1921 the workers of the Radium Experimental Factory produced a specimen of radium bromide—the first fruits of the Soviet rare elements industry. Several years later, the production of pure uranium compounds was organised in the USSR on the basis of the same raw material.

In 1922, studies on the chemistry and technology of tungsten and molybdenum were begun in the Inorganic Chemistry Laboratory of Moscow University. Some years later, this work, which was carried out by T. M. Serbin, G. A. Meerson, V. I. Spitsyn, and others, led to the organisation of tungsten and molybdenum wire production for the electric lamp industry. The creation of a basis for refractory rare metals production led subsequently to the manufacture of hard alloys based on tungsten carbide and to the preparation of other compounds of tungsten. G. A. Meerson, I. A. Shlygin, and other workers from the Moscow Electrical Factory also worked on problems associated with the production of metallic niobium and tantalum.

Under the direction of E. V. Britske, I. V. Shmanenkov, and K. Kh. Tagirov, important work was carried out in the Applied Mineralogy Institute on the utilisation of Urals titanomagnetites. This form of raw material, which is widely distributed in the Urals, cannot be subjected to ordi-

nary metallurgical processing because of its high titanium content, which leads to the formation of refractory slags in the blast furnace. At the same time, valuable amounts of vanadium were discovered in the titanomagnetites. This group of research workers proposed smelting the titanium magnetites in the blast furnace with the addition of rock salt, to give more fusible calcium sodium titanium slags and vanadium-containing cast iron. A method was developed for the conversion of the titanium slags into titanium dioxide.

M. P. Pavlov proposed another method for the processing of titanomagnetites, involving blast-furnace smelting with the use of dolomite as a flux; this also makes it possible to lower the melting point of the titanium slags and to obtain vanadium-containing cast iron. Thus the problem of the processing of titanomagnetite ores was solved completely by the persistent efforts of Soviet research scientists.

M. N. Sobolev, K. A. Bol'shakov, and N. V Krasil'nikov put forward a method, based on laboratory and pilot-plant studies, for the extraction of vanadium from the waste products obtained in the processing of vanadium-containing cast iron. The factory which was built for the production of vanadium compounds played an important role during the Great Patriotic War of 1941–1945, since it provided a complete supply of ferrovanadium for Soviet high-grade metallurgy.

Considerable work was also carried out on other, even rarer elements. Studies by E. S. Burkser and his coworkers in the Ukrainian SSR were directed towards the development of the technology of lithium, ribidium, and caesium compounds and ensured the supply of these elements.

V. I. Spitsyn and G. F. Silina in 1932 developed a method for the production of metallic beryllium and its compounds from natural raw material and organised the industrial production of beryllium.

A series of studies on the chemistry of the rare-earth elements was carried out by I. N. Zaozerskii, D. I. Ryabchikov, and others, and these permitted the production of compounds of these elements under industrial conditions.

O. A. Suvorov and his coworkers in the Kazakh SSR carried out a series of studies on the chemistry of rhenium, and this made possible the production of this metal from the waste products from the Balkhash copper smelting plant.

Work carried out in the USSR on the chemistry and technology of bromine and iodine led to the production of these elements from petroleum drilling waters on a scale sufficient to satisfy the requirements of the Soviet Union.

Outstanding studies of the chemistry of the platinum metals were carried out by L. A. Chugaev, I. I. Chernyaev, A. A. Grinberg, V. V. Lebedinskii, N. K. Pshenitsyn, and their coworkers.

L. A. Chugaev prepared a whole series of representatives of a new type of complex compound of quadrivalent platinum—its amido-derivatives. He worked on the hydrazine and hydroxylamine compounds of platinum, the study of which was later developed by his pupils. Chugaev also studied the physicochemical properties of the ammine complexes formed by platinum(II) nitrite and prepared the previously unknown chloropentammine.

L. A. Chugaev died very early (1922), before reaching the age of fifty. His outstanding achievement was the foundation of a research school which has carried out extremely interesting studies in the chemistry of platinum and the elements accompanying it.

Chugaev's pupil I. I. Chernyaev in 1925 discovered the "trans effect"—the most important theoretical generalisation in the chemistry of complex compounds in the last fifty years. Chernyaev established that in complexes with a square or octahedral structure the strength of the bond formed by a given ligand with the central atom depends on the nature of the ligand in the *trans*-position. This influences its replacement by other ions or molecules which are less influenced by the trans effect.

For example, a strong trans effect is shown by the nitro-group NO_2. In a study of hydroxylamine derivatives of platinum(II), Chernyaev established that in the compound

$$\begin{matrix} Cl\ NH_3 \\ Pt \\ NH_2OH\ NO_2 \end{matrix}$$

the chlorine atom in the *trans*-position relative to the nitro-group is particularly readily replaced by various radicals and neutral molecules, for example, ammonia or pyridine. In *cis*-chloronitrodiammineplatinum(II), the ammonia in the *trans*-position relative to the nitro-group is labile, whereas in *trans*-chloronitrodiammineplatinum(II) the chlorine atom is labile. The reactions with silver nitrate indicate that in the *cis*-compound the chlorine is attached by a covalent bond, whereas in the *trans*-compound the chlorine is ionic.

Atoms and molecules can be arranged in the following order of decreasing trans effect: R_2S, NO_2^-, SCN^-, I^-, Br^-, Cl^-, F^-, OH^-, ..., RNH_2, NH_3, H_2O.

A. D. Gel'man discovered that unsaturated organic molecules such as ethylene and acetylene have a large trans effect.

The systematic occurrence of the trans effect, discovered in platinum(II) compounds, was subsequently applied successfuly to compounds of platinum(IV), palladium(II), rhodium(III), iridium(III), and cobalt(III), and various other elements.

The systematic occurrence of the trans effect makes it possible to predict the direction of reactions in the inner sphere of coordination compounds. It has therefore played an outstanding part in the development of methods for the preparation of new complex compounds. As an example, mention may be made of the work of I. I. Chernyaev and O. N. Andrianova on the preparation of the geometric isomers of the triamine $[PtBrCl(NO_2)(NH_3)En]Cl$. This complicated task was completed with the preparation of three new compounds of the six predicted by theory. The preparations involved a large number of stages and were entirely based on the use of the systematic occurrence of the trans effect.

The phenomenon of the trans effect makes it possible to develop further the ideas of A. M. Butlerov and V. V. Markovnikov on the mutual chemical influence of atoms in the same molecule. The remarkable feature of the phenomenon discovered by I. I. Chernyaev is that it is shown not by neighbouring atoms, but by ligands separated by a central atom.

B. V. Nekrasov put forward a theoretical explanation for the trans effect based on the characteristic deformability of the complex-forming atom. According to his views, the nature of the trans effect is close to the effect of ion counter-polarisation. A. A. Grinberg calculated theoretically the decrease in the strength of attraction between the

platinum(II) ion and the chloride ion, which should be observed when a second chloride ion is attached in the *trans*-position relative to the first, and showed that this effect is sufficient to produce the trans effect. Thus the trans activity of a ligand is determined by the energy of the mutual polarisation of the ligand and the central atom.

In addition to this work, a large number of mixed hexammine, pentammine, tetrammine, and triammine complexes of platinum(IV) were prepared and studied (I.I. Chernyaev and coworkers). Complexes of platinum with organic substances —pyridine, nitriles, isonitriles, etc.—were prepared.

A.D. Gel'man and L.N. Essen prepared for the first time a complex of platinum(IV) with six different inner-sphere substituents.

V.V. Lebedinskii prepared the previously unknown mono-, di-, tri-, and tetra-ammine complexes of rhodium(III), and also compounds of rhodium with thiourea. A.A. Grinberg prepared derivatives of palladium monoammines, and V.I. Goremykin prepared compounds of palladium containing hydrazine and hydroxylamine. New compounds of iridium, with thiourea in particular, were prepared. O.E. Zvyagintsev and his coworkers prepared nitrosonitrato-compounds of rutheium(II). It was shown that ruthenium is not precipitated from solutions of these substances by various reagents, which readily precipitate it from other compounds. A.M. Rubinshtein carried out extensive studies on the preparation of spectroscopically pure specimens of platinum and some of the metals accompanying it.

A.A. Grinberg and his coworkers made extensive studies of the acid–base and redox properties of complex compounds. Measurement of the dissociation constants showed that as a result of the conversion of the NH_3 molecule into the NH_2 amido-group, the ammines of platinum(IV) act as weak acids. The amidoammine complexes of platinum undergo the opposite reaction and exhibit weakly basic properties upon reaction with water.

It was found that the redox properties of ionic complexes depend not only on the nature of the central atom but also to a particularly marked extent on the nature of the ligands in the inner sphere. The appreciable lability of the inner-sphere substituents in compounds such as $K_2[PtBr_4]$, $K_2[PtBr_6]$, $[PtBr_2(NH_3)_4]$, and various others was proved by A.A. Grinberg and F.M. Filinov by isotopic exchange with radioactive tracers. On the other hand, the central atoms of the compounds studied underwent almost no isotopic exchange with corresponding ions from the solution. On the basis of this work, new analytical methods were proposed for the determination of iridium and platinum.

As a result of these studies, thousands of new compounds of the platinum metals were obtained and original methods for their preparation were developed. The development of the chemistry of the platinum metals led to improved methods for the separation and purification of these elements. Before the Great October Socialist Revolution a considerable quantity of platinum-containing raw material was mined in Russia, but the industrial refinement of platinum and the metals accompanying it were not carried out. From the work of the Chugaev–Chernyaev research school, a platinum industry was created in the USSR, producing from native raw materials all the platinum metals in a high state of purity.

A considerable amount of work on the chemistry of complexes was carried out by Ya.A Fialkov and his coworkers in the Academy of Sciences of the Ukrainian SSR. The materials studied were chiefly coordination compounds in which the central atom is non-metallic—polyhalides, polysulphides, double halides of phosphorus, antimony, and other elements, derivatives of iodine halides with organic substances, etc. A new type of complex containing iodine as cation was discovered. In the study of phosphorus halides, the existence of the tetra-acido-cations $[PCl_4]^+$ and $[PBr_4]^+$ was proved for the first time.

Systematic studies in the thermochemistry of complexes have been carried out since 1946 by K.B. Yatsimirskii and his coworkers. The heats of formation of complexes of cobalt, nickel, copper, zinc, and other transition metals (ammine, ethylenediamine, pyrophosphato-, and oxalato-complexes, etc.) have been determined. Kapustinskii's equation and other generalisations have been used to calculate for the first time the heats of formation of gaseous complex species from the gaseous components (central atom and ligands). K.B. Yatsimirskii then realised the transition from thermochemistry to the complete thermodynamic characteristics of reactions involving complex formation (the changes in enthalpy, entropy, and free energy). New methods were put forward for studying the complex formation equilibria. These include a spectrophotometric method for solutions in which several coloured complexes exist together. A kinetic method for studying the equilibria has been developed, based on the change in catalytic activities on complex formation. New methods for the mathematical treatment of data on equilibria have been proposed. A large number of equilibria in solutions of complex compounds have been studied experimentally.

There has recently been an extensive development of studies of electronic spectra and their application to the investigation of the characteristic features of the structures of complex compounds (the symmetry of the inner sphere, chemical bonding, and the fine details of the structure of the inner sphere). These methods have been applied to the complex compounds of the rare-earth elements by K.B. Yatsimirskii, N.K. Davidenko, and N.A. Kostromina. The interpretation, correlation, and generalisation of the thermodynamic, kinetic, and optical characteristics of complex compounds have been carried out on the basis of modern theoretical concepts (crystal field theory, the method of molecular orbitals, etc.).

Studies of considerable scientific value have been carried out in the chemistry of radioactive elements by V.G. Khlopin and his pupils. Khlopin's work involved chiefly the study of the laws governing the coprecipitation of radioactive elements, present in solutions at extremely high dilutions, with crystalline or amorphous precipitates separating from the solutions. Khlopin established that entrainment of the radioactive element by the crystalline precipitate takes place only if its compound is isomorphous with the substance being precipitated. The micro-component is then distributed between the crystals and the solution as a dissolved substance is distributed between two immiscible solvents. An important part is played by recrystallisation of the solid phase to achieve homogeneity and to establish equilibrium in the system with respect to the macro-component. The study of more than thirty systems containing radium, polonium, radium-D (a lead isotope), and other radioactive elements as micro-components showed that the distribution law was obeyed rigorously. Salts of barium, lead, uranium, cerium, etc. were used as the macro-component.

The Soviet radium industry has made extensive use of the practical results of the research work of Khlopin's

school. Methods for separating radium and barium have been improved considerably and new methods have been developed in the technology of radioactive substances.

This work has also led to the following conclusion: the applicability of Khlopin's law to the distribution of a micro-component in a system containing crystals and a solution of a macro-component proves that in the given instance the micro-component is isomorphous with the macro-component and replaces it in the crystal lattice. The use of radioactive tracers has thus opened up new methods for the study of the phenomena of isomorphism.

In particular, this method can be used to establish the existence of unstable compounds or compounds present in negligibly small quantities, and to study their composition and structures. In this way, V.G.Khlopin and A.G.Samartseva established that polonium forms bivalent compounds which cocrystallise with sodium telluride Na_2Te. In an oxidising medium, cocrystallisation with lead tellurate $PbTeO_4$ revealed the existence of polonate ions, corresponding to the previously unknown sexivalent polonium.

The method of "isomorphous cocrystallisation" using radioactive tracers was used by V.G.Khlopin and B.A.Nikitin to study the phenomena of so-called second-order isomorphism, in which isomorphous replacement takes place when the substances have structures of the same chemical type, irrespective of any chemical analogy. Examples include the isomorphism of barium sulphate and potassium permanganate ($BaSO_4$, $KMnO_4$), barium chromate and potassium tetrafluoroborate ($BaCrO_4$, KBF_4), sodium bromide and lead sulphide (NaBr, PbS), etc. For the example of systems containing rubidium perchlorate and radium sulphate ($RbClO_4$, $BaSO_4$), Khlopin and Nikitin showed that at concentrations of about 10^{-6}% lead and radium do not enter the crystal lattice of the perchlorates. This established the existence of a lower miscibility limit for second-order isomorphous replacement. At the same time the perchlorates studied could entrain radium or lead sulphates if the latter were present in concentrations sufficient for the construction of their own crystal lattice. This leads to a conclusion of considerable scientific importance: in true isomorphism, replacement takes place ion for ion, atom for atom, or molecule for molecule; in second-order isomorphism, however, the replacement involves complete sections of the crystal lattice, with dimensions varying from one unit cell to a comparatively large number of unit cells.

B.A.Nikitin used the principle of isomorphous cocrystallisation to study possible compounds of the inert gases. He established that sulphur dioxide hydrate $SO_2.6H_2O$, below its eutectic point (−2.6°C) absorbs radon even at a negligibly low concentration of the latter. The process obeys the distribution law. This proved that radon forms a hydrate isomorphous with the hydrate of sulphur dioxide, with composition corresponding to the formula $Rn.6H_2O$.

An analogous phenomenon was observed for other inert gases—argon and neon. The distribution constants between the gaseous phase and the solid hydrate $SO_2.6H_2O$ were different for the inert gases studied. By carrying out the separation of the sulphur dioxide hydrate in several stages and controlling the temperature, it was found possible to achieve the fractional separation of the inert gases by this chemical method.

Subsequently, B.A.Nikitin demonstrated in analogous fashion the existence of compounds of the inert gases with toluene, phenol, and *para*-chlorophenol, for example, $Rn.2C_6H_5CH_3$, $Rn.3C_6H_5OH$, and $Rn.3ClC_6H_4OH$. The molecular compounds $HBr.2C_6H_5CH_3$, $H_2S.3C_6H_5OH$, $H_2S.3ClC_6H_4OH$, etc. were used as carriers. In this way it was established that the ability of inert gases to undergo chemical reaction is not restricted to the formation of hydrates, but also extends to many organic compounds. B.A.Nikitin considered that the stability of the compounds of the inert gases which he obtained approaches that of molecular compounds. The atoms of the inert gases behave as the molecules of chemical compounds.

One of the most important ways of increasing the efficiency of the separation of elements by cocrystallisation involves the use of complex-forming reagents. This approach, pointed out by V.G.Khlopin, was developed by N.B.Mikheev and L.M.Mikheeva, who put forward equations which make it possible to calculate the degree of separation of elements under conditions of equilibrium and non-equilibrium cocrystallisation. It was shown that electrically neutral complexes can take part to only a slight extent in the cocrystallisation of ionic salts. These studies represent an extension of the thermodynamic theory of cocrystallisation, developed by A.P.Ratner, a pupil of V.G.Khlopin.

The difficulty of attaining equilibrium between mixed crystals and solution presents an obstacle to the development of multiplicative schemes for the separation of elements. V.I.Spitsyn, N.B.Mikheev, and A.Khermann developed an electrochemical method for the forced recrystallisation of sparingly soluble salts and achieved the "elution" of impurities cocrystallising with the precipitate.

The theoretical principles of the processes of ion adsorption on precipitates were developed by A.P.Ratner and V.G.Khlopin, together with V.I.Grebenshchikova and M.S.Merkulova.

M.S.Merkulova and I.V.Melikhov have recently studied non-equilibrium cocrystallisation, which is often encountered in practice. They distinguish the various stages which may limit the process, depending on the conditions of cocrystallisation.

V.I.Spitsyn and V.V.Gromov established that radioactive irradiation of the specimens influences the cocrystallisation. High radioactivity in the precipitate leads to more intensive recrystallisation, and this increases the rate of attainment of equilibrium in the system.

In addition to the study of cocrystallisation processes, studies have been made of the application of various forms of ion-exchange adsorption to the separation of radioactive elements.

Using various sorbents (glass, activated carbon, ion-exchange resins, etc.), I.E.Starik determined the state of various multivalent elements in dilute solutions.

B.P.Nikol'skii and V.I.Paramonova used the method of ion exchange to study the composition and stability of complexes of radioactive elements and isotopes. Their studies were among the first in this field.

V.I.Spitsyn and V.V.Gromov showed that the radioactive irradiation of precipitates influences their sorptive properties. The magnitude of the adsorption of basic and acidic dyes on a barium sulphate precipitate containing radium or the radioactive tracer ^{35}S, depends on the magnitude and nature of the radioactive irradiation of the isotope present; this is directly related to the electric charges produced on the surface of the solid phase, depending on whether alpha- or beta-particles are emitted.

The considerable progress made in the development of the theory of cocrystallisation and adsorption processes has found extensive technological application in the preparation of radioactive isotopes.

Soviet scientists have carried out a considerable amount of experimental and theoretical studies, covering the chemistry of the elements of all groups of the Periodic System. Only some of these can be mentioned in this brief review.

The systematic study of metal hydrides in the Soviet Union was begun by I. I. Zhukov, who showed that they can be divided into several classes—individual chemical compounds and solid solutions of hydrogen in the metals or the individual hydrides.

The preparation of the hydrides of various refractory rare metals (titanium, vanadium, niobium, and tantalum) by the reaction of the oxide of the corresponding element with calcium hydride at an elevated temperature was studied by G. A. Meerson and his coworkers.

I. A Kazarnovskii and his coworkers, on the basis of a study of the hydrides of the alkali and alkaline earth elements, calculated the radius of the negative hydrogen ion and the electron affinity of the hydrogen atom.

The hydrides of boron and the hydrides of the light and transition metals have been studied since the early nineteen-fifties by V. I. Mikheeva and her coworkers. Stable molecular compounds of diborane with pyridine, aniline, and other amines have been prepared. Optimal conditions have been established for the preparation of the alkali metal and magnesium hydrides, and also hydride halides of the type MgClH, etc. A method has been developed for the preparation of the complex tetrahydroborates and tetrahydroaluminates of various metals by double decomposition in aqueous or organic solutions, and also in salt melts. The tetrahydroborates of calcium, magnesium, and aluminium, and the tetrahydroaluminates of magnesium, cerium, and other metals have been prepared in this way.

Soon after the discovery of the heavy isotope of hydrogen, studies using deuterium were carried out in the Ukraine by A. I. Brodskii, who organised the laboratory production of heavy water as early as 1934. Brodskii and his coworkers developed an interferometric method for the quantitative determination of deuterium and carried out a number of extremely interesting studies of the isotopic exchange of hydrogen in various inorganic and organic compounds. A. I. Shatenshtein developed methods for the preparation of many deuterium compounds and carried out extensive studies of hydrogen exchange in non-aqueous solvents between various classes of substance, using their deuterium derivatives.

In the field of the rare alkali metals, mention must be made of the work of V. E. Plyushchev, who proposed new methods for the extraction of lithium and caesium from natural raw material. The study of polyhalides and double compounds with the chlorides of antimony, bismuth, and tin made it possible to improve methods for the separation of rubidium and caesium. Solid-phase reactions were used to prepare mixed compounds of rubidium, caesium, and the rare-earth elements—various zirconates, niobates, tantalates, etc.

The chemistry of beryllium has developed considerably. A. V. Novoselova, O. I. Vorob'eva, K. N. Semenenko, and others have synthesised a whole series of new fluoro-complexes of beryllium and have established the physicochemical conditions of their formation. Previously unknown crystalline modifications of beryllium fluoride, sodium fluoroberyllate, and other compounds have been discovered. New data have been obtained on the structural and chemical analogies between the fluoroberyllates and sulphates of the alkali and alkaline earth elements.

The same research team has studied the properties of beryllium nitrate and sulphate—the composition of the crystal hydrates, the thermal stability of the compounds, etc. Various covalent beryllium compounds have been prepared, and their properties and structures have been studied: these include oxide salts—the oxide formate, oxide acetate, oxide propionate, and oxide benzoate—and their compounds with various organic and inorganic molecules, alkoxy-derivatives, and compounds with ammonia and amines, nitrogen dioxide, and sulphur dioxide. Studies have been made of the properties and structures of the compounds formed by beryllium chloride with various inorganic and organic molecules, and the nature of their reactions in non-aqueous solvents.

In an investigation of natural brines containing boron, A. V. Nikolaev made a detailed study of calcium, magnesium, sodium, and potassium borates, and discovered an extremely interesting phenomenon, which has been described as borate rearrangement: when a hydrated borate is heated, the endothermic dehydration is followed by a clearly defined exothermic effect, which causes the temperature of the borate to rise spontaneously to a value which is 50–100 deg higher than the temperature of the heater. The borate rearrangement results from the crystallisation of the amorphous anhydrous borate formed initially.

B. N. Ivanov-Emin and his coworkers have carried out interesting studies on the amphoteric properties of the elements of the gallium subgroup. Acidic properties are observed in the oxides of all elements of this subgroup, but the acidity decreases sharply in the order gallium–indium–thallium, corresponding to the rules which follow from D. I. Mendeleev's Periodic Law. Sodium hexahydroxoindate $Na_3[In(OH)_6].2H_2O$, which is stable only in strongly alkaline medium, was prepared for the first time.

E. N. Deichman carried out a number of studies on the chemistry of simple and complex compounds of indium. She prepared hydrogen sulphatoindates—$H_3In(SO_4)_3$ and others—and prepared sulphato-, oxalato-, mixed sulphato-oxalato-, fluorosulphato-, and phosphato-compounds of indium. In the pre-revolutionary period, outstanding studies on the chemistry of the rare-earth elements were carried out by the Russian chemist N. A. Orlov. His last work, concerned with the isolation, by fractional crystallisation, of specimens of the least readily accessible elements of this group—holmium, dysprosium, and others—was published in the Soviet period.

Scientific research work on the rare-earth elements in the Soviet Union was held up for a considerable time by the lack of suitable raw material for their extraction. In the nineteen-thirties, considerable attention was drawn to the rare-earth minerals of the Kola peninsula, particularly lovchorrite—a titanofluorosilicate of calcium and the rare-earth elements. I. N. Zaozerskii and P. I. Protserov put forward an acidic method for its decomposition, and E. S. Burkser and G. P. Aleksandrov put forward a chlorination method. These gave the first Soviet specimens of the rare earths.

During the period of industrialisation, Soviet industry began to make extensive use of Khibiny apatites as raw

material for the production of superphosphate. The apatite concentrate contains more than 1% of rare earths of the cerium group, and this is of considerable interest in view of the large scale of phosphorus fertiliser production. S.I. Vol'fkovich and A.I. Loginova put forward a method for the extraction of rare earths from apatite during its acid conversion into concentrated fertilisers. A rare earth concentrate can be isolated by fractional precipitation from the solution using lime.

The production of compounds of the rare-earth elements permitted their study and a start to be made in their practical application. D.I Ryabchikov and E.A. Terent'eva studied complexes of the rare-earth elements with organic acids and amines. The rare-earth element in every instance showed a coordination number equal to six. The most stable compounds were obtained with tricarballylic, aconitic, nitrilotriacetic, and citric acids. Study of the last of these established the composition of the complexes—$M^{I}_{3}[M^{III}(C_6H_5O_7)_2]$, where M^{III} represents the rare-earth element. Complexes of medium stability were obtained with antipyrine, pyramidone, and pyridine as inner-sphere substituents around the rare-earth element. In the lanthanide series, the tendency to form complexes was found to increase with decrease in ionic radius.

Subsequent studies on the separation of the rare-earth elements and the preparation of their compounds in pure form developed in two directions—chromatographic methods and extraction methods. In both, an important part is played by complex formation.

L.I. Martynenko and coworkers were the first to use ethylenediaminetetra-acetic acid as eluant in the ion-exchange chromatography of the rare-earth elements. This method was used to prepare for the first time spectroscopically pure specimens of all the rare-earth elements for research organisations.

To obtain a theoretical basis for the optimal conditions for the ion-exchange separation of mixtures of the rare-earth elements, the same group made a systematic study of the composition and properties of the complexes formed by the lanthanides (Ln) with ethylenediaminetetra-acetic acid, nitrilotriacetic acid, and iminodiacetic acid. It was found that the separation generally involves mixtures of complexes. For example, when ethylenediaminetetra-acetic acid H_4A is used, complexes of the type $[LnA]^-$ and $[Ln_2A]^{2+}$ are formed, and when nitrilotriacetic acid H_3X is used, the complexes $[LnX]$ and $[LnX_2]^{3-}$ are formed. In many instances the difference in the quantities of complexes with different compositions is of greater importance for the chromatographic separation of a given pair of rare-earth elements than the difference in the stabilities of the complexes with a given composition formed by the same pair.

The study of reactions in solid-phase systems at elevated temperatures showed that the oxides of the rare-earth elements can react with the oxides of the alkali and alkaline earth metals to form compounds which are isomorphous with the analogous ferrites. Thus the manifestation of amphoteric character, previously known in this family only for scandium, has now been recognised in all the rare-earth elements (L.I. Martynenko, L.M. Kovba, and others).

L.N. Komissarova and coworkers carried out a series of studies on the chemistry of scandium. The sulphates, nitrates, oxide salts, and complexes of this element were studied. New complexes formed by scandium carbonate were prepared, and also salts of oxyacids of phosphorus in various valency states (phosphites, hypophosphite, and a number of phosphates). The results obtained were used to improve methods for the isolation of scandium from natural raw material.

N.E. Brezhneva, V.I. Levin, G.V. Korpusov, and others studied the regular features of the separation of the rare-earth elements by extraction using organophosphorus compounds. The work was originally carried out in connection with the preparation, in a state of radiochemical and chemical purity, of promethium and the radioactive isotopes of the rare-earth elements present in the waste products from the atomic industry—uranium fission products. At the same time a study was made of the mechanism of the extraction of multivalent ions by organic solvents and a direct relationship was established between the structure of the molecules of the organophosphorus extracting agents and their extracting power. The results obtained have also found application in processes for the separation of the stable rare-earth elements. The introduction of the extraction method of separation permitted the large scale isolation of rare-earth elements, in particular yttrium, with a purity of 99.9999%; this has found industrial application.

Among the inorganic compounds of carbon the carbides are important, many of them so because of their hardness and high melting point.

G.A. Meerson and his coworkers have studied the formation conditions of refractory rare metal carbides. The reduction of the oxides, for example titanium dioxide, by carbon leads to the simultaneous formation, in solid solution, of the compounds TiC, TiO, and TiN (the last of these due to the presence of residual air). The problem of preparing pure carbides is proving extremely difficult. The reduction of titanium dioxide by carbon is facilitated by using an atmosphere of hydrogen. The hydrocarbons formed apparently act as carbon carriers. When the reduction is carried out in a vacuum, a mixture of titanium dioxide and carbon gives a solid solution of metallic titanium in the carbide. It is quite probable that the phenomena observed in the formation of titanium carbide are also shown by other carbides.

In the chemistry of silicon, mention must be made of the outstanding studies of I.V. Grebenshchikov on glasses. It is known that ordinary silicate glasses contain sodium disilicate, which is fairly readily soluble in water, and calcium silicate, which decomposes fairly rapidly under the influence of acids, yet a glass containing these compounds shows an unusually high stability towards water, acids, and other chemical reagents. According to Grebenshchikov's studies, all silicate glasses react extremely vigorously and rapidly (in a period of several seconds) with water with the formation of a thin colloidal film of silicic acid on the surface; this film is produced by hydrolysis of the silicates and it prevents further decomposition of the glass. The thickness of this film has been measured by various methods and the film has been found to be extremely thin (10–60 Å).

On the basis of the properties of the surface film of silicic acid, Grebenshchikov obtained information on the part played by chemical processes in the polishing of glass. It was found that it is not the hardness of glass, but its chemical stability, which primarily influences the rate of grinding and polishing. Change in temperature, the introduction of substances into the solution which are adsorbed by the protective film of silicic acid, and the replacement of water by other liquids all have a marked influence on the

thickness and properties of the protective film, and hence on the process of glass polishing.

A whole range of silicate systems has been subjected to detailed study by modern physical and physicochemical methods. On the basis of the research work carried out under the direction of I. V. Grebenshchikov and N. N. Kachalov, the production of first-class optical glass was organised in the USSR in the late nineteen-twenties.

Recently, N. A. Toropov and his coworkers have studied silicate systems containing the rare earths and other refractory oxides.

A large number of studies have been carried out by E. I. Gladyshevskii and his coworkers on the silicides and germanides of various metals. Studies have been made of binary and ternary systems containing vanadium, chromium, manganese, iron, cobalt, nickel, titanium, the rare-earth elements, and many other metals. It is only in a few instances that the compositions of the compounds obtained are determined directly by the main valencies of the components, and for the most part the compositions are determine by geometric and electrochemical factors and the degree of electron delocalisation. The compounds obtained include La_3Si_2, Lu_5Ge_3, VCoSi, $CaAl_2Si_2$, $Mo_5Co_3Ge_2$, etc. In the formation of silicides and germanides, an important part is played by the formation of covalent Si–Si and Ge–Ge chains.

Work on the chemistry of zirconium and hafnium has continued to develop. L. N. Komissarova, Yu. V. Granovskii, and others have studied the processes involved in the separation of these elements by extraction using tributyl phosphate; methods involving mathematical planning of the experiments were used. In the same laboratory, studies have been made of the solid-phase reactions between hafnium dioxide and oxides of the rare-earth elements.

N. A. Godina and others have studied the reaction of zirconium dioxide with the rare-earth elements and of hafnium dioxide with the alkaline earth elements; this has given more accurate information on the equilibrium diagrams for these systems.

Yu. V. Khodakov has shown experimentally that all previously proposed schemes for the hydration of phosphorus(V) oxide are erroneous, since they do not make allowance for the formation of intermediate products—higher polyphosphoric acids: the tetra-acid $H_6P_4O_{13}$ and the tri-acid $H_5P_3O_{10}$. The mechanism established for the hydration of phosphorus(V) oxide corresponds to the theory of the three-dimensional structure of the anhydrides of the oxo-acids, developed by Yu. V. Khodakov.

A. V. Lapitskii has published a number of studies of the chemistry of niobates and tantalates. In particular, he has made a detailed study of the dependence of the dehydration and thermal stability of these compounds on the nature of the cations present.

There has been a considerable increase in information on peroxo-compounds. I. A. Kazarnovskii and his coworkers have studied a new class of oxygen compound of the alkali metals—ozonides—obtained by the action of ozone on the correspoinding hydroxides. The products of the side-reactions were previously known, but the substances obtained in this instance could be isolated in pure form only because of the original method employed—extraction by liquid ammonia. A detailed chemical study was made of potassium ozonide; its structure was studied by X-ray diffraction and magnetic methods, and its heat of formation was measured. It was shown that the structure of potassium ozonide is given by the formula $K^+O_3^-$. Study of the isotopic exchange of oxygen between KO_3 and water enriched in $H_2{}^{18}O$ gave new data on the reactivity of the free hydroxyl radical. A mechanism for the reaction of ozone with alkalis was proposed on the basis of these studies.

Compounds of sulphur, selenium, and tellurium have been widely studied, since they are of considerable interest as semiconducting materials. A. V. Novoselova and coworkers prepared and studied the electrical properties of the binary and some ternary chalcogenides of titanium, zirconium, vanadium, niobium, tantalum, and other metallic elements. Semiconductors and dielectrics have been found among chalcogenides with general formula $A^{II}B^{IV}C_3^{VI}$. The change from dielectrics to semiconductors is accompanied by a change in structural type. The thermal stabilities of a number of selenides and tellurides have been studied. The equilibrium diagrams of the Ge–S, Ge–Se, and other systems have been obtained in fundamental studies on the preparation of semiconducting compounds.

Important studies on the preparation of various arsenides and antimonides have been carried out by N. A. Goryunova.

In the chemistry of the oxygen compounds of sulphur, mention must be made of the interesting derivatives of sulphamic acid prepared by A. V. Kirsanov: *N*-(chlorosulphonyl)phosphorimidic trichloride $ClSO_2.NPCl_3$, sulphanuryl chloride $(NSOCl)_3$, etc.

V. I. Spitsyn and his coworkers have carried out a number of studies on the chemistry of tungsten and molybdenum. The compositions of the isopolytungstates and isopolymolybdates formed by various metals have been established. Detailed study of the dehydration of many aquopoly- and heteropoly-compounds has shown the important constitutional role played by water in these substances. At the same time the use of tracer atoms has established the high mobility of its molecules in these compounds. Isotopic and ion exchange between the anions of various heteropolyacids has been studied. The simultaneous use of two radioactive tracers (^{32}P and ^{185}W) made it possible to establish, by the self-diffusion method, that the reaction between the anions of two acids capable of forming a heteropolycompound (for example, HPO_4^{2-} and WO_4^{2-}) begins even in the alkaline range and apparently involves hydrogen bonding. A new coordination treatment of the structure of aquopoly- and heteropoly-compounds has been put forward, based on oxonium groups and hydrogen bonding, the molecules of the corresponding acids, for example, H_2MoO_4 and H_2WO_4, being regarded as inner-sphere ligands.

E. A. Nikitina has studied problems associated with the preparation of heteropolycompounds and has proposed a method, which does not involve the use of ether, for preparing molybdophosphoric, molybdosilicic, and tungstophosphoric acids by the direct reaction of the corresponding reagents, for example, phosphoric acid and molybdenum(VI) oxide.

A. I. Kokorin and coworkers have studied tri- and tetraheteropolyacids and have prepared a number of new representatives—vanadomolybdophosphoric, tungstomolybdosilicic, vanadotungstomolybdophosphoric, and other similar acids.

Z. F. Shakhova and R. K. Motorkina have studied heteropolycompounds of germanium and certain rare-earth elements. They showed by various methods that the structures of the reduced and non-reduced forms of tungstogermanic and molybdogermanic acids are identical.

V.I. Spitsyn, V.F. Chuvaev, and V.Ya. Kabanov applied proton magnetic resonance to the problem of the basicity of heteropolyacids. According to the Miolati–Rosenheim theories, the central atom in these acids always has a coordination number of six, so that, for example, a high basicity, equal to seven, was assumed for molybdophosphoric acid: $H_7[P(Mo_2O_7)_6]$. X-Ray diffraction studies by Keggin and others led to the conclusion that the usual coordination number of phosphorus and silicon in heteropolyacids is four. The basicity of the heteropolyacids should then be lower; for example, the formula for molybdophosphoric acid should be $H_3[PO_4(MoO_3)_{12}]$. Chemical studies generally did not confirm the formation of salts with a high degree of substitution. The problem remained open, however.

The method of nuclear magnetic resonance makes it possible to distinguish the states of hydrogen atoms in compounds and to decide whether they correspond to H^+, OH^-, H_3O^+, or H_2O. The use of this method established unambiguously that the number of hydrogen ions in ordinary heteropolyacids corresponds to the low basicity which follows from their X-ray diffraction study. Thus the suggestion that there exist salts of heteropolyacids with a high degree of substitution should be rejected.

Simple and complex fluorides have been studied for a number of years by I.V. Tananaev and his coworkers, who were the first to prepare sodium hydrogen fluoride and lithium hydrogen fluoride. The hydrogen hexafluoroaluminates $AlF_3.3HF.6H_2O$ and $AlF_3.3HF.3H_2O$, previously unknown in the free state, have been prepared; these compounds have been described as cryolitic acids. The same group of workers have studied many double fluorides formed by metals. Natural cryolite has been found to have the composition $11NaF.4AlF_3$, and not $3NaF.AlF_3$, as previously assumed. Interesting data have been obtained on the stepwise electrolytic dissociation of the fluoride of multivalent elements.

I.V. Tananaev and his coworkers have also used various physicochemical methods to study heavy metal hexacyanoferrates(II) and the double salts which they form with alkali metal hexacyanoferrates(II). Double potassium–nickel, potassium–cobalt, caesium–cobalt, and other hexacyanoferrates(II) have been isolated for the first time. The compositions of the double hexacyanoferrates(II) formed by potassium with indium and gallium have been established: $KIn[Fe(CN)_6]$ and $KGa[Fe(CN)_6]$. This type of compound has proved to be characteristic for tervalent metals and is usually formed instead of the normal hexacyanoferrates(II). Analogous results were obtained for lanthanum hexacyanoferrates(II). A hexacyanoferrate(II) method has been proposed for the separation of yttrium from cerium and lanthanum. The use of the radioactive silver tracer ^{110}Ag has made it possible to study the replacement of the alkali and heavy metal in various simple and mixed hexacyanoferrates(II) by silver ions and hence to characterise the relative strengths of the bonds formed by the metals in the outer sphere with the hexacyanoferrate(II) ion.

Mention must also be made of the fact that Soviet inorganic chemists have paid considerable attention to the development of the chemistry of the little-studied radioactive elements. V.I. Spitsyn and A.F. Kuzina developed methods for isolating the long-lived isotope of technetium ^{99}Tc from neutron-irradiated molybdenum. These authors prepared various technetium compounds and studied their properties. In the same laboratory, R.A. D'yachkova studied the isolation of protoactinium from the waste products from the processing of uranium ores and for the first time in the Soviet Union obtained ponderable quantities of this element. The forms in which protoactinium exists in aqueous solutions with different acidities have been studied.

After the organisation of an atomic industry in the USSR, research workers were able to study the chemistry of plutonium and other transuranium elements. V.V. Fomin and coworkers showed that in addition to the fluoride $NaPuF_5$ described in the literature, compounds M_2PuF_6, where M = Na or NH_4, exist. Measurement of the vapour pressure of plutonium tribromide in bromine vapour established the formation of plutonium tetrabromide, unstable at low temperature. A detailed study was made of the decomposition of oxalates of plutonium under the influence of its own radiation, leading to the conversion of the oxalates into carbonates and reduction of plutonium. This change in the specimens readily explains their appreciable solubility in acids after they have been kept for some time. Other simple and complex compounds of plutonium were prepared and studied.

A.D. Gel'man, A.I. Moskvin, V.P. Zaitseva, M.P. Mefod'eva, and others have studied complex formation of neptunium, plutonium, americium, and curium in aqueous solutions with various ligands. The stability constants of the ionic complexes have been determined. The kinetics of the valency changes in neptunium and plutonium in nitric acid solutions have been studied, and the influence of complex formation on the redox reactions of these elements has been investigated.

A large number of simple and complex compounds of neptunium and plutonium have been isolated by these authors and characterised in the solid state. Examples include $M_4Np(C_2O_4)_4.nH_2O$, $NpO_2C_2O_4.3H_2O$, and the plutonium(V) compounds $NH_4PuO_2F_2$, $NH_4PuO_2CO_3.3H_2O$, $NH_4PuO_2HPO_4.4H_2O$, $(NH_4)_2PuO_2(OH)CO_3.nH_2O$, and $NH_4[PuO_2C_2O_4].6H_2O$. Pure concentrated solutions of tervalent uranium have been prepared, and various complex compounds have been isolated in solid form from these solutions.

V.M. Vdovenko and coworkers have made a number of studies of complex formation by uranium and plutonium in connection with methods for their separation by extraction. Nitrato-, sulphato-, chloro-, and other complexes have been studied. Tributyl phosphate, diethyl and dibutyl ethers, and various amines have been used as organic media. The structures of various compounds of uranium and plutonium have been established by infrared spectroscopy and proton magnetic resonance.

A traditional field of Soviet inorganic chemistry is the study of metallic alloys and the chemical compounds which they form.

N.S. Kurnakov, G.G. Urazov, and their coworkers have prepared many new alloys based on magnesium and aluminium, and have established their structures. This has made it possible to organise the production of most important materials for the aviation industry and other branches of the national economy.

Studies of heat-resistant alloys based on iron and chromium, carried out by I.I. Kornilov, have made it possible to produce new and valuable materials for high-temperature technology. V.A. Nemilov has prepared a whole series of palladium alloys which had not been studied before. E.M. Savitskii has studied the properties of alloys based on the rare-earth metals. In connection with problems associated with light alloys, A.V. Novoselova, N.D.

Nagorskaya, and others studied for the first time the equilibrium diagram of the Al–Be–Mg system, and also investigated the nature of crystallisation in beryllium-rich alloys of various systems (Be–Nb and Be–Re).

A series of important studies has been carried out by A. F. Kapustinskii on the dependence of the energetics of chemical reactions on the positions of the elements in the Periodic System. He made a systematic survey of the thermodynamic properties of the sulphides of various metals, and put forward a convenient simplified equation for calculating crystal lattice energy as a function of the valencies and radii of the ions forming it.

A valuable contribution to the thermodynamics of inorganic compounds, particularly the halides and oxides of the rare elements, was made by the work of S. A. Shchukarev.

The theoretical principles of chemical bonding in inorganic compounds has been developed by Ya. K. Syrkin and M. E. Dyatkina. A theory of directed valencies and a theory of the valency states of atoms in molecules have been developed, and the interactions of atoms with electrons have been studied from the viewpoint of quantum mechanics. Systematic studies of the valency states of both transition and non-transition elements have made it possible to reach a number of conclusions of importance for inorganic chemistry. In particular, the electronic structure of the tetrahedral oxoanions of the transition metals has been studied. Quantum-chemical calculations of the energies of inorganic compounds have made it possible to make predictions regarding the covalent character of the bonding in crystals; this is extremely significant for an understanding of the semiconducting properties of various inorganic substances.

---o0o---

In the fifty years for which the Soviet State has been in existence, inorganic chemistry has grown in the Soviet Union, together with the whole of chemical science. As can be seen from this necessarily brief review, considerable progress has been made in many important fields of the development of modern inorganic chemistry. However, the great task which stands before us—the construction of communism by the first workers' state in the world—is increasing to an even greater extent the need for the extensive utilisation of science as a direct productive force in society. The potential possibilities provided by inorganic chemistry in this respect are unusually great: inorganic polymers, laser crystals, refractory and super-hard materials, materials for superconductivity, and many other valuable materials can be provided only by inorganic chemistry.

Our country's anniversary is inspiring Soviet inorganic chemists to new scientific efforts and achievements!

U. D. C. 547

SOVIET ORGANIC CHEMISTRY AFTER 50 YEARS

N. S. Zefirov

Russian organic chemistry long ago won an honourable place in world science. The names of A. M. Butlerov, V. V. Markovnikov, N. N. Zinin, E. E. Vagner, and N. N. Men'shutkin have acquired a wide repute. Russia had strong chemical schools; in this connection special mention must be made of the Kazan' chemical school, which has produced a great number of brilliant organic chemists, to whom world science must be obliged for the greatest scientific achievements.

Despite this, it has fallen to the Soviet land after half a century to make the most grandiose work on the development of chemical science and industry. Before the revolution chemical science had developed only in individual scientific centres and the number of chemists with higher education amounted to not much more than 1000; the organic chemical industry was practically non-existent.

Fifty years later a powerful chemical industry has been created in our country. In the USSR a series of new means of production—coal tar chemicals, aniline dyes, petrochemical, chemico-pharmaceutical, etc.—have been set up where there was literally an empty place. This enormous construction required great forces in assimilating even the experience gained abroad. In addition our country developed novel solutions for various problems in the construction of a chemical industry. The clearest example is the organisation of the production of synthetic rubber, which was the first in the world.

The rapid development of the organic chemical industry in the USSR was based on the experience and traditions of Russian, and then Soviet, organic chemistry. On the other hand, with the development of the chemical industry, organic chemistry obtained a new firm foundation. After years of Soviet power, having opened wide the doors of educational establishments, there grew up in our land an enormous army of organic chemists. A marked extension of the "geography" of organic chemistry resulted—in addition to Moscow, Leningrad, Kazan', Kiev, Tomsk, Khar'kov, Odessa, and Riga, there are now large scientific centres at Gor'kii, Kuibyshev, Novosibirsk, Irkutsk, Vladivostok, Erevan, Tbilisi, Baku, Tashkent, etc.

It is impossible to list all who took part in this. We will only note that during the years of Soviet power new scientific schools have developed which are of worldwide repute and which determine the development of individual branches of organic chemistry not only in our own country but throughout the world. In this connection mention must be made of the school of N. D. Zelinskii, who tackled many problems of the chemistry of hydrocarbons and organic catalysis; the school of A. E. Favorskii and S. V. Lebedeva, who developed the chemistry of unsaturated aliphatic compounds; the school of A. E. Chichibabin, celebrated for their investigations in the field of heterocyclic compounds; the school of A. N. Nesmayanov, who worked at large classes of organoelemental compounds and moulded this division of organic chemistry into an independent field; the school of A. E. Arbuzov, whose studies in the field of the chemistry of organophosphorus compounds are well known.

The basis of organic chemistry, as for any other science, are its theoretical concepts. Russian chemists have always paid special attention to the fundamental rules. It is sufficient to name A. M. Butlerov, who created the structural theory, V. V. Markovnikov, well-known for the principal investigations into problems of the mutual interaction of atoms in a molecule, N. N. Menshutkin former pioneer of the use of kinetic methods of investigation in organic chemistry. This tradition lives on today.

A distinguishing feature of modern organic chemistry is the wide use of methods of mixed sciences—physics and biology. Undoubtedly the achievements of Soviet chemists

Nagorskaya, and others studied for the first time the equilibrium diagram of the Al–Be–Mg system, and also investigated the nature of crystallisation in beryllium-rich alloys of various systems (Be–Nb and Be–Re).

A series of important studies has been carried out by A. F. Kapustinskii on the dependence of the energetics of chemical reactions on the positions of the elements in the Periodic System. He made a systematic survey of the thermodynamic properties of the sulphides of various metals, and put forward a convenient simplified equation for calculating crystal lattice energy as a function of the valencies and radii of the ions forming it.

A valuable contribution to the thermodynamics of inorganic compounds, particularly the halides and oxides of the rare elements, was made by the work of S. A. Shchukarev.

The theoretical principles of chemical bonding in inorganic compounds has been developed by Ya. K. Syrkin and M. E. Dyatkina. A theory of directed valencies and a theory of the valency states of atoms in molecules have been developed, and the interactions of atoms with electrons have been studied from the viewpoint of quantum mechanics. Systematic studies of the valency states of both transition and non-transition elements have made it possible to reach a number of conclusions of importance for inorganic chemistry. In particular, the electronic structure of the tetrahedral oxoanions of the transition metals has been studied. Quantum-chemical calculations of the energies of inorganic compounds have made it possible to make predictions regarding the covalent character of the bonding in crystals; this is extremely significant for an understanding of the semiconducting properties of various inorganic substances.

SOVIET ORGANIC CHEMISTRY AFTER 50 YEARS

N. S. Zefirov

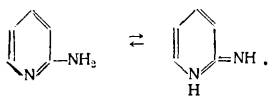
Russian organic chemistry long ago won an honourable place in world science. The names of A. M. Butlerov, V. V. Markovnikov, N. N. Zinin, E. E. Vagner, and N. N. Men'shutkin have acquired a wide repute. Russia had strong chemical schools; in this connection special mention must be made of the Kazan' chemical school, which has produced a great number of brilliant organic chemists, to whom world science must be obliged for the greatest scientific achievements.

Despite this, it has fallen to the Soviet land after half a century to make the most grandiose work on the development of chemical science and industry. Before the revolution chemical science had developed only in individual scientific centres and the number of chemists with higher education amounted to not much more than 1000; the organic chemical industry was practically non-existent.

Fifty years later a powerful chemical industry has been created in our country. In the USSR a series of new means of production—coal tar chemicals, aniline dyes, petrochemical, chemico-pharmaceutical, etc.—have been set up where there was literally an empty place. This enormous construction required great forces in assimilating even the experience gained abroad. In addition our country developed novel solutions for various problems in the construction of a chemical industry. The clearest example is the organisation of the production of synthetic rubber, which was the first in the world.

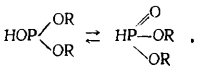
The rapid development of the organic chemical industry in the USSR was based on the experience and traditions of Russian, and then Soviet, organic chemistry. On the other hand, with the development of the chemical industry, organic chemistry obtained a new firm foundation. After years of Soviet power, having opened wide the doors of educational establishments, there grew up in our land an enormous army of organic chemists. A marked extension of the "geography" of organic chemistry resulted—in addition to Moscow, Leningrad, Kazan', Kiev, Tomsk, Khar'kov, Odessa, and Riga, there are now large scientific centres at Gor'kii, Kuibyshev, Novosibirsk, Irkutsk, Vladivostok, Erevan, Tbilisi, Baku, Tashkent, etc.

It is impossible to list all who took part in this. We will only note that during the years of Soviet power new scientific schools have developed which are of worldwide repute and which determine the development of individual branches of organic chemistry not only in our own country but throughout the world. In this connection mention must be made of the school of N. D. Zelinskii, who tackled many problems of the chemistry of hydrocarbons and organic catalysis; the school of A. E. Favorskii and S. V. Lebedeva, who developed the chemistry of unsaturated aliphatic compounds; the school of A. E. Chichibabin, celebrated for their investigations in the field of heterocyclic compounds; the school of A. N. Nesmayanov, who worked at large classes of organoelemental compounds and moulded this division of organic chemistry into an independent field; the school of A. E. Arbuzov, whose studies in the field of the chemistry of organophosphorus compounds are well known.



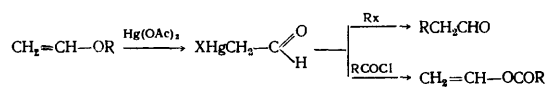
The basis of organic chemistry, as for any other science, are its theoretical concepts. Russian chemists have always paid special attention to the fundamental rules. It is sufficient to name A. M. Butlerov, who created the structural theory, V. V. Markovnikov, well-known for the principal investigations into problems of the mutual interaction of atoms in a molecule, N. N. Menshutkin former pioneer of the use of kinetic methods of investigation in organic chemistry. This tradition lives on today.

A distinguishing feature of modern organic chemistry is the wide use of methods of mixed sciences—physics and biology. Undoubtedly the achievements of Soviet chemists



in the fields of physical chemistry, the chemistry of polymers, and chemical physics have significantly enriched organic chemistry both as regards understanding the significance of chemical changes and also from the methodological point of view. An examination of this question goes beyond the bounds of the present review; however, in this connection mention must be made of the development of the kinetics and theory of chain processes in the studies of N. N. Semenov and his school, the works of V. A. Kargin, V. V. Korshak, S. S. Medvedev, B. A. Dolgoplosk, N. S. Enikolopyan, G. L. Slonimskii in the field of polymer chemistry; the work of V. V. Voevodskii and P. A. Blyumenfel'd on the use of the EPR method; the quantum-mechanical studies of Ya. K. Syrkin, M. E. Dyatkina and others; work on X-ray structural analysis by A. I. Kitaigorodskii and others; M. G. Gonikberg and B. S. El'yanov's studies of reactions at high and superhigh pressures; the electrochemical work of A. N. Frumkin and his school; studies in the field of photochemical processes made by A. N. Terenin; and those of S. G. Mairanovskii in the field of polarography.

A. N. Bakh's work on oxidation in biological systems, the biochemical studies of I. E. Severin, A. N. Belozerskii, and A. S. Spirin, and the work of M. M. Dubinin and I. A. Rappoport on chemical mutagens are of great importance.



Soviet organic chemistry has great fundamental achievements in various fields of theoretical organic chemistry connected with the study of tautomerism and dual reactivity, the mechanisms of organic reactions, skeleton rearrangements, stereochemistry, etc. As is well known, the phenomenon of tautomerism—equilibrium isomerism—was first considered by A. M. Butlerov. The work on the problem of tautomerism and the closely connected problems of dual reactivity began more than a century ago and is still continuing. Soviet chemists have paid great attention to this problem. Thus Chichibabin discovered the tautomerism of 2-aminopyridine [1]:

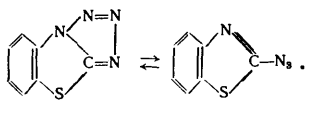
A. E. Arbuzov studied an interesting new form of tautomerism by the example of dialkyl phosphites [2,3]:

The work of A. N. Nesmeyanov and M. I. Kabachnik is of special importance in this field. Nesmeyanov's school made extensive studies of the dual reactivity of organometallic compounds in the absence of tautomerism. Thus Nesmeyanov, Freidlina, and Borisov obtained many unsaturated compounds of mercury, gallium, lead, and antimony, capable of a dual reaction and named "quasicomplex" compounds by virtue of the easy elimination of the unsaturated compound under the action of complexing agents [4,5]. Nesmeyanov and Lutsenko found a very clear instance of dual reactivity of non-tautomeric substances in the compound β-chloromercuriacetaldehyde [7-9]:

Subsequently Nesmeyanov and Sazonova studied the geometrical isomers of (β,β-diphenylpropionyl)mesitylene enolates, which enabled them to draw conclusions about the absence of a tautomeric equilibrium between the metal enolates and the keto-form and the C-alkyl forms which were obtained on carrying out the reaction with "transfer of the reaction centre" [10-12]. In this series of investigations the regions of tautomerism and dual reactivity were first demarcated; it was shown that the latter is wider than the former: dual reactivity is a more general property of compounds with conjugated bonds. In these investigations the conjugation of triple bonds was extensively examined. Subsequently Nesmeyanov and Kabachnik surveyed the experimental results on the problem of the relation between dual reactivity and tautomerism [13]. It was shown that it is possible for two series of derivatives to be formed from a single form; here dual reactivity is the consequence of the special electronic structure of the conjugated system (for example, πσ-conjugation). The reactions of πσ-conjugated systems are now being broadly studied by I. F. Lutsenko (see p. 835). It is interesting to note that the fragmentation decomposition in the reactions of carbonium ions which has been widely studied by Grob's school [14] is evidently a further development of the ideas about πσ-conjugation [15]. The problems of dual reactivity were recently studied by Novikov and Tartakovskii by the example of trinitromethane derivatives [16]. A new approach to the problem of dual reactivity of the enolates of acetoacetic ester is being developed by Reutov, Beletskaya, and Kurts with the use of the concept of "nucleophilic cooperation" in reactions of organometallic compounds (see p. 819). [17]

The greatest achievement in the field of tautomerism proper is connected with the work of M. I. Kabachnik and his school. By applying the Brønsted equation to prototropic tautomeric equilibria, Kabachnik developed a quantitative theory of tautomerism [18,19]: he derived fundamental relationships which were governed by the position of the tautomeric equilibrium as a function of acidity:

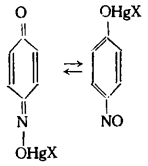
$$K_T = \frac{k_{a_I}}{k_{a_{II}}} \frac{f_I}{f_{II}}$$



and which reflect the effect of the medium on the position of the equilibrium:

$$pK_{TS_I} = pK_{TS_{II}} + \text{const}\ .$$

These two fundamental equations enabled an explanation to be found for such dependences as the relation of acidity to enolisability, and gave a theoretical explanation for empirical relations found earlier, for example, the formulae of Meyer and Dimrot [18-21]. Kabachnik, with his students Ioffe, Mastryukova, Polikarpov, and Gilyarov, made a detailed investigation of the problems of the tautomerism of keto–enols, lactim–lactams, organophosphorus thion–thiols, diaryl- and amidodialkyl-phosphites, and phosphamidines [22-26]. By using the quantitative relationships found by M. I. Kabachnik, Sheinker studied the tautomerism of various heterocyclic compounds, such as acylaminopyridines, aminothiazoles, etc. [27,28]



The use of correlation ratios enabled Kabachnik and Mastryukova to explain the departure from a simple linear relationship of the Hammett type for tautomeric systems and to derive a new equation with the aid of which equilibrium constants could be calculated [29].

Of the other studies in the field of tautomeric changes mention must be made of Postovskii's study of tetrazole–azide tautomerism [30]:

We note also the work of Novikov, Fainzil'berg, and Tartakovskii on acid equilibrium for polynitroalkanes, where the absence of the formation of an aci-form was demonstrated[31].

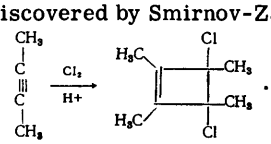
Of great fundamental interest is metallotropy, which was discovered and studied by Nesmeyanov and Kravtsov by the example of mercurated nitrosophenols[32,33]:

The study of the mechanisms of organic reactions is one of the key questions of organic chemistry; almost every organic chemist encounters these problems to some extent. The many investigations cannot be listed here and we will discuss the work of the main theoretical schools.

The most diverse problems of physical organic chemistry and the reaction mechanisms were studied in the work of O. A. Reutov, O. P. Beletskaya, and their students. Their main research deals with the mechanisms of electrophilic substitutions, by the example of organomercury compounds. Combined investigation of the stereochemistry (begun together with A. N. Nesmeyanov)[34] and kinetics of substitution of saturated organomercury compounds allowed a rule to be formulated about the retention of configuration in reactions which proceed by an S_E2 mechanism[34-39]. This rule can now be used to find the configuration of various functional derivatives of mercury[40,41].

The kinetic study of electrophilic substitutions of organomercury compounds of the aliphatic, aromatic, and alkenic series allowed general rules to be found for electrophilic substitutions at carbon atoms in various states of hybridisation. It was shown that a change in the structure or medium leads to a change in the bimolecular mechanism of the reaction to a unimolecular type S_E1.[37,42-44] A type S_E1 mechanism could be realised for all the types of carbon atom studied. It is especially interesting that the configuration at an alkenic carbon atom is retained, in accordance with the Nesmeyanov–Borisov rule, which will be discussed below, not only in S_E2 reactions, but also in reactions which take place by an S_E1 mechanism.

As a result of a study of much experimental material, the concepts of "inner" and "outer" nucleophilic catalysis have been created and it has been shown that catalysis of the latter type plays the decisive part in the realisation of electrophilic substitutions in several asymmetric organomercury compounds. This concept evidently has general significance in the reaction of organometallic compounds[33]. We note here that similar ideas about the role of complex formation for reactions of organoelemental compounds are being developed by Okhlobystin[45].

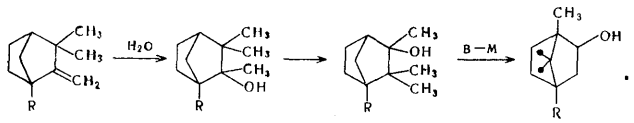


O. A. Reutov, I. P. Beletskaya, and K. P. Butin investigated the mechanisms of polarographic reduction of various types of organomercury compounds and showed the possibility of correlating the parameters of the electrolytic reduction $\alpha E_{1/2}$ of the symmetrical organomercury compounds R_2Hg with the pK_α of the corresponding hydrocarbons R–H. On the basis of the correlation obtained, a most complete scale of the acidity of hydrocarbons was compiled[46]. In this connection note must be taken of the systematic studies of the polarography of organic compounds made by Mairanovskii[47] and Stradin'[48].

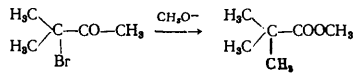
Shatenshtein and coworkers undertook a very extensive investigation to find the acidities of hydrocarbons with the aid of a study of reactions of isotopic exchange in the ammonia–potassium amide system[49,50]. In these papers the view was first expressed that isotopic exchange reactions and metallation reactions belong to a general type of protophilic reactions in which the limiting stage is the loss of a proton and the formation of a carbanion. With the works of Shatenshtein a systematic investigation began into the influence of the solvent and the structural factors in various anionic reactions (isotopic exchange, metallation, Wurtz reaction, the formation of anion-radicals) and the exceptional role of specific solvation in all the processes studied has been demonstrated.

It is difficult to overestimate the value of isotopic methods to study the mechanisms of the reactions. The founders of this method in the USSR were A. I. Brodskii, G. P. Miklukhin, and A. I. Shatenshtein. We will also mention the systematic investigations on deuterio-exchange in hydrocarbons carried out by Kursanov, Setkina, and Parnes[51,52]. Many of the studies of these investigators were devoted to an investigation of hydride transformations. Mention must also be made of the work of Gragerov on the mechanisms of reactions by an isotopic method[53,54].

Under the direction of B. A. Arbuzov an extensive research was mounted to study organic compounds by physicochemical methods. Thus with the aid of parachor measurements B. A. Arbuzov succeeded in showing a series of details of the structure of esters of phosphoric, orthocarbonic, orthosilicic, formic, and phosphinic acids, and in studying the nature of the intermolecular interaction. Some interesting studies of reactions were made by the thermographic method. Together with Vereshchagin, systematic investigations were made into the configuration of addition products of diene synthesis by the dipole moments method[55]. Finally, B. A. Arbuzov and Yu. Yu. Samitov were the pioneers in the USSR in the use of the NMR method[56,57] in organic chemistry. Many series of papers by these authors deal with the study of conformations of α-oxides of the terpene series, 1,3-dioxanes, cyclic sulphites, etc.



A systematic kinetic study of additions to alkenes was undertaken by E. A. Shilov and his student Smirnov-Zamkov. The study of these processes allowed Shilov to formulate the general principle of reactions proceeding through cyclic transition states[58,59]. The important role of termolecular complexes in heterolytic reactions was clearly demonstrated for the first time in the works of this school. The dimerisation of alkynes during chlorination is a very interesting reaction discovered by Smirnov-Zamkov[60]:

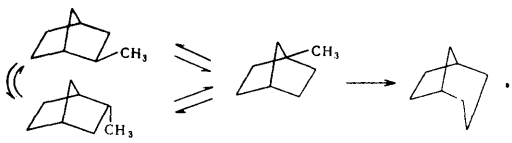


Such non-thermal reactions for cycloaddition are of great synthetic and theoretical interest.

Correlation equations are now widely used for solving many theoretical problems connected with reaction mechanisms. Pal'm[61] gave a theoretical basis for the principle of the linearities of free energies which lies at the basis of these equations. The correlation equations thus obtained were widely used for solving detailed problems of electronic structure, reactivity, and transmission of electronic effects by A. N. Nesmeyanov, E. G. Perevalova, S. I. Gubkin, M. I. Kabachnik, T. A. Mastryukova and V. A. Gilyarov, L. M. Litvinenko, Yu. A. Zhdanov, and V. I. Minkin.

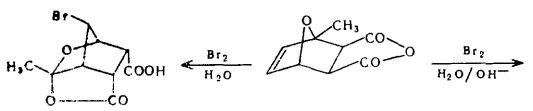
Chemists have always been interested in rearrangements. Russian scientists have made a large contribution to this field of organic chemistry, and it is sufficient to remember the "celebrated" rearrangements of Wagner, Arbuzov, and Dem'yanov. Nametkin and his students discovered a new skeletal rearrangement, which is named after this investigator [62]:

The rearrangement of halogeno-ketones discovered by Favorskii [63] and bearing his name [64] is of enormous synthetic value:



This rearrangement is widely used for the synthesis of various polycyclic and frame structures; it will be remembered that the synthesis of cubane includes a Favorskii rearrangement at two stages [65].

It is not accidental that Favorskii's students have paid great attention to studying skeleton rearrangements and related processes. The extensive investigations in the field of molecular rearrangements made by Danilov, Venus-Danilov [66], and Temnikova [67] are well known.

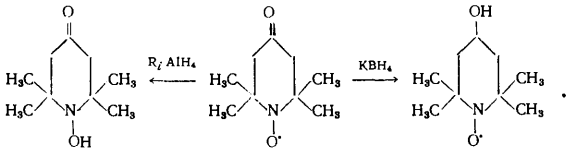


In recent years great attention has been paid to detailed aspects of the mechanisms of skeleton rearrangements. Thus Reutov and Shatkina have shown that in the deamination of propylamine a skeleton rearrangement does not take place; the observable distribution of an isotope tracer shows only the occurrence of a 1,3-hydride displacement [68]. Subsequently Reutov and Bundel' made a detailed study of carbonium ion rearrangements [69,70].

Plate, Belikova, and Mil'vitskaya [71-73] investigated the rearrangement of bicyclic hydrocarbons under the influence of acid, alkaline, and metallic catalysts. As an example we give the isomerisation of 2-methylnorbornane, which proceeds by the scheme:

In a similar way the rearrangement of bicyclic hydrocarbons with eight and ten carbon atoms was studied in a similar manner [74].

Yur'ev and Zefirov studied several problems connected with the factors which determine the skeleton rearrangement in additions at a double bond and during the opening of α-oxides [75,76]:



V. A. Mironov and A. N. Elizarova made interesting investigations in the field which is now unified under the name "valency tautomerisation and isomerisation". They studied the migration of double bonds in cyclopentadiene and its various homologues and showed that at low temperatures (depending on the type and extent of substitution) substituted cyclopentadienes—including deuteriocyclopentadiene—can exist as one of the isomers with a fixed position of the double bonds. On raising the temperature the double bonds migrate, and for substituted cyclopentadienes this leads to structural isomers:

Such isomerisation takes place in stages, and in several instances separate structural isomers can be isolated. It is interesting that the diene synthesis of cyclopentadienes with maleic anhydride can proceed without isomerisation of the double bonds [77,78].

Mention must be made of the theoretical studies of N. N. Vorozhtsov, Jnr. and V. A. Koptyug on rearrangements in aromatic systems. Extensive use of physical methods and particularly labelled atoms and NMR made possible a detailed investigation of various rearrangements in aromatic systems connected with the migration of a proton, or alkyl groups, and the explanation of the part played by acid catalysts. The extensive use of kinetic methods enabled several results of prime importance to be obtained on the mechanisms of the nucleophilic replacement of halogen, sulpho-, and nitro-groups. Of special interest is the study of the migration of methyl groups in polymethylbenzenonium ions [79,80].

The important role of free radicals in the most diverse chemical processes is now widely known. Note that in the field of the chemistry of stable free radicals a great part was played by the work of A. E. Chichibabin of the pre-revolutionary period. Work on the synthesis and study of the properties of stable radicals has continued ever since; in this connection note can be taken of Neiman and Rozantsev's work on the chemistry of iminoxyl free radicals [81]. These authors were the first to show the possibility of effecting the chemical conversions of these compounds without utilisation of the unshared electron:

Unstable free radicals were studied long ago by the school of N. N. Semenov. Thanks to these investigations the kinetics of chain gas reactions have been investigated in much greater detail than any other class of organic reactions.

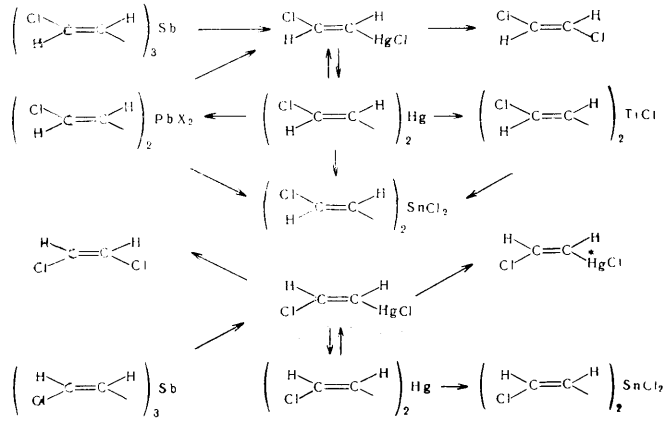
The investigation of liquid-phase radical reactions began in the USSR with the works of Razuvaev and Koton by the example of the thermal decomposition of organomercury compounds [82]. Subsequently G. A. Razuvaev systematically studied the most diverse problems connected with the chemistry of free radicals in solution. As sources of free radicals, the photolysis and thermolysis of organic derivatives of lithium, zinc, mercury, aluminium, titanium, silicon, tin, and lead were studied [83-85]. Problems connected with the mechanism of the oxidation of organic derivatives of magnesium, zinc, cadmium, boron, aluminium, and mercury were investigated.

A long series of papers by R. Kh. Freidlina and coworkers was devoted to the study of the rearrangement of radicals in solutions. Until these appeared the very possibility of

skeleton isomerisations of radicals in solution was doubted. The investigations of Nesmeyanov and Freidlina showed that the CCl_3 group is active in reactions of a homolytic nature[86]. In a detailed study of the chlorination of hydrocarbons many instances were found of homolytic rearrangements, for example:

$$CCl_3CBr{=}CH_2 \rightarrow CCl_2{=}CCl{-}CH_2Br\ .$$

Subsequently the general character of homolytic rearrangements was discovered[87]. It is interesting that homolytic rearrangements with the 1,2-migration of chlorine were observed in the polymerisation of trichloroethylene[88].

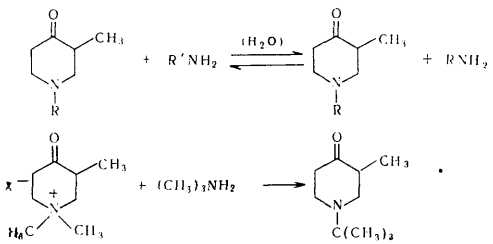


In addition, Reutov and Shatkina found that the propyl radical formed in the thermal decomposition of butyryl peroxide labelled in the α position undergoes rearrangement (to 4% extent), with 1,3-migration of hydrogen[89]:

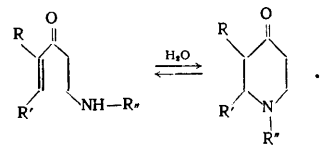
$$CH_3CH_2\overset{14}{C}H_2\cdot \rightarrow \cdot CH_2CH_2\overset{14}{C}H_3\ .$$

Stereochemical studies carried out in the Soviet Union deal with the most varied aspects of this subject. Here the work of A. P. Terent'ev and his students must be mentioned first of all. Thus Terent'ev and Klabunovskii showed the possibility in principle of carrying out an asymmetric catalytic synthesis on the laevo- and dextro-crystalline modifications of quartz[90,91]. In the studies of Terent'ev and Potapov the spectropolarimetric method was used for the first time in the USSR to investigate the most varied compounds (nitrogen-containing heterocycles, Schiff bases, etc.)[92-95]. In investigating the rotatory dispersion (RD) of Schiff bases these authors observed a complex relation between the form of the RD curves and the solvent. This relation was used to explain detailed features of the structure of a series of compounds distinguished by solvation, etc. Spectropolarimetry was successfully used in association with reduction methods for the analysis of perfumery and food products.

Reference must also be made to the work of Kamai and Klabunovskii on the separation of arsenic derivatives by adsorption on quartz[96,97]; Levchenko and Kozlov separated derivatives of tetra-substituted sulphur into antipodes[98].



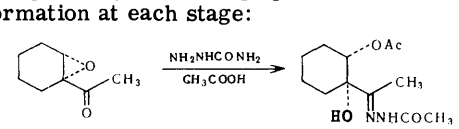
The stereochemistry of electrophilic substitution was examined in detail by A. N. Nesmeyanov. From extensive experimental material Nesmayanov and Borisov showed that homolytic and electrophilic substitutions at an alkene carbon atom proceed with retention of the configuration[99-104]:



The stereochemical studies of O. A. Reutov in the field of electrophilic substitutions have been mentioned above.

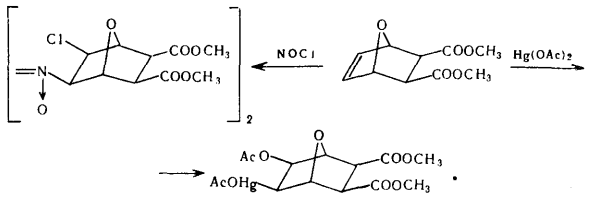
Nazarov, Kucherov, and their students made a series of investigations into the steric and structural directionality of the reactions of the diene synthesis[105]. Subsequently V. F. Kucherov, N. Ya. Grigor'ev, V. M. Andreev, E. P. Serebryakov, and A. S. Onishchenko extensively studied the influence of conformational factors on the conjugation of unsaturated groupings in cyclic systems, on the direction of the initial attack in additions at a multiple bond in mono-, di-, and tri-cyclic systems, and studied the stereochemistry of epoxidation and bromination of derivatives of norbornene, cyclohexene, unsaturated derivatives of decalin, hydrindane, etc.[106-108]

Kucherov and Mistryukov investigated the influence of conformational equilibrium on the reactivity of piperidine derivatives[109-111]. They found an "amino-exchange" in piperidines which is unique in the ease of reaction[111]:



Mistryukov made a detailed investigation of the reversible cyclisation of $\alpha\beta$-unsaturated amino-ketones as a function of the substituent[112]:

The studies of V. F. Kucherov, A. V. Semenovskii, and V. A. Smit on the acid cyclisation of isoprenoids is of special interest. They succeeded in selecting experimental conditions (nitroalkanes, 100% sulphuric acid) such that the cyclisation takes place with high yield and is structurally unambiguous. By selecting catalysts which initiate cyclisation the authors could ensure a completely stereospecific process at all centres and hence model the process of the biological cyclisation of terpenoids[113].



The stereochemical studies of A. A. Akhrem and his coworkers mainly developed in two directions. On the one hand there was the stereochemistry of nucleophilic addition at a carbonyl group. Akhrem and Kamernitskii examined much experimental material for the influence on the stereochemistry of nucleophilic addition of such factors as the conformation of the initial molecule, the dipole–dipole interaction of the functional groups and attacking agent, etc.[114,115]. The second direction is connected with a study of the interesting reaction of cis-opening of an α-oxide ring in keto-oxides under the action of various nucleophilic agents. Study of the mechanism of this reaction showed that this is probably a two-stage process with reversal of the conformation at each stage:

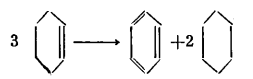
This reaction is used in steroid chemistry[116,117].

Yur'ev and Zefirov[118,119] studied the stereochemistry of the addition of electrophilic agents at a double bond in the 7-oxabicyclo[2,2,1]heptene system. They found an instance

of the cis-addition of weak electrophilic agents to the double bond:

A survey of the information on stereochemistry and the direction of electrophilic addition allowed these authors to advance the general concept of the dependence of the products of addition on alkene type, the electrophilic nature of the attacking agent, the nucleophilic nature of the anion, the polarity of the solvent, and additional stabilisation of the intermediate carbonium ion form of the substituent [119-121].

The studies of M. M. Shemyakin and L. D. Bergel'son showed that the stereochemical course of a Wittig reaction depends on the experimental conditions. The authors developed a variant of this reaction which leads almost exclusively to *cis*-alkenes. Subsequently this reaction was widely used for the synthesis of various natural unsaturated fatty acids [122], for example:



$$CH_3[CH_2]_nCHO + (C_6H_5)_3P{=}CH[CH_2]_7COOCH_3 \rightarrow CH_3[CH_2]_n{-}CH{=}CH{-}[CH_2]_7COOCH_3$$

The foundation for the chemistry of hydrocarbons was laid in our country by the investigations of the school of N. D. Zelinskii and A. E. Favorskii. Zelinskii's work in this field was extremely varied. Use of a combination of chemical and physicochemical methods allowed N. D. Zelinskii, S. S. Nametkin, N. I. Shuikin, and Yu. K. Yur'ev to study the composition of petroleums from all the main oil-bearing regions of our country. Inter alia they improved the old methods of refining and processing petroleum and developed methods new in principle, which allowed it to be converted into a promising starting material for the synthesis of various functional derivatives. The whole variety of these compounds was united by Zelinskii by the expression "products of the highest chemical value obtainable from petroleum hydrocarbons".

Kazanskii and Plate [123,124] discovered the reaction for C_6-dehydrocyclisation of alkanes in the presence of Pt/C. Similar reactions were effected simultaneously at higher temperatures by Moldavskii and Kamusher [125] on Cr_2O_3 and by Karzhev [126] on Cr–Cu phosphate catalyst. These reactions and their mechanism were thoroughly studied by Kazanskii and Zelinskii with the participation of Plate, Liberman, Sergienko, Rozengart, and others [127]. Active catalysts were found [128] which enabled benzene to be made industrially from petroleum hexane [129]. Kazanskii and Liberman discovered and studied in detail the C_5-dehydrocyclisation of alkanes into cyclopentanes [130]. Khromov together with these authors [131] found that 8-, 9-, and 10-membered rings are capable of transannular C_5- and C_6-dehydrocyclisation.

A new reaction for the hydrogenolysis of a 5-membered ring was effected by Kazanskii, Plate, and Zelinskii [132] and subsequently studied in detail [133].

Zelinskii discovered, and together with Pavlov, Kazanskii, and Levina [134] investigated, the reaction of "irreversible catalysis"—the redistribution of hydrogen in partly hydrogenated six-membered rings, with the simultaneous formation of more saturated six-membered and benzene rings. Gryaznov [135] studied the mechanism of these processes:

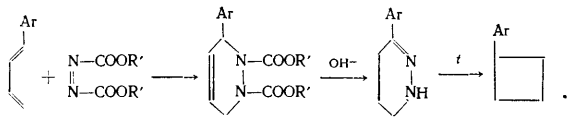
A reaction discovered by Zelinskii as long ago as 1911, the dehydrogenation of cyclohexanes, individually and in petroleum fractions, on Pt, Pd, and Ni/Al_2O_3 catalysts, found by him then for vapour-phase hydrogenation, has been thoroughly studied [134-138]. Yu. K. Yur'ev, P. P. Borisov, I. N. Tits-Skvortsova, N. I. Shuikin, R. Ya. Levina, A. F. Plate, A. M. Rubinshtein, Ya. I. Denisenko, and G. D. Gal'pern participated in these investigations. This is one of the reactions which lie at the basis of the well-known process of "platforming".

By studying the kinetics and mechanism of dehydrogenation of cyclohexanes, Balandin created the multiplet theory of catalysis, making use initially of the principle of structural [139-141], and then also energetic, correspondence between the reagents and catalyst [140], which stimulated work on the determination of the energies of the bonds between the reacting atoms and catalysts (Tolstopyatova [142] and Kiperman [143]). It was shown that [144-147] that reactions on oxides proceed by a doublet scheme with edge orientation of the ring, unlike the reactions on platinum and palladium, which proceed by a sextet model with planar orientation of the ring.

There have been very extensive investigations of the dehydrogenation of alkanes and alkenes to dienes, alkylbenzenes, and styrenes and also cyclopentanes to cyclopentenes, and further to cyclopentadienes. Zelinskii, Balandin, Marushkin, Bogdanova, Shcheglova, Isagulyants, Kazanskii, Sterligov, Shuikin, Smirnov, Lavrovskii, Lyubarskii, Sergienko, Rapoport, and others participated in these studies [148-161].

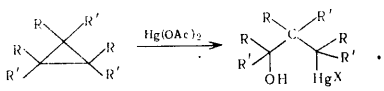
Liquid-phase hydrogenation catalysis is widely represented in the research of Zelinskii [134] and his school (Kazanskii, Sokol'skii, Freidlin [162-167]). The investigations of Levina and Skvarchenko [168,169] and also Kazanskii and coworkers [170,171] on reduction by hydrogen at the "moment of liberation" touch on this work.

The isomerisation of cyclic hydrocarbons under the action of Lewis acids—$AlCl_3$ and $AlBr_3$—was investigated by Zelinskii and Turova-Polyak [172-175], and Plate [71,74] investigated that of bicyclic hydrocarbons. Topchiev, Paushkin, A. D. Petrov, Sergienko, A. A. Petrov, and others studied the isomeric transformations of aliphatic hydrocarbons [148,176-179]. The work begun in our country by Ipat'ev [180] on the conversion of hydrocarbons under pressure, was continued in particular by Shuikin, Novikov, Minachev, and others [181-185] with the use of new catalysts. Gonikberg [186] studied the reactions of hydrocarbons and their derivatives, especially those with steric hindrance, under very high pressures. The alkylation of hydrocarbons was widely investigated by Topchiev, Yu. G. Mamedaliev, G. M. Mamedaliev, Lavrovskii, Shuikin, Viktorova, Panchenkov, Paushkin, Tsukervanik, Freidlin, and others [187-197]. The work on the cracking and pyrolysis of hydrocarbons begun even before the revolution and developed during its first years by N. D. Zelinskii was continued by Byzov, Lebedev, Topchiev, Voevodskii, and also by Lavrovskii and Brodskii, Agafonov, Topchieva, Paushkin, Panchenkov, and others [198-210]. After the pioneering investigations of A. N. Bakh in the field of the oxidation of hydrocarbons, important contributions were made by N. N. Semenov, N. M. Emanuel', S. S. Medvedev,



S. S. Nametkin, A. N. Bashkirov, and V. V. Kamzolkin, K. I. Ivanov, D. S. Velikovskii, K. K. Dubrovai, I. P. Losev, P. A. Moshkin, S. Z. Roginskii, and L. Ya. Margolis, P. V. Zimakov, V. Ya. Shtern, N. I. Chernozhukov, S. E. Krein, V. K. Tsyskovskii, and others[211-214].

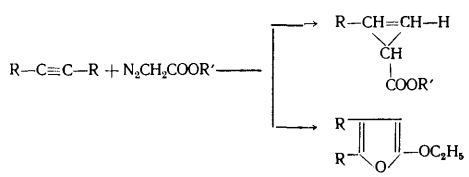
In the field of polymerisation and condensation we will note the reaction of cross-dimerisation of acetylene into 2-methylpropene (Petrov[215]), and the dimerisation of ethylene (Eidus, Kazanskii and coworkers[216-223]).



Physical and physicochemical investigations of catalysts for hydrocarbon conversions are represented in the works of Rubinshtein and coworkers[224,225] the rules for reactions in a monolayer in the studies of Vasserberg[226], and the stereochemical aspects of catalysis in those of Klabunovskii[227]. Klabunovskii's studies of the regularity of the configurational correlations in asymmetric catalysis are of great interest[227].

The work in the field of small rings is of great theoretical importance. N. M. Kizhner developed the celebrated method of synthesis of cyclopropanes through pyrazolines from $\alpha\beta$-unsaturated carbonyl compounds. In a long series of papers Levina and Shabarov studied the conjugation of a three-membered ring with a benzene ring[228].

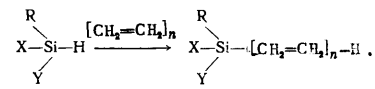
Levina and Shabarov developed an original method for the synthesis of arylcyclobutanes on the basis of a diene synthesis with azodicarboxylic ester[228]:



A study of the chemical and physical properties of derivatives of small rings enabled the specific characteristics of their electronic structure to be distinguished clearly. The especially marked relationship between cyclopropanes and alkenes was demonstrated by Levina in studying the opening of a three-membered ring by mercury salts[229]:

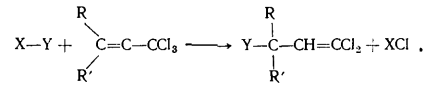
Here we can add the work of Kazanskii and Lukina on the study of the hydrogenolysis of small rings[229a].

Here mention must also be made of the work of D'yakonov and coworkers on the synthesis of derivatives of cyclopropane and cyclopropene on the basis of the reactions of diazo-compounds with alkenes[230]. The synthesis of cyclopropenes by the reaction of diazoacetic ester with acetylenes by the scheme[231]:



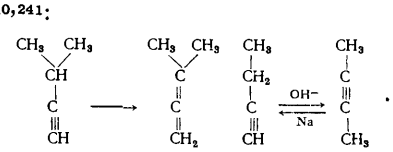
is especially interesting.

A. N. Nesmeyanov and R. Kh. Freidlina have shown that the telomerisation of alkenes with carbon tetrachloride and chloroform allows various $\alpha\alpha\alpha\omega$-tetrachloroalkanes to be obtained; these are intermediates in the synthesis of ω-amino-acids. Subsequently, R. Kh. Freidlina, L. I. Zakharkin, and V. N. Kost made a detailed investigation of the production of aminoheptanoic and aminononanoic acids according to the scheme:

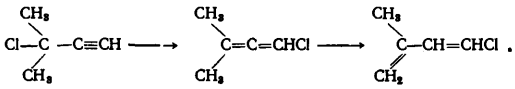


The compounds obtained are valuable intermediates in the manufacture of synthetic fibres ("Pelargon", "Enant"). Methods were also developed for the synthesis of α-amino-acids of the most varied structures and also thiols, sulphides, sulphenyl chlorides, and sulphonic acids. The compounds obtained are of undoubted interest as plasticisers, perfumes, lubricants, and intermediates for organic synthesis[232-237]. This reaction is especially interesting for the synthesis of organosilicon compounds. It was found that alkenes undergo telomerisation with silanes containing an Si–H bond, as follows[238]:

The peculiarity of this reaction is that it takes place in the absence of initiators at 300°C and a pressure of 100–500 atm (thermal telomerisation). It was found subsequently that the addition of silicon hydrides to alkenes is catalysed by various compounds such as metal carbonyls, zirconium and titanium tetrachlorides, etc.

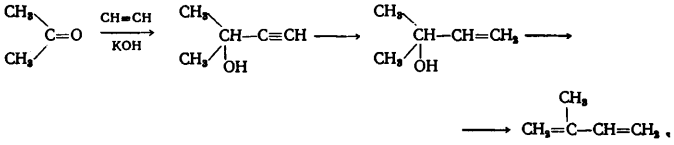


Of great significance in principle is an investigation, completed in connection with the study of telomerisation, into the chemical properties of compounds with the groupings CCl_3, CCl_3CHCl, $CCl_2{=}CH$, $CCl_3{=}C$, etc., and, in particular the action of various nucleophilic, electrophilic, and radical agents on these groupings. For example, it was shown that the action of nucleophilic agents on compounds with the $C{=}C{-}CCl_3$ grouping proceeds with rearrangement by the scheme[232]:



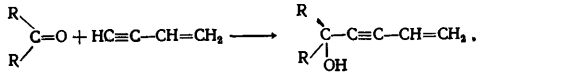
Finally, it is impossible to omit the extensive investigations of I. L. Knunyants in the field of polymer chemistry. In 1942–43, together with Rogovin and Rymashevskaya he first described the polymerisation of caprolactam into caprone. Later Knunyants proposed a new method of synthesis of adipodinitrile by the hydrodimerisation of acrylonitrile[239]. This method has great prospects in the production of nylon.

A very large group of papers by Soviet chemists is connected with the reactions of diene hydrocarbons, the greatest practical interest being in the investigations in the field of polymerisation, which started from the classical works of A. M. Butlerov. The development of this field of organic chemistry in the Soviet period is mainly associated with the name of Butlerov's student A. E. Favorskii, who created one of the largest chemical schools. His students included such celebrated chemists as Zh. I. Iotsich, S. V. Lebedev, I. N. Nazarov, M. F. Shostakovskii, V. A. Mokievskii, S. N. Danilov, T. A. Favorskaya, R. S. Zal'kind, B. V. Byzov, A. E. Porai-Koshits, and others.

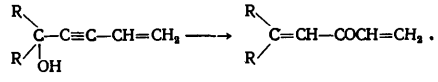


Even in the pre-Octobrian period Favorskii discovered the celebrated rearrangements of unsaturated compounds: acetylene–allene and the prototropic rearrangements of acetylenes[240,241]:

T. A. Favorskaya made thorough investigations of the acetylene–allene and allene–diene rearrangements of acetylenic halides, leading to chloroprene[242]:

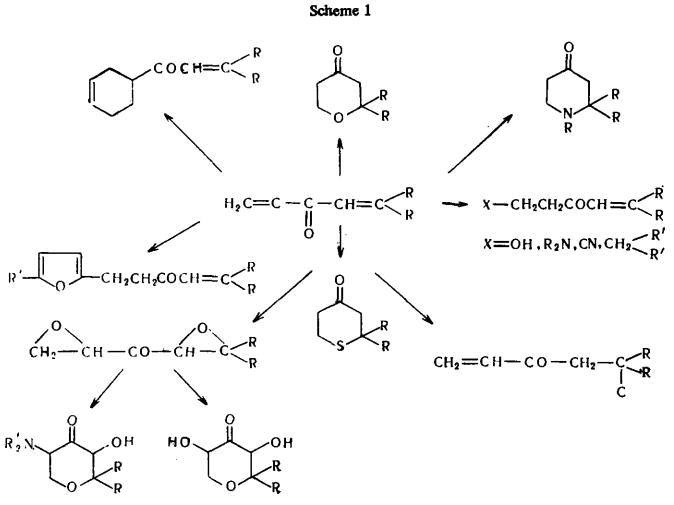


A. E. Favorskii discovered the reaction of alkaline condensation of acetylene with ketones, which made the alcohols of the acetylenic series readily accessible. A method of synthesising isoprene was developed on the basis of this reaction:

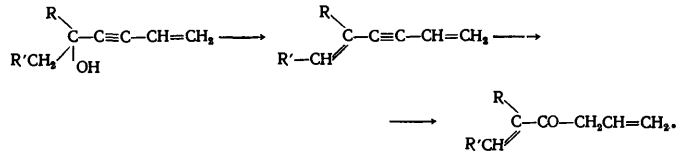


Subsequently this reaction was extensively used in the works of I. N. Nazarov and his students (V. F. Kucherov, L. D. Bergel'son, I. V. Torgov, A. A. Akhrem, I. L. Kotlyarevskii, and S. A. Vartanyan).

By using vinylacetylene as the acetylenic component in the Favorskii reaction, I. N. Nazarov succeeded in obtaining extremely reactive vinylethynylcarbinols:

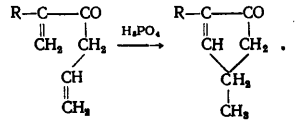


These compounds found practical application for the preparation of the so-called "carbinol glue". Vinylethynylcarbinols readily isomerise under the action of mercury salts into divinyl ketones:



The latter were used for the synthesis of the most varied compounds[242–245], including those of the heterocyclic series, as Scheme 1 shows.

Scheme 1



These studies of Nazarov and coworkers are well known and have been reviewed on several occasions[243]. Among the compounds obtained on the basis of the divinyl ketones are valuable pharmaceutical preparations—Promedol and Isopromedol[245].

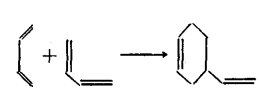
The dehydration of vinylethynylcarbinols, leading to divinylacetylenic hydrocarbons, and the subsequent hydration of the latter leads to allyl vinyl ketones, which are very reactive compounds[243,246]:

The cyclisation of allyl vinyl ketones under the action of acids leads to cyclopentenones:

Further development of this work consisted in the use of cyclopentenones in a diene synthesis to obtain polycyclic structures related to the steroids. These investigations served as the start of chemical research in the field of the synthesis and modification of steroids, which is developing successfully at the present time (A. A. Akhrem, I. V. Torgov, and S. N. Ananchenko).

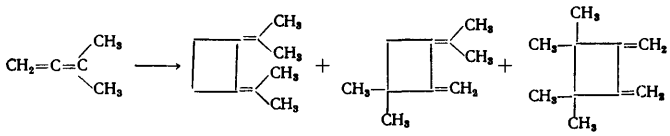
Mention must also be made of the work of Nazarov[247], Yanovskaya[248], and Mikhailov and Povarov[249–251] on the study of the condensation of acetals with vinyl esters which allowed various poly-unsaturated compounds similar in structure to the carotenoids to be obtained.

Favorskii and Shostakovskii developed a new method for the synthesis of vinyl ethers involving the reaction of acetylene with alcohols in the presence of alkali[252]:



The chemistry of vinyl ethers was subsequently studied extensively by M. F. Shostakovskii. The hydrolysis, addition, and polymerisation of vinyl ethers was studied and a series of compounds was obtained which could be used as pharmaceutical preparations and solvents[253]. Shostakovskii and Prilezhaeva studied vinyl sulphides[254].

The work of Shostakovskii and Vlasov[255,256] on the production of polyfunctional vinyl ethers is especially interesting, for example[255]:

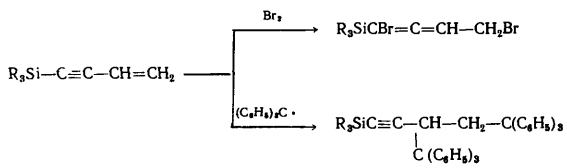


Another direction in the chemistry of diene hydrocarbons is associated with the name of S. V. Lebedev. Even in the pre-Octobrian period he began to study polymerisation processes; he investigated the polymerisation of 16 derivatives of divinyl. During this he formulated, long before the work of Diels and Alder, the principle of the condensation of diene hydrocarbons according to the scheme of the diene synthesis[257]:

We also note that cycloaddition leading to cyclobutanes[258] —a reaction now being widely studied—was also investi-

gated by Lebedev by the example of the dimerisation of allenes[257]:

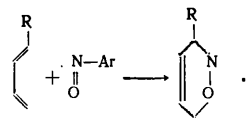
Without exaggeration it can be said that until recently Lebedev's results on allene chemistry remained the main information in this field.



However, S. V. Lebedev's greatest contribution is connected with the creation of the synthetic rubber industry in the USSR. Lebedev and his students developed a single-stage catalytic method for the synthesis of divinyl from alcohol; simultaneously a method was developed for polymerisation by use of metallic sodium. The synthetic rubber industry created by the Soviet state on the basis of Lebedev's work has now attained great success and completely satisfies the requirements of the country's national economy.

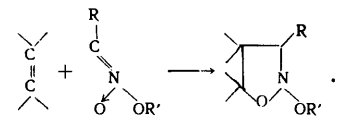
The Lebedev process has now been considerably improved as a result of the work of his students, among whom were A. I. Yakubchik, D. M. Slobodina, M. D. Gordina, S. A. Subbotina, Yu. A. Gorina, and I. A. Volzhinskii.

Various types of polymerisation of unsaturated compounds are now widely studied in various centres of the USSR and their consideration goes beyond the bounds of the present review. We will note only the work of Dolgoplosk on stereospecific polymerisation[259,260], that of Klebanskii on chloroprene rubber[261], that of Shilov and coworkers on the mechanism of polymerisation on Ziegler catalysts[262], and also the studies of the coworkers of the Yaroslavl' Scientific Research Institute for Monomers, Fel'dblyum and Obeshchalova[263].

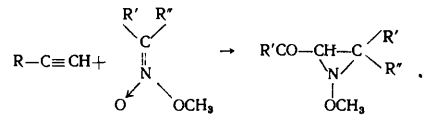


Many papers have been devoted to the study of the chemical properties in connection with the practical use of unsaturated hydrocarbons and in particular additions, the diene synthesis, 1,3-dipolar cycloaddition, etc.

First of all here we must note the extensive series of papers by A. A. Petrov who studied the addition of a wide variety of reagents, to diene, enyne, and diyne hydrocarbons[264-267]. The enyne derivatives of silicon are of especial interest; for them it was shown that the decisive factor which determines the direction of addition is $p_\pi d_\pi$-conjugation of the silicon atom and the double bond:



A. A. Petrov studied many acetylene derivatives of tin, phosphorus, and boron; they developed new methods of obtaining organophosphorus heterocycles based on the condensation of phosphides with dienes and $\alpha\beta$-unsaturated carbonyl compounds. As a result of studying the ionic telomerisation of unsaturated compounds with halogen derivatives, he developed an industrial method for the synthesis of citral from isoprene.



We note also here the work of Kazanskii and Levina on the hydrogenation of diene systems[268], that of Nazarov and Titov on the diene synthesis[269], that of Babayan on the synthesis of nitrogenous compounds from 1,3-dichlorobutane[270], that of B. A. Arbuzov and Konovalov on finding the mechanism of the diene synthesis[271]. A. N. Nesmeyanov and Yu. A. Arbuzov showed that aromatic nitroso-compounds can be used as the dienophile in the diene synthesis[272]:

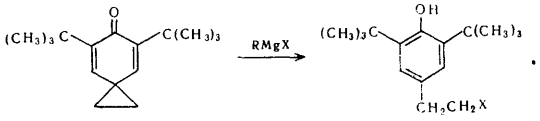
The original reaction of 1,3-dipolar addition was discovered by Novikov and Tartakovskii, who used esters of the *aci*-form of nitro-compounds as the "1,3-dipole" [16]:

This reaction has been extended to a wide circle of alkenes and dienes. The reaction of acetylenes with these 1,3-dipoles leads to the production of aziridines by the scheme:

Machinskaya and Barkhash extensively studied methods of obtaining and the use in synthesis of the enol acetates of carbonyl compounds[273].

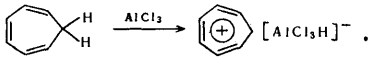
There is also the work of Perekalin[274] and Novikov and coworkers in the field of unsaturated nitro-compounds[275].

The development of the chemistry of aromatic compounds has been continually associated with the aniline dye and phamaceutical chemical industries. In this field, more than in any other, the main forces were directed towards assimilating the experience of foreign chemistry. M. I. Kabachnik took part in interpretation of the structure and the organisation of production of the first cyanine dyes. Conspicuous parts in the development of aniline dye chemistry were played by N. N. Vorozhtsov, Snr., N. N. Vorozhtsov, Jnr., A. E. Porai-Koshits, A. I. Kiprianov, and I. I. Levkoev. Soviet scientists paid special attention to the prolems of the theory of the colour of dyes. In this connection there is work of Izmail'skii on mesomerism[276], which in many respects preceded later ideas of foreign scientists; the work of Ioffe in the field of rhodamine dyes[277]; and that of Levkoev and Vompe, where problems of the dependence of the colour of cyanine dyes on the basicity of the heterocyclic nuclei were examined[278,279]. The work of A. I. Kiprianov is of great importance for the creation of a theory of colour. Critical problems of his work on the relation of the structure and colour of a dye are: the investigation of the influence of steric hindrance, the presence of polar substituents, and the absence of symmetry in the structure of the molecule and also the solvatochroism which is connected with this question. The concept he introduced of the dependence of the colour of polymethylene dyes on the equivalence of bonds in the chromophore of a dye was confirmed by studies in the field of unsymmetrical cyanine dyes. For the latter Kiprianov introduced the "hypsochromic shift" rule according to which with increase in the difference in the basicity or polarity of the terminal units of a chromophore there is an increase in the displacement of the absorption maximum towards shorter wavelengths from the arithmetic mean of the two corresponding symmetrical



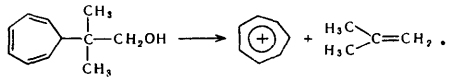
dyes[280]. Note also the work of A. I. Kiprianov on the synthesis of "Sanazine", a homologue of the natural antibiotic pyocyanine.

In addition to direct practical tasks Soviet chemists solved a series of questions of principle in the field of aromatic compounds. Here we must refer to the work of Vorozhtsov, Snr., and Bogdanov in the field of the chemistry of naphthalene derivatives[281,282], A. E. Porai-Koshits and B. A. Porai-Koshits on the structure and tautomerism of dyes, diazo-compounds, the mechanism of diazotisation, etc.[283], and that of Ioffe on the synthesis of binaphthyl derivatives[284].

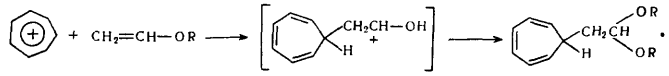


The work of Zeide and Dubinin on aromatic musks[285], and that of Rodionov on derivatives of opianic acid[286] belong to this field. Of the latter, there is special interest in the work of Belov and Kheifits on the alkylation of bicyclic terpenoids with phenols, which leads to the production of valuable perfumery preparations[287,288]. These reactions are interesting also from the theoretical standpoint, since the alkylation is accompanied by complex skeleton rearrangements and 2,6-hydride displacements.

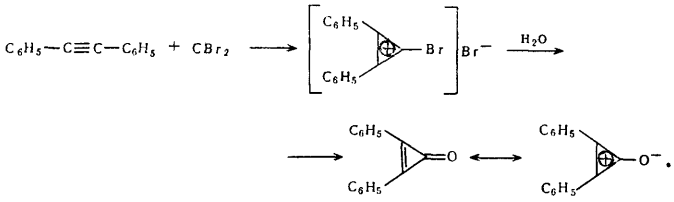
Mention must also be made of the new method of synthesis of aromatic compounds developed by R. Ya. Levina and V. P. Skvarchenko. These authors found that addition products from the diene synthesis with maleic anhydride readily aromatise on heating with phosphorus(V) oxide; this method was used successfully to make homologues of benzene, naphthalene, anthracene, fluorene, and polynuclear aromatic hydrocarbons[289].



A long series of studies of the field of sterically hindered phenols was made by Ershov and Volod'kin[290,291]. By a large number of examples it was shown that *o,o*-di-t-butylphenol readily forms quinolide structures under the action of various electrophilic reagents. The authors have extensively investigated the dienone–phenol rearrangements that take place in this. The dienone–phenol rearrangement of spirane systems which they studied is especially interesting. For example, under the action of a Grignard reagent 4,6-di-t-butylspiro[2,5]octa-3,6-dien-5-one reacts with cleavage of a C–C bond to form derivatives of phenol by the scheme[290]:

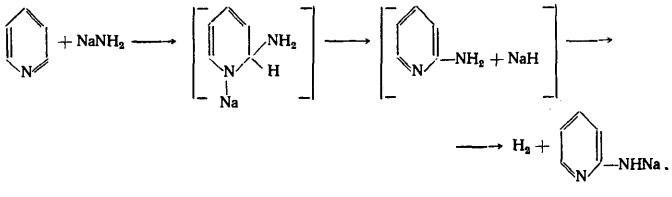


The problem of the structure of aromatic compounds and the reasons for their special properties is one of the central problems of theoretical organic chemistry. The development of quantum mechanics has significantly altered our views on the problem of aromaticity and has enabled a great number of compounds belonging to the class of non-benzenoid aromatic compounds (concerning π-complexes see below) to be obtained. The most important results in this field were obtained by D. N. Kursanov and M. E. Vol'pin. As they showed, under the action of the most varied electrophilic agents cycloheptatriene forms a tropylium salt by the scheme[291,292]:



The formation of tropylium can take place even with fission of the C–C bond. For example, 2-cycloheptatrienyl-2,2-dimethylethanol decomposes extremely readily in the presence of acids with the formation of tropylium salts[294]:

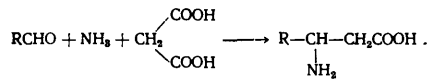
As a result of the work of D. N. Kursanov and M. E. Vol'pin the "tropylation" reaction can be used as a means for determining reaction mechanisms. For examples, these authors studied the possibility of a carbonium ion being formed in the reactions of acetals, for which they carried out the reaction of the stable tropylium ion with ethyl vinyl ether, which confirmed the possibility of an acetal condensation by a carbonium ion scheme[295]:



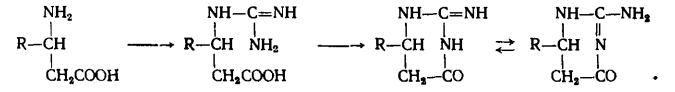
Another interesting direction of Kursanov and Vol'pin's work is connected with a three-membered aromatic system—diphenylcyclopropenone—which they succeeded in obtaining in the reaction of dichloro- and dibromo-carbene with tolane[296]:

As Syrkin and Shidlovskaya's investigation showed, diphenylcyclopropenone has a very high dipole moment, 5.08 D.[296] Of the other work on non-benzenoid aromatic compounds we will mention the investigations of Yashunskii and Kholodov on the chemistry of sydnones[297].

The chemistry of heterocyclic compounds is developing in our country at an explosive rate. Investigations in this field of organic chemistry enable new regularities in the behaviour of organic compounds to be discovered and facilitate the development of new theoretical concepts. On the other hand the enormous practical value of these investigations as a basis for creating new pharmacological preparations, dyes, plant growth regulators, and intermediates for fine organic synthesis is quite evident.



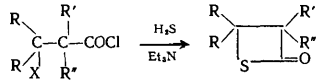
In this field it is necessary above all to refer to the investigations of A. E. Chichibabin. In 1914 Chichibabin and Zeide discovered the reaction of the amination of pyridine and its derivatives under the action of sodium amide, which has been given the name "Chichibabin reaction" in world literature[298–300]:



In the subsequent studies of Chichibabin and his school (O. A. Zeide, A. V. Kirsanov, I. L. Knunyants, N. N. Vorozhtsov, Z. V. Benevolenskaya, and A. F. Egorov) the chemistry of the amino-derivatives of pyridine, quinoline, pyrimidazole, and other heterocyclic systems was widely developed[299,300].

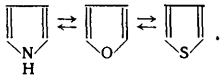
However, the chemistry of heterocyclic compounds underwent the greatest development in the post-war years; the chemists working in this field constitute one of the largest groups of Soviet organic chemists. The progress in this field is also shown by the appearance of the journal "Khimiya Geterotsiklicheskikh Soedinenii" [Chemistry of Heterocyclic Compounds] (published in Riga). Such great scientists as A. N. Nesmeyanov, V. M. Rodionov, I. L. Knunyants, Yu. K. Yur'ev, N. K. Kochetkov, amongst others, worked or are working in this field.

Rodionov developed a convenient method of synthesising β-amino-acids by the scheme [301,302]:



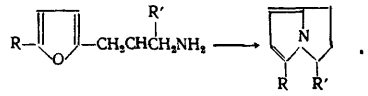
From β-amino-acids, V. M. Rodionov and coworkers synthesised various types of heterocyclic compound, such as glyoxalidones, pyrimidones, dihydrouracils, etc. As an example there is the synthesis of aminodihydropyrimidine [302]:

The first period of work of I. L. Knunyants was devoted to investigations in the field of the chemistry of nitrogen-containing heterocyclic compounds. He obtained various derivatives of alkylaminopyridines and also pyridine analogues of the dyes of the di- and tri-phenylmethane series. Mention must be made of the investigations in the field of cyanine dyes and also in that of acridine, on the basis of which the industrial production of Acrichin [atebrin] was organised.



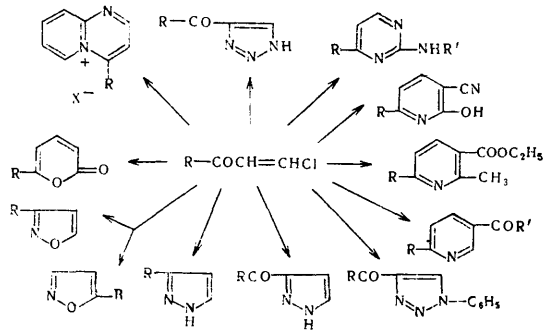
Knunyants and Lin'kova discovered a new class of four-membered heterocyclic system—β-propiothiolactone [303,304]. The most convenient method of synthesising derivatives of this class consists in the reaction of the acid chlorides of β-halogenocarbonyl compounds with hydrogen sulphide in the presence of triethylamine [303]:

Knunyants and coworkers effected a peptide synthesis based on β-thiolactones [305]. Knunyants and Kil'disheva studied the mutual relation of oxazolones and pseudo-oxazolones (2,4-disubstituted) and developed methods of establishing their structure [306].



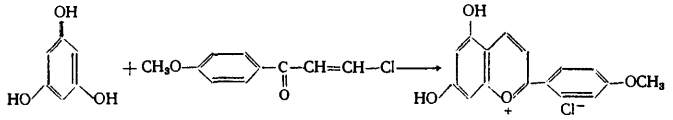
Together with Kil'disheva, Knunyants synthesised a large class of compounds containing a bis-β-chlorovinyl grouping and peptide chains which led to the creation of new mutagens, original cancerolytic preparations.

In 1935 Yur'ev discovered the reaction which bears his name, the interconversion of heterocycles under conditions of vapour-phase catalysis over aluminium oxide [307]:

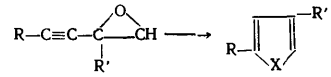


The conversion of the fully hydrogenated derivatives of these aromatic compounds takes place especially readily. In the extensive series of works of Yu. K. Yur'ev and coworkers (E. G. Vendel'shtein, I. K. Korobitsyn, and K. Yu. Novitskii) were synthesised a great number of varied heterocyclic systems [308].

A very interesting intramolecular variant is the Yur'ev reaction (Sorm, Ponomarev) which leads to a pyrrolizidine derivative [309,310]:



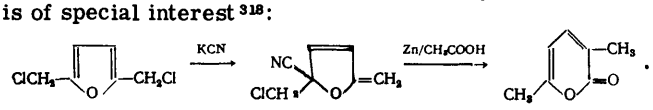
A general, unusually fruitful method of synthesis of a variety of heterocyclic compounds was developed by Nesmeyanov and Kochetkov on the basis of alkyl and aryl 2-chlorovinyl ketones—products of the condensation of acid chlorides with acetylene in the presence of aluminium chloride [311-313]. Scheme 2 shows the extensive theoretical possibilities of this method.



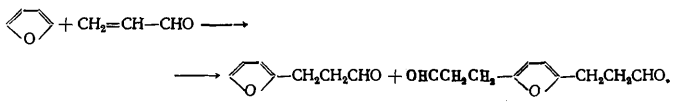
Scheme 2

Note that the reaction of β-chlorovinyl ketones with phenols takes place with the formation of benzopyrylium salts; in this way a natural anthocyanidin methyl ether, hesperidin, was synthesised from phloroglucinol and *p*-methoxyphenyl chlorovinyl ketone [314]:

Another general method of synthesis of various five-membered heterocyclic compounds was developed by Perveev and coworkers on the basis of acetylenic epoxides [315,316]

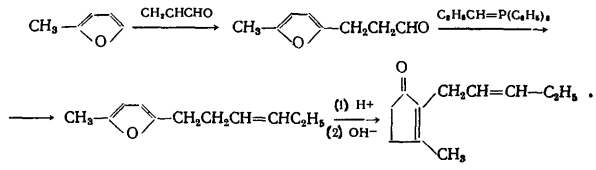


where X = NH, NR, S, O, Se.



The general nature of this reaction was confirmed by the synthesis of many representatives of furan, thiophen, pyrrole, and selenophen.

Furan chemistry was extensively developed in the studies of Soviet investigators, this being directly connected with the problem of the use of pentosan-containing raw materials, the primary product of the treatment of which is furfural.



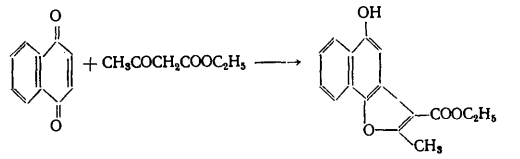
A great contribution was made in this region by Yu. K. Yur'ev and his school (K. Yu. Novitskii, N. K. Korobitsyna, N. S. Zefirov, V. P. Volkov, and M. A. Gal'bershtam). Yur'ev and Novitskii synthesised the most varied bifunctional derivatives of furan from bis(chloromethyl) derivatives of furan [317,318]. The example of an allyl rearrangement in the furan series which was found by these authors is of special interest [318]:

In 1938 Sherlin and Berlin and their coworkers showed that $\alpha\beta$-unsaturated carbonyl compounds react with furan by a substitutive addition[319]:

This reaction was subsequently studied by several authors[243]; however, only Yur'ev and Zefirov showed the general nature of this reaction[320]; it is now widely used for the synthesis of a variety of furan derivatives[321,322]. For an illustration we give the synthesis of jasmone, carried out by Yur'ev and Zefirov on the basis of this reaction[323]:

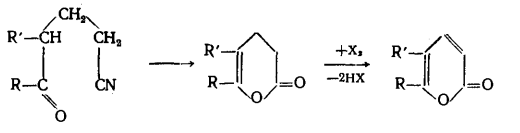
There is also the work of Yur'ev and Korobitsina on the synthesis of heterocycles from 3-keto- and 3,4-diketotetrahydrofurans[324], that of Yur'ev and Zefirov in the field of diene synthesis in the furan series[325], and that of Yur'ev and Gal'bershtam on the kinetics of the solvolysis of chloromethyl derivatives of heterocycles[326].

A great investigation on the synthesis, reactions, and practical applications of furan derivatives was carried out under the direction of S. A. Giller. Among the works of his school there are the development of a method of contact vapour-phase decarbonylation of furfural into furan (Karmil'chik[327]), the industrial synthesis of maleic anhydride from furfural (Shimanskaya[328]), work on the synthesis of physiologically active substances based on nitrofurans[329-331]; the alkylation of furan with alkenes (Berzin'[332]). The work of Stradin' and Giller on the polarography of the nitroderivatives of the furan series is especially interesting; it was shown that it was possible to study intermediate radicals by the EPR method[48,333].



Ponomarev made extensive investigations in the field of furan chemistry[334]; the main directions were connected with a study of the catalytic hydrogenation of these compounds. We may note also Ponomarev and coworkers' study of the synthesis of optically active dioxaspirononanes from derivatives of tetrahydrofuran by the scheme[335]:

The hydrogenolysis of furan compounds was widely studied by N. I. Shuikin and his coworkers I. F. Bel'skii, R. A. Karakhanov, and V. M. Shostakovskii. They studied synthetically the catalytic hydrogenation of furan derivatives of the most diverse types, the isomerisation of γ- and δ-oxides, and the thermal and catalytic conversions of 2,5- and 2,3-dihydrofurans[336-338].

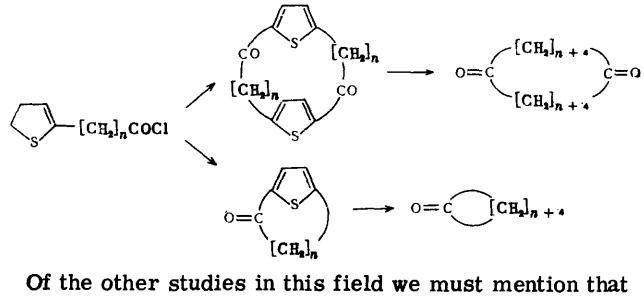


Mndzhoyan and coworkers[339-341] carried out systematic investigations to find physiologically active substances in the furan series. They tackled the problem of the chloromethylation of furan derivatives, on the basis of which they obtained an antitubercular preparation "Armazid" and a preparation against glaucoma "Dimefur". There are also papers by Nazarova[342], and Moshkin and Lutkova[343].

In the benzofuran field, mention must be made of the work of Terent'ev and Grinev, who developed a convenient method for the synthesis of the compounds of this series from p-quinones and acetoacetic ester[344]:

The compounds obtained were effective plant growth stimulators.

Levina and Shusherina developed a new method for the synthesis of 2-pyrones on the basis of δ-enol-lactones[345]:



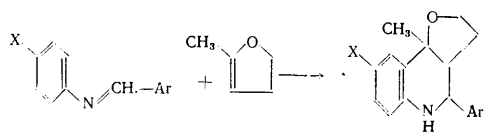
Subsequently these authors made detailed studies of electrophilic substitutions in the pyrone series and also investigated various conversions of the derivatives of this series. Zakharkin and Sorokina developed a new method for the synthesis of 2-pyrones based on the condensation of dichloroacrylaldehyde with compounds having a labile hydrogen atom (acetoacetic ester, pyrotartaric acid)[346]. Zhdanov and Dorofeenko synthesised pyrylium salts[347].

A new method for the sulphonation of acidophobic heterocyclic compounds was developed by Terent'ev and Kazitsina[348]. The sulphonation of furan, pyrrole, and their derivatives takes place smoothly under the action of pyridine–sulphur trioxide and leads to the mono- or the di-sulphonic acid, depending on the conditions.

Thiophen chemistry has formed the subject of broad systematic investigations by Ya. L. Gol'dfarb and his coworkers. The work on the synthesis of sulphides of the thiophen series has acquired an extensive scope; an effective method has been found for their synthesis from lithium derivatives of thiophen. A further development of these studies was the synthesis and study of conversions in the thiophen series[349].

Another type of reaction widely studied by Ya. L. Gol'dfarb, L. I. Belenkii, and coworkers is reduction desulphurisation. The removal of sulphur from thiophen derivatives by Raney nickel leads to aliphatic compounds. The use of this reaction enabled many difficultly accessible types of aliphatic and cyclic compounds to be obtained.

Among the compounds synthesised in this way are ketones from 14 to 17, 20, 26, and 28 carbon atoms in a ring; exaltone and dihydrocivetone were synthesised[349,350]. The following examples can serve as an illustration:

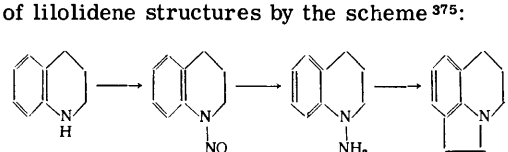


Of the other studies in this field we must mention that of Yur'ev, Elyakov, and Belyakova on the actylation of thiophen with silicoanhydrides[351,352], that of Tits-Skvortsova

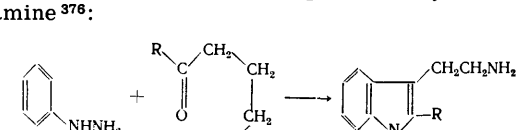
and Danilova[353], and also Obolentsev on the destruction of thiophanes[354], and that of Yur'ev and Rozantsev on the synthesis of standard thiophanes[355].

The electrophilic substitutions and reactivity of selenophen derivatives and their synthesis have been extensively studied by Yur'ev, Magdesieva, and Sadova[356,357].

Some of the studies in the field of nitrogen-containing heterocycles were considered above. There are also the work of Putokhin on the application of Den'yanov's ring enlargement reaction to heterocycles[358], that of Chumakov on the synthesis of pyridines from 2-alkoxy-3,4-dihydropyranones[359], that of Kozlov on the synthesis of quinolines from aromatic amines and acetaldehyde[360], that of Pushkareva on the study of derivatives of quinaldine and acridine[361], that of Vanag on the synthesis of complex heterocyclic systems from β-dicarbonyl compounds[362,363], Rubtsov's synthesis of bicyclic compounds with a nitrogen atom at the head of the bridge[364], that of Yakhontov on azaindoles[365], Grigorovskii's study of the chemistry of the luminescent reactions of lucigenin[366], Prostakov's synthesis[367] of pyridine derivatives from piperidones, and Vompe's[368] synthesis of pyridine and quinoline derivatives.



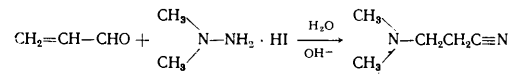
Povarov and Mikhailov developed a method of synthesising tetrahydroquinolines from alkyl vinyl ethers[241-251,369], for example:



As is well known, indole derivatives play a large part in biochemical processes, therefore the great interest of Soviet chemists in studying derivatives of this class is understandable. A large number of investigators have studied the Fischer reaction. As long ago as 1910, Arbuzov and Tikhvinskii showed that this reaction can be catalysed by additions of copper, zinc, or platinum chlorides[370,371]. By using this reaction, N. N. Suvorov developed a method of synthesis of a known root formation stimulator for plants—3-indolylbutyric acid. Suvorov's work played an important part in establishing the mechanism of the Fischer reaction[372,373].

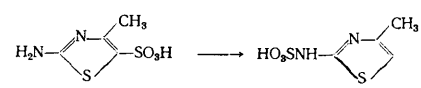
Kost and Yudin found that δ-ketonitriles can take part in the Fischer reaction and, depending on the conditions, nitriles of the indole or indolenine series are obtained[374].

These authors developed an elegant method for the synthesis of lilolidene structures by the scheme[375]:



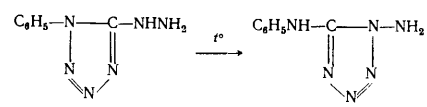
Grandberg developed an original method for the synthesis of important biogenic amines from arylhydrazones and γ-carbonyl compounds; an example is the synthesis of tryptamine[376]:

Of the other methods for building the indole ringe mention can be made of the work of Terent'ev and Grinev on the development of the Nenițescu reaction[344].



The extensive investigations of Kochetkov, Khomutova, and Sokolov were devoted to a study of isoxazole derivatives[377]. Electrophilic substitution in the izoxazole series was studied for a great number of examples.

A. N. Kost and I. I. Grandberg made a great contribution to the chemistry of heterocyclic derivatives of hydrazine. They developed a method for the synthesis of pyrazolines from azines, methods of dehydrogenating pyrazolines to pyrazoles[378], after which systematic investigations were begun into the chemistry of pyrazole[379]. Grandberg's investigations of the basicity of pyrazole systems include a series of general rules for the transfer of electronic influences through a pyrazole ring and the study of the influence of various factors (including conformational) on the conjugation of unsaturated groupings[380]. In papers of Ioffe and Zelinin[381] and also Grandberg the rearrangement of pyrazolines into nitriles was described; it is known in the literature as the "aminonitrile rearrangement"[382]. An example is the reaction of acrylaldehyde with dialkylhydrazines[383]:



Several papers have dealt with the limits of applicability of this rearrangement[381-384]. Grandberg investigated the rules affecting the course of the reaction with breaking of the N–N bond and showed the genetic relationship of the aminonitrile rearrangement with other reactions of hydrazine derivatives[384].

I. Ya. Postovskii made an large contribution to the chemistry of heterocycles with two heteroatoms. He made a detailed study of the sulpho-derivatives of thiazole, and during this found an interesting example of the isomerisation of aminosulphonic acids into sulphaminic acids[385]:

Postovskii discovered the unique reaction of thermal isomerisation of 5-hydrazino-1-phenyltetrazole into aminoanilinotetrazole by the scheme[386]:

There are also the studies of Grinshtein and Chipen on aminotriazoles[387]; Mushkalo on benzothiazine, thiazoline, and thiazolidine[388]; Elina and Magidson on *N*-oxides of quinoxaline and pyrazine[389]; and Zhiryakov on thienothiazole and thienopyrrolenine[390].

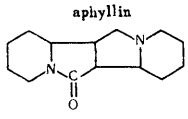
The chemistry of natural products and their analogues was begun in the investigations of A. E. Chichibabin, V. M. Rodionov, I. L. Knunyants, and N. A. Preobrazhenskii. We will note in this connection the studies of Knunyants, Chelintsev, and Magidson on the synthesis of antimalarial substances[391,392], and the synthesis of Vitamin B_1 by Chelintsev and Benevolenskaya[393].

The synthetic chemistry of natural products was broadly developed in the studies of N. A. Preobrazhenskii and his students (R. P. Evstigneeva and N. K. Sarycheva). The work on the synthesis of pilocarpine, begun by A. E. Chichibabin, was successfully finished by the complete synthesis of this

compound[394]. Later Preobrazhenskii was the first to effect the complete syntheses of emetine, cinchonamine, curarine[395], and to create the industrial methods for the production of arecoline, cocaine, and pilocarpine. Work on the synthesis of important triglycerides of vegetable oils (linseed, soybean, cocoa bean oil) was developed on a wide front. These investigations led to the development of methods for the synthesis of saturated and unsaturated fatty acids (lauric, linolic, linoleic, arachidonic). A series of phosphatides and plasmogens entering into the composition of the brain and spinal cord was obtained from them[396].

N. A. Preobrazhenskii and R. P. Evstigneeva's work on the synthesis of porphyrins is of special interest. The authors developed original synthetic approaches to the synthesis of compounds of this type and began to study the natural chromoproteins[397]. Industrial methods of synthesising Vitamins A, B_1, B_2, B_6, PP, and E were developed under N. A. Preobrazhenskii's leadership.

In the field of vitamin chemistry (apart from the work noted above) mention must also be made of Berezovskii's investigations[398].

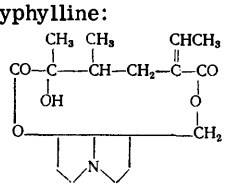


The work in the terpene field is directly connected with the use of turpentines and galipot, A. E. and B. A. Arbuzov[399] and Pigulevskii[400] made extensive investigations into the composition of turpentines.

The catalytic rearrangement of pinene into camphene, discovered by Tishchenko, gave a possibility of organising the production of camphors from turpentine[401].

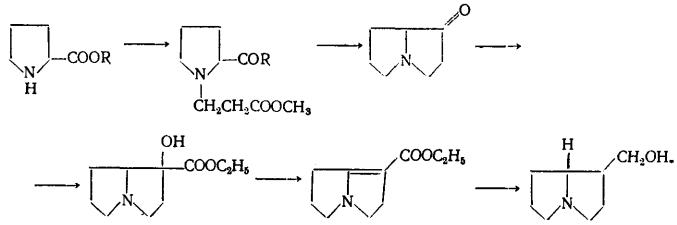
We have already noted the work of S. S. Nametkin and his students on skeletal rearrangement. Extensive investigations in the terpene field were carried out by B. A. Arbuzov, who discovered the rearrangement of pinene into alloöcimene, and, with Z. G. Isaeva, studied the properties of terpenic α-oxides in detail; B. A. Arbuzov conclusively established the structure of levopimaric acid[402].

A great range of investigations into alkaloid chemistry was reached in the work of A. P. Orekhov and his students. In these studies about eight hundred native alkaloid-bearing plants were examined, from which about fifty new alkaloids were isolated[403]. The structure of a significant proportion of them was established, and in several instances was confirmed by synthesis. The structure and pharmacological value of the alkaloid anabasine, first isolated by Orekhov and Men'shikov[404,405], are generally known. Of the other alkaloids, we note aphylline, lupinine, convolamine, and salsoline[405,406]:

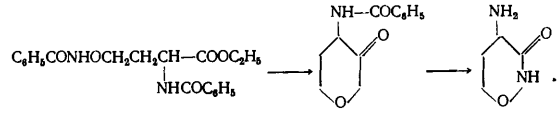


aphyllin

salsolin



Especially interesting investigations were made by A. P. Orekhov and his student G. P. Men'shikov in the field of alkaloids of the heliotridane group. As was established by the work of these investigators, the alkaloids heliotrine, trichodesmine, platyphylline, etc. are derivatives of nitrogen-free branched unsaturated hydroxy-acids and alcohols of the 1-methylpyrrolizidine[407]. We give as an example the structure of platyphylline:



Investigations of alkaloids have been successfully carried out in the Uzbek SSR by Yunusov and Sadykov. A. S. Sadykov isolated about 100 alkaloids from the plants of Central Asia, about half of these for the first time; he made extensive investigations in the field of synthesis of alkaloids and the establishment of their structure. We mention also the series of studies by Sadykov into the reactivity of bipyridyls[408].

However, there has been an especially intensive development of the chemistry of natural compounds in the last decade. This found expression in the creation of the Institute for the Chemistry of Natural Compounds (IKhPS) and in the organisation of the journal "Khimiya Prirodnykh Soedinenii" [Chemistry of Natural Compounds]. The work of two schools is of the greatest value here: those of N. K. Kochetkov and M. M. Shemyakin.

N. K. Kochetkov dealt with most diverse problems of the chemistry of natural compounds. Thus, Kochetkov and A. M. Likhosherstov developed methods for the synthesis of pyrrolizidine bases and acids, entering into the composition of the heliotridane series of alkaloids. An example is the synthesis of isoretronecanol effected by these authors[409,410]:

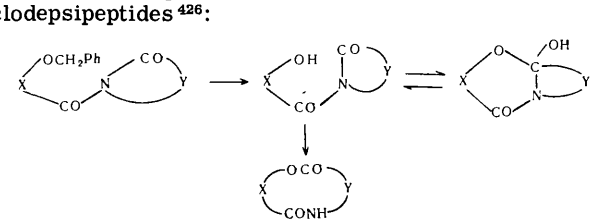
In the studies of Kochetkov, Khomutov, Karpeiskii, Budovskii, and Severin[411] methods were developed for the synthesis of cycloserine and its analogues with the aim of studying the connection between structure and physiological activity of this antibiotic. As a result of the study of the mechanism of physiological action of cycloserine it was shown that it is a powerful inhibitor of the enzymes of nitrogen exchange, the co-enzyme of which is pyridoxal phosphate. Physiological activity is also exhibited by homocycloserine, which was synthesised by the scheme[412]:

The mechanism of the physiological action of this antibiotic was subsequently studied in greater detail by Khomutov[413].

A large series of papers by N. K. Kochetkov is devoted to carbohydrate chemistry. On the one hand work in the field of monosaccharide chemistry developed over a wide front. Thus, Kochetkov studied the problems of the bromination of monosaccharides by complexes of bromine with phosphorus(III) derivatives and hence found an original approach to the production of deoxysugars[414]. Kochetkov and O. A. Chizhov found a new analytical method for determining monosaccharides with the use of fragment mass spectrometry. The combination of this method with that of the methylation with trideuteriomethyl iodide enabled the sequence of bonds in oligosaccharides to be established[415,416]. Undoubtedly this method has great prospects for finding the structure of oligo- and poly-saccharides.

Of the work in the polysaccharide field we note the investigation of Kochetkov and Derevitskaya on the isolation and

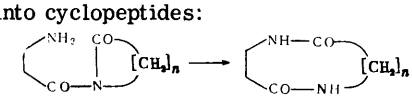
characteristics of the polysaccharides of the group of substances present in blood[417].



Many of the papers of N. K. Kochetkov and his coworkers (A. Ya. Khorlin, V. E. Vas'kovskii, Yu. S. Ovodov, O. A. Chizhov, and A. V. Bochkov) concern the study of natural glycosides. The first studies dealt with the isolation and establishment of the structure of the oligosides of Manchurian aralia [*Aralia mandschurica* Rupr. et Max. (Ed. of Translation)][418,419]. Kochetkov and G. B. Elyakov began the work on the isolation and characteristic of the ginseng [Panax ginseng C. A. Mey (Ed. of Translation)] alkaloids. G. V. Elyakov and coworkers have recently isolated glycosides (named panaxosides A–G) from gin seng roots, have established their main structure, and for several of the panaxosides have studied their detailed structure. It has been found that the panaxosides are oligosaccharides with 5–9 monosaccharide residues and a genin–panaxdiol–terpineol dammaranic series[420]. Now G. B. Elyakov, V. E. Vas'kovskii, and Yu. S. Ovodov have investigated physiologically active compounds isolated from marine organisms.

In conclusion we will note the work of Kochetkov and Budovskii on the chemistry of the nucleic acids[421]. Methods were developed for the selective splitting of heterocyclic nuclei entering into the composition of the nucleic acids (hydroxylamine method) which enabled original chemical approaches to studying the structure of these important biopolymers to be found.

The first studies of M. M. Shemyakin and his school in the field of the chemistry of natural compounds were devoted to the synthesis of the antibiotic levomycetin. The synthesis of racemic levomycetin—sintomycin—forms the basis for the industrial production of this antibiotic[422,423]:



$$NO_2C_6H_4COCH_2NH_2 \cdot HCl \rightarrow NO_2-C_6H_4-\underset{NHCOCHCl_2}{\underset{|}{COCHCH_2OH}} \rightarrow NO_2C_6H_4\underset{OH}{\underset{|}{CH}}-\underset{NHCOCHCl_2}{\underset{|}{CHCH_2OH}} \cdot$$

The series of papers by Shemyakin, Ovchinnikov, and their students deals with the depsipeptides[424,425]. The first direction is connected with the synthesis of natural antibiotics depsipeptides (the enniatins A, B, C, sporidesmolide, *o,o'*-diacetylserratomolide, etc.), and inter alia for some of them earlier formulae were corrected. There was also a very interesting study of the influence of conformational factors on the cyclisation of depsipeptides[425]. The second direction (M. M. Shemyakin, V. K. Antonov, and A. M. Shkrob) is connected with the study of oxacyclols. In these authors' research it was found that oxacyclols obtainable by the spontaneous isomerisation of *N*-hydroxyacylamines and sometimes existing in tautomeric equilibrium with them, are capable of irreversible isomerisation into cyclodepsipeptides[426]:

where X = CH_2 or $[CH_2]_2$; Y = $[CH_2]_3$, $[CH_2]_4$, $[CH_2]_5$, or $[CH_2]_{11}$.

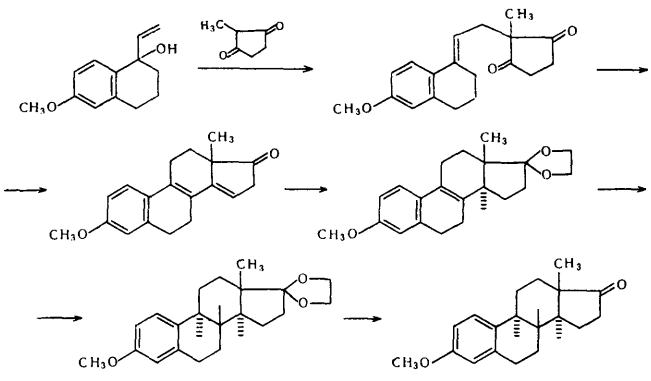
The azacyclols formed as a result of the isomerisation of *N*-aminoacyl-lactams are unstable and spontaneously are converted into cyclopeptides:

Possibly the rearrangements of the hydroxy- and aminoacylamides are some of the possible methods for the biosynthesis and transformation of peptides and depsipeptides.

A long series of papers by M. M. Shemyakin, M. N. Kolosov, and their students (Yu. A. Berlin, I. G. Bolesov, and V. V. Onoprienko) is connected with the establishment of the structure of antibiotic substances. Several years' investigations into syntheses[427] in the tetracycline field culminated recently in the complete synthesis of this antibiotic[428]. In the studies of this group methods were developed for the isolation and purification of antitumour and antivirus antibiotics of microbial origin—olivomycin, aburamycin, abicaviromycin, and the structure of some of them was established completely. In their studies these investigators discovered important relations between the structure and activity of a series of antibiotics and alkaloids, and showed the active centres and structural elements of the molecules which secured the biological activity at the cell and sub-cell levels. We note also the method developed by M. N. Kolosov for the synthesis of the analogues of chloroamphenicol. Here mention must also be made of Khokhlov's work on the isolation of new antibiotics[429].

We record also the work of V. P. Kucherov and coworkers (Gurevich, Grigor'ev, Serebryakov) on the development of methods for the isolation and synthetic modification of the gibberellins[430].

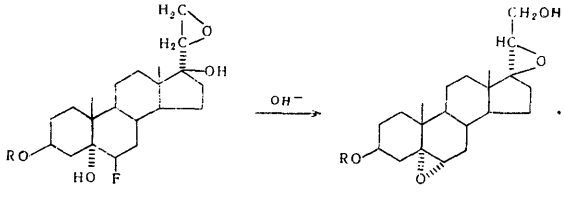
In the studies of Si. Zav'yalov and his coworkers (V. I. Gunar, M. P. Unanyan, and E. P. Gracheva) isoprenoids (for example, phytol) and homosteroids were synthesised from dihydroresorcinol. By use of the Deakin–West reaction the biogenetically similar synthesis of desthiobiotin was effected. Methods were developed for the synthesis of thymine, orotoic acid, 6-methyluracil, and 1,3-oxazines, the direct amination of uracils was achieved, and the selective *N*-glycosidation of silver salts of uracils[431,432].



The study of amino-acids, polypeptides, and proteins has been greatly developed in our country. Synthetic investigations in the field of amino-acids is connected in principle with the problem of artificial food. Among these studies we will note the investigations of Feofilaktov[433], Terent'ev[434], and Belikov[435].

The work in the protein field was begun in the USSR by Zelinskii, Sadikov, and Gavrilov[436,437]. The present investigations in this field deal with the most varied aspects of this problem, starting at the synthesis of peptides and ending with the problems of the biosynthesis of protein; a detailed examination of these studies is impossible within the space allotted to the present review. We will only note the work of Kaverzneva[438] and Khurgin[439] on the kinetics of certain hydrolytic conversions of peptides, that of Botvinnik and Avaeva in the field of peptides containing hydroxyamino-acids[440,441], those of Stepanov in the field of pepsin[442], that of Silaev and Poddubnaya on antibiotics of a peptidal nature[443,444], that of Poroshin and Shibnev[445], and also Debabov in the field of peptides isomorphous with collagen[446].

Mention must be made of the work of Prokof'ev, Shabarova, and Bogdanov[477] in which various aspects of the nucleic acid chemistry were examined, and problems of the protein–nucleic acid bond were dealt with. In a long series of studies Prokof'ev and Shvachkin succeeded in synthesising various pyrimidylamino-acids (including natural ones)[448].



As already mentioned above, the first studies in the field of steroids were undertaken by I. N. Nazarov. These were continued by Torgov and his students Ananchenko, Leonov,

and Zakharychev[449-451]. The greatest achievement of this group must be considered to be the complete synthesis of oestrone from vinylmethoxymethyltetralol by the scheme:

This method of synthesising oestrone also achieved recognition abroad, as is shown by the work on its subsequent improvement and introduction, carried out in the USA, Federal Republic of Germany, and Japan. We note also that some of the intermediate compounds in this synthesis can be used for the synthesis of other steroidal compounds, and in particular, the heart aglycones.

Interesting investigations in the steroid field were made by A. A. Akhrem and coworkers (A. V. Kamernitskii, I. G. Reshetova, V. N. Dobrynin, and A. M. Moiseenkov). In the studies of this group the interesting migration of an oxide ring under alkaline conditions was discovered[452], the stereochemistry of the Favorskii rearrangement was studied by the example of steroidal dibromoketones[453], new reactions were found for the closing of epoxide rings in the steroid series, and methods were developed for the synthesis of highly active analogues of steroids with a broken ring B[454,455]. As an example we will give an interesting migration of the epoxide ring in alkaline medium[455]:

The great development of the boundary regions with inorganic chemistry is characteristic of modern organic chemistry. This is connected with the great practical value of organoelemental materials, and, in particular, fluoro-organic compounds and organosilicon materials, with the exceptional importance of organometallic compounds for synthetic purposes, and with their important use as catalysts for the most varied processes, including polymerisations. We must mention the development of the production of organometallic antidetonators, of selective organophosphorus fluorinating agents, of highly effective insecticides, of organosilicon and fluoro-organic heat-resistant materials, rubbers, and synthetic fibres. Organometallic compounds are of great significance for theoretical investigations. Even in the last century A. M. Butlerov and A. M. Zaitsev extensively used organozinc and organomagnesium compounds for synthetic purposes; in the prerevolutionary period P. P. Shorygin discovered important reactions for metallation. A. E. Arbuzov is rightly considered a pioneer in the field of the organic chemistry of phorphorus.

However, the greatest development in organoelemental chemistry occurred only in the thirties and forties and has continued to develop explosively to the present day. The fundamental achievements in this field and essentially also the creation of the enormous divisions of the chemistry of organoelemental compounds are connected with the school of A. N. Nesmeyanov, who has raised a great pleiad of students, among whom we can mention O. A. Reutov, N. K. Kochetkov, R. Kh. Freidlina, A. E. Borisov, I. F. Lutsenko, L. G. Makarova, L. I. Zakharkin, K. N. Anisimov, V. A. Sazonova, E. G. Perevalova, N. A. Vol'kenau, T. P. Tolstaya, N. S. Kochetkova, M. I. Rybinskaya, S. P. Gubin, V. N. Drozd, Yu. A. Ustynyuk, and A. V. Grib.

Great achievements in this field are linked with the school of K. A. Kochetkov, among whose students were M. M. Nad', N. I. Sheverdina, T. S. Talalaev, A. P. Skoldinov, and N. N. Zemlyanskii.

The broadest investigations in the field of phosphorus chemistry were undertaken by A. E. Arbuzov's school: G. Kh. Kamai, A. N. Pudovik, A. I. Razumov, V. S. Abramov, K. V. Nikanorov, and N. I. Rizpolozhenskii; by the school of M. I. Kabachnik: T. A. Mastryukova, S. T. Ioffe, V. A. Gilyarov, K. V. Matsuro, A. E. Shipov, and N. N. Godovikov; and also by the school of A. V. Kirsanov.

The chemistry of fluoro-organic compounds is rightly connected with the name of I. L. Knunyants and his students: B. L. Dyatkin, L. S. German, Yu. A. Cheburkov, G. A. Sokol'skii, and R. N. Sterlin.

Organic derivatives of almost all the elements of the Periodic System have been investigated by Soviet scientists to some extent.

Extensive investigations in the field of organoelemental chemistry embracing a considerable part of Mendeleev's Table have been made by the foremost Soviet organoelemental chemist, A. N. Nesmeyanov. Of course many of his investigations extend beyond the boundaries of organoelemental chemistry and concern general questions of organic chemistry, and many of these have been considered above.

One of the principal directions of Nesmeyanov's work is the development of a new method for the synthesis of organometallic compounds on the basis of binary diazonium salts. This reaction, which appears in all the textbooks and bears the name of its discoverer, was successfully used for the synthesis of the most varied derivatives of mercury, tin, lead, bismuth, thallium, arsenic, antimony, and zinc[456-458]:

$$(ArN_2X)_m \times MX_n + \frac{2m}{p} \times M' \rightarrow Ar_mMX_{n-m} + \frac{m}{p} M'X_p + N_2 .$$

The mechanism of the decomposition of binary diazonium salts in the presence of reductants has been studied and it has been shown that these processes are homolytic in nature and constitute one of the most important paths for the development of the chemistry of free radicals and homolytic processes.

Nesmeyanov and coworkers (L. G. Makarova and T. P. Tolstaya) investigated the possibility of using the heterolytic decomposition of diazonium salts for synthetic purposes. The investigation of this type of decomposition of diazonium salts gave results far removed from the framework of organometallic chemistry and led to the creation of new types of organoelemental compound with unusual valency.

In this way diarylchloronium, diarylbromonium, and triaryloxonium salts were obtained[459-462]:

$$C_6H_5N_2BF_4 + C_6H_5Cl \rightarrow (C_6H_5)_2Cl \cdot BF_4 + N_2 ,$$
$$C_6H_5N_2BF_4 + C_6H_5Br \rightarrow (C_6H_5)_2Br \cdot BF_4 + N_2 ,$$
$$C_6H_5N_2BF_4 + C_6H_5{-}O{-}C_6H_5 \rightarrow (C_6H_5)_2O \cdot BF_4 + N_2 .$$

Study of the chemical properties of the latter and in particular, the orientation in electrophilic substitution (nitration takes place in the *para*-position) led to the hypothesis of a new "oxane" valence state for the oxygen atom[463-465]. The results of an investigation of the mechanism of decomposition of the salts of aromatic onium compounds[466] are of great interest.

Subsequently Reutov and Ptitsyna developed a method for the synthesis of organic compounds of bismuth, tin, mercury, and antimony through diaryliodonium salts[467,468].

A. N. Nesmeyanov showed that on reaction with metal salts aliphatic diazo-compounds could form organometallic compounds[469-471]. For example, the reaction between diazoacetic ester and mercury(I) chloride is[469]:

$$4N_2CH_2COOC_2H_5 + 3HgCl \rightarrow 2CH_2ClCOOC_2H_5 + Hg(CCl{-}COOC_2H_5)_2 + N_2 .$$

Diazomethane reacts with mercury salts to give various products according to the ratio of the reagents[470,471]:

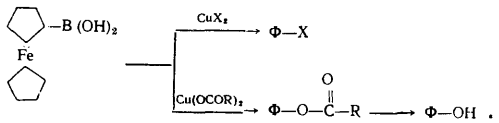
$$CH_2N_2 + HgX_2 \rightarrow XCH_2HgX \xrightarrow{CH_2N_2} XCH_2HgCH_2X .$$

Subsequently, studies of Braz, Yakubovich, and Ginsburg showed that this reaction is general—halogeno-derivatives of arsenic, antimony, bismuth, thallium, etc. were obtained[472,473].

Another method for the synthesis of onium compounds based on an exchange reaction was developed by Nesmeyanov, R. Kh. Freidlina, and E. M. Brainina. Thus the reaction of *trans*-di-2-chlorovinylmercury with iodine trichloride leads to dichlorovinyliodonium salts[474].

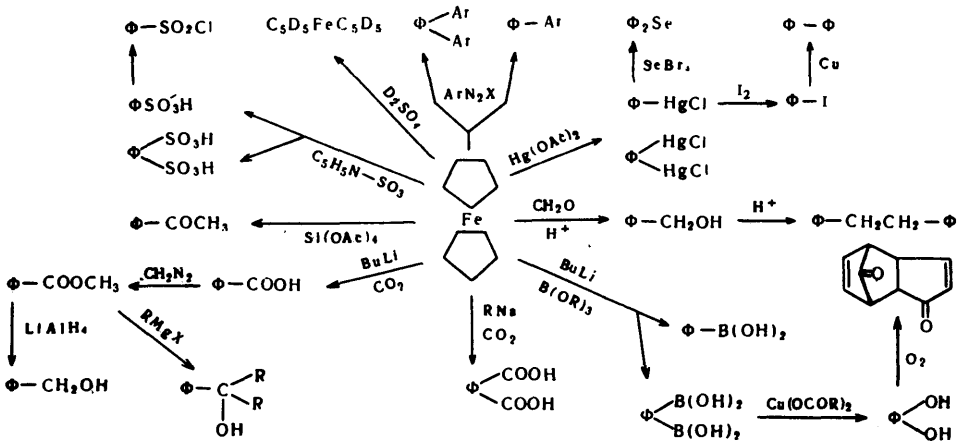
An interesting group of compounds is those provisionally termed "reverse onium compounds", where the multivalent atom is part of the anion, not the cation. Thus Nesmeyanov and Sazonova developed the synthesis of tetra-arylboric acids by the scheme[475]:

$$4RMgX + KBF_4 \rightarrow [R_4B]K + 4MgXF .$$



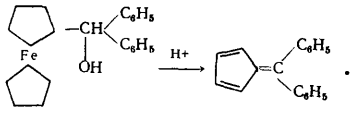
The compounds obtained are of interest as analytical reagents.

Nesmeyanov and coworkers[476-478] developed general methods for obtaining titanium compounds of the general formula $(RO)_nTiX_{4-n}$, where $n = 1, 2, 3, 4$, and X = Cl, Br; obtained titanium(III) compounds in the pure state, and obtained lower polyalkoxytitanoxanes.

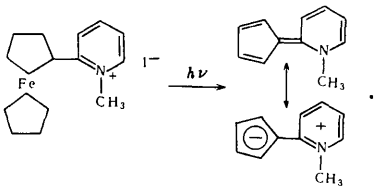


A. N. Nesmeyanov studied the reaction of chelate compounds of iron, zirconium, etc.[479]

As is well-known, the discovery of ferrocene heralded a flood of work in the field of π-complexes, deepened our knowledge of the nature of the chemical bond, and stimulated work on the ligand field theory and also synthetic investigations in the field of metal carbonyls. In our country the main studies in this region are connected with A. N. Nesmeyanov. Nesmeyanov, Perevalova, Gubin, and Ustynyuk began extensive investigations into ferrocene chemistry[480,481]. Scheme 3 shows the results of the studies of the reactions of aromatic substitution in the ferrocene nucleus.



Nesmeyanov and Gubin[482] studied the oxidation potentials of ferrocene derivatives which enabled them to show the nature of the transfer of electronic effects through the ferrocene nucleus, In a series of papers Nesmeyanov, Perevalova, and Ustynyuk studied the influence of the ferrocene nucleus on the stabilisation of neighbouring carbonium, carbanionic, and radical centres[483]. The principal results were obtained by A. N. Nesmeyanov, V. A. Sazonova, and V. N. Drozd. The elegant use of ferrocenylboric acids led to the production of such basic derivatives as hydroxyferrocene and halogenoferrocenes by the scheme[484]:



Scheme 3

These investigators studied ferrocenyldiazonium salts, nitrogen derivatives of ferrocene[485]. In studying ferrocenyldiphenylmethanol it was shown that the decomposition of the ferrocene to the fulvene by the following scheme is possible in principle[486]:

Nesmeyanov and Sazonova found a unique reaction of the photochemical decomposition of the ammonium derivatives of ferrocene by the scheme[487]:

Subsequently Nesmeyanov undertook extensive investigations of other types of π-complexes and in particular the π-complexes of palladium of σ- and π-bound cyclopentadienyl derivatives of various elements[488-490].

A. N. Nesmeyanov and K. N. Anisimov made extensive investigations into the synthesis of derivatives of metal carbonyls. Thus methods were developed for synthesising the carbonyls of chromium, molybdenum, and tungsten. Mixed carbonyls with two metal atoms in the molecule were synthesised, for example, $(CO)_5Mn-Re(CO)_5$ [491] and also some π-complexes, for example, π-cyclopentadienylcarbonylironchlorogermane by the scheme[492]:

$$\pi\text{-}C_5H_5Fe(CO)_2Cl + HGeCl_3 \longrightarrow \pi\text{-}C_5H_5Fe(CO)_2GeCl_3 + HCl$$

and cyclopentadienyldicarbonylniobiumtolane[493].

Of the works of other authors we note the investigations of Ya. K. Syrkin and I. I. Moiseev in the field of the π-complexes of palladium[494]. Of special interest are the investigations of M. E. Vol'pin and V. B. Shur in which the bonding of nitrogen by use of metallic π-complexes was shown to be possible in principle. For example, in the reaction of nitrogen with phenyl-lithium and cyclopentadienyl derivatives of titanium ammonia is obtained[495,496].

The work of Vol'pin and Shur give a powerful impulse to the investigation of the most diverse aspects of the chemistry and physical chemistry of molecular nitrogen; inevitably these ideas were immediately taken up and are being vigorously developed by a large number of investigators both in the USSR[497] and abroad[498].

K. A. Kocheshkov carried out extensive investigations in the field of organoelemental compounds. His first studies were made with A. N. Nesmayanov and concerned the extensive synthetic possibilities of the Nesmeyanov reaction. Kocheshkov's subsequent work was extremely varied and touches on many elements of the Periodic System. Thus, Kocheshkov and Sheverdina[499] made a detailed study of the metallation of aromatic hydrocarbons already discovered by Shorygin. It is interesting that a method was developed for the direct introduction of thallium into aromatic compounds[500]:

$$CH_3OC_6H_5 + Tl[OOCCH(CH_3)_2]_3 \rightarrow n\text{-}CH_3OC_6H_4Tl[OOCCH(CH_3)_2]_2 + (CH_3)_2CHCOOH.$$

Kocheshkov and Nesmeyanov studied a large number of reactions of double exchange of organometallic compounds; these reactions are a convenient method for making organoelemental compounds from readily accessible organomercury compounds[501-503]. Individual organomagnesium compounds were obtained in this way[503].

Sheverdin and Kocheshkov isolated individual mixed organozinc and organocadmium compounds and studied their properties in detail[504]: Kocheshkov and coworkers made a detailed study of organolithium compounds[505,506], on which basis an elegant method was developed for the synthesis of primary amines by the scheme[506]:

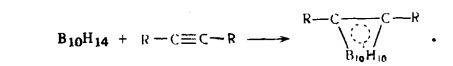
$$2RLi + CH_3ONH_2 \rightarrow R{-}NHLi + RH + CH_3OLi\ .$$

We note also the work of Kocheshkov and Zemlyanskii on the synthesis of plumboxanes and stannoxanes[507].

The interest in boron derivatives is due to the ever-increasing practical use of its derivatives. Undoubtedly there is also theoretical value in the chemistry of boron especially for dealing with problems of the nature of the chemical bond.

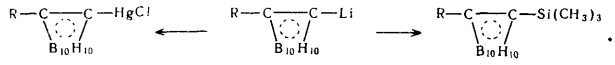
The greatest progress in boron chemistry was obtained, in the works of L. I. Zakharkin and coworkers (V. I. Stanko, O. Yu. Okhlobystin) and of B. M. Mikhailov and coworkers (Yu. V. Bubnov, V. A. Dorokhov, L. S. Vasil'ev).

In the studies of Mikhailov's group a path was developed for the synthesis of various derivatives of boron(III): trialkyl- and triaryl-borons, various oxygen-, sulphur-, and nitrogen-containing derivatives[508-511]. The study of mutual interchanges between different classes of organoboron compounds led to the discovery of the catalytic influence of the B–H bond on the exchange of radicals at the boron atom[510,511].



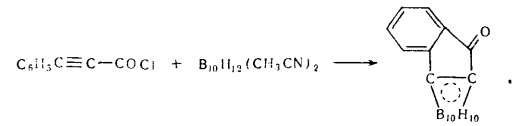
In Mikhailov's work great attention was paid to the study of the complex-forming ability of organoboron derivatives, with extensive studies of borenium and boronium compounds[508,512,513], neutral complexes, inner complexes[514,515], and also the effect of radicals at the boron atom on complex formation.

Special emphasis must be placed on certain aspects of the use of boron compounds in organic synthesis. Thus, extensive study of the derivatives of diborane, mercaptoborane, and aminoboranes made it possible to develop convenient methods for the synthesis of diols, alkenes with a known position of the double bond, and methylenecyclanes[516]. Of especial interest is the new reaction found by Mikhailov and Bubnov between triallylboron and acetylene[517]:



Study of the allyl derivatives of boron showed that these compounds exhibit reversible "valency isomerism" (proceeding according to the scheme of the allyl rearrangement)[518].

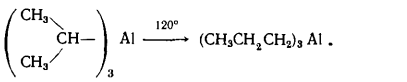
Zakharkin and coworkers synthesised some interesting compounds from acetylene derivatives and decaborane—they belonged to the group of carboranes, barene, and its derivatives[519]:



Barene has a high thermal stability; it is stable in relation to the action of alkalis and acids. It has been shown that the barene nucleus exhibits a pronounced electron-withdrawing effect: it hinders electrophilic addition to unsaturated derivatives and makes possible the metallation of the C–H bond[520,521]. A long series of papers by this group

of investigators was concerned with the metallation of barenes. The carbonisation of Grignard reagents gave barenylcarbonic and acetic acids. From the lithium derivatives they synthesised a series of organoelemental compounds of the barene series containing phosphorus, silicon, tin, and mercury [520-523]:

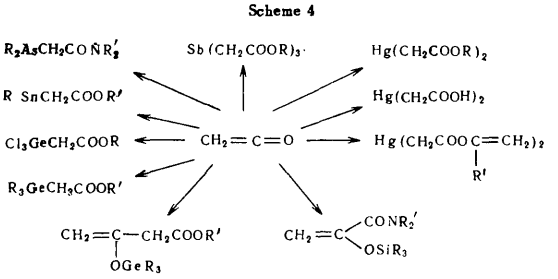
An interesting property of disubstituted barenes is the ease with which intramolecular cyclisations take place. For example, the reaction of phenylpropynoyl chloride with bis(acetonitrile)decaborane(12) gives a cyclic ketone by the scheme [522,523]:



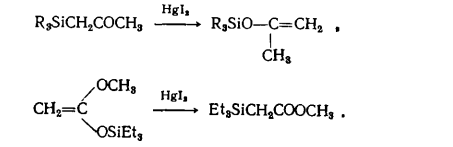
By the examples of esters of barenedicarboxylic acids and barenyl phenyl ketones it was shown that under the action of sodium ethoxide a C–C bond is broken [524,525]:

From the other studies of this group we note the work of Zakharkin and Strunin on the synthesis of organomagnesium compounds in ether-free media [526].

The chemistry of organoaluminium compounds has also been investigated by L. I. Zakharkin and O. Yu. Okhlobystin. For example, they made a detailed investigation of the reducing properties of di-isobutylaluminium hydride [527], and studied the exchange reactions between trialkylaluminiums and halides of mercury, phosphorus, boron, and lead [528,529]. These authors discovered the interesting reaction of the thermal isomerisation of isoalkylaluminium compounds into compounds with a straight chain [530]:

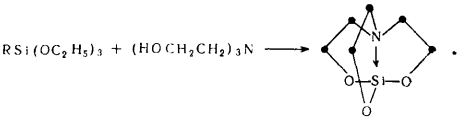


Of the elements of Group IV (of course, excepting carbon) the organic chemistry of silicon has been most developed.



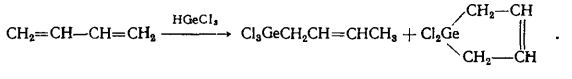
K. A. Andrianov can with justice be called the founder of the chemistry of organosilicon compounds in the USSR. Andrianov and his school studied problems of the synthesis of organosilicon monomers, ways of converting them into polymers, investigation of the properties of the polymers and materials based on them. Under Andrianov's guidance methods were developed for the vapour-phase synthesis of alkyl- and aryl-chlorosilanes, and also the theory of this process. The investigations of Andrianov and his school embrace the problems of the formation of polyorganosiloxanes of various types, the discovery of the laws of the formation of organosilicon polymers and oligomers, the study of hydrolytic polycondensation, the catalytic polymerisation of derivatives of inorganic rings and the establishment of mechanisms of these reactions, and the study of the physicochemical, mechanical, and dielectric properties of the polyorganosiloxanes. Andrianov and coworkers made extensive investigations into the synthesis of polymers with inorganic chain molecules which include (in addition to oxygen and silicon atoms) atoms of aluminium, boron, titanium, tin, phosphorus, and nitrogen. Andrianov and Khananashvili [531] examined theoretically the problem of the possibility of constructing polymers with inorganic chain molecules; they found the factors which influence the ability of the elements to form inorganic rings, framed with organic or organoelemental groups. The investigations of Andrianov and his school formed the basis for the creation of the organosilicon compounds industry.

Extensive investigations in the field of organoelemental compounds of Group IV were made by I. F. Lutsenko and his students (Yu. I. Baukov, V. L. Foss, S. V. Ponomarev, M. A. Kazankov, and Z. V. Kraits). They showed the great possibilities for the synthesis of various derivatives of silicon, germanium, and tin on the basis of keten, diketen, and enol acetates of carbonyl compounds [532-535]. They studied the conversions shown in Scheme 4.

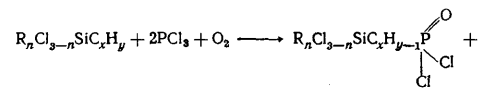


Scheme 4

In continuation of the earlier work of A. N. Nesmeyanov and I. F. Lutsenko mentioned above, a detailed study was made of the dual reactivity of α-mercurated and α-stannated compounds. This resulted in the production of a series of organoelemental *O*- and *C*-derivatives of vinyl esters of carboxylic acids, vinyloxysilanes, and phosphoric and phosphonic acids. Especially important results were obtained for derivatives of silicon and phosphorus, since here success was achieved in observing the conversion of the *O*- and *C*-forms. The greatest interest is in the isomeric conversions of organosilicon derivatives of acetone and methyl acetate, catalysable by mercury(II) iodide, which were discovered by Lutsenko and Baukov [535]:

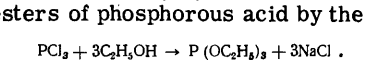


M. G. Voronkov completed successful investigations in the field of the chemistry of "atranes"—unique cyclic systems containing in a ring an atom of an element and a nitrogen atom. Silatranes are readily obtained by the reaction [536]:

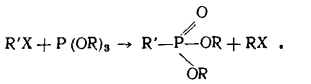


It is interesting that these compounds exhibit a definite physiological activity. In addition to silatrane, Voronkov and coworkers have synthesised boratrane, alumatrane, etc. [536].

A general property of all the "atranes" is strong coordination between the nitrogen and element atoms.

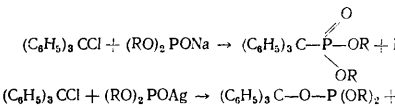


V. F. Mironov made extensive studies of the addition of silicon and germanium hydrides to unsaturated compounds [537,538]. Of especial interest is the reaction of trichlorogermane with dienes, leading to cyclic compounds [539]:



We note also the work of E. A. Chernyshev on the synthesis of compounds containing silicon and phosphorus [540]:

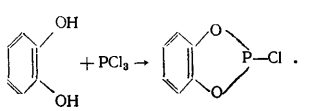
The chemistry of organophosphorus compounds was successfully developed in Kazan' by A. E. Arbuzov, B. A. Arbuzov and their students. As long ago as 1903 A. E. Arbuzov synthesised esters of phosphorous acid by the reaction:



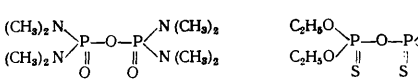
By studying the reaction of alkyl halides on the compounds he had obtained, A. E. Arbuzov discovered the rearrangement which bears his name [541]:

This reaction has proved to be one of the most important synthetic methods in organophosphorus chemistry. It has been used in the synthesis of esters of alkylphosphonic and dialkylphosphinic acids, phosphonocarboxylic acids, phosphonoketones, mixed oxides of tertiary phosphines, etc.; over 700 examples of this rearrangement have now been described [542,543].

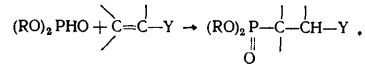
A. E. Arbuzov and B. A. Arbuzov made a detailed study of the reaction of the metallic derivatives of dialkyl phosphites with triphenylmethyl halides. This reaction proceeds differently depending on the metal and halogen [544,545]:



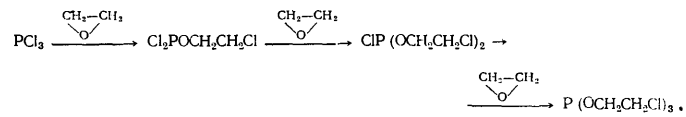
In addition, there are the studies of A. E. and B. A. Arbuzov on the structure of the so-called "Boyd's acid chloride". Of the two structures ascribed to this compound, $(C_6H_5)_3CPOCl_2$ and $(C_6H_5)_3COPCl_2$, the former was selected on the basis of a detailed experimental investigation.



In studying the conversions of "Boyd's acid chloride", A. E. Arbuzov and B. A. Arbuzov developed an interesting method for obtaining free radicals according to the scheme [544,545]:

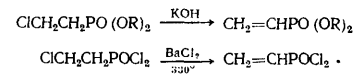


Some of the most interesting directions in A. E. Arbuzov's investigations are the synthesis of cyclic esters of phosphorous acid. A particularly detailed study was made of catecholphosphorochoridite, readily obtained by the reaction [546]:



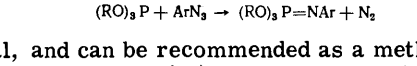
A large group of investigations by A. E. and B. A. Arbuzov are concerned with derivatives of pyrophosphoric acid [547], and are highly active insecticides. They include the well-known agricultural poisons "Oktametil" and "Ditiofos":

New preparations for the treatment of glaucoma ("Armin", "Fosarbin") were obtained. Of the relatively new achievements of the Kazan' school we will mention the discovery by B. A. Arbuzov and A. N. Pudovik of the addition of dialkyl phosphites to unsaturated compounds with an activated multiple bond; this reaction has been extensively studied by Pudovik and coworkers [548,549]:

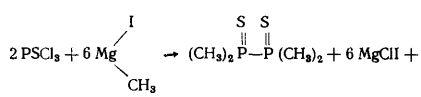


An original development in the chemistry of organophosphorus compounds occurred in the work of M. I. Kabachnik and his students, who found that the reaction of ethylene oxide with phosphorus(III) chloride leads to the synthesis of chloroethyl derivatives of phosphorous acid by the scheme [550]:

In subsequent papers, both of Kabachnik and of other authors (G. Kamai), the general nature of this reaction was demonstrated. On the basis of the chloroethyl derivatives various phosphorus(V) compounds were obtained (with the aid of the Arbuzov rearrangement).



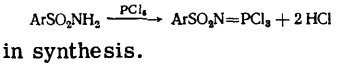
There is general interest in the production of esters of vinylphosphonic acid [551]:



The vinyl compounds obtained are interesting as monomers for the production of incombustible polymers.

In Kabachnik's investigations chloromethyl derivatives of phosphonic acids were obtained [552], esters of α-ketophosphonic acids were studied [553], and the synthesis of organothiophosphorus compounds by the reaction of phosphorus sulphides with alcohols was investigated [554].

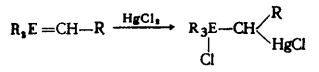
Kabachnik and Gilyarov showed that the reaction of aryl azides with phosphorus(III) derivatives, which proceeds by the scheme [555]:



is general, and can be recommended as a method for determining phosphorus(III). We note also that the reaction for the preparation of tetramethyldithiodiphosphyl found by Kabachnik and Shepeleva [556]:

is now the best method for the synthesis of compounds of the tetra-alkyldithiophosphyl series.

Kabachnik has recently carried out extensive investigations on conjugation in non-coplanar systems containing phosphorus, and in particular, in phosphazocyanines [557].

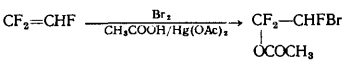


Mention must also be made of the work of Kirsanov and Derkach on the synthesis of trichlorophosphazosulphonaryls and trichlorophosphazocyls [558,559]:

and their use in synthesis.

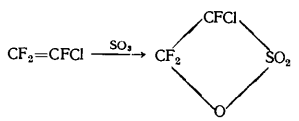
G. Kamai has studied the chemistry of organoarsenic compounds [560]. There is also the work of O. A. Reutov and N. A. Nesmeyanov on the yields of arsenic and phosphorus [561]. In these studies it was found that the yields readily add

mercury(II) chloride to form unusual addition products, which exhibit "quasicomplex properties":



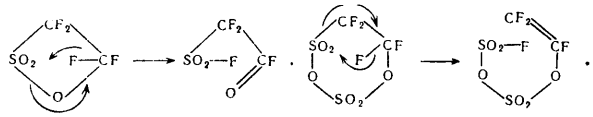
These compounds are fairly stable and may find applications in syntheses as "conservation" Wittig reagents.

We will mention also the systematic studies of E. G. Nifant'ev on methods of phosphorylation of polyols, monosaccharides, and polysaccharides [562].

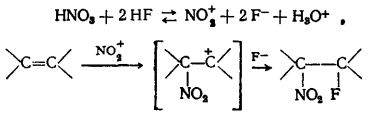


The greatest developments in the organic chemistry of fluorine have been in the research of I. L. Knunyants and his students [563,564]. The main direction of the work of this school was connected with showing the reactivity of fluoroalkenes, in studying the nature of the double bond in fluoroalkenes and the mutual influence of the groups in fluorinated derivatives of the most diverse classes. The rules for the electrophilic and nucleophilic addition in the fluoroalkene series were studied for a wide range of compounds.

There is special interest in the work of Knunyants and his students (B. L. Dyatkin, L. S. German, Yu. A. Cheburkov, and G. A. Sokol'skii) on the chemistry of fluoroacrylates, the chemistry of perfluoronitroso- and perfluoronitrocompounds, and on the study of reactions involving conjugated addition to fluoroalkenes.



For example, Knunyants and his coworkers showed that hydrogen-containing alkenes, such as $CF_3CH=CH_2$ or $CF_2=CHF$ react with bromine in acetic acid in the presence of mercury(II) acetate or sulphate to form bromohydrins [565]:



Fluoroalkenes readily add sulphur trioxide to form cycloaddition products of β-sultones [566]:

The development of the chemistry of fluorinated sultones led to the discovery of interesting isomerisations, which probably proceed through a "bicyclic mechanism" [567]:

I. L. Knunyants has made extensive studies of the nitrofluorination of fluoroalkenes, which proceeds by the scheme [568]:

This reaction was first effected by Titov by the example of tetrafluoroethylene [569].

It is impossible to omit the work of Knunyants and Sterlin on the synthesis and investigation of the properties of perfluorovinylmercury [570].

Of the other work in this field we note the investigations of I. V. Martynov and Yu. L. Kruglyak on the nitration of fluoroalkenes by a sulphuric–nitric acid mixture [571] and that of A. Ya. Yakubovich's study of nitrosation [572].

---o0o---

Obviously, within the framework of a journal article it is impossible to review thoroughly all the great achievements of Soviet organic chemists. However, even in this brief survey the enormous attainments of Soviet scientists in the most diverse branches of science are evident. This guarantees future progress in organic chemistry in our country.

U.D.C. 541

FIFTY YEARS OF SOVIET PHYSICAL CHEMISTRY

N. M. Emanuel'

The Soviet period in the development of physical chemistry in our country is characterised by an extremely rapid increase in the volume of scientific research and in the number of specialised scientific topics investigated.

The appearance of the physicochemical laboratory underwent a radical change. The Soviet generation of physical chemists has witnessed on more than one occasion an almost complete technical re-equipment of its laboratories, brought about by the impact of modern experimental methods borrowed from physics, electronics, and computer science. The interface between physical, organic, inorganic, and analytical chemistry is now almost completely blurred. Physicochemical methods and concepts have become predominant in the study and interpretation of the results obtained in fundamental studies of every aspect of chemical science.

The rapid and fruitful penetration of the theoretical and experimental methods of modern physics concerns practically every problem in physical chemistry (structure of matter, valence theory, chemical equilibria, kinetics and mechanism of chemical change, problems in photochemistry and radiation chemistry, electrochemistry, semiconductor chemistry, theory of heterogeneous catalysis, chemistry of surface phenomena, colloidal chemistry). In the last fifty years, important advances have been made in all these fields, and many of the most important fundamental ideas of chemistry have had to be revised. The close association of organic and inorganic chemistry with physical chemistry (the "chemification" of physical chemistry) has given rise on the one hand to the appearance of new and rapidly developing branches of science such as physical organic chemistry, and on the other hand to the far-reaching penetration of mathematics into the whole of theoretical and applied chemistry. This tendency has become even more marked as a result of the increasing use of modern computing techniques.

Significant advances in the principles and methods of industrial chemistry have been both the result and the motivation of the development of physical chemistry. New methods of carrying out chemical reactions were quickly introduced into the chemical industry: these include the separation and purification of liquids and gases, sorption techniques, new and versatile continuous catalytic processes, and definite progress towards the rational control of chemical reactions including the development of chemical cybernetics. The physical chemistry of surface phenomena, electrochemistry, and radiation chemistry are helping to solve important technical problems, such as the development of new methods of preparation of disperse materials, the conversion of chemical into electrical energy, and problems in radiation-chemical synthesis. The growth of physical chemistry has been of tremendous importance also in the polymer field. The present review will not deal specifically with this field, which has become a self-contained branch of modern chemistry.

If we compare the development of Soviet chemistry with that of the rest of the world we see that our Soviet science leads (or keeps pace with) the science and technology of advanced capitalist countries in many important branches of chemistry. These include chemical kinetics, the theory of catalysis, electrochemical kinetics, adsorption theory, physicochemical mechanics, combustion and explosion problems, and many others.

These important advances in physical chemistry cannot be understood otherwise than in the context of earlier developments in this science. It is well known that physical chemistry first arose in our country at about the time when chemistry began to claim the status of a science in its own right. Lomonosov was the first to propose the term "physical chemistry" for the branch of science which straddles the boundary between chemistry and physics, and gave the following definition of this scientific discipline: "physical chemistry is a science which explains in terms of the concepts and experiments of physics that which takes place in mixed bodies during chemical operations"[1]. Lomonosov also carried out the earliest experimental physicochemical investigations in the chemical laboratory of the Academy of Sciences, now inseparably associated with his name.

Nearly all the main sections of physical chemistry began gradually to take shape during the second half of the nineteenth century. The first ideas on catalysis were put forward, studies of chemical affinity began, progress was made in the study of electrochemical phenomena, heat effects accompanying chemical change were investigated, the universal gas law was established, the simplest laws of chemical kinetics were formulated, and above all the fundamental laws of thermodynamics were determined.

Physical chemistry experienced a particularly significant development during the period immediately preceding that discussed in the present review (from the 1880's to the 1920's). Much was accomplished during this period, particularly development in chemical thermodynamics.

During the nineteenth and especially the early twentieth centuries some higher scientific institutions in St. Petersburg, Moscow, Kazan', Kiev, Khar'kov, Yur'ev, and other cities had better laboratories than those of the Academy, and therefore the role of the Academy of Sciences in the development of chemistry (and in particular physical chemistry) was not so much to strengthen experimental research within its own walls as to stimulate the scientific life of the nation by electing leading scientists as Members, by sponsoring prizes, and by publishing scientific work[2].

After the Great October Socialist Revolution, following Lenin's instructions, the Academy of Sciences began a systematic study and survey of the natural industrial resources of Russia, and set up the first Chemical Institutes. At the same time, various subsidiary research institutes were founded, and some of these have played a major role in the development of Soviet physical chemistry[3,4].

At present, the most important physicochemical institutes of the Academy of Sciences are the Institute of Chemical Physics, the Institute of Physical Chemistry, and the Institute of Electrochemistry.

In May 1958 the Central Committee of the Communist Party of the Soviet Union issued important directives for the faster development of chemical industry and science. Since then, the Academy of Sciences has created and successfully developed a number of new physicochemical institutes. These include the Institute of Electrochemistry

of the Urals' branch, which specialises in the electrochemistry of fused salts and solid electrolytes, and also the Institutes of Catalysis and of Chemical Kinetics and Combustion of the Siberian Section of the Academy of Sciences of the USSR.

Many other institutes of the Academy have some involvement in physicochemical investigations: the Institute of Organoelemental Compounds, the Zelinskii Institute of Organic Chemistry, the Kurnakov Institute of General and Inorganic Chemistry, the Institute of High-Molecular-Weight Compounds, the Institute of Petrochemical Synthesis, etc.

Physicochemical studies at one of the oldest of the chemical institutes of the Academy of Sciences—the Radium Institute—also produced notable contributions. In 1961 this Institute was transferred from the Academy of Sciences to a different administration.

Foremost among the other physicochemical institutes are the Karpov Physicochemical Institute, the Pisarzhevskii Institute of Physical Chemistry of the Academy of Sciences of the Ukrainian SSR, and the Faculty of Chemistry of Moscow State University.

The origin and the earliest development of chemical physics took place at the Leningrad Physico-Technical and Radiographic Institute (GFTRI) under the direction of A. F. Ioffe. In 1921, a small team led by N. N. Semenov was set up within the GFTRI to study electronic effects in chemistry[5]. This laboratory investigated electric fields, molecular physics, and electronic phenomena. Towards the beginning of 1931 the activities of the electron chemistry laboratory had progressed well beyond the scope of a section of a research institute. At about this time the whole of the scientific world had began to associate research in chemical physics with the name of Semenov and his coworkers. As a result of the phenomenal growth of the Leningrad Institute, the decision was made in September 1931 to reorganise it into a physico-technical scientific research complex, consisting of three independent research institutes. One of these institutes, opened on the 15th October 1931, was the Leningrad Research Institute for Chemical Physics. Since that day, having achieved independent status, the Institute of Chemical Physics (IKhF) has intensified its efforts towards its basic objective: to introduce the theories and methods of physics into chemistry, the chemical industry, and many other branches of the national economy.

The scientists of the Institute have gone a long way from the first researches, made thirty-five years ago, to the modern work in the most varied aspects of chemical physics. In 1939 the Institute was admitted into the Academy of Sciences of the USSR.

The branch of the Institute created in 1957 and staffed almost exclusively by young scientists is beginning to produce good results. The Institute is still directed by its founder, Nobel Laureate and Hero of Socialist Labour N. N. Semenov.

The Institute is now investigating the kinetics and mechanism of chemical reactions (chain reactions in particular), and the kinetics and mechanism of catalytic processes, chemical processes induced by penetrating radiations, at low and at high temperatures, under high pressures, etc. It is developing new processes and improving existing processes for the production of polymers and monomers, it is studying the degradation and stabilisation of polymers, it is developing new physical methods and apparatus for chemical investigations such as mass spectrometry, radiation spectrometry, the Mössbauer effect, etc. It is refining the theory of combustion and detonation processes in gaseous and condensed systems, studying the kinetics of biological processes, and applying physicochemical investigations to the mode of action of chemicals and of physical agents on various biological systems.

In 1967 the Institute of Chemical Physics was awarded the Order of Lenin for its achievements in the development of chemical physics and the training of specialists.

Another important centre of physical chemistry in the Academy of Sciences of the USSR is the Institute of Physical Chemistry. The history of this Institute goes back to 1930, when the Laboratory for Colloid Chemistry and Electrochemistry (LAKE) was set up at the initiative of V. A. Kistyakovskii[6]. In this laboratory, he and his pupils studied problems of metal corrosion, electrocrystallisation [electrodeposition], and flotation.

When the Academy of Sciences moved to Moscow in 1934 the Praesidium of the Academy reorganised the Laboratory into an Institute for Colloid Chemistry and Electrochemistry (KEIN), with a more comprehensive research programme. In addition to the above topics, the Institute undertook problems in colloid chemistry, the physicochemical dispersion of metals, the theory of lubrication, the formation of metallic coatings, and several others.

V. A. Kistyakovskii was the director of these establishments until 1939, when he was succeeded by A. N. Frumkin, whose main activities had previously been centred at the Karpov Physicochemical Institute and Moscow State University.

In 1945 the Institute of Physical Chemistry (IFKh) was created from the Institute for Colloid and Electrochemistry.

From 1949 until 1953 the Institute of Physical Chemistry was directed by G. V. Akimov. During this period the Corrosion Section, led by Akimov, grew rapidly.

At the moment the following topics are being pursued at the Institute: the physicochemical mechanics of metals, concrete, and colloidal systems; the forces acting close to phase boundaries and in thin films; the formation and precipitation of aerosols; the thermodynamics and kinetics of sorption on carbon and mineral sorbents, and chromatography; the protection of metals against corrosion; the preparation of polymer coatings. Problems in radiochemistry and radiation chemistry also claim a significant part of the effort of the Institute.

Since 1953 V. I. Spitsyn has been the director of the Institute as well as leader of the work on radiochemistry.

In 1958 the Institute of Electrochemistry (IELAN), based on the Electrochemistry Section of the Institute of Physical Chemistry, was created on the initiative of A. N. Frumkin in response to the need for more extensive work on electrochemical kinetics (the theoretical basis of the most important practical applications of electrochemistry).

In the 1950's some problems of major importance to the national economy and demanding an increased effort in the field of electrochemical kinetics began to be clearly recognised. These include the realisation of electrochemical power sources (fuel cells) able to convert the chemical energy of a fuel directly and continuously into electrical energy; the development of electrochemical transducers

for automation, control, and guidance systems having a number of valuable properties, especially the ability to operate at low frequencies; the provision of methods of electro-synthesis of organic compounds offering very pure products; and various other problems.

Investigations are now proceeding at the Institute in the following directions: the theory of electrochemical processes and the structure of the metal/electrolyte interface; the electrochemistry of organic compounds; the mechanism of processes in electrochemical power sources (particularly fuel cells), in electrochemical transducers, and in the electrochemical machining of metals; surface phenomena on semiconductors (including organic semiconductors); the mechanism of radiation processes; the quantum theory of chemical reactions; physicochemical hydrodynamics and its application to the theory of technological processes.

Since its foundation the Institute has been directed by A.N. Frumkin, Hero of Socialist Labour and president in 1965–66 of the Comité International de Thermodynamique et de Cinétique Électrochimiques (CITCE).

The structure and reactivity of a wide range of organoelemental compounds are being investigated at the Institute of Organoelemental Compounds (INEOS). The Zelinskii Institute of Organic Chemistry (IOKh) is examining spectroscopically the molecules of organic compounds. Nearly half of the work of the Institute is directed towards a study of the catalytic interconversions of hydrocarbons. The Topchiev Institute of Petrochemical Synthesis (INKhS) is developing catalytic methods for converting hydrocarbons into valuable chemicals, and is working on plasma chemistry and on the physical chemistry of polymers. Work on the physical chemistry of the oriented state has reached an advanced stage at the Institute of High-Molecular Compounds (IVS). The Kurnakov Institute of General and Inorganic Chemistry (IONKh) is the principal centre in our country for the development of the field of research originated by Kurnakov: physicochemical analysis. This includes studies of the physicochemical properties of various groups of compounds, metals, salts, semiconductors, organic compounds, and also the conditions of equilibrium in multiphase systems. Extensive investigations are proceeding at the Institute on the structure of complex compounds of a great variety of metals, including the platinum, transuranium, and rare elements. At the Kazan' Institute of Organic and Physical Chemistry (IOFKh) work is directed towards electrochemical methods of metal treatment and the electrocrystallisation [electrodeposition] of metals.

The Karpov Physicochemical Institute was the first (and, until the 1930's, the only) institute in this country with a physicochemical objective. The Institute began operations in 1918 as the Central Laboratory of the Chemistry Section of the Supreme Economic Council (VSNKh). A.N. Bakh[7-9] was one of the founders of the Institute, which he directed continuously for 28 years.

Since those early years, Bakh has gathered together some talented young scientists, and has created, with the support of the Government, an ideally equipped institute whose scientists are continually striving towards linking science with technology.

A.N. Frumkin took an active part in developing the Institute as a physicochemical establishment, and was its Deputy Director from 1929 until 1947, when he was succeeded by V.A. Kargin. The present Director of the Institute is Ya.M. Kolotyrkin.

The leading physicochemical experimentation and the major theoretical advances for which the Institute was responsible have won the acclaim of scientists in the Soviet Union and abroad. During the pre-war period, the activities of the Institute were aimed mainly at three large sections of physical chemistry: surface phenomena and electrode processes, the structure of matter, and chemical kinetics and catalysis. Since the war, there has been a considerable increase in the effort devoted to polymer science and catalysis. Studies in radiation chemistry and in the separation of mixtures have grown into fields of study in their own right. Important problems solved at the Institute include the development of new processes and the improvement of existing processes for chemical technology.

The Karpov Institute has also undertaken a heavy load of organisational work to assist the development of Soviet physical chemistry. It has convened regular series of conferences and published physicochemical journals. The Institute still retains close links with the Academy of Sciences. Many dozens of scientists now working in our country have been trained at the Institute.

The Institute of Physical Chemistry of the Academy of Sciences of the Ukrainian SSR[10] was founded a few years after the Karpov Institute (in 1927), but it has also won a leading place among the Soviet institutes specialising in physical chemistry.

Much of the work of this Institute is devoted to studies, by ESR, infrared spectroscopy, and other methods, of the structure, reactivity, and transformations of free radicals formed during electrochemical reduction, and of the sterically stabilised radicals which act as oxidation inhibitors in polymers. Other activities include the mass-spectrometric and isotopic study of various organic reaction mechanisms, of the mechanism of oxidation of various ions by peroxides, of adsorption phenomena, of the mechanism of the radiation-induced and the oxidative degradation of polymers, and an ESR study of the kinetics of fast protolytic reactions.

Extensive developments have taken place in mechanistic and kinetic studies of industrial catalytic processes, and of the part played by macrokinetic factors, in relating catalytic activity to thermodynamic properties, in systematising and correlating data on catalysis with a view to developing a theory for the selection of catalysts.

Furthermore, the Institute is now successfully engaged in the following directions: the utilisation of solar energy, the use of nuclear radiations in chemistry, the synthesis of zeolites, and studies of sorption mechanisms.

Physicochemical investigations at the Institute of General and Inorganic Chemistry of the Academy of Sciences of the Ukrainian SSR have been highly significant: this applies particularly to the work on the thermodynamics and kinetics of complex-formation reactions and on the theory of chemical bonding in complexes (K.B. Yatsimirskii), on comprehensive studies of different problems in the electrochemistry of fused salts (Yu.K. Delimarskii), on colloidal chemistry, and on a number of other problems.

Many important physicochemical projects are being developed in the Academies of other republics of the Soviet Union: the electrodeposition of metals at the Academy of Sciences of the Lithuanian SSR (Yu.Yu. Matulis), heterogeneous catalysis and the theory of acids and bases at the Academy of Sciences of the Kazakh SSR (D.B. Sokol'skii and M.I. Usanovich), polymer mechanics at the Academy of Sciences of the Latvian SSR, the structure of inorganic

compounds at the Academy of Sciences of the Moldavian SSR, etc.

Among the institutions engaged in physicochemical research, a leading place belongs to the Chemistry Faculty of the Lomonosov Moscow State University [11,12]. The history of this faculty goes back to the creation, during the earliest years of Soviet rule (1919–1921), of a chemistry section of the Faculty of Mathematics and Physics, and to the organisation (in 1922) of a Scientific Research Institute for Chemistry within the University. The Chemistry Faculty of Moscow State University achieved independent status in 1929–1930.

In 1929 a Chair in Physical Chemistry was created as part of the Chemistry Faculty. This department grew quickly, and established a number of laboratories. By 1930–1932 it included the following laboratories: electrochemistry (A. N. Frumkin), contact processes for the heavy chemical industry (N. N. Petin), halurgy (A. V. Rakovskii), photochemistry (A. I. Rabinovich), and colloid chemistry (V. A. Naumov). Some of these laboratories eventually grew into independent departments.

When the Chemistry Faculty was organised, the Chair of Physical Chemistry was entrusted to A. V. Rakovskii. After his death (in 1941) it passed to A. V. Frost, and is now held by Ya. I. Gerasimov.

The Department of Physical Chemistry is a large scientific research establishment engaged in wide-ranging investigations into chemical thermodynamics and thermochemistry, catalytic reaction mechanisms, adsorption, molecular spectroscopy, colloid chemistry, the electrochemistry of gases, and electron diffraction studies of molecules. Other sections of the department are investigating the physical chemistry of disperse systems, electrochemical kinetics, the physical chemistry of high polymers, and chemical kinetics. Many of the sections are led by Academicians and Corresponding Members of the Academy of Sciences of the USSR. The Chemistry Faculty of the Zhdanov Leningrad State University is investigating ion-exchange theory (B. P. Nikol'skii), the thermodynamics of multicomponent systems and electrochemical kinetics. Physicochemical research is active also in other institutes of higher education such as the Mendeleev Moscow Institute of Chemical Technology, the Lomonosov Moscow Institute of Fine Chemical Technology, the Odessa State University, the Tomsk State University, etc.

Thus, in contrast to the pre-revolutionary period, physicochemical research is being carried out in large scientific complexes operating by a predetermined plan which reflects modern trends of research as well as the needs of the national economy, and not by individual scientists assisted at the most by a few coworkers.

In conclusion, we note that in recent years the network of physicochemical journals has grown appreciably (but less so than in the advanced capitalist countries). Before the war only two specialist physicochemical journals were published in our country: Zhurnal Fizicheskoi Khimii and Kolloidnyi Zhurnal, as well as the foreign-language publication Acta physicochimica USSR (which ceased to exist in 1946). Now, in addition to these, we have Elektrokhimiya, Khimiya Vysokikh Energii, Zhurnal Strukturnoi Khimii, Kinetika i Kataliz (the last two being published by the Siberian section of the Academy of Sciences of the USSR), and Zashchita Metallov (published jointly by the State Committee for Science and Technology, the Ministry of the Chemical Industry, and the Academy of Sciences).

Having briefly described the growth of the network of scientific establishments specialising in physical chemistry and their role in the overall scientific context, we shall discuss the major results obtained during the past 50 years. Through lack of space, this review must be a fragmentary one, and many important achievements have had to be omitted.

MOLECULAR STRUCTURE. REACTIVITY. QUANTUM CHEMISTRY. PHOTOCHEMISTRY

Soviet scientists are successfully investigating the relationship between the structure and the reactivity of molecules, the theory of elementary chemical processes and of energy-transfer processes, the theory underlying the application of radio-frequency spectroscopy (ESR and NMR) to the study of the structure and properties of matter, chemical spectroscopy, the Mössbauer effect, X-ray and electron diffraction, and the theory of molecular vibrations. In many of these topics important progress has been made in spite of the relatively small number of workers engaged.

Scientists of the Soviet Union have made outstanding contributions to developments in the chemistry of complexes, and to studies of their structural features. The foundations were laid by the work of L. A. Chugaev, who carried out systematic studies of the complexes of platinum metals even before the revolution [13]. Chugaev founded one of the leading schools of research on complexes. The able scientists who joined Chugaev (I. I. Chernyaev, A. A. Grinberg, V. V. Lebedinskii, N. K. Pshenitsyn, O. E. Zvyagintsev, and others) carried on the work of their teacher with outstanding success. They prepared hundreds of previously unknown complexes, studied their properties, and found practical uses for them. Chernyaev put forward the rule of the trans effect—an important generalisation of the influence of inner-sphere substituents in the coordination compounds. The trans effect concept gave a theoretical foundation to the development of multistage methods of preparation of complexes having a prescribed structure and configuration. Studies of the mutual effect of ligands (of which the trans effect is a special example) became the central theme of a great deal of chemical work in the USSR and abroad. The trans effect was demonstrated not only on platinum, but on many other elements: rhodium, cobalt, iridium, rhenium, etc. In ruthenium compounds the cis effect (first discovered by Grinberg) was investigated as well as the trans effect.

Grinberg and his coworkers were among the first to apply radioactive isotopes to the study of the structure and properties of complexes. Specially important results were obtained in their work on the kinetics of exchange between ligands and ions in solution.

Recent structural studies, carried out mainly at the Kurnakov Institute of General and Inorganic Chemistry, have added considerably to our understanding of the shapes (spatial structures) of complex ions of various metals. In particular, it was shown that the less usual polyhedra (coordination numbers five and seven) are fairly common among transition metals, and that frequently the structure is polymeric either due to bridging atoms or groups of atoms (halogens, oxygen, water, or hydrazine molecules, etc.) or due to metal–metal bonds (as in the acetato-complexes of univalent and bivalent rhodium and the halides of bivalent rhenium). These structural studies, together with the results of other physicochemical investigations, have identified and characterised some new types of chemical

bond (many-centre bonds in transition metal compounds, partial bonds, and particularly metal–metal bonds). Much valuable information on the structure of inorganic compounds was obtained in studies of the infrared spectra of coordination compounds.

The research on quantum chemistry led by Ya. K. Syrkin and M. E. Dyatkina deserves a special place among these investigations.

Syrkin was among the first in the USSR to undertake work on quantum chemistry and has developed it successfully up to the present time. His quantum chemical calculations of the energy and other properties of organic and inorganic compounds have led to many important predictions. He successively developed the theory of covalent bonds in inorganic compounds and the concept of covalent bonding in crystals which has proved so valuable in understanding the properties of semiconductors.

Much of Syrkin's effort was devoted to problems in the physics of the elementary chemical act. He put forward the original view that the elementary acts of many chemical reactions occur through five-, six-, or seven-membered rings with a sextet of electrons.

In recent years he has actively investigated the mechanism of reactions involving aromatic metal complexes (ferrocene, ruthenocene, etc..) and the π-complexes of some platinum group metals.

Dyatkina made a significant contribution to the theory of inorganic chemistry. She published many papers on the theory of directional valencies and the theory of the valency states of atoms in molecules. These include the most systematic investigation of the valency states of both transition and non-transition elements, from which many conclusions of the greatest importance in inorganic chemistry may be drawn.

Syrkin and Dyatkina developed the most satisfactory of the existing theories of aromatic and π-complexes of metals, and made a systematic study of the electronic structure of the tetrahedral oxo-anions of the transition metals.

A fundamental contribution to the application of the X-ray structural method to problems in inorganic chemistry, resulting in the development of crystal chemistry, came from N. V. Belov and his students (Institute of Crystallography of the Academy of Sciences of the USSR). They identified the structural units in silicates, explained the function of the cations, and computed a large number of complicated silicate crystal structures.

Since 1944, the Institute of Organoelemental Compounds led by A. I Kitaigorodskii has studied the packing of organic molecules in crystals. The concept of close packing of molecules, the principle of identifying the structure on that basis (the so-called "geometrical analysis"), and the symmetry rules following from the basic packing law—all these were rapidly adopted both in the field of low-molecular compounds and in the high polymer field. The laboratory developed improved physical methods for the structural investigation of organic and organoelemental compounds, originated and developed a new branch of crystal chemistry (organic crystal chemistry), proposed a method of quantitative conformational analysis, and is now successfully engaged on developing the basic aspects of the physics of organic crystals.

The same laboratory is carrying out wide-ranging investigations of the reactivity of organic and particularly of organoelemental molecules.

An extensive series of investigations by D. N. Kursanov on the chemistry of the carbonium ion, the mechanism of dehydration of alcohols, and the reactions of quaternary ammonium ions has shown that these processes involve a carbonium mechanism.

Other work by Kursanov on heterolytic reactions has dealt with hydride transition reactions. This work has made significant contributions to modern views on the hydride mobility of hydrogen in organic compounds.

The classical work of Kursanov on the reactivity of non-benzenoid aromatic systems is widely known.

Organometallic compounds have made possible a clear demonstration of dual reactivity in the absence of tautomerism. On this basis, M. I. Kabachnik drew a distinction between the phenomena of dual reactivity and tautomerism as equilibrium isomerism. He subsequently developed a quantitative theory of tautomeric equilibrium as an acid–base equilibrium, and discovered new experimental approaches to the study of these phenomena.

The work of R. Kh. Freidlina in new areas of organic chemistry has become widely known: it includes radical telomerisation and the regrouping of radicals in solution, as well as methods of synthesis based on these phenomena.

The simultaneous discovery by the Soviet physicists L. I. Mandel'shtam and G. S. Landsberg and by the Indian physicist Raman of the molecular light-scattering method was of incalculable importance in developing the science of the structure of matter. Thie method was widely used by B. A Kazanskii at the Institute of Organic Chemistry in studies on hydrocarbons.

A systematic investigation of the spectra of compounds having different combinations of atomic groups, by P. P. Shorygin of the Institute of Organic Chemistry, allowed him to establish the main rules which relate the spectra of molecules to the specific parameters of the chemical bonds and of the system of energy levels in a molecule. From these studies it has been possible to characterise the effect of substituents on π-bond systems as a function of the position of the substituent atom in the Periodic Table, of the type of intermediate units, of the orientation in space of the interacting groups, and of the chain length of the conjugated structural elements. A specific effect of heavy atoms contacting π-bond systems through an intermediate atom (oxygen, methylene, or other groups) has been discovered and investigated.

The work of A. N. Terenin[14] on the photodissociation of molecules has played a fundamental role. This worker was the first to put forward a correct model of the mechanism of the primary interaction of a quantum of light with a molecule. Terenin's work provided the foundations of the electronic theory of the structure and energetics of molecules. The classical papers by Terenin on the photochemistry of halide vapours are of fundamental importance to the basic problem of photochemistry—the mechanism of the primary elementary process. These investigations are attracting renewed interest in connection with the problem of a quantum light source.

Studies of compounds in the gas phase led to the discovery of various new phenomena: the "activation" of the fluorescence of complex molecules by adding other gases, and the effect of light gases (helium and hydrogen) on the intensity of absorption by complex gas molecules.

One of Terenin's students, B. S. Neporent, made an important contribution to the spectroscopy of complex mole-

cules: he proposed a rational physical classification based on intramolecular interactions of the various types of state (electronic and vibrational).

A series of papers by Neporent was devoted to spectral studies of intermolecular interactions in condensed media. He found a solution of the complicated problem of the influence of the solvent on the intensity of molecular spectra: this provided the foundations for the development of general methods of absorption spectral analysis.

M. V. Vol'kenshtein (Institute of High-Molecular Compounds, Academy of Science of the USSR) made a number of theoretical investigations of intensities in the infrared and Raman spectra of polyatomic molecules, of problems in rotational isomerism, and in the field of molecular optics. Some of Vol'kenshtein's work dealt with problems in quantum chemistry.

An important series of investigations into quantum chemistry was carried out recently in Sokolov's laboratory of the Institute of Chemical Physics. A quantum-mechanical model of the hydrogen bond was developed, an effective method was found for optimising approximate wave functions and the operators used to calculate various characteristics of atoms and molecules, and a simple and effective method was proposed for calculating the magnetic screening constants of nuclei in NMR spectra.

The study of elementary processes in gases led to the development of a theory of the thermal decomposition of molecules which takes account of the non-equilibrium nature of the process. Problems arising in the application of resonance spectroscopy in chemistry were investigated, and a useful method was developed for calculating the transition probabilities of spin–lattice relaxation for paramagnetic ions and radicals in solids.

Wide-ranging investigations of the structure and reactivity of molecules are in progress at the Moscow State University.

O. A. Reutov's team is working on a number of theoretical problems in organic chemistry, with special reference to organometallic compounds, and is using many physicochemical research techniques: the stereochemistry and kinetics of substitution reactions at a saturated carbon atom, the mechanism of free-radical reactions in the liquid phase, the mechanism of the synthesis of organometallic compounds, and many others.

The laboratory of V. M. Tatevskii is investigating the detailed relationship between the spectra and the structures of hydrocarbons of various classes, and is looking into some problems in the theory of molecular structure and in the dynamics and statics of molecular systems.

A. I. Shatenshtein (Karpov Institute) made a systematic study of the kinetics and mechanism of hydrogen exchange in non-aqueous solvents (NH_3, HF, etc.). The assumption underlying this work is the acid–base character of hydrogen exchange in solutions, with the postulate that hydrocarbons can take part in protolytic reactions with strong bases and acids.

The X-ray laboratory of this Institute (G. S. Zhdanov) has also made substantial contributions to our knowledge of the structure of matter and to our understanding of the nature of the chemical bond by systematic crystal-chemical studies of important groups of chemical compounds.

CHEMICAL KINETICS. THEORY OF COMBUSTION AND EXPLOSION PROCESSES

During the past few decades it has become clear that chemical reactions as a rule are complicated processes consisting of many elementary acts and proceeding with the participation of various frequently unstable intermediates. It is not surprising, therefore, that the scope of chemical kinetics should have begun to increase even in the 1920's, when workers began to seek out the laws controlling complex reactions, and the general features responsible for the peculiar course of the majority of chemical reactions. The young Soviet physical chemistry took an active part in the creation of the new chemical kinetics, achieving a position of leadership in a number of aspects [15].

The acknowledged centre of this work in the Soviet Union was the Institute of Chemical Physics, with its affiliated establishment. However, the ideas and methods of modern chemical kinetics spread far and wide to other institutes, both academic and affiliated, and also to university laboratories.

The largest contribution to the development of this branch of science came from the school of N. N. Semenov, who created the modern theory of chain reactions by unifying an enormous fund of experimental data. These were exhaustively explained by considering the relationship between the rates of the various processes involved in the mechanism of chain reactions (generation, propagation, branching, and breaking).

The results obtained in 1926 by Semenov's coworkers Yu. B. Khariton and Z. F Val't in their work on the quenching of luminescence in a mixture of phosphorus vapour and oxygen gave additional impetus to the development of the theory of chain reactions. New phenomena were discovered which transcended the scope of existing views on the mechanism of chemical change: these were the strikingly sharp transitions of reactive mixtures from a state of almost complete inertness to a violent reaction, accompanied by ignition.

To explain this phenomena Semenov put forward the concept of branching chain reactions, which quickly gained wide acceptance. If the number of chain-branching events is greater than the number of chain-breaking events, the reaction rate steadily increases due to the continuous appearance of new chains until ignition of the mixture of reactants sets in ("chain explosion"). Semenov proposed the idea of chain breaking at the walls of the reactor. The theory of chain breaking in the volume of the reactor was developed independently by Semenov and Hinshelwood.

Semenov and his coworkers (Yu. N. Ryabinin, A. V. Zagulin, A. A. Koval'skii, and others) discovered in 1928–1930 the existence of sharp explosion limits in the oxidation of sulphur vapour, hydrogen, carbon monoxide, and hydrogen sulphide, thus increasing manyfold the number of known examples of ignition and demonstrating the generality of branching chain reactions.

Besides the chain explosion process, another very important and common type of ignition is known: the so-called thermal explosion. This type of explosion is due to the disruption of thermal equilibrium in the system, leading to a progressive increase in the reaction rate until explosion sets in.

In 1928, Semenov published a quantitative theory of thermal explosion, as well as the theory of chain ignition,

entitled "Theory of Combustion Processes". In that same year A. V. Zagulin confirmed Semenov's formula relating the explosion pressure to temperature for a number of systems (explosion of chlorine dioxide, explosion of hydrogen/chlorine mixtures, etc.), thus demonstrating the correctness of the thermal explosion theory. Semenov's monograph "Chain Reactions", published in 1934 in the Soviet Union and in 1935 in England, was based on the whole of this work. The book treats the massive array of existing experimental data on the kinetics of gas-phase reactions (and some liquid-phase reactions) from the point of view of the theory of chains [16,17].

In the years that followed, research on chemical chain reactions reached enormous proportions both in our country and abroad. Among the workers at the Institute of Chemical Physics, M. B. Neiman and his coworkers produced extensive evidence that the oxidation of hydrocarbons involves a degenerate branching mechanism. Neiman also examined in detail the two-stage ignition of organic compounds; the essential feature is that hydrocarbons, aldehydes, alcohols, etc., often burn in two stages: the cold flame stage and the hot flame stage. Mention must also be made of the work of A. A. Koval'skii and M. V. Polyakov on homogeneous–heterogeneous reactions and of Koval'skii's localised calorimetric method, which enabled him to show that many catalytic reactions begin at the catalyst surface but continue in the gas phase, where they follow a chain mechanism. A. B. Nalbandyan demonstrated that branching chain reactions can be controlled by controlling the rate of heterogeneous chain breaking; with N. M. Emanuel' and others he also investigated homogeneous catalysis in oxidations and many other reactions. The work on the influence of catalytically active additives on the initial stages of chain oxidations in the gas or the liquid phase has revealed new methods of controlling chemical processes under industrial conditions.

More recently, new and useful concepts have appeared in this work, such as the stimulation of slow branching chain oxidations, which make use of the self-accelerating and self-maintaining properties of branching chains.

In joint work by Nalbandyan and members of the Institute for the Chemical Industry, homogeneous catalysis was used to develop a new technological approach to the production of formaldehyde by the oxidation of natural gas.

Chain theory had been formulated on the basis of formal kinetics: it still needed additional chemical foundations. It was essential to establish the nature of the active centres in chain reactions and of the elementary processes which constitute the mechanism of a chain reaction, and to measure the rate constants of these processes. Only by the application of the newer physical methods could these problems be solved. For a number of years, V. N. Kondrat'ev and his coworkers have been developing various methods of this type which allow free atoms and radicals to be studied under the conditions existing during a chemical reaction (the spectroscopic resonance, absorption method, the catalytic recombination method). By these methods it was shown that OH radicals and H atoms are present in the combustion zone of hydrogen, carbon monoxide, and other gases at the appropriate concentrations for flame conditions. These active particles were shown to play an essential role in the development of the reaction. The rate constants of the elementary processes involving OH radicals and H atoms were measured, and in this way a full quantitative description of a branching chain reaction was obtained: the oxidation of hydrogen, a model gas-phase oxidation reaction. A monograph by A. B Nalbandyan and V. V. Voevodskii gives a detailed quantitative analysis of this reaction.

Voevodskii introduced the concept of the role of heterogeneous factors in the theory of the cracking of alkanes. This allowed him to explain a number of difficulties encountered by the generally accepted theory of Rice. As a result of his work on the structure and properties of free radicals, he discovered a new type of free-radical reaction and put forward a quantitative theory of the cracking of alkenes. In his studies of the recombination of atomic hydrogen on catalytically active surfaces, Voevodskii identified two régimes under which this process can take place: a high-temperature and a low-temperature régime; he also measured the recombination efficiency on metallic and oxide catalysts. These results, combined with a number of theoretical generalisations, led to the realisation that heterogeneous–catalytic reactions can occur by a mechanism analogous to the chain mechanism.

V. I. Gol'danskii made a detailed study of the general theory of tunnelling transitions in chemical reaction kinetics assuming both maxwellian and quantum energy distributions of the reacting molecules.

These, and many other investigations on a variety of reactions of different classes of compounds, have produced convincing evidence that, as suggested by Semenov in his book, chain reactions are of common occurrence.

Furthermore, even in 1939–1940 (in the year following the discovery of the fission of atomic nuclei by Hahn and Strassmann), N. N. Semenov's coworkers Yu. B. Khariton and Ya. B. Zel'dovich had published the first essentially correct theory of the uranium fission chain reaction.

The mass spectrograph was used for the first time ever to solve a problem in chemical kinetics in V. N. Kondrat'ev's laboratory. As a result of the work of V. L. Tal'roze, the mass spectrometric method is now widely used to study complex chemical mixtures and processes.

S. Z. Roginskii and his coworkers were among the first (together with A. I. Brodskii of the Institute of Physical Chemistry of the Academy of Sciences of the Ukrainian SSR) to use labelled atoms in chemical kinetics.

The use of polarography to investigate molecular intermediates in complex chain reactions has thrown light on the mechanism of many oxidations of organic compounds (V. Ya. Shtern and coworkers).

Nowadays, new methods are used to study the mechanism of electronic processes: the electron spin resonance and the nuclear magnetic resonance method, and gamma-resonance spectroscopy (V. V. Voevodskii, V. I. Gol'danskii, L. A. Blyumenfel'd, V. B. Kazanskii, and others).

The electron spin resonance method, discovered by the Soviet physicist E. K. Zavoiskii at Kazan', has become standard all over the world for the detection and structural investigation of free radicals formed as reaction intermediates or in other ways.

The Institute of Chemical Kinetics and Combustion of the Siberian Section of the Academy of Sciences of the USSR is extensively studying the kinetics and mechanism of chain and radiation-chemical reactions. The kinetics of chemical change in gaseous and condensed media are being investigated.

M. G. Gonikberg is making interesting studies in the field of chemical kinetics at the Institute of Organic Chemistry.

This work is mainly aimed at the effect of pressure on the rate constants of liquid-phase reactions. One of the most important results obtained is the conclusion, based on extensive experimental data, that the accelerating effect of pressure increases as the reaction becomes more sterically hindered. The reason for this is the partial overlapping of the van der Waals spheres of the atoms which screen the reaction centres in the activated complex: thus, additional compression becomes possible during the formation of the activated complex. These results were the basis of a proposed new method for studying the structure and properties of the transition state and the mechanism of organic reactions by kinetic studies at high pressure.

Beginning in the second half of the 1950's, many investigations have been devoted to the kinetics of polymerisation processes. Lack of space compels us to mention only a few of these.

The pioneer in this field was S. V. Lebedev, who studied the kinetics of the polymerisation of diene and allene hydrocarbons in the late 1920's.

S. S. Medvedev and his school (Kh. S. Bagdasaryan, A. D. Abkin, A. R. Gantmakher, and others) made an important contribution to studies of polymerisation processes. By treating polymerisation on the basis of chain reaction theory they put forward the fundamental view that polymerisation processes occur through free radicals. This led to an understanding of the chemical nature of the elementary stages of polymerisation and copolymerisation processes.

Much effort was devoted in Medvedev's work to the kinetics of anionic and cationic polymerisation, and also to coordination polymerisation of hydrocarbon and polar monomers.

Some important contributions to polymerisation kinetics were made by B. A. Dolgoplosk, whose scientific output was aimed primarily at the chemistry of synthetic rubber. In particular, much of his work was connected with the oxidation–reduction initiation of radical chain polymerisation, cross-linking, and degradation processes in polymers.

V. A. Kargin and his school are widely known for their fundamental studies of the structure and properties of polymers in a condensed phase and in solution. During the past 10 years Kargin, working in the Department of High-Molecular-Weight Compounds of the Chemistry Faculty of Moscow State University and at the Institute of Petrochemicals Synthesis, has carried out studies aimed at finding new methods of synthesis of macromolecules and at controlling polymerisation processes. This work was largely based on the methods of chemical kinetics.

In recent years, studies of the kinetics of polymerisation processes have attracted a great deal of attention at the Institute of Chemical Physics.

A detailed study of the kinetics and mechanism of the ionic polymerisation of monomers containing a heteroatom, made in the laboratory of N. S. Enikolopov, led to the discovery of a new elementary act (chain transfer with chain breaking).

At the same Institute, N. M. Chirkov has been studying since 1958 the polymerisation and copolymerisation processes of alkenes on complex catalysts. A. A. Berlin demonstrated, in his studies of the three-dimensional polymerisation of oligoacrylates, the essential role of the relative decrease in the chain breaking and chain growth constants with increasing viscosity of the medium during the course of the reaction.

Investigations of combustion and explosion processes are closely linked with work in the field of chemical kinetics. Scientists from the Academy of Sciences made important contributions to the development of this area: these include the thermal theory of flame propagation (developed by Ya. B. Zel'dovich, D. A. Frank-Kamenetskii, and N. N. Semenov, 1939–1948) and the theory of detonation developed by Zel'dovich in 1940. The thermal theory of combustion is the most systematic in taking account of the kinetics of the chemical reaction at the combustion front, of the heat transfer processes, and of diffusion. In some of the simplest examples the thermal theory gives a simple analytical expression for the rate of normal combustion, which is a great advance over alternative theories of flame propagation and allows the main rate-determining factors of normal combustion to be identified. The thermal theory is also applicable to combustion in condensed systems: it was shown experimentally in the case of explosives (by A. F. Belyaev of the Institute of Chemical Physics, 1938) that combustion is preceded by evaporation or sublimation of the combustible condensed material.

The first contributions to the theory of turbulent combustion came from the Soviet school of physical chemistry.

The theory of detonation formulated by Zel'dovich is based on the assumption of negligible heat conduction during flame propagation by detonation, which implies a definite structure of the detonation wave front. Zel'dovich specially stressed the role of the chemical (kinetic) factor in the phenomenon of detonating combustion. An important instance of detonation (spherical detonation) was discovered by S. M. Kogarko, who also noted the broadening of the detonation limits in wide-bore tubes and made numerous contributions to safety techniques. Special combustion régimes were discovered and investigated by K. I. Shchelkin and his coworkers.

Comprehensive studies of the main characteristics of explosion and of explosives were published by V. K. Bobolev, P. F. Pokhil, A. Ya. Apin, F. I. Dubovitskii, and others.

At the same Institute, A. S. Sokolik and A. N. Voinov (1936) proposed and exhaustively investigated a new method of ignition of the fuel mixture in internal combustion engines: mixing-chamber flame ignition. This method offers a lower specific fuel consumption and considerable economy. At present, the Institute (L. A. Gussak) in cooperation with workers in industry has developed a new type of automobile mixing-chamber engine. The results of this work are being exploited in the motor-car industry of the country.

CATALYSIS

In the field of catalysis, Soviet science can claim important and universally recognised achievements.

Studies in catalysis developed in parallel with studies in other ancillary areas (chemical kinetics, thermodynamics, adsorption, solid-state theory).

At present, catalytic reactions form the basis of most modern industrial chemical and petrochemical processes, in particular large tonnage processes such as cracking and reforming, and the preparation of many products and intermediates of heavy organic synthesis by oxidation, dehydrogenation, dehydration, isomerisation, alkylation, dealkylation, etc. Studies of the reactions of hydrocarbons contained in natural gas or formed during petroleum refining are of great importance in present-day chemistry.

These investigations have given rise, during the last few decades, to a new branch of the chemical industry—petroleum chemistry, which is producing many hundreds of valuable products second to none in their practical importance.

The extensive development in a short time of this new branch of the chemical industry was made possible first and foremost by the vast scientific effort of the Soviet school of organic chemists working on catalysis under the direction of N. D. Zelinskii. The work of this school was wholly aimed at the catalytic conversions of hydrocarbons: the broad outlines of this work were very clearly described by Zelinskii in his paper read before the session of the Academy of Sciences in 1936, entitled "Contact Phenomena and Changes in the Chemical Nature of Hydrocarbons" [18]. Zelinskii's school included A. A. Balandin, B. A. Kazanskii, N. I. Shuikin, and later A. F. Plate, A. M. Rubinshtein, L. Kh. Freidlin, Kh. M. Minachev, R. Ya. Levina, M. B. Turova-Polyak, S. R. Sergienko, Ya. T. Eidus, and many others. The work of this school (mostly associated with the Zelinskii Institute of Organic Chemistry and Moscow State University) was largely devoted to the study of organic reactions. In this review we shall consider only the physicochemical aspects of this work.

One of Zelinskii's closest collaborators, Balandin, proposed and extensively developed the multiplet theory of catalysis, which to a considerable extent set the pattern of Soviet work in the field of organic catalysis. This theory (whose basic premises were published as long ago as 1929) [19] combines modern views on the structure of matter with the theory of the structure of organic compounds, and can satisfactorily explain the catalytic transformations of organic compounds. Balandin showed that the elementary catalytic act is possible only for some definite ratios of the interatomic distances in the reactant molecules and in the crystal lattice of the catalyst (structural correspondence principle). He also explained the role of factors such as the energy of the bonds which are formed and broken during the reaction, the adsorption potentials, and the heats of reaction (energy correspondence principle).

These principles enable us to take account of the specific features of a catalytic reaction and of the catalysts needed to carry it out, and offer the possibility of predicting the behaviour of a molecule on a catalyst surface.

Besides this work, Balandin and his coworkers also made substantial contributions to the study of the kinetics of heterogeneous catalytic reactions.

Among other activities at the Institute of Organic Chemistry on the physicochemical aspects of heterogeneous catalysis, we must mention first of all the work of A. M. Rubinshtein and his coworkers on the topochemistry of catalysts, on the influence of phase composition, degree of dispersion, and crystal lattice distortions on the catalytic properties and on the texture of catalysts, the detailed investigations of the origin of catalysts, and the work on developing methods of catalyst preparation, etc.

The work of Kh. M. Minachev and coworkers on the catalytic properties of rare-earth elements, and on the use of various types of synthetic zeolites as hydrocarbon isomerisation and alkylation catalysts, is also very important.

Another great theoretical achievement of Soviet scientists in the field of heterogeneous catalysis is the electronic theory. The pioneer of the emphasis on electronic aspects in Soviet physical and inorganic chemistry was L. V. Pisarzhevskii [20], to whom are credited the now familiar definition of oxidation as the loss of an electron, the earliest experiments on the effect of radiation on catalytic reactions, the suggestion that the electrons of the catalyst take part in the catalytic reaction, and the correlation of the electronic properties of solids with their catalytic properties [21].

The foundations of the electronic theory of catalysis were laid by S. Z. Roginskii. The theory states that electrons from the catalyst take part in oxidation–reduction reactions, and the catalytic activity is related to the electronic structure of the catalyst. It was an obvious development to proceed from the postulated link between the catalytic activity and the electronic structure of solids to a study of the semiconductor nature of catalysts. These developments led Roginskii (together with F. F. Vol'kenshtein) to the electronic theory of catalysis at semiconductors, and to the discovery (with O. V. Krylov) of new types of redox catalysts. The application of the electronic theory to the mild oxidation of hydrocarbons and to the ammonia synthesis has resulted in significant improvements in existing catalysts and in the possibility of further development in these important industries (Institute of Chemical Physics, Institute of Physical Chemistry).

The work of Roginskii and his collaborators (O. V. Krylov, L. Ya. Margolis, G. M. Zhabrova, and others) has established new rules relating the catalytic activity of solids to the position of their elements in the Periodic Table, and relating catalytic properties to semiconductor properties, to the peculiarities of the catalytic spectrum, and to the choice of catalyst.

Another important result associated with the name of Roginskii is his very recent proposal to carry out catalytic reactions in a chromatographic régime. In this method the catalytic conversion of the reactants in the reactor is combined with chromatographic separation of the products. Higher conversion efficiencies can be achieved than under normal conditions, and significantly lower reaction temperatures are possible. Furthermore, the desired product can be obtained in a higher state of purity. Subsequently, Roginskii and Yanovskii proposed a method for carrying out catalytic reactions in a pulsed chromatographic régime which allows catalysts to be assessed much faster on the laboratory and pilot-plant scale.

Another interesting aspect is the hypothesis put forward by N. N. Semenov, V. V. Voevodskii, and F. F. Vol'kenshtein that adsorbed free radicals have an important part to play in heterogeneous catalysis: the corollary is that catalytic reactions can proceed by a chain mechanism. Although it was subsequently shown that chain reactions are less common in catalysis than had originally been thought, the prediction was confirmed in a number of instances (compare the work of Ya. T. Eidus on the catalytically initiated hydropolymerisation of alkanes, Roginskii's work on the Fischer–Tropsch synthesis, etc.). However, the study of adsorbed free radicals has attracted a great deal of interest in recent years in connection with the extensive development of ESR work. In many instances it has been possible to examine in detail the structure and properties of adsorbed free radicals, and to demonstrate their key role in adsorption, catalysis, and radiation catalysis processes (V. B. Kazanskii).

Studies in the field of catalysis are developing successfully at the newly created Institute of Catalysis of the Siberian Section of the Academy of Sciences of the USSR, led by G. K. Boreskov.

Boreskov was responsible for fundamental investigations on the theory of catalysis and on the scientific foundations

of the practical application of catalytic reactions. He introduced the concept of specific catalytic activity and showed that this quantity is approximately constant for most catalysts. Using tracer techniques, he developed methods for measuring the energy of the bond between the reactants and the catalyst, and demonstrated the importance of this parameter in the prediction of catalytic activity, he published a number of major investigations of the kinetics of catalytic reactions, and he gave a general formulation of the importance of interactions between the reaction mixture and the catalyst.

The Institute has formulated the principles which control the preparation of catalysts with an optimum pore structure: as a result, a new catalyst for the production of sulphuric acid giving a twofold increase in reaction rate has been developed.

Studies of model reactions and of the optimisation of catalytic processes, aimed at shortening the time between laboratory investigations of catalytic reactions and industrial exploitation, claim a significant part of the work of the Institute.

M.I.Temkin (Karpov Institute) put forward the theory of reaction kinetics at inhomogeneous surfaces. He proposed a logarithmic adsorption isotherm (the Temkin isotherm) which is widely used all over the world in work on chemisorption, heterogeneous catalysis, and electrochemical kinetics. By using this isotherm, Temkin was able to derive theoretically valid kinetic equations for a number of industrial catalytic processes. The first example of the fruitful application of these ideas was the development of a theory for one of the most important processes of chemical technology—the synthesis of ammonia. Temkin also established the kinetics and the mechanism of other important processes, such as the conversion of carbon monoxide, the gasification of coal, isotope exchange, the oxidation of ammonia and ethylene, the hydration of acetylene, and the hydration of ethylene.

The work of Temkin on the kinetics of catalytic processes is being widely applied in the design of catalytic plant and in the optimisation of processes with the help of electronic computers. The flow-circulation method, which offers a number of advantages for experimental studies of the kinetics of heterogeneous catalytic reactions, was suggested by Temkin. His contribution to the development of the general foundations of the kinetics of multistage chemical reactions was also a major one.

Mention must also be made of the large effort at the Institute of Petrochemical Synthesis on thermocatalytic methods for refining petroleum and petroleum products (K.P.Lavrovskii) and on the catalytic production from petroleum hydrocarbons of higher fatty alcohols suitable for the preparation of wetting agents (A.N.Bashkirov and V.V.Kamzolkin).

In recent years the Institute of Physical Chemistry (P.A.Rebinder and E.D.Shchukin) has worked on the principles underlying the control of the mechanical stability of catalysts by applying the concepts of physicochemical mechanics. In particular, they were able to increase the strength of the bismuth–molybdenum catalyst used for the oxidative dehydrogenation of propene and butene.

During the period of Soviet rule, a large number of catalytic investigations was carried out at Moscow State University. In the mid-1920's E.I.Shpital'skii (followed by N.N.Petin and N.I.Kobozev) developed and established experimentally the theory of intermediate compounds in homogeneous catalysis. In 1939 Kobozev proposed the theory of active ensembles. The theory of the kinetics of reactions under flow conditions was developed by the work of A.V.Frost and G.M.Panchenkov. Frost and Panchenkov, with K.V.Topchieva, successfully investigated catalysis on alumina–silicas.

We cannot ignore the contribution of the Institute of Physical Chemistry of the Academy of Sciences of the Ukrainian SSR (A.I.Brodskii and V.A.Roiter) to studies of the mechanism of catalytic reactions by the tracer atom method, or that of the Kazakh University (D.V.Sokol'skii) to the development of continuous catalytic hydrogenation of vegetable fats at low temperatures.

Sokol'skii developed new methods of investigation and control for hydrogenation catalysts, and in particular he discovered an interesting new phenomenon: the sharp decrease in electrical conductivity of a catalyst moistened with solvent upon removing the adsorbed hydrogen.

All these researches, together with some others in the field of heterogeneous catalysis, provided a wealth of information on the kinetics of heterogeneous reactions and on methods for investigating these reactions, on the theory of topochemical processes, and on the statistics of non-uniform surfaces. Lastly, the calculations needed in industrial processes involving heterogeneous catalysis were greatly assisted by the original and intensive development of the macroscopic kinetics of heterogeneous processes in the USSR, including diffusion kinetics, physicochemical hydromechanics, the calculation of thermal régimes, and the theory of reactions in a fluidised bed (V.G.Levich, O.M.Todes, D.A.Frank-Kamenetskii).

The work of Levich was a fundamental contribution to this field of research: he even proposed the term "physicochemical hydrodynamics" for the branch of science which deals with the multiplicity of problems presented by the effect of the motion of liquids and gases on chemical reactions and the influence of physicochemical factors on the motion of liquids. Levich and his coworkers developed a theory of convective diffusion and heat transfer in turbulent liquid flow, a theory of the elementary act in liquid extraction and gas scrubbing, and methods of solving mass- and heat-transfer problems in a static or fluidised granular bed. The pioneering work on diffusion kinetics in the USSR was done by Frank-Kamenetskii, but Yu.S.Elovich and O.M.Todes also made contributions in this area.

M.F.Nagiev, Yu.G.Mamedaliev, and S.D.Mekhtiev (Academy of Sciences of the Azerbaidzhan SSR) investigated the kinetics of industrial systems, mainly with a view to developing improved methods of petroleum refining.

The volume of work on homogeneous catalytic reaction in our country is also very considerable, but relatively little research has been aimed specifically at the mechanism of homogeneous catalysis.

Thus, the Institute of Chemical Physics has developed, from its studies of the kinetics and mechanism of slow, liquid-phase alkene oxidation reactions, a method for the production of acetic acid, ethyl methyl ketone, and ethyl acetate by the oxidation of compressed butane, and also a promising method of preparation of alkene oxides by the simultaneous oxidation of alkenes and other organic compounds in the liquid phase.

E.A.Shilov (Academy of Sciences of the Ukrainian SSR) has made valuable contributions to the study of homogeneous catalytic reactions.

The problem of homogeneous catalytic synthetic reactions with organometallic complex catalysts is of intrinsic interest. These catalysts are widely used in the chemistry of high-molecular-weight compounds. We shall mention only the work at the Institute of Organoelemental Compounds, which demonstrated in principle the possibility of the fixation of atmospheric nitrogen by means of compounds of this type (M. E. Vol'pin), and similar work at the outstation of the Institute of Chemical Physics (E. A. Shilov).

ELECTROCHEMISTRY

The earliest electrochemical work in our country is associated with the names of M. V. Lomonosov, V. V. Petrov, F. F. Grotthus, B. S. Yakobi, E. Kh. Lents, A. S. Savel'ev, A. P. Sokolov, and others.

With the Soviet era, broad and comprehensive development began; this allowed Soviet electrochemistry to occupy one of the leading positions in world science.

The interest in electrochemical problems, and particularly in electrochemical kinetics, grew even stronger in the following years.

The work done in our country (initially, at the Academy of Sciences) on the theory of the electrical double layer, on the influence of adsorption on the kinetics of electrode processes, on the role of diffusion factors, on the theory of hydrogen overpotential, on the quantum-mechanical theory of electrode processes, on the electrochemical theory of corrosion and passivity, on the mechanism of metal electrodeposition, and on fused salt electrochemistry all played a major role in developing the theoretical foundations and the experimental methods of modern electrochemistry [22,23].

The establishments engaged on the solution of these problems include: the Institute of Electrochemistry of the Academy of Sciences of the USSR, the Institute of Physical Chemistry of the Academy of Sciences of the USSR, the Institute of Electrochemistry of the Urals Section of the Academy of Sciences of the USSR, the Institute of Physical and Organic Chemistry of the Academy of Sciences of the USSR (Kazan'), the Institute of Chemistry of the Academy of Sciences of the Lithuanian SSR, the Institutes of the Academy of Sciences of the Ukrainian SSR, the Karpov Physicochemical Institute, and many universities.

The most important electrochemical school in our country is the school of A. N. Frumkin, whose activities were associated at various times with the Karpov Physicochemical Institute, the Institute of Physical Chemistry of the Academy of Sciences of the USSR, and since 1958 with the Institute of Electrochemistry of the Academy of Sciences of the USSR [24].

Frumkin and his coworkers (B. N. Kabanov, R. Kh. Burshtein, N. A. Bakh, Ya. M. Kolotyrkin, M. A. Proskurnin, O. A. Esin, B. V. Ershler, V. I. Veselovskii, P. D. Lukovtsev, P. I. Dolin, Z. A. Iofa, V. S. Bagotskii, B. B. Damaskin, and others) started from the assumption that a close link exists between the mechanism of an electrochemical process on the one hand and the structure and electrochemical properties of metal surfaces and of the metal–solution interface on the other hand. Their theoretical and experimental work, for which new methods had to be developed, has added considerable depth to our understanding of the structure of these interfaces, and in particular they have allowed us for the first time to identify the correct value of the double layer capacitance and to correlate adsorption from solutions with the appearance of potential jumps at the electrode. They provided a solution for the so-called Volta problem (which had occupied electrochemists since the beginning of the previous century) regarding the relationship between the electromotive force of a galvanic cell and the contact potentials which appear when the metals are placed in contact in a vacuum.

The zero-charge potential was introduced into electrochemistry as a factor defining the adsorption properties and many electrochemical properties of metals, and various methods of measuring this potential were developed.

The work of the Soviet school of electrochemists has made possible some striking advances in our theoretical understanding of the structure of the electrical double layer. A paper by Frumkin published in 1919 gave a thermodynamic derivation and a test of the basic equation of electrocapillarity, by means of which the charge on the electrode and the adsorption of various components from the solution on the electrode surface can be calculated from measurements of surface tension. The electrocapillarity method was used to investigate the electrical double layer in non-aqueous solutions. Subsequently, electrocapillarity measurements and measurements of electrode capacity were widely used by Soviet electrochemists in studies of the electrical double layer on many liquid and solid metals.

The work of O. A. Esin, B. V. Ershler, and V. G. Levich contributed significantly to the development of double layer theory.

This school established the mechanism and the kinetics of some important electrode processes, such as hydrogen evolution, the evolution and the reduction of oxygen, and the reduction of chlorine in a number of anions and organic compounds; they showed that in many instances the rate of the overall process is determined by the rate of the electron transfer stage (from the metal surface to the reacting species).

Ershler and P. I. Dolin showed that the rates of fast electrochemical reactions can be measured by using alternating current: this was the first step towards the measurement of electrode processes under non-stationary conditions.

All this work played a major part in the creation of a new branch of chemical science—electrochemical kinetics—and provided a bridge linking electrochemistry to colloid chemistry, adsorption theory, catalysis theory, etc.

More recently, Levich developed the first physically sound theory of diffusion in moving liquids and of matter transport to the electrode surface, which enables the maximal current to be calculated under given conditions of mixing. On the basis of this theory, he proposed the rotating disc electrode as a tool for studying diffusion phenomena in electrochemical processes: this electrode is now widely used both in this country and abroad. Workers at the Institute of Electrochemistry of the Academy of Sciences and in the Department of Electrochemistry of Moscow State University developed a theory of the structure of the double layer on platinum group metals (A. N. Frumkin, N. A. Balashova, and O. A. Petrii), discovered a new form of discharge (which they termed barrierless discharge), and published the first experimental determination of an important constant—the adsorption energy of a hydrogen atom on a mercury electrode surface (L. I. Krishtalik).

Among the theoretical work on the electrochemistry of organic compounds we must mention also an extensive

series of investigations of electrolytic reduction reactions involving the participation of adsorbed organic molecules, carried out at the Institute of Electrochemistry of the Academy of Sciences (G. A. Tedoradze) and at the Institute of Organic Chemistry of the Academy of Sciences (S.G. Mairanovskii).

Theoretical electrochemistry provides the foundations for the solution of a number of problems of major importance to the national economy. A problem of the utmost importance is the realisation of fuel cells—devices in which the chemical energy of the fuel can be directly converted into electrical energy. Fuel cells are already used in astronautics: in the relatively near future we can expect to see them used in transport and in a number of specialised applications, and later perhaps in power generation. The pioneering work in this field in the Soviet Union was done by O.K. Davtyan of the Energetics Institute of the Academy of Sciences of the USSR. In recent years success was reported in studying the mechanism of processes taking place in fuel cells. Model systems have been analysed and a theory of porous electrodes was developed to allow their surface to be used efficiently (Institute of Electrochemistry of the Academy of Sciences, Karpov Institute, Odessa State University, Dnepropetrovsk Institute of Chemical Technology). The most satisfactory method (disc electrode with a ring) was developed for studying the electrolytic reduction of oxygen at the positive electrode of a fuel cell (Institute of Electrochemistry and Moscow State University). Progress is being made on the mechanism of electrolytic oxidation of organic compounds likely to be used as electrochemical fuels (Institute of Electrochemistry). A theory of the electronic conduction of solid electrolytes in equilibrium with a gas phase has been developed to describe the operation of fuel cells based on these electrolytes (Institute of Electrochemistry of the Urals Section of the Academy of Sciences of the USSR).

A great deal of interest attaches to the recently developed electrochemical transducers (memory cells, integrators, pressure and acceleration detectors, etc.) which effectively complement semiconductor devices in the low-frequency and the low-signal-power field. These devices are particularly suited for use in learning and self-organising systems. Various transducers have already been developed, including electrochemical transmitters capable of detecting mechanical vibrations with a sensitivity often orders of magnitude greater than that of existing systems, notwithstanding their much smaller size (P. D. Lukovtsev, Institute of Electrochemistry, and N.S. Lidorenko, All-Union Scientific Research Institute for Fuel Utilisation).

Research is in progress on advanced electrochemical methods of metal treatment: electrochemical machining, based on intensive anodic dissolution at high current densities, and electrochemical polishing. These methods are often more effective, faster, and cheaper than mechanical methods, particularly for very hard and refractory alloys {TsNIMS [Central Research Institute for Mechanical Construction? (Ed. of Translation)], Institute of Electrochemistry}. The mechanism of these processes has been investigated, and the role of kinetic and ohmic factors identified. The collaboration between industry and the Academy of Sciences produced excellent results in this instance.

Among the contributions of the institutes of the Academy of Sciences, mention must be made of the work of the Institute of Organic and Physical Chemistry on electrodeposition, anodic dissolution, and electropolishing of metals (G.S. Vozdvizhenskii) and of the work of the Institute of Physical Chemistry on the electrodeposition of metals.

The work of K.M. Gorbunova and P.D. Dankov on the mechanism of crystal growth and on nucleation processes during electrolysis was a pioneering effort. It was followed by numerous important investigations of the electrodeposition of alloys at the Institute of Physical Chemistry (K.M. Gorbunova and Yu. M. Polukarov), of the growth mechanism of dendrites during electrolysis, of the influence of adsorbed foreign materials on the electrodeposition of metals, and of the effect of temperature on the behaviour of electrodes with a slow exchange step (A.T. Vagramyan and coworkers).

At the Mendeleev Institute of Chemical Technology, the kinetics of electrode processes has been investigated over a wide range of temperatures (S.V. Gorbachev), the mechanism of electrochemical dimerisation has been examined in connection with the problem of electrolytic synthesis (M. Ya. Fioshin), new methods of electroplating have been developed, and their mechanism has been investigated (N.T. Kudryavtsev). More recently, the mode of action of levelling agents has been examined (S.S. Kruglikov).

Studies of electrochemical kinetics in fused salts are of great importance both from the practical and the theoretical point of view. The earliest work of this type was reported by S. V. Karpachev in the 1930's. O. A. Esin made systematic polarisation measurements in fused slags, M. V. Smirnov and S.I. Rempel' in halides. These researches showed that although the majority of chemical reactions are diffusion-controlled at high temperatures, slow discharge processes are also observed in some instances (for example, hydrogen evolution.

All the main data on the structure of the electrical double layer at the boundary between fused metals and electrolytes have also been established in our country (S.V. Karpachev, A.T. Stromberg, V.A. Kuznetsov, E.A. Ukshe).

Yu.K. Delimarskii and other Ukrainian electrochemists developed the polarography of fused salts and studied the specific features of diffusion-controlled kinetics in the same media. One important result of this work was to show that solid electrodes can be used for polarography, and also the application of polarography to the study of complex formation in melts.

Mention must be made also of the recently developed studies of the kinetics of electrodeposition from fused salts (K.M. Gorbunova of the Institute of Physical Chemistry, M.V. Smirnov of the Institute of Electrochemistry of the Urals Section of the Academy of Sciences, and others). In this work, which was primarily aimed at the electrolytic production of refractory metals, phenomena such as the dependence of the number of crystallisation centres upon the electrolysis parameters were first discovered and investigated in fused salts.

The study of corrosion processes is an aspect of electrochemistry of great practical importance. The basic studies of corrosion processes and of corrosion protection were started by V.A. Kistyakovskii at the Academy of Sciences; the work of N.A. Izgaryshev also contributed to the early development of corrosion science. The study of corrosion processes began to develop very rapidly as a result of the work of G.V. Akimov and his students (N.D. Tomashov, I.L. Rozenfel'd), who developed the theory of multi-electrode systems to predict the corrosion behaviour of each

constituent of a complex system, to investigate structural corrosion and the role of local cells, to explain the mechanism of corrosion in the presence of atmospheric oxygen, and to study the nature and protective properties of oxide films[24].

A.N. Frumkin, Yu.M. Kolotyrkin, Ya.V. Durdin, and others established the mechanism of corrosion of uniform metal surfaces, thus creating a bridge between corrosion theory and electrochemical kinetics.

As well as solving the above theoretical corrosion problems, the corrosion scientists of the Academy of Sciences contributed to the solution of many practical problems in the fields of atomic energy, aircraft and rocket design, shipbuilding, and the chemical and petroleum industry.

At the Institute of Physical Chemistry, the main centre of corrosion studies of the Academy of Sciences, many important investigations were carried out. Various coatings were tested, some of which have been adopted for the national network of pipelines, including the "Druzhba" oil pipeline. Electrochemical protection methods for underground and submarine equipment were developed and widely exploited. New gas pipelines were provided with protective devices. A new method of protection against stray currents, relying on the simultaneous use of protectors and germanium rectifiers, has been proposed and is being introduced into industrial practice. A new class of compounds has been synthesised (salts of amines and nitrobenzoic acids) with strongly corrosion-inhibiting properties towards both ferrous and non-ferrous metals. New methods of protection of components and complicated structures by volatile and contact inhibitors have been developed and handed over to industry. The scientific principle of corrosion resistant alloys based on titanium and zirconium and offering high-grade mechanical and anticorrosion properties have been proposed. The methods of protection of building structures developed at the Institute have been adopted and specified by the Department of State Construction.

A method of deposition of thin ferromagnetic films by chemical nickel plating has been worked out. The films produced in this way show a low coercive force and can be used for magnetic screening of complicated radio components. The basic features of the electrodeposition of alloys of refractory metals (titanium, tungsten, etc.) have been studied. The formulations and operating conditions proposed for electropolishing have been widely used in the finishing of heat-resistant alloys for aviation engines.

Valuable work in the field of protection against metal corrosion has been done also at the Karpov Institute. Thus, Kolotyrkin investigated the corrosion and electrochemical behaviour of a series of metals and alloys in aqueous media and pointed out the rules controlling their passivation. This work strengthened and stimulated the adsorption theory of passivity, whose foundations had been laid by B.V. Ershler and B.N. Kabanov.

Kolotyrkin's work on the mechanism of passivator action, which led to the formulation of the basic theory of the mode of action of oxidation and cathodic inhibitors, was applied to the solution of many problems of the corrosion stability of metals and alloys at high temperatures and pressure, and also in the presence of energetic radiations. At the present time Kolotyrkin is engaged on the practical exploitation of anodic protection of metals against corrosion.

Kolotyrkin also formulated the basic theory of pitting corrosion, which was confirmed by systematic studies of the dissolution of zirconium, iron, and iron alloys.

Recent work at the Department of Electrochemistry of Moscow State University (V.N. Korshunov) and at the Karpov Institute (Ya.M. Kolotyrkin, T.M. Florianovich) has shown that metal corrosion in aqueous solutions may occur not only by an electrochemical but also by a chemical mechanism, that is, without distinguishable anodic and cathodic processes. L.I. Antropov (Kiev Polytechnic Institute) has carried out a major series of investigations on the effect of the point of zero charge on the corrosion behaviour of metals and on the adsorption of corrosion inhibitors.

LIQUIDS. SOLUTIONS

Soviet scientists have always occupied a leading position in the study of solutions. Those who were already highly respected workers at the time of the October Revolution, such as M.S. Vrevskii, I.A. Kablukov, V.A. Kistyakovskii, and D.P. Konovalov, later gathered around themselves younger talent and thus laid the foundations of a number of Soviet schools of physical chemists, some of whose names are now widely known.

We shall mention first of all the work which had the greatest influence on the overall problem. Ya.I. Frenkel' was the first to attempt a systematic phenomenological theory of the liquid state on the basis of the nature of the motion of molecules in liquids. For a given molecule, this motion is determined by the molecular field generated by its surroundings and by its own kinetic energy, it follows a discontinuous path, and is characterised by a mean lifetime in temporary equilibrium positions. The basic ideas evolved by Frenkel' provided the foundations for the work of many authors.

N.N. Bogolyubov developed a general approach to the calculation of the thermodynamic properties of one-component and multicomponent systems from studies of the molecular distribution functions of groups of particles. A statistically consistent method of calculating the thermodynamic properties of strong electrolyte solutions, based on the correlation function and variational derivative method, is now widely used by Soviet and foreign theoreticians to solve stochastic problems. The method has been developed in papers by I.Z. Fisher, who examined in particular its application to problems of liquid structure. V.I. Danilov and his school carried out some fundamental work on an experimental method for determining the structure of pure liquids and solutions.

The most interesting and general result obtained by this method was to demonstrate the presence in liquids of short-range order as found in crystals. In a series of theoretical and experimental investigations, M.I. Shakhparonov developed a method of studying the microstructure of liquids and solutions by radiofrequency, optical, and acoustic measurements. His main result was to show that the positions of molecules fluctuate, causing the local physical properties of liquids to differ from their macroscopic values. A.V. Storonkin established by a formal thermodynamic analysis the possible types of phase equilibrium curves in heterogeneous multicomponent systems, including the vapour phase.

A series of papers by I.R. Krichevskii on phase transformations in solutions of non-electrolytes under high pressure made an important contribution to a correct understanding of the relationship between particle–particle interactions and the thermodynamic properties.

Many important results were obtained in the field of electrolyte solution theory. V.K.Semenchenko first put forward the view that ion pair formation affects the behaviour of electrolyte solutions, and gave a physical model of the phenomenon and an approximate mathematical treatment. A similar hypothesis was independently put forward, somewhat later, by Bjerrum, but improvements to his mathematical treatment are still being proposed. S.V.Tyablik and V.V.Tolmachev showed, by Bogolyubov's correlation function method, that the Semenchenko–Bjerrum correction for ionic association is obtained automatically when the free energy of an electrolyte solution is calculated by a systematic statistical approach. V.G. Levich and V.A.Kir'yanov used Bogolyubov's method to derive the most general expression for the free energy of an electrolyte solution, in which the Coulombic potential at small distances is replaced by an arbitrary potential. The expression obtained can, according to the form of the potential chosen, describe purely Coulombic interaction or alternatively it can describe the Brønsted–Guggenheim "specific" interaction of ions with a non-Coulombic short-range interaction. Yu.M.Kossler discussed the physical principles underlying the non-Coulombic components of the potential. G.I.Mikulin proposed a numerical method of solving the Poisson–Boltzmann equation in which account is taken of the variation of the dielectric constant with distance from the centre of the ion. This method is strictly accurate, unlike some even more recent work by various foreign authors.

The thermodynamics of ion solvation has made significant progress through the efforts of a number of scientists. V.A.Pleskov put forward the idea that the solvation energies in different solvents must tend towards a common value as the radius of the ion increases. Hence, by choosing an electrode reversible to the ion for which these energies are practically equal it is possible to compare the chemical solvation energies of various ions (which are not experimentally measurable). His researches with a series of non-aqueous solvents showed that caesium or rubidium can be used as the electrode. A.F.Kapustinskii had some interesting views on the difference between the true radii of ions in aqueous solutions and their crystal-chemical radii. His corrections (±0.28 Å) were applied by N.A.Izmailov to resolve the total hydration energy into its components for ions. Unlike others who made similar attempts, Izmailov suggested extrapolating the sums and differences of the solvation energies of a given ion with a number of other ions of increasing radius to infinite ionic radius. This method is independent of any hypothesis on the structure of solutions. K.B.Yatsimirskii made valuable studies of specific aspects of the energy of formation of ions, of proton affinity, and of ion hydration.

Problems of the structure of electrolyte solutions are attracting a great deal of attention at the moment in the USSR. This work is largely associated with the name of Kapustinskii, who used Fowler and Bernal's tetrahedral model of the water structure in his study of the heat capacity of ions in aqueous solutions and showed that the structure of the solvent must be considered when discussing the thermal motion of ions. O.Ya Samoilov perfected the tetrahedral model by allowing for partial filling of the holes in the ice-like skeleton by water molecules set free by its thermal motion and, by using the ideas of Frenkel', he constructed a consistent model of the structure of water solutions and of the hydration of ions. His concept of positive and negative hydration proved very fruitful in allowing structural and thermodynamic approaches to be unified (for example, the distribution of an electrolyte between water and an immiscible solvent). A series of contributions by K P.Mishchenko and coworkers used the thermodynamic relative partial molal properties to characterise the structure of electrolyte solutions. The specific intersection of composition–property isotherms led Mishchenko to introduce the concept of a real solvation boundary, which reflects the structural and energetic aspects of the process.

A large group of papers by V.A.Plotnikov and his students, who studied the physicochemical and electrochemical properties of a wide range of non-aqueous solutions, forms a slightly isolated topic. Their main contribution was to demonstrate the relationship between these properties and complex formation, and a vast fund of factual data on the cathodic deposition of metals.

Studies of solutions under extreme conditions (temperatures up to 400°C) were undertaken on a broad scale for the first time in the USSR by I.S.Galinker. These studies produced interesting experimental results, relevant to an understanding of the structural properties of water.

The glass electrode, whose theory was developed in detail by B.P.Nikol'skii, plays an important part in measurements of the electrode potentials of hydrogen and alkali metal ions, which are needed in thermodynamic calculations Techniques for the preparation of glass electrodes suited to different types of measurement were also developed in Nikol'skii's laboratory.

The theory of acids and based was considerably developed by the work of A.I Shatenshtein, N A Izmailov, and M.I. Usanovich. Shatenshtein and Usanovich broadened and generalised the concept of acids and bases so as to include acid–base interactions not involving ionisation. This allowed them to include reactions not considered in Brønsted's previous scheme, to introduce the concept of acid-like aprotic substances and to show that the acidic (or basic) properties of a substance depend to a considerable extent on the protonophilic (or acidic) properties of its reaction partner. Izmailov discovered and investigated the influence of solvent on the relative strength of acids and bases, which results from interactions with the solvent (solvation), and originated unified studies of acidity.

RADIATION CHEMISTRY

Radiation chemistry became a discipline in its own right during the last two decades, coinciding with the practical application of atomic energy.

Our scientists have contributed very significantly to the creation of the theoretical foundations of radiation chemistry by their work on ion–molecule reactions, energy transfer during radiolysis, the radiolysis of aqueous and of organic systems, the formation and transformations of free radicals and ions in irradiated solids, radiation-induced polymerisation in the solid phase, etc.[26-28]

It may now be claimed that radiation chemistry in the Soviet Union is on a level with world radiation chemistry.

The institutes of the Academy of Sciences (Institute of Chemical Physics, Institute of Electrochemistry, Institute of Physical Chemistry, Institute of Petrochemical Synthesis), the Karpov Institute, and the Chemistry Faculty of Moscow State University have all been involved in the development of radiation chemistry.

Studies of the radiolysis of inorganic and organic systems occupy an important place among Soviet researches in this field.

The work on radiation-chemical changes in solid and in liquid organic compounds was done mainly by N. A. Bakh, Kh. S. Bagdasar'yan, M. A. Proskurnin, N. Ya. Buben, L. S. Polak, and V. L. Tal'roze. These workers clarified the role of ions, free thermalised electrons, and free radicals in radiolysis processes in condensed media. The radiolysis products were identified and investigated, and many radiation-chemical changes in organic compounds were characterised quantitatively.

Much of the work on free radicals in condensed phases was done by the ESR method, whose development owes a great deal to Soviet workers. The method allows the detection, identification, and quantitative estimation of free radicals formed as intermediate radiolysis products. This work was done by N. A. Bakh, N. Ya. Buben, V. V. Voevodskii, L. S. Polak, S. Ya. Pshezhetskii, and others.

Studies of radiation-induced oxidation began in 1949 in the Soviet Union, mainly under the direction of Bakh. The first studies were aimed at the determination and identification of the oxidation products of liquid hydrocarbons of different structures. It was shown that the yield depends on the nature of the hydrocarbon and on the irradiation conditions, whereas the mechanism of the processes involved depends on the temperature.

The radiolysis of water and aqueous solutions is the most widely investigated topic in radiation chemistry, because of the extensive use of water in atomic technology and reactor design. The work of the Soviet scientists P. I. Dolin, V. I. Veselovskii, B. V. Ershler, M. A. Proskurnin, and others, in the period 1946–1955, led to the development of the free-radical mechanism of the radiolysis of water independently of foreign workers, who reached similar conclusions.

The sensitising effect of solid surfaces on radiation-chemical processes in liquid systems was discovered by the Soviet scientists L. V. Pisarzhevskii and V. I. Veselovskii. This work is now continuing at the Institute of Petrochemical Synthesis, at the Institute of Physical Chemistry of the Academy of Sciences of the Ukrainian SSR, and elsewhere; the effect of irradiation on catalytic processes in general is also being investigated (Karpov Physicochemical Institute, Institute of Physical Chemistry, and Institute of Chemical Physics of the Academy of Sciences of the USSR, etc.).

The first papers on the acceleration of topochemical processes by previous treatment by ionising radiation appeared in 1955–1956. In the following years a large number of investigations in this field, carried out under the direction of S. Z. Roginskii, G. M. Zhabrova, and V. V. Boldyreva, were reported.

Systematic studies of the radiation chemistry of polymers were pursued mainly at the Karpov Physicochemical Institute and at the Institute of Physical Chemistry of the Academy of Sciences of the USSR. Initially, this work was aimed at solving problems arising in the use of polymeric materials in the handling and application of radioactive materials. The main effort was directed towards the radiation-induced degradation of polymeric materials and changes in their physico-mechanical properties under the influence of radiation. However, the essential experimental facts about radiation-chemical changes in polymeric systems were established at an early stage and the first views on the nature of the processes involved were put forward.

Subsequently, the effort on various aspects of the radiation chemistry of polymers was extended by the numerous research institutions whose primary interest was to investigate the possible use of radiation-chemical processes for the controlled modification of polymeric materials, principally in the direction of radiation-induced vulcanisation.

V. A. Kargin and V. L. Karpov proposed the use of ionising radiations for vulcanising polyethylene, which could not be vulcanised in any other way. S. S. Medvedev and A. D. Abkin made a detailed study of the radiation polymerisation of various monomers in the liquid and the gas phase. V. I. Gol'danskii's method of cross-linking different monomers by the localised action of thermal neutrons has proved very valuable.

The radiation method offers very wide scope for including polymerisation reactions in the solid phase. A very promising technique has been developed at the Institute of Electrochemistry of the Academy of Sciences of the USSR and at the Institute of Physical Chemistry of the Academy of Sciences of the USSR for gas-phase radiation-induced graft copolymerisation, which allows combined inorganic–organic materials to be prepared as well as sheathed filaments and two-layer films combining the properties of the initial (inner) layer with those of the outer layer formed by the grafted polymer.

A method of improving wood cellulose by impregnating it with various monomers and polymerising them with gamma radiation, proposed in 1958 in the Soviet Union, has achieved great technological importance.

A number of radiation-chemical processes are now fully developed and have reached the stage of pilot-plant production: they include the cross-linking of thermally stabilised polyethylene, the telomerisation of ethylene, the oxidation of paraffins, the sulphochlorination of Synthin [a fuel (Ed. of Translation)], and the production of special-purpose rubbers.

PHYSICAL CHEMISTRY OF SURFACE PHENOMENA. ADSORPTION. CHROMATOGRAPHY

The variation of the properties of colloidal systems with the degree of subdivision of the disperse phase and the stability of these systems were investigated by A. V. Dumanskii (Institute of General and Inorganic Chemistry of the Academy of Sciences of the Ukrainian SSR) and by N. P. Peskov. Their conclusions have been widely applied in Soviet soil science as well as in the control side of the food industry.

The rapid growth of the high-polymers industry (plastics, elastomers, viscose, synthetic fibres) has stimulated the development of research on lyophilic colloids, a term which was then applied to polymers in colloidal chemistry. The work of A. V. Dumanskii, S. M. Lipatov, V. A. Kargin, and B. A. Dogadkin[29] is noteworthy in this area. This topic subsequently merged into the developing field of polymer chemistry.

Research on the physical chemistry of surface phenomena is centred at the moment on the Institute of Physical Chemistry, the Karpov Institute, Moscow State University, and some associated institutes.

By 1935, a Disperse Systems Division had been set up at the Institute of Colloidal and Electrochemistry under the leadership of P. A. Rebinder. He and his coworkers (A. B. Taubman, V. I. Likhtman, E. D. Shchukin, and others) developed a number of aspects of modern colloid chemistry, and they also created a new interdisciplinary area of chemical science—the physicochemical mechanics of disperse structures, solids, and technical materials. The features and mechanisms of the formation and development of disperse structures, leading to the synthesis of fine-grained, strong, and durable solids and technical materials, were investigated, as well as the deformation and disintegration of solids of various compositions and degrees of dispersion (from fully dense and strong bodies to finely porous solids of varying and occasionally high porosity[30]).

This work led to many essentially new results of great scientific and economic importance. We note first of all the effect producing easy deformation of solids and decreased strength under the influence of an active medium or low amounts of adsorbed substances (the so-called Rebinder effect). The discovery of this effect led to the development of methods now used under industrial conditions for ultrafine grinding and to the softening solution method for raising the efficiency of drilling in hard rock. New high-efficiency lubricating coolants for the working and cutting of metals were proposed. Scientific foundations were developed for optimising the manufacture of precast concrete and reinforced concrete, and also sand concrete without coarse fillers.

Rebinder developed new physicochemical ideas on the three-dimensional structures arising with disperse and colloidal systems. He established the rheological characteristics of structures of various types, the rules governing their structural and mechanical properties, and methods of controlling these properties. The effect of the interfacial surface energy on the formation of disperse systems—whether involving dispersion or condensation (formation of new disperse phases)—was investigated theoretically and experimentally, including the conditions for spontaneous dispersion. The detailed study of the properties of soap-like surface-active agents (semicolloids of both the ionogenic and the non-ionogenic type) led to the scientific formulation of many valuable applications of surface-active materials in many areas of the national economy (detergents, wetting agents, flotation agents, stabilising and dispersing agents, de-emulsifiers, lubricating coolants, and lubricants, etc.).

Another new development begun in 1935 at the Institute for Colloidal and Electrochemistry under the direction of B. V. Deryagin was the study of surface phenomena with special emphasis on the action of surface forces close to the interface. The extensive investigations made by Deryagin and his coworkers played a fundamental part in the development of the science of surface forces and of their role in the kinetics of physicochemical processes in heterogeneous systems and in colloidal chemistry.

Having discovered and investigated one of the fundamental thermodynamic characteristics of thin layers—the disjoining pressure—Deryagin developed a quantitative theory of the stability of lyophobic colloids. The methods of calculation which he first developed for the repulsion forces arising from the overlapping of ionic atmospheres provided a basis for the currently accepted theory of the stability of lyophobic colloids.

The same laboratory developed a theory of the flotation of mineral particles whose conclusions have been applied practically. Allowance for ion diffusion led to refinements in the modern theory of electrokinetic phenomena, including electrophoresis. The chemical and morphological characteristics of individual soil particles were correlated with the behaviour of soils during application and removal of loads, slip, and filtration. From studies of the physical chemistry of thin water films, a theory was developed to explain the mechanism of migration of moisture and petroleum in porous media.

Deryagin made the first direct measurements of molecular attraction as a function of distance between different solids. His results were subsequently repeated by workers in England and in the Netherlands, and confirmed the modern theory of molecular forces.

Various methods worked out by Deryagin led to the conclusion that the surface of a lyophilic solid can modify the structure and properties of the adjacent layers of liquid to a depth of at least tens of molecular diameters. More recently, previously unknown properties of bulk liquids were discovered as a result of this work.

Researches in the field of aerosols have had far-reaching practical results; in particular, new methods of dispersion and precipitation of clouds and fog have been developed, and very efficient and economical condensation filters for the purification of air in mines have been designed.

At the Institute of Physical Chemistry, A. A. Trapeznikov developed new concepts and exploited methods of investigation and apparatus for the rheology of structured systems, and for studying the combined effects of deformation-resisting properties and relaxation in the pre-stationary stage; he also proposed generalised concepts of fluidity limits. His contribution included studies of the mechanical properties of monolayers and soap films formed by insoluble and by soluble surface-active materials.

A laboratory for colloid chemistry was set up by A. P. Rabinovich at the Karpov Institute in 1924. The relationship between ion adsorption processes and the stability of hydrophobic colloids was studied by electrochemical methods, and the important role of ion exchange at the surface of colloidal particles was recognised. Rabinovich was also responsible for the adsorption theory of development, which now forms the basis of photographic science.

Subsequent work in this laboratory, by V. A. Kargin and Z. Ya. Berestneva, demonstrated the important role of chemical phenomena in the behaviour of colloidal systems. It was found that practically all colloidal solutions contain significant amounts of stabilising electrolytes which react chemically with coagulants, and that dealing exclusively with the physical phenomena which take place during coagulation is too coarse an approximation. Chemical reactions between substances in the colloidal state were found to proceed in true solution by gradual dissolution of the particles.

More recently, the application of electron microscopy has enabled the mechanism of formation of colloidal particles to be identified. The first stage was shown to be the formation of large, usually spherical, amorphous particles which then recrystallise and break down into the very fine crystalline particles typical of colloidal solutions.

I. V. Petryanov-Sokolov of the Karpov Institute carried out comprehensive studies in the physical chemistry of aerosol systems. His work and that of his colleagues on the physicochemical properties of aerosols, extending over many years, proved to be a fundamental contribution to science. They developed quantitative methods for the

experimental study of the degree of dispersion of aerosols which are now widely applied, and which have led to the solution of a number of problems concerning the electrical properties of aerosols.

Petryanov-Sokolov made a detailed study of the stability of undischarged aerosols. A series of researches was devoted to the previously unrecognised problem of the behaviour of the disperse phase of an aerosol when the particles are deposited on the fibres of a filter. This work led to the development of novel, important, and widely used processes.

A. N. Fuks and N. N. Tunitskii did some important work at the Institute on the formation and coagulation of aerosols.

Ya. I. Kogan made some important contributions to the development of experimental techniques for studying aerosols, and of methods, devices, and apparatus for testing under industrial conditions the efficiency of a wide range of aerosol filters.

From their studies of the optical properties of aerosols, Kogan and his coworkers designed highly sensitive nephelometers which are now extensively used. The application of his aerosol flocculation method led Kogan to the discovery of molecular condensation nuclei and to the development of unusually sensitive methods of measuring gaseous impurities in air. This work suggested that molecular counters for gaseous impurities can be designed.

A. M. Amelin made an extensive investigation of all instances of formation of supersaturated vapour. He derived numerical formulae for predicting fog formation, for determining its concentration, and for developing fog prevention measures. He put forward a general theory of the formation of aerosols by condensation which is widely used to solve a variety of practical problems.

A Sorption Processes Laboratory (later, Section), led by M. M. Dubinin, was created in 1946 at the Institute of Physical Chemistry of the Academy of Sciences of the USSR. Its main scientific objective was to formulate and refine the theory of the physical adsorption of gases on porous solids. The activities of this laboratory maintained the continuity and the scientific traditions of the school of N. A. Shilov, one of the pioneers of adsorption studies in our country [31].

Extensive experimental and theoretical studies led to a rational classification of porosity which is at the same time a classification of the sorption processes. A quantitative theory of adsorption was developed for the so-called microporous adsorbents (active carbons, zeolites, etc.). This is the theory of volume filling, which permits calculation (from a limited amount of experimental data) of the parameters of the adsorption equilibrium with a precision beyond the scope of alternative modern theories of physical adsorption. In later work the theory was refined and generalised.

Significant results were obtained in the relatively unexplored but practically important field of the adsorption of mixtures of gases.

In addition to studies of adsorption equilibrium, the Section produced valuable results on adsorption kinetics which led to the solution of important problems in sorption technology. Mention must also be made of the important organising and coordinating role played by the Section in the general stream of scientific and technological research on sorption processes in the USSR. This role was recently formally recognised by the creation of the Scientific Committee on Adsorbents.

The Surface Chemistry Laboratory of the same Institute (A. V. Kiselev) has devoted its main effort to a comprehensive study of the chemistry of adsorbent surfaces and the nature of adsorption interactions. The basic adsorption and gas-chromatographic thermodynamic characteristics for various molecules, including hydrocarbons, have been calculated by the methods of statistical mechanics. Heats of adsorption and heat capacities have been measured in new, highly sensitive calorimeters for a number of important systems. The adsorption energy has been directly correlated with the structure of the adsorbed molecules (including macromolecules).

Work in the field of chromatographic analysis began to develop on a wide front in the USSR in 1946–1949, creating the need for a central institution which would coordinate and unify these investigations. A Chromatography Laboratory was created in 1949 at the Institute of Physical Chemistry of the Academy of Sciences of the USSR under K. V. Chmutov, and in 1950 the Scientific Committee on Chromatography was created. The Laboratory has been responsible for some major developments on theoretical and applied aspects of chromatography, including: the laws governing the statics, kinetics, and dynamics of the chromatographic process, the development and theoretical formulation of methods for separating the rare-earth elements, complex formation in chromatography, the radiation stability of ion-exchange materials, the development of new chromatographic methods (the adsorption–complexing method, the distribution chromatography of inorganic substances), the intensification of chromatographic processes (high temperatures and pressures), theoretical models of chromatographic processes, and the development of the most recent automatic apparatus for chromatography. Much of this work has great practical importance and has influenced industrial practice.

The work of A. A. Zhukhovitskii has contributed significantly to the development of a number of scientific topics: the thermodynamics of surface phenomena, the dynamics of adsorption processes, the theory of chromatography, and new variants of chromatographic analysis. Zhukhovitskii developed the theory of adsorption of mixed vapours and the theory of adsorption from solutions. He also made notable contributions to the theoretical foundations of gas and gas–liquid chromatography, and proposed new methods of chromatographic analysis.

The work on the theory of chromatography by N. N. Tunitskii (Karpov Institute) showed that the diffuseness of chromatographic bands arises from fluctuations in the lifetime of particles in the sorbed state. He developed new calculation methods for sorption separation processes which are relevant to the intensive purification of materials. Tunitskii has proposed a theory of the rate of ion exchange with allowance for the mobility of the ions taking part.

G. V. Samsonov (Institute of High-Molecular Compounds of the Academy of Sciences of the USSR) developed a theory of ion exchange on swelling resins which permits a rational choice of sorbent for the removal of some organic ions from complex mixtures. He synthesised carboxylic acid resins having an enhanced selectivity towards certain organic ions (streptomycin, colimycin). His work in the field of sorption is closely associated with the solution of practical problems in the development of technological methods of separation and purification.

In addition to the wide application of existing procedures and apparatus for gas chromatography, many institutions have contributed to the further development of chromatographic practice. The result of this work was a considerable increase in the sensitivity, generality, precision, and reliability of chromatographic methods. The Instrument Design Bureau of the Institute of Petrochemical Synthesis and that of the Institute of Organic Chemistry have played a major role in the development and practical exploitation of gas chromatography apparatus.

THERMODYNAMICS

Advances having major practical importance have been made in the Soviet Union in the study of the thermodynamic properties of special groups of materials used in modern technology (new fuels, semiconductor materials, rare metals, strong alloys, heat-resisting coatings, hard alloys, etc.).

Ya. I. Gerasimov is the leader of a major centre of thermodynamic research in our country—the Physical Chemistry Department of Moscow State University.

The scientific activities of Gerasimov and his coworkers are mainly aimed at the chemical thermodynamics of non-ferrous metallurgy, the thermodynamics of heat-resistant alloys, metal oxides, and semiconducting compounds. They successfully developed many new methods of measurement and investigation of thermodynamic quantities at high temperatures: this work has had a considerable impact on highly energetic systems and other areas of modern technology.

In the same Department, S. M. Skuratov of the Luginin Thermochemistry Laboratory is making high-precision measurements of the heats of combustion of organic compounds. The laboratory has developed a number of new methods.

The work of M. Kh. Karapet'yants in the field of thermodynamics, carried out at the Mendeleev Moscow Chemical Technology Institute, has gained wide recognition. He leads a new scientific project, involving the development and application of a group of methods, which he had originally suggested, of comparative calculation of the physicochemical properties of various substances and process parameters. These methods make possible the calculation of many physical and physicochemical constants from a limited number of experimental data (reference points). Particularly successful was the application by Karapet'yants of his comparative calculation method to evaluating the properties of homologous series of organic compounds (petrochemical calculations), isotope effects, the properties of complex compounds, the physical and physicochemical properties of semiconductors, silicate glasses, etc.

I. R. Krichevskii (State Institute for the Nitrogen Industry) discovered the new phenomenon of limited miscibility of gas phases and made a quantitative study of it in a number of systems. Equally noteworthy is a series of investigations under his direction of the solubility of gases in liquids under high pressures. Having developed accurate methods of investigation in the difficult high-pressure area up to tens of thousands of atmospheres, Krichevskii and his coworkers made a series of technologically important measurements. They also contributed to the development of the thermodynamics of dilute solutions and provided data for the development of the theory of intermolecular forces.

The problem of chemical equilibrium in complex mixtures at high temperatures is of importance in many fields of technology. We should note the experimental studies of equilibria in the thermal and catalytic cracking of hydrocarbons (A. V. Frost, A. A. Vvedenskii, and others), and the development of methods for thermodynamic calculations of combustion and explosion processes (Ya. B. Zel'dovich, A. N. Gurvich, Yu. M. Shaulov.

In the same general area, we note the work on the systematic statistical calculation of thermodynamic quantities for gases at high temperatures (A. V. Frost, I. N. Godnev, and a group of workers at the Institute of Fossil Fuels and the State Institute for Applied Chemistry).

Among the foremost theoretical investigations, mention must be made of the interesting work on second-order phase transformations (L. D. Landau, V. K. Semenchenko). A. V. Storonkin did some interesting work on solution–vapour equilibria in complex multicomponent systems. D. S. Korzhinskii evolved the theory of heterogeneous equilibria in multi-phase, multicomponent open systems, applicable to geological processes.

Many workers have investigated the thermodynamic functions of specific inorganic compounds, groups of compounds, solutions, and alloys, both in theoretical generalisations and in practical problems (mainly in the field of metallurgy). They include E. V. Britske (Scientific Institute of Fertilisers, Insecticides, and Fungicides), A. F. Kapustinskii, V. A. Sokolov, and N. K. Voskresenskaya (Institute of General and Inorganic Chemistry), A. I. Vol'skii (Mineral Institute for Non-Ferrous Metals and Gold), Ya. I. Gerasimov (Moscow State University), A. A. Zhukhovitskii (Institute of Steel), V. A. Kireev (Karpov Institute of Physical Chemistry), G. V. Kurdyumov (Central Scientific Research Institute for Ferrous Metallurgy), K. P. Mishchenko (Leningrad Chemical Technology Institute), M. M. Popov, K. G. Khomyakov, A. V. Rakovskii, S. M Skuratov, An. N. Nesmeyanov (Moscow State University), A. M. Samarin, N. V. Ageev, I. I. Kornilov (Institute of Metallurgy), and S. A. Shchukarev (Leningrad State University).

PHYSICOCHEMICAL ANALYSIS

Closely related to the thermodynamic investigations are the studies in the field of physicochemical analysis, which was created and widely developed in our country by the efforts of N. S. Kurnakov and his school (N. V. Ageev, V. Ya. Anosov, A. G. Grigor'ev, N. N. Efremov, S. F. Zhemchuzhnyi, V. A. Nemilov, S. A. Pogodin, N. I. Stepanov, G. G. Urazov, I. N. Lepeshkov, and others).

The work of Kurnakov's school has established the general principles of physicochemical analysis, led to new experimental methods, and accumulated and unified a vast amount of experimental information on systems consisting of the most varied components such as metals, oxides, sulphides, salts, organic compounds, etc.

From studies of these equilibrium diagrams, accurate conclusions have been made on the nature of the interactions between the components in the systems and on the nature and stability boundaries of the resulting phases (whether individual compounds or solid or liquid solutions).

The concept of singular points in chemical diagrams, introduced by Kurnakov, has made possible accurate discrimination of the chemical individuality of substances, and

has clarified the distinction between daltonides and berthollides, azeotropes, eutectics, cryohydrates, etc.

We cannot overemphasise the importance of the work of Kurnakov and his students in rationalising pyrometallurgical processes, preparing a large number of important alloys, and exploiting the mineral (particularly salt) resources of our country.

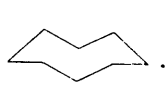
THE TRANSFORMATION OF HYDROCARBONS WITH MEDIUM-SIZED RINGS IN THE PRESENCE OF PLATINUM CATALYSTS

B.A.Kazanskii, E.S.Balenkova, and S.I.Khromov

The chemistry of cyclic compounds with rings of medium dimensions, containing 8–12 carbon atoms in the molecule, has developed considerably in recent years. The interest in these compounds results from the important part which they played in theoretical organic chemistry, due to a number of unique features characteristic of this class of compound. These features include the unique geometric shape of the molecule and the consequent possibility of interaction between atoms of the same molecule, not directly joined to one another. This interaction in medium-sized rings may take place through the ring (transannular interaction) and may be produced between hydrogen atoms attached to neighbouring carbon atoms (vicinal interaction). Both of these factors lead to an increased energy content in medium-sized rings; this has been called "non-classical" conformational strain and is responsible for a number of characteristic features in the chemical and physical properties.

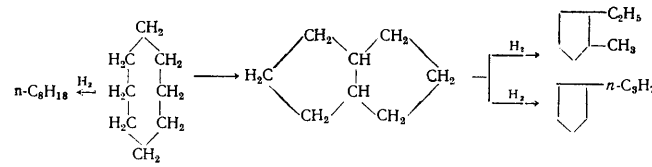
Transannular reactions not only are characteristic of functional derivatives of medium-sized rings but also take place in the catalytic transformation of hydrocarbons with rings of medium dimensions over hydrogenation–dehydrogenation catalysts. In 1955, Prelog and coworkers [1] observed for the first time the transformation of hydrocarbons containing 9–18 carbon atoms in the ring, over a palladium catalyst at 400°C. Depending on the number of



carbon atoms in the ring, removal of hydrogen gave various polycyclic, aromatic, and pseudo-aromatic hydrocarbons (indene, azulene, naphthalene, phenanthrene, etc. up to triphenylene). The hydrocarbons studied were divided into four groups, according to the nature of the transformations and the number of carbon atoms in the original ring:

(I) $C_5 + 4n$ C_9H_{18}; $C_{13}H_{26}$; $C_{17}H_{34}$
(II) $C_6 + 4n$ $C_{10}H_{20}$; $C_{14}H_{28}$; $C_{18}H_{36}$
(III) $C_7 + 4n$ $C_{11}H_{22}$; $C_{15}H_{30}$
(IV) $C_8 + 4n$ $C_{12}H_{24}$; $C_{16}H_{32}$

Hydrocarbons of group (I) are transformed into condensed systems with five-membered rings (for example, cyclononane forms indene). Of the hydrocarbons in group (II), cyclodecane gives azulene and naphthalene, and the others are converted into condensed compounds containing six-membered rings. Hydrocarbons of groups (III) and (IV) are converted into more complex condensed systems. For example, acenaphthene and acenaphthylene were found in the catalysate from cyclododecane.



Prelog found only aromatic hydrocarbons in the reaction products. There is no doubt that by carrying out the reaction under different conditions, it is possible to find among them both primary and intermediate transformation products. The first stage of transannular dehydrocyclisation in alicyclic hydrocarbons with a medium-sized ring is probably C_5- or C_6-dehydrocyclisation[2] inside the ring. In this instance it would be expected that platinised carbon, which is a more specific dehydrocyclisation catalyst than palladised carbon, would be a more suitable catalyst for such transformations and that by carrying out the reaction at temperatures lower than those used in Prelog's work it would be possible to trap the products of the first stage of the transannular dehydrocyclisation, namely, such bicyclic hydrocarbons as hydrindane, decalin, perhydroazulene, etc.

As early as 1930, Zelinskii and Freiman[3] studied the behaviour of cyclo-octane in the presence of platinised carbon at 300°C and suggested that it is converted into bicyclo[3,3,0]octane (pentalane) and methylcycloheptane. From the modern viewpoint, the suggestion that pentalane is formed from cyclo-octane under these conditions is quite well-founded. In actual fact, according to modern conformational theories, cyclo-octane has the shape of a crown[4], in which four quasi-axial hydrogen atoms lie above the central plane of the eight-membered ring, and four lie below it: the atoms of each group of four are moved closer to one another towards the centre of the molecule; this on the one hand creates additional internal conformational strain and on the other hand facilitates the removal of the 1,5 hydrogen atoms when cyclo-octane is adsorbed on a catalyst surface at elevated temperature, as a result of which a transannular 1,5 C–C bond may be produced, with the formation of pentalane

In 1960 it was shown that on the surface of platinised carbon at 310°C cyclo-octane is almost completely converted into *cis*-pentalane, which then undergoes hydrogenolysis[5]. On a specially selected catalyst the yield of *cis*-pentalane can be increased to 70%.[6]

The reaction scheme is:

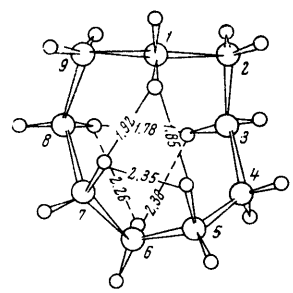
A small quantity of n-octane was found in the products of the transformation of cyclo-octane, so that the eight-membered ring undergoes direct hydrogenolysis, albeit to a very slight extent.

It might be assumed that the conformational characteristics of other multi-unit hydrocarbons would also play an important part in their transformations. Here, however, it must be borne in mind that the conditions of the reaction—elevated temperature and the presence of a catalyst—may lead to certain conformational changes in these cyclanes and the appearance of reaction products which do not come from their most stable conformations.

In 1960 an X-ray diffraction study was made of the structures of nine-, ten-, and twelve-membered rings[7-11]. The X-ray diffraction data were used to calculate the C–C–C valency angles, the torsion angles, and the length of the C–C bonds; this made it possible to obtain a picture of the most stable conformations of these rings and the position of the hydrogen atoms in the rings. It was found that the carbon framework of the cyclononane molecule is completely asymmetric, so that all 18 hydrogen atoms in it are non-equivalent. For practical purposes, however, Dunitz and Prelog[12] proposed their division into two groups: six intra-annular hydrogen atoms, directed into the ring, and twelve extra-annular Each of the six intra-annular hydrogen atoms approaches two others in space so that the shortest distance between them is about 1.8 Å (Fig. 1). This close positioning of the intra-annular hydrogen atoms facilitates their removal when the hydrocarbon molecule is adsorbed on a catalyst surface.

The ability of platinised carbon to catalyst the reactions of C_5- and C_6-dehydrocyclisation with the formation of five- and six-membered cyclanes and also condensed hydrocarbons with five- and six-membered rings suggests that when cyclononane is adsorbed on a catalyst surface, removal of the intra-annular hydrogen atoms on the first and fifth or third and eighth carbon atoms will take place readily, leading to the formation of hydrindane as chief reaction product.

In actual fact, the chief primary product of the transformations of cyclononane on platinised carbon at 300°C is



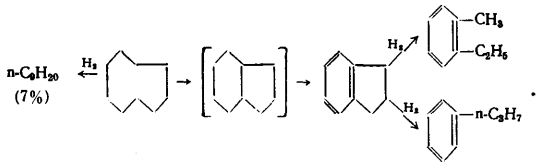


Fig. 1. Conformation of cyclononane.

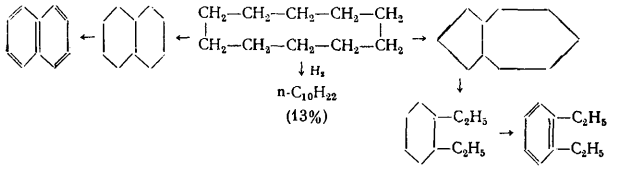
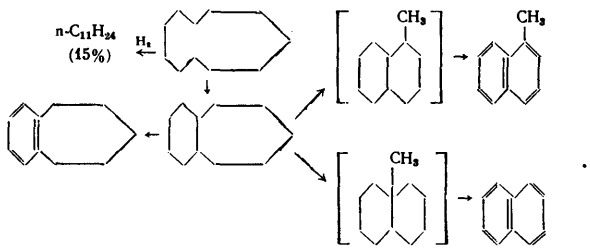
hydrindane, which under the conditions of the experiment is immediately converted into indane. Hydrogenolysis of the five-membered ring in indane gives *o*-ethyltoluene and n-propylbenzene. For cyclononane a greater part is played by the second direction of the reaction—direct hydrogenolysis of the ring. The yield of n-nonane amounts to 7%.[13]



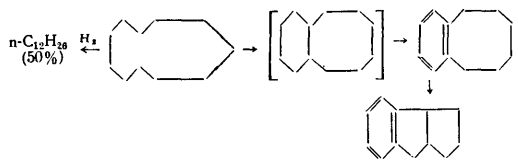
The cyclononane reacted according to the scheme:



The cyclodecane molecule (Fig. 2) also has six intra-annular hydrogen atoms directed into the ring, and in this sense the geometries of the nine- and ten-membered rings show considerable similarity. Among the intra-annular hydrogen atoms, two pairs of atoms are moved together in the 1,5 position, and their removal under the reaction conditions should lead to the formation of decahydroazulene.

The products of the catalytic transformations of cyclodecane consisted of *cis*-decahydroazulene, 1,2-diethylcyclohexane, and 1,2-diethylbenzene, small quantities of *trans*-decalin and naphthalene, and n-decane. The formation of 1,2-diethylcyclohexane and 1,2-diethylbenzene can apparently be attributed to hydrogenolysis of the five-membered ring to decahydroazulene, with subsequent isomerisation of the seven-membered ring.

As expected from the conformational characteristics of cyclodecane, the chief direction of its transformations proved to be the transannular C_5-dehydrocyclisation into decahydroazulene. n-Decane—the product of the direct hydrogenolysis of the ten-membered ring—made up 13% of the weight of the catalysate[14]:



There are no published data on the conformational characteristics of an eleven-membered ring. Transannular reactions are characteristic of cycloundecane compounds, however, just as they are for 8–10-membered cyclic compounds[15]. Therefore cycloundecane apparently has transannular hydrogen atoms close to one another, so that for this compound, as for the cyclanes examined above, transannular dehydrocyclisation should take place readily. In contact with platinised carbon at 300°C, cycloundecane reacted to give 15% direct hydrogenolysis of the ring with the formation of n-undecane and dehydrocyclisation into *trans*-bicyclo[5,4,0]undecane, which under the conditions of the experiment was then converted into benzosuberane. The appearance of small quantities of α-methylnaphthalene and naphthalene in the catalysate can be attributed to isomerisation of the seven-membered ring into bicyclo[5,4,0]undecane with the formation of 1-methyldecalin and 9-methyldecalin, which then undergoes dehydrogenation under the conditions of the experiment:

Study of the structure of cyclododecane (Fig. 3) showed that there is no significant transannular interaction between opposite hydrogen atoms, and that the shortest distance between the hydrogen atoms is 2.1 Å. If it is assumed that transannular dehydrocyclisation takes place with the removal of the hydrogen atoms closest to one another, increase in the dimensions of the ring and increase in the distance between the transannular hydrogen atoms should decrease the ability of the cyclane to undergo transannular dehydrocyclisation.

In actual fact, it was found that the dehydrocyclisation of cyclododecane takes place to the extent of only 50%, with the formation of bicyclo[6,4,0]dodecane, which on dehydrogenation is converted into benzocyclo-octane; the latter, like cyclo-octane[5,6], is then converted into benzopentalane, the yield of n-dodecane amounting to 50%.[16]

Thus the catalytic transformations of hydrocarbons containing rings of medium dimensions in the present of platinised carbon at 300°C take place in two main directions:

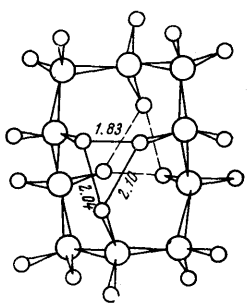


Fig. 2. Conformation of cyclodecane.

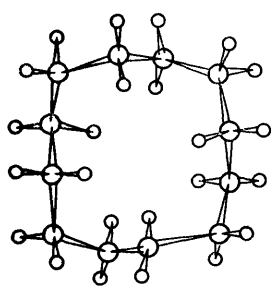

Fig. 3. Conformation of cyclododecane.

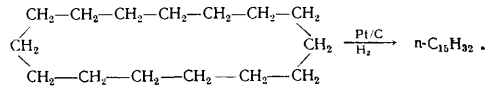

transannular dehydrocyclisation with the formation of condensed aromatic and non-aromatic hydrocarbons, and direct hydrogenolysis of the ring with the formation of normal paraffinic hydrocarbons. This last observation is of fundamental importance, since until recently hydrogenolysis in the presence of platinised carbon was known only for rings containing not more than five carbon atoms.

In 1962 it was shown that the products of the transformations of cycloheptane in the presence of platinised carbon at 300°C include n-heptane, from which it follows that the seven-membered ring also undergoes direct hydrogenolysis [17]. Liberman and coworkers [18] showed that cyclohexane does not undergo ring opening in the presence of a platinum catalyst, but hydrogenation of the six-membered ring is observed with ruthenium, iridium, and osmium, deposited on carbon.

The ability of the cyclane with a ring of medium dimensions to undergo hydrogenolysis in the presence of a platinum catalyst increases from cyclo-octane to cyclododecane; with the twelve-membered ring, the degree of hydrogenolysis increases sharply and the yield of normal alkane reaches 50%. The ability of the cyclane to undergo transannular dehydrocyclisation changes in the opposite sequence: the transannular dehydrocyclisation of cyclo-octane takes place to the extent of almost 100%, that of cycloundecane to the extent of 85%. and that of cyclododecane to the extent of only 50%. The structures of the resulting bicyclic hydrocarbons are determined by the conformational characteristics of the original cyclanes.

The hydrogenolysis and transannular dehydrocyclisation which take place in a number of medium-sized rings in the presence of a platinum catalyst are apparently competing reactions: for 8–10-membered cyclanes, because of their conformational characteristics, dehydrocyclisation takes place readily, and the rate of dehydrocyclisation is greater than the rate of hydrogenolysis, whereas with cyclododecane, which does not have such a favourable structure for dehydrocyclisation, the rates of the two reactions become commensurate. With large rings, the appreciable dimensions of the ring and the fact that there are no opposed hydrogen atoms at a short distance from one another should hinder intramolecular dehydrocyclisation, and hydrogenolysis may become the chief reaction.

As a representative of hydrocarbons containing rings with large dimensions, we took cyclopentadecane. It was found that cyclopentadecane in the presence of platinised carbon at 300°C in fact undergoes only hydrogenolysis of the ring with the formation of n-pentadecane as the only reaction product [19].

The dependence of the degree of hydrogenolysis on the number of units in the ring is shown in Fig. 4.

Usually, in the discussion of the reactivity of cyclic compounds containing rings with medium dimensions, allowance is made for the change in the strain, in addition to other factors characteristic of the given reaction. The problem of the strain in medium-sized rings is extremely complex. In its examination, allowance must be made for three factors: the distortion of the valency angles, producing Bayer strain, the energy of the torsion angles—Pitzer strain—and the transannular interaction of atoms which are not joined to one another.

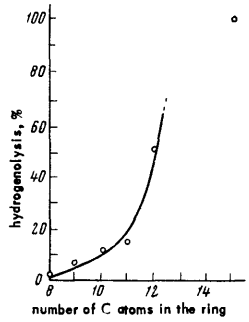

Fig.4. Dependence of the degree of hydrogenolysis on the number of C atoms in the ring.

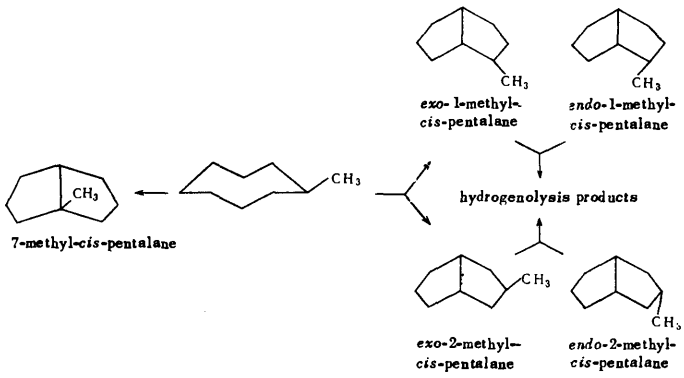
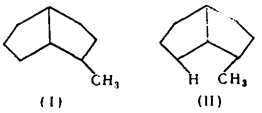
X-Ray diffraction study of the structures of 8-, 9-, 10-, and 12-membered rings has provided a picture of the strain in these rings. The structure of the eight-membered ring has been described in less detail, but for the others, as already noted, the values of the C–C–C valency angles, the torsion angles, and the shortest distance between the transannular hydrogen atoms have been calculated.

From these data it may be concluded that among the medium-sized rings, the greatest strain should be shown by cyclononane and cyclo-octane, since they are characterised by considerable Bayer and Pitzer strain, and also by strain due to transannular interaction. Cyclodecane has almost no Pitzer strain, but its valency angles are much greater than tetrahedral, indicating appreciable Bayer strain. Cyclodecane is also characterised by strain due to transannular interaction. Unfortunately, the structure of cycloundecane has not been studied, but on the basis of the heat of combustion [20], which may give information on the strain in cyclic compounds, it may be concluded that cycloundecane is not free from strain, and that, like cyclodecane, it is apparently characterised by strain due to transannular interaction. X-Ray diffraction study shows that in cyclododecane there is no Pitzer or Bayer strain, nor significant transannular interaction. Cyclopentadecane is free from all forms of strain.



Examination of the above material in the light of modern views on ring strain indicates that the formation of a bicyclic hydrocarbon by intramolecular dehydrocyclisation removes the transannular strain produced as a result of the repulsion of opposite hydrogen atoms and hence is energetically favourable for 8–11-membered cyclanes. For cyclododecane, in which there is no significant transannular interaction, dehydrocyclisation will not be so energetically favourable as for the other cyclanes with medium-sized rings. In actual fact, cyclo-octane undergoes dehydrocyclisation to the extent of almost 100%, cyclononane to the extent of 93%, and cyclododecane to the extent of only 50%.

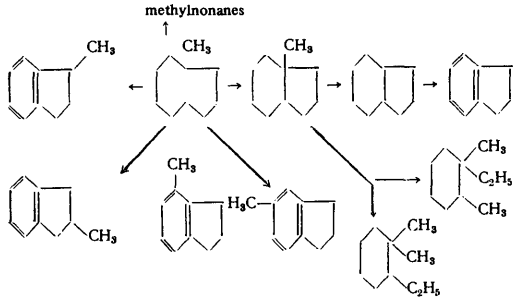
In hydrogenolysis, the chief role is apparently played not by the strain in the original molecule but by the strain produced in the transition complex when the cyclane molecule is adsorbed on the catalyst surface.



To investigate the influence of an alkyl substituent on the direction of the transformation of hydrocarbons with medium-sized rings, a study was made of the behaviour of methylcyclo-octane, methylcyclononane, and methylcyclodecane in the presence of platinum catalysts [21,22].

On platinised carbon at 300°C, methylcyclo-octane, like cyclo-octane itself, shows only slight (~ 1%) direct hydrogenolysis of the ring with the formation of isomeric methyloctanes. The chief reaction undergone by methylcyclo-octane under the above conditions is C_5-dehydrocyclisation, leading to the formation of all isomeric methyl-*cis*-pentalanes. Of these, 1-methyl-*cis*-pentalane is formed preferentially, and 2-methyl-*cis*-pentalane and 7-methyl-*cis*-pentalane are formed in smaller quantities. The catalysate also contains products of the hydrogenolysis of the methylpentalanes; to decrease the amount, the methylcyclo-octane was subjected to catalysis on a specially selected platinum catalyst containing 2% iron[23]. An interesting feature is that in this instance the formation of isomeric methylpentalanes in the same proportions as on platinised carbon is observed.

The ratio of methyl-*cis*-pentalanes formed by the transannular dehydrocyclisation of methylcyclo-octane does not depend on the nature of the platinum catalysts studied and is apparently determined by the conformational characteristics of the methylcyclo-octane molecule.

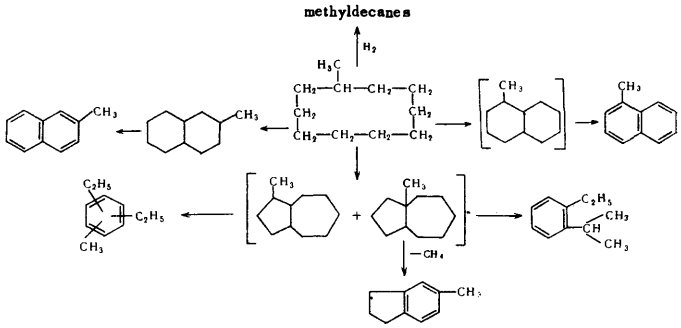


Another noteworthy feature is that, of the *exo*- and *endo*-1-methyl-*cis*-pentalanes formed, the *exo*-isomer predominates, whereas *exo*- and *endo*-2-methyl-*cis*-pentalanes are formed in comparable quantities. The preferential formation of the *exo*-form of 1-methyl-*cis*-pentalanes (I) relative to the *endo*-form (II) is apparently due to the characteristic features of the three-dimensional structure of this hydrocarbon. In the *endo*-form the methyl group and the hydrogen attached to the sixth carbon atom come so close together that the forces of repulsion between them make this form of the molecule more strained than the *exo*-form. In 2-methyl-*cis*-pentalane the *endo*- and *exo*-forms of the molecule have equally favourable arrangements of the methyl group, so that these isomers are apparently equally stable, and the *exo*- and *endo*-forms of 2-methyl-*cis*-pentalane are formed in almost equal quantities.

The chief primary product of the transformations of methylcyclononane in the presence of a platinum catalyst was *cis*-8-methylhydrindane; this hydrocarbon and the products of its secondary transformations made up ~ 50% of the weight of catalysate. 8-Methylhydrindane could be formed by the transannular dehydrocyclisation of methylcyclononane only if the methyl group is attached to a carbon atom with an intra-annular hydrogen atom which is moved closer, in the 1,5 position, to an intra-annular hydrogen atom of the opposite carbon atom. The removal of a methyl group in 8-methylhydrindane leads to the formation of hydrindane, and the dehydrogenation of the six-membered ring in hydrindane produces indane. Ethyldimethylcyclohexanes are formed as a result of the hydrogenolysis of the five-membered ring in 8-methylhydrindane.

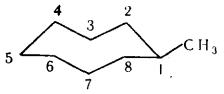
Thus methylcyclononane is characterised by a type of transannular dehydrocyclisation which takes place preferentially with the participation of the hydrogen attached to the carbon atom of the ring carrying the substituent. The presence of 1-, 2-, 4-, and 5-methylindanes in the catalysate, however, indicates that other intra-annular hydrogen atoms, brought closer together in the 1,5 position, may also take part in this reaction. The catalysate contained isomeric methylnonanes, formed by the direct hydrogenolysis of the nine-membered ring in the same amounts as the n-nonane in the catalytic transformations of cyclononane.

The chief primary reaction of methylcyclodecane in the presence of platinised carbon is transannular dehydrocyclisation, which takes place in two directions: firstly, C_5-dehydrocyclisation takes place with the formation of methyldecahydroazulenes, and secondly, C_6-dehydrocyclisation takes place, producing methyldecalins and methylnaphthalenes. Like cyclodecane, methylcyclodecane is characterised to a greater extent by C_5-dehydrocyclisation than by C_6-dehydrocyclisation, since the products formed by the first reaction make up more than 70% of the total weight of transformation products.



Methyldecahydroazulenes are unstable under the conditions of the experiment and undergo further transformation. Secondary transformations of the methyldecahydroazulenes

TABLE. Composition of the products of the transformation of methylcyclo-octane at 800°C.



Hydrocarbons	Percentage concentration	
	Pt/C	Pt/Fe/C
Methyloctanes	1	>1
7-Methyl-*cis*-pentalane	8	13
endo-1-Methyl-*cis*-pentalane	6	8
exo-1-Methyl-*cis*-pentalane	34	35
endo-2-Methyl-*cis*-pentalane	11	15
exo-2-Methyl-*cis*-pentalane	17	18
Products of the hydrogenation of methyl-*cis*-pentalanes		
I- and 2-Methylpentalanes	12	11
7-Methylpentalane	11	

apparently lead to the formation of 1-ethyl-2-isopropylbenzene, which makes up almost half of the weight of the methylcyclodecane transformation products. Of all the possible isomers of methyldecahydroazulene, only 9-methyldecahydroazulene and 1-methyldecahydroazulene can lead to the formation of 1-ethyl-2-isopropylbenzene as a result of hydrogenolysis of the five-membered ring and isomerisation of the seven-membered ring. Secondary transformations of these hydrocarbons may also explain the presence of diethylmethylbenzene and 5-methylindane in the catalysate.

Thus the final products of the transformations of methylcyclodecane indicate that on transannular C_5-dehydrocyclisation of this hydrocarbon not all the isomeric methyldecahydroazulenes are formed to equal extents, and that 9-methyldecahydroazulene and 1-methyldecahydroazulene apparently predominate. The presence of isomeric methyldecanes in the catalysate indicates direct hydrogenolysis of the ten-membered ring. Comparison of the degrees of hydrogenolysis of cyclodecane and methylcyclodecane indicates that cyclodecane itself undergoes hydrogenolysis more readily than its homologue: the yield of paraffinic hydrocarbons for methylcyclodecane amounts to only 2% of the weight of transformation products, whereas for cyclodecane under the same conditions, 13% n-decane is formed:

Transannular dehydrocyclisation in the series of alkylcyclanes with medium-sized rings is directed in character: the preferential direction of this process is not determined by the hydrogen atom attached to the tertiary carbon atom of the ring but is apparently related to the conformational characteristics of the cyclanes. In fact, in the dehydrocyclisation of methylcyclo-octane, the formation of 1-methylpentalane predominates, whereas from methylcyclononane under the same conditions, the bicyclic hydrocarbon with angular arrangement of the methyl group is formed preferentially, and the dehydrocyclisation of methylcyclodecane apparently produces chiefly 9- and 1-methyldecahydroazulenes. In the transannular dehydrocyclisation of methylcyclo-octane

there are two possibilities for the formation of 1-methylpentalane: by the removal of two quasi-axial hydrogen atoms attached to $C_{(2)}$ and $C_{(6)}$ or $C_{(4)}$ and $C_{(8)}$, and one possibility each for the formation of 2- and 7-methylpentalane (removal of the hydrogen on $C_{(3)}$ and $C_{(7)}$ for 2-methylpentalane and on $C_{(1)}$ and $C_{(5)}$ for 7-methylpentalane). If it is assumed that these possibilities for the formation of methylpentalanes are equally probable, the quantity of 1-methylpentalane in the methylcyclo-octane catalysate should have been double the quantities of 2- or 7-methylpentalane. In fact, 1-methylpentalane predominates in the catalysate for this reaction.

In cyclononane (see Fig. 1) the substituents probably can occupy only the extra-annular positions. Data obtained by X-ray diffraction studies show that substituents are preferred among the extra-annular positions. An example is the position of the substituent on $C_{(1)}$. The preferential positioning of the methyl group in the nine-membered ring also apparently explains the preferential formation of 8-methylhydrindane in the transannular dehydrocyclisation of methylcyclononane. The methyl group is attached to the carbon atom carrying an intra-annular hydrogen atom which has been brought closer to the intra-annular hydrogen atom of the opposite carbon atom of the ring. The transannular dehydrocyclisation apparently takes place with the removal of the intra-annular hydrogen atoms which have been brought together with the production of a new C–C bond.

Analogous reasoning can be applied to methylcyclodecane, in which directed transannular dehydrocyclisation is also observed, with the preferential formation of 9- and 1-methyldecahydroazulenes as primary reaction products.

The transformations of hydrocarbons with medium-sized rings in the presence of a platinum catalyst take place in two independent directions: transannular dehydrocyclisation and direct hydrogenolysis of the ring. The first stage of the transannular dehydrocyclisation leads to the formation of a bicyclic hydrocarbon, whose nature is determined chiefly by the conformational characteristics of the original cyclane. Under the conditions of the experiment, bicyclic hydrocarbons undergo further transformations: aromatisation, hydrogenolysis of five-membered rings, and isomerisation of seven-membered rings, to give reaction mixtures with extremely complex compositions. For methylcyclanes with 8–10-membered rings, transannular dehydrocyclisation is directed in character; the preferential direction of the catalytic process is determined by the conformation of the original hydrocarbon.

With increase in the dimensions of the ring there is a decrease in the extent to which transannular dehydrocyclisation takes place and an increase in the extent to which hydrogenolysis takes place; for large rings, hydrogenolysis becomes the main direction of the transformations. These data show that hydrogenolysis is general in the chemistry of cyclic hydrocarbons: hydrogenolysis is the only direction of the transformations for rings containing not more than five carbon atoms, and takes place in addition to dehydrocyclisation in medium-sized rings.

1. INTRODUCTION

The rate constant of an elementary chemical reaction is usually expressed in the form of the Arrhenius equation:

$$k = A\exp(-E_0/kT) \qquad (1.1)$$

(where A and E_0 are constants) or of the formula

$$k = A_0T^{1/2}\exp(-E_0/kT), \qquad (1.2)$$

which follows from kinetic theory for when the activation energy is provided by the component of the kinetic energy of the relative motion of the interacting particles lying along the line of their centres[1]. Formula (1.2) can be obtained also in the more general example by assuming a particular dependence of the reaction cross-section upon the energy of relative motion[2]. Kassel[3] proposed also an empirical formula of the type:

$$k = CT^m\exp(-E_0/kT) \qquad (1.3)$$

($m > 0$), and gave some theoretical justification for it.

The dissociation rate constant is also frequently expressed in the form

$$k_d = A_0T^{-n}\exp(-D/kT), \qquad (1.4)$$

which takes account of the contribution of internal degrees of freedom to the activation of the molecule undergoing dissociation[1].

The rate constant of the recombination process, which is the reverse of the dissociation process, is most often described by the formula:

$$k_r = A_0T^{-m}. \qquad (1.5)$$

Whereas the formulae describing the rate constants of the dissociation and recombination processes have recently achieved some—but far from complete—theoretical justification, as discussed below, exchange processes on the other hand have hardly been investigated at all in spite of the fact that they are the commonest type of elementary reaction. Yet, it is possible to introduce some significant advances into the quantitative kinetics of exchange processes on the basis of the (still imperfect) theory of the transition state alone, and also on the basis of quantum statistics.

The main problem in the theoretical calculation of the rate constant is to evaluate the contribution of the various degrees of freedom and to make allowance for the perturbation of the equilibrium distribution brought about by the reaction itself. The transition state method avoids both these difficulties by assuming that the complicated energy exchange process can be described by the motion of the representative point along some reaction coordinate q_γ whose choice is not strictly unique, whilst completely ignoring the perturbation of the equilibrium distribution of the reactants over the states. To some extent, correct allowance for these two factors can be made independently. First, we calculate the reaction cross-section σ_γ as a function of the dynamic parameters of the partners during a collision—the initial vibrational states n_i and rotational states j, and also the relative velocity v of the colliding molecules. As a second step, the reaction rate R is calculated by averaging σ_γ over all the n, j, v initial states by means of the expression

$$R = \int \sigma_r(n, j, v)\, v f(n, j, v)\, d\Gamma. \qquad (1.6)$$

Here $f(n, j, v)$ is the distribution function (in general, non-equilibrium) of the colliding molecules, normalised for the total number of reacting molecules. If the concentrations of the initial molecules are taken out of f as common factors, the reaction rate R can be expressed in the form

$$R = k(C_A)^\alpha(C_B)^\beta \qquad (1.7)$$

where k now has the significance of the rate constant of a reaction of order α with respect to reactant A, of order β with respect to reactant B, etc. The calculation of the

function f in expression (1.6) becomes a statistical problem which can be solved by examining the system of equations describing at the same time the relaxation (that is, the transitions between the various energy states of the reacting molecules) and the true chemical reaction (that is, the regrouping of atoms upon collision of the molecules).

Both these factors (the contribution of different degrees of freedom and the perturbation of the equilibrium distribution) influence the temperature dependence of the rate constant, and hence it is important to resolve explicitly the dynamic and the static parts of the pre-exponential factor of dissociation rate constants in order to understand the mechanism of the elementary act. In what follows, we shall briefly discuss the temperature dependence of dissociation, recombination, and exchange reactions in the gas phase.

2. DISSOCIATION

It is well established that the thermal dissociation of molecules is kinetically characterised by a first-order law at high pressures and by a second-order law at low pressures[4]. Between these two extremes is found a transition region of pressures where the reaction order varies from first to second. The pressure dependence of the dissociation rate constant arises, essentially, from the disturbance of the equilibrium distribution over the internal degrees of the reacting molecules. Since the extent of this disturbance varies with pressure, it is desirable to consider separately the possible limiting cases of the reaction

$$AB+M\rightarrow A+B+M \qquad (2.1)$$

First-Order Reactions

It is evident from physical considerations that at high pressures, when the rate of intermolecular energy transfer is greater than the rate of intramolecular energy transfer, the disturbance of the equilibrium distribution is a minimum†. Therefore we must assume that here the transition state method should lead to a satisfactory approximation for the rate constant k of the reaction. The general expression for k within the limits of this approximation is[6]

$$(k_d)_\infty = g^+\chi\frac{kT}{2\pi\hbar}\frac{F^+_{AB}}{F_{AB}}\exp(-E_0/kT), \qquad (2.2)$$

where F_{AB} and F^+_{AB} are the partition functions of the stable and the activated molecule, g^+ is the number of independent decomposition paths, and χ is the transmission coefficient.

† Throughout this paper we shall assume, when dealing with the mechanism of intramolecular energy transfer in an active molecule, that the statistical approximation is applicable. According to the modern concepts of the statistical theory[4,5] of unimolecular reactions, all the degrees of freedom of active and of activated molecules can be classified into inactive, adiabatic, and active. The first do not generally take part in energy redistribution and they do not appear explicitly in the expression for the rate constant. As regards the second, it is assumed that during the intervals between collisions the quantum numbers which characterise these degrees of freedom do not alter, but on going from an active to an activated molecule a change in these degrees of freedom is assumed—in particular, a change from vibrations to rotations[5].

The factor F^+_{AB} can be said to be known if the configuration of the activated molecule is known, or alternatively if the critical surface S^+ in (A + B) phase space is known, since its intersection with the representative point can be identified with the completion of the elementary chemical act. If we adopt a system of harmonic oscillators as a model of the molecule, and the transmission coefficient is close to unity, it follows from Eqn. (2.2) that at high temperatures ($kT \gg \hbar\omega_i$) the pre-exponential factor is of the same order as the molecular vibration frequency. Furthermore, using the theory of small vibrations it can be shown that the term $\frac{kT}{2\pi\hbar}\frac{F^+_{AB}}{F_{AB}}$ in Eqn. (2.2) always falls between the lowest and the highest frequency of the active molecule. Nevertheless, the general treatment in principle does not set an upper limit to the pre-exponential factor. However, since the frequency factor of the majority of experimentally investigated uni molecular reactions is found to be of the same order as the vibration frequency, reactions whose pre-exponential factor is greater than 10^{14} s^{-1} are often treated in the literature as having an anomalously high pre-exponential factor. High pre-exponential factors are associated with the appearance of a high degree of anharmonicity in the internal vibrations of the molecule. Anharmonicity loosens the intramolecular bonds and leads to the formation of a weakly bound activated molecule. This effect is often referred to as a large entropic contribution by the activated molecule to the partition function F^+.

The simplest (and from the quantitative aspect the most important) manifestation of anharmonicity during dissociation is the conversion of various types of vibration of the active molecule into free rotation of the activated molecule.

We can make an order-of-magnitude estimate of the contribution made by the conversion of one vibrational degree of freedom of the AB molecule into a rotational degree of freedom of the activated molecule. Under classical conditions ($kT \ll \hbar\omega_i$) we have

$$F_{vibr} = kT/\hbar\omega,\ F_{rot} = (2IkT)^{1/2}/2\pi\hbar\,. \qquad (2.3)$$

Calculation of the frequency on the basis of the Morse potential leads to $\frac{F_{rot}}{F_{vibr}} \simeq (D/kT)^{1/2}$, where D is the energy of the chemical bond.

As an example of a reaction with an anomalously large frequency factor we may consider the thermal dissociation of ethane into two CH_3 radicals. The calculation by Setser and Rabinovitch[7] uses a model of the C_2H_6 molecule in the activated state involving 12 oscillators (2 non-interacting CH_3 radicals) and 5 active rotators (free internal rotation of the CH_3 groups about the C–C axis and 4 degrees of freedom corresponding to the swing of the planes of the H_3 atoms of each CH_3 group). The C–C bond is chosen as the reaction coordinate. The calculation leads to a pre-exponential factor for the reaction of 10^{17} s^{-1} at 600°C. This figure agrees with the value derived from the experimental bimolecular recombination constant by using the relationship between the dissociation and recombination constants given by the equilibrium constant.

Formula (2.2) for the rate constant k_∞ is strictly accurate if the quantity F_{AB} is taken to be the total partition function of the activated molecule. When the problem is formulated in this way the whole of the difficulty attending the calculation of the constant is transferred to a correct definition of the critical surface. This task is generally extremely complex. Therefore in every instance when the critical surface is determined from simple qualitative

considerations a factor χ, which makes allowance for the repeated passage of a representative point through the critical surface, is introduced. Exact calculation of χ is equivalent to solving the many-body problem. An attempt to solve this problem is equivalent to denying the simplifying assumptions associated with the introduction of a reaction coordinate. However, since the latter approach is thought to be justified, we shall use the expression for χ (and discuss the temperature dependence of the transmission coefficient) which applies to the one-dimensional model.

For adiabatic reactions, assuming negligible contribution of the tunnel effect, we can put $\chi = 1$. For non-adiabatic reactions involving a change in electronic state the situation $\chi \ll 1$ is entirely possible. In this case we obtain the following expression for χ on the basis of the Landau–Zener formula[8]:

$$\chi = 2\pi W^2/\Delta F\hbar\,(kT/2\pi\mu)^{1/2}\,, \qquad (2.3a)$$

where μ is the effective mass corresponding to the motion along the reaction coordinate, ΔF is defined by the difference between the slopes of the intersecting terms U_1 and U_2 ($\Delta F = |dU_1/dq_1 - dU_2/dq_2|$); W is the matrix element which connects the relevant electronic energy levels. If the connection is through spin–orbital interaction, W is independent of T, and Eqn. (2.3a) leads to the expression

$$\chi(T) \simeq T^{-1/2}\,. \qquad (2.4)$$

If the non-adiabatic connection is due to Coriolis forces acting on the electrons, W is proportional to the speed of rotation of the molecule, so that $W^2 \simeq T$. Hence, from (2.3), we have

$$\chi(T) \simeq T^{1/2}\,. \qquad (2.5)$$

The tunnel corrections, which alter the value of χ when quasi-classical conditions cease to apply to the motion of the representative point near the critical surface, have different forms for adiabatic and non-adiabatic reactions. For the former, the tunnel correction arises from the penetration of the particle under a potential barrier which is approximately parabolic (at least, near the top of the barrier), and the approximate expression for χ is of the form[9]

$$\chi(T) \simeq (\hbar\omega^*/2kT)\sin(\hbar\omega^*/2kT)\,, \qquad (2.6)$$

where ω^* denotes the vibration frequency close to the minimum of the "inverted" potential hump.

In the second instance, penetration by the tunnel effect takes place below the point of quasi-intersection of the terms, and the shape of the barrier is nearer to triangular than to parabolic. Under these conditions χ is described[10] as the product of the over-the-barrier transmission coefficient (2.3a) and an exponential tunnel correction:

$$\chi(T) = \frac{2\pi W^2}{\Delta F\hbar\,(kT/2\pi\mu)^{1/2}}\exp\left[\frac{1}{12}(\varepsilon/kT)^3\right],\quad \varepsilon = \left[\hbar\,\frac{\partial U_1}{\partial q_1}\frac{\partial U_2}{\partial q_2}\Big/\sqrt{2\mu\Delta F}\right]^{2/3}. \qquad (2.7)$$

Evidently, a situation in which $\chi > 1$ becomes possible if tunnel transmission is taken into account. In other words, the effective activation energy becomes lower than the energy E_0 of the potential barrier. The correction for barrier lowering has a complicated temperature dependence, and it is therefore assigned to the pre-exponential factor.

Calculation of the statistical summations in (2.2) leads to the following formulae for the temperature dependence of the pre-exponential term if the model of the dissociating molecule is set up in terms of a system of s oscillators and r rotators and that of the activated molecules in terms of s^+ oscillators and r^+ rotators:

$$A(T) \simeq \chi(T)\,T^{(r^+-r/2)+1},\ \hbar\omega_i,\ \hbar\omega_i^+ \gg kT \qquad (2.8)$$

$$A(T) \simeq \chi(T)\,T^{(r-r^+)/2},\ \hbar\omega_i,\ \hbar\omega_i^+ \ll kT \qquad (2.9)$$

with $r^+ > r$ in most cases. Thus, leaving aside the transmission coefficient χ, the quantity A is characterised by a positive temperature dependence at low temperatures and a negative (or zero for $r^+ = r$) temperature dependence at high temperatures.

Second-Order Reactions

At low pressures the rate of decomposition is substantially influenced by the disturbance of the Boltzmann distribution over the internal degrees of freedom of the decomposing molecule. Hence the transition state method cannot be used to calculate the rate constant k of the reaction. For the same reason, the temperature dependence of $A(T)$ can be calculated only if the detailed excitation mechanism of the molecule AB to the dissociation threshold is known, since in the low-pressure region the rate of decomposition is limited by the rate of vibrational relaxation of excited vibrational states. Since we still lack adequate information on the probability of energy exchange during the collision of vibrationally excited molecules, we may conveniently consider the two limiting cases of activation which allow k_d to be calculated in a closed form and lead to a number of conclusions on the temperature dependence of A.

These limiting cases are known in the literature as the strong collision mechanism and the stepwise excitation mechanism[5]. The former mechanism assumes that the AB molecules which decompose at low pressures are those with energy $E_{vibr} > D$ (the active AB* molecules), and that the rate of deactivation of the active molecules does not depend on their state and is determined by the effective number of collisions between AB* and M per unit time. In this instance the principle of detailed balance requires a rate of decomposition, identical to the rate of excitation to energy states $E_{vibr} > D$, given by

$$k_d = Z\int_D^\infty \rho(E)\exp(-E/kT)\,dE/F_{AB}\,. \qquad (2.10)$$

In this excitation mechanism the dissociation produces a disturbance of the equilibrium distribution only above the threshold level. For $E_{vibr} < D$ the vibrational distribution function retains its equilibrium value.

In the stepwise excitation mechanism it is assumed that each collision between AB and M transfers an amount of energy small compared to the dissociation energy D. Thus, the molecules which react at low pressures have approached the energy threshold from below, and the concentration of active molecules is negligibly small.

If excitation of the AB molecules occurs as a result of single-step vibrational transitions ($n \to n+1$) the expression for k_d has the form

$$k_d = Z_0\left[\sum_{n=0}^{N}\exp[E_n/kT]/P_{n,n-1}\right]^{-1}\Big/F_{AB}\,; \qquad (2.11)$$

N is the number of the level corresponding to the dissociation threshold, and $P_{n,n-1}$ is the transition probability referred to a single gas-kinetic collision. For ease of comparison with (2.10), this expression can be transformed

in a way which allows generalisation to many-quantum transitions and contains as a parameter the mean square of the energy transferred at each collision $\langle\Delta E^2\rangle$. By definition we have

$$\langle\Delta E^2\rangle = (\Delta E_{n-1,n})^2 P_{n-1,n} + (\Delta E_{n,n+1})^2 P_{n,n+1} . \quad (2.12)$$

Assuming that the transition energy $\Delta E_{n,n-1}$ is an insensitive function of n, Eqn. (2.12) can be rewritten in the form

$$\langle\Delta E^2\rangle = 2\,(\Delta E_{n,n-1}^2)^2\, P_n , \quad (2.13)$$

where we have used the terminology $P_n \simeq P_{n,n-1} \simeq P_{n,n+1}$. Substituting P_n from (2.12) into (2.11) and replacing the summation by an integral (which is permissible for $\langle\Delta E^2\rangle^{1/2} \ll kT$) we find

$$k_d = Z_0\left[\int_0^D \exp(E/kT)\frac{2dE}{\rho(E)\,\langle\Delta E^2(E)\rangle}\right]^{-1}\Big/F_{AB} . \quad (2.14)$$

It is assumed that the density of levels $\rho(E)$ is related to ΔE by $\rho(E) \simeq (\Delta E)^{-1}$. The quantity $\langle\Delta E^2\rangle$ in (2.14) is equivalent to a diffusion coefficient of the representative point over the energy levels. Hence we may suggest that Eqn. (2.14) will be correct also for many-quantum transitions provided that the excitation process can be described by the Fokker–Planck equation in energy space. Following Pitaevskii[11], we may test this assumption by direct integration of the equation as given, for example, by Nikitin[5].

The conditions under which the diffusion equation is applicable, already used above, are defined by the inequality $\langle\Delta E^2\rangle \ll (kT)^2$.

Comparing (2.14) with (2.10) we see that in the stepwise dissociation mechanism it is only molecules below the dissociation threshold ($E_{vibr} < D$) which contribute to the rate of decomposition. Thus, decomposition leads to zero population of the active molecule states and to breakdown of the equilibrium distribution below the F threshold[5]. The actual mechanism of the activation is intermediate between the two discussed above, and in general the rate of decomposition will be affected by the distribution of molecules both above and below the threshold.

By separating the exponential term from (2.10) and (2.14) we arrive at the following expressions for the pre-exponential term

$$A_1 = Z_0\int_0^\infty \rho(D+\varepsilon)\exp(-\varepsilon/kT)\,d\varepsilon/F_{AB} \quad (2.15)$$

$$A_2 = Z_0\left[\int_{-\infty}^0 \exp(\varepsilon/kT)\frac{2d\varepsilon}{\rho(D+\varepsilon)\,\langle\Delta E^2(D+\varepsilon)\rangle}\right]^{-1}\Big/F_{AB} . \quad (2.16)$$

Eqn. (2.15) applies to the strong collision mechanism, whereas Eqn. (2.16) applies to the stepwise excitation mechanism. In these expressions the quantity ϵ is measured from the dissociation limit; Eqn. (2.16) also assumes that the lower integration limit in (2.14) is insignificant.

We shall now turn to the temperature dependence of the pre-exponential A in the decomposition of polyatomic molecules. The calculation becomes particularly simple when the molecule can be described with acceptable precision by a model consisting of a system of s harmonic oscillators and r rotators. In the semi-classical approximation we have

$$\rho(E) = \frac{F_{rot}}{(kT)^{s/2}}\,\frac{(E+E_z)^{s+r/2-1}}{\Gamma(s+r/2)\,\Pi\hbar\omega_i} \quad (2.17)$$

where the zero-point vibration energy E_z is expressed in terms of the vibration frequency ω_i of the molecule AB by the relation

$$E_z = \frac{1}{2}\sum_i \hbar\omega_i \quad (2.18)$$

and F_{rot} denotes the rotational partition functions. Inserting (2.17) into (2.15) and taking $\rho(D+\epsilon)$ out of the integral at the point $\epsilon = 0$, we obtain

$$A_1 = \frac{Zg_{el}}{(s+r/2-1)!}\,\frac{(D+E_z)^{s+r/2-1}kT^{1-r/2}}{\prod_{i=1}^{s}\hbar\omega_i}\prod_i[1-\exp(-\hbar\omega_i/kT)]. \quad (2.19)$$

In this expression we have placed in evidence the term g_{el}, which allows for the contribution of electronically excited states lying below the dissociation threshold to the rate of decomposition. Formula (2.19) is correct within the following limitations, which are necessary to justify the use of Eqn. (2.17) and the approximation made in the integration of Eqn. (2.14):

$$D \gg skT, \quad (2.20a)$$

$$D > \sqrt{s}E_z . \quad (2.20b)$$

Formal insertion of the limit $s \to 1$ in Eqn. (2.19) leads (for $\hbar\omega/kT \ll 1$) to the well-known formula of the simplest collision theory if we put $g_{el} = 1$. This formula does not take account of the perturbation of the equilibrium distribution brought about by the decomposition.

In the classical limit Eqn. (2.19) leads to

$$A_1 \to Z_0 g_{el}\left(\frac{D+E_z}{kT}\right)^{s+r/2-1}\Big/\left(s-1+\frac{r}{2}\right)! \quad (2.21)$$

We now turn to a discussion of formula (2.16). In all real systems the functions $\langle\Delta E^2\rangle$ and $\rho(E)$ vary more slowly than exponentially for $E/kT \gg 1$. Hence, to evaluate the temperature dependence of A these functions can be taken out of the integral at the point $E = E_0$, that is, we can assign the energy transferred and the density of levels to states lying below the dissociation boundary by an amount kT. This leads to the expression

$$A_2 = Z_0 g_{el}\,\frac{\langle\Delta E^2\rangle}{(kT)^2}\,\rho(E_0-kT)\,\delta E\prod_{i=1}^{s}[1-\exp(-\hbar\omega_i/kT)]. \quad (2.23)\ddagger$$

In this expression the energy interval δE, which characterises the width of the region in which the equilibrium distribution is substantially disturbed, can be determined only by evaluating the integral in (2.16). As applied to the oscillator model of a polyatomic molecule, Eqn. (2.23) can be re written

$$A_2 = Z_0 g_{el}\,\frac{1}{2}\,\frac{\langle\Delta E^2\rangle}{kT}\,\frac{(E_0+E_r)^{s-1}}{\prod_{i=1}^{s}(\hbar\omega_i)}\prod_{i=1}^{s}[1-\exp(-\hbar\omega_i/kT)]. \quad (2.24)$$

In the classical limit ($\hbar\omega_i \ll kT$), expression (2.23) takes the form

$$A_2 = Z_0 g_{el}\,\frac{1}{2}\,\frac{\langle\Delta E^2\rangle}{(kT)^2}\left(\frac{E_0+E_n}{kT}\right)^{s-1}\Big/(s-1)! \quad (2.25)$$

Unlike formula (2.21), this expression contains the factor $\frac{1}{2}\langle\Delta E^2\rangle/(kT)^2$, which should be much smaller than unity as long as diffusion theory applies. However, if we put $\langle\Delta E^2\rangle \simeq (kT)^2$, Eqn. (2.25) is formally converted into (2.21). The temperature dependence introduced by this term cannot be established in general. A few conclusions

‡ No Eqn. (2.22) in Russian (Ed. of Translation).

are possible only if the anharmonicity of the vibrations is large, so that collisions have a high probability of leading to combination transitions in which various normal vibrations are excited and deactivated at the same time. No limits are imposed on the magnitude of the energy transferred. The only criterion which can probably be applied to evaluate $\langle\Delta E^2\rangle$ is the criterion put forward by Massey: the energy transferred with the highest probability is ΔE^*, defined by the condition

$$\Delta E^*/\hbar\alpha\bar{v} \sim 1 \qquad (2.26)$$

where $\bar{v}$ is the mean velocity of the colliding molecules and α^{-1} is the radius of action of the intermolecular potential. From (2.26) we arrive at

$$\langle\Delta E^2\rangle/(kT)^2 \sim \frac{1}{T} \qquad (2.27)$$

by putting $(\Delta E^*)^2 \simeq \langle\Delta E^2\rangle$ which is consistent with the condition (2.27). The stepwise excitation mechanism introduces an additional factor (T^{-1}) as compared with the strong collision mechanism.

These general ideas need to be made more precise before they can be applied to diatomic molecules. In general, there is no way of predicting which of the activation mechanisms will apply to the dissociation of diatomic molecules. Only in the simplest example—dissociation in an inert gas atmosphere—can we assert that excitation will be by the stepwise mechanism (see below). The non-equilibrium distribution function for vibrational states is zero at $E_{vibr} > D$ in the decomposition of diatomic molecules whatever the activation mechanism. Below the dissociation threshold the distribution function is close to its equilibrium value for strong collisions, and is very different from its equilibrium value (although it approaches it on moving away from the threshold) for stepwise excitation.

Expression (2.23) must be slightly modified for diatomic molecules. This is because rotation of the molecule causes significant distortion of the potential curve, thus altering the effective dissociation energy. Therefore, strictly speaking, the dissociation of a diatomic molecule cannot be described only in terms of diffusion in total energy space: we must also take into consideration diffusion in angular momentum space. In this instance, allowance for the rotational partition function F_{AB}^{rot} introduces into Eqn. (2.23) the factor g_{rot}, which has a weak temperature dependence ($g_{rot} \simeq T^{-1/2}$–$T^{-1/3}$). If the reduced mass of A and B is less than (or of the same order as) the reduced mass of AB and M, one-quantum transitions will take place up to the dissociation limit. Here we put $\langle\Delta E^2\rangle \simeq (\Delta E^*)^2$, $\rho(E_0 - kT) \simeq 1/\Delta E^*$. These lead to the expression

$$A_2 \simeq Z g_{el} g_{rot} \frac{\Delta E^*}{kT}[1 - \exp(-\hbar\omega/kT)]. \qquad (2.28)$$

In the opposite case, when dissociation of a heavy diatomic gas is proceeding in an atmosphere of a lighter gas, the average energy transferred $\langle\Delta E^2\rangle$ can be obtained (impulsive approximation) by considering the two-body collisions A–M and B–M. In this approximation we can write

$$\langle\Delta E^2\rangle \sim \frac{\mu_{AB-M}}{\mu_{AB}} E_{kin}^{AB}\, kT\,, \qquad (2.29)$$

where E_{kin}^{AB} is the mean kinetic energy of the nuclei of the AB molecules. A detailed investigation[12,13] has shown that the product $\rho(E)E_{kin}^{AB}$ close to the dissociation boundary, which appears in the general expression (2.23) for the rate constant, is relatively insensitive to the model chosen for the decomposing molecule. In particular, identical temperature dependences of A_2 are obtained for a chopped harmonic oscillator and for a Morse oscillator:

$$A_2^{harm} \sim A_2^{Morse} \sim Z g_{el} g_{rot}\,[1 - \exp(-\hbar\omega/kT)]\,. \qquad (2.30)$$

Formulae (2.18) and (2.30) have been obtained for different limiting assumptions regarding the parameter which determines the effectiveness of energy transfer—the ratio of the collision time $\tau \simeq 1/\alpha\bar{v}$ to the vibration period of the nuclei $1/\omega$. Hence we may assume that in all intermediate cases the temperature dependence of the pre-exponential term A describing the dissociation of diatomic molecules will be of the form

$$A \sim T^{1/2}[1 - \exp(-\hbar\omega/kT)]g_{rot}(T)\,. \qquad (2.31)$$

Experiments in shock tubes at high temperatures ($\hbar\omega/kT \ll 1$) lead to an expression of the type of (2.31) for the dissociation of diatomic molecules in an inert gas atmosphere. If, on the other hand, the dissociation takes place in an atmosphere of the diatomic gas or in an atmosphere of a monatomic gas of the same element (for example, dissociation of O_2 by O_2–O_2 and O_2–O collisions), the experimentally observed value of the factor A shows a stronger, negative temperature dependence than predicted by the above theory. A theoretical explanation of this discrepancy involves making allowance for energy transfer between the vibrational, rotational, and translational degrees of freedom of the reactants, and also evaluating possible non-adiabatic effects. Unfortunately, reliable calculations of these processes are still lacking.

Intermediate Pressure Region

In the transition region between first-order and second-order reactions the observed rate of decomposition is determined by competition between intermolecular and intramolecular energy exchange processes. Therefore, in addition to the considerations of activation and deactivation mechanisms discussed above, the theory must include assumptions on the kinetics of energy redistribution within the molecule. These kinetics are characterised by the distribution function $h(\tau)$ of active molecules over the relaxation times τ. The available information on the function $h(\tau)$ is mainly based on a theoretical study of model systems and does not allow us to relate the distribution function uniquely to the dynamic characteristics of real molecules[14]. Therefore, calculations of the constant k in the intermediate pressure region usually involve the assumption of instantaneous statistical redistribution of the energy within the molecules§. This is equivalent to assuming an exponential form of the function $h(\tau)$:

$$h(\tau) = k(E)\exp[-k(E)\tau]\,, \qquad (2.32)$$

where $k(E)$ is the rate constant of the spontaneous decomposition of the active molecule. If we adopt the hypothesis (2.32), we can find the rate constant $k(E)$ by solving the kinetic equations describing the spontaneous decomposition and relaxation in terms of the two alternative activation mechanisms. Of course, the strong collision mechanism and the stepwise activation mechanism lead to different general expressions for $k(T)$. We note only that a relatively simple formula, often used to interpret experimental

§ The term instantaneous in this context means that the characteristic time for the statistical redistribution is much smaller than the time between successive collisions.

results, can be obtained solely from the strong collision mechanism. It is of the form

$$k = \frac{kT}{2\pi\hbar}\frac{F_1^+}{F_1F_2}\exp(-E_0/kT)\int_{E^+=0}^{\infty}\frac{g^+W_2^+(E^+)\exp(-E^+/kT)\,dE^+/kT}{1+g^+W_2^+(E^+)/2\pi\hbar\rho_2(E_0+E^+)Z}, \quad (2.33)$$

where, to avoid excessive complication, the contribution of adiabatic degrees of freedom has been ignored¶ and $\chi = 1$ has been assumed.

We cannot write an explicit expression for $k(T)$ using the stepwise excitation mechanism in the transition region, because the non-equilibrium distribution function must be determined by solving a system of related equations or from the Fokker–Planck equation. A few results have been obtained for relatively simple models discussed by Nikitin[16].

3. RECOMBINATION

The rate of recombination—the reverse process to dissociation—can be calculated in terms of the rate of dissociation and the thermodynamic equilibrium constant. In spite of the fact that both dissociation and recombination produce a disturbance of the equilibrium distribution, there are conditions under which the following relation holds true:

$$k_d/k_r = K_{eq}\ . \quad (3.1)$$

We shall not discuss them here: the reader is referred to the literature[17-26]. We shall only point out that two limiting regions of pressure exist also for recombination, corresponding to third-order and second-order kinetics respectively, as well as a transition region of pressures. Since the following equality applies

$$K_{eq} = F_AF_B/F_{AB}\exp(-D/kT)\ , \quad (3.2)$$

the recombination constant can be written, in terms of the factor $A(T)$ which characterises the rate of decomposition, in the form

$$k_r = A(T)\frac{F_{AB}}{F_AF_B}\ . \quad (3.3)$$

We shall discuss this expression in greater detail for the case of recombination of atoms. Using the fact that $Z \simeq T^{1/2}$ and $F_AF_B \simeq T^3f_A^{el}f_B^{el}$, we arrive at the following expression for the temperature dependence of k_r:

$$k_r \simeq Zg_{el}g_{rot}\ \frac{\Delta E^*}{kT} = \frac{T^{3/2}T}{T^3f_A^{el}\ f_B^{el}}\,g_{el}\,g_{rot}\ \frac{\Delta E^*}{kT}\ . \quad (3.4)$$

Eqn. (3.4) assumes the single-quantum transition model, whereas Eqn. (3.5) is based on the diffusion model ignoring the temperature dependence of f_A^{el} and f_B^{el}:

$$k_r \simeq Zg_{el}g_{rot}\ \frac{\langle\Delta E^2\rangle}{2(kT)^2}\rho(E_0-kT)\frac{T^{3/2}T^2}{T^3f_A^{el}f_B^{el}} \simeq g_{el}\,g_{rot}\ \frac{\langle\Delta E^2\rangle}{kT}\rho(E_0-kT) \quad (3.5)$$

In many instances, however, the electronic part of the partition functions of atoms is a sensitive function of temperature because of the contribution from the lower excited states, and this must of course be taken into consideration when calculating the temperature dependence of the constant k_r by formula (3.3).

¶ The influence of adiabatic degrees of freedom, which is relatively small for polyatomic molecules, has been considered in the work of Marcus[15].

If the molecule is described approximately by means of a Morse oscillator, the quantity ΔE^* is evaluated by the Massey criterion (2.26), and account is taken of the temperature dependence of g_{el}, the following equation can be derived from Eqns. (3.4) and (3.5):

$$k_r \simeq g_{rot}\ (T)\frac{\Delta E^*}{kT} \simeq T^{-m-1/2},\ m \simeq 1/2 \text{ to } 1/3. \quad (3.6)$$

Thus, the theory predicts a negative temperature coefficicient for the rate constant of recombination. However, the following restrictions must be borne in mind.

Firstly, Eqns. (3.4), (3.5), and (3.6) have been derived on the assumption that the third body M is an inert gas atom. If internal degrees of freedom in M can play a significant role in the deactivation of the excited AB pair, the temperature dependence of the constant k_r may be different from Eqn. (3.6). We may assume that the main difference will be that here the quantity ΔE^* is not given by formula (2.26).

Secondly, the possibility of recombination through the formation of an intermediate complex has been ignored in the derivation of Eqns. (3.4) and (3.5):

$$A + M \rightarrow AM \quad (3.7a)$$

$$AM + B \rightarrow AB + M\ . \quad (3.7b)$$

In this recombination mechanism the constant k_r must contain the exponential term $\exp(\epsilon/kT)$, arising essentially because the recombination reaction involves bound AM pairs with a bond energy ϵ. The value of ϵ varies between 0.5 and 5 kcal mole^{-1} for different molecules†. Hence expressions of the type of (3.6) are applicable only at relatively high temperatures, when $\epsilon/kT \ll 1$.

Lastly, we should note that when recombination occurs under conditions such that three-body A + A + A collisions are significant, the temperature dependence of the recombination constant may be noticeably affected by the exchange reaction[27]

$$A_2 + A \rightarrow A + A_2\ . \quad (3.8)$$

Direct experimental evidence exists that the reaction (3.8) is important in the vibrational relaxation of diatomic molecules even at low levels[28]. Since the rate of reaction (3.8) must increase as the vibrational energy of the A_2 molecule increases, it is reasonable to expect that reaction (3.8) can provide an effective means of removing energy from the latterly formed A_2 molecule in the vibrational deactivation of the higher states.

The recombination of oxygen in an argon atmosphere[29] is one of the few examples of recombination processes for which the temperature dependence of the rate constant has been definitely characterised.

4. EXCHANGE

Exchange reactions, like dissociation and recombination, can give rise to varying degrees of disturbance of the equilibrium distribution. However, unlike the other reactions, the exchange reaction does not usually show a change in reaction order due to disturbance of the equilibrium distribution. This is because both the relaxation and particularly the redistribution of atoms occur during collisions of molecules of the same type. Perturbation of the equilibrium distribution will change the order of the reaction

† This mechanism was studied in detail by Rice[26].

with respect to the concentration of the reacting molecules only if conditions are such that relaxation and exchange occur as a result of collisions between different molecules. We shall deal later with one example of a process of this type, but first we must discuss the calculation of $k_{ex}(T)$ within the bounds of equilibrium theory. This approximation is known to be realistic for exchange reactions occurring in a dense atmosphere of inert gas, which ensures sufficiently fast relaxation.

Starting with the basic formula of the transition state method, we shall consider processes involving three or four atoms. Take the simplest exchange process, of the type

$$A + BC \rightarrow AB + C \ . \qquad (4.1)$$

We note that the critical surfaces S^+ are chosen in different ways according to whether or not the reaction involves an activation energy. For surfaces with a potential barrier the reaction coordinate is most naturally identified as the line of fastest descent from the saddle point. We assume that rotation can be separated from vibration and from motion along the reaction coordinate, both in the starting systems and in the activated complex. Then the general formula of the transition state method can be written in detail as follows:

$$k_{ex} = \frac{kT}{2\pi\hbar}\varkappa g^+ \frac{F^+_{AB}}{F_A F_B}\exp(-E_a/kT) =$$

$$= \frac{kT}{2\pi\hbar}\varkappa g^+ \frac{(F^+_{AB})_{tr}\,(F^+_{AB})_{vibr}(F^+_{AB})_{rot}}{(F_AF_B)_{tr}\,(F_AF_B)_{vibr}(F_AF_B)_{rot}}\exp(-E_a/kT) \ . \quad 4.2)$$

Having thus adopted a concrete model for S^+, we find that the partition function F^+ in the general formula (4.2) acquires a definite meaning: $(F^+_{AB})_{rot}$ is calculated as the partition function of a solid with atoms fixed at the points q^+_i, and $(F^+_{AB})_{vibr}$ as the partition function of a system of harmonic oscillators with normal frequencies ω^+_i, referred to the non-rotating system of atoms with a fixed value of the reaction coordinate q^+_r.

For a reaction involving three atoms, the expression for k_{ex} takes different forms for linear and triangular complexes. In the former we have three vibrational and two rotational degrees of freedom; In the latter, two vibrational and three rotational. The temperature dependence of k is as follows:

linear complex

$$k_{ex} \simeq T^{1/2}\frac{(1-e^{-\hbar\omega_{BC}/kT})}{\prod_{i=1}^{2}(1-e^{-\hbar\omega^+_i/kT})}\exp(-E_a/kT) =$$

$$= \begin{cases} T^{-1/2}\exp(-E_a/kT), & \hbar\omega_i/kT \gg 1 \qquad (4.3a) \\ T^{3/2}\exp(-E_a/kT), & \hbar\omega_i/kT \ll 1\ ; \qquad (4.3b) \end{cases}$$

triangular complex

$$k_{ex} \sim \frac{(1-e^{-\hbar\omega_{BC}/kT})}{\prod_{i=1}^{3}(1-e^{-\hbar\omega^+_i/kT})}\exp(-E_a/kT) = \begin{cases} \exp(-E_a/kT), & \hbar\omega_i/kT \gg 1 \ (4.4a) \\ T\exp(-E_a/kT), & \hbar\omega_i/kT \ll 1 \ (4.4b) \end{cases}$$

We can follow the transition between these two examples by taking account of the interaction between vibrations and rotation in the calculation of F^+, and by abandoning the "rigid rotator–harmonic oscillator" model used for computing the spectroscopic approximation. The rate constant expressed in the form of (4.4) is applicable only to a complex ABC^+ in which the angular departure from the linear configuration is significantly larger than the angular amplitude of the bending vibrations. As regards the temperature dependence of the pre-exponential term in (4.3) and (4.4) we note that at low temperatures the indicated dependence will apply only as long as the tunnel corrections can be ignored. The limitation at high temperatures arises from the condition that the mean vibration amplitude must be small as compared with the effective width of the potential well $1/\alpha$‡. This limitation can be expressed as a requirement that the value of the full pre-exponential factor must be substantially less than the number of collisions given by gas kinetics. If the relationship

$$\frac{kT}{2\pi\hbar}\frac{F^+_{ABC}}{F_A F_{BC}} < Z_{A-BC} \ , \qquad (4.5)$$

were formally found not to be obeyed, we would need to use as pre-exponential term the factor Z_{A-BC}, which gives a $T^{1/2}$ temperature dependence[30] to the pre-exponential term instead of $T^{3/2}$ as in (4.3) or T as in (4.4).

We shall now consider the potential energy surface in the absence of an activation barrier. The situation is typical of ion–molecule reactions, and can also arise in the reaction of various atoms with molecules.

If the interaction between the species A and BC at large enough distances corresponds to attraction, the reaction rate is in many instances determined by the rate of formation of the long-lived ABC* complex. In practice, of course, the complex ABC* can decompose either in the direction of AB + C or in the direction of A + BC, but conditions are often met when decomposition in the reverse direction can be ignored. With these assumptions, reaction (4.1) can be described by the following model: if the radial velocity of the approaching particles is sufficient to overcome the centrifugal barrier, the complex ABC* is formed, and then decomposes into the molecules AB + C. If the interaction potential is centro-symmetrical the model is described by a critical surface S^+ coinciding with a sphere of radius R_m corresponding to the coordinate of the centrifugal barrier.

Such an S^+ surface is determined not only by the characteristics of the potential, but also by the integrals describing the motion of the system under study, since R_m depends on the angular momentum of the relative motion of A and BC.

Calculations of this type[31] for potentials $U(R) \simeq R^{-s}$, with $s = 4$ (polarisation interaction) and $s = 6$ (van der Waals interaction) lead to the following expressions for the rate constants

$$k_{ex} = 2\pi e\,(\alpha/\mu)^{1/2} \ , \qquad (4.6)$$

$$k_{ex} = 2^{3/2}\,3^{1/2}\,\Gamma(2/3)\frac{\pi^{1/2}}{\sigma^+}(kT)^{1/6}\left[\frac{\alpha_1\alpha_2 I_1 I_2}{I_1+I_2}\right]^{1/2}\mu^{-1/2} \ . \qquad (4.7)$$

Here α denotes the polarisability of the neutral partner in an ion–molecule reaction characterised by the polarisation potential $U(R) = -e^2\alpha/2R^4$; α_1 and α_2 are the polarisabilities of the neutral partners, for which the long-range component of the potential can be approximated by the expression involving the ionisation potentials I_1 and I_2 of the partners $U(R) = \frac{1}{2}\frac{\alpha_1\alpha_2}{R^6}\frac{I_1 I_2}{I_1+I_2}$. It is important to note that the partition functions for the internal motion of the partners do not appear in (4.6) and (4.7). This is

‡ This limitation allows us to separate rotation from vibrations, and also to treat vibrations by the harmonic approximation.

simply because with the critical surface S^+ assumed here the reaction (that is, the intersection of S^+) occurs at such large distances that the contributions of internal motions to F and F^+ can be taken to be identical and drop out of the ratio F^+/F.

It is permissible to ignore the short-range part of the potential in the calculation of R_m only if R_m is much greater than the gas-kinetic cross-section R_0. This sets a high-temperature limit to the validity of expressions (4.6) and (4.7): the condition

$$k_{ex} > Z_0 . \qquad (4.8)$$

which states that only the long-range part of the potential contributes to the rate constant, must apply.

We shall now discuss the way in which formulae (4.3) and (4.4) are related to the expression (1.1).

If we describe the rate constant of our exchange process by the Arrhenius formula (1.1) with a constant factor, and if we express the exponential functions of temperature for the low- and the high-temperature regions in the form

$$T^n = (e\bar{T}_l)^n \exp(-nkT_l/kT), \qquad (4.9a)$$

and

$$T^m = (e\bar{T}_h)^m \exp(-mkT_h/kT), \qquad (4.9b)$$

where $\bar{T}_l$ and $\bar{T}_h$ denote some mean temperature in the low- and in the high-temperature region respectively, we obtain

$$E_l = E_0 + nk\bar{T}_l, E_h = E_0 + mk\bar{T}_h. \qquad (4.10)$$

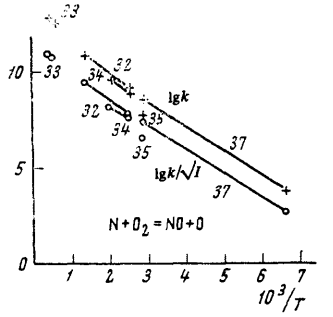
Hence,

$$\Delta E = E_h - E_l = k(m\bar{T}_h - n\bar{T}_l) . \qquad (4.11)$$

Since, according to formulae (4.3) and (4.4), we have $n = -\frac{1}{2}$ and $m = \frac{3}{2}$ for a linear complex and $n = 0$ and $m = 1$ for a triangular complex, in the former instance expression (4.11) takes the form

$$\Delta E = \frac{k}{2}(3\bar{T}_h - \bar{T}_l) \qquad (4.12a)$$

and in the latter



$$\Delta E = k\bar{T}_h . \qquad (4.12b)$$

We see that in both the quantity ΔE is greater than 0, that is, $E_h > E_l$. Thus, the activated complex theory requires that the activation energy should not remain constant on going from low to high temperatures but should increase with increase of temperature if the rate constant of an exchange process is described by the Arrhenius law (1.1).

The following example confirms the conclusions of the theory. One of the constants for which the numerical values obtained by different workers show the most satisfactory agreement is the rate constant of the reaction

$$N + O_2 \rightarrow NO + O + 32\ \text{kcal mole}^{-1}. \qquad (4.13)$$

Data obtained by the formulae proposed by different authors [32-37] for the appropriate temperature ranges are graphically compared in the Figure, where the quantities $\lg k_{ex}$ or $\lg[k_{ex}/\sqrt{T}]$ are plotted as ordinate and $10^3/T$ is the abscissa. It is evident from the Figure that neither $\lg k_{ex}$ nor $\lg[k_{ex}/\sqrt{T}]$ is a linear function of $1/T$. It follows that formulae (1.1) and (1.2) do not adequately describe this constant over the whole of the experimental temperature range (145-3300°K). It can also be seen from the Figure that, as the above theory requires, the effective activation energy increases with increase of temperature.

Temperature dependence of the rate constant of the reaction $N + O_2 \rightarrow NO + O$. The numbers by the points are literature references.

The following considerations also militate against the description of the rate constant of an exchange reaction by a formula of type (1.1) or (1.2) over a wide temperature range. The temperature dependence of the equilibrium constant of the reaction A + BC = AB + C is given by the expression

$$K_{eq} \simeq \frac{1-\exp(-\hbar\omega_{BC}/kT)}{1-\exp(-\hbar\omega_{AB}/kT)} \exp(-Q_0/kT). \qquad (4.14)$$

Since the equilibrium constant is the ratio of the rate constants for the forward and the reverse reaction, expressing these constants by Arrhenius formulae of the type (1.1) or (1.2) gives

$$K_{eq} = \frac{A}{A'} \exp[-(E_0 - E_0')/kT)] = \frac{A}{A'} \exp(-Q_0/kT)], \qquad (4.15a)$$

$$K_{eq} = \frac{A_0\sqrt{T}}{A_0'\sqrt{T}} \exp[-(E_0 - E_0')/kT) = \frac{A_0}{A_0'} \exp(-Q_0/kT). \qquad (4.15b)$$

Comparing these formulae with (4.10) we see that A and A' (or A_0 and A_0') can be treated as constant and temperature-independent only when $\omega_{BC} = \omega_{AB}$. Thus, if, for example, $\omega_{AB} = 2\omega_{BC}$, the quantity

$$[1 - \exp(-\hbar\omega_{BC}/kT]/[1 - \exp(-\hbar\omega_{AB}/kT)]$$

and therefore also the ratio A/A' or A_0/A_0', will decrease by a factor of two on going from the low-temperature to the high-temperature region.

The ratio of the pre-exponential factors should be even more clearly a function of temperature for an exchange reaction of the type

$$AB + CD \rightarrow ABC + D . \qquad (4.16)$$

The temperature dependence of the equilibrium constant, making the same assumptions as in (4.1), should now be given by the expression

$$k_{ex} \simeq T^{-1/2} \frac{(1-e^{-\hbar\omega_{AB}/kT})(1-e^{-\hbar\omega_{CD}/kT})}{\prod_{i=1}^{3}[1-\exp(-\hbar\omega_{ABC}^i/kT)]} \exp(-Q_0/kT). \qquad (4.17)$$

In the low-temperature region this leads to

$$k_{ex} \simeq T^{-1/2} \exp(-Q_0/kT) , \qquad (4.18)$$

and in the high-temperature region

$$k_{ex} \simeq T^{1/2} \exp(-Q_0/kT). \qquad (4.19)$$

The basic postulate of the transition state method, concerning the possibility of introducing a single reaction coordinate, cannot be tested by comparing theory with experiment because, on the one hand, the characteristics of the potential energy surface are not usually known, and on the other hand the degree of perturbation of the equilibrium distribution is not known. Therefore it is particularly interesting to compare the values of $k_{ex}(T)$ calculated for the same model by the transition state method and by averaging the occurrence of the reaction over the equilibrium distribution function. Calculation of σ is possible only with the help of fast computers, and only within the limits of classical mechanics for the present. Such a comparison made by Karplus and coworkers [38] for the reaction H + H_2, does not allow us to assess unequivocally the precision of the transition state method, but it provides evidence that no serious error is introduced into the temperature dependence of the rate constant $k_{ex}(T)$ by using this method. Similar investigations were recently carried out by Marcus [39,40].

Thus, it is at least possible that the transition state method will provide an acceptable estimate of the temperature dependence of $k(T)$ provided that the reaction does not significantly disturb the equilibrium distribution. It is essential, of course, to take account of the temperature dependence of the transmission coefficient for non-adiabatic reactions and reactions with light atoms, as in formulae (2.3)-(2.7).

Theoretical attempts to explain the influence of perturbation of the equilibrium distribution on the rate of an exchange reaction have concentrated not so much on calculating the non-equilibrium rate constant as on defining the conditions under which the effect is small [41-44]. It was assumed that the cross-section of the reaction depends on the relative kinetic energy, but no attempt was made to derive a concrete expression. Since the Maxwell distribution is re-established in a very short time—after a few collisions—an exchange reaction involving a sufficiently high activation energy cannot significantly affect the equilibrium distribution of velocities. This ceases to be true when the main contribution to overcoming the energy barrier is provided by the vibrational energy of the partners. We cannot exclude the situation in which the rate of vibrational relaxation is comparable with or even smaller than the rate of reaction calculated on the assumption that the Boltzmann distribution in the vibrational states is preserved. Then the true rate of the exchange reaction will be determined only by the rate of vibrational relaxation, or rather by the rate at which the reacting molecules reach the particular vibrational level which makes the largest contribution to the cross-section of the reaction. In this sense we have complete analogy with unimolecular reactions, for which the rate of decomposition at low pressures is determined by the rate of vibrational excitation of the molecules. Since the temperature dependence of the vibrational relaxation time is described not by the Arrhenius formula (1.1) but by the Landau-Teller formula [4]

$$k_{vibr} \sim \exp[-(T_0/T)^{1/3}], \qquad (4.20)$$

it may happen that the rate of an exchange reaction also will not contain an Arrhenius factor. No definite statements regarding the particular degrees of freedom which contribute most significantly to the cross-sections of various exchange reactions can as yet be made.

The study [38] of the H + H_2 → H_2 + H reaction, already mentioned, showed that the main contribution to overcoming the activation barrier comes from kinetic energy. This points to a relatively insignificant disturbance of the equilibrium distribution by the reaction. On the other hand, in a reaction of the type $H_2 + D_2 \rightarrow HD + HD$ the main contribution may come from the vibrational energy of the partners, since the decomposition of the $[H_2D_2]$ complex into two HD fragments is caused by vibrations. In this example a substantial disturbance of the equilibrium distribution can be expected. A recent investigation by Bauer and coworkers [45,46] has shown that the kinetics of this reaction do not obey a second-order law, and that the rate depends on the concentration of argon (used only as a thermal reservoir to ensure vibrational relaxation of H_2 and D_2). This change in reaction order is evidence of a disturbance in the equilibrium distribution§, and therefore that the transition state method is not applicable to the calculation of $k_{ex}(T)$. Unfortunately, no alternative method of calculating the rate constant can be suggested at present.

I. INTRODUCTION

Diene polymers are now the most widely used of all known polymeric materials. The polymerisation of dienes leads to the production of elastomers which acquire all the necessary properties during further treatment (plasticising, vulcanising). In addition to the problem of the processing and modification there is the problem of stabilising the polymer material. The effective solution of these problems is impossible without a knowledge of the chemical nature of the polymers used.

It is necessary to point out that there has not yet been any detailed investigation of the reactivity of diene polymers as a class of organic compounds. Most of the studies in the field of the chemistry of diene polymers are of an applied nature and are connected with the study of the vulcanisation and stabilisation of polymers or are directed to the study of individual reactions of diene polymers, such as chlorination, hydrochlorination, etc. At the same time, without knowing the general features of the chemistry of diene polymers it is impossible to carry out effectively work of an applied character, directed to the solution of particular practical problems.

The present review aims to be a critical consideration and systematisation of the published information on the chemistry of diene polymers up to the end of 1965. An attempt has been made to find the characteristics of the double bonds in polymers having a regular 1,5-polyene structure. The review does not attempt a detailed examination of the information on vulcanisation and oxidation that has appeared in monographs.

II. ADDITION TO A DOUBLE BOND

1. Reaction with Compounds Containing a Mercapto-Group

The reactions of hydrogen sulphide and thiols with alkenes have been studied in detail by Naylor[1]. Under the catalytic action of sulphur, hydrogen sulphide is readily added at the double bond of polyisoprene in accordance with the Markovnikov rule. The thiol formed can react with another double bond to give a sulphide. The oxidation of two thiols leads to the formation of a disulphide. As a result of the last two reactions, cross-linking of the macromolecules of the rubber takes place. In the presence of a peroxide or on ultraviolet irradiation, hydrogen sulphide adds at the double bond of polyisoprene contrary to the Markovnikov rule.

The addition of alkyl and aryl thiols to a double bond also proceeds in accordance with the Markovnikov rule in the presence of sulphur and contrary to the rule when the reaction is carried out in the presence of peroxide[2]. The easier it is for homolytic rupture of the S–H bond, the greater the acidity of the thiol, and the more active the thiol relative to the double bond. Prilezhaeva and Shostakovskii[3] give the following series for the activity of thiols in relation to alkenes:

$$C_6H_5SH > HOOC.CH_2SH > RCH_2SH > R_2CHSH > R_3C.SH.$$

Electron-donating groups in the thiyl [mercapto-] radical reduce its reactivity towards double bonds; electron-withdrawing groups, on the other hand, increase its activity. A drop in the electron density of the double bond leads to a decrease in its reactivity towards thiols.

I. INTRODUCTION

Diene polymers are now the most widely used of all known polymeric materials. The polymerisation of dienes leads to the production of elastomers which acquire all the necessary properties during further treatment (plasticising, vulcanising). In addition to the problem of the processing and modification there is the problem of stabilising the polymer material. The effective solution of these problems is impossible without a knowledge of the chemical nature of the polymers used.

It is necessary to point out that there has not yet been any detailed investigation of the reactivity of diene polymers as a class of organic compounds. Most of the studies in the field of the chemistry of diene polymers are of an applied nature and are connected with the study of the vulcanisation and stabilisation of polymers or are directed to the study of individual reactions of diene polymers, such as chlorination, hydrochlorination, etc. At the same time, without knowing the general features of the chemistry of diene polymers it is impossible to carry out effectively work of an applied character, directed to the solution of particular practical problems.

The present review aims to be a critical consideration and systematisation of the published information on the chemistry of diene polymers up to the end of 1965. An attempt has been made to find the characteristics of the double bonds in polymers having a regular 1,5-polyene structure. The review does not attempt a detailed examination of the information on vulcanisation and oxidation that has appeared in monographs.

II. ADDITION TO A DOUBLE BOND

1. Reaction with Compounds Containing a Mercapto-Group

The reactions of hydrogen sulphide and thiols with alkenes have been studied in detail by Naylor[1]. Under the catalytic action of sulphur, hydrogen sulphide is readily added at the double bond of polyisoprene in accordance with the Markovnikov rule. The thiol formed can react with another double bond to give a sulphide. The oxidation of two thiols leads to the formation of a disulphide. As a result of the last two reactions, cross-linking of the macromolecules of the rubber takes place. In the presence of a peroxide or on ultraviolet irradiation, hydrogen sulphide adds at the double bond of polyisoprene contrary to the Markovnikov rule.

The addition of alkyl and aryl thiols to a double bond also proceeds in accordance with the Markovnikov rule in the presence of sulphur and contrary to the rule when the reaction is carried out in the presence of peroxide[2]. The easier it is for homolytic rupture of the S–H bond, the greater the acidity of the thiol, and the more active the thiol relative to the double bond. Prilezhaeva and Shostakovskii[3] give the following series for the activity of thiols in relation to alkenes:

$$C_6H_5SH > HOOC.CH_2SH > RCH_2SH > R_2CHSH > R_3C.SH.$$

Electron-donating groups in the thiyl [mercapto-] radical reduce its reactivity towards double bonds; electron-withdrawing groups, on the other hand, increase its activity. A drop in the electron density of the double bond leads to a decrease in its reactivity towards thiols.

Conjugated, vinyl, terminal double bonds, and also double bonds in rings react readily with thiols, but inner non-conjugated double bonds are less reactive towards thiols[4].

Natural rubber exhibits a low reactivity towards thiols. It does not react with ethyl thiol, isopentyl thiol, thiophenol[5], or tri- and hexa-methylenedithiols[6] when the reaction is performed in an inert medium in the presence of peroxide or under ultraviolet irradiation. At the same time the addition of thiols to low-molecular-weight alkenes, which model the structure of polyisoprene, does take place under analogous conditions. Cunneen found the following series for the activity of alkenes in relation to thiols: cyclohexene > dihydromyrcene > squalene > natural *cis*-polyisoprene.

The addition of thiols to the double bonds of diene polymers takes place when atmospheric oxygen participates in the reaction as a third component or when the reaction is carried out in latex. Hull and coworkers[7] vulcanised natural rubber on rollers in air with the aid of aliphatic and aromatic dithiols, inert relative to polyisoprene when the reaction is carried out in a solvent in the absence of atmospheric oxygen. Foxly[8] notes the reactivity of dodecanethiol towards polyisoprene when the reaction is performed in solution in the presence of oxygen, whereas in an inert medium these substances do not react. Dogadkin and coworkers[9] observed the reaction of thiols with polyisoprene in the presence of oxygen and the absence of reaction between them in an inert medium, even at elevated temperatures. Pierson and coworkers[10] achieved a high saturation of polybutadiene with methanethiol by carrying out the reaction in latex with an excess of the thiol at 30–60°C in the presence of azoisobutyronitrile. Serniuk and coworkers[4] described the reaction of ethanethiol with diene polymers in latex.

The reaction of thioglycollic acid and its derivatives with diene polymers has received considerable attention. It was found that when the reaction of natural polyisoprene with thioglycollic acid[5] and its esters[11,12] was carried out in an inert medium, over a wide range of temperatures, in the presence of initiators (azoisobutyronitrile, cumene hydroperoxide), and with ultraviolet irradiation, addition of the above thiols at the double bond did not occur. Nevertheless thioglycollic acid adds readily to cyclohexene, 1-methylcyclohexene, and dihydromyrcene in the presence of peroxides at room temperature, and to squalene under ultraviolet irradiation[5]. Ethyl thioglycollate adds to isopentene to 67% extent and to dihydromyrcene to 30%, but does not react with natural *cis*- and *trans*-polyisoprenes under the same conditions[11,12].

Such difference in the reactivity of the polyisoprenes and model low-molecular-weight compounds to relatively weak electrophilic agents is explained by the mutual influence of the double bonds in the 1,5-polyene systems, leading to a decrease in their electron density[13].

From the standpoint of classical chemistry, the possibility of the mutual influence of double bonds through two C–C bonds, and especially through three, is inadmissable. However, the experimental results show that a methylene bridge is not a serious impediment or high barrier for the conjugation of a chain[14]. As Voevodskii and coworkers found by the EPR method[15,16], this interaction of double bonds is also possible where there is an ethylene bridge. The establishment of the mutual interaction of double bonds through one C–C bond is accompanied by considerable drop in the energy of the molecule (5–50 kcal mole^{-1}). For the 1,5-diene this interaction energy is appreciably less, but nevertheless sufficient to show the significant influence of the double bonds on reactivity[15]. On going from a 1,5-diene to a 1,5-polyene system the energy of the mutual influence of double bonds increases, which appears as the observable drop in reactivity.

The inertness of the polyisoprenes to thioglycollic acid and its esters does not appear when atmospheric oxygen[17,18] participates in the reaction as a third component or when the reaction is effected in latex[4,19]. In the latter instance the reaction is apparently catalysed by the substances of the non-rubber part of the latex globules. The mechanism of this catalysis has not been discussed in the literature.

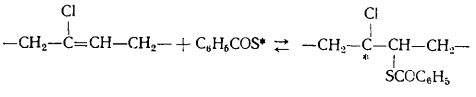
Cunneen[20] studied the reaction of thioacetic acid and its chloro-derivatives with natural *cis*-polyisoprene and with model compounds. Thioacetic acid adds quantitatively to polyisoprene in benzene on ultraviolet irradiation for several hours. In the absence of radiation the reaction does not occur even at 100–130°C. Monochlorothioacetic acid adds quantitatively to polyisoprene in the dark in the presence of ascaridole. Ultraviolet radiation accelerates the reaction. The reaction of polyisoprene with di- and trichlorothioacetic acids takes place similarly.

A comparison of the reactivity of double bonds in polyisoprene, cyclohexene, dihydromyrcene, and squalene towards thioacetic acids showed that the order of activity of these alkenes is as found for reaction with thiols.

Ritter[21,22] gives the following series for the activity of thio-acids towards natural *cis*-polyisoprene: thiocaprylic > > thiobenzoic > thio-2-naphthoic > thioacetic > thiostearic > trichlorothioacetic acid. The reaction was effected in xylene (6% solution of the polymer) in two stages. In the first stage a slight excess of the thio-acid was introduced, and the reaction was carried out at room temperature in carbon dioxide atmosphere, in the light for a week. In the second stage the product reacted with a 25% excess of the thio-acid for 8 days at room temperature in the light, in carbon dioxide atmosphere. The finding that thioacetic acid is more reactive than trichlorothioacetic contradicts Cunneen's results[20] and seems doubtful to us.

Dithioadipic and dithiosebacic acids[6] add to natural *cis*-polyisoprene on rolling, leading to cross linking of the macromolecules. Peroxides and ultraviolet irradiation accelerate the reaction. The reaction of dithioadipic acid with polyisoprene in benzene (10% solution of the polymer) reaches 45% at 100°C.

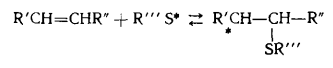
The dithio-acids obtained as a result of the replacement of both oxygen atoms of the carboxyl group by sulphur do not add to natural *cis*-polyisoprene[21].



The reaction of thiobenzoic acid with natural *cis*- and *trans*-polyisoprenes has been investigated in detail[11,12,23]. The reaction was effected in an inert medium (argon), in xylene and chlorobenzene, over a wide range of temperatures (20–125°C) and concentration range 0.05–1.0%. The polymer and thio-acid were taken in an equimolecular ratio with cumene hydroperoxide as initiator of the reaction. The reaction proceeds by a radical mechanism, and the extent of the reaction is proportional to the amount of initiator; the temperature dependence has a maximum at about 60–80°C. There is an anomalous dependence of the extent of reaction on the concentrations of the reactants, with a maximum at 0.1–0.3%, this being connected with the

association of macromolecules of polyisoprene in this concentration region. A significant difference in reactivity between *cis*- and *trans*-polyisoprenes to thiobenzoic acid was not observed.

The amount of thiobenzoic acid in the high-molecular-weight fraction of the reaction products greatly exceeds the mean consumption of the thio-acid in the reaction, which is possible only under the non-statistical occurrence of the reaction of polyisoprenes with thiobenzoic acid. The non-statistical nature of the addition of thiobenzoic acid to polyisoprenes is the result of the development of a reaction by an intramolecular chain mechanism. As noted above, in 1,5-polyene systems there is interaction of the double bonds, leading to a drop in their reactivity. The addition of molecules of the thio-acid at one double bond in such a system leads to an increase in the electron density at two neighbouring double bonds owing to the breakdown of the conditions for their interaction. Hence a single act of addition leads to the activation of two double bonds. The probability of addition of subsequent molecules of thio-acid at such double bonds increases, and subsequently the addition of thiobenzoic acid takes place selectively, that is, it is not a random double bond that reacts, but a double bond in the vicinity of the one that has already reacted. The disappearance of an activated double bond during the reaction in turn leads to the activation of a new double bond. Conditions are created for the development of a chain intramolecular mechanism of reactions of 1,5-polyene systems.



An investigation of the reaction of polychloroprene with thiobenzoic acid[24] showed the influence of the strongly electronegative atom of chlorine located at the double bond, on the reactivity of double bonds regularly alternating in the 1,5 positions. Whereas the addition of thiobenzoic acid to polyisoprenes takes place by a radical mechanism, with polychloroprene this mechanism is not realised. The introduction of up to 12 mole % cumene hydroperoxide into the reaction mixture has no effect on the rate or extent of reaction.

Evidently the macroradical which is formed as a result of the addition of a thioyl radical at a double bond:

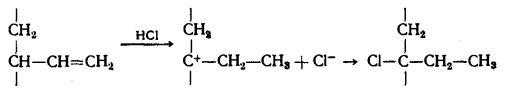
is considerably stabilised by the action of the electronegative chlorine atom and is incapable of continuing the reaction chain. An ionic mechanism for the reaction is also excluded, since the dielectric constant of the solvent, when varied within wide limits, has no influence on the rate or extent of the reaction. It was suggested that the addition of thiobenzoic acid at the double bond of polychloroprene takes place with the formation of an intermediate molecular complex.

Sivertz and coworkers' kinetic studies[25-28] showed the addition of a thiyl radical at a double bond to be highly reversible when the reaction took place in the gas or liquid phase:

As a result of the decomposition of the intermediate complex the double bond is regenerated in either the *cis*- or the *trans*-configuration. In the reaction of methanethiol with but-2-ene the rate of decomposition of the intermediate complex to form *trans*-butene is four times that to form the *cis*-butene and 80 times the rate of formation of the addition product. The high reversibility of the addition of thio-compounds at double bonds is responsible for the isomerisation of the double bonds in such reactions.

Cunneen and Shipley[29] observed the isomerisation of natural *cis*-polyisoprene during its reaction with thio-acids. Small quantities (0.1–1.0%) of chlorothioacetic, trichlorothioacetic, and thionaphthoic acids were used. The reaction was carried out in solution and in latex, under vacuum, without a catalyst, for 6 h at 100°C. Thionaphthoic acid was the most effective.

The isomerisation of the natural *cis*- and *trans*-polyisoprenes in their reaction with thiobenzoic acid was studied on rollers, in solution, and in latex[30,31]. The equilibrium ratio of *cis*- and *trans*-structures in the isomerised products was found to be 43 : 57. The high efficiency of the isomerising agent is noted—a considerable degree of isomerisation is obtained when the system has one molecule of thiobenzoic acid per 1270 isoprene links. Monochlorothioacetic, trichlorothioacetic, thionaphthoic, thiosalicylic, and thiostearic acids had similar effectiveness as isomerisation agents[32].



Results on the isomerisation of *cis*-polybutadiene in the presence of thio-compounds are somewhat contradictory. Golub[33] and Seely[34] consider that in equilibrium isomerisation the *cis*- and *trans*-isomers reach a ratio of 5 : 95. Berger and Buckley[35], on carrying out the isomerisation of *cis*- and *trans*-polybutadiene after Golub, found the equilibrium ratio of the *cis*- and *trans*-structures to be 25 : 75. The isomerisation was performed in solution at 25°C, with benzene and toluene as solvents. The isomerisation agents were thionaphthoic acid and diphenyl sulphide, the reaction was carried out under ultraviolet irradiation. The rate of isomerisation increased with the polymer concentration and with the intensity of the radiation; it was independent of concentration of the isomerising agent in the range 1–10 g litre^{-1}.

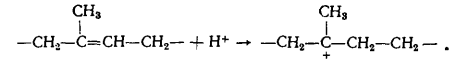
2. Reactions with Hydrogen Halides

The reaction of natural *cis*-polyisoprene with hydrogen fluoride was described by Tom[36]. The reaction was carried out in solution at temperatures between −26° and +40°C. In the addition of hydrogen fluoride to the double bonds considerable cyclisation is observed, brought about by the back reaction which eliminates HF, and with rise in temperature the rate of cyclisation increases. At 40°C, there is no addition, only cyclisation. The final product always contains some unreacted double bonds. The best solvent for the addition is xylene; there is considerable cyclisation in benzene and toluene; addition does not take place in carbon tetrachloride and chloroform. In xylene at −26°C the hydrogen fluoride added is 70% of that theoretically possible, and 25% of the double bonds participate in the cyclisation. The temperature and time dependences of the extent of the addition reaction are curves with a maximum.

The reaction of diene polymers with hydrogen chloride has received considerable attention. Hydrogen chloride adds readily to natural *cis*-polyisoprene at moderate temperatures in the bulk, in solution, and in latex[37]. In the presence of peroxide the addition proceeds by a radical mechanism contrary to the Markovnikov rule[38,39]. Synthetic polyisoprene[37] gives a product with incomplete addition. The methylated double bonds in polyisoprene are more reactive than the double bonds of polybutadiene.

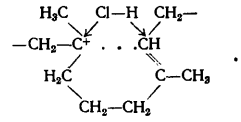
As a result of the addition of hydrogen chloride to polyisoprene a tertiary chloride is formed. The vinyl bonds in polybutadiene can also form a tertiary chloride thanks to the Whitmore rearrangement:

Staudinger[40] found a considerable decrease in the viscosity of solutions of natural *cis*- and *trans*-polyisoprenes during hydrochlorination and showed that this is the result of cyclisation taking place simultaneously with addition.



The formation of intramolecular rings during hydrochlorination of natural rubber was also observed by Gehman[41]. Later investigations were quite contradictory and indicated that either there is complete cyclisation during hydrochlorination with subsequent ring opening under the action of HCl[42] or the reaction is restricted to addition and *cis*–*trans*-isomerisation, and cyclisation does not take place at all[43,44]. This conclusion was reached by the authors from calculations of the balance of the double bonds in the reaction products. The sum of the remaining double bonds and the bonds which had disappeared as a result of the addition of chlorine is equal to the degree of unsaturation of the original polymer. Golub and Heller[45] showed, with the aid of high-resolution NMR, that hydrochlorination of natural rubber and balata is accompanied by cyclisation, whereas *cis*–*trans*-isomerisation takes place to a negligible extent or does not occur at all.

In the reaction of 3,4-polyisoprene with hydrogen chloride[46] a predominantly monocyclic structure is formed, with the addition of one molecule of HCl to two double bonds. The cyclohydrochlorination of 3,4-polyisoprene proceeds by an ionic mechanism. Support for the formation of a monocyclic structure is provided by the proportion of chlorine in the reaction products and also by the results of NMR and infrared spectroscopy.



Whereas the cyclohydrochlorination of 3,4-polyisoprene takes place at 10–80°C, the analogous reaction for 1,2-polybutadiene requires much more severe conditions. The product of the cyclohydrochlorination of 1,2-polybutadiene also has a monocyclic structure.

van Veersen[47] investigated the influence of solvents on the hydrochlorination of natural *cis*-polyisoprene. When the reaction takes place in toluene the kinetic curves are smooth. In a mixture of toluene with ethyl acetate or dioxan, the reaction shows a definite induction period. The appearance of an induction period was associated by van Veersen with the reaction proceeding through the intermediate stage of the formation of a π-complex. Competition by oxygen-containing solvents, which can also form π-complexes with hydrogen chloride, also leads to the appearance of the observed induction period for the reaction. The negative temperature coefficient of the reaction is also considered as proof that the reaction proceeds through the formation of a π-complex[47,48].

Gordon and Taylor[49] assume that the addition of hydrogen chloride to *cis*-polyisoprene proceeds via the formation of an intermediate carbonium ion, as occurs in the cyclisation. In accordance with the suggested scheme of reaction a proton is added at the double bond to form a carbonium ion:

The latter forms a pseudocyclocarbonium ion:

Next a neutral molecule of hydrogen chloride is added at the pseudobond. The latter act leads to the regeneration of the carbonium ion. In accordance with this scheme the addition of neutral molecules of hydrogen chloride at the double bonds of polyisoprene, which alternate regularly in the 1,5-position, should proceed by an intramolecular chain mechanism. The high rate of hydrochlorination is considered by the authors to be one of the arguments supporting an intramolecular chain mechanism for the addition of hydrogen chloride to polyisoprene. In this they do not admit the possibility of electronic interaction of double bonds separated by three C–C bonds. We assume that just such interaction of double bonds in the 1,5 position creates the conditions for the development of hydrochlorination by a chain intramolecular mechanism. The greater activity of inner double bonds towards hydrogen chloride compared with vinyl bonds[37,50] is interesting.

The hydrochlorination of polyisoprenes in latex has been studied in detail[47,49,51–53]. At normal pressure the reaction rate in very low, owing to the low rate of diffusion of hydrogen chloride in the latex globules. Raising the pressure to 2 atm increases the reaction rate tenfold. Here the concentration of hydrogen chloride in the latex is increased by only a few per cent. The reaction has a negative temperature coefficient. The hydrochlorination of natural *cis*-polyisoprene in latex reaches 98–99%, and cyclisation is absent.

The addition of hydrogen bromide to natural *cis*-polyisoprene in the presence of peroxide takes place by a radical mechanism with the formation of a secondary bromide[37]. A kinetic analysis of the hydrobromination products showed the high activity of bromine in the addition products characteristic of tertiary bromides. Tuot[54] explains this by the influence of the methyl group situated in the α position to the secondary bromine. With secondary chlorides such an influence of the methyl group on the reactivity of the chlorine is not observed.

3. Hydrogenation

Hydrogenation occupies a special place in the chemistry of diene polymers. In the classical studies of the hydrogenation of natural rubber, made by Staudinger[55] and Pummerer[56], a series of important observations were made and the concept of macromolecules was formulated. Recently the hydrogenation of polyisoprene has been studied by Yakubchik and coworkers[57]. Natural and synthetic *cis*-polyisoprenes at 0.5% concentration in decalin are hydrogenated on a nickel catalyst at 80–140°C and a pressure of 80–100 atm, in the presence of 1% antioxidant. Synthetic polyisoprene, which has a lower molecular weight, is hydrogenated more readily; in the opinion of the authors this is due to the greater mobility of segments of its macromolecules as compared with natural *cis*-polyisoprene. The extent of the reaction increases with the temperature and with increase in the amount of catalyst. The maximal extent of the reaction is ~ 80% saturation of the double bonds. Spectrochemical analysis showed the absence of *trans*-links in the hydrogenation product. The refractive index

decreases linearly with the extent of reaction, on the basis of which the authors conclude that there is no cyclisation. However, this conclusion requires additional proof, since a decrease in refractive index due to decrease in the number of double bonds can exceed its increase due to cyclisation.

Bateman and coworkers[58] noted a diminished reactivity for natural *cis*-polyisoprene compared with the low-molecular model alkenes in the hydrogenation. Evidently this is connected with the reduction in electron density of the double bonds in 1,5-polyene systems due to the interaction of the double bonds. As already noted above, the interaction of double bonds in such systems creates conditions for the development of reactions of 1,5-polyenes by an intramolecular chain mechanism.

The hydrogenation of polybutadiene has received great attention. Jones[59] studied its hydrogenation on a nickel catalyst at 140–180°C; the quantity of catalyst employed is the determining factor in the reaction. The introduction of all the catalyst at once is more effective than its introduction in portions. The temperature has a marked effect on the extent of the reaction. Raising the temperature from 140° to 180°C reduces the unsaturation of the product from 34.6% to 9.5%.

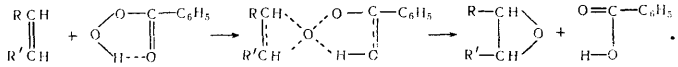
Degradation of the polymer does not take place in the hydrogenation. According to infrared spectroscopy, the vinyl bonds are hydrogenated somewhat more rapidly than the inner double bonds, but at a residual unsaturation of 20%, vinyl groups are still present.

Yakubchik and coworkers[60,61] studied the hydrogenation of a polybutadiene with 57% 1,4-structure in heptane and hexane at 20°C on a nickel catalyst at a pressure of 1 atm. Varying the concentration of the solution within the range 0.2–0.8% did not affect the reaction. The reaction was finished in 20–30 min when its extent was ~ 60%. Apparently cyclisation was absent, as was shown by the diminished refractive index. The relative viscosity was somewhat reduced, owing to a change in the configuration of the macromolecules, but the molecular weight remained constant. For hydrogenation in iso-octane at 60–140°C the reaction rate was almost independent of temperature.

The hydrogenation of *cis*-polybutadiene (unsaturation 95% of theoretical, 5% *trans*-1,4-units, 6% vinyl bonds) was investigated in decalin in the presence of 1% Neozon D, on palladium, platinum, and nickel catalysts[62–64]. Whereas the hydrogenation of low-molecular alkenes proceeds at constant rate up to 50% conversion, the rate of hydrogenation of the macromolecules of *cis*-polybutadiene drops during the course of the reaction owing to the marked change in the rigidity of the chain, accompanied by a sharp rise in viscosity on going from a polydiene with a *cis*-configuration to a saturated polyethylene. Non-regular polybutadiene does not exhibit the flexibility of *cis*-polybutadiene, therefore its hydrogenation is not accompanied by so significant an increase in viscosity.

In the hydrogenation of an unfractionated specimen of polybutadiene a mixture of macromolecules with different degrees of unsaturation is formed[65–67]. This non-homogeneity of the hydrogenation products may be due both to the heterogenic nature of the reaction, the influence of the molecular weight of the polymer, and also to the interaction of the double bonds in the 1,5-polyene systems.

Fractionation of the products of the incomplete hydrogenation of sodium butadiene rubber on a palladium catalyst leads to the production of a fraction with a marked difference in unsaturation (see Table)[66,67].



Polybutadiene can also be hydrogenated under homogeneous conditions in the presence of a soluble catalytic system of the Ziegler type[68,69]. The tri-isobutylaluminium–isopropyl titanate system can be used as the catalyst. The hydrogenation is effected in an autoclave at a pressure of 2–5 atm, 20–70°C, for 2–4 h. The ratio of the metal in the organometallic component to the transition metal is varied from 3 : 1 to 10 : 1.

As compared with the heterogeneous reaction, homogeneous hydrogenation permits a marked decrease in the amount of catalyst in the system, a reduction in the temperature and pressure, and there is less destruction of the polymer. Nothing has been published about the fractionation of the products of incomplete hydrogenation under homogeneous conditions.

4. Reaction with Perbenzoic Acid

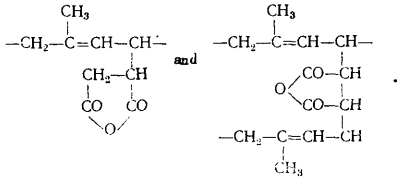
The reaction of unsaturated compounds with perbenzoic acid was studied in detail by Prilezhaev[70–72]. It was found that the rate of reaction depends on the position and nature of the substituent at the double bond. The main reaction path yields epoxy-groups in an amount equivalent to the benzoic acid formed.

Apparently this reaction proceeds by a molecular mechanism as a result of the direct addition of oxygen at the site of the double bond[73]:

Chloroform and chlorobenzene are usually employed as solvents for carrying out reactions with diene polymers[73–80]. The reaction rate is increased fivefold on going from 6° to 24°C, but with rise in temperature side-reactions begin to occur.

Electronegative oxygen-containing groups (ether, carboxyl, aldehyde) at a double bond retard the reaction, alkyl groups accelerate the addition of perbenzoic acid. The difference in the rates of reaction of *cis*- and *trans*-double bonds is comparatively small. The rate of reaction of terminal and vinyl double bonds is less than the rate of reaction of the internal double bonds. The last fact forms the basis of a kinetic method of determining the structure of diene polymers developed by Dogadkin and Dobromyslova[75].

TABLE. Fractionation of the products of the hydrogenation of sodium butadiene rubber in the pentane–dioxan system



Specimen fractionated	Fraction No.	Weight fraction, %	Unsaturation, %
Hydropolybutadiene with 42% unsaturation	1	22.3	1.0
	2	18.6	1.5
	3	3.0	2.6
	4	29.4	66.0
	5	26.8	77.2
Hydropolybutadiene with 24% unsaturation	1	50.0	1.0
	2	7.0	1.6
	3	10.6	1.0
	4	5.4	4.0
	5	27.0	66.0

III. REACTIONS INVOLVING THE PARTICIPATION OF DOUBLE AND ALLYL BONDS

1. Reaction with Ethylenic Monomers

The reaction of maleic anhydride with natural polyisoprene was first examined by Bacon and Farmer[81]. The reaction was carried out in the presence of benzoyl peroxide at 100°C. The extent of the reaction is proportional to the concentration of the peroxide and the remaining concentration of maleic anhydride. The best solvents for carrying out the reaction are carbon tetrachloride, decalin, and cyclohexane. In benzene, toluene, and xylene reaction is slight. At polymer concentrations $> 3\%$ or at a peroxide concentration $> 1\%$, calculated on the rubber, gel formation takes place. Temperature has little effect on the reaction. The authors assume that each molecule of the anhydride is attached to two double bonds of the polyisoprene, neighbours in a single macromolecule, adjacent in two macromolecules, or adjacent in a single macromolecule.

Later, Farmer proposed a different reaction mechanism with participation of α-methylene groups[86]. The double bonds do not participate in the reaction. The addition products are represented by the formulae:

Delalande[82-84] investigated the reaction of polyisoprenes with ethylene monomers under the conditions of thorough purification of the polymer and complete exclusion of oxygen from the reaction medium. *N*-methylmaleimide was used instead of maleic anhydride, which allowed the extent of the reaction to be determined from the proportion of bound nitrogen in the polymer. *p*-Bromobenzoyl peroxide was used instead of benzoyl peroxide, and its addition was determined from the amount of bromine in the reaction products. The reaction was carried out at 60–130°C. At higher reaction temperatures less gel was formed. At a peroxide concentrations $> 3\%$, gel formation was observed at any temperatures.

With increase in the concentration of the imide and peroxide the extent of the reaction increases. It was found that half the peroxide radicals add to the polyisoprene, the other half form an acid.

The reaction takes place in two stages. In the first stage of the reaction at 130°C there is a rapid addition of the imide and peroxide, then follows the second stage—the addition of the imide without the peroxide. The rate of the second stage is less by a factor of 200. Reducing the temperature from 130° to 60°C cuts the reaction rate by a factor of 130.

In addition to the kinetics of addition, the change in the degree of unsaturation of the polyisoprene in the reaction was studied by an iodometric method. The decrease in the unsaturated nature is always less than theoretical (assuming the imide was added to the double bond) and correlates better with the addition of peroxide radicals. The reaction proceeds according to the following scheme. Initially the peroxide decomposes into radicals:

$$AA \rightleftarrows 2A^{*} .$$

Then a peroxide radical detaches an α-methylene hydrogen of the polyisoprene

$$A^{*} + RH \rightarrow AH + R^{*} .$$

The macroradical formed reacts with the double bond of the imide:

$$R^{*} + E \rightarrow RE^{*} .$$

The macroradical which is formed detaches an α-methylene hydrogen from another polyisoprene molecule, etc.:

$$RE^{*} + RH \rightarrow REH + R^{*} .$$

Kinetic studies at 170°C in the absence of peroxide were carried out with the aim of explaining the mechanism of the slow stage of the reaction[84]. Gel formation is not observed at a concentration of polyisoprene in the solution up to 10%. At 170°C the amount of imide attached is seven times that at 110°C. The rate and extent of the thermal reaction increase with the initial concentrations of imide and polyisoprene.

The change in the unsaturation of the polymer during the thermal reaction was determined iodometrically and bromometrically. The values obtained by the second method were lower by a factor of two. In both instances the decrease in unsaturation is significantly less than theoretical (addition of imide at the double bond), which shows that the reaction proceeds by substitution. The considerably greater yield of double bonds in the iodometric determination is evidently connected with the fact that the bromine atom adds more readily at the double bond whereas the larger iodine atom is hindered by the imide moiety attached directly to the double bond. The small real change in unsaturation is probably due to cyclisation of the polyisoprene.

Delalande proposes the following mechanism for the thermal reaction of *N*-methylmaleimide with polyisoprene. Initially the double bond of the imide is opened, with the formation of a biradical:

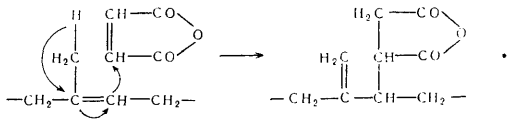
$$E \rightarrow E^{**} .$$

The biradical detaches an α-methylene hydrogen from a polyisoprene molecule:

$$E^{**} + RH \rightarrow {}^{*}EH + R^{*} .$$

The macroradical which is formed adds the imide at the double bond:

$$R^{*} + E \rightarrow RE^{*} .$$



The re-formed macroradical reacts with the following polyisoprene molecule:

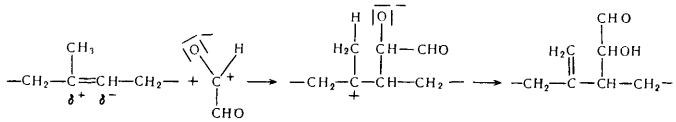
$$RE^{*} + RH \rightarrow REH + R^{*} .$$

Pinazzi and coworkers[85] and de Merlier and Le Bras[86] cast doubt on the radical nature of the thermal reaction, since thiophenol, which is a strong acceptor of radicals, has no effect on the thermal reaction although it retards the radical reaction which takes place in the presence of peroxide.

The presence of maleic anhydride was observed spectroscopically in the products of its reaction with polyisoprene in the presence of initiators[85]. Saturation of the double

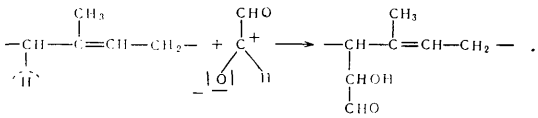
bonds of polyisoprene or their isomerisation is not observed. In the thermal reaction (without initiator) the unsaturation of the polyisoprene does not alter and the reaction proceeds according to the scheme:

The NMR studies confirm the displacement of the double bond.



The more readily an ethylene monomer is polymerised, the greater the amount of graft polymer formed in its reaction with diene polymers. The ethylenic monomers with diminished electronic density of the double bond are readily added to *cis*-polyisoprene (maleic anhydride, γ-crotonolactone, *N*-methylmaleimide, fumaric and maleic acids, *p*-benzoquinone, acrylonitrile, chloromaleic anhydride) when there is no steric hindrance (fumarodinitrile, vinylidene chloride, etc.).

Monomers with enhanced electron density at the double bond (styrene, allyl alcohol) or with normal electron density (cyclohexene, indene) do not react with *cis*-polyisoprene.



2. Reaction with Aldehydes

Pinazzi and Pautrat[87,88,91] investigated the reaction of *cis*-polyisoprene with glyoxal in xylene, under conditions where oxygen was thoroughly excluded from the reaction medium. The reaction was carried out at 25–180°C and the extent of the reaction was estimated from the oxygen content of the product. The reaction of glyoxal with polyisoprene is accompanied by a considerable gel formation, especially at low temperatures. At 180°C a soluble product can be obtained if the amount of glyoxal does not exceed 40 mole %, calculated on the polymer.

Usually, 24–32 moles glyoxal are added per 100 isoprene units. Examination of the reaction products by infrared spectroscopy and chemical analysis showed the presence of carbonyl and hydroxyl groups. The authors propose the following reaction mechanism:

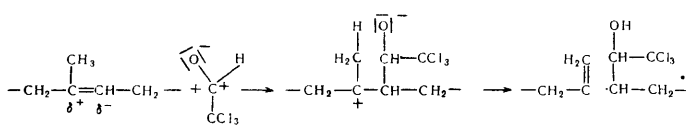
and also assume that reaction can occur by the scheme:

The products of the reaction of glyoxal with polyisoprene are not homogeneous: unreacted polyisoprene could be extracted from the reaction medium; the amount extracted increased with decrease in temperature.

The reaction of natural *cis*-polyisoprene with chloral[89–91] has been investigated in solution in cyclohexane and decalin, free from peroxides. The reaction was carried out in an inert atmosphere (pure nitrogen) in the presence of 1–3% catalyst ($AlCl_3$, BF_3), calculated on the polyisoprene, at a polymer concentration in the solution of 2%. The product was fractionated in a methanol–chloroform mixture. For the main fraction, the concentration of combined chlorine gave the number of added molecules of chloral per 100 polyisoprene units (n). The reaction temperature was varied between 25° and 200°C and the excess of chloral from 0 to 1000%.

In the absence of a catalyst the reaction did not proceed far ($n = 3$) and was almost independent of temperature. In the range 25–180°C boron trifluoride is the more efficient catalyst; in the range 180–200°C, aluminium chloride is better. The catalyst efficiency increases with the temperature.

Increasing the excess of chloral to 300% leads to an increased extent of reaction, but a further increase has hardly any effect on it. The reaction of chloral with polyisoprene is accompanied by gel formation, the intensity of which depends on the type of catalyst (greatest gel formation on using $HgCl_2$, least with $AlCl_3$).

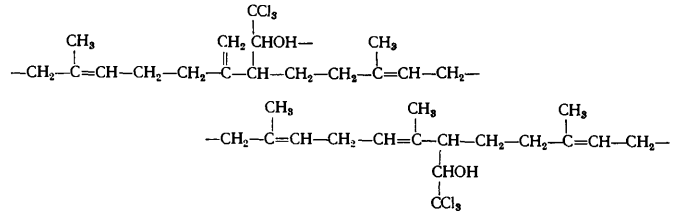


The effect of radical acceptors on the extent of reaction was investigated. The introduction of 3% thiophenol, *p*-benzoquinone, nitrobenzene, or sodium diethyldithiocarbamate had hardly any effect on the reaction of chloral with polyisoprene. To show whether a radical mechanism was possible, the reaction of chloral with polyisoprene in the absence of catalysts was studied. The initiators used were peroxides, azo-compounds, disulphides, and ultraviolet irradiation; all were ineffective.

The maximal addition ($n = 22$) was obtained by carrying out the reaction in cyclohexane at 180°C with aluminium chloride (3%) and a 300% excess of chloral. In the absence of a solvent at 180°C the reaction proceeds to $n = 5.5$. With thorough purification of the *cis*-polyisoprene the same results are obtained as for natural *cis*-polyisoprene. On carrying out the reaction with butyl rubber (3.5% isoprene) more than half of the double bonds react with the chloral. The extent of the reaction of *cis*-polybutadiene with chloral is very slight ($n = 1.5$).

Infrared analysis of the products of the addition of chloral to *cis*-polyisoprene showed the presence of hydroxyl groups (3300–3500 cm^{-1}) and chlorine (570, 620, 680, 730, and 1080 cm^{-1}), that is, the side chain has the structure $-CHOH-CCl_3$.

The characteristic frequencies of the cis-1,4-structure are weakened. The broadening of the 1640 cm^{-1} peak and the appearance of a band at 860 cm^{-1} show the formation of vinyldiene double bonds. The presence of a $-CHOH-CCl_3$ group has also been shown by chemical methods (reaction with sodium, phenyl-lithium, acetyl chloride, and alcoholic solution of potassium hydroxide). The appearance of absorption bands at 770 and 1040 cm^{-1} and also the decrease in the viscosity of the polymer during the reaction shows that cyclisation takes place. There is little cyclisation in the presence of aluminium chloride and extremely little when boron trifluoride is used.



The addition of chloral proceeds at random along the chain. The probable reaction mechanism is:

The reaction mechanism for *cis*-polybutadiene is different. Here the group added is $-CCl_2-CHO$, as is shown by the appearance in the spectrum of a band at 1780 cm^{-1},

characteristic for the carbonyl group, and the absence of the absorption band for hydroxyl.

The different reaction mechanisms for polyisoprene and polybutadiene with glyoxal can be explained as follows. The Prins reaction presumes the migration of a double bond with change of a methyl group into an exomethylene group or migration along the chain for polyisoprene.

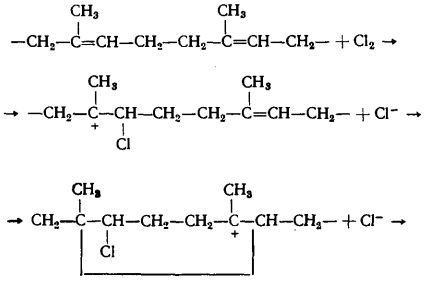
and only along the chain for polybutadiene. The migration of one double bond along the chain reduces the effectiveness of the utilisation of the electrons in at least three isoprene units, since two double bonds prove to be in the 1,4-position, and two in the 1,6-position [13]. Hence the increase in the free energy of the system with the breakdown of the 1,5-sequence in the double bond alternation prevents the reaction with migration of a double bond.

3. Reaction with Molecular Chlorine

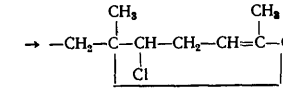
One of the most widely studied reactions of diene polymers is the chlorination of polyisoprenes and polybutadienes. Bloomfield's classical investigations allowed three main stages in the chlorination of natural rubber to be distinguished. In the first stage a molecule of chlorine reacts with an isoprene unit wholly by substitution:

$$C_{10}H_{16} + 2\,Cl_2 \rightarrow C_{10}H_{14}Cl_2\ (34.6\%\ Cl) + 2\,HCl\ .$$

In the second stage addition and substitution occur:



$$C_{10}H_{14}Cl_2 + 2\,Cl_2 \rightarrow C_{10}H_{13}Cl_5\ (57.2\%\ Cl) + HCl\ .$$



In the third stage there is only substitution:

$$C_{10}H_{13}Cl_5 + 2\,Cl_2 \rightarrow C_{10}H_{11}Cl_7\ (65.4\%\ Cl) + 2\,HCl\ .$$

The reaction was carried out in carbon tetrachloride in the temperature range −80° to +77°C, in the dark and in the light. The concentration of chlorine in the reaction products was determined by product analysis.

The chlorination of natural polyisoprene is accompanied a considerable drop in the viscosity of the solution (factor of 2–7) owing to the simultaneous occurrence of cyclisation (Bloomfield ascribes this effect to oxidation). At low temperatures cyclisation is insignificant and viscosity is reduced by a factor of 1.3. In the first stage of the reaction the unsaturation in the polymer diminishes (iodometric determination). Bloomfield suggests the following mechanism for cyclisation during chlorination:

Staudinger [40] suggests that cyclisation takes place with participation of the methyl groups.

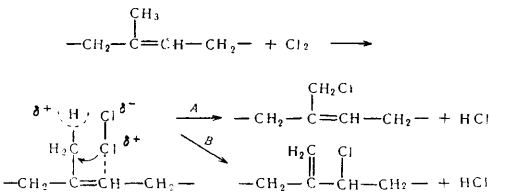
Apart from cyclisation, the decrease in unsaturation shown iodometrically can be due to steric hindrance of the double bonds by neighbouring chlorine.

The chlorination of natural rubber does not take place by a radical mechanism since light, oxygen, peroxides, and antioxidants do not affect the reaction. When using sulphuryl chloride and phenyl dichloroiodate a radical mechanism of chlorination leads to the addition of chlorine at the double bond. An attempt was made to form radicals from molecular chlorine by irradiation and the introduction of peroxides. However, here also not addition of but substitution by chlorine was observed.

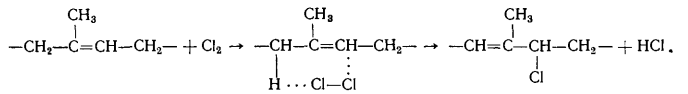
Kraus and Reynolds [93] investigated the chlorination of natural *cis*- and *trans*-synthetic polyisoprenes. The latter contained 90% *cis*- and *trans*-1,4-structures and 10% of the 1,2-structures. The properties of the chlorinated products were identical. The complete identity of natural *cis*- and *trans*-polyisoprenes on chlorination in the presence of antioxidant has been noted. The chlorination of synthetic polyisoprene proceeds similarly when the reaction takes place in the dark. In the light and in the presence of 0.3% oxygen (antioxidant absent) the addition to synthetic polyisoprene occurs even in the first stage of the reaction, and is increased on ultraviolet irradiation in the presence of 1% benzoyl peroxide.

Cyclisation is less pronounced in synthetic polyisoprene owing to the irregularity of the structure. In the early stages of the chlorination there is formation of one ring per three substitutions of chlorine. Until cyclisation has finished chlorine does not add to double bonds apart from those which are formed as a result of cyclisation and the vinyl bonds. In the presence of light and peroxides this rule is broken and addition proceeds at the expense of cyclisation.

A series of papers by Van Amerongen and coworkers [94-99] is devoted to the detailed explanation of the reaction mechanism of the chlorination of natural rubber. The structure of the products of the halogenation of rubber was determined by kinetic analysis, from the rate of reaction of the chloride with organic bases. Depending on the structure of the monochloride, the various types of chlorine are arranged in the following series of activity relative to aniline: allyl > tertiary ≫ primary > secondary ≫ ≫ vinyl.



The order of reactivity of polyhalides has the following form:



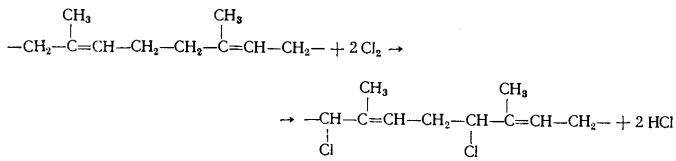
Kinetic investigations showed that the higher the chlorine content of the reaction product the more stable it is. The stability of the chlorination products depends on the total chlorine content and is independent of such experimental conditions as the presence of light or catalysts, temperature, chlorine pressure, or the effecting of the reaction in bulk or in solution with liquid or gaseous chlorine. This shows that the sequence of stages is retained during chlorination under different conditions: at first there is substitution then addition at the double bonds.

When there is less than 25% chlorine in the chloride of natural *cis*-polyisoprene, all the chlorine is allyl, as is shown by its high reactivity in the aniline experiment. In products with 65% chlorine the content of allyl chloride drops to 10%, owing to saturation of the double bonds. Further chlorination leads to an increase in the percentage of reactive chlorine due to the formation of the dichloride $-CCl_2-$.

Bloomfield and Van Amerongen and their coworkers adopt an ionic mechanism for the chlorination of diene polymers. The heterolytic breaking of a purely covalent bond seems improbable to us. The reaction of chlorine with a double bond by a molecular mechanism is more probable, as McNeill believes [100] for the chlorination of butyl rubber:

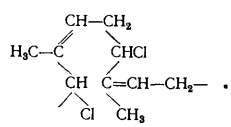
When an α-methylene group participates in the reaction (for polybutadiene of 1,4-structure this is the only possibility) the double bond migrates along the macromolecular chain:

Whereas for the isolated double bonds of butyl rubber the migration of a double bond along a chain during chlorination does not encounter hindrance, a similar migration of one double bond in a 1,5-polyene chain should be accompanied by an increase in the free energy of the system owing to the breakdown of the condition of delocalisation of three double bonds, as was shown by the example of the reaction of polybutadiene or polyisoprene with chloral. However, when the intermediate complexes form successive links of a polymeric chain and the macromolecule or part of it changes into a collective excited state, forming a cooperative intermediate complex (CIC); the decomposition of such a CIC of any dimensions will be accompanied by the breakdown of interaction of only four double bonds (two at each end of the CIC). At the same time the gain in energy during the breakdown of the CIC to form addition products will increase additively with the inclusion in the CIC of each new link of the macromolecule and can considerably exceed the increase in energy of the system due to the breakdown of the conditions for the interaction of four double bonds. Hence a reaction of cooperative interaction can take place where a single addition with migration of a double bond along the chain is impossible.



The formation of a CIC in reactions of diene polymers is favoured by the fact that the production of one intermediate complex facilitates the formation of analogous complexes by neighbouring links of a macromolecule owing to the increased reactivity of the double bonds in the 1,5-position relative to those which have reacted.

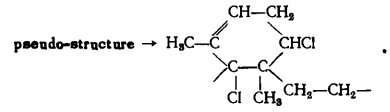
The cooperative mechanism for the first stage of the chlorination of polyisoprene provides an explanation for the fact that at this stage double bonds do not participate in cyclisation and addition [92,101]. If it be assumed that a CIC embraces the whole macromolecule it becomes understandable that double bonds can no longer participate in reactions up to the decomposition of the CIC with regeneration of double bonds in a new position.



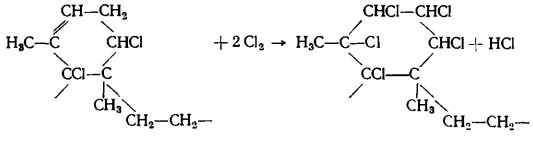
The products of incomplete chlorination of natural *cis*-polyisoprene (up to 30% bound chlorine) are non-homogeneous [94,101] even when chlorine dissolved in carbon tetrachloride is added dropwise to a solution of polyisoprene with vigorous stirring. In the chlorination products there is always a fraction with 31–33% chlorine [101]. With 34–35% chlorine the product is almost homogeneous, and the same is true for products with a higher content of chlorine [102]. According to Bloomfield 35% chlorine in the product corresponds to the end of the first stage of reaction, When the total chlorine in the product is $< 30\%$, 90–95% of this chlorine is reactive. Van Amerongen [94] explains the non-homogeneity of the product of incomplete chlorination by a high reaction rate in the first stage and by the existence of a zone of high concentration owing to the high viscosity of the solution. Trousier [101] considers that for a chlorine concentration of $< 34\%$ the chlorine which has been added favours the extension of the macromolecule, which facilitates further addition of chlorine to the same macromolecule. The viscosity results do not confirm this point of view. We assume that the reason for the products of the first stage of chlorination of polyisoprene being non-homogeneous is the cooperative intramolecular chain mechanism of the reaction.

An infrared analysis of the products of the chlorination of natural *cis*-polyisoprene [97,101,103–105] showed a weakening of the 3.4 μm (C–H bond) and 12 μm (*cis*-C=C) absorption bands until the latter disappeared completely during the chlorination. The 6 μm band ascribed to the C=C bond is constant up to 35% chlorine, then rises, but disappears at the end of chlorination. The intensity of the 6.9 μm band (C–H bond) remains constant. The 8 μm band (ring) appears at 35% chlorine and then rises. The 11 μm band (ring) appears during chlorination but its intensity falls for chlorine concentrations $> 35\%$.

Salomon and coworkers [97] ascribe the change in intensity of the 6 μm band and the appearance of the 11 μm band to the formation of vinyl bonds during chlorination. Allirot and Orsini [105] note a marked similarity between the spectra of the chlorides of polyisoprene and cyclohexane, and consider this to be confirmation of the cyclic structure of chlorinated polyisoprene. Trousier [101] considers that the changes in the spectrum are great only in the first stage of chlorination and ascribe them all to cyclisation. He represents the cyclisation mechanism as follows. After the first stage of chlorination:

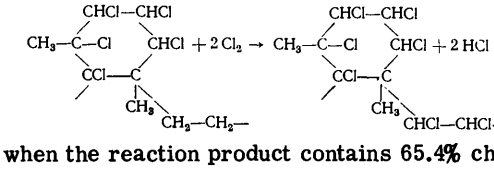


a pseudocyclic structure is formed:



During this there are no significant changes in the spectrum, but a decrease in viscosity shows the contraction of

the macromolecular chains. Until the molecule is saturated with 35% Cl it does not cyclise. On reaching this threshold the individual macromolecules are cyclised according to the scheme:



The results of the kinetic analysis confirm this picture: when the chlorine content of the reaction product is < 35% all the chlorine is allyl; on reaching 35% bound chlorine there is a sharp drop in the allyl chlorine content—its amount is cut by half. Further chlorination is accompanied by an increase in the reactive chlorine content; starting from 45% bound chlorine, the fraction of reactive chlorine drops monotonically.

The drop in viscosity stops after completion of the first stage of chlorination. Further chlorination proceeds under the condition that all the product was cyclised and there are no macromolecules with < 35% chlorine.

The products of this stage of chlorination are homogeneous. Substitution predominates over addition, as is shown by the increased content of allyl chlorine. The final stage of chlorination—the substitution

—ends when the reaction product contains 65.4% chlorine.

Ramakrishnan [106] studied the change in the unsaturation of natural *cis*-polyisoprene during chlorination by ozonation of the reaction products. A 4% solution of the polymer in carbon tetrachloride was saturated with gaseous chlorine at 2° and 78°C. With the aim of excluding the addition of hydrogen chloride formed in the substitution reaction, nitrogen was bubbled through the solution. The results obtained agree with the chlorination mechanism proposed by Trousier.

Canterino [107] notes the marked influence of the solvent on the chlorination of natural *cis*-polyisoprene. When the reaction is carried out in benzene hardly any cyclisation is observed—the double bonds do not disappear and the viscosity does not change. In the presence of phosphorus(III) chloride the cyclisation is greatly accelerated.

The chlorination of polybutadiene emulsion [107] proceeds somewhat more slowly and the product is more stable. When the reaction is carried out in carbon tetrachloride a cross-linked product is obtained; in benzene, chloroform, toluene, and tetrachloroethane, gel formation does not take place. The introduction into the reaction of iodine, phosphorus(III) chloride, phosphorus(V) chloride, or sulphuryl chloride prevents cross-linking, the phosphorus chlorides being the most effective in this respect. The chlorination products do not contain phosphorus. The substitution in polybutadiene is less pronounced than that in *cis*-polyisoprene and diminishes on going from carbon tetrachloride to benzene. The cyclisation occurs weakly in benzene, somewhat more in carbon tetrachloride, and is absent in both instances when phosphorus(III) chloride is used.

Van Amerongen [98] described the chlorination of natural and polychloroprene latex in strongly acid medium with an emulsifier. The latex concentration was 30–55% and the reaction was carried out at 15–90°C. Natural latex was chlorinated up to 60% combined chlorine in the reaction product, and the polychloroprene latex up to 48% combined chlorine. Within the limits given the temperature had hardly any effect on the rate or extent of the reaction.

4. Reaction with Bromine and Other Halogenating Agents

The quantitative addition of bromine at double bonds with the formation of a tetrabromide is used in gravimetric analysis [108–111]:

$$(C_{10}H_{16})_n + 2n Br_2 \rightarrow (C_{10}H_{15}Br_4)_n$$

and in volumetric [112–114] methods of determining the unsaturation of diene polymers. The rate of bromination of the polyisoprenes increases with the temperature, but at temperatures above 0°C the addition of bromine is accompanied by substitutions and cyclisations [115–119]. The usual solvents employed for the reaction are benzene, chloroform, and carbon tetrachloride. Radiation accelerates the reaction but favours substitution. Substitution can be suppressed by use of a polar reagent (glacial acetic acid) [116].

The bromination of *cis*-polybutadiene was investigated at temperatures between 0° and −20°C in chloroform. Under these conditions there is only addition of bromine at the double bonds; cleavage, substitution, and cyclisation do not take place [120].

The products of the incomplete bromination of natural rubber and gutta-percha are not homogeneous [13, 121]. The bromination [13] was carried out in benzene (0.3% solution of polyisoprene), and the brominating solution (5% bromine in carbon tetrachloride) was introduced with cooling with ice and vigorous stirring. The amount of bromine corresponded to the theoretical for the desired degree of bromination.

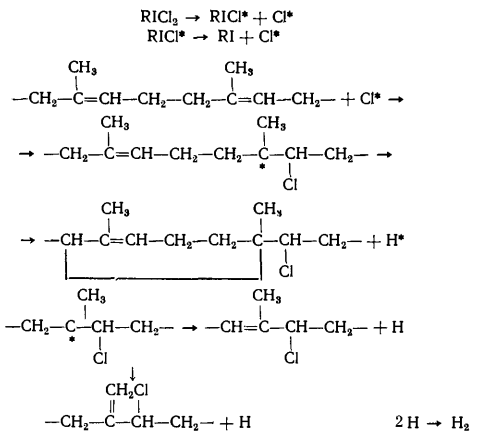
To obtain homogeneous products from an incomplete bromination, various procedures were tried, mainly based on the introduction of a third component, but none of them gave positive results. Evidently the bromination does not obey statistical laws and takes place by the intramolecular chain mechanism considered above.

On reacting with polyisoprenes [96], sulphuryl chloride forms a dichloride when the polymer has been thoroughly purified; otherwise, substitution is observed. At high temperatures or in the presence of iodine, the sulphuryl chloride decomposes and the chlorination of the rubber under these conditions follows the usual path. At 40–60°C in the light and in the presence of a catalyst (pyridine), sulphuryl chloride is added at the double bonds. In the presence of initiators (ascaridole, benzoyl peroxide), the Kharasch reaction takes place:

$$\text{peroxide} \rightleftarrows 2R^*$$

$$R^* + SO_2Cl_2 \rightarrow RCl + SO_2Cl^*$$

$$SO_2Cl^* \rightarrow SO_2 + Cl^*$$



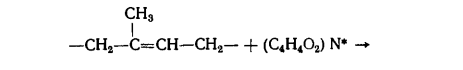
$$Cl^* + >C{=}C< \rightarrow >C(Cl)-C^*<$$

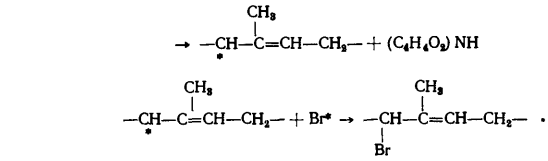
$$>C(Cl)-C^*< + SO_2Cl_2 \rightarrow >C(Cl)-C(Cl)< + SO_2Cl^* \cdot$$

The reaction of sulphuryl chloride with natural *trans*-polyisoprene was investigated at 5–77°C in carbon tetrachloride. The presence of peroxide and ultraviolet radiation accelerates reaction. The content of reactive chlorine, capable of reaction with aniline, was always 5–7%. Little hydrogen chloride was formed. The temperature had little effect on the reaction. In the presence of inhibitors (hydroquinone, 2-naphthol) the reaction is slow and proceeds by substitution (~ 70% reactive chlorine), to a slight extent. Amino- and nitroso-compounds have a similar effect on the reaction.

The reaction of sulphuryl chloride with polyisoprenes is accompanied by gel formation, the extent of which increases with drop in temperature (when the rate of gel formation decreases), on irradiation, and in the presence of traces of water. Antioxidants do not affect the gel formation but nitrogen oxides hinder it. The introduction of 5% hydroperoxides, hydrogen iodide, iodine, or chlorine leads to a drop in the viscosity of the solution. Apparently hydrogen iodide deactivates radicals, leading to the cross-linking of the macromolecules; chlorine and peroxides break down the cross-linking.

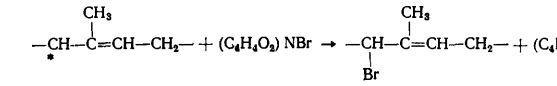
In accordance with Bloomfield's results [122] phenyl dichloroiodate forms the dichloride almost exclusively when it reacts with natural *cis*-polyisoprene in the absence of oxygen. There is considerable substitution in the presence of inhibitors. Ramakrishnan [123], who studied the reaction products by use of ozonisation, considers that as well as the addition of chlorine at the double bonds, cyclisation, depolymerisation, decyclisation, and migration of double bonds with the release of a proton take place. The reaction mechanism is described by the following scheme:





The migration of the double bond with release of a free proton is improbable. It was found that the release of hydrogen chloride in the individual stages of the reaction does not exceed 1–2%, and atmospheric oxygen has no effect on the reaction.

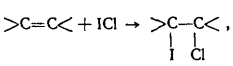
Bromination with *N*-bromosuccinimide [120] takes place through a change in the radical nature of the reaction. The first stage of the reaction is the decomposition of *N*-bromosuccinimide into radicals:



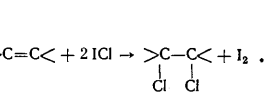
$$(C_4H_4O_2)NBr \rightarrow (C_4H_3O_2)N^{\bullet} + Br^{\bullet}.$$

The radicals formed react with the polyisoprene:

The macroradical can also react with the following molecule of *N*-bromosuccinimide:



Cyclisation takes place simultaneously.



Iodine chloride adds quantitatively to polybutadiene when the reaction is carried out in a non-polar solvent at 25°C with an excess of iodine chloride [116]. In dichloroethane the addition is accompanied by substitution. For polyisoprene of non-regular structure the addition of iodine chloride is accompanied by substitution and cleavage. The hydrogen iodide liberated in the last two reactions reacts with iodine chloride to form molecular iodine:

$$HI + ICl \rightarrow HCl + I_2.$$

The addition of chlorine iodide proceeds according to the scheme:

and not as follows

The reaction takes place by an ionic mechanism and initiators and inhibitors of radical reactions have no effect on it. The presence of alkyl groups at the double bond accelerate the addition, a halogen atom at the double bond retards the reaction. It is suggested that an internal double bond should react 2–4 times more rapidly than a vinyl group [119]. According to their activity in relation to iodine chloride, diene polymers form the following series: polyisoprene > polybutadiene > polychloroprene. When there are conjugated bonds the iodine chloride rapidly adds to the first bond and slowly to the second.

Iodine bromide adds to polybutadiene in carbon tetrachloride without release of hydrogen halide [124]. The formation of hydrogen iodide increases with the solvent used in the following order: chloroform–dichloroethane–tetrachloroethane. Ultraviolet irradiation assists substitution. The liberation of hydrogen iodide is much greater with polyisoprene.

---o0o---

The above analysis of the reactions of diene polymers allows us to find characteristics for 1,5-polyene systems, consisting in the interaction of the double bonds, the reduction of their reactivity, and the possibility of development of the reactions of such systems according to an intramolecular chain mechanism. Such interaction of double bonds greatly complicates the solution of practical problems connected with the treatment and stabilisation of diene polymers. Thus for vulcanisation the development of reactions by an intramolecular chain mechanism should lead to

an extremely inefficient use of the vulcanising agent and to an undesirable modification of the polymeric chains which actually occurs during sulphur vulcanisation, especially in the absence of an accelerator. The autocatalytic nature of the oxidation of 1,5-polyenes and the accumulation of oxidation products in separate macromolecules[125] are also evidently connected with the interaction of the double bonds in these polymers. We suggest that detailed study of the possibility of developing the reactions of diene polymers by an intramolecular chain mechanism is now one of the most pressing problems of the chemistry of 1,5-polyenes.

THE REARRANGEMENT OF HYDRAZO-COMPOUNDS

V. O. Lukashevich

1. INTRODUCTION

In spite of the many investigations since the times of Zinin [1] and Hofmann [2], no satisfactory solution has yet been found to the problem of rearrangement as a whole.

The early papers report valuable experimental work. The labours of several chemists (Hofmann [2], Schultz and his coworkers [3-6], Jacobson and his coworkers [7,8], Täuber [9], Witt [10]) during the nineteenth century revealed four types of rearrangement—(1) benzidine, (2) biphenyline, (3) *o*-semidine, (4) *p*-semidine—a fifth rearrangement—*oo'*-biphenyl (in the benzene series)—being discovered by us [11] much later.

Special mention must be made of the work of Jacobson and his collaborators [12] and of Wieland [13], on the basis of which the intramolecular character of the rearrangement was demonstrated. Wieland [14] pointed out the possibility of obtaining hydrazobenzene hydrochloride by the action of dry hydrogen chloride on hydrazobenzene in ether. However, he found that, when certain *para*-substituted hydrazobenzenes were heated in an inert medium, the corresponding semidines were formed [15]. For a long time these observations were not developed further.

During the past two decades attention has been directed mainly at solving by kinetic methods the problem involved in the initial stage of rearrangement in the presence of ionised acids: does the hydrazo-compound react as a univalent or as a bivalent cation? No satisfactory answer has been obtained to this question.

References to what is often termed the "benzidine rearrangement" are usually concerned with the process occurring in an ionised acid medium, as a result of which benzidines and biphenylines [biphenyl-2,4'-diamines] are obtained. Small amounts of other substances are often disregarded.

An important aspect is the very little studied rearrangement in unionised acids. The reaction takes place in a heterogeneous medium, the composition of the products varying greatly with the conditions. The usual methods of investigation employed by organic chemists are applicable to these cases. It is sometimes possible to obtain good yields of monoprotonated hydrazo-compounds and to study some of their properties and reactions. At the same time the stepwise character of the process as a whole is determined: the salt of the hydrazo-compound formed in the first stage rearranges under the further action of the acid.

Not long ago we were able [16] to demonstrate, with hydrazonaphthalenes as examples, a special type of rearrangement produced by the action of heat. This so-called thermal rearrangement is especially complicated in the naphthalene series, where the results are often strongly solvent-dependent.

The present review first describes work on salts of hydrazo-compounds, together with some of their properties and reactions, then discusses rearrangement in acid media, and in conclusion considers rearrangement under the influence of heat.

2. SALTS OF HYDRAZO-COMPOUNDS—SOME OF THEIR PROPERTIES AND REACTIONS

Until recently information on the salts of hydrazo-compounds was confined in effect to Wieland's exploratory experiment [14]. A paper by Orelkin et al., [17] which contained an interesting underlying idea, did not contribute to progress in this field because the experiment was not properly thought out.

Solutions of hydrogen chloride in ether have proved most suitable for the preparation of salts of hydrazo-compounds, and they can be regarded as equilibrium systems:

$$[(C_2H_5)_2\overset{+}{O}H]\,\overline{X} \rightleftarrows (C_2H_5)_2O \ldots HX.$$

Since the acidity of the hydrogen chloride is approximately weakened as a result of intermolecular interaction in the ether, it is easy to prepare hydrochlorides of several hydrazo-compounds. To a solution of the hydrazo-compound, e.g. hydrazobenzene in ether at −8° to −10°C, an equimolecular amount of hydrogen chloride in ether is added rapidly in drops. The hydrochloride is filtered quickly (preferably in an atmosphere of nitrogen), the solution is made alkaline with methanolic sodium hydroxide, and it is oxidised with mercuric oxide, an equivalent quantity of azobenzene being obtained. Salt formation does not go to completion owing to dissociation of the hydrochloride, which is especially marked with the less basic compounds: with 2-chloro- and 3,3′-dichloro-hydrazobenzene, for example, 30–40% of the hydrazo-compound remains [unchanged] in solution, even if double the quantity of hydrogen chloride is taken.

Ethers other than diethyl ether—e.g. di-isopropyl and di-isopentyl ethers—can be used in the preparation of the salts. With hydrogen bromide 40–50% of the hydrobromides of 3-chloro- and 3,3′-dichloro-hydrazobenzene can be isolated.

By no means all hydrazo-compounds form stable salts: it has proved impossible to isolate salts of 4,4′-substituted derivatives. Table 1 gives the yields of salts of several hydrazo-compounds prepared by the method outlined for hydrazobenzene hydrochloride. If in expts. 10 and 20, immediately after precipitation of the hydrochlorides, the whole mixture is made alkaline and is oxidised with mercuric oxide, 70% and 90% respectively of the original hydrazo-compounds are regenerated as the azo-compounds.

Salts of hydrazonaphthalenes cannot be isolated. However, their existence can be demonstrated as follows: 0.002 mole of 1,1′-, 1,2′-, or 2,2′-hydrazonaphthalene is dissolved in the minimum quantity of dioxan, the solution is diluted with ether at −8° to −10°C, and 1 mole of hydrogen chloride in ether is instantly added. A copious, very finely divided precipitate comes down; the whole mixture is made alkaline and oxidised with mercuric oxide as quickly as possible. The initial hydrazo-compounds are regenerated to the extent of 70–75%. Visual inspection shows that precipitates of the hydrochlorides of the corresponding diamines (calculated quantities) are present here in only small amount.

Basic Strength of Certain Hydrazo-Compounds

Several hydrazo-compounds can be compared in basic strength with chloroanilines. Relatively definite results are obtained with hydrazo-compounds which form the more stable salts.

The procedure is to prepare the hydrobromide of a suitable chloroaniline (0.002 mole) in ether (20 ml), into which is immediately run a solution of the hydrazo-compound (0.002 mole) in ether (20 ml), the temperature lying between −8° to −10°C. After 2 min the precipitate is quickly filtered off (preferably under nitrogen), and both precipitate and solution are made alkaline and are oxidised. The quantity of azo-compound obtained indicates the distribution of the acid between the hydrazo-compound and the chloroaniline†.

With unstable salts of hydrazo-compounds the situation is greatly complicated: a pair of chloroanilines is selected of most closely similar basic strengths, and such that the rearrangement would be strongly retarded in the presence of the first member of the pair, whereas it would occur readily in the presence of the second member. As before, the hydrobromide (sometimes also the hydrochloride) of the chloroaniline having been obtained in ether and the hydrazo-compound added, after 2–3 min the whole mixture is neutralised and oxidised, the quantities of amines formed and of hydrazo-compound remaining then being determined.

Reactions of Hydrochlorides of Hydrazo-Compounds

Hydrazobenzene and 3,3′-dimethylhydrazobenzene hydrochlorides have been tested. Experiments 1 and 6 (Table 2) give for comparison results of the ordinary rearrangement of these hydrazo-compounds in ethereal hydrogen chloride. It is seen that considerable quantities of *oo′*-diamines are

† For reasons which have not been elucidated, 3,4,5-trichloroaniline and also 2,3,5,6-tetrachloroaniline are unsuitable for comparison with hydrazo-compounds.

* Results of the usual rearrangement of hydrazo-compounds in ethereal solution.

obtained besides benzidines, biphenylines, and *o*-semidines. The hydrochlorides of hydrazo-compounds break down after prolonged storage at 20°C in the apparatus in which they had been prepared in ether by treatment of the hydrazo-compound with hydrogen chloride at a 1 : 1 molar ratio. The hydrogen chloride formed by dissociation of the salt gradually brings about rearrangement of part of the salt. It is remarkable that no *oo'*-diamines at all are formed in the absence of a considerable excess of acid. Large quantities of amines and azo-compounds result from the redox reaction

$$2\,[RNH{-}\overset{+}{N}H_2R]\,\overline{Cl} \rightarrow RN{=}NR + 2\,R\overset{+}{N}H_3\,\overline{Cl}$$

which inevitably accompanies the rearrangement. This is revealed when, for example, hydrazobenzene hydrochloride (0.01 mole) reacts with an equimolecular quantity of another suitable compound, e.g. 2,2'-dimethoxyhydrazobenzene in ether. Neither benzidine nor aniline can be detected after such a mixture has been allowed to stand at 0°C for 24 h. The compounds obtained, besides partly regenerated hydrazobenzene and products of the rearrangement of 2,2'-dimethoxyhydrazobenzene, are 2,2'-dimethoxyazobenzene (5.3%), azobenzene (28.8%), and *o*-anisidine (32%). The proceeds by gradual conversion of the 2,2'-dimethoxyhydrazobenzene into the hydrochloride; some of this salt rearranges under the influence of traces of hydrogen chloride, while some of it, being involved in the redox reaction, acts mainly as an oxidant.

Experiments 3, 4, 8, and 9 in Table 2 give results for the breakdown of individual hydrochlorides in a gentle current of dry nitrogen, the apparatus being cooled externally to 20° and heated at 80°C. In expts. 5 and 10 the hydrochlorides were decomposed in an atmosphere of dry hydrogen chloride with external cooling by means of ice and salt. In expt. 4 about half the benzidine was obtained in the form of the monohydrochloride, which was sparingly soluble in water, and this suggested that with rise in temperature hydrazobenzene hydrochloride rearranged without the participation of a second molecule of acid; this would seem to be indicated by the material balance with respect to acid and amino-compounds during the reaction.

However, it was soon shown [18] that hydrochlorides of amino-compounds catalyse the disproportionation of free hydrazo-compounds at elevated temperatures. When, for example, an equimolecular mixture of hydrazobenzene and aniline hydrochloride is heated at 105–110°C for 15 min, disproportionation of the hydrazobenzene reaches 80%; this reaction is catalysed also by weak acids (benzoic, acetic, and butyric acids).

In the mechanism of the reaction very small amounts of hydrogen chloride, resulting from dissociation of the amine hydrochlorides, combine with the hydrazo-compound to form the corresponding hydrochloride, which undergoes a redox reaction. Among the rearrangement products it is possible to detect only traces of *o*-semidines, which are formed by the "thermal" rearrangement of hydrazo-compounds in the absence of acids (see Table 5).

So Called Diacid Salts of Hydrazo-Compounds

Pongratz et al. [19] reported the preparation of hydrazobenzene dihydriodide

$$[C_6H_5\overset{+}{N}H_2 + \overset{+}{N}H_2C_6H_5]I_2^{2-}$$

by the action of a large excess of methyl iodide on hydrazobenzene. A check revealed, however, that the "dihydriodide" could be fractionally crystallised from alcohol, when trimethylphenylammonium iodide (1 mole) and aniline hydriodide (2 moles) were isolated. This product has been synthesised also by the action of a large excess of methyl iodide on aniline [20].

The second diacid salt of hydrazobenzene was the dihydrochloride, Orelkin's "green salt" [17]. When Orelkin's experiment was repeated, a greenish product was obtained which proved to be a mixture of substances resulting from the rearrangement and the disproportionation of hydrazobenzene. Thus later references by Hammond [21] and by Carlin [23] to diacid salts of hydrazo-compounds are devoid of foundation.

Special experiments showed [24] that the formation of appreciable amounts of diacid salts of *N*-methyl-*N'*-phenylhydrazine [25] is excluded in both ethereal and benzene–toluene solutions of hydrogen chloride and hydrogen bromide. Monoprotonated aliphatic–aromatic hydrazines are evidently very weak bases, and double protonation of them is greatly hindered. This must apply even more to the double protonation of considerably more feebly basic substances such as hydrazo-compounds, many of which rearrange very rapidly in weak acids at ordinary temperatures (see Table 1).

3. REARRANGEMENT IN ACID MEDIA

Tables 3 and 4 give results for the rearrangement of hydrazo-compounds in unionised and in ionised acids respectively. The principal representatives selected were hydrazobenzene (I), 2,2'-dimethylhydrazobenzene (II), 3,3'-dimethylhydrazobenzene (III), 4,4'-dimethylhydrazobenzene (IV), 2,2'-dimethoxyhydrazobenzene (V), and 2,2'-diethoxyhydrazobenzene (VI). It is evident from Table 3 that results for the rearrangement differ markedly: in unionised acids the yields of benzidines are not very high; however, far larger quantities of biphenylines are obtained than in ionised acids. A more interesting fact, perhaps, is that with hydrazobenzene and 3,3'-dimethylhydrazobenzene were encounter new substances, *oo'*-diamines, while the quantities of *o*-semidines also increase sharply.

Rearrangement in Unionised Acids[24]

The hydrazo-compound (0.01 mole) is completely dissolved in absolute ether or a mixture of absolute benzene and absolute toluene (benz–tol) in the proportions 2 : 1, and a solution of hydrogen chloride or hydrogen bromide (3–4 moles) in the same solvents is added at between –8° and –10°C. In expt. 10 (Table 3) an ethereal solution of the acid (4 moles) is added at once to a solution of the hydrazo-compound in ether. When solvents are not used, a slow stream of dry hydrogen chloride or hydrogen bromide is passed over the surface of the finely divided hydrazo-compound, the apparatus being gently shaken in a mixture of ice and salt.

The almost colourless aqueous solutions of the reaction products are again shaken with ether, the feebly basic *o*-semidines and azo-compounds being extracted. *o*-Semidines can be determined quantitatively by titration with nitrite.

It is interesting that brominated *o*-semidines—2-amino-4′-bromodiphenylamine and 2-amino-4′-bromo-2′,3-dimethyldiphenylamine—are formed by the action of dry hydrogen bromide on crystalline hydrazobenzene and 2,2′-dimethylhydrazobenzene. Large quantities of aniline (expt. 4) and of *o*-toluidine (expt. 7) are also obtained. These substances result from a secondary reaction: the hydrobromides of the hydrazo-compounds which are formed are reduced by hydrogen bromide to anilines with simultaneous bromination of the substances—the *o*-semidines—which are most readily brominated in the reaction mixtures. Benzidine is reprecipitated as the sulphate; other benzidines are salted out from strongly acidified solutions and purified. The filtrates are used to determine anilines, which are volatile in steam, *oo*′-diamines, and biphenylines; these last are easily separated after conversion into the dibenzoyl derivatives, by means of their differing solubilities in alcohol and in ether.

Rearrangement in Ionised Acids[26,27]

The process is conducted in aqueous–alcoholic solutions of hydrogen chloride; in some experiments anhydrous alcohol is used. A solution of hydrazobenzene (0.01 mole) in alcohol, which has been strongly cooled under nitrogen, is at once mixed with a solution of hydrogen chloride (0.1 mole), the total volume being 100 ml and the temperature ~ 0°C. After 2 h crystals of benzidine hydrochloride are separated and are converted into the sulphate. The alcohol is evaporated off at 10–20°C. The residue is diluted with water, the major portion of the acid is carefully neutralised, and the *o*-semidine and azobenzene are completely extracted with ether. The aqueous portion contains traces of benzidine, biphenyline, and aniline. The benzidine having been separated, the total biphenyline plus aniline is determined by diazotisation, the quantity of aniline being found after repeated distillation in steam. In expt. 3 (Table 3) (I) is added to the acid at 45–50°C during 15 min. Compounds (II) and (IV)–(VI) are added steadily to a solution of hydrogen chloride (0.1 mole) in alcohol (100 ml) at 0°C steadily over 30 min. After $1\frac{1}{2}$ h the reaction mixtures are treated as in the directions just given for (I), and also for rearrangement in unionised acids.

In part of the analysis investigators are usually guided by the data of Carlin et al.[28] (who employed a spectrophotometric method), according to which hydrazobenzene is completely converted, over a wide range of conditions in 95% ethanol, into a mixture of benzidine and biphenyline in the proportions 70 : 30. Actually, we have seen (Table 4) that the ratio of benzidine to biphenyline differs from the values obtained by Carlin, and moreover is closely connected with the alcohol concentration: in 95%, 75%, and 45% ethanol the proportions are respectively 79 : 21, 84 : 16, and 87 : 13 (compared with 92.8 in aqueous hydrochloric acid). With rise in temperature the quantity of benzidine diminishes appreciably relative to biphenyline and other substances, among which is *o*-aminodiphenylamine. Finally, the amounts of disproportionation product increase greatly with rise in temperature.

With regard to other hydrazo-compounds, according to Carlin and Odioso[22] the rearrangement of 2,2′- and 3,3′-dimethylhydrazobenzenes yields solely the corresponding benzidines‡. But it is well known in industry that, even under special conditions, secondary products are inevitably obtained together with *o*-tolidine. In alcoholic medium with hydrogen chloride (Table 4, expt. 8), however, ~ 11% of 3,3′-dimethylbiphenyl-2,4′-diamine is obtained. In the case of 3,3′-dimethylhydrazobenzene (Table 4, expt. 9) 11% of 2′,4-dimethylbiphenyl-2,4′-diamine and 3% of 2-amino-3′,4-dimethyldiphenylamine are obtained.

Ingold and Kidd[30] considered the intramolecular character of the rearrangement to be proved by the melting-point

‡ The same error has been made in a recent paper by Ingold and his coworkers[29], who consider that *o*-tolidine is obtained uncontaminated with its isomers.

diagrams of the mixtures of substances formed by the simultaneous rearrangement of 2,2'-dimethoxy- and 2,2'-diethoxy-hydrazobenzenes: according to their results the only substances obtained besides disproportionation products are pure 3,3'-dimethoxy- and 3,3'-diethoxy-benzidines, moreover in identical yield (73%). Actually, however, under Ingold and Kidd's conditions the yields in anhydrous ethanol are ~66% of 3,3'-dimethoxybenzidine (expt. 11) and 76% of 3,3'-diethoxybenzidine (expt. 12). Besides dianisidine ~ 20% of isomers are obtained, and in the case of diphenetidine up to 12% of isomers, which can be separated without loss of the main substances only by special acid purification.

Determinations by the Reviewer[24] indicate that hydrazobenzene rearranges more rapidly in ethereal than in 95%-ethanolic solutions of hydrogen chloride by factors of 30–40, and the rate of rearrangement in 99.9% ethanol exceeds that in 95% ethanol by a factor of ~ 150. The rates are incomparably higher in benzene–toluene solutions of hydrogen chloride than in ethereal solutions.

2,2'-Dimethylhydrazobenzene rearranges more rapidly than hydrazobenzene itself in ethereal solutions of hydrogen chloride by factors of ~ 1000, but more rapidly than in solutions of hydrogen chloride in 95% ethanol by a factor of only 4. Rates of rearrangement in ethereal and benzene–toluene solutions of hydrogen bromide exceed the rates in hydrogen chloride by factors of 10^5, results being comparable only in ethereal or in the benzene–toluene solutions.

In 95% ethanol hydrazobenzene rearranges at almost the same rate with hydrogen chloride and with hydrogen bromide. 2,2'-Dimethylhydrazobenzene rearranges twice as fast with hydrogen bromide as with hydrogen chloride.

Mechanism of the Rearrangement of Hydrazo-Compounds in the Presence of Acids

Not long ago almost all research workers considered that the rate of rearrangement in ionised acids was directly proportional to the first power of the concentration of the hydrazo-compound and the square of the concentration of protons[31]. The Reviewer published a paper opposing this hypothesis[26], and the protagonists of this theory found themselves compelled to re-examine their positions[32–37].

Hydrazo-compounds are unsuitable for important kinetic investigations, since their resemblance to diacid bases of the usual type is purely formal: although the rate of monoprotonation depends on the basic strength of the initial hydrazo-compound, the rate of the ensuing stage is related only indirectly to the basic strength of the monoprotonated molecule, being determined by a different property of the latter, its *stability in the presence of the acidic agent*. If the difference between the rates of the first and second stages is considerable, the illusion is created of a double protonation, which occurs with compounds capable of forming salts which are relatively stable to the further action of the acid (Table 1). In several cases (Table 1, expts. 13, 16, 17, 19, 20, and 22–25), however, the monoprotonated hydrazo-compounds are extremely unstable to acids: in other words, the rate of the second stage is very high. This simple fact becomes obvious from a knowledge of the salts of hydrazo-compounds; it proves the occurrence of a "spontaneous" rearrangement of monoprotonated hydrazo-compounds.

In the presence of acids rearrangement is invariably stepwise: the monoprotonated molecule which is formed rearranges *only under the further influence of the acid*. The very great difference between the results obtained in unionised and in ionised acids is probably due primarily to fundamental differences in the transition states produced. The reaction of crystalline hydrazo-compounds with hydrogen chloride or hydrogen bromide is apparently most characteristic of the former case. The process occurs in the solid phase, and can be represented as

$$[RNH—\overset{+}{N}H_2R]\,\bar{X} + H \rightleftarrows [RNH—\overset{+}{N}H_2R]\,X \ldots HX \rightarrow \text{Rearranged product}.$$

The presence of solvents has a fundamental influence: they change the strength of acids, and may to some extent dissolve the salts of hydrazo-compounds, with the result that rearrangement takes place partly in solution. Finally, the nature of the acid may very likely have an effect, as follows from a comparison of the results obtained with hydrogen chloride and with hydrogen bromide.

While disagreeing with the hypothesis of a spontaneous partial rearrangement put forward by Blackadder and Hinshelwood, the Reviewer considers that they have made a useful contribution in suggesting that in ionised acids a monoprotonated hydrazo-compound rearranges on the approach of a proton[37]. The transition state in aqueous and aqueous–alcoholic solutions can be written

$$RNH—\overset{+}{N}H_2R \quad H_3\overset{+}{O}.$$

In anhydrous alcohol the reaction is catalysed by the ethyloxonium ion. It is significant that, although the rate of the reaction is greater in 99.9% than in 95% ethanol by a factor of approximately 150, the results for the rearrangement of hydrazobenzene are almost the same (Table 4, expt. 1). And yet the results are affected by the nature of the solvent and of the acid. We have already seen that, when alcohol is diluted with water, the ratio of benzidine to biphenyline is increased. This ratio in 95% alcohol (87 : 13) is appreciably increased also by replacing hydrochloric with sulphuric acid. This may be linked with a specific effect of the unionised acid on the monoprotonated hydrazo-compound, which is probable also with rearrangement in weak acids.

From Table 1 it is possible to obtain a rough idea of the relative rates of rearrangement of a series of hydrazo-compounds, and also to find further support for the ideas on the mechanism of rearrangement. Acetic acid (95%) was used.

The rates of rearrangement of many hydrazo-compounds differ so greatly that it is not possible to express them on the same scale. In several cases, therefore, dioxan was added to slow down the rearrangement. This resulted in a marked diminution in the reaction velocity: thus in 95% acetic acid the conversion of hydrazobenzene reaches 50.5% after 3 h, whereas when 8 ml of dioxan has been added a period of 800 h is required for the transformation to attain 68%; with 2,2'-dimethylhydrazobenzene a time of 8 min produces a change of 42.5%, but on the addition of dioxan 24 h will yield 62%.

The examples of hydrazonaphthalenes selected by Banthorpe, Hughes, and Ingold were an unhappy choice for ascertaining the true nature of the rearrangement. Because of the extreme instability of the monoprotonated hydrazo-compounds, the rates of the first and second stages differ little, and it is extremely difficult to divide the rearrangement into stages, the whole process occurring very rapidly (expts. 23–25). And yet, in contrast to

these workers' results, salts of 1,1'- and 1,2'-hydrazonaphthalenes can be detected in dioxan diluted with ether, as has been stated in the Section on the salts of hydrazo-compounds.

2,2'-Diethoxy- and 2,2'-dimethoxy-hydrazobenzenes (expts. 20 and 17) can usefully be contrasted with 1,1'- and 1,2'-hydrazonaphthalenes. Their rates of rearrangement are close to those for the hydrazonaphthalenes, and there can hardly be any doubt that the "kinetic order with respect to the acid" will not differ significantly from 1.0 here. But the example of 2,2'-diethoxyhydrazobenzene clearly reveals the presence of two stages in the rearrangement: the hydrochloride of the hydrazo-compound can be isolated in 60–65% yield (Table 1, expt. 20), obviously owing to the coarse-grained character of the precipitate in ether. In spite of a lower rate of rearrangement, the quantity of 2,2'-dimethoxyhydrazobenzene hydrochloride which can be isolated does not exceed 10% (see Table 1, expt. 17).

4,4'-Dimethoxy- and 4,4'-diethoxy-hydrazobenzenes are very interesting (expts. 19 and 22). Their rates of conversion in acids are especially high, ~ 80% of disproportionation products being formed, whereas the maximum quantity of *o*-semidines which can be isolated under special conditions does not exceed 10%. Clearly, there is no possibility of recovering intermediate products, but nevertheless the stepwise character of the whole process is demonstrated perfectly by these examples: as has been stated repeatedly, disproportionation products result from a secondary reaction, the interaction of two molecules of the monoprotonated hydrazo-compound. The figures given (80% and 10%) indicate that the rate of this bimolecular reaction considerably exceeds the rate of conversion of the monoprotonated hydrazo-compound into the *o*-semidine.

Remarks on the Rearrangement of 4,4'-Substituted Hydrazobenzenes

An increasing number of attempts have been made recently to establish by kinetic methods the mechanism of the rearrangement of 4,4'-substituted hydrazobenzenes. Carlin and Wich[23] found that the rearrangement of 4,4'-dimethylhydrazobenzene is of the second order with respect to the acid: the reaction products were *o*-semidine, *p*-toluidine, and *p*-azotoluene in the proportions 40 : 40 : 20. It has already been mentioned that in reality the proportions of these products are different—58 : 23 : 16 (Table 4, expt. 10)—the slight predominance of toluidine over azotoluene being explained, in the Reviewer's opinion, by the reducing action of alcohol on the monoprotonated molecule of the hydrazo-compound.

Dewar and McNicoll[38] obtained values of 1.58 and 1.51 for the kinetic order with respect to the acid in the cases of 4-chloro-4'-methylhydrazobenzene and 4-chloro-4'-t-butylhydrazobenzene respectively, but they did not ascertain the composition of the products of the rearrangement. The results obtained by the Reviewer indicate the proportions of *o*-semidine, anilines, and azo-compound to be 24 : 33.5 : 35.5 in the former case, and 38 : 25 : 28 in the latter case.

Shine and his coworkers[39,40] studied the rearrangement of 4,4'-di-t-butylhydrazobenzene and 4,4'-divinylhydrazobenzene; in the former case 45–54% of the hydrazo-compound underwent rearrangement, and 48–50% disproportionation. In the latter case the order of the reaction with respect to acid was found to be 1.0, but the products resulting from the interaction of the divinylhydrazobenzene and hydrogen chloride in ethanol remained unknown: in any case, they were stated to be neither a semidine nor disproportionation products. From what has been stated the authors' view cannot be accepted that a "benzidine rearrangement" is taking place here.

Thus in the course of the rearrangement of 4,4'-substituted hydrazobenzenes the monoprotonation of the hydrazo-compound is followed by two parallel reactions—rearrangement of the monoprotonated hydrazo-compound to an *o*-semidine, and interaction of the latter two monoprotonated molecules to give anilines and azo-compounds.

4. "THERMAL" REARRANGEMENT OF HYDRAZO-COMPOUNDS

Meisenheimer and Witte[41] discovered that, when 2,2'-azonaphthalene dissolved in alcoholic alkali is boiled with zinc dust, 1,1'-binaphthyl-2,2'-diamine is formed. These workers, and subsequently also Jacobson[12], interpreted this phenomenon as a rearrangement under the influence of the alkali, but it has been shown[16] that it is not the alkali but the heating which leads to rearrangement both of 2,2'- and of 1,1'-hydrazonaphthalene.

A few years later the products of the rearrangement were determined, though only qualitatively, by Večeřa et al.[42] as a result of the very prolonged heating (at 150°C) of hydrazobenzene and 2,2'-dimethylhydrazobenzene (as well as of 4-methylhydrazobenzene and 1,1'-hydrazonaphthalene). Almost at the same time the "thermal" rearrangement of 2,2'-hydrazonaphthalene was studied by Shine[43], who obtained satisfactory results after only a few years[44]. With regard to 1,1'-hydrazonaphthalene, the author himself admits that this case proved to be too difficult for him.

When studying the "thermal" rearrangement is is important to establish the optimum temperature conditions. Overheating leads to copious tar formation, which probably occurred in Večeřa's experiments.

Rearrangement of Hydrazo-Compounds of the Benzene Series

The compounds which the Reviewer has tested can be divided into two groups: the first comprises hydrazo-compounds which form disproportionation products almost exclusively, this group including 4-chloro-, 4-bromo-, and 4,4'-dichloro-hydrazobenzenes; the second group contains the principal hydrazo-compounds (Table 5). Heating was conducted in an atmosphere of nitrogen in sealed tubes. Products of rearrangement are formed as well as products of disproportionation, their quantity sometimes exceeding 25%. They are *o*- and *p*-semidines, with one or other isomer predominating in individual cases. 4-Methylhydrazobenzene gives not only 2-amino-5-methyldiphenylamine but also a second possible isomer—2-amino-4'-methyldiphenylamine—which had not been observed by Jacobson[45] in the acid rearrangement, and was not detected in Večeřa's "thermal" rearrangement[42].

In several cases considerable quantities of *p*-semidines appear, which are not formed at all in the rearrangement of the same hydrazo-compounds in acid media. Benzidines and biphenylines could not be detected in any appreciable quantities.

TABLE 5. "Thermal" rearrangement in the benzene series.

Substituted hydrazobenzene	Temp., °C	Duration of heating, h	Products, %			
			o-semidines	p-semidines	anilines	azo-cpds.
Hydrazobenzene	140—145	120	16.7	12.5	31.5	33.4
4-Chloro-	140—145	20	—	—	45.2	47.5
4-Bromo-	110	16	—	—	46.5	50.3
4-Methyl-	140—145	116	18.6	8.1	33.5	35.6
2,2′-Dimethyl-	140—145	120	8.3	13.1	36.0	38.0
3,3′-Dimethyl-	140	100	32.0	8.2	26.2	29.1
4,4′-Dimethyl-	140—145	100	15.5	—	38.0	38.2
2,2′-Dimethoxy-	120—125	26	16.0	9.2	28.5	40.2

Rearrangement of Hydrazo-Compounds of the Naphthalene Series—Influence of Solvents

Hydrazonaphthalenes are worthy of special attention in the study of the "thermal" rearrangement. The composition of the final products varies greatly depending on factors which have hardly any effect on the rearrangement of hydrazo-compounds of the benzene series. Attention has been paid mainly to the more complicated but also more interesting rearrangement of the 1,1′-isomer[46,47]. The rate of rearrangement is considerably greater in alcohols, ethylene glycol, and formamide than in other solvents. In ethanol at 100°C some 87% of the dissolved 1,1′-hydrazonaphthalene has decomposed after only 10 min, the corresponding proportions of the 1,2′- and 2,2′-isomers being 53% and 27% respectively; the rates are still higher in formamide. In benzene 52%, 11%, and 3.5% are obtained respectively, in acetonitrile 45%, 8%, and 3.5%, and in pyridine 23.5%, 3.4%, and 1.0% of transformed hydrazo-compounds. However, a far more important fact is that the quantitative composition of the rearrangement products is often linked with the nature of the solvent. These products can be divided into two groups according to the mechanism of their formation, which will be discussed below. The first group comprises *o*- and *p*-diamines and the 2,2′-binaphthyl-1,1′-imine [dibenzocarbazole] corresponding to the *o*-diamine; the second group comprises the *o*- and *p*-semidines. In weakly polar solvents (cyclohexane, benzene, toluene, 1,4-dioxan) the quantities of semidines sometimes exceed 50% of the total rearrangement products. The quantity of semidines diminishes with increasing polarity of the solvent. The addition to weakly polar solvents of water, having a high dielectric constant, may result in a considerable decrease in the yields of semidines; this occurs in benzene and in dioxan, but water has far less effect in experiments with ethanol and with pyridine.

It is interesting to trace the influence of solvents on the relative proportions of 1,1′- and 4,4′-diamines. The ratio of 1,1′- to 4,4′-diamine is usually 0.67, the latter being obtained as the formyl derivative, whereas the less basic 1,1′-diamine is obtained in the free state§.

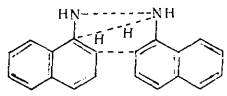
The quantities of dibenzocarbazole also depend sometimes on the nature of the solvent: far more is obtained in hydrocarbons and alcohols, in amounts exceeding those of the 1,1′-diamine by factors of 3–4; in pyridine, however, the yields of the dibenzocarbazole are very low, only ~ 20% of those of the *oo*′-diamine.

§ There appears to be an omission in the Russian text, since there is no reference to the solvent in this sentence (Ed. of Translation).

Rearrangement in alcoholic alkali gives very interesting results for all three isomeric dibenzocarbazoles. In anhydrous methanol and ethanol ~ 25% of dibenzo[*ai*]-carbazole is obtained, together with more than 50% of the [*ag*] isomer and ~ 20% of the 2,2′-dinaphthylamine. If, however, metallic sodium has first been dissolved in dehydrated alcohol to obtain a 0.1 *N* solution of the alkoxide, rearrangement is just as rapid, but it is remarkable that no dibenzocarbazoles are formed at all.

Results for the rearrangement of 1,2′- and 2,2′-hydrazonaphthalenes are simpler[47]. The former isomer yields an *oo*′-diamine, a dibenzocarbazole, and 4-amino-1,2′-dinaphthylamine; disproportionation is insignificant. Just as with 1,1′-hydrazonaphthalene, very considerable quantities of the *p*-semidine are obtained in benzene and in dioxan; the semidine is almost completely absent in alcohols. Only the *oo*′-diamine and the dibenzocarbazole are formed from 2,2′-hydrazonaphthalene.

In view of the above observations on the influence of the solvent on the rearrangement, it seems possible that the molecules undergoing rearrangement may interact with the solvent molecules not only before but also during the reaction. Thus the solvent, by tending to increase the lability of the hydrazo-compound, facilitates the initial stage in the process and also influences the composition of the final products.



If rearrangement is difficult, *o*- and *p*-semidines are obtained; this occurs in the benzene series, and also in several cases with 1,1′- and 1,2′-hydrazonaphthalenes. In agreement with Večeřa's hypothesis[42] it is very likely that the formation of semidines results from the interaction of radicals produced by cleavage of the HN—NH bond in the hydrazo-compound. It must be added, however, that such a radical reaction should be associated with conditions consistent with our views on the rearrangement as an intramolecular process: in other words, either this is an intramolecular radical reaction[48] or, if the radicals are kinetically independent, their lifetime is extraordinarily brief.

Solvents having well defined polarity facilitate the rearrangement, resulting in a considerable diminution in the

TABLE 6. "Thermal" rearrangement of 1,1′-hydrazonaphthalene.

Solvent	ml	Duration of reaction, h	Products, %							Semidines total products %
			1,1′-diamine	dibenzocarbazole	4,4′-diamine	o-semidine	p-semidine	naphthylamine	azonaphthalene

quantities of semidines from 1,1′- and 1,2′-hydrazonaphthalenes and a corresponding increase in the yields of diamines and dibenzocarbazoles. It is very significant that none of the three isomeric dibenzocarbazoles, which are sometimes formed in very large quantities, can be obtained from the binaphthyldiamines, since this would require more severe conditions [16]. This has been verified with all three isomers. Hence they must be formed at the instant of rearrangement. A conceivable transition state is

when the bond between the nitrogen atoms is not finally broken, and nor are new bonds finally established.

Azo-compounds and anilines are formed by an intermolecular redox reaction. In the benzene series, where rearrangement is greatly hindered, predominantly disproportionation products are obtained; but in the naphthalene series disproportionation occurs mainly in the case of 1,1′-hydrazonaphthalene, where rearrangement goes far more easily than with the 1,2′- and 2,2′-isomers. It is obvious that the redox reaction also goes very rapidly with 1,1′-hydrazonaphthalene. A striking feature is that usually the quantity of naphthylamine considerably exceeds that of 1,1′-azonaphthalene, especially with alcohols, ethylene glycol, aqueous pyridine, and aqueous dioxan. It is very likely that in these solvents we must reckon with water and alcohols exerting a reducing action on 1,1′-hydrazonaphthalene.

In conclusion it must be noted that the exceptional instability of certain hydrazo-compounds permits their rearrangement to be accomplished at ordinary temperatures. Thus 1,1′-hydrazonaphthalene dissolved in a mixture of formamide and pyridine, for example, is completely decomposed after 3 weeks, 50% of the *oo′*-diamine, 2% of the dibenzocarbazole, 40% of the *pp′*-diamine, and ~ 2% of the azo-compound being obtained. The breakdown of 1,2′-hydrazonaphthalene in a mixture of formamide and pyridine is somewhat slower, ~ 80% of the *oo′*-diamine being obtained together with small quantities of the dibenzocarbazole and the azo-compound. 2,2′-Hydrazonaphthalene decomposes far more slowly: after extremely prolonged storage under freshly boiled alcohol filling the whole apparatus, ~ 16% of pure 1,1′-binaphthyl-2,2′-diamine was formed together with a large quantity of an azo-compound. 4,4′-Dimethoxy- and 4,4′-diethoxy-hydrazobenzenes decompose very rapidly in a mixture of pyridine and formamide: no hydrazo-compound remained in the reaction mixtures after only a few days. They were oxidised mainly to azo-compounds (45–50%); in addition, 25–30% of the corresponding arylhydroxylamines and small quantities of anilines were formed. In other solvents the decomposition of hydrazo-compounds takes place more slowly. For example, 4,4′-dimethoxyhydrazobenzene in a solution of dioxan and methanol disappears completely after storage for 1 month, ~ 50% of an azo-compound, 25% of the arylhydroxylamine, and 8% of the aniline being obtained.

POLYCARBORANES

V. V. Korshak, I. G. Sarishvili,
A. F. Zhigach, and M. V. Sobolevskii

Great progress has recently been made with polymers containing boron, and several reviews of this work have appeared[1-5]. The polymer chemistry of boron has recently been enriched with a new class of compounds—the so-called polycarboranes.

Carboranes—products of the reaction between decaborane and acetylenic compounds—are obtained via the intermediate product in the interaction of decaborane with Lewis bases (nitriles, amines, amides, isocyanates), with subsequent displacement of the base by the action of acetylene and its derivatives:

$$B_{10}H_{14} + 2CH_3CN \longrightarrow (CH_3CN)_2B_{10}H_{12} + H_2$$

$$(CH_3CN)_2B_{10}H_{12} + RC{\equiv}CR' \longrightarrow RC\!-\!CR' + 2CH_3CN + H_2 .$$

The formation of carborane derivatives was described simultaneously by Soviet[6,7] and by American[8-18] research workers.

X-Ray examination as well as theoretical calculations of possible structures of several carboranes[19-25] suggest that a system of ten boron atoms is combined with two carbon atoms to form an icosahedron in which the C–C σ-bond is oriented at right angles to the plane of the 6,2,4,9-positions of the boron atoms in the decaborane unit (Fig. 1). In conformity with the recommendation of the Committee on Nomenclature of the Division of Inorganic Chemistry of the American Chemical Society[26] the name "carboranes" is used to denote compounds containing the system

in which the carbon atoms are regarded as heteroatoms and are numbered 1 and 2.

When carborane is heated above 475°C [18] it isomerises into a new compound, which has been termed "neocarborane". It is assumed that the thermal isomerisation involves transformation of the icosahedral structure with a strained C–C bond into the stable regular structure of neocarborane, which is free from strain. In such an icosahedral structure the carbon atoms are completely analogous to the boron atoms, and form three-centre bonds

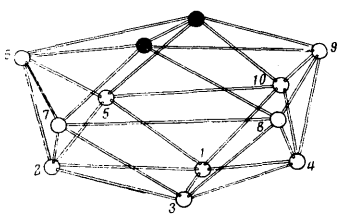

Fig. 1. Structure of the carborane molecule.

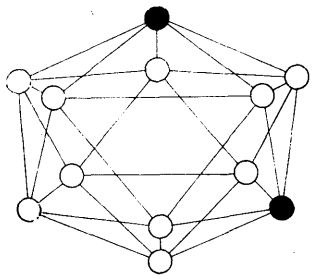

Fig. 2. Structure of the neocarborane molecule.

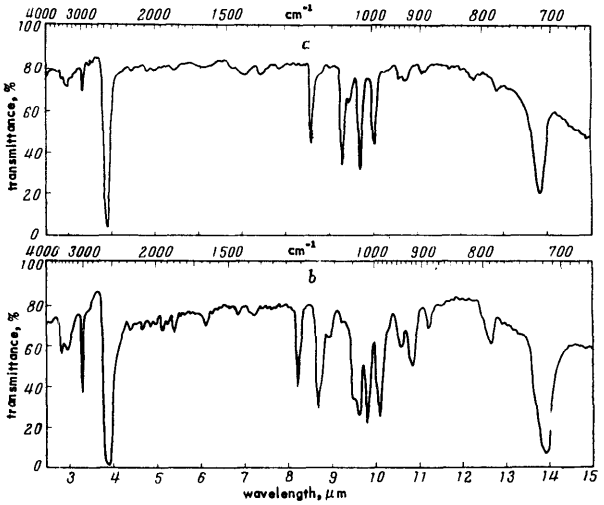
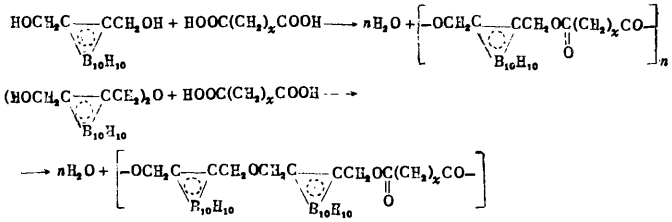
with the nearest boron atoms (Fig. 2). Neocarboranes resemble carboranes in their properties. However, the infrared spectra differ markedly (Fig. 3), as also certain physical and chemical properties (lower polarity, lower melting points, inability to form cyclic compounds, etc.).

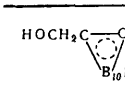
Comparison of the infrared spectra of neocarborane and carborane reveals considerable differences in the range 1250–900 cm^{-1}. The high peak at 1212 cm^{-1} characteristic of carborane is completely absent from the spectrum of neocarborane. The bands in the region of 1149, 1043, 1015, and 995 cm^{-1}, which are characteristic of carborane, disappear from the spectrum of neocarborane, and new bands appear in the region of 1158, 1069, 1022, and 991 cm^{-1}.

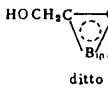
Carborane derivatives can be prepared both from acetylenic compounds and also by converting some carborane derivatives into others. A series of monomers have been obtained based on carboranes (diols, dicarboranic acids, dichlorides, diesters, di-isocyanates, vinyl derivatives, acrylates, epoxides, silanes, etc.), which are used for the preparation of various carborane polymers[9,11,12,14-17].

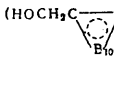
The present paper describes methods for obtaining various polymers of carborane, and also their properties.











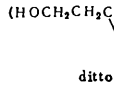


Fig. 3. Infrared spectra of: *a*) neocarborane; *b*) carborane.

Among the polymers of carborane which have been described, the polyesters are widely represented in the literature[27-29]. Numerous carborane derivatives[27]—diols, acids, acid chlorides, esters—have been used for the synthesis of polyesters. The latter has been accomplished by the polycondensation of organic and fluorinated organic diols of carborane with dibasic acids or with their chlorides. Polyesters of molecular weight 2000–3000 have been prepared by the polycondensation of carboranediols with various dicarboxylic acids or chlorides:

The polymers obtained and their properties are listed in Table 1.

TABLE 1. Properties of carborane polyesters.

Diol	Dibasic acid	Properties of polyesters		Ref.

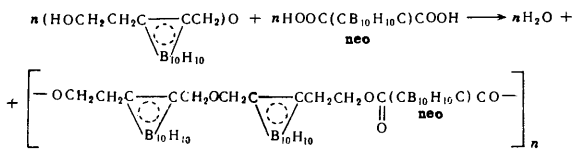
* Molecular weight determined by cryoscopic or precision ebullioscopic methods.

Inspection of the melting points of the carborane polyesters has revealed (though not very clearly, because of the incompleteness of the homologous series) the "evenness factor" discovered by Korshak and Vinogradova[30], consisting in the fact that polyesters of polymethylenedicarboranic acids having an odd number of carbon atoms melt at lower temperatures than both compounds of the polyester having an even number of carbon atoms in the molecule. This phenomenon is explained by polar effects in the dicarboxylic acid and diol molecules.

Examination of Table 1 shows that the replacement of CH_2 by CF_2 groups also lowers the softening point of a carborane polyester.

The carborane group consists of a sphere of effective van der Waals radius 4 Å. It is strongly electrophilic. Difficulties arising in the synthesis of the polymers and the properties of the products are determined both by steric and by electronic factors.

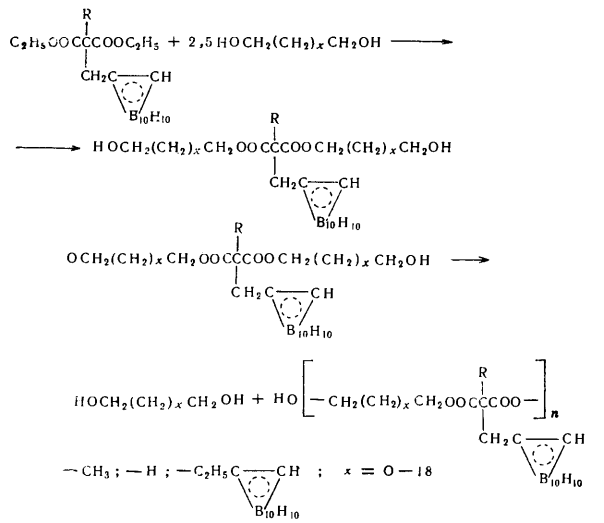
The effect of the carborane group on the properties of the polymers was studied on the polyadipates[31] obtained by the polycondensation of adipic acid with 1,2-bishydroxymethylcarborane, butane-1,4-diol, and butyne-1,4-diol. The first of these products was a viscous liquid, exhibiting no tendency to crystallise. The analogous organic polymers of equivalent molecular weight were crystalline waxes. Hence it can be concluded that the carborane group impedes the dense packing of the molecules and the subsequent crystallisation of the polymer. Investigations have shown[27] that the polyesterification of carboranediols proceeds considerably more slowly than that of organic diols. Thus a polyadipate of molecular weight 2500 can be obtained from butane-1,4-diol and adipic acid in 24 h, whereas synthesis of a poly(carborane adipate) at the same temperature lasts 5 days. This is indicated also by the fairly low rate constants given in Table 2 for the formation of a poly(carborane adipate)[32].



If both diol and dicarboxylic acid contain a carborane group, the adverse effect of the two carborane groups is so great that either no polymeric compound is obtained at all or else the resulting polymer has a low molecular weight.

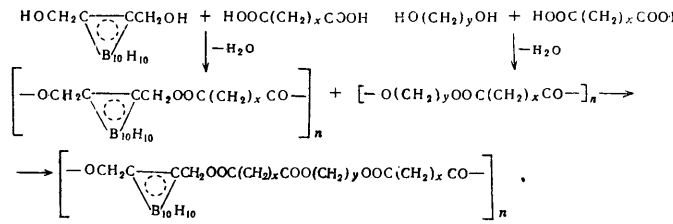
It is possible that increasing the distance between the carborane system and the functional groups of the molecule will tend to diminish the influence of the steric factor of the carborane unit. Table 1 shows that, when bishydroxymethylcarborane is replaced by bis-(2-hydroxymethylcarboran-1-ylmethyl) ether, which contains two carborane groups, the molecular weight of the product decreases from 2500 to 960. When, however, bis-(2-hydroxyethylcarboran-1-ylmethyl) ether is used, i.e. when the distance between the carborane nucleus and the hydroxyls in the molecule is increased, the molecular weight of the compounds is somewhat higher (1600 instead of 960).

TABLE 2. Rate constants of the formation of carborane adipate polyester.



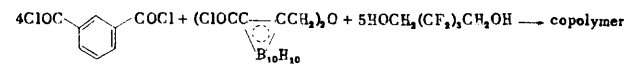
Temp., °C	Rate constant, mole g^{-1} min^{-1}
170	$7.46 \cdot 10^{-4}$
190	$1.59 \cdot 10^{-3}$
205	$2.48 \cdot 10^{-3}$

Interaction of bis-(2-hydroxyethylcarboran-1-ylmethyl) ether with neocarboranedicarboxylic acid according to the equation



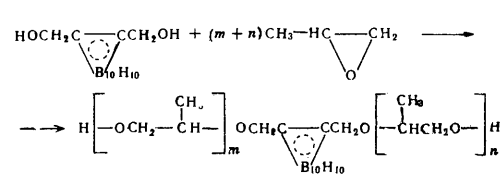
yields vitreous polymers of molecular weight 1730 and softening point 125°C. The resulting neocarborane polyesters are more crystalline than the carborane polymers, probably as a consequence of more compact packing of the molecules.

The steric and inductive effects of carborane groups which inhibit polymerisation may be exhibited when these groups are present in the side-chain. Thus polycarboranemalonates can be obtained by the esterification of carboranemalonates with glycols[27]. The process involves formation of an intermediate addition product of the diol and the carborane diester, followed by its self-condensation to a linear polymer accompanied by elimination of the glycol:



The products are vitreous materials of relatively low molecular weight. Attempts to increase the molecular weight were unsuccessful even when solvents of high boiling point were used and the molar ratio of the reactants was varied.

To obtain polymeric compounds having lower softening points and pour points, ternary copolymers were synthesised from bishydroxymethylcarborane, diethylene glycol, and dicarboxylic acids[28]. The mixed carborane polyesters were prepared by first synthesising polyesters of low molecular weight by the interaction of bishydroxymethylcarborane and a polymethylenedicarboxylic acid (adipic or glutaric acid), and also of diethylene glycol with the dicarboxylic acid, and then bringing about polyesterification between the two polyesters of low molecular weight to yield the mixed carborane polyester of higher molecular weight:



The copolymers were liquids of viscosity 33–35 P and molecular weight 2000–2200.

Ternary copolymers have been synthesised[27] from terephthaloyl and carboranedicarbonyl chlorides and a fluorocarbon diol:

The molecular weight of the product is 2500. The polymer softens at 35°C, possesses elastic properties over the range 35–56°C, and is converted above 56°C into a sticky liquid. The molecular weight of another copolymer obtained also from terephthaloyl chloride, together with 1,2-bishydroxymethylcarborane and hexafluoropentanediol, is 3300.

Oligomeric compounds having low softening points and pour points have been obtained by the migration copolymerisation of bishydroxymethylcarborane with alkyloxirans[33]. The migration copolymerisation of the former component with propylene oxide at 75–100°C and 3–5 atm yields a polyoxypropylenecarboranediol which is a liquid of viscosity 22 P comprising 5–6 structural units:

Fractionation of the polymer by adsorption chromatography[34] showed it to be polydisperse with a mean molecular weight of 500.

Attempts to increase the molecular weight of the polymer by varying the temperature of the synthesis or increasing the molar ratio of propylene oxide to bishydroxymethylcarborane were unsuccessful: the carborane units probably tend to inhibit polymerisation. However, the rates of formation of the polyoxypropylenecarboranediol are considerably higher than the rates of formation of carborane polyesters of dicarboxylic acids[32,35] (Table 3).

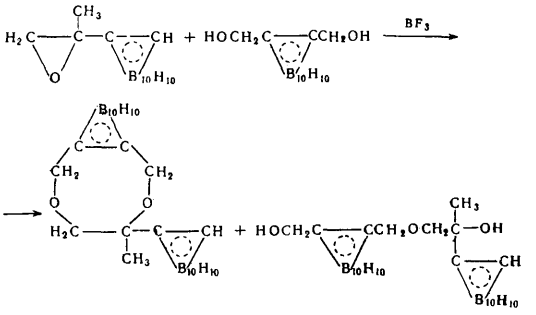


TABLE 3.

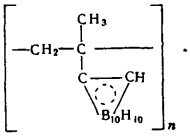
Thermographic and thermogravimetric studies have been made to obtain information on the thermal stability of the polyoxypropylenecarboranediol. The results show that vigorous decomposition of the product begins above 250°C, and is accompanied by exothermic peaks at 330° and 435°C, probably associated with oxidising processes.

The Reviewers have made attempts to prepare a polymer by the migration polymerisation of 2'-methyloxiran-2'-ylcarborane, a product of the oxidation of isopropylcarborane with perfluoroacetic anhydride. In the presence of traces of water a resinous polymeric compound of molecular weight ~ 1000 was obtained. It proved impossible to prepare a substance of higher molecular weight. It is probable that the steric and inductive effects of the carborane nucleus are also operative here, tending to inhibit polymerisation of the 2'-methyloxiran-2'-ylcarborane.

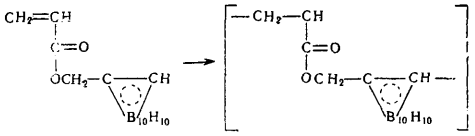
The reaction between 2'-methyloxiran-2'-ylcarborane and bishydroxymethylcarborane is also adversely affected by the carborane system[36]. In the presence of boron trifluoride cyclic—not polymeric—compounds are formed:



It is probable that the distance between the carborane system and the epoxy-group must be increased in order to diminish the steric effect of the carborane group. It has been remarked[31] also that attempts to polymerise 2'-methyloxiran-2'-ylcarborane have not always yielded positive results.

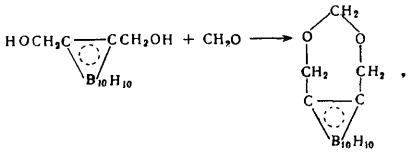
Carboraneurethane elastomers have been prepared by the interaction of di-isocyanates with carborane polyesters of polymethylenedicarboxylic acids[28] and also with polyoxypropylenecarboranediol[33]. The di-isocyanate is taken in slight excess over the stoichiometric quantity in order to form allophanic and biuret cross-links, which improve the mechanical properties of the elastomers. To increase the frequency of the vulcanisation network and improve the elastic properties it is proposed in certain cases[28] to introduce various polyols (glycerol, castor oil, 1,1,1-trishydroxymethylpropane, etc.) into the linear polyurethane polyester. The carboraneurethane elastomers obtained possess superior elastic properties.

Attempts have been made to obtain carborane elastomers by the polymerisation of carborane monomers, such as vinyl-, isopropenyl-, butenyl-, and allyl-carboranes. However, attempts to obtain polymers by the radical or ionic polymerisation of these compounds were unsuccessful.



Information appeared later[37] on the polymerisation of isopropenylcarborane in the presence of 5% of aluminium chloride at 150–170°C, with the formation of a solid product of molecular weight 1790, soluble in benzene and melting above 300°C. The infrared spectra of the polymer corresponded to polyisopropenylcarborane

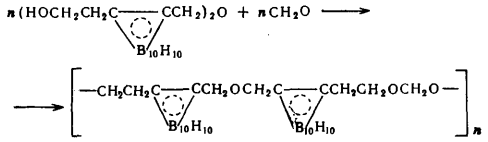
Trimeric isopropenylcarborane has been obtained[37] by using 50 wt.% of di-t-butyl peroxide as catalyst. With a smaller amount of the peroxide polymerisation was not observed.



Isopropenylcarborane has been copolymerised with methyl acrylate in the presence of azoisobutyronitrile to form a polymer which softens at 45–50°C.[37] The polymerisation has been reported[38] of 1-vinylcarborane, 1-methyl-2-vinylcarborane, and 1-isopropenyl-2-methylcarborane in the presence of phenyl-lithium in ethereal solution.

Investigations have been made on the polymerisation of carboranylmethyl acrylate[27]. Radical bulk polymerisation gave a homopolymer, a brittle solid which became rubber-like at 165°C:

Copolymers of carboranylmethyl acrylate with various fluorinated acrylates have been obtained[27] by radical bulk and emulsion polymerisation.



Cyclic and polymeric dialkoxymethanes have been described[27], resulting from the interaction of carboranediols with formaldehyde or with dipropoxymethane. The character of the products depends on the conditions of the reaction and the nature of the glycol used, either 1,2-bishydroxymethylcarborane or 2-carboranylpropane-1,2-diol. 1,2-Bishydroxymethylcarborane reacts with formaldehyde to yield linear polymers. Cyclic products are formed by bulk polymerisation in the presence of toluene-*p*-sulphonic acid:

Attempts to open the ring with formation of a linear dialkoxymethylene polymer were unsuccessful. The stability of the ring can be explained both by the stability of cyclic methylenedioxycarboranes and by steric hindrance to formation of a carborane polymer chain. It has been found that 1,2-substituted carboranes readily form three-membered exocyclic rings. This tendency to form cyclic structures is explained by the diminished bond length and the relatively acute external angle at which the group is attached to the carborane system.

Dimers and trimers (of molecular weight 400 and 700 respectively), or mixtures thereof, have been obtained by the interaction of 1,2-bishydroxymethylcarborane with formaldehyde in the presence of hydrochloric acid. The products were assigned a linear structure on the basis of their infrared spectra, which contained absorption bands due to terminal hydroxy-groups (2.88 μm). Other evidence of a linear structure is provided by the reaction of these products with adipoyl chloride, which results in a polymer of molecular weight 2839.

A polymer of molecular weight 4400 has been obtained by the interaction of bis-(2-hydroxyethylcarboran-1-ylmethyl) ether with formaldehyde:

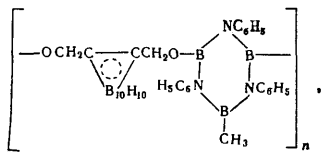
The linear structure of the polymer is confirmed by the presence in the infrared spectrum of an absorption band at 2.95 μm, corresponding to terminal hydroxy-groups, and also by the interaction of the polymer with 4-methyl-1,3-phenylene di-isocyanate to give a rubberlike polymer.

However, neither cyclic nor polymeric products could be obtained from bis-(2-hydroxymethylcarboran-1-ylmethyl) ether. This fact also indicates steric hindrance by the carborane groups, inhibiting polymerisation.

Materials exhibiting high thermal stability can be obtained on the basis of carborane polymers. The production of thermostable polymers is based on a chemical bond of high energy between the atoms constituting the main polymer chain and the groups surrounding it. However, the types of bonds leading to polymers which are stable to heat are very limited. Table 4 gives the energies of rupture [sic] of a few chemical bonds.

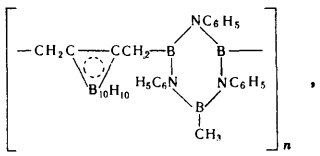
It may be supposed that carborane polymers containing the above types of bonds as well as the carborane group will have enhanced thermal stability. Indeed, polymers containing B–O bonds together with carborane groups are stable above 400°C. Such polymers have been obtained[28] by the interaction of boric acid with 1,2-bishydroxymethylcarborane and also with 2'-methyloxiran-2'-ylcarborane. They are solids of molecular weight 1000–1200, which have softening points of 118–87°C.

Thermographic and thermogravimetric studies have been made on the thermal stability of the polymers. They show that vigorous decomposition of the product begins above 300°C. At 400°C the polymers lose about 10% of their original weight. At 800°C the losses in weight amount to 21.2%. The process is accompanied by exothermic effects over the range 490–540° and also at 725°C, probably associated with structural changes in the polymer.



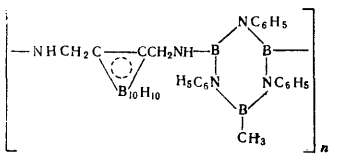
Interest has grown recently in the use of cyclic compounds of boron and nitrogen—the borazoles—for the synthesis of thermostable polymers[41]. The reason is the great thermal stability of the borazole ring, resulting from the fact that the σ-bond between boron and nitrogen atoms is supplemented by a coordinate link produced by displacement of the electron density of the lone pair of electrons from the nitrogen to the boron[42,43].

TABLE 4. Energy of rupture* of chemical bonds[39,40].

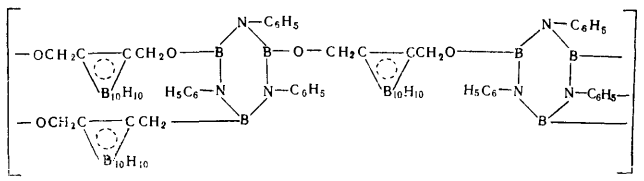


Bond	Bond energy, kcal mole^{-1}
B–O	119.3
B–N	104.3
B–C	100.0
Si–O	89.3
P–O	81.7

* Presumably the Reviewers have bond dissociation energies in mind (Ed. of Translation).



Polymers resistant to heat and to chemical reagents have been prepared from borazole and carborane compounds[44]. Polymers have been obtained from *B*-methyl-*N*-triphenylborazole together with 1,2-bishydroxymethylcarborane



bischloromethylcarborane

or bisaminomethylcarborane

and from *N*-triphenylborazole together with 1,2-bishydroxymethylcarborane

Polymers obtained by polycondensation in the melt are brittle, transparent, pale yellow substances having molecular weights ≫ 2000. In contrast to most polyborazoles, which are readily hydrolysed in air, these polycarborane-borazoles are completely resistant to atmospheric moisture. The resistance to hydrolysis is probably influenced by steric hindrance due to the carborane groups. The structure of the polymers was assessed from their molecular weights and their infrared spectra.

Fig. 4 gives the infrared spectra of *N*-triphenylborazole *1*, bishydroxymethylcarborane *2*, and the oligomer *3* obtained from them. It is seen that the band at 1401 cm^{-1}, corresponding to the cyclic B–N bond in *N*-triphenylborazole *1* is preserved in the spectra of the oligomer *3*. The band at 2590 cm^{-1}, corresponding to the B–H bond in the carborane rings of bishydroxymethylcarborane *2* also occurs in the spectra of the oligomer. Hence it may be concluded that the oligomer consists of carborane and borazole rings.

The thermal stability of these polymers has been investigated. The heat-resistance was determined by recording thermomechanical compression curves with P = 50 g (Fig. 5). The greatest heat-resistance is shown

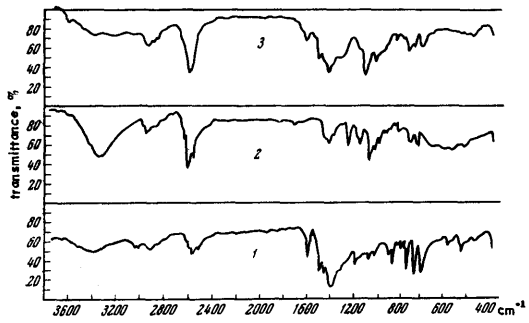


Fig.4. Infrared spectra of: 1) *N*-triphenylborazole; 2) bishydroxymethylcarborane; 3) oligomer obtained from them.

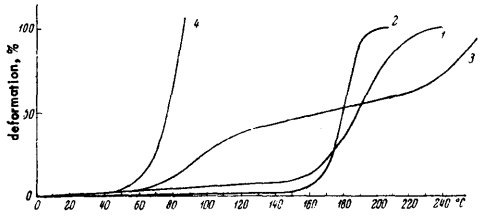

Fig.5. Thermomechanical curves of polymers based on: 1) *N*-triphenylborazole and bishydroxymethylcarborane; 2) *B*-methyl-*N*-triphenylborazole and bishydroxymethylcarborane; 3) *B*-methyl-*N*-triphenylborazole and bisaminomethylcarborane; 4) *B*-methyl-*N*-triphenylborazole and bischloromethylcarborane.

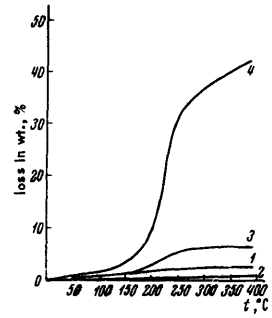
by polymers obtained from 1,2-bishydroxymethylcarborane with *N*-triphenylborazole *1* and with *B*-methyl-*N*-triphenylborazole *2*. The softening points of these polymers lie in the range 150–160°C. Those of polymers obtained from *B*-methyl-*N*-triphenylborazole with bisaminomethylcarborane *3* and with bischloromethylcarborane *4* are respectively 60° and 45°C.

The thermal stability of a polymer was determined from the change in weight of a specimen when heated in air (Fig. 6). The greatest stability is exhibited by polymers based on 1,2-bishydroxymethylcarborane with *N*-triphenylborazole *1* and with *B*-methyl-*N*-triphenylborazole *2*. When the polymers are heated in air to 400–450°C the loss in weight is ~ 1% (Fig. 6). The improved thermal stability of the polymers is possibly due to the presence of the thermostable borazole and carborane groups linked by a B–O bond, which has a high energy (Table 4). Polymers obtained from *B*-methyl-*N*-triphenylborazole with bisaminomethylcarborane *3* and with bischloromethylcarborane *4* begin to decompose vigorously above 150°C.

Phosphinocarboranes, obtained by the action of dilithium carborane on chlorophosphines containing 1–3 chlorine atoms, are highly resistant to heat and hydrolysis[45]. The product from dilithium carborane and phosphorus trichloride gives with sodium azide a compound $(B_{10}H_{10}C_2PN_2)_2$,



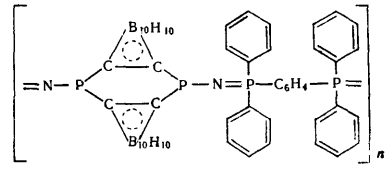


Fig.6. Thermal stability curves of borazole–carborane polymers. Numbering of curves as for Fig.5.

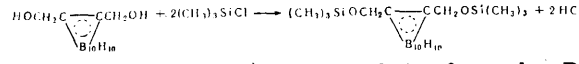
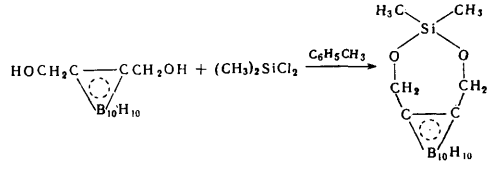


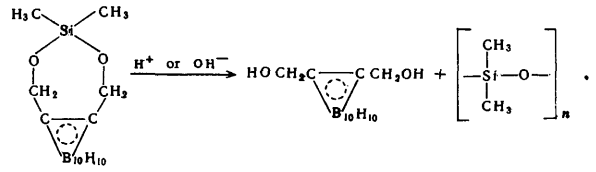
which copolymerises with $[(C_6H_5)_2P]_2C_6H_4$ to form a polymer having the structure



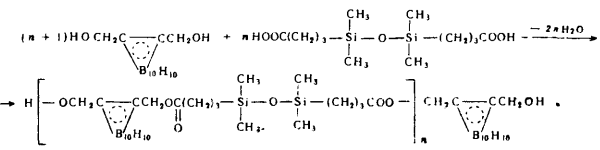
Recent investigations by the Thiokol Chemical Corporation, an American firm, show[46] that polymers highly resistant to oxidation and heat can be obtained by introducing carborane groups into a polybenzimidazole chain. Thus the sodium salt of polybenzimidazole reacts with 1-bromomethylcarborane to give the very stable polymer, polycarboranylmethylbenzimidazole. Thermogravimetric studies have shown losses of 18% and up to 25% of the original weight when the polymer is heated to 900°C in nitrogen and in air respectively.

Extremely interesting information[8,12] has been obtained on thermally stable carborane polymers containing silicon, which remain unchanged when heated to 450–500°C. Monomeric silicon-containing carboranes can be obtained[47] by the reaction of silicon chlorides with alkenylcarboranes. These reactions are catalysed by chloroplatinic acid and ferric chloride.

Reactions have been described[48] between carboranediols and methylchlorosilanes. The reaction of 1,2-bishydroxymethylcarborane with trimethylchlorosilane is represented by the equation



bis(trimethylsiloxymethyl)carborane being formed. Dimethyldichlorosilane reacts with the carboranediol to give a seven-membered cyclic compound



which consists of white crystals of molecular weight 260 and melting point 100°C. Attempts to open the ring to obtain a linear polymer were unsuccessful even when a catalyst was used (toluene-*p*-sulphonic acid or caustic potash),

the product being hydrolysed to the original carboranediol with formation of a polydimethylsiloxane:

An analogous compound has been synthesised[49] by the interaction of 1,2-bishydroxymethylcarborane and dimethyldichlorosilane.

The same workers[49] obtained also a series of linear carboranesiloxane polymers by the reaction between dichloropolymethylsiloxanes and 1,2-bishydroxymethylcarborane. The properties of the compounds obtained are listed in Table 5. These workers prepared carboranesiloxane oligomers by the polycondensation of bishydroxymethylcarborane with 5,5,7,7-tetramethyl-6-oxa-5,7-disilaundecane-1,11-dioic acid:

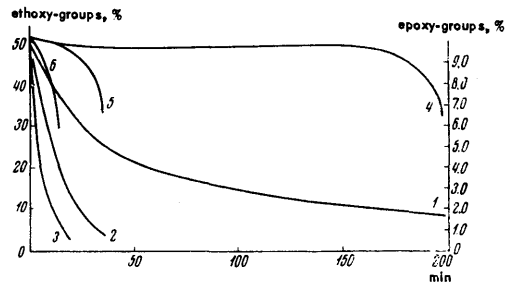
Carboranesiloxane oligomers are transparent colourless liquids of viscosity 80–90 P and molecular weight ~1000, soluble in aromatic hydrocarbons and chlorinated hydrocarbons but insoluble in alcohols and water. Thermogravimetric examination showed that the oligomers were stable up to 350°C.

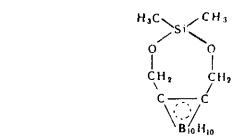
Organosilicon carborane oligomers have been obtained[50] by the interaction of epoxyalkylsilanes with bishydroxymethylcarborane.

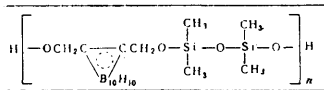
A study has been made of the migration copolymerisation of epoxypropoxypropyltriethoxysilane with bishydroxymethylcarborane. In the first stage of the process a linear polymer is formed by interaction of the epoxy-groups with the hydroxy-groups of the carborane (curves *1*, *2*, *3* at 160°, 180°, and 190°C respectively). In the second stage, when the content of epoxy-groups reaches its minimum value, the ethoxy-groups undergo alcoholysis (curves *4*, *5*, *6*, at 160°, 180°, and 190°C respectively); their content in the reaction mixture drops sharply, and the product passes from a viscous liquid to an elastic state (Fig. 7).

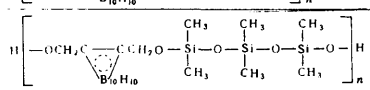
The resistance of the polymers to deformation on being heated was examined by determining thermomechanical curves with loads of 50 g and 100 g (Fig. 8, curves *1* and *2*). This work showed that, unlike most polymers, the product, with rise in temperature, passes into an infusible state without softening, the volume increasing at temperatures above 360°C. In view of the great thermal stability of the carboranesiloxane polymers obtained, coupled with their strong adhesion to glass and metals, and also the good dielectric properties inherent in carborane compounds, the polymers have been recommended for use as heat-insulating coatings.

There are indications that carboranesiloxane polymers having the carborane groups in side-chains possess greater thermal stability than do linear polymers having alternating carborane and siloxane units, in which the carborane groups are linked to a silicon atom directly through a methyl, methoxyl, ether, or ester group. Thus the synthesis has been described[31] of carboranesiloxane homopolymers and their copolymers with dimethylsilane having carborane groups in the side-chain, which are stable up to









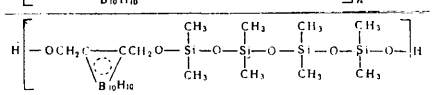


Fig. 7. Variation in quantities of epoxy-groups (1, 2, 3) and of ethoxy-groups (4, 5, 6) during reaction between epoxypropoxypropyltriethoxysilane and bishydroxymethylcarborane at temperatures of 160°, 180°, and 190°C respectively.

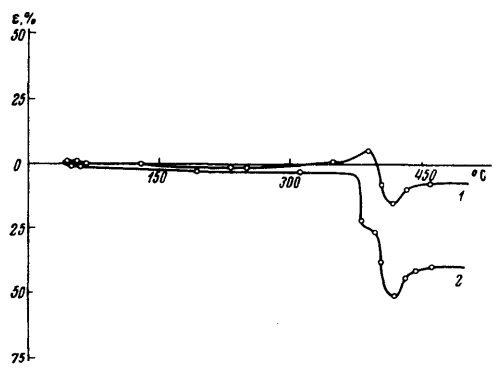

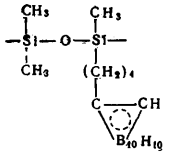

Fig. 8. Thermomechanical curves for the copolymer of epoxypropoxypropyltriethoxysilane with bishydroxymethylcarborane at loads of: 1) 50 g; 2) 100 g.

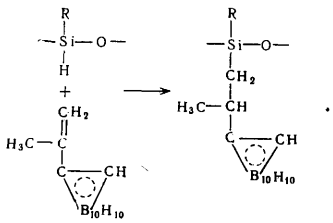


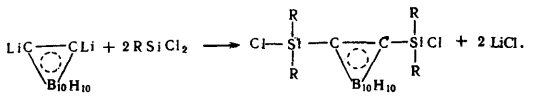
450°C. These polymers were obtained by hydrolysis and condensation reactions:†

The homopolymers have a low molecular weight owing to the formation of a large number of cyclic compounds. The copolymers are elastic solids of molecular weight ~ 13 000 and a pour point of ~ 100°C.

Thermogravimetric examination indicates that these carboranesiloxane polymers are stable up to 400–450°C in nitrogen and in air. The infrared spectra show that the carborane group remains unchanged at these temperatures. Investigation of the thermal degradation of the carboranesiloxane polymers shows that they are unaffected by heating at 350°C for 100–200 h.

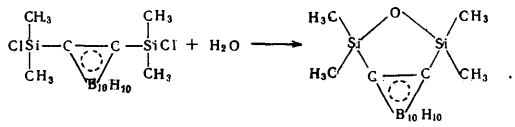
Carboranesiloxane polymers have been described[51,52] with the carborane groups framing the main siloxane chain. They were obtained by the migration copolymerisation of alkenylcarboranes with polyalkylsiloxanes:

The resulting polymers are viscous or solid depending on the degree of substitution by carborane groups of hydrogen attached to the silicon atom. The solubility of the polymers in aromatic hydrocarbons and in alcohols diminishes with increase in their content of carborane groups.



The investigations have shown that reaction between a polyalkylsiloxane and isopropenylcarborane takes place at temperatures above 200°C, hardly any reaction occurring below this temperature. However, the rates of formation of carboranesiloxane compounds are not very high even at high temperatures, as is indicated also by the formation rate constants (Table 6). The low rates of formation of carboranylsiloxanes are probably explained by steric and electronic factors due to the presence of the carborane group. Thermogravimetric analysis indicated that these polymers were stable in air up to 400–500°C.

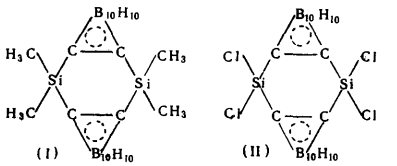
TABLE 6. Rate constants of the formation of carborane–siloxane compounds.



Compound	Rate constant, mmole g^{-1} min^{-1}, at		
	250°	270°	290°
Methylcarboranyloligosiloxane	$4.4 \cdot 10^{-5}$	$1.1 \cdot 10^{-4}$	$1.82 \cdot 10^{-4}$
Methylcarboranylcyclosiloxane	$6.25 \cdot 10^{-5}$	$1.3 \cdot 10^{-4}$	$1.92 \cdot 10^{-4}$

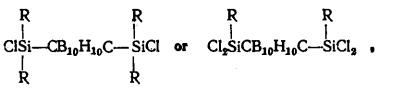
† Equations appear to have been omitted from the Russian text (Ed. of Translation).

Chlorosilyl derivatives of carborane in which the silicon atoms were directly attached to the carborane group were obtained via dilithium carborane[12]: e.g.



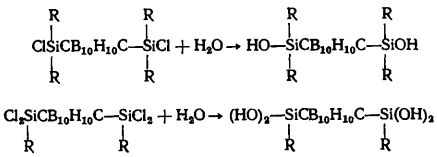
The hydrolysis of such compounds, in contrast to those described above, leads to the formation of cyclic carborane–organosilicon compounds, not the original carborane and a polysiloxane. Treatment of bischlorodimethylsilylcarborane with water yields a cyclic bisdimethylsilylcarborane:

The ammonolysis of bischlorodimethylsilylcarborane and also of bismethyldichlorosilylcarborane gave cyclic carboranedisilazanes[53]. Unlike ordinary silazanes, which react with water, the carboranesilazanes were stable to hydrolysis.

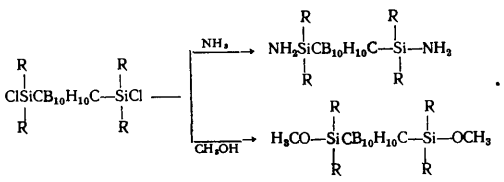


Cyclic carboranedisiloxanes and carboranedisilazanes are thermally stable up to 400°C. Above 500°C they decompose with the evolution of methane. Further rise in temperature to 600°C is accompanied by rapid decomposition with the evolution of hydrogen. Replacement by methyl groups of hydrogen attached to nitrogen improved the stability of the compounds.

Two types of thermally stable cyclic compounds

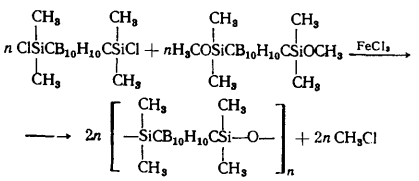


have been obtained[53]. Bisdimethylsilylenedicarborane (I) is stable to heat and hydrolysis up to 485°C. Bisdichlorosilylenedicarborane (II) does not react with water, but with ammonia the chlorine atoms are replaced by amino-groups, the carborane systems being preserved. Attempts to open the rings to give linear polymers were unsuccessful.

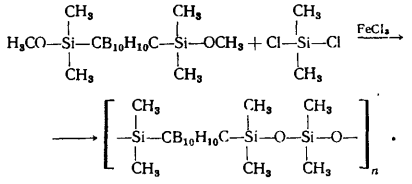


For the synthesis of thermostable carborane–organosilicon polymers, research workers turned to *m*-carborane (or neocarborane) systems, in which the positions of the carbon atoms exclude the possibility of the formation of exocyclic structures, while the stability at high temperatures is maintained. Chlorosilyl derivatives of neocarborane

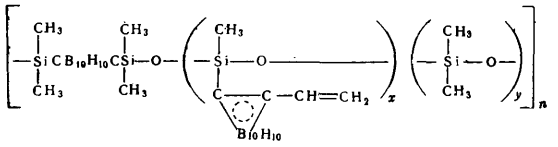
were obtained via dilithium neocarborane[54]. Hydrolysis of these compounds yielded linear carborane–organosilicon compounds having terminal hydroxy-groups:



Treatment of bischlorosilylneocarboranes with ammonia and with methanol yields respectively bisaminosilyl- and bismethoxysilyl-neocarboranes:



A series of silylneocarboranes have been obtained in this way [54].



Polymers may be obtained [55] based on these compounds. The reaction of bischlorodimethylsilylneocarborane with bismethoxydimethylsilylneocarborane in the presence of iron(III) chloride at 140–190°C according to the equation

yields a polymer of molecular weight 16 000 and melting point 235–255°C, soluble in hot *N*-methylpyrrolid-2-one, decalin, chlorobenzene, and bromobenzene. Analogous polymers having different numbers of dimethylsiloxy-units have been obtained [55] by the interaction of bismethoxydimethylsilylneocarborane with dimethyldichlorosilane (or dichloropolymethylsiloxanes):

To obtain polymers by a free-radical mechanism, a few methyl groups (not more than 8%) were replaced by vinyl groups [55], especially for dichlorovinyl derivatives of carborane, yielding a polymer having the structure

The resulting polyneocarboranylenesiloxanes exhibited thermal stability above 500°C and resistance to oxidation up to 350°C. Thus, as was to be expected, these polymers were rather more thermostable than polycarboranesiloxanes with the carborane groups framing the main siloxane chain [51,52], which were stable in air up to 400–450°C.

---o0o---

Summarising, we may predict that the peculiar chemical, physicochemical, and mechanical properties of polycarboranes (high thermal stability, strength, dielectric properties, adhesion to glass, metals, wood, etc.) will deservedly induce research workers to take an interest in these compounds, with the result that many new carborane polymers will be discovered which may find application in various branches of technology.

I. INTRODUCTION

Modern technology has an urgent need of thermostable polymeric materials. Apart from retaining their strength at high temperatures, the polymers must meet such requirements as resistance to hydrolysis, organic solvents, and mineral acids, good dielectric properties, etc. This results from the development of such new branches of technology as rocket construction, high-speed aviation, electronics, and instrumentation, and also from the more severe demands made on polymers which are widely used in electrical and mechanical engineering, paints and varnishes, and many other branches of industry.

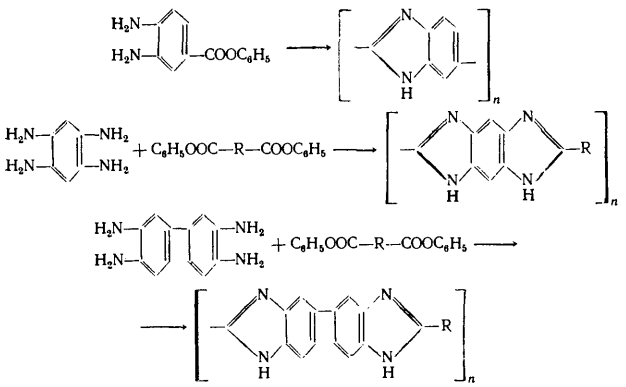
The demands made on the thermal stability of polymers depend on how long the polymer will be located in a high-temperature zone. For example, modern aircraft require materials which have the limiting operating temperatures indicated below[1]. Still higher demands are made on materials for spacecraft.

Length of operation, h	30 000	1000	1	5 min
Temperature, °C	177	260	540	830

During recent years broad investigations have been conducted, both abroad and in the Soviet Union, on the synthesis of heat-resistant polymers, among which the most interesting are those containing heterocycles in the main chain of the macromolecule.

Polybenzimidazoles and polypyromellitimides have already found application. It is probable that in the immediate future use will also be made of polyquinoxalines[2], polymethylquinazolones[3], polyimidazolopyrrones (pyrrones)[4,5], and polymers containing 1,3,5-triazine[6,7] and other rings.

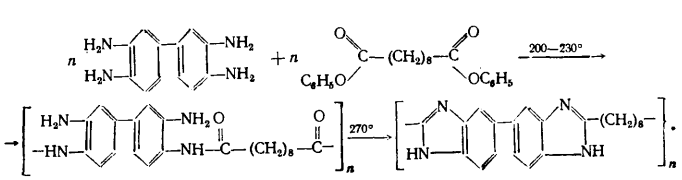
At the present time the class of heterocyclic polymers which has been studied most thoroughly comprises the polyazoles. However, this class of polymers has not been adequately represented in the numerous reviews devoted to heat-resistant polymers[8-14]. We have tried to fill this gap, and reflect the overall progress made in synthesising polyazoles containing azole rings in the main chain and in studying their properties.



Imdividual representatives of the polyazoles—e.g. polyaminotriazoles and polythiazoles—were obtained long ago. Extraordinary interest in polyazoles as promising heat-resistant materials arose after 1959, when Brinker and Robinson, and later Marvel and his coworkers, published papers on the synthesis of polybenzimidazoles.

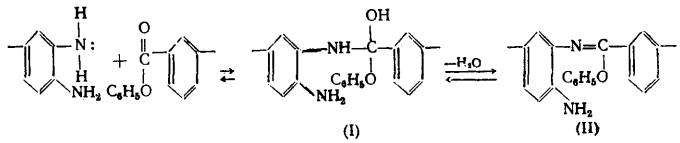
II. POLYBENZAZOLES

Polybenzazoles were first described by Brinker, Robinson, and Cameron [15,16], who obtained polybenzimidazoles based on biphenyl-3,3′,4,4′-tetra-amine and aliphatic dicarboxylic acids, and polybenzoxazoles based on *o*-hydroxyaminophenylalkanoic acids. The polybenzimidazoles obtained proved to be more stable than polyamides to the action of light and water. From this moment an intensive study began of the properties of polybenzazoles, in the first instance of polybenzimidazoles.



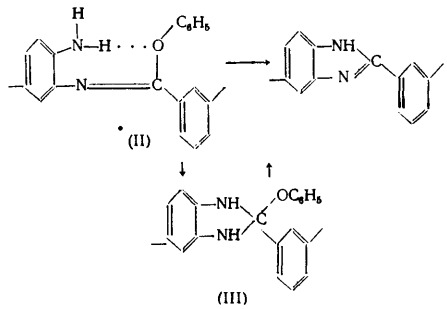
1. Methods of Preparing Polybenzazoles

Polybenzazoles have been obtained in various ways. Vogel and Marvel [17] found that aromatic polybenzimidazoles of high molecular weight can be prepared by the polycondensation of tetra-amines with diphenyl esters of dicarboxylic acids:



The general method developed for most of the polymers described consists in heating the reactants in the complete absence of oxygen, initially at 220–280°C, and then with the temperature raised to 400°C at 0.1 mmHg. The mass does not melt at this temperature, and the method consists essentially in solid-phase polycondensation. To obtain better results Marvel [8] proposes conducting the reaction in a rotating stainless-steel vessel, a few steel balls being placed in the mass of the polymer with the aims of stirring and improving heat transfer.

Korshak, Izyneev, and their coworkers [18-21] suggested, on the basis of elementary analysis and potentiometric titration of the reaction products, that the process in this case occurs in two stages, a polyaminoamide being formed in the first stage:



Wrasidlo and Levine [22] concluded from a detailed study of the formation of polybenzimidazoles that the reaction begins with nucleophilic attack by the amine on a carbonyl carbon atom in the diphenyl ester, an intermediate product of aldol type (I) being formed, which after dehydration gives a new intermediate product having the structure of a Schiff's base (II):

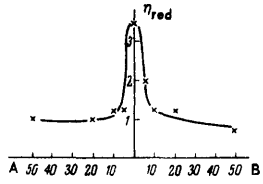
The intermediate product (II) can exhibit stereoisomerism, so that the *syn*-form can undergo intramolecular hydrogen bonding. According to these workers the formation of such hydrogen bonds promotes the intramolecular elimination of phenol and prevents the appearance of cross-linked and branched products.

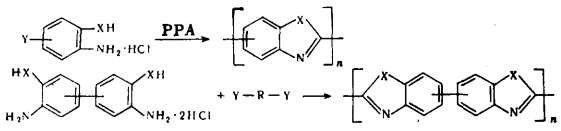
The intermediate product (II) can probably exist in equilibrium with the benzimidazoline structure (III). The final process in the condensation is the elimination of phenol and formation of the polybenzimidazole:

Polybenzoxazoles of various structures have also been obtained by this process [23,24].

The overall mechanism of the formation of polybenzazoles is quite complicated. In the early stages, involving mainly the formation of polyamide units, the reaction is obviously reversible, and obeys the laws characteristic of equilibrium polycondensation. This applies in particular to the effect of excess of the reactants (Fig. 1) and to additions of monofunctional compounds. The chain termination which is usual for equilibrium polycondensation then occurs [25,26]. In the first stage, acidolysis and aminolysis of the polymer chains can obviously take place.

In the later stages, when the macromolecules contain mainly benzazole rings, the process loses its reversible character, since azole rings are exceptionally stable, as Korshak et al. [27] showed, and such polymers do not undergo degradative or exchange reactions.





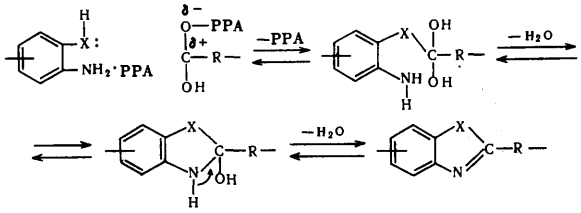


Fig. 1. Variation in reduced viscosity in formic-acid solution of poly-2,2′-octamethylene-5,5′-bibenzimidazolyl with excess (mole %) of the initial reactants:
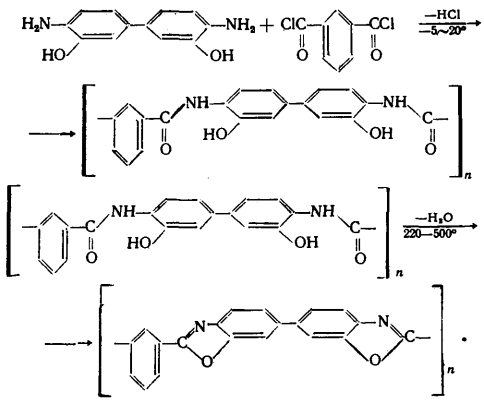
A) biphenyl-3,3′,4,4′-tetra-amine;
B) diphenyl sebacate.

Iwakura and his coworkers[28-30] worked out a method for obtaining polybenzazoles in polyphosphoric acid (PPA). Polybenzimidazoles, polybenzoxazoles, and polybenzothiazoles of various structures were obtained according to the general scheme



where X = NH.HCl, O, S and Y = COOH, $COOCH_3$, $CONH_2$, CN. An advantage of this method is the use of the more stable hydrochlorides instead of a tetra-amine, or an *oo'*-dihydroxy- or *oo'*-dimercapto-diamine. According to these workers[29] the benzazole polymers are formed by the reaction mechanism

where X = NH, O, S. The polyphosphoric acid enhances the reactivity of the electrophilic carbon atom in the carbonyl group, and acts as an efficient dehydrating agent.

Vogel and Marvel[17] showed that the method of interfacial polycondensation is not very suitable for the synthesis of polybenzimidazoles of high molecular weight: the polybenzimidazoles obtained had a reduced viscosity of only 0.09–0.22 dl g^{-1}.

A method which has been successfully applied to the synthesis of polybenzazoles consists in low-temperature polycondensation in a solvent followed by cyclisation of the resulting polymers at a high temperature. Kubota and Nakanishi[31], using this method, were the first to obtain completely aromatic polybenzoxazoles. In the first stage of the reaction a hydroxylated polyamide was obtained in dimethylacetamide solution, and its cyclisation yielded a polybenzoxazole:

Maksimov et al.[32] applied this method to the synthesis of polybenzothiazoles. A difficulty in this case was that the instability of the benzidinedithiol made necessary its use in the form of its hydrochloride, which was less active than the base under conditions of low-temperature polycondensation. The variation in the molecular weight during synthesis of the polymercaptopolyamide is illustrated in Fig. 2. The degree of polymerisation remains practically unchanged on cyclisation.

2. Polybenzimidazoles

Table 1 lists the properties of the polybenzimidazoles which have been described in the literature. It is seen that the properties of polybenzazoles depend fundamentally both on the structure of the original amine and on that of the acid component.

Vogel and Marvel[17] synthesised fully aromatic polybenzimidazoles from biphenyl-3,3',4,4'-tetra-amine and diphenyl esters of aromatic dicarboxylic acids. They showed that the phenyl esters gave with the tetra-amine polymers of higher molecular weight than when the acids or their methyl esters were used, since in the latter two cases polycondensation was accompanied by methylation of the amino-groups or decarboxylation as side-processes. The poly-2,2'-(*p*-phenylene)-5,5'-bibenzimidazolyl and poly-2,2'-(*m*-phenylene)-5,5'-bibenzimidazolyl which these workers obtained were highly thermostable, beginning to decompose in air only at temperatures above 500°C.

Plummer and Marvel[37] obtained polybenzimidazoles based on biphenyl-3,3',4,4'-tetra-amine and isomeric naphthalenedicarboxylic acids. The products were not so thermostable as the above polymers. These same workers showed that the condensation of diphenyl ferrocene-1,1'-dicarboxylate and of diphenyl imidazole-4,5-dicarboxylate with biphenyl-3,3',4,4'-tetra-amine yields polybenzimidazoles of fairly low reduced viscosity. The former of these polymers exhibited high thermal stability, while the latter was considerably less stable.

Dark brown or black polymers are obtained by the condensation of diphenyl fumarate or of a mixture of maleic anhydride and phenol with biphenyl-3,3',4,4'-tetra-amine. These polybenzimidazoles are to a considerable extent decomposed at 300°C.

Korshak, Izyneev, and their coworkers[18,19] obtained a poly-2,2'-octamethylene-5,5'-bibenzimidazolyl having a reduced viscosity in formic acid of 14 dl g^{-1}. Use of a vacuum of 0.01–0.001 mmHg in the second stage of the polycondensation contributed to the production of a polymer of high molecular weight and good mechanical properties.

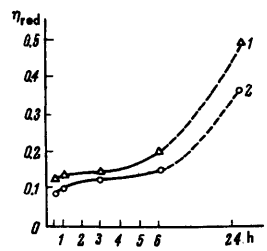


Fig. 2. Dependence of reduced viscosity of poly-3,3'-dimercaptobiphenyl-4,4'-yleneisophthalamide in H_2SO_4 on duration of reaction:
1) in the absence of pyridine; 2) in the presence of pyridine.

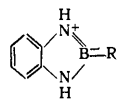
Plummer and Marvel[37] synthesised polybenzimidazoles based on biphenyl-3,3',4,4'-tetra-amine and perfluoropolymethylenedicarboxylic acids, in the hope that they would be more thermostable than polymers based on ordinary aliphatic acids. However, the fluorinated polybenzimidazoles already begin to decompose at 200–250°C. Other workers[47,48] have also referred to the low thermal stability of polyperfluoromethylenebenzimidazoles.

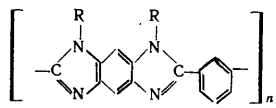
Mulvaney and Marvel[41] described the properties of a polybenzimidazole having the structure



This polymer is less thermostable, possesses a higher solubility, and melts at a far lower temperature than aromatic polybenzimidazoles. The polymer begins to melt at 420–450°C, but even after being heated to 450°C it retains its solubility in dimethyl sulphoxide, dimethylformamide, and formic acid.

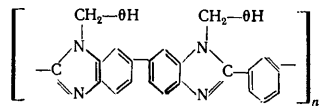
Mulvaney, Bloomfield, and Marvel[43], as well as Bamford and Fordham[42], obtained polybenzoborimidazolines from biphenyl-3,3′,4,4′-tetra-amine and the appropriate diboronic esters:

A cyclic molecule containing a boron atom



possesses a system of π-electrons, and its ultraviolet spectrum is similar to that of benzimidazole[49-51]. In view of their aromatic character these polymers are quite thermostable, the loss in weight in nitrogen at 450–500°C being ~10% for the polymer based on benzene-*p*-diboronic acid.

Polybenzazoles containing respectively oxygen and phosphorus in the main chain have been prepared and investigated. Polybenzimidazoles containing these elements have been described by Frunze et al.[38] and also by Foster and Marvel[39]. The introduction of oxygen improves the solubility and should probably improve the mechanical characteristics of polybenzazoles. Thus from biphenyl-3,3′,4,4′-tetra-amine and diphenyl oxy-*pp*′-dibenzoate a polymer has been obtained possessing a crystalline structure and soluble in sulphuric acid, formic acid, and dimethyl sulphoxide in the cold, and in dimethylformamide and tricresol on heating. The polymer obtained from diphenylmethane-3,3′,4,4′-tetra-amine and the same ester is soluble in dimethylformamide in the cold. A polybenzimidazole containing phosphorus, which has the interesting and important property of non-flammability, has been obtained by the interaction of diphenylmethanetetra-amine and diphenyl methyloxodiphenylphosphorane-*pp*′-dicarboxylate. When the polymer is introduced into the burner flame, it slowly smoulders and chars, but on withdrawal from the flame it is immediately extinguished. The self-quenching of this polymer is due to the presence of the phosphoryl group (phosphorus content 6.8%). An analogous phenomenon has been observed with phosphorus-containing polyamides[52].

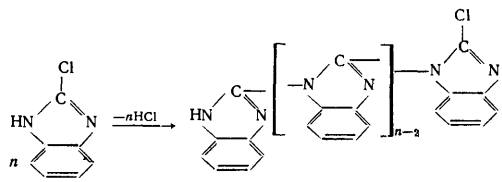


In all the preceding cases the properties—mainly the solubility—of the polybenzimidazoles were varied by a suitable choice of acid components having various structures. However, it is evident from the data which are cited that a considerable improvement in solubility was accompanied by a sharp fall in thermal stability. More recent work has shown that the properties of polybenzimidazoles can be modified, while adequate thermal stability is maintained, also by varying the structure of the initial amine, e.g. by introducing various substituents into the molecule of a fully aromatic tetra-amine, or by obtaining mixed polymers.

Marvel and his coworkers[33,34] prepared *N*-substituted polybenzimidazoles of general formula

where R = C_6H_5, CH_3. The phenylated polymer showed practically the same thermal stability as the analogous unsubstituted polybenzimidazole. The methylated polymer began to decompose in air at 300°C.

An *N*-substituted polybenzimidazole has recently been synthesised[53] having the structure



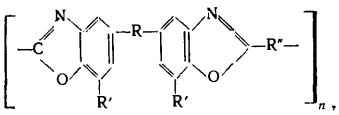
where θ represents

by reaction between the sodium salt of polybenzimidazole and 1-bromomethylcarborane. Polycarboranylmethylbenzimidazole loses only 25% of its weight when heated in air to 900°C.

By heating 2-chlorobenzimidazole at its melting point, Harrison and Ralph[54] obtained an insoluble high-melting polymer, which did not decompose up to 400°C:

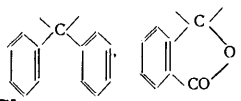
Frunze et al.[45] have synthesised several polybenzimidazoles based on diphenylmethanetetra-amine and dicarboxylic acids. These polymers are yellow to brownish vitreous products, which soften between 260° and 400°C and possess a mainly amorphous structure. The ultraviolet spectra of these polybenzimidazoles[55] have absorption maxima close to those of model compounds, but exhibit some bathochromic and hypsochromic shifts, which were referred to also by Vogel and Marvel[17] when discussing fully aromatic polybenzimidazoles. The polybenzimidazoles based on diphenylmethanetetra-amine possess somewhat better solubility than the corresponding polymers based on benzidinediamine, while having approximately the same thermal stability.

Polybenzimidazoles have been described based on a tetra-amine containing an ether link between phenyl groups[39,46]. Korshak et al.[56] suggested preparing polybenzazoles containing various substituents on the central carbon atom of



the initial amine. The resulting polymers were distinguished by better solubility.

Mixed polybenzimidazoles containing residues of two different dicarboxylic acids have been synthesised by Korshak and his coworkers[40,57]. The thermal stability of the mixed polybenzimidazoles is somewhat below that of the homopolymers, as is evident from Fig. 3, which shows the variation in the decomposition temperature with the composition of the initial mixture. Mixed polybenzimidazoles containing units of an aliphatic dicarboxylic acid decompose at lower temperatures (in the range 400–520°C) than do polybenzimidazoles synthesised solely from aromatic components. Thus the decomposition point of polybenzimidazoles obtained from biphenyl-3,3′,4,4′-tetra-amine and diphenyl isophthalate and terephthalate lies in the range 460–520°C.



3. Polybenzoxazoles and Polybenzothiazoles

Great interest has recently been evinced in polybenzoxazoles and polybenzothiazoles (Table 2), analogues of polybenzimidazoles, since it has been supposed that they will show greater resistance than polybenzimidazoles to oxidative thermal degradation.

Several communications appeared almost simultaneously on the synthesis of polybenzoxazoles based on 4,4′-diaminobiphenyl-3,3′-diol[23,31,58]. It was noted that polybenzoxazoles are inferior to polybenzimidazoles in solubility. In order to improve the solubility of the former, Korshak et al.[24,60,61] synthesised polymers containing various substituents in the benzene ring of the benzoxazole, of general formula

where R = $C(CH_3)_2$, $C(CH_3)(C_6H_5)$, $C(C_6H_5)_2$,

and R′ = H, CH_3, Cl.

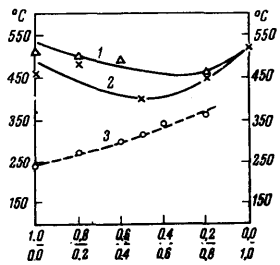


Fig. 3. Variation, with molar composition of mixed polybenzimidazoles based on biphenyl-3,3′,4,4′-tetra-amine, in:
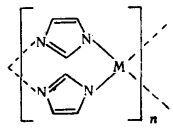
1) decomposition temperature of polymers from sebacic and isophthalic acids;
2) decomposition temperature of polymers from terephthalic and isophthalic acids;
3) softening point of polymers from sebacic and isophthalic acids.

The resulting polymers, while possessing high thermal stability (loss in weight begins at 400–500°C when R″ represents an aromatic group), dissolve in a wide range of organic solvents—chloroform, tetrachloroethane, tricresol, benzyl alcohol, pyridine, dimethylformamide, etc.—except in the case of polymers containing halogen in the side-chain and with the central carbon atom forming part of a phthalidylidene group. Polymers in which R″ represents an aromatic radical pass into an infusible and insoluble state when heated to 450°C. Unfortunately, the authors do not discuss the effect of molecular weight on the solubility of the polybenzoxazoles obtained.



Polybenzothiazoles were first synthesised in 1962 by Kipriyanov and Mushkalo[63]. However, these workers merely obtained an oligomeric condensation product of 4-amino-3-mercaptobenzoic acid. Hergenrother et al.[62] suggested that polybenzothiazoles should be synthesised in two stages: in the first stage a precondensate of low molecular weight is formed in boiling diethylaniline solution, and this passes on further condensation in the solid phase into a polybenzothiazole of high molecular weight. Imai et al.[29,30] synthesised several new polybenzothiazoles and isomeric polybenzoxazoles by their method of polycondensation in polyphosphoric acid.

All the authors note the great stability to heat and thermal oxidation of the polybenzothiazoles, which, however, are soluble only in concentrated sulphuric acid.

III. POLYIMIDAZOLES

In the case of polyazoles not containing fused rings—in contrast to polybenzazoles, where until recently attention has been paid mainly to benzimidazole derivatives—most of the work has been done on the synthesis of polythiazoles, the first information on which appeared during the Second World War. Few papers have been concerned with the synthesis of polyimidazoles, and we have found none on that of polyoxazoles.

Brown and Aftergut[64] prepared polyimidazoles of general formula

where M is a bivalent metal. The products were insoluble in organic solvents, infusible, and quite thermostable, showing no loss in weight when heated in nitrogen to 500–575°C.

A polymer possessing semiconductor properties was obtained by the pyrolysis of 2,4,5-tri-iodoimidazole and 1,2,4,5-tetraiodoimidazole[65].

IV. POLYTHIAZOLES

Erlenmeyer and his coworkers[66,67] were the first to obtain polythiazoles, but they did not examine the properties of the products. Mulvaney and Marvel[68], and somewhat earlier some Japanese investigators[69], continued Erlenmeyer's work on the synthesis of polythiazoles. Several papers have appeared recently reporting detailed investigations of the properties of polymers of this type, information on which is given in Table 3.

* In air.

Longone and Un[70] obtained polybenzothiazoles from a dithioamide and aromatic and mixed aliphatic and aromatic bis-α-bromoketones. All the polymers obtained were insoluble in organic solvents, including dimethyl sulphoxide, dimethylacetamide, and formic acid, but readily dissolved in concentrated sulphuric acid, and were infusible highly crystalline substances of high molecular weight. These polymers possess excellent thermal stability, but probably will not find wide practical application owing to difficulties arising in processing and their poor mechanical characteristics.

The most thorough study has been made by Sheehan el at.[71] They prepared a series of polythiazoles by the reaction

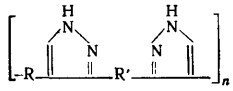
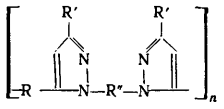
and concluded that only those polymers which had low heat-resistance possessed satisfactory mechanical properties. Other workers hold the same view[72].



An interesting result of the work of Sheehan et al. is the preparation of polythiazoles based on *oo'*-bisbromoacetylbiphenyl, possessing satisfactory mechanical properties and high thermal stability (up to 500°C). They also obtained[73] a fibre-forming polythiazole.

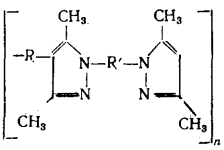
The introduction of side-chains—methyl and carboxyl substituents—into the thiazole ring produces no appreciable improvement in the properties of the polythiazoles[71].

V. POLYPYRAZOLES



In 1963 Korshak et al.[74] described for the first time the preparation of polypyrazoles by the reaction of bis-β-diketones with dihydrazides of dicarboxylic acids. A later paper by Korshak et al.[75] has further elaborated methods for the synthesis of polypyrazoles. American workers have also published papers on the synthesis of polypyrazoles[76,77]. According to their structure these polymers can be divided into three main types.

Polypyrazoles of general formula

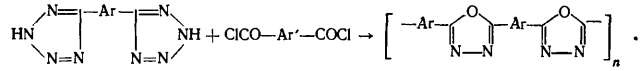


have been obtained by the method of Korshak et al.[78] from bisdiazo-compounds and *p*-diethynylbenzene or butadiyne. They were high-melting products of molecular weight around 10 000, soluble in dimethylformamide and cresol. Unfortunately, the authors gave no indication of the thermal stability of these polymers.

Polypyrazoles of general formula

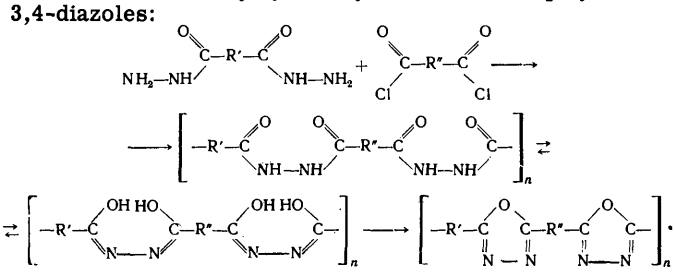
have been obtained by the interaction of bis-β-diketones of the type $R'COCH_2CORCOCH_2COR'$ with various dihydrazines or dihydrazides[74,77,79-81]. In this case the reaction goes in two stages, involving the initial formation of a polyhydrazone, which then cyclises to produce the polypyrazole. The first stage can be conducted in a solvent[77,79]. With dihydrazides of dicarboxylic acids[74] polypyrazoles are obtained which can be regarded formally as *N*-substituted polyamides.

A third group of polypyrazoles corresponds to the general formula



The heat-resistance of polymers of this type is lower than that of polypyrazoles containing no alkyl substituents, but their thermal stability must be expected to be higher owing to the absence of a mobile hydrogen atom in the pyrazole ring.

VI. POLYOXADIAZOLES



Most of the work on the synthesis of polyoxadiazoles has been done on the preparation of polyoxa-3,4-diazoles. Fully aromatic polyoxa-3,4-diazoles possess not only excellent resistance to heat, chemicals, and light but also good mechanical properties, which enables films and fibres to be made from them. Table 5 gives some properties of polyoxa-3,4-diazoles obtained by various methods.

Abshire and Marvel[86], elaborating the method of Sauer et al.,[87] prepared polyoxa-3,4-diazoles from bistetrazoles and chlorides of dicarboxylic acids by the reaction

However, the molecular weights of polymers obtained by this method were not very high.

Frazer and Wallenberger[85,88,89] proposed a two-stage method for the synthesis of polyoxadiazoles. Under conditions of low-temperature polycondensation in the first stage macromolecular polyhydrazides are obtained, which are then converted by cyclodehydration into the polyoxa-3,4-diazoles:

Films and fibres can be obtained from the melt only with those polyoxadiazoles which fuse below 350°C. Aromatic polyoxadiazoles which melt above this temperature are processed at the polyhydrazide stage, and cyclisation is accomplished in the finished goods.

A two-stage synthesis of polyoxa-3,4-diazoles has been used also by Korshak et al.[84,90,91], who obtained a polyoxadiazole containing ether links which was a promising material for the manufacture of a heat-resistant fibre.

It has also been proposed to obtain polyoxa-3,4-diazoles in the melt, starting from the corresponding polyhydrazides[82]. However, this method is restricted to a narrow range of aliphatic polyoxadiazoles.

Iwakura et al.[83] synthesised polyphenyleneoxa-3,4-diazoles in polyphosphoric acid or oleum solution, the latter solvent giving polymers of higher molecular weight. Soviet workers have also reported[92] the preparation of polyoxa-3,4-diazoles in oleum.

A paper has appeared recently[93] on the synthesis of polyoxa-2,4-diazoles by the series of reactions

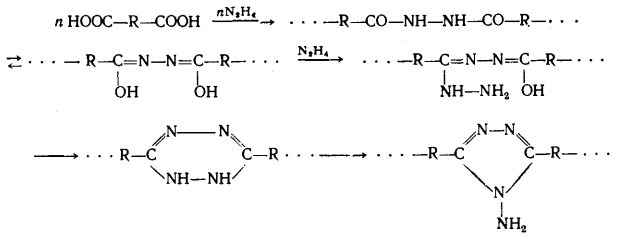
* Intrinsic viscosity.

However, the thermal stability of such a polymer is considerably poorer than that of the polyoxa-3,4-diazole of analogous structure.

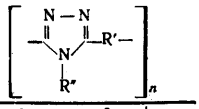
Overberger and Fujimoto[94] obtained polymers containing oxazole *N*-oxide groups by the polymerisation of terephthalonitrile oxide. The copolymerisation of terephthalonitrile oxide with terephthalonitrile leads to the formation of polyoxa-2,4-diazoles:



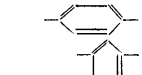
VII. POLYTRIAZOLES

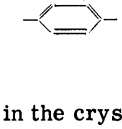
There is a large published literature, consisting mainly of patents, on the synthesis of aliphatic polytriazoles.

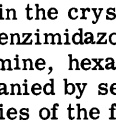
In 1941 Prichard[95] described fibre-forming polymers obtained from dihydrazides of dicarboxylic acids. He was the first to point out the difference between the two reactions taking place on heating a salt of hydrazine and a dicarboxylic acid (equimolecular proportions of hydrazine and the acid) and on heating a dihydrazide of a dicarboxylic acid, i.e. 2 moles of hydrazine and 1 mole of the acid. Prichard suggested that in the latter case the polymer contains 1,2,4-triazole-4-amine rings. His work served as a basis for several investigations in this field, conducted during recent years by Moncrieff, Fisher, and their coworkers in England, and by Korshak, Chelnokova, and Shkolina in the USSR.



In the view of Fisher et al.[96] the formation of poly-1,2,4-triazole-4-amine can be represented by the scheme







Polyaminotriazoles will not be discussed in detail in the present review, since the synthesis, the properties, and the applications of these polymers have been subjects of detailed consideration in the literature[97-100].

Table 6 gives the chief properties of homopolytriazoles of various structures. Korshak et al.[27] obtained also mixed poly-1,2,4-triazole-4-amines, which exhibit rather better solubility than do the homopolymers. These workers found that polyaminotriazoles are not subject to degradative exchange processes due to interchain exchange reactions.

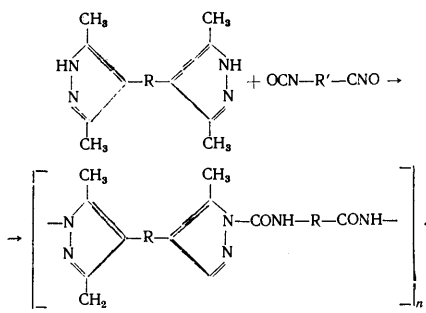
VIII. COPOLYMERS WITH AZOLE RINGS

Copolymers containing azole rings which have been described in the literature can be divided into two groups—cyclolinear copolymers, e.g. polyamides or polyesters containing benzimidazole rings, and cyclic copolymers, e.g. copolymers containing benzimidazole and pyromellitimide rings in the chain.

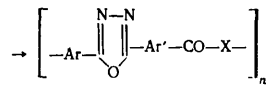
In copolymers of the first group several workers wished to combine the thermal stability characteristic of polyazoles with adequate solubility and other valuable properties inherent in linear polymers (polyamides, polyesters, etc.). However, the introduction of polyamide and polyester segments produced a substantial diminution in the thermal stability of the copolymers.



Korshak et al.[110,111] obtained aliphatic poly(amidobenzimidazoles) from diphenyl sebacate, biphenyl-3,3′,4,4′-tetra-amine or diphenylmethane-3,3′,4,4′-tetra-amine, and hexamethylenediamine. The melting point of the copolymers varied with the relative proportions of the initial diamine and the tetra-amine, passing through a minimum at 164°C in the case of biphenyl-3,3′,4,4′-tetra-amine. Increase in the polyamide content is accompanied by an increase in the crystallinity of the copolymers. The synthesis of benzimidazole polyesters from biphenyl-3,3′,4,4′-tetra-amine, hexane-1,6-diol, and diphenyl sebacate is accompanied by secondary reactions, which impair the properties of the final copolymer[111].

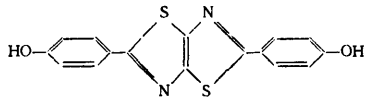
Iwakura et al.[112] described a series of polyamides obtained in polyphosphoric acid from dicarboxylic acids and a diamine containing benzimidazole rings:

The polyamide based on sebacic acid begins to decompose in air at 250°C whereas those based on aromatic dicarboxylic acids begin to decompose above 400°C.



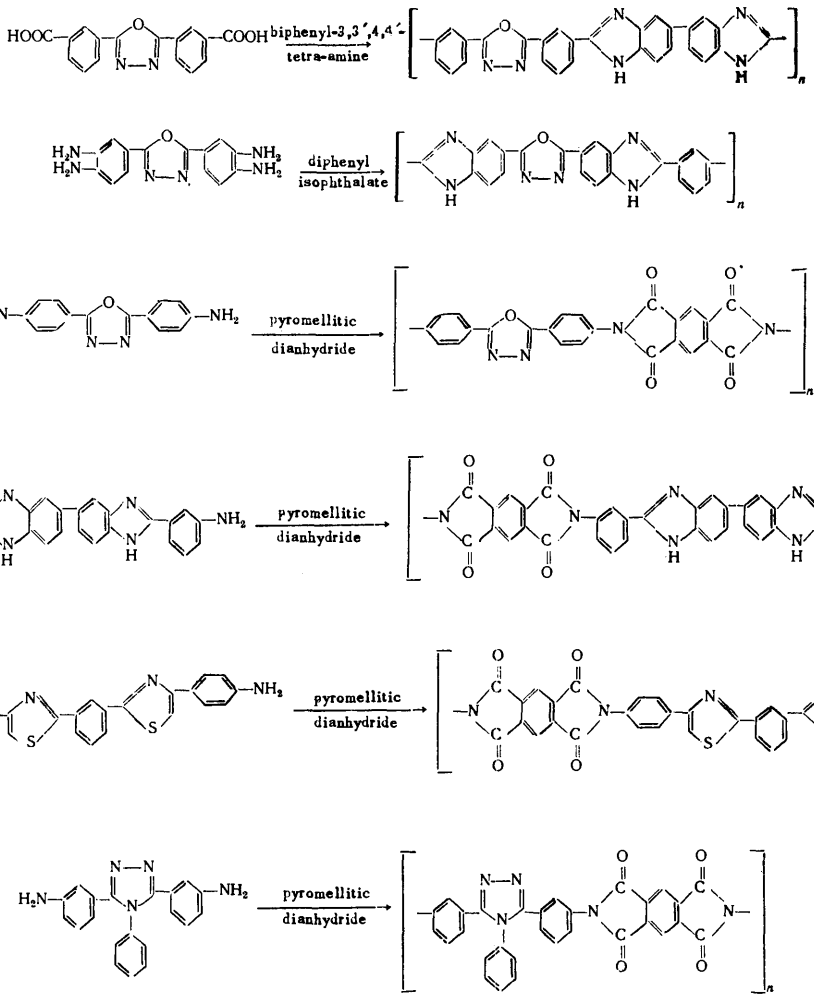
Polyamides containing pyrazole rings were obtained by Korshak et al.[79] by the reaction of dipyrazoles with hexamethylene and methylphenylene di-isocyanates:

These polymers possess viscoelastic properties over the range 200–300°C. They can be regarded as *N*-substituted polyureas. As Fedotova et al.[113] showed, the latter are not very heat-resistant and are amorphous polymers.



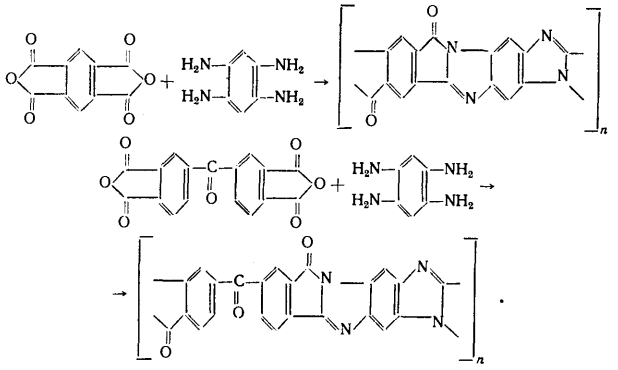
The synthesis of aliphatic polyamides containing triazole rings has been described in several patents and has been reflected in a corresponding review literature[97–100]. Block copolymers of ε-caprolactam and polytriazoles were prepared by Iwakura et al.[101] and later by Grekov et al.[114]

Aromatic polyamides and polyesters of regular structure containing oxadiazole rings have been obtained[104,115] via the corresponding polyhydrazides:



where X = NH or O. The polyamides and the polyesters softened over the ranges 400–470° and 300–400°C respectively.

Fox[116] accomplished the synthesis of various polyesters containing thiazolo[5,4-*d*]thiazole rings using a bisphenol having the structure



as starting material. When such a bisphenol is treated with carbonyl chloride or a bischloroformate, polycarbonates are produced, whereas treatment with chlorides of aliphatic dicarboxylic acids yields polyesters.

It is probable that the preparation of copolymers of the second group, containing different rings in the chain, will be more effective in preserving the thermal stability of the polyazoles. Unfortunately, very little work has been done in this field, so that it is difficult to reach final conclusions. However, a paper by Preston and Black[117] already substantiates this hypothesis. These workers prepared heterocyclic copolymers of ordered structure, the synthesis of which can be represented schematically as:

These copolymers are extremely thermostable, beginning to decompose in an inert atmosphere at 500–550°C. The authors did not examine other properties of the copolymers.

Adrova [118] reported the synthesis of copolymers containing benzimidazole and benzophosphorimidazoline rings. In the second group of copolymers can be included also the polyimidazopyrolones (polybenzimidazolimides, pyrrones) obtained [5] from aromatic tetra-amines and aromatic dianhydrides:

However, the properties of such polymers are influenced predominantly by the ladderlike or partly ladderlike structure.

IX. GENERAL PROPERTIES OF POLYAZOLES

At the present time the study of polyazoles has been concerned mainly with developing the synthesis of polymers having sufficiently high molecular weights, and considerably less attention has been paid to the properties of these polymers.

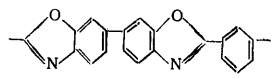
1. Chemical Properties

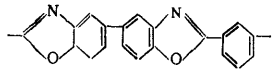
(a) Hydrolytic stability. Polyazoles are characterised by excellent resistance to hydrolysis, as a consequence of the presence of a stable aromatic heterocycle in the macromolecule. There are indications of hydrolytic stability and resistance to the action of acids and alkalis in such polymers as polybenzimidazoles [17,20], polybenzothiazoles and polybenzoxazoles [29], polyoxadiazoles [85], polythiazoles [71], aliphatic polyaminotriazoles [98,99], and polyphenyltriazoles [109].

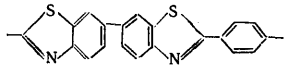
Vogel and Marvel [17] showed that heating poly-2,2′-(*m*-phenylene)-5,5′-bibenzimidazolyl in 70% sulphuric acid produces only a slight diminution in the reduced viscosity. There is practically no hydrolysis when this polymer is boiled in 25% alkali solution for 10 h. Imai et al. [29] made an analogous investigation on polybenzoxazoles and polybenzothiazoles (Table 7). They found that polybenzoxazoles were less resistant to hydrolysis than were polybenzothiazoles, while the latter were less resistant than the corresponding polybenzimidazoles.

The chemical resistance of the polybenzimidazole based on biphenyl-3,3′,4,4′-tetra-amine and sebacic acid has been examined in some detail [20]. It is seen from Table 8 that no significant decrease in the weight of the specimens is produced by either hydrochloric acid or alkali. This indicates that the polymer is stable to acid and alkaline hydrolysis.

TABLE 7. Change in reduced viscosity of polymers as a result of hydrolysis in 5 *N* KOH or 10 *N* H_2SO_4 at 120°C for 5 h.







Structural unit	Hydrolysis		
	before	acid	alkaline
	1.50	0.44	0.76
	2.09	0.32	1.01
	1,02	0.61	0.97

TABLE 8. Chemical resistance of poly-2,2′-octamethylene-5,5′-bibenzimidazolyl.

Reagent	Concn. of reagent, %	Conditions		Initial polymer		Polymer after degradation	
		temp., °C	time, h	wt., g	η_{red} in HCOOH	wt., g	η_{red} in HCOOH
HCOOH	90	65	3	—	3.62	—	3.54
HCOOH	90	65	10	—	3.62	—	3.28
HCOOH	90	100	3	—	3.62	—	3.46
HCOOH	90	100	10	—	3.62	—	3.78
HCl	38	180	3	0,25	4.12	0.27	3.16
HCl	38	180	3	0.21	4.32	0.25	2.90
KOH	30	100	10	0,50	3.50	0.50	3.62
$HOOC(CH_2)_8COOH$	100	250	3	—	3.50	—	0.86
$H_2N(CH_2)_6NH_2$	100	190	3	—	3.50	—	2.88

Among all the polyazoles only the polybenzoborimidazolines [43,44] have proved to be unstable to hydrolysis, owing to the peculiarity of the borazole ring. With the polymer obtained from biphenyl-3,3′,4,4′-tetra-amine and tetra-acetyl diborate, for example, the intrinsic viscosity decreased to almost one-third after keeping over water in a desiccator for a week.

The results on the hydrolytic stability of the polyazoles show that it is determined primarily by the nature of the azole ring in the polymer.

(b) Resistance to other chemical reagents. Korshak et al. [27], in a study of polyaminotriazoles, referred to the exceptional stability of the azole ring towards various degradative agents. When two different polyaminotriazoles were heated together for a long time, no exchange reactions were detected, such as are characteristic of other classes of heterochain polymers [119–121].

The solubility of polyazoles in a narrow range of solvents (predominantly of polar type) governs their resistance to oils and organic solvents, but the literature contains no actual papers on this.

Copolymers of polyazoles of the first group will probably have considerably poorer chemical stability than have polyazoles or copolymers of polyazoles of the second group. Thus polyesters containing oxadiazole rings, unlike polyoxadiazoles, are decomposed by the action of sulphuric acid [122].

(c) Stability to heat and oxidation. The thermal stability of polyazoles has been assessed by the

method of thermogravimetric analysis. Although certain differences are possible between results obtained by different workers, caused by different experimental conditions, e.g. different rates of heating, this method is sufficiently reliable to yield comparative data on the thermal stability of polyazoles. It is seen from Tables 1–6 and Figs. 4–7 that all polyazoles made up of alternating azole and phenylene rings are characterised by approximately the same start of intense decomposition in air in the range 450–600°C, whereas polyazoles containing polymethylene or other aliphatic chains usually decompose in the range 300–400°C.

Several polyazoles (e.g. polybenzimidazoles) containing ferrocene or perfluoromethylene units break down at relatively low temperatures, owing to their structural peculiarities. Thus the poor thermal stability of polyperfluoromethylenebenzimidazoles is due to the ease with which hydrogen fluoride is formed from fluorine in the perfluoromethylene chain and hydrogen in the imidazole ring[48]. Nevertheless, a purely perfluoromethylene molecule, e.g. in polytetrafluoroethylene, possesses excellent thermal stability.

Work on the thermal stability of polymers[123] is based on the "cage" theory. On this theory the thermal stability is determined by the phase state of the polymer, so that it depends on the melting point. However, the results for polyazoles show that this principle is not always valid. Thus polythiazoles based on 2,2′-biphenylylene units melt at 164–265°C, whereas a polythiazole based on 4,4′-biphenylylene units does not melt up to 500°C, although all these polymers start to decompose at the same temperature of 500°C (Table 3).

	430	+	×	–	forms films and fibres from soln.

* DMA = dimethylacetamide; DMF = dimethylformamide; BA = benzyl alcohol.

2. Physical Properties

Solubility. The problem of the thermal stability of polyazoles is closely linked with the preparation of polymers having satisfactory mechanical characteristics and sufficient solubility for goods to be manufactured from them. Polyazoles containing alternating azole and phenylene units often exhibit inadequate mechanical strength and solubility. Therefore various groups are introduced into the polyazole molecule which, without significantly lowering the thermal stability, increase the flexibility of the chain or produce an internal plasticising effect. The introduction of ether links between the phenylene units has proved to be the most successful. Table 9 gives data showing the effect of an oxygen bridge on the properties of polyazoles.

With the polybenzoxazoles as example Korshak et al.[60] showed that the introduction of bulky substituents into polymer molecules considerably improves their solubility. Such polybenzoxazoles dissolve in many organic solvents—chloroform, tetrachloroethane, tricresol, benzyl alcohol, pyridine, dimethylformamide, etc.—while possessing high thermal stability. The solubility is improved also by preparing mixed polymers, but the effect is rather smaller than with linear heterochain polymers, e.g. polyamides. Thus a polyaminotriazole based on sebacic and azelaic acids has a maximum solubility in ethyl alcohol of 8%,[27] and a polyamide based on hexamethylenediamine and the same acids is 100% soluble[124], whereas homopolyaminotriazoles and homopolyamides based on these acids are insoluble in alcohol.

X. USES OF POLYAZOLES

The chief property determining the use of polyazoles is their exceptional thermal stability. In this connection it must be borne in mind that aromatic polyazoles are more promising than aliphatic polyazoles in this respect, although the mechanical properties of the latter are better.

The first striking results on the application of aromatic polyazoles were achieved in the use of polybenzimidazoles as high-temperature and constructional adhesives, coatings, high-temperature fibres, thermal insulation, and binders for glass plastics[122,125-131].

Marvel[8] reported the fibre-forming and film-forming properties of the polybenzimidazole from biphenyl-3,3',4,4'-tetra-amine and diphenyl isophthalate. The unoriented film obtained from a solution of the polymer is dimethyl sulphoxide exhibited at 25°C the properties—tensile strength 0.7 g denier^{-1}, elongation 7%, modulus 35 g denier^{-1}—the corresponding values at 200°C being 0.5, 9%, and 15 respectively. After some orientation, filaments obtained from the solution had a strength of 4.5 g denier^{-1}, which they maintained in air up to 300°C.

Aliphatic polybenzimidazoles possess, together with adequate thermal stability, excellent mechanical properties, which enables them to be used for films, fibres, adhesive compositions, and other purposes. Thus the isotropic film from 2,2'-octamethylene-5,5'-dibenzimidazolyl possesses a tensile strength of 1200–1300 kgf cm^{-2}, an elongation of 18–20%, and good dielectric characteristics. On orientation the strength of the film reaches 5000 kgf cm^{-2}.[132]

It has been stated[65,133] that imidazole polymers can be used as semiconductor materials.

Reports have appeared recently of the use of other aromatic polyazoles. This applies primarily to polyoxadiazoles[134,135], from which it has proved possible to obtain a fibre having excellent thermal stability, chemical resistance, and good mechanical characteristics. The properties of the fibre do not change up to 200°, and only 40% loss in strength occurs at 300°C.

Holsten and Lilyquist[109] showed that polytriazoles also yield excellent thermostable filaments and films. This was to be expected, since aliphatic aminotriazoles have long been known as excellent fibre-forming materials.

The large amount of work which has been done on the structure of polythiazoles[71,73] has enabled products to be obtained having satisfactory mechanical properties and great thermal stability, suitable for the manufacture of films and fibres.

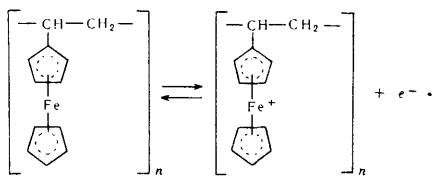
III.	Ferrocene polymers obtained by polyrecombination	934
IV.	Ferrocene polymers obtained by polycondensation	935
V.	Fields of application for polymers containing ferrocene	944

I. INTRODUCTION

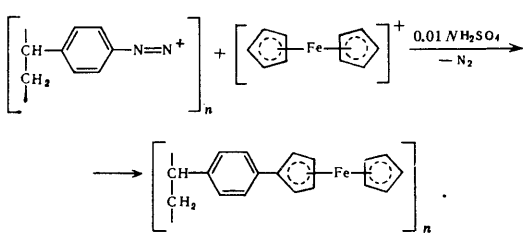
Ferrocene is the most accessible and stable—and hence the most thoroughly investigated—representative of a novel type of organometallic compound. Several detailed reviews[1-3] have appeared on ferrocene and its derivatives. The aromatic character of ferrocene, its structural peculiarities, the high reactivity, and the thermal stability—unusual for organometallic compounds—have attracted the attention of many research workers, and explain the attempts to use various of its derivatives for the synthesis of polymers.



Some hundred different ferrocene-containing polymers are already known, but there has not yet been a thorough review covering this new and fairly extensive field of polymer chemistry. There has merely been mention of certain polymers of ferrocene in reviews by Haiduc on coordination polymers[4] and by Korshak[5] and by Brown[6] on organoelementary macromolecular compounds. Reviews appeared in 1966 by Zimakova[7] and by Zelenetskii[8], but these do not cover completely the vast amount of information on the chemistry of ferrocene polymers.

Ferrocene-containing polymers can be divided into three groups depending on whether they are obtained by polymerisation, polyrecombination, or polycondensation.

2. FERROCENE POLYMERS OBTAINED BY POLYMERISATION



The first polymer of this type, polyvinylferrocene, was prepared from vinylferrocene by Arimoto and Haven[9] in 1955. In the presence of 85% phosphoric acid or potassium persulphate, a viscous oil, soluble in benzene, was formed. When azoisobutyronitrile was used, vinylferrocene polymerised at 80°C to form a benzene-soluble solid melting at 280–285°C. Copolymers of vinylferrocene with methyl methacrylate, styrene, and chloroprene were also obtained[9,10]. All the polymers were soluble in benzene and insoluble in methanol. Clear, brittle films could be obtained from solutions of the solid polymers.

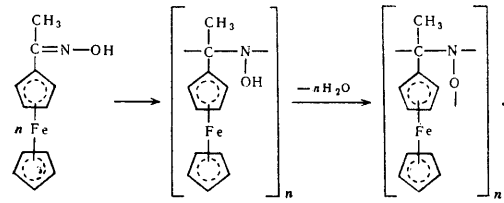
Table 1 lists some properties of homopolymers and copolymers of vinylferrocene. Treatment of the copolymers with formaldehyde yields cross-linked products having redox properties:

Solid polymers of vinylferrocene also possess redox properties, though polyvinylferrocene is insoluble in the solvents normally used for potentiometric titration.

The electron-exchange properties of polyvinylferrocene were studied by sulphonating it in the ring[11]. Analysis showed that two sulpho-groups entered the ring linked by the polymer chain, and one entered the second ring. Sulphonated polyvinylferrocenes are soluble, but they cannot be titrated owing to their rapid decomposition. A further electron-exchange resin, a ferrocene–polystyrene analogue of a redoxite[12], has been obtained from ferrocene:

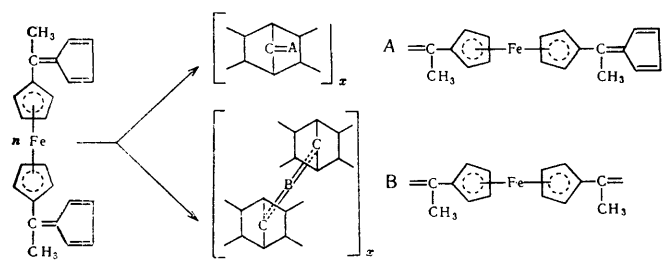
Rausch and Coleman[13] described various copolymers based on ferrocene β-styryl ketone [cinnamoylferrocene], which was synthesised in 81.5% yield from cinnamoyl chloride and ferrocene by the Friedel–Crafts reaction. The

TABLE 1. Homopolymers and copolymers of vinylferrocene.



Catalyst	Comonomer	Product	M.p., °C
85% Orthophosphoric acid	—	viscous oil	—
Potassium persulphate	—	oil	—
	—	solid	280—285
Azoisobutyronitrile	methyl methacrylate	solid	190—210
	styrene	solid	158—165
Potassium persulphate	chloroprene	elastomer	—

ketone itself does not polymerise, but it forms copolymers with many vinyl and diene compounds, such as styrene, acrylonitrile, acrylates, butadiene, and isoprene[14,15]. Copolymers with vinyl monomers have been obtained by block polymerisation in the presence of benzoyl peroxide, or by polymerisation in benzene solution (in the absence of thiophen) or in dimethylformamide with azoisobutyronitrile as initiator. Copolymers with dienes were obtained by emulsion polymerisation using dodecanethiol as modifier. These copolymers were coloured powders, elastic materials, or solids melting at 130–275°C.



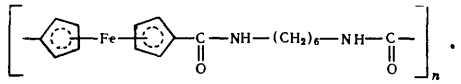
Knox and Pauson[16] attempted to prepare divinyl- and dibutadienyl-ferrocenes via the fulvenes, but were unable to isolate these derivatives, since they underwent rapid polymerisation. The polymer formed from these ferrocenes may have the structure

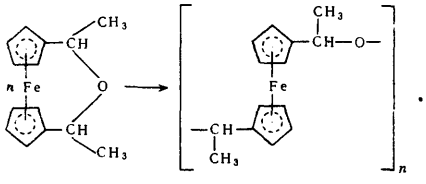
Ferrocene-containing polymers are formed also by the polymerisation of acetylferrocene oxime and 1,1′-bis-(1-cyclopentadienylidene-ethyl)ferrocene. The oxime undergoes polymerisation at or above its melting point to produce an almost quantitative yield of insoluble polymers[17]:

The thermal, catalytic, and radiation polymerisation of the difulvene is represented by the scheme[17]

Thermal polymerisation was conducted in sealed tubes at various temperatures for 1–8 h. Insoluble and infusible polymers were produced above 150°C. Polymerisation of the difulvene derivative in the presence of benzoyl peroxide in dioxan solution after 8 h yielded 28.2% of polymers having a linear structure and 9.1% of cross-linked polymers (with 2% of benzoyl peroxide at 65°C). With 3% of the peroxide at 100°C the polymerisation was almost quantitative.

The copolymerisation of ferrocene with hexamethylene di-isocyanate gave a 73% yield of an infusible copolymer, a polyferrocenylenepolyamide, which was insoluble in the usual organic solvents[17]. This copolymer results from the addition of ferrocene hydrogen atoms to the isocyanate groups, which suggests that these atoms are very mobile in comparison with the hydrogen atoms in benzene, for the latter does not react with di-isocyanates. The elementary composition and the infrared spectra of the copolymer indicate that it has the structure





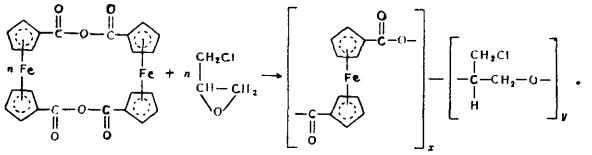


Table 2 lists the characteristics of the above ferrocene-containing polymers, obtained by the polymerisation of acetylferrocene oxime and of 1,1′-bis-(1-cyclopentadienylidene-ethyl)ferrocene, and by the copolymerisation of ferrocene with hexamethylene di-isocyanate.

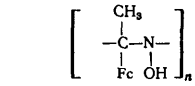
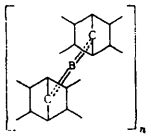
A recent paper[18] has reported the synthesis, by polymerisation accompanied by ring-opening of ferrocene derivatives containing reactive bridging chains between the two cyclopentadienyl rings, of polymers containing ferrocene in the main chain. Treatment of 1,1′-(1,1′-epoxydiethyl)ferrocene with certain Lewis acids used as catalysts gave a yellow–orange polymeric product. Infrared spectroscopy showed that the polymeric product obtained by polymerisation at room temperature contained ether chains, but that obtained at 75°C did not contain them. The reaction occurred according to the scheme

Copolymerisation has been accomplished[18] also between ferrocene-1,1′-dicarboxylic anhydride and 1-chloro-2,3-epoxypropane, the products being dark brown esters insoluble in the usual organic solvents:

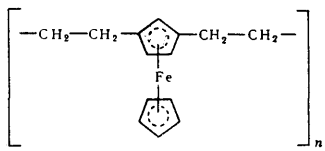
The polymerisation of acryloylferrocene in the presence of various initiators has been studied, as well as the copolymerisation of acrylylferrocene with acrylonitrile[19].





3. FERROCENE POLYMERS OBTAINED BY POLYRECOMBINATION

Polyrecombination is distinguished fundamentally from polymerisation by the fact that the starting materials are saturated compounds and that it is a stepwise reaction—not a chain reaction—although it occurs by a radical mechanism. Polyrecombination consists in treating a hydrocarbon with a peroxide, e.g. with t-butyl peroxide in an atmosphere of nitrogen at 200°C. The t-butoxyl and methyl radicals resulting from breakdown of the peroxides abstract hydrogen from the ferrocene (or α-hydrogen from its alkyl substituent), and the radicals thus formed recombine among themselves to form a polymer[20].



In 1958 Korshak et al. were the first to use polyrecombination to obtain a ferrocene-containing polymer based on a homoannular di-isopropylferrocene[21]. Later they made a detailed investigation of the polymer[22]. Its synthesis was conducted at 170°C with equimolecular proportions of peroxide and monomer. The polymer was a reddish powder, soluble in benzene and chloroform, with molecular weight 8200 and melting point 155–180°C.

Polyrecombination was used to obtain polymers (polyferrocenylenes) from ferrocene itself[20,23–25]. Formation of a linear polyferrocenylene, readily soluble in benzene, was accompanied by that of an insoluble polymer, probably possessing a cross-linked structure. The two polymeric forms were separated by treating the reaction mixture

TABLE 2. Characteristics of some ferrocene-containing polymers obtained by polymerisation.

Structure of polymer	Method of polymerisation	Elementary composition, wt. %								Characteristic absorption bands, cm^{-1}
		C		H		Fe		N		
		found	calc.	found	calc.	found	calc.	found	calc.	
	thermal	59.17	59.25	4.99	5.3	24.01	23	4.69	5.75	818, 1000, 1100, 1426, 1603

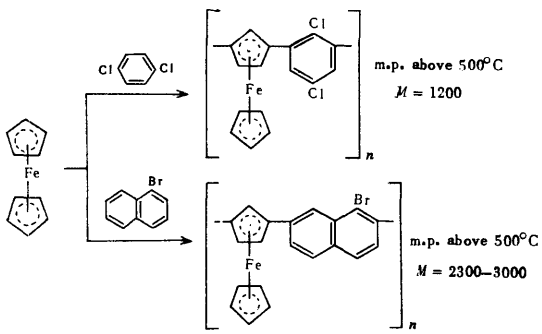
	catalytic	77.91	78.6	6.16	6.01	14.9	15.3	—	—	1586–1700
	radiation	77.18	78.6	6.18	6.01	14.55	15.3	—	—	
	thermal	61.5	61.1	6.72	6.20	15.25	15.8	7.2	7.9	814, 1000, 1100, 1360, 1450, 1670

with benzene. The soluble polyferrocenylenes had molecular weights of 370–7000 and softening points of 290–300°C. The insoluble polyferrocenylene softened at 400°C, which probably indicates that cross-linkages between the chains were comparatively rare. The structure of the polyferrocenylenes, and also of the polymers obtained by the polyrecombination of di-isopropylferrocene, is supported by the infrared spectra, which contain absorption maxima, characteristic of a free cyclopentadienyl ring, in the region of 820, 1000, and 1100 cm^{-1}. On this basis the soluble polymers probably have the structure

(I).

Refinement of the polymer structure (I) permits it to be regarded as a chain of ferrocene structures linked by methylene bridges formed as a result of preliminary methylation of the ferrocene.

The work of Korshak, Sosin, and other Soviet investigators on the preparation of polyferrocenylenes by polyrecombination in the presence of t-butyl peroxide has been repeated by foreign workers [26], who have obtained under carefully controlled reaction conditions soluble polymeric compounds comparable in molecular weight and physical properties with those obtained earlier. However, the elementary composition of the products differs from that calculated for polyferrocenylenes. Spectroscopic examination and determination of the elementary composition, confirmed by the isolation not only of bi- and ter-ferrocenyl but also of diferrocenylmethane and diferrocenylmethyl t-butyl ether, substantiated the Soviet authors' results indicating that the compounds obtained were polymeric chains comprising polyferrocene segments linked by methylene and other aliphatic groups. These bridging groups result from methylene and t-butyl radicals.



The polyrecombination of various alkyl derivatives of ferrocene was studied [27]. Polymers were obtained based on isobutylferrocene, di-isobutylferrocene, isopentylferrocene, and cyanoferrocene, as well as copolymers of ferrocene with isobutylferrocene, stilbene, and dimethyl dodecanedioate. The polyrecombination was conducted at 200°C, the molar ratio of t-butyl peroxide to the initial compound being 1.2 : 1. The alkylferrocene polymers were dark yellow and brown powders of molecular weight 3000–9000. The infrared spectra of soluble polymers exhibited in all cases absorption maxima in the region of 1000 and 1100 cm^{-1}, which are characteristic of free cyclopentadienyl rings. Hence only one of the cyclopentadienyl rings was involved in polymer formation in the above cases.

Electron spin resonance (e.s.r.) and a positive magnetic susceptibility were observed with these polymers [20,28]. However, further investigation showed [29] that the anomalous magnetic properties of ferrocene polymers were entirely due to the presence of paramagnetic and ferromagnetic impurities. Specially purified specimens of the above ferrocene polymers gave no e.s.r. signal.

The effect of preliminary heating in a vacuum at 200° and 270°C was studied on the electrical and magnetic properties of polyferrocenylenes obtained by polyrecombination [30]. Heating the polymers in a vacuum at 270°C results in a substantial change in their physical properties. The electrical resistance and the activation energy E_σ diminish appreciably, and a break appears on the conductivity–temperature straight lines. The magnetic susceptibility of polymers which have been heated in a vacuum at 270°C is much higher than that of the unheated polymers (by factors of 10^2–10^3). A marked dependence of χ on the magnetic field strength H appears, which is characteristic of ferromagnetic substances, χH exhibiting a saturation effect at the fields used. The appreciable ferromagnetism of ferrocene polymers which have been compressed and heated in a vacuum is due to the ferromagnetic properties of organometallic compounds of iron, although the possibility of thermal decomposition of the polymer with the formation of ordinary ferromagnetic compounds of ferrocene cannot be completely excluded with the preparations studied.

Paushkin, Vishnyakova, and their coworkers [31–34] investigated the polyrecombination of various alkylferrocenes and the copolyrecombination of ferrocene with 1-bromonaphthalene, *p*-dichlorobenzene, benzonitrile, salicylic acid, salicylaldehyde, benzaldehyde, phthalic anhydride, and other aromatic compounds. The reaction was conducted in the presence of various amounts of t-butyl peroxide at 175–200°C.

Copolyrecombination yields products of the following types:

Soluble (dark brown) and insoluble (black) solid polymers were obtained. The experimental results and the characteristics of the products are given in Table 3. All the specimens show a positive temperature coefficient of conductance, and the dependence of conductance on temperature is exponential in character.

4. FERROCENE POLYMERS OBTAINED BY POLYCONDENSATION

Nesmeyanov and Kochetkova prepared polymers by the polyalkenylation of ferrocene with 1,2-dichloroethane and dichloromethane in the presence of aluminium chloride at the boiling point of dichloroethane [20,28,35,36]. Interaction of ferrocene with a large excess of 1,2-dichloroethane under severe conditions in the absence of a foreign solvent yielded a series of "pentaethanopolyferrocenes" not containing halogen, soluble in chloroform and benzene and insoluble in methanol, instead of the diferrocenylethane and resins of relatively high molecular weight obtained previously [37], in which several ferrocene units were linked by CH_2–CH_2 bridges. The products obtained differed among themselves in their solubility in ether, this property being utilised for their separation. On the basis of elementary analysis the substance of lowest molecular weight, which

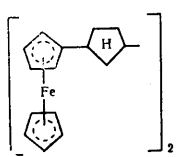
* Electrical properties given for the insoluble polymers.

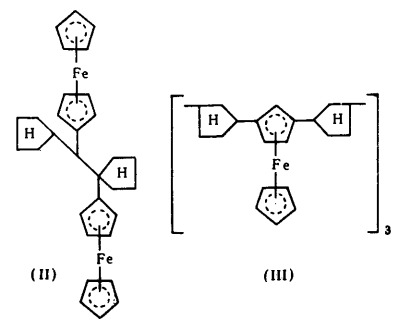
decomposed at 130°C, was regarded as a pentaethanodiferrocene, containing two ferrocene units and five ethano-bridges. The products of molecular weight 1000–2000, which were less soluble in ether, contained 4–8 ferrocene residues. Their analyses were close to that of the previous substance. This suggested that they had an analogous structure.



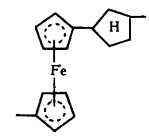
Nesmeyanov et al.[38] obtained acetyl derivatives of "pentaethanodiferrocene". The acylation of this compound with acetic anhydride in the presence of 85% phosphoric acid gives a monoacetyl derivative. Acylation with acetyl chloride in the presence of anhydrous aluminium chloride in dichloromethane (solvent) yields "diacetylpentaethanodiferrocene" and other "polyacetylpentaethanodiferrocenes". The formation of a diacetyl product confirmed the presence of two acylatable cyclopentadienyls.

In a brief communication Goldberg[39] mentioned the possibility of obtaining a substance with the same properties as "pentaethanodiferrocene" by the action of aluminium chloride on ferrocene in benzene solution in the absence of dichloroethane.

Further investigations by Nesmeyanov and Kochetkova[40] on the action of aluminium chloride on ferrocene, comparison with the action of anhydrous hydrogen fluoride on ferrocene[41], and an attempt to hydrogenate the resulting "pentaethanodiferrocene" led these workers[40] to the conclusion that their compound was 1,1′-diferrocenylbicyclopentyl



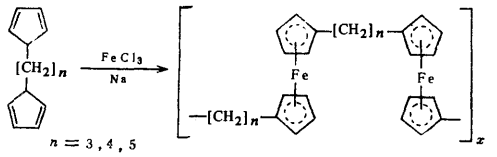
The presence of small quantities of other isomers



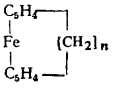
was also possible. However, the substances of molecular weight 1000 and 2000 described previously were probably polymers of cyclopentenylferrocene.

Cottis and Rosenberg[42] were able to separate the compound described earlier as "pentaethanoferrocene" into two parts—a reddish-orange rubberlike substance (II) soluble in ether and partly soluble in methanol, and a yellow solid (III)—

Other workers[43] have studied the action of $ZnCl_2$–H_2O on ferrocene in the absence of any solvent. The reaction was conducted in the melt (at 180°C) with relative proportions of ferrocene : $ZnCl_2$: H_2O = 1 : 0.3 : 0.01. The reaction gave products soluble in hexane, which were separated chromatographically and were shown by analysis to be 1,1′-(cyclopent-1,3-ylene)ferrocene and two isomers of diferrocenylcyclopentane. The product, which was insoluble in hexane but soluble in dioxan, benzene, and chlorinated hydrocarbons, had melting point 125–135°C and molecular weight 2030, and from analysis was an oligomer containing as unit

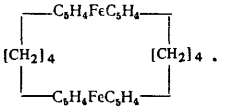


In 1961 Knobloch and Rauscher reported the preparation by interfacial polycondensation of polyamides and polyesters containing ferrocene, the starting materials being ferrocene-1,1′-dicarbonyl chloride and certain diols (2,2-diphenylpropane-*pp*′-diol, quinol, and ethylene glycol) and diamines (ethylenediamine, hexamethylenediamine, piperazine, and *p*-phenylenediamine).[44] The properties of the polyesters and polyamides are listed in Table 4. With the exception of the polymer based on *p*-phenylenediamine,

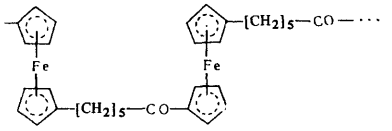


they all dissolve in the usual solvents for polyamides—*m*-cresol and 90% formic acid—and swell in 1,1,2,2-tetrachloroethane, acetone, pyridine, 1,4-dioxan, and tetrahydrofuran. Polymers obtained from hexamethylenediamine dissolve in dimethylformamide, while the polyamide based on piperazine readily dissolves in 1,1,2,2-tetrachloroethane. The polyamide obtained from hexamethylenediamine breaks down at an appreciable rate in formic acid. The molecular weights of the polymers, calculated from viscosities, were 8300–12 000.

Polyurethanes of melting points 91–225°C have been obtained by the polycondensation of ferrocene di-isocyanate with glycols—ethanediol, hexane-1,6-diol, decane-1,10-diol, *p*-phenylenedimethanol, ferrocene-1,1′-diol, and quinol—the polymers being partly soluble in dimethylformamide and dissolving well in formic acid[45].

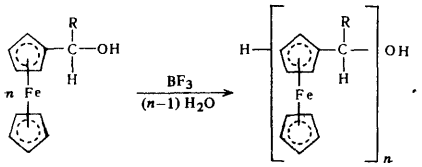


It is theoretically possible to synthesise polymers containing ferrocene in their structure from the disodium derivatives of $\alpha\omega$-dicyclopentadienylalkanes with iron(III) chloride in tetrahydrofuran[46,47]:



Carrying out this reaction led not only to the production of the polymers but also to the isolation of monomeric ansaferrocenes

and a small amount of cyclic dimers, e.g.

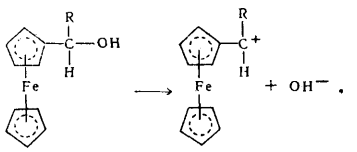


The preparation of polymers having the structure

has also been described[48].

The polycondensation of 2-hydroxyalkylferrocenes yields polymers containing alternating ferrocene and alkyl groups in the main chain[49]:

Formation of a C–C bond, which occurs very readily with the elimination of water, can be explained by the great tendency of these compounds to form ferrocenylcarbonium ions:



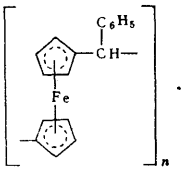


TABLE 4. Properties of polyamides and polyesters obtained from ferrocene-1,1′-dicarbonyl chloride.

Diamine or diol	Organic phase	Base	Duration of reaction, min	Yield, %	[η]	Properties of polymer
Ethylenediamine	toluene	excess of amine	1.0	–	–	–
Ethylenediamine	benzene	excess of amine	2.0	79	0.14	yellow–orange powder, dark at 180°C, brownish and rubberlike at 225°C
Hexamethylenediamine	benzene		2.0	87	0.21	yellow–orange powder decomposing at 110°C, rubberlike at 165°C, dark at 220°C
Piperazine	benzene		3.0	80	0.22	yellow–orange powder, softening at 160°C, transparent at 190°C, orange at 300°C
p-Phenylenediamine	dichloromethane		3.0	93	insol.	brown powder, dark at 230°C, black at 300°C
2,2′-Diphenylpropane-*pp*′-diol	dichloromethane		3.0	70	0.10	orange powder, m.p. 165°C
Quinol	dichloromethane		3.0	63	insol.	brown powder, dark at 200°C

The stability of ferrocenylcarbonium ions has been referred to in other papers[50,51]. By treating ferrocenylmethanol with an acid solution of alumina in benzene Schlögl and Mohar[52] obtained liquid polymers, to which they attributed the above structure (the molecular weight of the products was not stated). The polymer from hydroxybenzylferrocene was a yellow-green powder soluble in the usual solvents, brittle films of which could be obtained from the solution in benzene.

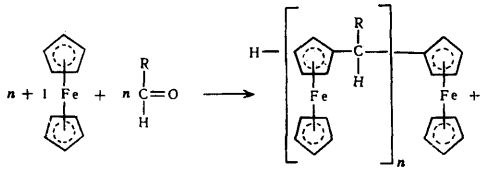
A product, insoluble as a consequence of possible cross-linking, is formed (in 3% yield) by the polycondensation of 1,1′-bis-(1-hydroxyethyl)ferrocene in benzene solution[52]. It is an infusible yellow-green powder, insoluble in the usual solvents, and decomposing at 170–180°C.

Neuse and Trifan[53] studied the polycondensation of ferrocenylmethanols having the structure FcCH(OH)R, where R = H, CH_3, C_6H_5. The polycondensation was conducted in the presence of Lewis acids, the best result being obtained in the presence of zinc chloride, the yield of polymer being 96%. The polycondensation of α-ferrocenylbenzyl alcohol[54] leads to the formation of polymeric ethers of low molecular weight, which in the presence of Lewis acids at elevated temperatures yield products of higher molecular weight having the structure

From 1954 papers began to appear on the condensation of ferrocene with aldehydes in the presence of strong acids (sulphuric, hydrochloric, hydrofluoric) and Lewis acids, leading to the formation of products of low molecular weight (diferrocenylmethane and bisferrocenylphenylmethane) and ferrocene-containing polymers of molecular weight up to 5000. Nesmeyanov and Kritskaya[55] found that ferrocene reacts with aqueous formaldehyde and with benzaldehyde in the presence of concentrated sulphuric acid at 65–70°C, with equimolecular proportions of ferrocene and aldehyde. The total yield of condensation products then reached 65–75% of theoretical. Diferrocenylmethane was obtained, a substance soluble in benzene, chloroform, and dioxan and melting at 191°C, as well as bisferrocenylphenylmethane, soluble in acetone and melting

at 218–220°C. The interaction of ferrocene with benzaldehyde yielded a compound of m.p. 268–270°C, having the composition

$$(C_5H_4)_2Fe[CH(C_6H_5)][CH(OH)C_6H_5]Fe(C_5H_4)(C_5H_5)\ . \qquad (IV)$$



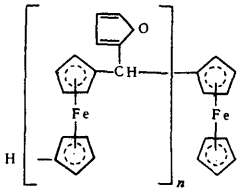
Valot[56] points out that the condensation of ferrocene with formaldehyde in sulphuric acid yields, in addition to diferrocenylmethane and traces of 1,2-diferrocenylethane, a polycondensation product which is a light brown powder of molecular weight 4800, readily soluble in benzene, toluene, and pyridine, sparingly soluble in dimethylformamide, and insoluble in ether and acetone. This product partly darkens at 150°C, and at 170°C is converted into a brownish-red viscous mass. It was proposed[57] that the condensation of ferrocene with formaldehyde and with benzaldehyde should be accomplished in the presence of a large quantity of anhydrous hydrogen fluoride. Analysis suggests that the compound obtained is formed by the condensation of two ferrocene molecules with two aldehyde molecules, accompanied by the elimination of two molecules of water. It is noteworthy that the melting point of this compound corresponds to that of the product (IV) obtained by Nesmeyanov and his coworkers[55].

A considerable quantity of insoluble products were formed by the condensation of ferrocene with benzaldehyde and with formaldehyde in the presence of sulphuric acid and hydrogen fluoride, but these were not isolated or investigated.

The condensation of ferrocene with benzaldehyde has been accomplished also in the presence of 1 ml of concentrated hydrochloric acid in glacial acetic acid at room temperature[58]. The mixture is allowed to stand without stirring for a week, and is then processed. A black powder of indefinite melting point is obtained, its elementary composition corresponding to the empirical formula $C_{17.8}H_{15.3}FeO_{1.4}$. The possibility is mentioned of condensing ferrocene with other aldehydes—such as acetaldehyde, propionaldehyde, butyraldehyde, chloral, *p*-nitrobenzaldehyde, etc.—with ferrocene : aldehyde ratios of 1 : 1–10 and above. The catalysts used are strong acids—phosphoric, sulphuric, hydrobromic, toluene-*p*-sulphonic, hydrochloric, and trichloroacetic—the quantity of which should not exceed 1 part in 10–1000 parts of ferrocene.

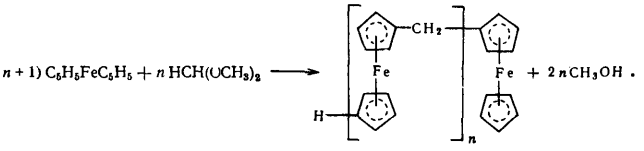
The polycondensation of ferrocene with benzaldehyde has been conducted also in the presence of the complex catalyst $ZnCl_2$–HCl(gas) [59] at temperatures ranging from −20° to +140°C.

Neuse and Trifan[60,61] have studied the polycondensation of ferrocene with aldehydes in the presence of Lewis acids (mainly zinc chloride), in amounts of 3–30% on the weight of ferrocene. These workers assume that condensation proceeds via the formation of intermediate ferrocenylmethanols and the corresponding carbonium ions, the final product of the reaction having the structure (V):



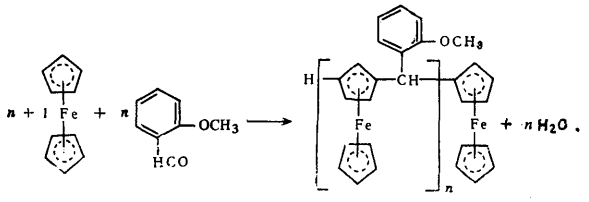
(V)

The condensation was conducted in an atmosphere of nitrogen in an autoclave at 130–180°C. Soluble, readily fusible polymers of molecular weight 2500 were obtained having the structure (V) with R = H, CH_3, C_6H_5; the yield reached 70%. Crotonaldehyde also yields polymers having the structure (V) under the same conditions, but owing to side-reactions at the double bonds in the aldehyde the yield does not exceed 20–30%.



The condensation of ferrocene with furfuraldehyde and with the *o*-methoxy-, *p*-hydroxy-, *p*-carboxy-, and *p*-cyano-derivatives of benzaldehyde at atmospheric pressure gave soluble polymers of molecular weight up to 5000. In these cases the elementary composition differed slightly from that expected for the structure (V), owing to steric and electronic effects of the substituent groups and their tendency to undergo competing side-reactions.

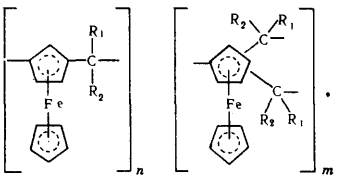
The polycondensation of ferrocene with furfuraldehyde has since been studied in greater detail[62]. Lewis acids were used as catalysts. The molecular weight of the resulting polymers



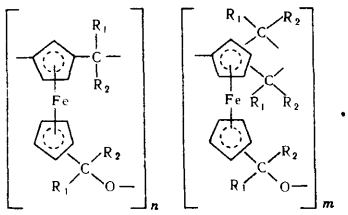
lay within the range 800–4500.

The polycondensation of ferrocene with dimethoxymethane in the presence of zinc chloride at 150–170°C for 8 to 12 h gave a polymer of the structure indicated below[63]:

The polycondensation of ferrocene with anisaldehyde was effected with various proportions of the starting materials in the presence of zinc chloride at 135° and 165°C for 0.9–13 h:[64]



A yield of soluble polymers of 54–78% has been obtained by the polycondensation of ferrocene with *p*- and *o*-formylbenzoic acids, with a molar ferrocene : aldehyde ratio of 0.9 : 3.0, at 115–170°C for 0.4–1.7 h.[65]

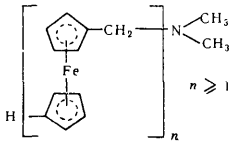


Kotrelev et al.[66] have obtained products of the polycondensation of ferrocene with diazotised benzidine (with various proportions of the starting materials) and of 1,1′-diacetylferrocene with furfuraldehyde. Determinations were made of the thermomechanical properties of the resulting polymers and of their moulding compositions with kaolin.

The polycondensation of ferrocene with various ketones —acetone, butan-2-one, cyclohexanone, acetophenone, and benzophenone—has been studied in the presence of the complex catalyst $ZnCl_2$ + HCl(gas). With relative proportions of ferrocene : ketone = 1 : 2 the yield of ferrocene-containing polymers varied from 29.1% to 76.5%.[67] From

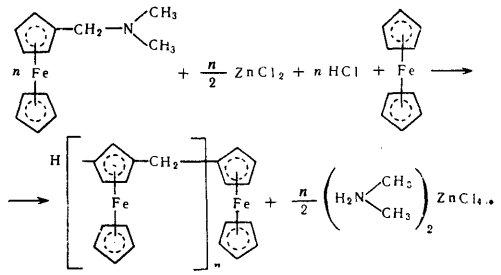
a study of the properties of the polymers it is suggested that with these proportions of the reactants the polycondensation involves the elimination of water, perhaps via intermediate ferrocenylmethanols, with the formation of soluble and insoluble polymers. In the soluble polymers one molecule of ferrocene is associated with 1.5–2 $>CR_1R_2$ groups: i.e. the polymers probably have the structure

On the basis of the elementary analysis the insoluble polymers are assigned the structure



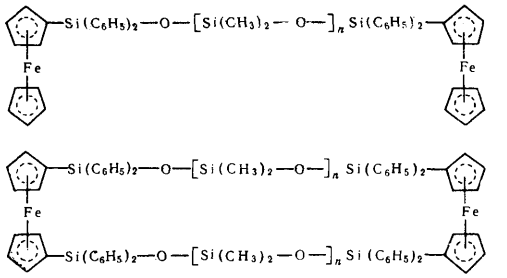
In the absence of ferrocene the condensation of ketones in the presence of $ZnCl_2$ + HCl as catalyst proceeds only as far as formation of dimers and trimers. Addition of 5 mole % of ferrocene to this mixture enhances the activity of the system, so that liquid and solid polymers not containing iron are formed, and also polymeric ferrocene-containing products.

Interaction of ferrocenyl cyanide with ferrocenyl-lithium[68] gives a diferrocenyl ketone in 55–60% yield, and reaction of the latter with ferrocenyl-lithium leads to the formation of triferrocenylmethanol (yield 60%). Reduction of the carbinol with zinc dust in acetic acid gives triferrocenylmethane:



$$C_5H_5FeC_5H_4CN \xrightarrow{C_5H_5FeC_5H_4Li} (C_5H_5FeC_5H_4)_2CO \xrightarrow{C_5H_4FeC_5H_4Li} \rightarrow (C_5H_5FeC_5H_4)_3COH \xrightarrow{Zn+CH_3COOH} (C_5H_4FeC_5H_4)_3CH.$$

The condensation of *NN*-dimethylaminomethylferrocene has also been studied[69,70], in the presence of the $ZnCl_2$–HCl catalytic system in the melt. Polymers

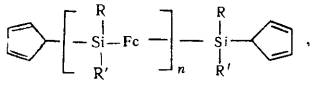


were obtained, containing ferrocenylene structures separated by methylene groups. The products had molecular weights lying in the range 4000–8000. The optimum molar proportions were Mannich base : $ZnCl_2$: HCl = 2 : 1 : 2.

NN-Dimethylaminomethylferrocene has been subjected also[71] to polycondensation with ferrocene:

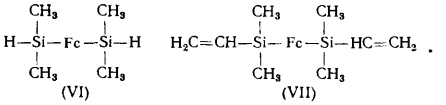
The structure of the resulting polymer has been confirmed by elementary analysis and the infrared spectra.

The synthesis of several derivatives of ferrocene containing silicon has been described[72]. Various compounds have been obtained containing two ferrocene molecules linked by chains containing silicon atoms



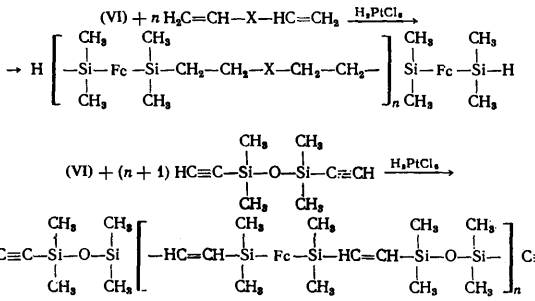
The patent claims[72] that these compounds can be used as lubricants and as defoaming agents for several organic substances.

A series of symmetrical silanylferrocenes—1,1′-bis-(3-phenyltetramethyldisiloxanyl)ferrocene, 1,1′-bis-(5-phenylhexamethyltrisiloxanyl)ferrocene, 1,1′-bis-(7-phenyloctamethyltetrasiloxanyl)ferrocene, etc.—have been obtained. These silanylferrocenes possess good lubricating properties and high thermal stability[73].



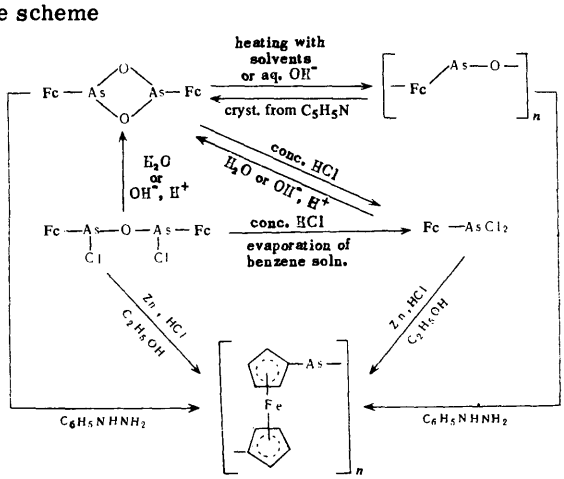
Various unsymmetrical siloxanylferrocene derivatives have also been synthesised[74], by a very complicated multistage method.

The preparation has been described[75] of polymers containing alternating ferrocen-1,1′-ylene and disubstituted silylene groups

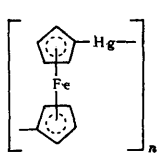


where Fc is a ferrocene residue, and R and R′ are hydrocarbon radicals containing aliphatic, cycloalkyl, aromatic groups and halogenated derivatives, alkoxy-groups, or halogens. These polymers maintain their chemical and thermal stability over a wide range of temperatures.

The reduction of 1,1′-bisethoxydimethylsilylferrocene with lithium tetrahydroaluminate gave a yield exceeding 90% of 1,1′-bisdimethylsilylferrocene (VI), which added acetylene to form 1,1′-bisvinyldimethylsilylferrocene (VII):



The polyaddition of (VI) to (VII) or to other organosilicon compounds containing two unsaturated terminal groups, and also the addition of (VII) to organosilicon compounds having two $SiHR_2$ terminal groups, lead to the formation of thermostable polymers in which ferrocene is located in the main chain. By varying the proportions of the components it is possible to obtain macromolecules containing two $SiHR_2$ or two unsaturated terminal groups[76]. The reaction proceeds according to the scheme

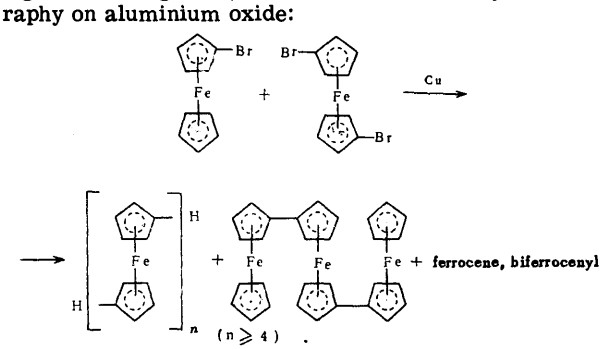


where X = $-Si(CH_3)_2.O.Si(CH_3)_2-$ and Fc = $-C_5H_4FeC_5H_4-$.

Arsenic trichloride[77] gives macromolecular compounds as well as new monoferrocene derivatives of arsenic. The polymers were readily obtained by heating dimeric arsenoferrocene in aqueous alkali, this being explained by thermal hydrolysis of the ferrocenearsonite anion. The conversion of the dimer into a polymer in various solvents is explained by these workers[77] as due to solvolysis of the As–O bond by the solvents. The formation of polymers is represented by the scheme

The synthesis has been described[78] of macromolecular mercury compounds of ferrocene of the type

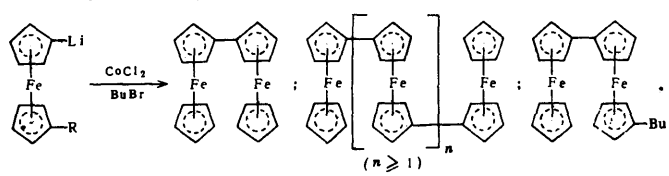
Products having the composition $(C_{10}H_8FeHg)_x$ were obtained by treating 1,1′-bischloromercuriferrocene with a solution of sodium iodide in a mixture of ether and alcohol or with an aqueous solution of sodium thiosulphate.



The polycondensation of ferrocene and its derivatives yielded polymers having a system of conjugated double bonds, which possessed semiconductor properties.

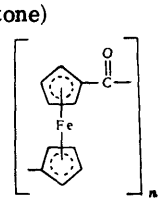
Several polyferrocenylenes have recently been synthesised by various methods (besides the polyrecombination reaction described above).

Nesmeyanova and Perevalova[79] obtained ferrocene polymers insoluble in organic solvents and also biferrocenyl by heating diferrocenylmercury with palladium black. Later Rausch[80] used silver in this reaction. Biferrocenyl was isolated as a byproduct of the interaction of a mixture of ferrocenyl-lithium and ferrocen-1,1′-ylenedilithium with tri-n-hexylbromosilane[81].



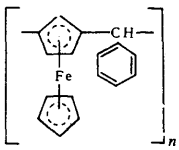
Nesmeyanov et al.[82] found that the action of an ammoniacal solution of silver oxide or of copper sulphate solution on ferrocenylboronic acid yields biferrocenyl together with ferrocene. According to Perevalova and Nesmeyanova[83] and also Rausch[80,84,85] halogenated ferrocenes undergo the Ullmann reaction with copper to give a high yield of biferrocenyl.

Rausch[80] and Nesmeyanov et al.[86] synthesised various derivatives of biferrocenyl. Reaction of a mixture of bromoferrocene and 1,1′-dibromoferrocene with copper at 105–120°C yielded biferrocenyl, 1,1′-terferrocenyl, and higher homologues[86], which were isolated by chromatography on aluminium oxide:



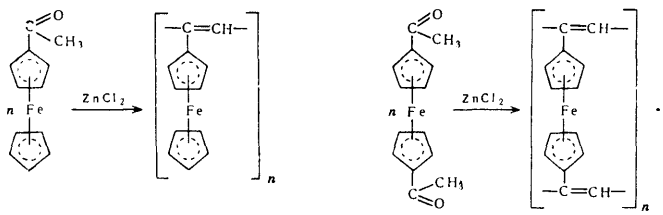
When only 1,1′-dibromoferrocene was used, 1,1′-terferrocenyl was formed in lower yield. The disubstituted terferrocenyl-1,1′-diferrocenyl-3,3′-diferrocenylferrocene was also obtained.

The preparation of a polyferrocenyl directly from ferrocenyl-lithium has been described[87,88]. The latter compound and cobalt chloride react, in the presence or in the absence of n-butyl bromide, to give various polyferrocenyls and butylated polyferrocenyls:



Many polyferrocenyls, butylated polyferrocenyls, and also biferrocenyl, terferrocenyl, and butylated biferrocenyl were isolated.

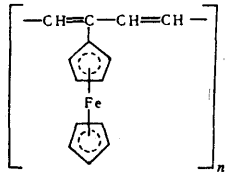
Pohl [? (Ed. of Translation)] reports the semiconductor properties of several ferrocene-containing polymers[89,90]. The poly(ferrocene ketone)



containing ferrocene molecules linked by carbonyl groups, has a conductivity of 10^{-13}–10^{-12} ohm^{-1} cm^{-1}†. The polymer having the highest conductivity is able to rectify a current in the presence of a silver–platinum couple. The polymer obtained by the condensation of ferrocene with benzylidene derivatives

exhibits a conductivity of 10^{-7}–10^{-8} ohm^{-1} cm^{-1}. Several of these polymers are thermoplastic materials.

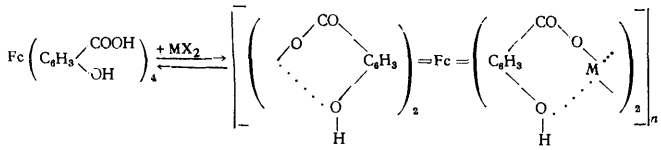
Conjugated ferrocene-containing polymers possessing semiconductor properties were prepared by Paushkin, Vishnyakova, and their coworkers[31-33] by the polycondensation of acetyl- and 1,1′-diacetyl-ferrocene in the presence of zinc chloride in an autoclave at 200°C. Polyferrocenylvinylenes were obtained in good yields. The bulk of the polymers was insoluble and did not melt up to 500°C, while the benzene-soluble fraction melted at 260–270°C. The synthesis of the polyferrocenylvinylenes can be represented by the scheme



All these polymers exhibit signals in the e.s.r. spectrum and an exponential temperature dependence of the electrical conductivity, which is characteristic of semiconductors. An interesting temperature dependence is shown by the polymer obtained by the polycondensation of 1,1′-diacetylferrocene. Heating this specimen at 10^{-4} mm to 250°C leads to a sharp increase in its conductivity by a factor of 10^7, the activation energy being 1.5 eV. Subsequent heating and cooling of the specimen at 10^{-4} mm does not produce any appreciable change in its conductivity. The activation energy in such a process is 0.05 eV, which lies at the limit of accuracy of the measurements.

Polyferrocenylvinylenes, as well as several ferrocene-containing polymers obtained by polyrecombination, have been investigated by means of Mössbauer spectroscopy, which will make it possible to obtain information both on the electronic state of the iron atoms present in the polymers and on the general structure of the polymer[91].

A method has also been elaborated for synthesising polyferrocenylvinylenes from acetyl- and 1,1′-diacetylferrocene and calcium carbide[92]. The explanation is that the calcium carbide, while abstracting water from the acetylferrocene, is hydrolysed by it. The acetylene thus liberated may give polymers containing conjugated double bonds with the starting materials and with the initial products of the reaction.



† The Russian original has 10^{-3}–10^{-12} Ω^{-1} cm^{-1} (Ed. of Translation).

The polymer is an infusible black powder, for which elementary analysis indicates the structure

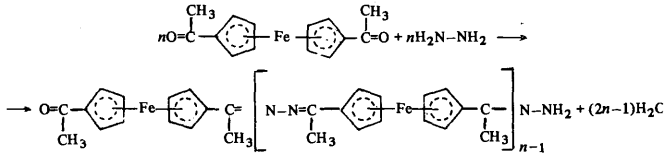
Several papers have been published recently on the synthesis of polymeric chelate compounds and on their thermal stability and specific properties[93,94]. Until a few years ago, however, there was no information on polymeric chelates based on ferrocene or any other non-benzenoid aromatic compounds. Attempts to synthesise such polymers from the corresponding tetraketones of ferrocenes were in vain owing to intramolecular cyclisation[95]. Berlin and Kostroma[96] obtained polymeric chelate compounds of salicylic derivatives of ferrocene, using mainly ferrocenedisalicylic and ferrocenetetrasalicylic acids[95,97], which were treated with methyl acetylacetonates or with solutions of the corresponding salts.

Chelate compounds of ferrocenedisalicylic acid with silver and copper and polychelates of ferrocenetetrasalicylic acid with copper, magnesium, aluminium, beryllium, and tervalent iron were synthesised in yields[64] of 99%, these being almost black powders, insoluble in organic solvents and decomposed by water and alkalis. The tetrasalicylic acid, in contrast to the disalicylic acid, exhibits a strong tendency to polycondensation:

where Fc represents a ferrocene residue.

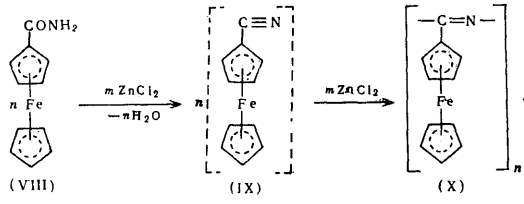
Examination of the thermal stability of the resulting polymeric chelate compounds of ferrocenetetrasalicylic acid at temperatures from 150° to 300°C showed that the beryllium complexes were the most stable, losing less than 5% of their weight when heated at 200°C for 5 h. The presence of conjugated bonds, ferrocene units, and metal atoms of variable valency in these polymeric chelates is responsible for their specific magnetic and electrical properties. Monomeric ferrocenedisalicylic and ferrocenetetrasalicylic acids are diamagnetic. When the temperature is raised (to 165°C) they acquire paramagnetic properties. The magnitude of the magnetic susceptibility of the polymeric chelate compounds is determined to a considerable extent by the nature of the metal forming part of the ring.

The electrical properties of polymers containing conjugated double bonds can be improved by including in the conjugated chain nitrogen atoms, the lone electrons of which participate in the π-electron system of the conjugated double bonds.



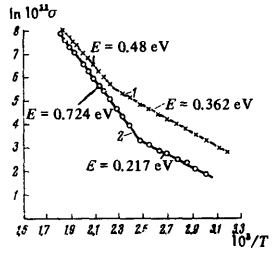
Berlin et al.[98] prepared ferrocene polymers containing nitrogen and a conjugated system by the interaction of ferrocene with biphenyl-4,4′-bisdiazonium and 3,3′-dicarboxybiphenyl-4,4′-bisdiazonium derivatives. From the elementary analysis, infrared spectra, solubility, and viscosity of the resulting polymers these workers considered that

the most probable structure had a parallel arrangement of the biphenyl or biphenyldicarboxylic acid residues:



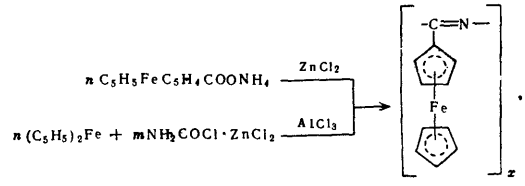
The fractions of the resulting polymers which were insoluble in organic solvents were infusible and thermostable in an inert atmosphere, losing ~ 8% of their weight at 700°C. On the admission of oxygen the polymers ceased to be thermostable. The polyazophenyleneferrocenes obtained give e.s.r. signals and possess static paramagnetism. Their electrical conductivity at room temperature is 10^{-16}–10^{-10} ohm^{-1} cm^{-1}.

The polycondensation of 1,1′-diacetylferrocene with hydrazine yields a ferrocene-containing polyazine, in which nitrogen atoms are linked together directly[99]:

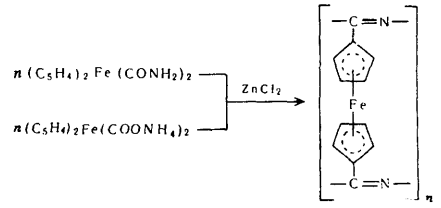


1,1′-Diacetylferrocene has been subjected to polycondensation also with diamines (*p*-phenylenediamine, benzidine, and hexamethylenediamine).[100] Conjugated ferrocene polymers containing nitrogen have been obtained by the polycondensation of ferrocene with hydroxylamine hydrochloride in the presence of zinc chloride[101].

Poly(ferrocenyl cyanide) has been obtained[102] by the polycondensation of ferrocenylformamide in the presence of zinc chloride. The first stage of the reaction involves the formation of ferrocenyl cyanide (IX), this being followed by complex formation and the ordering of its molecules with zinc chloride, and subsequent polymerisation at the C≡N bond leads to the formation of poly(ferrocenyl cyanide) (X):



The reaction was carried out, with molar proportions of monomer : catalyst = 1 : 0.2–1, at temperatures of 80–170°C for 1½–5 h.

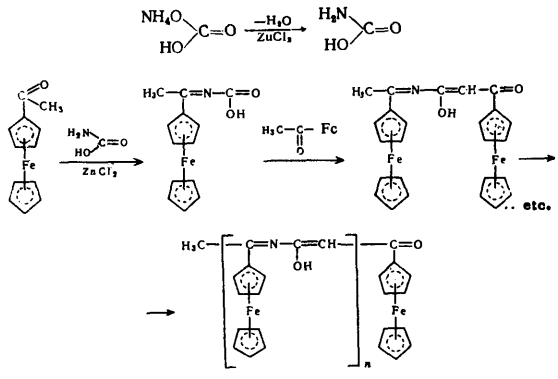


Temperature dependence of electrical conductivity of poly(ferrocenyl cyanide) after: 1) conditioning up to 50°C; 2) conditioning up to 50° and three conditionings up to 300°C.

All the insoluble products remain unmolten up to 500°C, are soluble in dimethylformamide, decompose over the range 420–500°C, and have a molecular weight of 1200. The poly(ferrocenyl cyanide) obtained gives an e.s.r. signal. The number of electrons having unpaired spins is 10^{18} g^{-1}. The temperature dependence of the electrical conductivity is exponential in character (see diagram).

Poly(ferrocenyl cyanide) has since been obtained by the polycondensation of ammonium ferrocenecarboxylate, and also directly from ferrocene and carbamoyl chloride (in the form of its zinc chloride complex)[103]. The infrared spectra and the elementary composition of the polymers were the same as for the poly(ferrocenyl cyanide) synthesised by the polycondensation of ferrocenylformamide. The reaction was conducted in an autoclave under various conditions.

The polycondensation of the diamide and of the diammonium salt of ferrocene-1,1′-dicarboxylic acid in the presence of zinc chloride yields poly(ferrocenylene dicyanide)[103,104]:



Poly(ferrocenyl cyanides) are dark coloured powders. The insoluble fractions do not melt up to 500°C, and the soluble fractions change colour at 350–500°C. The molecular weight of the soluble fractions determined isopiestically lies between 1200 and 1600. All the polymers give a narrow signal in the e.s.r. spectrum (10^{17}–10^{20} spins g^{-1}). The conductivity of the specimens is 10^{-14}–10^{-8} ohm^{-1} cm^{-1} at 50°C.

A ferrocene polymer containing nitrogen and a conjugated system has been obtained also by the polycondensation of acetylferrocene with urea in the presence of zinc chloride[105]. It give a single symmetrical signal in the e.s.r. spectrum having an integral intensity of 10^{18} spins g^{-1}, and its conductivity is 4.7×10^{-7} ohm^{-1} cm^{-1}.

An investigation has been made also of the polycondensation of acetylferrocene with ammonium hydrogen carbonate in the presence of zinc chloride, as a result of which novel ferrocene polymers have been obtained containing nitrogen, conjugated double bonds, and hydroxy-groups in the side-chains[106]. The reaction was conducted with various proportions of monomers and catalyst in an autoclave and at atmospheric pressure at 100–300°C for several hours. The yield of reaction products was 28–80% of theoretical.

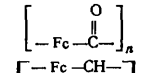
The initial stage of the process probably involves conversion of the ammonium hydrogen carbonate into carbamic acid, which then reacts with the acetylferrocene:

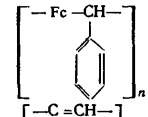
It is possible also that the polymer chains may be cross-linked by means of the hydroxy-groups with the formation of ether links. The rearrangement

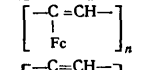
probably does not take place, since analyses show the presence of hydroxy-groups in the polymers.

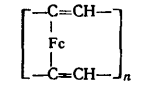
Conjugated ferrocene polymers containing nitrogen have been obtained also by the polycondensation of ferrocenylformamide with acetaldehyde and butyraldehyde[107]. The reaction was conducted with various proportions of monomers and catalyst (zinc chloride) at 100–350°C for 3–10 h. The resulting polymers were paramagnetic. They give single symmetrical e.s.r. signals having a g-factor of ~ 2, a width of 2.7–5.4 oersteds, and an integral intensity of 10^{16}–10^{18} spins g^{-1}. The conductivity at 50°C is 10^{-10}–10^{-11} ohm^{-1} cm^{-1}.

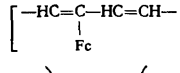
TABLE 5. Electrical properties of conjugated ferrocene polymers obtained by polycondensation.

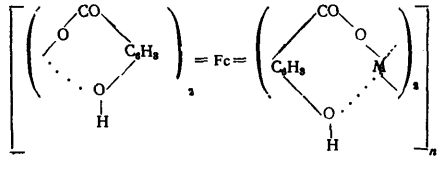


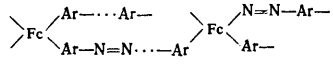


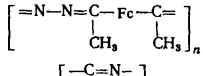


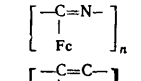


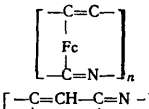


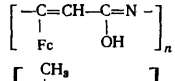


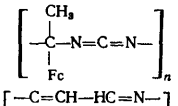


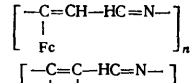


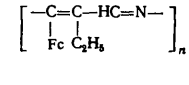












Structure of polymer	Concn. of unpaired electrons, g^{-1}	Conductivity σ_{50}, ohm^{-1} cm^{-1}	Activation energy ΔE, eV
	—	10^{-9}—10^{-12}	—
	—	10^{-7}—10^{-8}	—
	10^{17}	10^{-10}	1.45
	10^{17}	10^{-11}	0.42
	10^{16}	—	—
	signal in e.s.r. spectrum	10^{-8}—10^{-10}	—
	ditto	10^{-10}—10^{-10}	—
	10^{15}	—	1.48—2.78
	10^{17}—10^{19}	10^{-10}—10^{-12}	0.190—0.620
	10^{17}—10^{18}	10^{-11}—10^{-12}	0.115—0.630
	10^{17}	10^{-10}	0.05—0.350
	10^{20}	10^{-8}	0.070—0.455
	10^{18}	10^{-10}	0.047—0.271
	10^{18}	10^{-10}	0.158—0.230

Table 5 gives some electrical properties of the conjugated ferrocene polymers obtained by polycondensation.

5. FIELDS OF APPLICATION FOR POLYMERS CONTAINING FERROCENE

Polymers containing ferrocene are novel, as yet little studied macromolecular compounds. But the possibility of using these polymers for various purposes has already been demonstrated.

Several ferrocene-containing polymers exhibit the properties of electron-exchange resins[9-12], which can be used for the preparation of hydrogen peroxide, the removal of dissolved oxygen from water, the preparation of free iodine, the reduction of noble metals in solutions of their salts, etc.

Various silicon-containing polymers of ferrocene[75] can be used as the chief or secondary components of lubricants, hydraulic liquids, elastomers, plastics, and additives. It is possible also to formulate from them a series of compositions which can be employed as intermediates for the synthesis of resins, elastic materials, and organic metal carriers.

Ferrocene-containing polymers having conjugated double bonds, e.g. poly(ferrocene ketone)[89,90], possess the properties of organic semiconductors.

The possibility has been shown of using conjugated ferrocene polymers[102-107] as inhibitors of the degradation of rubbers by heat and oxidation and of the polymerisation of styrene[108]. Such polymers containing nitrogen are capable of forming complexes with salts of noble metals, which makes possible their use for extracting the latter from solutions.

Conjugated ferrocene polymers are catalysts of semiconductor type for the decomposition of alcohols and the synthesis of ammonia.

Several ferrocene polymers, e.g. products of the polycondensation of ferrocene with aldehydes and ketones[67], can be used as oxidation catalysts.

The diverse fields of application of ferrocene-containing polymers explain the ever increasing interest taken in these compounds, and make it certain that researches on these lines will lead to important practical results.

THE SOLUBILITY OF AMINE SALTS IN SOLVENTS OF LOW POLARITY AND THE INFLUENCE OF DILUENTS ON THE EXTRACTION PROPERTIES OF AMINE SALTS

V.S.Shmidt, V.N.Shesterikov, and E.A.Mezhov

CONTENTS

I. Introduction 946

II. The state of amine salts dissolved in solvents of low polarity 946

III. The influence of the structures and properties of amines and diluents on the solubility of amine salts in systems without specific solvation 950

IV. The influence of specific solvation on the solubility of amine salts in diluents of low polarity 952

V. The influence of non-solvating diluents on the extraction properties of amine salts 955

VI. The influence of specific solvation on the extraction properties of amine salts 956

I. INTRODUCTION

Amine salts have found extensive application for the extraction of acids and metal salts from aqueous solutions[1]. Since the amine salts are viscous substances and in some instances even solids, they are used, like many other extractants, as solutions in solvents of low polarity, immiscible with water. Being substances of polar structure, amine salts are in many cases relatively sparingly soluble in such diluents, and their extractive power is greatly influenced by several of the latter. Thus the selection of a suitable diluent for the amine salts, i.e. a diluent in which the amine salts are readily soluble and do not lose their extractive properties, is an important task, and the investigation of the regular features relating the structures and properties of the amine salts and the diluents to their mutual solubility and the extractive power of the solutions is of considerable practical importance.

The regular features of the solubility of amine salts in various diluents and the influence of the diluents on the extractive power of the dissolved salts are closely related to one another, since they are determined by the same factors. The most important of these factors is the ratio of the energies of interaction of the molecules of the extractant and the compound being extracted with one another and with the molecules of the diluent[2]. The ratio of the energies of these interactions also determines the state of the molecules of the salt in solution, and this determines to a considerable extent the extractive power and solubility of these salts[3,4]. A particularly marked influence on the extractive power and solubility of amine salts is shown by the specific solvation of the positively and negatively charged parts of their molecules: this solvation results from the formation of hydrogen bonds or donor–acceptor bonds with the solvent, and leads to binding of the extractant or to a marked change in its properties[5].

A large amount of experimental data has now been published on the solubilities of amine salts in various diluents and on the influence of diluents on the extractive properties of these salts. The aim of the present review is to systematise these data and to explain the observed regular features. Since the nature of these regularities and the approach to their explanation may depend on whether specific solvation of the molecules of the amine salt by the molecules of the diluent takes place, it is convenient to examine separately the phenomena taking place in systems with and without specific solvation. To explain the phenomena observed in systems without specific solvation, thermodynamic methods are chiefly used, since the mechanism of the relatively weak intermolecular interactions in these systems has as yet been comparatively little studied. For systems in which specific solvation is observed, the regular features of the solubility and the influence of the diluent on the extractive power of amine salts with various structures can be explained qualitatively on the basis of published information on the reactions of the diluent molecules with the molecules of the amine salts. The present review first gives data on the state of amine salts in solvents of low polarity, necessary for an understanding of the mechanism of these interactions.

II. THE STATE OF AMINE SALTS DISSOLVED IN SOLVENTS OF LOW POLARITY

Amine salts capable of extracting acids and metal salts are usually polar substances[5]. The dipole moments of their molecules[6] may reach 10–12 D. The factors determining the structures of these salts have been examined in detail[5,7-11].

In non-solvating solvents of low polarity, because of the low dielectric constant of the medium, dissolved amine salts are present almost completely in the undissociated state[8-16]. Moreover, the molecules of the salts in these solutions are usually appreciably associated (polymerised). It is appropriate in the present review to examine in detail data on the association of amine salts, since the degree of association of a dissolved substance is directly related to its solubility. When the size of the associated complexes of dissolved molecules reaches a definite limit, formation of a new phase takes place†. It is to be expected that all the factors facilitating a decrease in the association of an amine salt in solution should lead to an increase in its solubility.

The degree of association is determined by the ratio of the energies of interaction of the polar molecules (ion pairs) of the salt with one another and with the molecules of the solvent. It is evident that the interaction of the molecules of the salt with one another facilitates association, whereas interaction with the medium hinders it.

The interaction of the polar molecules or ion pairs of a solute with one another and with the medium is determined by a number of forces of different kinds[17-22]—electrostatic forces and dispersion forces—and an important part may also be played by weak donor–acceptor interactions,

† Voyutskii[3] points out that "... association complexes form the nuclei of a new phase in the old, so that here we have a striking example of a quantity-quality transition".

leading to the formation of charge-transfer complexes of low stability. In some instances hydrogen bonds or relatively strong donor–acceptor bonds are formed by the solute molecules with one another or with the solvent molecules. These main forms of interaction are characterised briefly below, and their influence on the association of molecules of amine salts having different structures in diluents of low polarity is examined.

The electrostatic interaction energy of the cation and the anion of the salt with the solvent is determined according to Born[23] by the relationship

$$A = \frac{Z^2e^2}{2r}\left(1 - \frac{1}{D}\right) \quad (1)$$

(where Ze and r are the charge and the radius of the ion respectively, and D is the dielectric constant of the medium) and it follows that the electrostatic interaction energy of the ions with the medium decreases with decrease in the dielectric constant of the medium. In non-polar solvents or solvents of low polarity (saturated hydrocarbons, benzene, its alkyl derivatives, etc.), this energy is extremely low. The same is true of the dipole–dipole interaction energy between solute and solvent molecules. According to Keesom[24], the mean energy of attraction between dipoles is given by the formula

$$A = -\frac{2\mu_1^2\mu_2^2}{3r^6kT}, \quad (2)$$

where μ_1 and μ_2 are the dipole moments of the ion pairs or molecules, r is the distance between them, k Boltzmann's constant, and T the absolute temperature. It is evident that dipole–dipole interaction between the dipoles of a salt and the molecules of a non-polar solvent can take place only as a result of the production of induced dipoles in the molecules, and for non-polar solvents whose molecules are only slightly polarisable, this interaction should also be small. According to formula (2), the electrostatic interaction of the polar molecules of the salt with one another should be relatively large. This interaction is intensified with increase in the dipole moments of the molecules, with decrease in the distance between the dipoles (i.e. with decrease in the size of the salt molecules), and also with fall in the temperature.

Since in non-polar, non-solvating solvents the interaction of salt molecules with the medium is small, while their interaction with one another is considerable, appreciable association of the salts is observed in these systems. With increase in the polarity of the solvent we should expect an intensification of the electrostatic interaction of the molecules of the salt with the solvent and a decrease in the association.

The interaction of the molecules of amine salts with the molecules of non-polar organic solvents is determined to a considerable extent by dispersion forces, which increase with increase in the electronic polarisability of these molecules[25,26]. These forces oppose the association of the dissolved salts, but since they are relatively weak, they can bring about a significant decrease in association only when the electrostatic interaction of the salt molecules with one another is reduced as a result of marked screening of their charges by long hydrocarbon chains in the salt.

Charge-transfer complexes may be formed in the reactions of many compounds, including non-polar compounds[21,27-43]. In these complexes, one of the compounds acts as a Lewis acid and the other as a base. The stability constants of these complexes usually do not exceed a few units, and the interaction energy does not exceed 0.5–1 kcal mole^{-1}.[40] Nevertheless, these interactions can apparently have a marked influence on the state of certain salts in solution[44]. The ability of many aromatic hydrocarbons to form charge-transfer complexes has been reported[41,45-48]. In most instances the aromatic hydrocarbons in these complexes act as bases, but examples of their behaviour as Lewis acids have also been described[49,50]. The salts of primary and secondary amines in such complexes can in principle act as Lewis acids if the interaction takes place through the cation of the salt, or as bases if the interaction takes place through the anion of the salt. The salts of long-chain tertiary alkylamines, unlike the salts of secondary and primary amines, apparently cannot act as Lewis acids, since the positive charge of the cation in these compounds is strongly screened by the alkyl groups, and the compounds can act only as bases. The stability of charge-transfer complexes in which the aromatic diluent acts as a base increases with increase in its basic character, which can be assessed from data on the inductive effects of substituents in the benzene ring[25]. The formation of charge-transfer complexes between the molecules of amine salts and diluents would evidently oppose association in these systems. It should be noted, however, that the formation of charge-transfer complexes cannot always alter significantly the association of the amine salt, since the energy of bonding in these complexes is low.

The strongest interactions of the molecules of an amine salt with the molecules of a solvent and with one another are produced when hydrogen bonds are formed between these molecules. Hydrogen bonds may be formed between the anions of amine salts (which exhibit electron-donating properties[5]) and the molecules of the solvent if the latter contain electropositive hydrogen atoms‡. Hydrogen bonds may also be formed between the cations of amine salts, which contain electropositive hydrogen atoms, and the molecules of solvents which are electron donors§[14,15,52-60]. These bonds are so stable (energy 4–6 kcal mole^{-1}) that in many cases they have a decisive influence on the association of salts in solutions[61]. In systems with specific solvation of this type, the dissolved salts of tertiary amines are usually present in the monomeric state.

The most stable association complexes of salt molecules are produced when hydrogen bonds are formed between the anions of some molecules of the amine salt and the cations of other molecules of this salt. Such aggregates can obviously be formed chiefly in solutions of salts of primary amines, whose cations contain electropositive hydrogen atoms which are not screened by a large number of alkyl chains.

It follows from the foregoing that in non-solvating solvents of low polarity the interaction of the polar molecules of amine salts with one another, and hence their association, should increase with increase in the dipole moments of these molecules, and should decrease with increase in the dimensions of the latter and with increase in temperature. The association of the salts should decrease with increase in the polarity of the diluent and in its ability to form charge-transfer complexes or hydrogen bonds with the salt, and should increase when bonds of these types are

‡ Examples of these solvents are alcohols, acids, chloroform, etc.[21,25].

§ Examples of these solvents are ketones, ethers, esters, aromatic compounds containing mobile π-electrons, nitro-compounds, nitriles, etc.[21,25].

formed by the salt molecules with one another. Published data on the influence of some of these factors on the association of amine salts in solutions are given below.

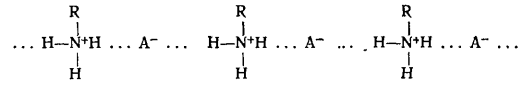
1. Influence of the Polarity of the Molecules of Dissolved Amine Salts on Their Association in Solution

For a series of salts with similar structures, whose molecules have dipole moments of 0.29, 1.20, 1.66, and 2.67,[64-66] the degree of association in benzene solutions has the values 9, 12, 20, and 60 respectively[62,63]. The degree of association of amine salts also increases with increase in the polarity of their molecules[67-71]. Comparison of published data shows that in benzene solutions the degree of association of trioctylammonium salts varies in the sequence—perchlorate[72] > hydrogen sulphate[73-77] > nitrate[68,69] > sulphate[78]—in accordance with the order of their polarity. The association of tridodecylammonium halides in benzene, carbon tetrachloride, and cyclohexane varies in the order—iodide > bromide > chloride[79]—again in accordance with the change in polarity of these salts.

2. Influence of the Dimensions and Shape of the Molecules of Dissolved Amine Salts on Their State in Solution

Increase in the length of the alkyl chains in amines leads to a decrease in the association of their nitrates[6,52,68,80-87]. The degree of association of decyldimethylammonium, tri-n-octylammonium, tri-n-decylammonium, and tri-n-dodecylammonium nitrates at the same concentrations in *p*-xylene has the values ~ 12, 3–4, 2, and 2 respectively[68]. Tri-n-alkylammonium nitrates with hydrocarbon chains longer than C_{10} in solvents of the xylene and benzene type apparently do not form aggregates larger than the dimers[68,88,89]. The tendency of amine sulphates to undergo association also decreases with increase in the length of their alkyl chains[90].

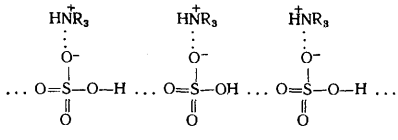
The salts of some secondary amines are more extensively associated in solvents of low polarity than are the salts of the corresponding tertiary amines, formed with the same acids[91,92]. This can be attributed to the lower steric hindrance to the approach and mutual attraction of the dipole molecules for the salts of secondary amines compared with the salts of tertiary amines¶.



A decrease in the association of many salts containing organic radicals[62,63,93], including amine salts[9], is facilitated by the presence of double bonds in the hydrocarbon chains of their molecules, since the double bonds increase the rigidity of the chains and hence increase the steric hindrance to mutual approach of the salt molecules.

The degree of association of amine salts in non-polar solvents may depend on their concentration in the solutions[69,71], the nature of the dependence being different for salts with different structures[9]. The association of most salts of tertiary amines increases with increase in their concentration, passes through a maximum, and then decreases with further increase in the salt concentration[9,69]. For salts of tertiary amines with large anions the degree of association at moderate concentrations increases in conformity with the law of mass action[67,71,72,75,79,94]. For salts with relatively small anions[9], e.g. tri-n-octylammonium nitrate[95-97], tri-n-hexylammonium nitrate[98,99], tribenzylammonium halides[9], and various other salts having similar structures[100], the association increases with concentration more slowly than is required by the law of mass action†.

Highly associated salts are unique: their polymerisation is due to the formation of intermolecular hydrogen bonds. These salts are extensively associated at all concentrations.



3. Influence of Intermolecular Hydrogen Bonding in Amine Salts on Their State in Solution

The formation of intermolecular hydrogen bonds is most characteristic of salts of primary amines, since the cations of these salts each contain three electropositive hydrogen atoms capable of taking part in the formation of these bonds[4,53-60,100-107]. On the other hand, the anions of amine salts may act as proton acceptors[5]. It is therefore suggested[5,51,68] that hydrogen bonds may be formed between cations and anions in different molecules of the salt of a primary amine, with the formation of relatively large and stable aggregates of the type

The salts of tertiary amines, particularly amines with long chains, cannot form such bonds because of steric hindrance and the smaller number of electropositive hydrogen atoms. With the salts of secondary amines, in view of the lower steric hindrance, the formation of intermolecular hydrogen bonds is more likely. Cryoscopic studies[68] show, however, that the nitrates of secondary amines are not associated much more extensively than are the nitrates of tertiary amines. The formation of intermolecular hydrogen bonds is apparently not characteristic of salts of secondary amines having long alkyl chains.

With the salts of secondary and tertiary amines intermolecular hydrogen bonding can be expected only when they are acid salts of dibasic or polybasic acids[76,108]. We can then assume the formation of aggregates of the type

in which the protons of the anions of some molecules of the salt interact with the electron-donating atoms of the anions of other molecules of the salt. It has in fact been shown that tri-n-octylammonium hydrogen sulphate[74-78,108] and hydrogen oxalate[109] are more extensively associated than are the corresponding normal salts of these acids. The more extensive association of the acid salts, however, may be due, not only to the formation of intermolecular hydrogen bonds between their molecules, but also to the higher polarity of these salts[78], resulting from the asymmetry of their structure.

It is to be expected that the association of amine salts may be influenced by the formation of hydrogen bonds between the anions of these salts and water molecules, when

¶ Another reason for the weaker association of salts of tertiary amines is the absence of intermolecular hydrogen bonds between the molecules of the salts of these amines.

† For the association of these salts the law of mass action is probably observed only at very low concentrations.

the latter are present in the system. Barrow and his coworkers[103] showed that the presence of water may lead to the dimerisation of amine salts with the formation of compounds of the type AmineHA... H–O–H... AHAmine, where HA is the acid forming the salt. Vdovenko and his coworkers[88] and also Högfeldt[104] had previously established that tri-n-octylammonium nitrate forms hydrates in the presence of water. Work by others[68,69], however, shows that the influence of water on the association of trialkylammonium nitrates is slight.

When hydrogen bonds are formed between the molecules of an amine salt, the association of the salt may be diminished significantly only as a result of specific solvation of the molecules of the salt by solvent molecules: non-solvating solvents have relatively little influence on the state of the salt in solution. If, however, the association of the amine salt takes place only as a result of dipole–dipole interactions, the nature and properties of a non-solvating solvent (dielectric constant, etc.) have a considerable influence.

4. Influence of the Dielectric Constant of the Medium on the State of Amine Salts in Solution

The influence of the properties of solvents on the association of the molecules of amine salts in solution has been investigated by a number of authors in studies of the electrical conductivities of these salts[8,9,80–86,100–112], and also in studies of the extraction of acids and metal salts by amine salts[68,69,73–77,79,87,98,113–116]. Sukhotin[8] and Kraus and his coworkers[6,9,80–86] have shown that the salts of tertiary amines and quaternary ammonium bases, which are present in the monomeric state in polar solvents (e.g. nitrobenzene), are associated in benzene and other non-polar solvents. Fomin and his coworkers[69,74], Shmidt and Shesterikov[68], Frolov and Sergievskii[77], Vdovenko, Chaikhorskii, and their coworkers[88,98], and others[70,79,87,113,115,116] have studied the state of the salts of various tertiary alkylamines in *p*-xylene, benzene, and toluene, and have shown that the amine salts are appreciably associated in these solvents of low polarity. The increase in the degree of association observed with decrease in the dielectric constant of the medium is consistent with the decrease in the strength of electrostatic interaction of the salt molecules with the medium, following from formulae (1) and (2).

5. Association of Salt Molecules in Various Non-Polar Solvents

The dielectric constant is not the only property of a solvent determining the association of a salt dissolved in that solvent. For example, the association of trialkylammonium nitrates in octane[113] is much greater than the association of these salts in benzene and *p*-xylene[68], although the dielectric constants of all these solvents are similar and the dipole moments of their molecules are zero[117]. According to Palit's data[118], the degree of association in benzene and in cyclohexane has the values ~ 5 and ~ 10 respectively for dodecylammonium propionate, and ~ 3 and 10 respectively for dodecylammonium oleate, although the molecules of both these solvents are non-polar. The degrees of association of tridodecylammonium halides are also different for these solvents of equal polarity[79].

These differences in the degree of association of salts in different non-polar solvents are due to differences in the strength of the non-Coulombic interactions (dispersion interactions, etc.) of these non-polar solvents with the dissolved amine salts, and also, apparently, to the formation of unstable charge-transfer complexes between the amine salts and certain solvents. For a rough estimate of the influence of these interactions on association, we can use the values of the Hildebrand parameter δ, characterising the strength of the interaction of the molecules of each component of the solution with one another[2,19,45,119,120]. The greater the difference in the force fields of the molecules of the various components of the solution, i.e. the greater the difference between the parameters δ characterising these components, the greater should be the tendency for identical molecules to associate‡. The values of δ for amine salts are usually much greater than those for most non-polar diluents, and amount to 10–14 $cal^{1/2}\ cm^{-3/2}$.[121,122] For solvents of low polarity, the values of δ lie in the range 7–9 $cal^{1/2}\ cm^{-3/2}$ (see Table). The difference in the values of δ for the salt and the solvent increases on going from aromatic to aliphatic hydrocarbons (see Table), in agreement with published data on the association of amine salts in these solvents. The Table also shows that the value of δ for cyclohexane is lower than that for benzene. This agrees with the observed more extensive association of mono- and tri-dodecylammonium salts in cyclohexane compared with benzene[118]. Published data[123] indicate that the degree of association of trioctylammonium chloride is greater in cyclohexane than in toluene, and this again agrees with the higher value of δ for toluene. The degree of association of these salts has its highest values in open-chain saturated hydrocarbons, whose δ-values are much less than those for cyclic hydrocarbons and differ to the greatest extent from the values of δ for amine salts[113]. Amine salts are less associated in carbon tetrachloride than in cyclohexane[79], since the former solvent has the higher value of δ. The data in the Table also suggest that the association of salts dissolved in alicyclic hydrocarbons should decrease on going from cyclopentane to cyclo-octane.

The force of interaction between the molecules of different substances in solution depends also on their molar volumes[45]. Thus within a given class of solvents, satisfactory correspondence between the values of δ and the degree of association of salts is observed only when solvents having similar molar volumes are compared.

6. Association of Salts and Their Solubility

On the basis of the above data on the influence of the properties of salts and solvents on association, it is possible to reach preliminary conclusions regarding the influence of these properties on the solubility of amine salts in non-polar diluents and those of low polarity. Since diminished association of a salt leads to an increase in its solubility, it may be expected that the solubility of amine salts should increase with decrease in the dipole moments of their molecules, with increase in the number and length of the alkyl chains in the molecules, with the introduction of double bonds into the alkyl chains, with increase in the dielectric constant of the solvent, and (for non-solvating non-polar solvents having similar molar volumes) with increase in the parameters δ for these solvents, as well as

‡ This argument will obviously be completely valid only in the absence of specific interactions between solvent and solute.

TABLE. Parameters δ for various solvents[19,45,119,124-126].

Class of compound	Solvent	δ	Class of compound	Solvent	δ
Saturated open-chain hydrocarbons	Neopentane	6.2	Aromatic hydrocarbons	n-Butylbenzene	8.6
	Isopentane	6.8		n-Propylbenzene	8.6
	n-Pentane	7.1		Ethylbenzene	8.8
	n-Hexane	7.3		Toluene	8.9
	n-Heptane	7.4		Benzene	9.2
	n-Octane	7.5		o-Xylene	9.0
	n-Nonane	7.6		m-Xylene	8.8
	n-Decane	7.7		p-Xylene	8.8
	n-Dodecane	7.8		Mesitylene	8.8
	n-Tetradecane	7.9		Styrene	9.3
	n-Hexadecane	8.0		Naphthalene	9.9
	2,2,4-Trimethylpentane	6.8		Nitrobenzene	10.0
	Isopentane [sic]	6.6	Halogenated hydrocarbons	Bromobenzene	10.0
		7.3		o-Dichlorobenzene	11.0
		7.6		Chlorobenzene	9.5
Unsaturated hydrocarbons	Hex-1-ene	7.7		CCl_4	8.6
	Oct-1-ene			$CHCl_3$	9.3
	Hexa-1,5-diene	8.2		$CHBr_3$	10.5
				CH_2Cl-CH_2Cl	9.0
Saturated cyclic hydrocarbons	Cyclopentane	8.5		CH_2Br-CH_2Br	9.6
	Cyclohexane	8.6			
	Cycloheptane	7.8	Other compounds	Nitromethane	12.6
	Cyclo-octane			Carbon disulphide	10.0
	Methylcyclohexane			Dioxan	10.0
				Pyridine	10.7
				Acetonitrile	11.9
				Methyl ether	8.8

with rise in temperature. The formation of intermolecular hydrogen bonds or donor–acceptor and charge-transfer complexes between the molecules of the amine salt should decrease its solubility (as a result of which the salts of primary amines and the acid salts of polybasic acids have a low solubility), whereas the formation of corresponding bonds with the diluents should increase the solubility. The published regular features of solubility show good agreement with these conclusions.

III. THE INFLUENCE OF THE STRUCTURES AND PROPERTIES OF AMINES AND DILUENTS ON THE SOLUBILITY OF AMINE SALTS IN SYSTEMS WITHOUT SPECIFIC SOLVATION

Many of the conclusions regarding the regular features of the solubility of amine salts in diluents of low polarity, reached above from an examination of the state of these salts in solutions, can be reached also by thermodynamic methods. In some instances it is possible to predict the solubility quantitatively.

From the thermodynamic viewpoint, solubility may be determined by factors of two different types—(1) factors independent of the nature of the solvent and determined entirely by the nature of the solute, and (2) factors depending on the properties not only of the solute but also of the solvent.

For systems obeying the laws governing ideal solutions, the solubility of solids is independent of the nature of the liquid solvent. Liquids in ideal systems are miscible in all proportions.

For many real systems, the mutual solubility of liquids is restricted, and the solubility of solids in the liquids depends not only on their properties but also on the nature of the solvent. When real systems obey the laws of regular solution[19], the solubility values can be calculated from the parameters δ of solute and solvent. For solutions whose behaviour differs from that predicted by the theory of regular solutions, quantitative prediction of the solubility is difficult. Large changes in solubility on passing from one system to another, however, can be predicted qualitatively on the basis of this theory with allowance for the deviations expected on the basis of data on specific interactions in these systems. It is therefore of interest to examine the correspondence between solubility data for amine salts and the regular features expected for ideal and regular solutions.

1. Solubility in Ideal Systems

In ideal systems the solubility of solids is given by Shreder's equation[127,128]

$$\ln N = -\frac{\Delta H_f\,(T_f - T)}{RT_f\,T} \qquad (3)$$

where N is the mole fraction of the solute in a saturated solution, ΔH_f the heat of fusion of the solute, T_f the melting point of the solute, and T the temperature of the system.

It follows from Eqn. (3) that the solubility of solids in ideal liquid systems decreases with increase in the melting point and the heat of fusion, and increases with rise in the temperature of the system. This equation also shows that at the melting point the solubility is unlimited: i.e. ideal liquids are miscible in all proportions. The experimental data show good agreement with Shreder's equation for solutions of various non-polar substances in non-polar diluents[129]. It is evident that even qualitative conclusions regarding the solubility of amine salts in diluents of low polarity can be reached from Eqn. (3) only for amines of high molecular weight containing very large organic radicals, which screen the dipole moments of the salts, so that their behaviour and properties approach those of non-polar hydrocarbons.

The salts of tertiary amines with sufficiently high molecular weights are solids, and their melting points increase with increase in molecular weight. The salts of amines with very long hydrocarbon chains are sparingly soluble even in relatively polar solvents, in agreement with conclusions reached from Eqn. (3). From this it follows that the increase in the solubility of amine salts in non-polar solvents with increase in the length of the hydrocarbon chains of the amines, expected from considerations related to association of the salts, should be observed only within definite limits. The salts of amines with extremely long alkyl chains are sparingly soluble because of the increase in their melting point.

2. Solubility in Systems Obeying the Laws Governing Regular Solutions

Regular solutions are those in which the distribution of the components is completely homogeneous and disordered, the force fields of the molecules are symmetrical, and the molecular volumes of the molecules do not differ greatly from one another[19]. Solutions of non-polar substances in non-polar solvents correspond most closely to this definition and show the closest agreement with the rules derived for regular solutions[45,119,120]. For regular solutions the solubility differs from the ideal solubility, but quantitative allowance can be made for this deviation by means of equations containing the parameters δ. The solubility of solids

in regular solutions is determined[45] by the equation

$$\ln a^{i}_{\text{solid}} = \ln \varphi_2 + \varphi_1\left(1 - \frac{V_2}{V_1}\right) + \frac{V_2\varphi_1^2(\delta_2 - \delta_1)^2}{RT}, \quad (4)$$

where a^{i}_{solid} is the ideal solubility, calculated from Eqn. (3), φ_1 and φ_2 are the volume fractions of solvent and solute in the saturated solution, V_1 and V_2 the molar volumes of these substances, and δ_1 and δ_2 their solubility parameters.

It follows from Eqn. (4) that, other conditions being equal, the solubility should be greater, the smaller the difference $\delta_2 - \delta_1$. Hildebrand[130-132] points out that Eqn. (4) is approximate and that caution must be exercised in using this equation to calculate the solubilities of polar substances[19], despite the fact that values of δ for a large number of polar substances have been published[133]. Although amine salts are polar substances, the principles of the theory of regular solutions are observed for many polar substances containing a bulky hydrocarbon portion, with an accuracy which is greater, the greater the volume of the non-polar radicals in the molecules of these substances[134]. The first attempt to apply the theory of regular solutions to the determination of the solubility of amine salts in non-polar solvents was made by Kertes[121,122], who determined the values of δ for a number of tertiary, secondary, and primary alkylammonium chlorides from their solubilities in various solvents. Similar values of δ were obtained for each salt in different solvents, indicating that the characteristic features of regular solutions are observed (approximately at least) with solutions of long-chain alkylamines. For primary, secondary, and tertiary alkylammonium chlorides the values of δ[121,122] are ~ 13–14, ~ 11–12, and 10.5–10.6 respectively, in agreement with the higher solubility of tertiary amine salts in solvents of low polarity. In accordance with Eqn. (4) and the values of δ given in the Table, the solubility of amine salts in saturated hydrocarbons is much less than that in aromatic hydrocarbons or in carbon tetrachloride. It may be expected that the regular features of solubility in non-solvating solvents will be analogous for other amine salts.

With solvents whose molar volumes have similar values, the solubility of amine salts should increase with increase in the value of δ for the solvent. The data in the Table indicate that for aromatic hydrocarbons the order of solvent power will be—nitrobenzene > chlorobenzene > benzene > toluene > xylene ≃ ethylbenzene > n-propylbenzene —which corresponds to the observed solvent power of these solvents for amine salts[135]. The observed sequence indicates that the solvent power of the diluent decreases with increase in the number and length of the alkyl substituents in benzene. An interesting parallelism is observed between the increase in the acidic properties (increase in ionisation potential[136]) of substituted benzene derivatives and their solvent power for the salts of tertiary amines. In this series of compounds the solvent power decreases with decrease in the acidic properties. If this regular feature is observed for other benzene derivatives, we may expect that all derivatives with substituents having positive inductive effects will be weaker solvents than derivatives containing substituents with negative inductive effects[137,138]. These results can be explained if we assume that the solubility of amine salts increases with increase in the acid–base interaction of the anions of the amine salts with the solvent molecules.

The data in the Table suggest that cyclohexane is a more effective solvent than open-chain hydrocarbons, but is less effective than aromatic hydrocarbons. The solubility of tri-n-octylammonium chloride in cyclohexane is in fact less than that in toluene, but much greater than that in saturated hydrocarbons[123]. In the selection of aromatic hydrocarbons for the dissolution of amine salts, compounds with a large number of long alkyl chains attached to the benzene ring should evidently be avoided as far as possible. The data in the Table show good agreement with the familiar ready solubility of amine salts in nitromethane, chloroform, and pyridine[139]. The data also suggest that the presence of naphthalene in benzene or carbon tetrachloride may increase their solvent power, and also that the solvent power of alicyclic hydrocarbons should vary in the order—cyclo-octane > cycloheptane > cyclohexane > cyclopentane > methylcyclohexane.

In the theory of regular solutions, the solubility of a liquid is determined by the relationship[19,5,119]

$$\ln N_2 = -\frac{V_2\varphi_1^2}{RT}(\delta_2 - \delta_1)^2, \quad (5)$$

where the subscripts 2 and 1 denote quantities relating to solute and solvent respectively§. Thus for liquids also, the solubility is determined by the difference $\delta_2 - \delta_1$, and we should expect the regular features of the solubility of liquid amine salts to be analogous to those observed for the solid salts.

For a preliminary estimate of the possibility of dissolving amine salts in solvents which do not exhibit specific solvation, an equation derived from the theory of regular solutions[45], relating the consolute temperature of a mixture of liquids with the parameters δ, is of interest:

$$T_{\text{cons}} = (\delta_1 - \delta_2)^2(V_1 + V_2)/4R \quad (6)$$

where V_1 and V_2 are the molar volumes of the components of the mixture. This equation and the value of δ for the amine salt can be used to determine approximately the solvents in which the salt will be soluble at ordinary temperatures. By substituting in Eqn. (6) the values of δ for amine salts determined by Kertes[121,122] and the known values of δ for various solvents, it can readily be established that for solutions of these salts in aromatic and chlorinated hydrocarbons the values of T_{cons} lie considerably below room temperature, whereas those for solutions in aliphatic hydrocarbons are much higher than room temperature, in agreement with the solubility data.

Thus the conclusions reached on the basis of the theory of solubility for regular solutions agree with the observed regular features of the solubility of amine salts, and the formulae of this theory, together with known values of δ, can be used to predict semi-quantitatively the solubility of the salts in various solvents.

All saturated hydrocarbons are poor solvents for amine salts. At the same time there are significant differences in the solvent power of individual saturated hydrocarbons. Thus the volume solubility of amine salts and various other polar organic compounds in hydrocarbons decreases with increase in the length of the hydrocarbon chain[121,122,140-142]. For example, the solubility of tridodecylammonium nitrate in octane is greater than that in decane[143]. At the same time, the values of δ for hydrocarbons increase slightly with increase in the chain length. Similar regular features

§ This equation is applicable when $V_2 \simeq V_1$. More complex equations are used when the difference between these volumes is large[45].

were observed in a study of the solubility of water in saturated hydrocarbons[144]. The solubility of water, expressed in mole fractions, increases slightly with increase in the length of the alkyl chains, the increase corresponding exactly to that expected from formula (5). On passing to long-chain hydrocarbons, however, the increase in molar volumes takes place so rapidly that the volume solubility of water in these hydrocarbons decreases, whereas the solubility expressed in mole fractions increases.

Thus in those instances where the values of δ change only slightly on going from one substance to another, the solubility (in volume fractions) is influenced chiefly by the change in the molar volumes, the volume solubility of the solute decreasing with increase in the molar volume of the solvent. This conclusion also agrees with the solubility rule derived by Semenchenko[145-147], according to which the mutual solubility of two substances increases with decrease in the difference in their "generalised moments" given by the ratios of the dipole moments of the molecules to their molar volumes. Since the polarity of the molecules of the amine salts is much greater than the polarity of the diluent molecules, the generalised moments of the amine salts are also greater than the generalised moments of the diluents. Thus the solubility of the salts in the diluents should increase with increase in the generalised moment of the diluent and with decrease in the generalised moment of the amine salt. When the dipole moments change little from one compound to another, the solubility should evidently be influenced chiefly by the values of the molar volumes. The solubility of a salt should increase with increase in its molar volume (since this leads to a decrease in its generalised moment) and with decrease in the molar volume of the solvent. The observed regular features of the solubility of amine salts in various solvents agree with these conclusions from Semenchenko's rule. For example, the solubilities of trialkylammonium nitrates in non-polar solvents change in the order—tridodecylamine > tridecylamine > trioctylamine[143]—and the solubilities of the sulphates change in the order—tertiary amine > secondary amine > primary amine[108,114,135].

These data also indicate that the solubility of salts of aromatic amines and amines with cyclic radicals should be less than the solubility of the salts of n-alkylamines containing the same number of carbon atoms, since the molar volumes of arylamines and cycloalkylamines are less than the molar volumes of the corresponding n-alkylamines.

Thus either Semenchenko's rule or the equations of the theory of regular solutions can be used to predict semi-quantitatively the solubility of various amine salts in diluents with different structures. The possibility of applying the theory of regular solutions for this purpose will probably increase with increase in the availability of data on the values of δ for various amine salts and diluents.

As already noted, these criteria are not valid when strong specific interaction takes place between the components of the solutions. Thus in a number of instances chloroform is a more powerful solvent than benzene, despite the fact that the value of δ for chloroform differs little from that for benzene. These deviations are due to the fact that specific solvation, which has a marked influence on solubility, takes place in amine salt–chloroform systems.

IV. THE INFLUENCE OF SPECIFIC SOLVATION ON THE SOLUBILITY OF AMINE SALTS IN DILUENTS OF LOW POLARITY

Amine salts dissolve readily in solvents which solvate their cations or anions as a result of the formation of hydrogen bonds. Thus acidic substances, capable of hydrogen bonding with the anions of amine salts[5,86,95,96,148-155] (organic acids and alcohols, and various chlorinated hydrocarbons), and also basic substances, capable of hydrogen bonding with the cations of amine salts[5,97,148,156] (ethers, ketones, nitro-compounds, and various amines), are usually effective solvents for amine salts and are miscible with them in all proportions. These substances prevent the association of amine salts by forming compounds with them, bringing them into solution¶. Basic diluents are more effective solvents for the salts of primary and secondary amines than for the salts of tertiary amines, since, as noted above, the formation of hydrogen bonds with these substances is least characteristic of the cations of the salts of tertiary amines. Acidic diluents dissolve the salts of tertiary amines more effectively than the salts of primary amines.

Substances which solvate amine salts are capable of dissolving these salts even when they are not used in the pure form; the addition of small quantities of many of these substances to amine salts increases considerably the solubility of the latter in non-solvating solvents of low polarity, e.g. in saturated aliphatic hydrocarbons[95,135,157-164]. The marked influence of various substances, added as a third component, on the mutual solubility of liquids and the solubility of solids in liquids was described at an early date. The action of a third component which increases solubility, known as solubilisation, was noted by Alekseev as early as 1879.[165] Timmermans[166] established that a third substance is able to increase the mutual solubility of two other substances if it is soluble in both of them. It is evident that an increase in the solubility of amine salts in non-solvating diluents may be achieved by the addition of substances which are capable not only of solvating the amine salts but also of dissolving in the diluents, i.e. substances of the types indicated above, whose molecules contain large hydrocarbon portions.

Several theories have been put forward to explain the mechanism and the regular features of solubilisation[167-169]. The most widespread are McBain's colloidal–adsorption theory[167], according to which the substance being dissolved passes into solution by being sorbed inside colloidal particles of the added solubilising agent, distributed in the solvent; and Winsor's solvation theory[168,169], which attributes the action of the solubilising agent to its simultaneous interaction with the substances in both the phases exhibiting negligible or limited miscibility. Experimental data obtained in recent years on the solubility of water in non-polar organic solvents[118,170,171] show more complete agreement with Winsor's theory than with McBain's theory. Apart from this, the colloidal–adsorption theory cannot be used to explain the regular features of the solubilisation of amine salts, since the solubilising agents added (alcohols,

¶ An example of the complete absence of association as a result of solvation of the anions of a salt by diluent molecules is provided by solutions of tridodecylammonium halides in chloroform[79]. In benzene these salts are appreciably associated.

ketones, and nitro-compounds) are not present in the organic solvents in colloidal form. Examination of the experimental data on the solubility of amine salts in solvents of low polarity in the presence of solubilising additives shows that these data can also be explained on the basis of the concepts of solvation theory.

1. The Use of Solvation Theory to Explain the Phenomena of the Solubilisation of Amine Salts

According to Winsor's theory[168,169], the efficiency of a solubilising agent depends on the value of the "affinity ratio" $R = A_{co}/A_{cw}$, where A_{co} measures the affinity of the solubilising agent for the phase of low polarity, and A_{cw} the affinity of the solubilising agent for the more polar phase. According to Winsor, the maximum increase in solubility per mole of solubilising agent added is reached when R is close to unity, i.e. when the affinities of the added third component for the two phases are the same. If two liquids—one polar and one non-polar—are immiscible and the value of R for an added third substance is greater than unity, this substance, when added to the system, enters the non-polar phase to a greater extent, and preferential dissolution of the polar substance in the non-polar phase takes place. When $R < 1$, the addition of the solubilising agent is accompanied by dissolution of the material of the non-polar phase in the polar phase. The quantity of solubilising agent required to homogenise the system when $R < 1$ and when $R > 1$ is greater than the quantity required when $R = 1$.

These qualitative ideas make it possible to predict the nature and the strength of the solubilising action of various additives on the solubility of amine salts in solvents of low polarity, in particular the action of alcohols having various structures.

The mechanism of the solubilising action of alcohols can be explained as follows. Alcohols are capable of solvating the anions of trialkylammonium nitrates, sulphates, chlorides, and iodides[95,96,172-175] with the formation of the relatively stable solvates $AmineHNO_3.2ROH$,[96] $[AmineH]_2SO_4.2ROH$,[172,173] $AmineHCl.ROH$,[61,174,175] and $AmineHI.ROH$.[176] This solvation leads on the one hand to breakdown of the salt aggregates to monomers[177] and on the other hand to dissolution of the salt in the solvent of low polarity, since the attachment of the alcohol molecules to the amine salt molecule leads to a decrease in the overall dipole moment of the resulting solvate and a simultaneous increase in its dimensions, including the dimensions of its hydrocarbon portion†. The number of alcohol molecules required for the solubilisation of low concentrations of tri-n-octylammonium nitrate in a non-polar diluent has recently been determined[178], and found to be 2 moles mole^{-1}, which agrees with the value of the solvate number found by other workers[96], who have studied the amine nitrate–alcohol system by physicochemical analysis. It also follows[178] that the dissolution of the amine nitrate in a non-polar solvent requires the formation of its solvate with the alcohol. The solvates formed by alcohols with amine salts are relatively stable. According to published data[96], the stability constants of the compounds $AmineHNO_3.2ROH$ for alcohols containing 6–12 carbon atoms in the chain are $\sim 10^3$ and differ little from one another, although the values decrease slightly with increase in the length of the alkyl chain of the alcohol. Since the interaction of alcohols with solvents of low polarity, e.g. saturated hydrocarbons, which is due entirely to van der Waals forces, is much weaker than with amine salts, the values of R in alcohol–amine salt–non-polar diluent systems are apparently much less than unity. Thus in a homologous series of alcohols a stronger solubilising action should be shown by alcohols characterised by a higher value of R, i.e. by alcohols with a higher affinity for the non-polar phase. We may thus expect that the solubilising action of aliphatic alcohols in amine salt–non-polar solvent systems will increase with increase in the length of the alkyl chains of the alcohols. This dependence of the solubilising power of alcohols on their structure was observed by Izmailov and Franke[171] and by Purnell and Bowden[179] for systems in which the bonding of the alcohol with the main material of the polar phase was much greater than that with the material of the non-polar phase.

With change in the properties of the amine salt, however, another type of relationship is possible. If the electron-donating power of the anion of the amine salt is low or if there is steric hindrance to the solvation of the anion by the alcohol, and if as a consequence the affinity of the alcohol for the salt is so low that it is less than its affinity for the non-polar solvent and $R > 1$, an increase in the solubilising action of the alcohol will be brought about by changes in its structure which lead to a decrease in R, i.e. to an intensification of its interaction with the amine salt and a decrease in the interaction with the non-polar diluent. This will evidently be observed with decrease in the length of the alkyl chain of the alcohol, since this intensifies the interaction of the alcohol with the amine salt[96]. These regular features are probably characteristic of the solubilisation of salts having bulky anions, whose electron-donating properties are weakened considerably, for example the salts of organic acids or the compounds of various metal salts, extractable by amines. The electron-donating properties of the anions of these salts may be very weak, so that their solvation by alcohols is very weak[179].

A solubilising action with respect to amine salts in non-polar solvents may evidently be shown not only by alcohols but also by other organic compounds which are capable of solvating these salts and are readily soluble in non-polar solvents. As noted above, this ability may probably be shown not only by alcohols but also by aliphatic acids with sufficiently long alkyl chains, phenol and its derivatives soluble in non-polar diluents, and other organic compounds with a large hydrocarbon portion which are electron acceptors, i.e. which have at least weak acidic properties and hence are capable of solvating the anions of amine salts. On the basis of Winsor's theory, it may be expected that, of the solubilising agents which are readily soluble in non-polar solvents, the most effective for the solubilisation of salts whose anions exhibit significant electron-donating properties, e.g. amine nitrates and chlorides, should be substances with weaker acidic properties than alcohols. These substances may be very weak aprotic acids, interacting with the anions of amine salts by a donor–acceptor mechanism. If, however, the acidic properties of these solvents, added as solubilising agents, are so weak that $R > 1$ and the strength of the donor–acceptor interaction of these substances with anions is comparable with that of the dispersion interactions with the non-polar solvent, Winsor's theory indicates that increase in the acidic properties of the solubilising agent should lead to an increase in solubility in the system. In this connection it is of interest to

† These changes lead to a decrease in the generalised moment[145-147] of the salt.

recall that the solvent power of aromatic hydrocarbons increases with increase in their acidic properties. The existence of this relationship indicates the possibility that these "non-solvating" diluents of low polarity dissolve amine salts as a result of weak donor–acceptor interactions with the anions of these salts.

Solubilisation can apparently take place as a result of solvation not only of the anions but also of the cations of amine salts. The solvation of cations may be of greatest importance for the solubilisation of the salts of primary amines[68] and the acid salts of dibasic and polybasic acids with any anions: it prevents the polymerisation of these salts which takes place as a result of the formation of hydrogen bonds between the cations of some molecules of the salt and the anions of other molecules of the salt[51]. The solubilising influence of the solvation of cations is less with secondary and tertiary amines, since less extensive solvation takes place than with primary amines, because of the greater steric hindrance and the smaller number of acidic hydrogen atoms in these amines[97]. The ability to solvate the cations of the salts of primary amines and to solubilise these salts is shown by substances which are electron donors[180,181]—ketones, ethers, esters, amides of carboxylic acids, nitro-compounds, etc.—and the ability (albeit weak) to solubilise the salts of primary amines is also shown by various substances which have very weak basic properties, e.g. benzene.

An interesting conclusion from Winsor's ideas is the possibility of the non-additive ("synergic") solubilising action of various agents. Studies of solubilisation in water–non-polar solvent systems[118,170] established that mixtures of solubilising agents, for one of which $R < 1$ while for the other $R > 1$, have a much greater solubilising action than each agent taken separately at the same concentration. Winsor attributes this to the fact that for this synergic mixture the value of R becomes close to unity. A very marked increase in solubilising power is observed at definite ratios of these solubilising agents, corresponding to $R = 1$.[118,171] It may be expected that, with solubilisation in amine salt–non-polar solvent systems, it is also possible to select solubilising agents, one mole of a mixture of which would give a greater (synergic) solubilising effect than would one mole of either component taken separately.

2. Solubilisation of the Extractable Compound by Excess of the Extractant

Various amine salts having a bulky inorganic complex anion do not dissolve even in relatively polar solvents, in which other salts of these amines, containing smaller anions, are readily soluble[158]. In these instances the solubility of the sparingly soluble amine salt can be increased as a result of its solvation by the molecules of a more soluble salt of the amine, present in solution. The salt $[R_3NH]_2[CoCl_4]$ in *p*-xylene is solvated by molecules of the extractant R_3NHCl.[182] Solvation of extractable amine salts by an excess of the extractant is also indicated by the fact that, in order to prevent separation into layers in organic solutions of low polarity, containing salts formed during extraction such as $[AmineH]_2[Pu(NO_3)_6]$ or $[AmineH].[UO_2(NO_3)_3]$, the presence of an excess of the simple salt $AmineHNO_3$ in the solution is required[158,183]. The dissolution of the salt $[AmineH]_4[U(SO_4)_4]$ in butylbenzene[184] also requires the presence, in the solvent, of the simple salt $[AmineH]_2SO_4$ in quantities sufficient for formation of the solvate $\{[AmineH]_2SO_4\}\{[AmineH]_4[U(SO_4)_4]\}$. Smulek and Siekierski[185], in a study of the dependence of the activity coefficients of the dissolved iron(III)–$[AmineH][FeCl_4]$ complex on the concentration of the extractant (AmineHCl), established that these coefficients decrease with increase in the extractant concentration. This phenomenon also can be attributed to a decrease in the concentration of free $[AmineH][FeCl_4]$ as a result of its solvation by AmineHCl molecules. The solvation of extractable complexes by molecules of amine salts used as extractants is also indicated by published data[186–188]. As in the solubilisation of amine salts by the addition of alcohols, the efficiency of the solubilising action of the amine salt used as extractant is greater the greater its affinity for the diluent, i.e. the greater its solubility in non-polar solvents. Thus it follows from published data[158] that in those instances where the amine salt ($AmineHNO_3$) is more soluble in the diluent, the quantity required for dissolution of the insoluble salt $[AmineH]_2[Pu(NO_3)_6]$ is smaller; the quantity of amine salt required for solubilisation of the complex salt also decreases in diluents which are more effective solvents for the simple amine salt. The composition of the organic phase corresponding to the limiting solubility[158] corresponds to the solvates $[TOAH]_2[Pu(NO_3)_6]$‡ in nitromethane, $[TOAH]_2[Pu(NO_3)_6].4TOAHNO_3$ in xylene, and $[TOAH]_2[Pu(NO_3)_6].2TOAHNO_3$ in dibromomethane. In the polar nitromethane, the salt being extracted dissolves without solvation, but in the other diluents solvation by the amine salt increases with decrease in the solvent power of the diluent. Shmidt et al.[182] demonstrated the existence of a relationship between the degree of solvation of $[TOAH]_2[CoCl_4]$ by molecules of the amine salt TOAHCl and the degree of association of the latter in the diluent. In the opinion of these authors, the degree of association of the amine salt used as extractant does not change in many extraction systems when the amine salt forms extractable compounds with metal salts. Wilson's data also agree with this suggestion, since in nitromethane, in which tri-*n*-octylammonium nitrate is monomeric, only two molecules of $TOAHNO_3$ take part in formation of the complex, whereas in xylene, in which the degree of association[68] of $TOAHNO_3$ is ~ 3, formation of the complex $[TOAH]_2[Pu(NO_3)_6].4TOAHNO_3$ involves the participation of three times the number of amine salt molecules, i.e. six molecules.

The solubilisation of extractable compounds by an excess of the extractant is a widespread phenomenon, which is observed not only in extraction with amine salts. The dissolution of salts of dibutyl hydrogen phosphate in non-polar diluents is possible only in the presence of an excess of this acid ester[189], i.e. when the molecules of the salt are solvated by molecules of the corresponding acid. The solubility of the solid salt is proportional to the concentration of acid in the solution raised to a power corresponding to the solvate number[189]. Thus in the dissolution of the solid salt, as a result of solvation by the corresponding acid, the law of mass action is observed in accordance with the stoichiometry of the solvate. In the solubilisation of liquid amine salts as far as complete dissolution of the salt, these stoichiometric relationships are not observed, since the solvate formed usually has a higher affinity for the amine salt phase; it remains in this phase and is not transferred to the non-polar phase until almost all the insoluble liquid amine salt is converted into a solvate soluble in the non-polar phase. Homogenisation of the two-phase liquid system takes place after addition of almost the

‡ TOA = $(n\text{-}C_8H_{17})_3N$ (Ed. of Translation).

total quantity of solubilising agent required for conversion of the polar phase into the solvate.

It should be noted that stoichiometric relationships between the solubilising agent and the amine salt, corresponding to the degree of solvation under the conditions of homogenisation, are observed only at relatively low concentrations of these substances in the non-polar solvents. At higher concentrations the quantity of solubilising agent required for the transfer of one mole of the insoluble salt into the medium of low polarity decreases[190], since solubility begins to be affected not only by solvation but also by the overall increase in the dielectric constant of the solvent occurring in the presence of the solubilising agent, which is usually a more or less polar substance. Increase in the dielectric constant of the medium, as noted in Section III, leads to a decrease in the association of the molecules of the amine salts and hence to an increase in their solubility.

V. THE INFLUENCE OF NON-SOLVATING DILUENTS ON THE EXTRACTION PROPERTIES OF AMINE SALTS

The influence of non-solvating diluents on extraction has been relatively little studied. In the early work on this problem, attempts were made to establish a relationship between the partition coefficients or extraction constants and the dielectric constant of the medium or the polarisability of the diluent[191-197]. Because of the strong influence of factors additional to those studied by the authors cited, unambiguous relationships could not be established in most instances. More fruitful work has been carried out in recent years by Rozen and Khorkhorina[198], based on the molecular theory of solutions, and also by Siekierski[185,199-203] and Vdovenko et al.[204], who based their conclusions on the theory of regular solutions and used the parameters δ for the extractants, diluents, and extractable complexes to take account of the influence of the diluents.

The position of equilibrium for a reaction in solution (including extraction) and the solubility of the reactants are determined to a considerable extent by the same thermodynamic functions. Thus the higher solubility of a given substance corresponds to a decrease in its activity coefficient in solution[45]. The decrease in the activity coefficient of an amine salt dissolved in a diluent also corresponds to a decrease in its extraction properties. At the same time it is evident that a decrease in the activity coefficient of a reaction product, e.g. the compound being extracted, leads to a displacement of the equilibrium towards formation of this compound[119]. As early as 1938 Hildebrand[119], pointing out the relationship between the position of equilibrium for reactions and the values of δ for the reactants, wrote: "In general we may summarise by saying that in order to get a large amount of a certain substance in an equilibrium reached in solution, one should employ a solvent which is a good one for the substance desired and a poor one for the substance or substances on the other side of the equation of equilibrium. The quality of a solvent in this connection may be determined by any or all of the factors considered in connection with solubility in general, viz. polarity, chemical combination and internal pressure." The internal pressure, which is one of the chief factors determining solubility in non-polar solvents which do not react chemically with the solute and which obey the laws governing regular solutions, is given by the parameter δ. The influence of the values of δ on the extraction equilibrium can be seen by examining the simplest thermodynamic equations for extraction equilibria[202-204]. If the extraction of a metal salt (A) by an amine salt (E) takes place according to the equation

$$A_{aq} + n\,E_{org} \rightleftarrows A \cdot n\,E_{org} \equiv EC_{org},$$

where EC is the extractable compound of the salt A with the amine salt, the equilibrium constant for this reaction is given by the formula

$$K = \frac{[EC]\gamma_{EC}}{[A][E]^n \gamma_E^n \gamma_A}, \qquad (7)$$

where γ_{EC}, γ_E, and γ_A represent respectively the activity coefficients of the compound being extracted, the extractant, and the extractable salt. If [EC] is the concentration of the element being extracted in the organic phase, and [A] its concentration in the aqueous phase, it follows from Eqn. (7) that the distribution constant for this element α at constant composition of the aqueous phase is given by the formula

$$\alpha = K'[E]^n \frac{\gamma_E^n}{\gamma_{EC}}. \qquad (8)$$

If the concentration of the extractant also remains constant, we have

$$\alpha = K'' \frac{\gamma_E^n}{\gamma_{EC}}, \qquad (9)$$

where K'' is a constant.

It can be seen from formula (9) that, when the diluent is replaced at constant composition of the phases, the changes in α will depend on the changes in the ratio γ_E^n/γ_{EC}, for which Rozen[198] proposed the symbol *dil*. According to the theory of regular solutions[205], the activity coefficients of solutes are related to the solubility parameters by the expression

$$\ln \gamma_2 = \ln \frac{\varphi_2}{x_2} + \frac{V_2\varphi_1^2}{RT}(\delta_2 - \delta_1)^2 + \varphi_1\left(1 - \frac{V_2}{V_1}\right), \qquad (10)$$

where the subscripts 2 and 1 relate to solute and solvent respectively (x_2 is the mole fraction of solute in the solution). Smulek[195] and Siekierski[199] showed that, in complete agreement with this equation, the activity coefficients of amine salts dissolved in various diluents decrease with increase in the value of δ for the diluent. By substituting in Eqn. (9) the activity coefficients of the extractant and the complex being extracted given by Eqn. (10), Vdovenko et al.[204] obtained the following equation relating the distribution constant of the metal being extracted α_M with the values of δ and the molar volumes V of the extractant, the diluent, and the compound being extracted

$$\lg \alpha = \text{const} + \frac{0.8686}{RT}(V_{EC}\delta_{EC} - nV_E\delta_E)\,\delta_{dilt} + 0.4343\,(nV_E - V_{EC})\left(\frac{\delta_{dilt}^2}{RT} - \frac{1}{V_{dilt}}\right), \qquad (11)$$

where the subscripts EC, E, and dilt denote quantities relating to the compound being extracted, the extractant, and the diluent respectively. Analysis of Eqn. (11) shows[204] that the dependence of α_M on δ_{dilt} for a constant value of V_{dilt} should in general pass through an extremal value. Differentiation of Eqn. (11) with respect to δ_{dilt} shows that the position of the extremal value is determined by the relationship

$$\delta_{dilt}^{extr} = \frac{V_{EC}\delta_{EC} - nV_E\delta_E}{V_{EC} - nV_E}. \qquad (12)$$

In the systems examined by Vdovenko and his coworkers[204] this extremal value was a maximum. It follows from

Eqn. (11) that the second derivative of $\lg \alpha$ with respect to δ_{dilt} is proportional to $nV_E - V_{EC}$, so that the extremal value may be a maximum when the molar volume of the compound being extracted is greater than the sum of the molar volumes of the molecules of extractant in the compound. In these instances, with diluents of low polarity and the lowest values of δ, increase in δ for the diluent should lead to an increase in the extractive power of the amine salt solution. In most extraction systems, however, such a relationship is not realised, and only a decrease in the extractive power of the salts takes place with increase in the value of δ for the diluent. It follows from Eqns. (11) and (12) that this may also be observed when $nV_E > V_{EC}$, i.e. when the dependence of $\lg \alpha$ on δ_{dilt} passes through a minimum. Such a relationship has been described for the extraction of metal salts by tri-(2,2,4-trimethylpentyl)ammonium chloride[206], for which the partition coefficients decrease with increase in the value of δ for the diluent (in the order—hexane > toluene > benzene) and for extraction by tri-n-octylammonium chloride[51,200-210] (decane > mesitylene > xylene > toluene > benzene) and tridodecylammonium nitrate (cyclohexane > xylene > benzene)[211]. An unambiguous prediction of the nature of the dependence of $\lg \alpha$ on δ_{dilt} obviously requires an estimate of the ratio of the values of V_{EC} and nV_E.

It follows from the foregoing that, when there is no significant specific solvation, the influence of a diluent on the extractive power of amine salts, like its influence on their solubility, can be estimated approximately on the basis of the theory of regular solutions, from the known values of δ for a wide range of solvents. A knowledge of the values of δ_E and δ_{EC} for a larger number of amine salts and extractable compounds is required for the most extensive verification and application of this approach to estimating the influence of solvents.

Another approach has recently been proposed, which makes it possible to predict quantitatively the influence of various diluents on extraction. It is based on the observed[207] linear relationships shown by the free energies of many extraction systems with different diluents. The existence of these relationships has made it possible to develop a scale of DE-values (diluent effects) by means of which extraction constants K can be calculated for extraction systems with different diluents, if the corresponding constants K_0 for systems with a standard diluent are known[207]. The calculation is carried out using the formula $\lg K = \lg K_0 + \rho DE$, where ρ is a coefficient which is constant for a series of extraction systems of constant composition with different diluents, and DE is a constant which depends only on the nature of the diluent. The results of the calculation show good agreement with the experimental data for a large number of systems.

VI. THE INFLUENCE OF SPECIFIC SOLVATION ON THE EXTRACTION PROPERTIES OF AMINE SALTS

All solvation interactions of a solvent or of added reagents with a substance to be dissolved, leading to solubilisation of the latter, produce a decrease in the activity of this substance in the solution§. For example, solvation of the anions of amine salts by alcohols, leading to an increase in the solubility of these salts, simultaneously produces a decrease in the effective concentration of the free amine salt in the extractant, i.e. a decrease in its thermodynamic activity. As noted in the preceding Section, the change in extractive power produced by a diluent depends on the ratio of the changes in the activity coefficients of the extractant and the compound being extracted. Thus a decrease in the distribution constant for an element when an alcohol or other solubilising agent is added to the extraction system will take place if the extractant—the amine salt—is more extensively solvated than the compound being extracted.

In the extraction of metal salts by amine salts, the volume of the anions of the compounds being extracted is usually much greater than the volume of the anions of the simple salts used as extractants. This leads to greater delocalisation of the negative charges on the anions of the compounds being extracted, diminishes their electron-donating power, and hence decreases their solvation by electron-acceptor molecules relative to the solvation of the anions of the extractant. Thus the addition of alcohols usually leads to a marked decrease in the extractive power of amine salts. The extraction of uranium(VI) and zinc by tri-n-octylamine from hydrochloric-acid solutions[51,160] is decreased considerably when octanol is added to the extractant. The extraction of nitric acid[213-215] and a number of quadrivalent actinide elements by amine nitrates from nitric-acid solutions[164,216], the extraction of many elements by amine chlorides from hydrochloric-acid solutions[163,217-220], and the extraction of uranium(IV) sulphate by amine sulphates from sulphuric-acid solutions[221] also decrease when alcohols and chloroform are added. A similar effect should be observed on the addition of other solubilising agents which are electron acceptors capable of solvating anions—organic acids, halogenated hydrocarbons, etc.

It should be noted that, in the extraction of metal salts, this action of solubilising agents is observed only when the metal concentrations are low compared with the concentration in the non-polar diluent of the dissolved amine salt used as extractant. If the concentration of metal salt in the organic phase is high, the partition coefficient may even be greater in the presence of solubilising agents than in their absence. This phenomenon is due to the fact that, when a diluent of low polarity does not contain a solubilising agent, a considerable proportion of the amine salt is used up not only in the formation but also in the solvation of the compound being extracted, as a result of which, with increase in the concentration of the latter, the concentration of the extractant decreases rapidly with a corresponding rapid decrease in the partition coefficient[182]. In the presence of an excess of solubilising agent, the molecules of the compound being extracted are solvated not by the extractant but by molecules of this solubilising agent, and this leads to a decrease in the consumption of extractant and to a slower decrease in the distribution constant with increase in the concentration of the compound being extracted. As a result, at high concentrations of the compound being extracted, the value of the distribution constant in the presence of the solubilising agent may be greater than that in the absence of the solubilising agent.

The energy of solvation of the anions of an amine salt by alcohols and other acidic substances depends on the

§ Some authors[212] therefore suggest that the term solubilisation should be taken to mean not only the solvent action of additives, but also any decrease in the activity of a dissolved substance in a homogeneous binary solution when a third component is added.

electron-donating power of these anions[5,61,222,223]. With decrease in the electron-donating power and the associated decrease in the solvation of the anions, the influence of solvating solvents is reduced[149,154,224]. Thus the influence of the addition of alcohols and chloroform on the extractive power of amine sulphates is less than its influence on that of the corresponding nitrates, and its influence is less on the properties of the salts of secondary amines than on those of the salts of tertiary amines[225,226].

In the extraction of acids by an anion-exchange mechanism, a solvating solvent may not influence the extraction equilibrium if the free energy of solvation of the anions of the compound being extracted differs from the hydration energy of these anions in the aqueous phase by an amount close to the corresponding difference for the anions of the amine salt used as extractant. Thus addition of the solvating solvent chloroform to the extractant does not decrease the distribution constants in the extraction of TcO_4^- by amine sulphates[227]. In the extraction of TcO_4^- by an amine nitrate, the addition of solvents which solvate the anions decreases the distribution constant of technetium[228], since the amine nitrate is solvated by the solvent molecules to a greater extent than is the sulphate[224,229,230].

As noted above, the solvation of anions is an acid–base interaction. On this basis, it has been suggested[51] that this solvation is also important for diluents which have extremely weak acidic properties, e.g. aromatic hydrocarbons. Study of the extraction of zinc by tri-n-octylammonium chloride from hydrochloric-acid solutions[51] has in fact shown that, when a series of aromatic diluents is used, the partition coefficients of zinc decrease to a greater extent the stronger the acidic (electrophilic) properties of the diluent.

When the solubilising agent solvates the cations of the amine salt, the result may be not only a decrease in the distribution constant of the metal salt, but also in some instances an increase in the distribution constant[5,51]. Decrease in the distribution constant for extraction by tertiary amines takes place for reasons which are the same as those for solvation of the anion. Solvation of both cations and anions of amine salts leads to a decrease in the association of their molecules. Change in the degree of association of the normal salts of tertiary amines[182] does not lead to a significant change in their extractive power. In contrast to this, with the salts of primary amines and to some extent secondary amines, and also with the acid salts of tertiary amines, change in the degree of association leads to a significant change in extractive power, since the association of these salts is due to the formation of intermolecular hydrogen bonds involving their anions, and this decreases considerably their extractive power. As noted in Section III, the presence of solubilising agents which solvate the cations leads to depolymerisation of the salts and also an increase in their polarity[5], and hence to a marked increase in their extractive power[51]. Nemodruk[231] observed a marked increase in the extractive power of a salt of the primary amine aniline in the presence of a ketone. An increase in the extractive power of dioctylamine was also observed[51] when 4-methylpentan-2-one was added to the diluent; this phenomenon was not observed when the ketone was added to the salts of tertiary amines. From these data it follows that a necessary condition for an understanding of the general features of the influence of solvating diluents on extraction is an investigation to determine which part of the molecule of the amine salt is solvated by molecules of the diluent.

THE ELECTRONIC STRUCTURE AND PROPERTIES OF THE σ-BONDS IN THE MOLECULES OF ORGANIC COMPOUNDS

N. D. Sokolov

1. INTRODUCTION

The importance of σ-bonds in organic chemistry lies not only in the fact that most organic compounds do not contain other types of bond but also in the fact that σ-bonds form the framework of all molecules in general. Approximately 80% of the energy of formation of aromatic molecules corresponds to σ-bonds, their elastic properties are determined to a considerable extent by σ-electrons, most chemical reactions are accompanied by the rupture and formation of σ-bonds, in many instances the sign of the dipole moments is determined by the σ-electrons, etc.

It is often assumed that the σ-bonds in polyatomic molecules are localised and that their interaction can be neglected. This view is refuted by a large number of experimental facts, for example the dependence of the ionisation potential of alkanes on the length of the chain of σ-bonds, the dependence of the position of the electronic absorption bands in the optical spectra on the length of this chain, the non-additivity of the dipole moments of halogenated alkanes, the hyperfine structure of their nuclear magnetic resonance (n.m.r.) and electron spin resonance (e.s.r.) spectra, and many others.

From the viewpoint of quantum mechanics, strictly speaking, it cannot be assumed that the electronic wave functions in a molecule are localised on individual bonds or groups of bonds. Since the molecule is a single unit, the electronic wave functions should characterise the molecule as a whole. When the LCAO-MO† method is used, this means that the one-electron wave functions of the molecule ψ_i should be made up of linear combinations of the atomic orbitals φ_k of *all* the atoms in the molecule:

$$\psi_i = \sum_k c_{ik} \varphi_k. \qquad (1)$$

According to this formula generally speaking in the stationary state each electron has a finite probability of being found close to each atom in the molecule. The need to represent the molecular orbital in form (1) for molecules with saturated bonds was demonstrated by Walsh[1] in his interpretation of the electronic spectra of a number of simple molecules AB_2, ABC, AB_3, HAAH, H_2AB, etc. Starting from the delocalised molecular-orbital model, Walsh developed a method by which it was possible not only to interpret the spectrum but also to predict the geometry of the molecule in the ground and excited states and also the vibrational structure of the spectrum, to determine the selection rules and polarisation of the bands, etc. The need to use delocalised molecular orbitals of type (1) can be seen particularly clearly for symmetrical molecules.

† LCAO-MO = molecular orbital approximated by a linear combination of atomic orbitals.

The necessary requirement that the molecular wave function should exhibit the same symmetry elements as the molecule can in general be satisfied within the framework of the LCAO-MO method only by means of a linear combination containing the atomic orbitals of all the atoms‡.

The delocalised character of the molecular orbital does not in itself mean that changes or perturbations taking place in one part of the molecule will necessarily influence all other parts of the molecule. The transfer of an effect depends on the magnitude of the interatomic and (for saturated molecules) intra-atomic interactions. Within the framework of the LCAO-MO method, the interatomic interaction is characterised by the resonance integral between neighbouring atomic orbitals, which depends on their degree of overlap. For a conjugated chain of π-bonds, one atomic orbital from each atom appears in formula (1), and all the resonance integrals β are the same; each atom (except the end members) interacts to the same extent with two neighbours (Fig. 1*a*). For an unbranched chain of C–C σ-bonds (if for simplicity we neglect the C–H bonds), formula (1) contains two atomic orbitals from each atom (one from the terminal atoms); each atomic orbital "interacts" with two neighbouring atomic orbitals, but these interactions are different. For example, let us consider atomic orbital *2* (Fig. 1*b*). It interacts with atomic orbital *1* of the neighbouring atom; as before, we denote the corresponding resonance integral by the symbol β. On the other hand, atomic orbital *2* interacts with atomic orbital *3* belonging to the same atom; the corresponding resonance integral can be denoted by β', whose absolute magnitude is less than that of β.

If the ratio $m = \beta'/\beta$ were zero, the C–C bonds in the molecule would be strictly localised. All its properties would be additive; the influence of each atom would be transmitted only to neighbouring atoms. In actual fact $m \neq 0$, so that, strictly speaking, additivity of properties should not be observed in saturated chains. The magnitude of β' is approximately proportional to the splitting of the *s* and *p*-levels of the carbon atom (i.e. the energy of the transition $s^2p^2 \rightarrow sp^3$). From experimental data for alkane molecules it follows that $m = 0.34$ (see for example Klopman[3])§. The interaction of the σ-bonds, which is taken into account by the integral β', is called the inductive effect.

The interaction of σ-bonds depends not only on the intra-atomic integral β', but also on the resonance integral β'', characterising the overlap of two even or two odd atomic orbitals of the chain e.g. atomic orbitals *2–4* or *1–3* (Fig. 1). This integral is of the same order of magnitude as β'; for simplicity, however, the integral β'' is neglected.

The fact that $|\beta'| < |\beta|$ is one of the factors which makes σ-systems differ from π-conjugated systems. Another reason for this difference, as will be seen later, is that in an unbranched chain of σ-bonds there are two atomic orbitals for each atom, and not one, as in π-conjugated systems.

‡ A systematic treatment of molecules by the LCAO-MO method, taking account of all the atomic orbitals, was proposed by Hoffmann[2]. See also papers by Clementi[21]—cf. footnote on p. 964.

§ Calculations show that the energy and the distribution of electron density depend only on the absolute value of m (see for example Yoshimuzi[4]).

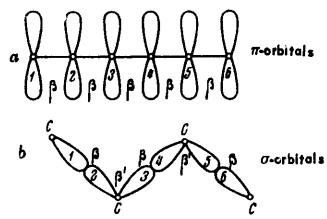

Fig. 1. Atomic orbitals: *a*) in chains of π-conjugated bonds ($m = 1$; $n = N$); *b*) in chains of σ-bonds ($m = 0.34$; $n = 2N - 2$).

2. ENERGY CHARACTERISTICS

Let us consider the simplest case, an unbranched chain of N linked atoms. For a chain molecule with conjugated π-bonds, we shall take account of only the π-electrons. Each atom will then have one p atomic orbital; the number of atomic orbitals n will therefore equal the number of atoms N. By setting up the molecular orbitals in form (1), substituting this expression in the Schrödinger equation, and solving the appropriate variational problem, we obtain n energy eigenvalues (see for example Streitwieser[5]):

$$\varepsilon_i' = \alpha + \lambda_i\beta, \; i = 1, 2, \ldots, n. \qquad (2)$$

Here α and β are the Coulombic and resonance integrals respectively, and λ_i the roots of the corresponding determinantal equation, which are different for different values of n. The solid lines in Fig. 2 show the arrangement of eigenvalues for different values of n; $\epsilon_i = \epsilon_i' - \alpha$. The upper and lower systems of levels (below and above the line $\epsilon = 0$) are fairly far apart for small values of n. The distance $\Delta\epsilon$ between the lower positive and upper negative levels (the so-called gap width), however, decreases with increase in n, and tends to zero as $n \rightarrow \infty$.

In a chain of σ-bonds, as noted above, we must take account of two types of integral, β and β'. Calculation[4,6,7] analogous to that carried out for π-systems gives for the energy the same formula (2), but now λ depends implicitly on m; as before, the number of molecular orbitals obtained is equal to the original number n of atomic orbitals, but now $n = 2N - 2$. If we assume the value $m = \beta'/\beta = 0.34$ indicated above, the energy levels obtained for different values of n will occupy the positions indicated by the broken lines in Fig. 2. The distances between energy levels with the same sign (+ or –) (Fig. 2) are much smaller than for conjugated systems ($m = 1$). Moreover, the gap width $\Delta\epsilon$ decreases with increase in n much more slowly than for π-conjugated systems, and as $n \rightarrow \infty$ it tends not to zero but to a finite value equal to 1.32β.

Fig. 2 shows the difference between the dependence on chain length of the total energy for π-conjugated bonds and for σ-bonds. In the approximation being considered, the total electronic energy is obtained if in each level, starting from the lowest, we place two electrons and take the sum of the energies of all the electrons. We then have $E = 2\sum_i \epsilon_i$. It is found that all the negative levels (number $n/2$) will be doubly occupied, and all the positive levels will be empty. If we now consider the energy corresponding to one bond (a pair of electrons), it can be seen from Fig. 2 that the absolute value of this quantity for $m = 1$ (solid lines) on going, for example, from $n = 2$ (ethylene) to $n = 4$ (butadiene) increases considerably, since the lowering of

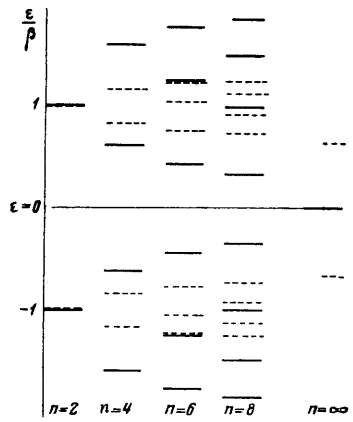

Fig.2. Energy levels for π-conjugated chains (solid lines) and for chains of σ-bonds (broken lines).

the lower level is much greater than the raising of the upper level. On the other hand, for $m = 0.34$ (broken lines) the lower and upper levels are displaced relative to the original level ($\epsilon = -1$) by approximately the same absolute amount, as a result of which the energy corresponding to each bond remains almost unchanged. For larger values of n the difference in these displacements is even smaller. This leads directly to the non-additivity of the energy for π-conjugated chains and, on the other hand, to the approximate additivity of the energy of formation of alkanes[8]; small deviations from this additivity are observed only for the first members of the homologous series.

From the foregoing it follows that additivity in energy of formation does not indicate localisation of electrons on bonds. As noted above, complete localisation would correspond to $m = 0$. Additivity in energy simply results from the mutual compensation of small effects of opposite sign.

The quantitative calculation of the deviations from additivity is much more complex, however. The molecular model chosen is too approximate to provide a basis for a calculation with the required accuracy, although many attempts have been made (e.g. for aromatic compounds[9] and alkanes[3,7,10]). Attention must first of all be drawn to the fact that the simplest version of the LCAO-MO method chosen (Hückel's method) does not give one of the fundamental properties of chemical bonds, their degree of saturation (see e.g. Ref. 11, pp. 146, 163, *et seq.*). This simplified scheme of calculation would indicate, for example, that the approach of two H_2 molecules should lead to the formation of a stable complex H_4, since the calculated energy decreases. In actual fact, on the approach of two H_2 molecules (or in general two covalent bonds A–B), the energy increases, and this indicates the saturated character of the bonds. This result is a consequence of the fact that in the simplest version of the molecular-orbital method the calculation is carried out with non-antisymmetrised functions, and no allowance is made for the interaction of the electrons with one another. Moreover, in a systematic calculation, all the bonds and all the electrons of the molecules must naturally be taken into account[12,13].

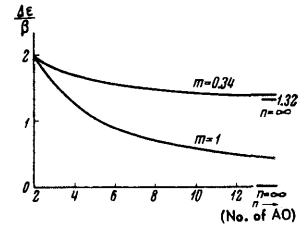

Fig.3. Dependence of the relative gap width ($\Delta\epsilon/\beta$) on the number of atomic orbitals (AO).

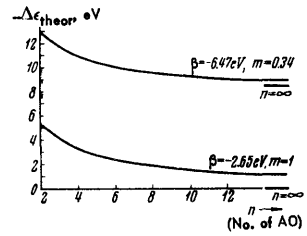

Fig.4. Dependence of the gap width ($\Delta\epsilon$) on the number of AO for $\beta_\pi = -2.65$ eV and $m = 1$ (lower curve) and for $\beta_\sigma = -6.47$ eV and $m = 0.34$ (upper curve).

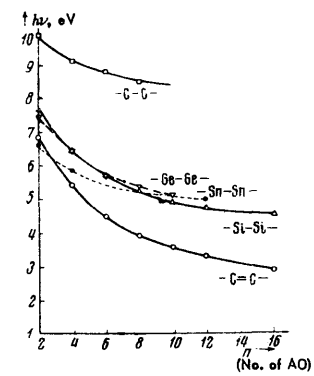

Fig.5. Experimental dependence of the absorption frequency on the length of the molecular chain[15].

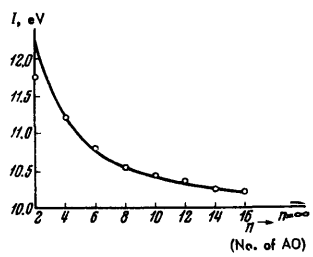

Fig.6. Dependence of the ionisation potential on the number of AO in the alkane chain.

The problem of calculating the non-additivity of energy is most clearly formulated when we compare the energies of two isoelectronic and isomeric molecules, one of which has conjugated π-bonds while the other has not. Thus, for example, for the two isomeric molecules

(A) $H_2C=CH—CH_2—CH=CH_2$ (penta-1,4-diene)
(B) $H_3C—CH=CH—CH=CH_2$ (penta-1,3-diene)

the latter has 6 kcal less energy than the former; this is usually attributed to the conjugation of the two π-bonds. In actual fact, however, this difference in energies results from the algebraic summation and partial compensation of a number of effects (by itself, the approach of the two π-bonds on going from A to B leads not to a decrease but to an increase in energy!). Thus, for example, the number of C–H bonds formed by carbon atoms having sp^2 hybridisation is six for molecule A and five for molecule B; the energies of these bonds may differ by 10–20 kcal. Analogous differences are observed in the energies of rupture of C–C bonds, in the energies of the interaction of different σ-bonds with one another and with π-bonds, etc. It is only when allowance is made for all these differences that we can hope to obtain a correct explanation [13] for the above decrease in energy on going from A to B.

Our initial simple model is adequate, however, for a semi-quantitative explanation of a number of the properties of molecules, e.g. the energy of electronic absorption. Within the framework of this model, the long-wave absorption band should correspond to a transition from the upper occupied level to the lower empty level, the distance between which is equal to the gap width $\Delta\epsilon$.

This quantity should be directly equated to $h\nu$, where ν is the frequency of the transition. Fig. 3 shows the calculated dependence of the quantity $\Delta\epsilon/\beta$ on n for a chain of π-conjugated bonds ($m = 1$) and for a chain of σ-bonds ($m = 0.34$). The quantity $\Delta\epsilon/\beta$ decreases much more slowly in the second instance than in the first. It should however be remembered that the resonance integrals for π-bonds (β_π) are smaller than those for σ-bonds (β_σ). Thus for the values $\beta_\pi = -2.65$ eV and $\beta_\sigma = -6.47$ eV adopted by Pople and Santry [14], for example, we obtain for $\Delta\epsilon$ the curves shown in Fig. 4. The similarity between these curves is greater than for identical values of β.

Fig. 5 gives experimental curves showing the dependence of $h\nu$ on n for polyenes (–C=C–), alkanes (–C–C–), and various other chain molecules containing σ-bonds (–Ge–Ge–, –Sn–Sn–, and –Si–Si–) according to published data [15]. The nature of the dependence of $h\nu$ on n is analogous to that expected on the basis of the model being considered. In each instance values of m and β can be selected which make it possible to reproduce these curves approximately by calculating $\Delta\epsilon$. The steep descent of the curve for the chain of silicon atoms apparently indicates that the corresponding integral β' has a comparatively large absolute value.

According to these calculations, the significant difference between the electronic spectra of polyenes and linear molecules having σ-bonds lies in the nature of the $\nu(n)$ relationships at large values of n. As noted above, as $n \to \infty$ within the framework of our model, the gap width in polyenes ($\Delta\epsilon_\pi$) tends to zero, whereas for chains of σ-bonds ($\Delta\epsilon_\sigma$) it tends to a finite limit of the same order of magnitude as β. This last feature is a direct consequence of the fact that $\beta' \neq \beta$. If we had $\beta' = \beta$, then $\Delta\epsilon_\sigma$ would also tend to zero as $n \to \infty$.

Our model, however, greatly simplifies the situation for polyenes with large values of n. Here effects which go beyond the scope of the model begin to play a part. Thus it is possible that alternation of bond lengths begins at large values of n in polyenes, yielding two different resonance integrals for adjacent bonds [16]; it can be seen from the foregoing that in such a situation the gap width does not tend to zero. Moreover, when $\Delta\epsilon$ is sufficiently small, the spacing between the electronic levels reaches the same order of magnitude as the vibrational quanta, so that the electronic and vibrational motion, strictly speaking, can no longer be considered independently. Moreover, with long chains there may be very significant interaction between the electrons [17,18]. This factor is apparently the most significant.

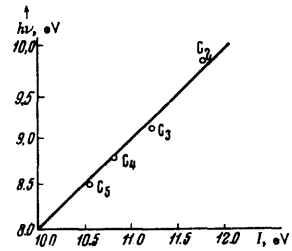

Fig. 7. Relationship between ionisation potential and absorption frequency.

The ionisation potential of a molecule in this model is simply equal to the energy (with opposite sign) of the upper filled orbital, for which $i = n/2$ in formula (2):

$$-I = \varepsilon_{n/2} = \alpha + \lambda_{n/2}\beta. \qquad (3)$$

Fukui and his coworkers [10] showed that, with $\alpha = -5.85$ eV, $\beta = -6.36$, and $m = 0.34$, good agreement is observed between the calculated and experimental values of I (with the exception of ethane, Fig. 6).

Since both the frequency of absorption and the ionisation potential are linearly dependent on $\lambda_{n/2}$, we should expect a linear relationship between these quantities, and this is confirmed for the alkanes (Fig. 7). For other classes of compound there are insufficient published experimental data to enable us to make a similar comparison of ν and I.

3. ELECTRON DENSITY DISTRIBUTION AND DELOCALISATION

The distribution of electronic charge in conjugated systems exhibits characteristic features, resulting from the delocalisation of the π-electrons. The most remarkable feature is that, under the influence of a substituent or a heteroatom, the electron density distribution changes throughout the conjugated chain, and alternation of charge is observed. This involves the alternation of the charges of the atoms with respect to sign or magnitude.

The charges q on the atoms in a polyene chain XC_5 (where X represents e.g. a halogen atom) are given in Fig. 8 (broken line) [6]. The "amplitude" of the alternation falls off very slowly with increasing distance from X. This alternation of the charges of the atoms does not take place in alkane chains XC_5 (solid line in Fig. 8). The positive charge produced on the C atoms by the substituent X decreases fairly rapidly to zero: it is almost equal to zero on the third atom from X [6¶].

¶ In Sandorfy's paper [6] the calculations for the σ-chains were carried out with $m = 0.25$.

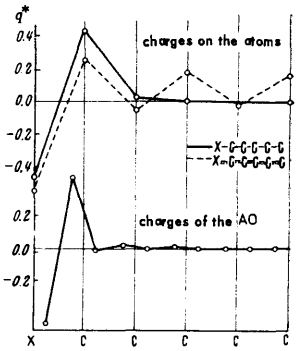

Fig. 8. Upper—charges on the atoms in an XC_5 σ-chain (solid line) and an XC_5 π-conjugated chain (broken line); lower—"charges" of the atomic orbitals in an XC_5 σ-chain.

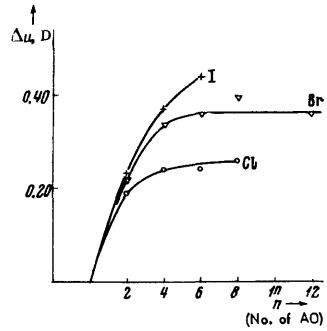

Fig. 9. Dependence of the difference in dipole moments $\Delta\mu = \mu(XC_NH_{2N+1}) - \mu(XCH_3)$ on the number of atomic orbitals [4].

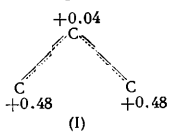
It may be noted that, if we were speaking of the charges not on the atoms but corresponding to individual atomic orbitals (for polyenes these concepts are the same), we would find rapidly damped alternation for the latter in a chain of σ-bonds [6] (Fig. 8). The alternation disappears on passing to the charges on the atoms, since in order to obtain the latter it is necessary to sum the charges of the two atomic orbitals of each atom. Even if $m = 1$, alternation of the charges on the atoms would not take place in a chain of σ-bonds in which each atom had two atomic orbitals.

Calculation [19] has shown that the negative charge on the halogen atom X in halogenoalkanes XR increases with increasing length of the hydrocarbon radical R, as a direct consequence of the delocalisation of electrons along the chain of bonds. Thus an effect familiar in chemistry is obtained even with a simplified model which does not take account of the hydrogen atoms. It is found [19] that this increase in charge is accompanied by a simultaneous increase in the rate of nucleophilic substitution. Table 1 gives as example values of the charge q^* on the Br atom and of the relative rates of the reaction

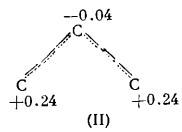
$$RX + OH^- \rightarrow OH + X^-$$

for a number of normal alkanes and isoalkanes.



Knowing the charges of the atomic orbitals of a chain of σ-bonds and assuming that they are situated at the "centres of gravity" of these atomic orbitals, we can calculate the dipole moments of substituted alkanes [4]. Since the positive charge produced on the alkane radical under the influence of an electronegative substituent X is not localised on the single carbon atom nearest to X, the dipole moments are non-additive. The dependence of the difference $\Delta\mu = \mu(XC_NH_{2N+1}) - \mu(XCH_3)$ on the number of atomic orbitals is shown in Fig. 9. [4] The theoretical curves were calculated for $m = 0.34$. The dipole moment becomes constant at $n \geq 6$ (Fig. 9), i.e. beginning approximately at substituted propanes. Thus the delocalised character of the electrons in monosubstituted halogenoalkanes apparently has a significant influence on the charge distribution over not more than three atoms of the σ-chain.

TABLE 1. Charges on the Br atom and relative reaction rates.



RBr	q^*	Relative rate of reaction $RX + OH^- \rightarrow ROX + X^-$	RBr	q^*	Relative rate of reaction $RX+OH^- \rightarrow ROX+X^-$
C–Br	0.423	1		0.467	10^8
C–C–Br	0.436	1.7			
C–C–C–Br	0.440	—			
	0 444	45		0.487	—

The example of the halogenoalkanes shows that the dipole moments of the σ-framework μ_σ may lead to non-additivity of the dipole moments for molecules having conjugated π-bonds. Allowance must be made for the fact that the value of β' is about 30% greater for sp^2 hybridisation than for sp^3 hybridisation. In general, μ_σ and μ_π are of the same order of magnitude; in some instances μ_σ may even exceed μ_π (for example, according to Berthod and Pullman [20], for pyridine $\mu_\sigma = 1.44$ D, $\mu_\pi = 0.86$ D, and $\mu_{exp} = 2.23$ D).

The change in the calculated charge distribution in a molecule containing π-bonds, occurring when allowance is made for the σ-electrons, can be assessed from the example of the allyl cation [2]. The electron density distribution represented in scheme (I) was calculated in the π-electron approximation without allowance for the C–H bonds. Scheme (II) gives the charges on the carbon atoms of the same cation, determined with allowance for both the π-electrons and the σ-electrons. It is found that the sign of the charge on the central carbon atom has changed, and that the magnitude of the charges on the terminal carbon atoms has decreased considerably, owing to the appearance of positive charges on the hydrogen atoms†.

(I)

(II)

† E. Clementi (U.S.A.) reported at the International Symposium on Quantum Chemistry in Kutna Hora, Czechoslovakia (1967), that, according to his calculations for polyatomic molecules, carried out in the self-consistent field approximation with allowance for all the electrons and integrals, the calculated electron density distribution of conjugated systems changes considerably when allowance is made for σ-electrons. Some of this work by Clementi has been published in the Journal of Chemical Physics [21].

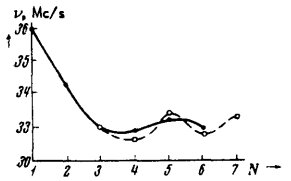


Fig. 10. Dependence of the n.q.r. frequency of the Cl atoms in compounds $Cl-[CH_2]_N-Cl$ on N (solid line—experimental, broken line—calculated).

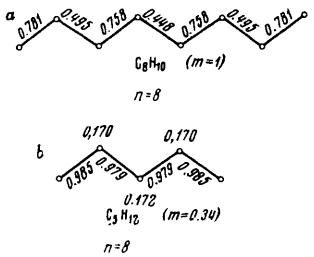

Fig. 11. Bond orders:
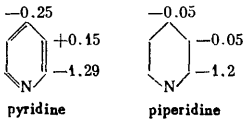
a) in a π-conjugated chain for $n = 8$ ($m = 1$);
b) in the chain of σ-bonds for $n = 8$ ($m = 0.34$).



With symmetrical αω-dihalogenoalkanes the situation is apparently slightly different from that with monosubstituted alkanes. Calculations carried out by the molecular-orbital method for $m = 0.34$ show that the effective (negative) charge on the chlorine atoms in molecules of the type $Cl-[CH_2]_N-Cl$ show a characteristic dependence on the number N of CH_2 groups. When $N > 3$, the charges on the chlorine atoms vary periodically with increase in N: they are slightly greater for even values of N than for odd values, the difference amounting to 0.005–0.01 of a unit charge for the calculated examples with $N = 3$–7. This effect is apparently manifested in the nuclear quadrupole resonance (n.q.r.) spectra [22]. According to the calculations, the n.q.r. frequency of the chlorine atoms in these molecules is smaller for $N = 4$ than for $N = 3$ or 5 (Fig. 10). For $N > 5$ the dependence of the n.q.r. frequency on N is apparently more complex.

As with π-conjugated systems, it is possible to calculate the bond orders $p_{\mu\nu}$ for alkane molecules. A corresponding value of $p_{\mu\nu}$ is obtained for each pair of neighbouring atomic orbitals. For conjugated systems the values of $p_{\mu\nu}$ alternate along the chain of carbon atoms. The values of $p_{\mu\nu}$ for octatriene are given in Fig. 11*a*. Many conjugated systems show parallel changes in the bond orders, bond lengths, and force constants (see for example Streitwieser [5]). According to Konarski's calculations [23] the alternation of $p_{\mu\nu}$ is even more marked for a chain of σ-bonds (Fig. 11*b*); the low values of $p_{\mu\nu}$, however, are due to the intra-atomic interaction, characterised by the integral β'. Thus there is almost no alternation in the orders of real bonds in saturated hydrocarbons. On this basis it may be expected that these compounds should show alternation neither of bond lengths nor of force constants.

4. MAGNETIC RESONANCE SPECTRA AND DELOCALISATION

The experimental data on chemical shifts in n.m.r. spectra occurring when a substituent or a heteroatom is introduced into a molecule indicate that their influence is transmitted for a fairly large distance along a chain of either π-bonds or σ-bonds.

This influence, associated with delocalisation of electrons, resembles slightly the influence of substituents and heteroatoms on electron density distribution, but it does not reduce to this. The magnetic screening of nuclei is due to the precession of electrons in the external magnetic field, and in general it depends in a complex fashion on the properties of the molecule. Measurements of the proton chemical shifts σ_H and calculations of the π-electron charges for a number of nitrogen-containing aromatic compounds [24] showed that the discrepancy between the experimentally observed values of σ_H and the values calculated from data on the π-charge distribution is large: it may amount to 100–250% and have either sign. This comparison, it is true, made no allowance for the fact that not only the π-electrons, but also the σ-electrons, are in fact responsible for the chemical shift. The contribution made by the σ-electrons of the molecular framework is apparently fairly large. This follows, for example, from a comparison of σ_H for pyridine and piperidine [24]. The proton chemical shifts given below were measured relative to benzene and cyclohexane respectively.

As in the production of charges by induction, the influence of the perturbation on the atoms joined by σ-bonds is rapidly damped, and, in contrast to π-conjugated systems, the values of σ_H do not show alternation.

One consequence of electron delocalisation in aromatic compounds is the displacement of the n.m.r. signal from the protons towards weaker fields under the influence of the magnetic field of the "ring current". A similar effect, of small magnitude, is apparently observed with cyclic saturated hydrocarbons. For example, the equatorial hydrogen atoms in cyclohexane give an n.m.r. signal which is displaced slightly towards weaker fields relative to the signal from the axial protons [25]. The possibility of the production of ring currents in rings with alternation in the magnitude of the resonance integral was examined by London [26] in connection with the theory of the anisotropy of diamagnetic susceptibility in aromatic compounds. He concluded that the magnitude of the ring current is proportional to $(\beta'/\beta)_{n/2}$, i.e. that it is comparatively small.

The indirect spin–spin coupling of nuclei, taking place through the electron clouds separating them, is one of the most striking manifestations of the delocalisation of electrons through a system of σ-bonds. This coupling is due to "magnetic polarisation" of the electron cloud by the magnetic field of the nuclei. This polarisation can readily be imagined if we start from the picture of two-electron bonds interacting with one another. The magnetic field of the nucleus leads to partial (very small) "unpairing" of the spins of the pair of electrons in direct contact with this nucleus. The electronic magnetic moment produced in this way in turn produces a magnetic moment in the electron

pair of the neighbouring bond (as a result of the interaction of the bonds), etc.; the induced magnetic moment of one of the electron pairs interacts with the second nucleus and thus leads to magnetic interaction of the nuclei with one another. If the interaction (β') between the bonds, examined above, did not take place, indirect spin–spin coupling would not exist.

The energy of the spin–spin coupling is

$$W = K_{HH} I_1 I_2, \qquad (4)$$

where I_1 and I_2 are the spin moments of the first and second nuclei respectively, and K_{HH} is the so-called spin–spin coupling constant. Some values of K_{HH} for hydrogen and fluorine nuclei are given in Table 2.

These data show that conjugation does not always lead to an increase in K_{HH} (examples 5–7 in Table 2). The dependence of the absolute magnitude and sign of K_{HH} on the length of the chain of bonds and on the structure is apparently fairly complex. It is possible that in some instances, the curvature of a long chain allows the terminal atoms to interact directly with one another.

The simplest example is provided by the interaction of geminal hydrogen atoms (i.e. hydrogen atoms attached to the same carbon atom). It has been established experimentally that for these atoms the constant K_{HH} increases (becomes less negative or more positive) when the H–C–H valency angle increases. Moreover, the introduction of an electronegative X atom in the α-position to the CH_2 group leads to an increase in K_{HH} (e.g. for ethylene $K_{HH} = +2.5$, and for formaldehyde $K_{HH} = +4.0$). These regular features can be explained qualitatively as follows [27].

Two mechanisms apparently exist for the interaction of geminal atoms. Firstly, the magnetic moment of the nucleus may induce a magnetic moment in the electron pair of the $CH^{(1)}$ bond; as a result of the difference in the signs of the gyromagnetic ratio of the proton and electron, the direction of this moment will be the same as that of the nucleus (Fig. 12*a*). The electronic moment of the $CH^{(1)}$ bond will in turn "polarise" the electron pair of the $CH^{(2)}$ bond, whose induced magnetic moment will interact with the second H nucleus. The moment of the latter (Fig. 12*a*) is antiparallel to the spin of $H^{(1)}$. In accordance with Eqn. (4), the energy W will be negative (i.e. have a minimum) for the condition $K_{HH} > 0$. Secondly, we may have a mechanism in which the magnetic moment of the proton $H^{(1)}$, as a result of contact with the electron pair of the $CH^{(2)}$ bond, directly induces a magnetic moment in this bond (Fig. 12*b*). Analogous arguments lead to the conclusion that in this instance the spins of the nuclei will be parallel, and K_{HH} will be negative.

TABLE 2. Spin–spin coupling constants.

No.	No. of bonds	Carbon framework of molecule	K_{HH}, c/s
1	2	H–C–H (methane)	−12.4
2	2	H–C–H (cyclopropane)	− 4.0
3	2	H–C–H (ethylene)	+ 2.5
4	4	H–C–C–C–H	7–13
5	4	H–C=C=C–H	6
6	5	H–C–C=C–C–H	+2.7
7	5	H–C=C–C–C–H	0.7–1.3
8	6	H–C≡C–C–C≡C–H	1.3
9	7	H–C–C=C–C=C–C–H	1.0
10	5	F–C$_6$H$_4$–F	11
11	5	F–C–C–C–C–F	4.3
12	6	F–C–C–C–C–C–F	1.9

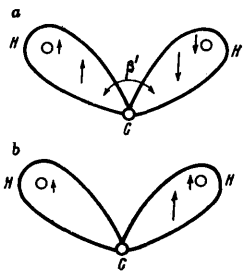


Fig. 12. Indirect magnetic interaction of geminal hydrogen atoms.

These two mechanisms compete with one another. The first is determined by the magnitude of the exchange integral β', which, as noted above, depends on the energy of the s–p splitting in the carbon atom, and the second is determined by the magnitude of the exchange integral between the atomic orbital of the $H^{(1)}$ atom and the atomic orbital of the carbon atom of the second bond. With increase in the s-character of the hydridisation of the carbon atom, the absolute magnitude of the integral β' increases [14] by 33%—$\beta'(sp^3) = -2.45$ eV, $\beta'(sp^2) = -3.27$ eV—whereas the absolute magnitude of the second integral decreases, because of the increase in the valency angle. Thus it is to be expected that K_{HH} will increase, i.e. will become more positive, and this is confirmed experimentally (see examples *1–3* in Table 2). The attachment of an electronegative atom X to the carbon atom will lead to a decrease in the population of the C–H orbitals and hence to a decrease in the negative contribution from the second mechanism: i.e. it will lead to an increase in K_{HH}.

A semi-quantitative treatment of these effects was put forward by Pople and Bothner-By [27]. There is as yet, however, no completely satisfactory theory of spin–spin coupling in molecules.

Electron delocalisation is revealed in e.s.r. spectra in the presence of a hyperfine structure from not one but several nuclei. The hyperfine structure of e.s.r. spectra is due chiefly to "contact" spin–spin coupling of the unpaired electron with protons or other nuclei having spins differing from zero. This interaction is possible as a result not only of the actual delocalisation of the unpaired electron but also of spin polarisation of the electron cloud, similar to the polarisation examined above, causing indirect spin–spin coupling of nuclei. It follows from the e.s.r. spectra of alkyl radicals [28,29] that the hyperfine structure is due not only to hydrogen atoms which are attached to α- and β-carbon atoms, but also to those on γ-carbon atoms. This means that in the e.s.r. spectra of these radicals the delocalised character of the unpaired electron influences atoms which are separated by three σ-bonds from the "mother" carbon atom‡.

---o0o---

‡ The e.s.r. spectra show another extremely characteristic manifestation of delocalisation of the unpaired electron, which is observed in the spectra of organic radical-anions consisting of two aromatic rings joined by a bridging group. Here, however, the delocalisation does not take place through a chain of σ-bonds and is apparently due to π–σ conjugation, so that this effect lies beyond the scope of the present review [30–35] (the theory of the effect has been examined by a number of authors [36–38]).

This analysis of the electronic structure of molecules of saturated hydrocarbons confirms the view that in the theoretical examination of these molecules, as in π-conjugated systems, it is necessary to use delocalised molecular orbitals. The delocalised character of a molecular σ-orbital is reflected in the properties of the molecules much less strongly, however, than with a molecular π-orbital, as a consequence of the fact that, in contrast to π-conjugated systems, not all the resonance integrals in a chain of σ-bonds are equal. The intra-atomic resonance integral β', characterising the interaction of the σ-bonds, is smaller than the interatomic resonance integral β, responsible for the formation of the σ-bonds themselves.

The delocalised character of the σ-electrons is reflected to varying extents in different properties of saturated hydrocarbons. It has almost no influence on the energy of formation, which can therefore be calculated by an additive scheme. The delocalised character of the σ-electrons has a significant influence on the positions of the electronic absorption bands, the ionisation potentials, the electron density distributions, and in particular the dipole moments of the molecules. As a rule, however, the influence of electron delocalisation on these properties does not extend over more than 3–4 atoms in the chain of σ-bonds. It extends over a large number of atoms, for example, in the spin–spin coupling in n.m.r. spectra, because of the high sensitivity of nuclear magnetic radiospectroscopy.

The influence of delocalisation of σ-electrons is more marked in conjugated systems than in saturated molecules, since the intra-atomic exchange integral β' is 30% greater in these bonds than in saturated molecules. Thus, in the study of the transmission of the effect of structural changes along a chain of bonds in conjugated systems, it is necessary to make allowance not only for the part played by π-electrons but also for that played by σ-electrons.

The calculations of the properties of chains of σ-bonds given above are of course greatly simplified. They are based on the simplest version of the one-electron approximation, and a number of additional, strictly speaking unjustified, assumptions have been made. These include neglect of the integral β'' mentioned above, neglect of the C–H bonds, etc. In the treatment of comparatively simple properties such as the dependence of the ionisation potential on the length of the chain, appropriate refinements in the calculation would make it possible to obtain quantitative results, but should not alter significantly the qualitative picture obtained. For such complex properties as e.g. the spin–spin coupling of nuclei, however, comparatively extensive approximation is necessary in order to obtain even qualitative results. Thus the above interpretation of the indirect interaction of nuclear spins is based on more refined calculations than the treatment of the ionisation potentials or dipole moments.
