SPONTANEOUS IGNITION AND CHAIN REACTIONS†

N. N. Semenov

CONTENTS

I. Introduction 1

II. Thermal spontaneous ignition 1

III. Chain spontaneous ignition 3

I. INTRODUCTION

Our work in the field of chemical kinetics was begun about 1924 in the Electronic Chemistry Laboratory which I at that time directed in the Leningrad Physicotechnical Institute. My first coworkers were Kondrat'ev and Khariton, who were then quite young, and are now Academicians. Our group of physicists was augmented with young people and by the nineteen-thirties it had grown into the fairly large group of the Chemical Physics Institute of the Academy of Sciences of the USSR.

In 1925 we were concerned with the problem of the spontaneous ignition of gases capable of undergoing combustion and exploding. From the viewpoint of chemical kinetics, this problem was almost untouched. In any case it had never been the centre of a research effort. This situation was probably responsible for our rapid progress. In a period of 5–7 years we laid the foundations of the theory of spontaneous ignition and established that there are two and only two types of spontaneous ignition, namely: (1) thermal spontaneous ignition; and (2) chain spontaneous ignition (branched chain reactions).

I believe that this is the most important result which I and my closest associates achieved in the course of my long life.

Thermal spontaneous ignition results from the liberation of heat in exothermic reactions and the production of a thermal avalanche, since the heat liberated, and hence the increase in the temperature of the gas, leads to an increase in the reaction rate, which in turn leads to an increase in the liberation of heat and to a further increase in temperature, and so on.

Chain spontaneous ignition also results from the liberation of energy in chemical reactions, not in the form of heat, but at a stage before the energy is converted into heat. This energy being liberated leads to an increase in the number of free atoms, radicals, and electronically-excited particles with extremely high chemical activity, that is, to the development of a so-called chain avalanche. Here the increase in the temperature of the gas is a result, and not the cause, of the spontaneous ignition.

All subsequent studies in this country and abroad confirmed these conclusions, not only qualitatively, but quantitatively. Even when nuclear explosions were discovered, they were also found to be of the same two types — thermonuclear and branched-chain. Formally, the theories were also found to be similar, although they naturally differed quantitatively.

II. THERMAL SPONTANEOUS IGNITION

The earliest work (on thermal explosion) began with the development of a quantitative theory, which was subsequently verified by experiment. The history of our development of the thermal theory of explosion is extremely

† This review is based on a paper presented at the Symposium on Chain and Radical Reactions on the 11th April 1966 in the Scientists' Club, Moscow.

curious. In addition to our early work on chemical kinetics in 1923–1926, Val'ter and I were concerned with the problem of the breakdown of dielectrics. As a result of this work[1,2], we formulated the thermal theory of breakdown due to the breakdown of thermal equilibrium between the Joule heat being liberated and the heat removed from the body of the dielectric to the electrodes.

The fortunate idea that all the conclusions from the thermal theory of breakdown were applicable to the theory of spontaneous ignition or — which is the same thing — spontaneous explosion, came to us in 1927. Here the liberation of heat was associated with a chemical reaction, albeit a very slow one: $Q_1 = q_1 W$, where q_1 is the heat of reaction and W the reaction rate calculated for the entire volume of the vessel v. Thus $W = vw$, where w is the reaction rate in unit volume. In the simplest example $w = k_0 a^n e^{-E/RT}$, where k_0 is the pre-exponential term of the reaction rate constant, E the activation energy, $n = 1$ for unimolecular reactions and $n = 2$ for bimolecular reactions, and a the number of parent molecules per unit volume (if w is expressed as the number of molecules which have reacted in unit time). Thus the quantity Q_1 increases rapidly with the initial temperature of the gas T_0 according to the exponential $e^{-E/RT}$ law. The heat transfer Q_2 takes place through the walls of the vessel. For convective heat transfer we have $Q_2 = \kappa(T - T_0)s$, where T is the temperature of the gas being heated by the reaction, T_0 the temperature of the walls, and s the surface area of the vessel. The form of the expression is the same for conductive heat transfer.

Let us plot Q_1 and Q_2 as functions of temperature on the same diagram. Let us consider the example where p is constant and T_0 is variable (Fig. 1) and that where T_0 is constant and p is variable (Fig. 2). Curves *1* in both diagrams correspond to thermal equilibrium with an increase in the temperature of the gas by the small quantity ΔT. Curves *3* in both figures, for which Q_2 is always less than Q_1, correspond to there being no thermal equilibrium, that is, to the production of a thermal avalanche leading to spontaneous explosion. Curves *2*, for which the heat-transfer straight line touches the heat-production curve, separate the two regions and determine in Fig. 2 the ignition temperature T_0 at a given pressure or in Fig. 1 the ignition pressure at a given temperature T_0. At the point of tangency $Q_1 = Q_2$ and $\frac{dQ_1}{dT} = \frac{dQ_2}{dT}$.

By solving these equations, we obtain the critical condition for explosion:

$$\delta_{cr} = \frac{qvk_0 a^n Ee}{NRT_0^2 \kappa s} e^{-E/RT_0} = 1, \qquad (1)$$

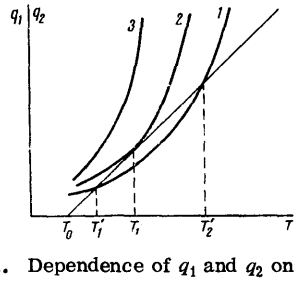

Fig. 1. Dependence of q_1 and q_2 on T (see text for explanation).

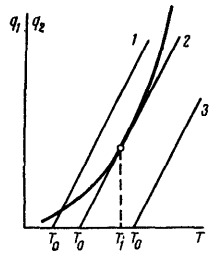

Fig. 2. Dependence of q_1 and q_2 on T (see text for explanation).

where a is expressed as the number of molecules per unit volume, and q is the molar heat of reaction.

If $\delta_{cr} \geqslant 1$, explosion will always take place, and if $\delta_{cr} \leqslant 1$, no explosion will take place.

Since $a \simeq 10^{19}(p/T)$, we can write the equation

$$\delta_{cr} = \frac{qk_0 Eevp^n \times 10^{19}}{NR\kappa s T_0^{2+n}} e^{-E/RT_0} = 1. \qquad (2)$$

For a given vessel and a given heat-transfer coefficient κ, we obtain the following relationship between the critical values of T_0 and p:

$$\log \frac{p}{T_0^{1+2/n}} = \frac{A}{T_0} + B. \qquad (2')$$

The constant B is determined by the kinetic and thermal constants and by the shape and dimensions of the vessel, and the quantity $A = 0.217E/n$. The theory was formulated in this form in my paper[3,4] in 1928. In the same year our colleague Zagulin published a paper[5] in which it was shown for the example of the spontaneous ignition of Cl_2O, that formula (2′) is confirmed experimentally.

From earlier kinetic experiments, carried out abroad, it was known that the decomposition of Cl_2O takes place by a bimolecular reaction with activation energy $E \simeq 25\,000$ cal × × mole^{-1}. Knowing the value of A, Zagulin was able to determine the value of E from explosion experiments, and in this way he obtained the same value $E = 25\,000$ cal mole^{-1}.

In 1935 Rice and Allen[6] obtained analogous verification for the example of the decomposition of azomethane. From kinetic data it was established that the reaction is unimolecular and has an activation energy of 51 000 cal mole^{-1}. In a study of the spontaneous ignition of azomethane, Rice and Allen confirmed the correctness of formula (2′) and from the value of A they found the activation energy E to be 50 000 cal mole^{-1}, in excellent agreement with the kinetic data.

These experiments convinced everyone that the thermal theory correctly takes account of the part played by kinetics in spontaneous-ignition processes. For complete confidence, however, it was necessary to show that, from a knowledge of the kinetic and thermal parameters, we were able, by applying the theory of thermal explosion, to calculate theoretically the ignition temperature for various gas pressures. This was achieved in our Institute by Frank-Kamenetskii[7], who examined the case of conductive heat transfer in a cylindrical vessel. The only change in the value of the critical parameter δ_{cr} in this example is that in

formula (2) the coefficient κ is replaced by $4\lambda/r$ and $v/s = r/2$. Substituting the values of λ, r, E, and q, Frank-Kamenetskii calculated the spontaneous-ignition temperatures of azomethane, methyl nitrite, and dinitrogen monoxide at various pressures. The calculated values were found to be very close to the experimentally determined spontaneous-ignition temperatures. This confirmed conclusively the quantitative reliability of the thermal theory of explosion[8].

Thermal explosion will always take place if $\delta_{cr} \geq 1$; this can be written in the form

$$t_r \leqslant \frac{qEet_e}{CRT_0^2}, \qquad (3)$$

where t_e is the thermal relaxation time of the system, that is, the time required to cool by a factor of e a gas heated by the reaction, C the heat capacity of the gas, and t_r the duration of the reaction, an arbitrary quantity which can be readily determined by measuring the initial reaction rate

$$t_r = \frac{d}{k_0 a^n e^{-E/RT}}, \qquad (4)$$

where a is the number of molecules per unit volume for the original fuel gas. If $t_r \geqslant \frac{qEet_e}{CRT_0^2}$, thermal ignition is impossible. If $t_r \leqslant \frac{qEet_e}{CRT_0^2}$, the fuel gas is always ignited thermally. The time t_r for a given gas pressure, that is, for a given number of molecules a in unit volume, is inversely proportional to the reaction rate close to the explosion temperature. Thus in order to determine whether an explosion is thermal in character, it is sufficient to measure the initial reaction rate at a pressure only just less than the explosion pressure, to measure or calculate the relaxation time t_e, and to estimate, even approximately, the value of the activation energy E. If the reaction rate corresponds even approximately to the expression (3), the explosion is undoubtedly thermal in character. If, however, t_r is found to be greater by one or several orders of magnitude, this is a reliable indication that the ignition is not thermal in character but is a chain process.

Until now we have restricted ourselves to simple unimolecular and bimolecular reactions. The theory can readily be generalised to more complicated kinetic laws, for example to autocatalytic reactions, chain reactions with unbranched chains, etc. The problem here reduces basically to the problem of making allowance for the more complicated kinetic laws.

We also studied experimentally the problem of the course of a thermal explosion with time. It was found that thermal explosion does not take place instantaneously, but after a certain induction period (usually of the order of one second or fractions of a second for non-autocatalytic reactions). The problem was developed theoretically by Todes[9,10], in complete agreement with experiment. This examination showed that the temperature of pre-ignition heating $\Delta T = \frac{RT_0^2}{E}$ is reached comparatively slowly, but that explosion takes place almost instantaneously when this temperature has been reached. When the thermal spontaneous-ignition temperature or pressure are much greater than the critical values and we can neglect heat transfer, we obtain from theory, for the induction period t_i, the expression $t_i = t_r \frac{CRT_0^2}{Eq}$, in good agreement with experiment.

Let us now consider the idealised case of a purely adiabatic thermal explosion, in which the heat transfer is equal to zero, and $t_e = \infty$. It can readily be seen from the criterion that thermal explosion is possible at any value of t_r, no matter how great, or, which is the same thing, at any values of the reaction rate, no matter how small. We have seen from the previous formula, however, that the induction period will then reach improbably high values. Thus if for a given fuel gas with E = 40 kcal mole^{-1} at a temperature T_0 = 600°K the induction period t_i is equal to 1 s, the value of t_i at T_2 = 300°K will be greater by a factor of $\exp\left[\frac{E}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)\right]$, that is, the time required for thermal explosion to take place reaches millions of years. This is of course, the same result as if the explosion were impossible. If, however, the temperature is not 300° but 450°K the induction period will be equal to 14 h. The problems of predicting long induction periods for long relaxation times, particularly in the case of solid explosives, is of some practical importance. It should be noted that under given conditions these extremely long induction periods in practice retain their very precise value.

It should be noted that up to the mid nineteen-twenties the problems of spontaneous ignition and flame propagation had been examined by explosives experts, heat engineers, and to some extent by physicists and mechanical engineers. Since the time of van't Hoff, these problems had been of little interest to physical chemists. As a rule, no account was taken of chemical kinetics in problems of combustion. In its place there was introduced the concept of spontaneous-ignition temperature as a constant characteristic of each fuel. We have shown above that the spontaneous-ignition temperature is not a constant quantity. In our work, the phenomenon of combustion was based on chemical kinetics, complicated by the liberation of heat and by the existence of an inverse relationship between increase in temperature and kinetics. This was the first instance of a wider class of phenomena, now known as macrokinetics. It was on this basis that it was subsequently possible to convert not only the theory of spontaneous ignition but also the theory of various forms of flame propagation into a chapter of chemical kinetics. This principle subsequently formed the basis for the theory of flame propagation (B. Lewis, Ya. B. Zel'dovich, D. A. Frank-Kamenetskii, N. N. Semenov, and others), the concentration limits of the ignition and propagation of a normal flame (Zel'dovich), some problems of turbulent flame propagation (in particular K. I. Shchelkin), problems of the concentration limits of the detonation and combustion of powders (A. F. Belyaev and O. I. Leipunskii), etc. In recent years we have developed a theory of the spontaneous ignition of condensed explosives.

III. CHAIN SPONTANEOUS IGNITION

In contrast to thermal spontaneous ignition, the work here began not from theory but from experiment. In 1926, Khariton[11], who was occupied with problems of the extinction of the chemiluminescence of phosphorus vapour at low oxygen pressures, unexpectedly discovered that at a certain fairly low oxygen pressure, below a limiting pressure p_1, phosphorus vapour did not ignite. The vapour pressure of phosphorus (over a piece of phosphorus in a vessel at room temperature) and oxygen was so low (0.1–0.001 mmHg depending on the conditions of the experiment) that there could be no question of thermal ignition. This was also proved by direct experiment.

Moreover, phosphorus vapour undergoing combustion at $p > p_1$ is extinguished immediately as soon as the oxygen pressure falls, as a result of the oxidation of phosphorus, to a pressure only just less than p_1, although the apparatus still contains oxygen and phosphorus. If a certain quantity of inert gas (argon) is added at $p < p_1$, a flash is produced. Thus the limiting value of the partial pressure of oxygen p_1 is for some reason decreased in the presence of argon.

These observations radically contradicted the theories held at that time, since the rate of a reaction always decreases smoothly as the components are consumed, and there seemed to be no reason for the reaction to stop suddenly.

The extent to which these results of ours appeared paradoxical at that time can be seen from the criticism of the famous scientist Bodenstein [12], who was the leader in world chemical kinetics at that time. He wrote that Khariton's experiments were erroneous, and asserted that the characteristic features of Khariton's apparatus caused a diffusion stream of phosphorus oxide vapour from the reaction vessel. This stream removed oxygen from the vessel, and when the McLeod gauge (which was separated from the vessel by a trap cooled with liquid air) showed a pressure p_1 the reaction vessel in fact contained no oxygen. Later he wrote that Khariton and Val'ta were trying, in their paper, to reintroduce the ideas of the existence of so-called "false" equilibria, which had been clearly shown to be erroneous early in the nineteen-hundreds by many careful studies, including his own. This paper was therefore incorrect, like all earlier papers of this sort. In conclusion, Bodenstein did not advise anyone to concern themselves with these hopeless problems.

Bodenstein's criticism appeared convincing to my colleagues at the Physicotechnical Institute, and even to my coworkers in my laboratory. Even I lived through not a few unpleasant hours. Without delay, I undertook to verify and continue Khariton's work, and with some numerical refinements confirmed his results [13-16].

I carried out a series of experiments in which the possibility of a diffusion stream was eliminated completely; in spite of this, all the unusual phenomena reported by Khariton and Val'ta were preserved.

Conclusive proof was thus obtained for one of the most surprising phenomena in nature — the sharp transition from the almost complete inertness of a substance to its vigorous reaction, with a negligible change in its density. I would remind you that in our time the existence of a similar phenomenon has made it possible to produce energy in atomic reactors and to use atomic bombs.

Let us return, however, to late 1926 and the inoffensive experiments with phosphorus. I made a thorough quantitative study of the various regular features of the phenomenon of the lower pressure limit and its dependence on the degree of dilution with inert gas, phosphorus vapour pressure, and temperature. Shal'nikov and I discovered another surprising phenomenon — the existence of critical vessel dimensions. It was found that the critical pressure is inversely proportional to the square of the diameter d of a spherical vessel. At this point we ceased to understand anything at all. It appeared that the reactivity of phosphorus is determined not only by its density but also by what seemed to be completely unrelated parameters — the volume or dimensions of the reaction vessel. We then tried to summarise all the data which we had obtained in the form of an empirical criterion for the spontaneous ignition of phosphorus vapour (analogous to that described above for thermal explosion).

This criterion had the form

$$d^2(O_2)(P_4)\left[1+\frac{(A)}{(P_4)+(O_2)}\right]=C, \qquad (5)$$

where A represents argon and the parentheses denote the partial pressures of the corresponding gases. For cylindrical vessels, the value of the constant C was found to be about 10^{-3} when the pressure is expressed in mmHg and the diameter d of the vessel is expressed in cm.

We first suggested that the oxidation of phosphorus was a Bodenstein chain reaction with alternation of the active particles (here biradicals) — O atoms and P_4O, for example, according to the scheme:

(1) $O + P_4 \rightarrow P_4O$.
(2) $P_4O + O_2 \rightarrow P_4O_2 + O$ etc. $\qquad P_4O_2 \rightarrow P_4O_{10}$.

The oxides P_4O_2 (probably also biradicals) were rapidly oxidised further to P_4O_8 and P_4O_{10} with the liberation of a large amount of energy. Even at this stage we introduced a hypothesis which departed from that of Bodenstein. We suggested that the active particles (for example O atoms), may disappear at the walls of the vessel, by adsorption (with subsequent heterogeneous reaction, for example $O + O \rightarrow O_2$). The left-hand side of the empirical expression is then found to be proportional to the length of the chain ν, that is, to the number of elementary reactions (1) and (2) between the initiation of the chain and its termination at the walls of the vessel. In 1928 Trifonov [17] in our laboratory proved by direct experiment that in the photochemical chain reaction $H_2 + Cl_2$ at a pressure of about 20 mmHg chain rupture in fact takes place almost exclusively at the walls of the vessel. The reaction rate and hence the length of the chain here was found to be proportional to d^2.

These unbranched reactions, however, take place at a constant rate $n_0\nu$, where n_0 is the number of primary P_4O radicals or O atoms initiated in one second. Their number, like the length of the chain, changes smoothly with pressure, so that this suggestion does not explain the existence of the lower limit of oxygen pressure $(O_2)_1 = P_1$.

At this point an idea occurred to us.

What if, in addition to Bodenstein's unbranched chains (Fig. 3), there also existed branched chains (occasional branching as in Fig. 4 or multiple branching as in Fig. 5)? In other words, let us assume that there is a certain mathematical expectation δ that at each step in the chain an average of one new O atom is produced by the energy of the

Fig. 3. Schematic representation of an unbranched chain reaction.

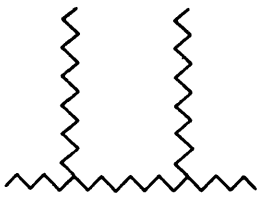

Fig. 4. Schematic represention of a chain reaction with occasional branching.

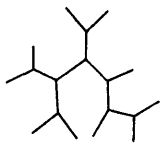

Fig. 5. Schematic representation of an intensively branched chain reaction.

oxidation of P_4O_2 to P_4O_{10}. If the branching is only occasional, δ is a small fraction. If then $\nu\delta = 1$, each act of chain termination will be compensated by the necessary production of one new chain as a result of the act of branching. When $\nu\delta > 1$ (for example, $\nu\delta = 2$), however, the number of chains will automatically increase with time, and ignition will take place. Thus the condition $\nu\delta = 1$ is the criterion for the transition from a negligible rate of reaction (with small value of n_0) to the vigorous reaction of chain ignition.

Since for each starting material the value of δ is constant, the condition $\nu = C$ is the condition for ignition; this remained to be proved.

The mechanism of the branching was still not clear. Soon afterwards, however, Leipunsky [18] passed a beam of slow electrons through phosphorus vapour burning at low pressures, and showed that the kinetic energy of the electrons increases considerably (up to 10 eV, that is, up to energies which are almost double the energy of the dissociation of oxygen into atoms). From this we concluded that in the oxidation of P_4O_2 to P_4O_{10} electronically-excited particles are produced, capable, on collision with an O_2 molecule, of bringing about the dissociation of the latter into two atoms, leading to energetic chain branching.

My paper was published in 1927. Almost immediately I received a letter from Bodenstein, in which he withdrew his objections and accepted our discovery; soon afterwards, at a meeting of electrochemists, he did this publicly. I am very grateful to Professor Bodenstein for his criticism, without which we would hardly have continued Khariton's work, and also for his subsequent systematic support of my work in this field.

A. F. Ioffe and all my colleagues in Leningrad accepted our work and congratulated us on our discovery.

In 1928 I reported the preliminary results obtained by Ryabinin [19] and myself on the chain ignition of sulphur vapour in oxygen, where the results obtained were analogous to those of the experiments on the ignition of phosphorus, and also Zagulin's results [20] on the chain ignition of $H_2 + O_2$ and $CO + O_2$ mixtures (in the last two instances the lower limit of p_1 for the mixture is observed only at a temperature above a certain critical temperature, below which no ignition takes place).

In 1928 Hinshelwood and Thompson [21] published the first results of their study of the so-called upper limit for the oxidation of mixtures of hydrogen and oxygen. Surprisingly, spontaneous ignition did not take place at pressures in the mixture greater than a certain limiting value p_2, whose magnitude decreased fairly rapidly with decrease in temperature. By combining Zagulin's data on the lower limit with Hinshelwood's data on the upper limit, it was possible to draw, on pressure–temperature coordinates, the region of spontaneous ignition in the form of a peninsula terminating in a sharp point (Fig. 6). Unlike the lower limit, the upper limit does not depend on the dimensions and state of the walls of the vessel, so long as the upper limit is not too close to the point. Hinshelwood also found that the magnitude of p_2 was influenced considerably by an inert gas, which reduced the partial pressure of the $H_2 + O_2$ mixture at the upper limit. The decrease in this partial pressure was found to be close to the partial pressure of the inert gas, so that with respect to total pressure the upper limit remained almost unchanged. The merit of Hinshelwood's work was that he interpreted the phenomenon of the upper limit within the framework of the theories of branched chain reactions. He suggested that termination at high pressures is determined by the ternary collision of the active particle with a molecule of oxygen and any other molecule M, in particular the inert gas, whereas the branching, as in the situation close to the lower limit, is determined by the binary collision of the active particle with oxygen. In this case, however, with increase in the total pressure of the mixture, the chain termination will increase in proportion to the quantity $(O_2)(M)$, whereas the branching will increase in proportion to (O_2), and at a certain total pressure p_2 the termination will become equal to the branching. At $p > p_2$, spontaneous ignition is impossible. The temperature dependence of the limiting value of p_2 is related to the activation energy of the branching process, since chain termination, which takes place on ternary collisions, involves almost no activation energy.

The chemical mechanism of the oxidation of hydrogen became known only after Lewis [22] put forward his celebrated scheme for this reaction. It was found that the branching is associated with the reaction of an H atom with oxygen: $H + O_2 \rightarrow OH + O$ followed by the rapid reaction $O + H_2 \rightarrow \rightarrow OH + H$, whereas termination in the bulk is associated with the reaction $H + O_2 + M \rightarrow HO_2 + M$. Under these conditions HO_2 is a radical with low activity, incapable of propagating the chain. For many reactions taking place at relatively low temperatures, where an important part is played by the presence of oxygen atoms, chain termination by the reaction $O + O_2 + M \rightarrow O_3 + M$ is possible, as shown by Hinshelwood and Dalton [23].

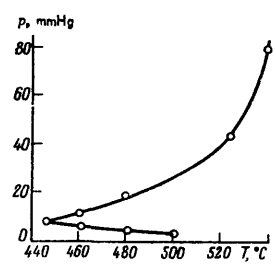

Fig. 6. Range of ignition of hydrogen [20].

Since chain termination may take place both at the walls of the vessel and within the vessel (by ternary collisions), I put forward in the early nineteen-thirties a quantitative theory of the entire field of spontaneous reactions.

In 1929 my coworkers and I showed that an analogous ignition peninsula is observed for the reaction $CO + O_2$.[20] Similar regions of chain spontaneous reaction are characteristic of many other oxidations, for example, the oxidation of phosphine[24] (Fig. 7) and silane[25] (Fig. 8).

Early in 1928, I published papers[3,4] on the two types of spontaneous reaction. The theory of thermal spontaneous reaction outlined above was described for the first time, and the first ideas were put forward regarding chain spontaneous reaction and the development of the chain avalanche.

I propose to describe here the theory of branched chain reactions in the form in which we put it forward several years later[26-29].

It can readily be seen that when one type of active particle (atoms or radicals) is present, the kinetic equation determining their concentration n is of the form

$$\frac{dn}{dt} = n_0 + (f-g)n, \qquad (6)$$

where fn is the rate of the branching reaction, gn the rate of chain termination, and n_0 the number of active centres produced in one second as a result of thermal motion. At constant concentrations of the original gases or at the start of the reaction, when combustion can be neglected, f and g are constant quantities. At low pressures, when the disappearance of the active centres is determined by their capture by the walls of the vessel, the value of g (for a probability ϵ of capture by the wall equal to 1) for cylindrical vessels is given by the equation

$$g = \frac{25.2D_0}{d^2p},$$

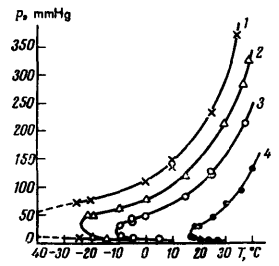

Fig. 7. Range of ignition of phosphine[24]: 1) 57% PH_3; 2) 43% PH_3; 3) 22% PH_3; 4) 10% PH_3.

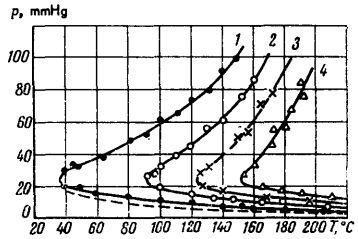

Fig. 8. Range of ignition of silane[25]: 1) 49% SiH_4; 2) 39% SiH_4; 3) 30% SiH_4; 4) 14% SiH_4.

where D_0 is the diffusion coefficient of the active centres at p = 1 mmHg, and d the diameter of the vessel. At very low values of ϵ we have $g = \epsilon u/d$, where u is the thermal velocity of the active particles. The values of g for intermediate values can be found from papers published by Lewis and myself. By treating the walls of a glass or quartz reaction vessel with various substances or in other ways, it is possible to vary the value of the limit p_1 over a wide range (by a factor of up to 100) for a given diameter.

As a rule, in all chain reactions we are dealing with not one but several (a minimum of two) active centres (for example P_4O and O), and hence we are dealing with not one but two or several kinetic differential equations. Usually, however, one of these active particles reacts much more slowly than the other, and this makes it possible, with a certain degree of approximation, to reduce the system of differential equations to one differential equation, which describes the change in the concentration of this least active centre, whose concentration is much greater than that of the others. Then, of course, the constant f becomes a complex quantity including the reaction rate constants of all the centres. By integrating Eqn. (6), we obtain:

$$n = \frac{n_0}{f-g}(e^{(f-g)t} - 1) = \frac{n_0}{\varphi}(e^{\varphi t} - 1) \quad \text{for } (f-g) = \varphi > 0, \qquad (7)$$

$$n = n_0 t \quad \text{for } (f-g) = \varphi\, 0, \qquad (8)$$

$$n = \frac{n_0}{g-f}(1 - e^{-(g-f)t}) \quad \text{for } (f-g) = \varphi < 0. \qquad (9)$$

The equality $f = g$ is simply the criterion determining the limit. For $f > g$, the concentration of active centres increases exponentially with time. The reaction rate $w_t = kn$ (where $1/k$ is the mean time required for the active centre to react with the original molecule) increases according to the same exponential law. The quantity of substance x which has reacted at moment of time t also increases exponentially with time: $x_t = \int_0^t w_t dt$. For infrequent chain branching we have $k \gg f$, and for intensive chain branching we have $k = f$. Subsequently, we shall consider the development of chain branching at pressures which are only slightly greater than the lower limit, since at these pressures, as a result of the high thermal conductivity, the increase in the temperature of the mixture during the reaction is small.

Close to the lower limit, $\frac{g}{f} = \frac{p_1}{p_0}$, where p_1 is the pressure of the lower limit, and p_0 the original pressure of the mixture above the lower limit.

It follows from formula (7) that the reason for the chain avalanche is the rapid increase in the number of active centres capable of reacting. Even at low pressures, exceeding the lower limit by a factor of only 1.5–2, the value of f is very large and varies from several tens to several hundred reciprocal seconds. Thus the development of the reaction with time takes place within tenths or even hundredths of a second.

For $f < g$ the reaction rate is always less than the quantity $n_0 t$ and soon reaches a steady value (in the absence of appreciable combustion) $w = kn = \frac{kn_0}{g-f}$ or (for intensive chain branching, when $k \simeq f$):

$$w = \frac{n_0}{(g/f-1)} = \frac{n_0}{p_1/p_0 - 1}, \qquad (10)$$

where $p_0 < p_1$ (for $f < g$).

Thus the characteristic feature for branched reactions taking place under the limit is a rapid increase in rate, which does not correspond to the increase for ordinary reactions, as the limit is approached (Fig. 9). For $p_1/p_0 = 1$, the rate naturally does not tend towards infinity, but reaches values kn_0t, that is, it begins to increase linearly with time. The closer we are to the limit, the greater the time required for the steady rate to be reached. Even for $\frac{g}{f} - 1 = 0.01$, however, that is, when the value of p_0 is only 1% less than p_1, the reaction rate will in practice reach a steady state within one second.

In order to show clearly the change in the reaction rate w and the quantity x of substance reacted as a function of time, we can construct, for intensive chain branching with $n_0 = 10^3$, $f = 500$, and different values of the ratio p_1/p_0, corresponding curves for the quantity x, on a smaller scale for $f > g$ and on a much larger scale for $f < g$ (Figs. 10 and 11).

It should be noted that the quantity n_0, that is, the rate of spontaneous initiation of the primary radicals, is relatively very small. In actual fact, this process is associated with the production of the primary active particles — free atoms and radicals — from neutral molecules under the influence of thermal motion. Almost no thermal dissociation of the original molecules to give two free atoms or radicals takes place at room temperatures. The production of free radicals as a result of reaction between the original molecules, for example, $P_4 + O_2 \rightarrow P_4O + O$ or $H_2 + O_2 = 2OH$, has a much higher probability. Even these processes, however, are associated with a fairly large activation energy, so that n_0 is always small. It should, however, be noted, that the growth of the chain avalanche takes place so rapidly that the appearance of only a few primary active particles is sufficient to lead to their production in vast quantities within one second.

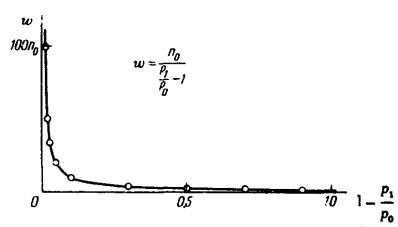

Fig. 9. Dependence of w on p_1/p_0 (for $f < g$).

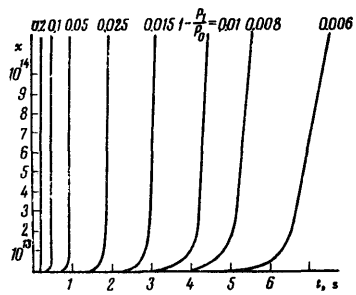

Fig. 10. Dependence of x (quantity of substance reacted) on t at various values of p_1/p_0 (n_0 = $= 10^3$ mole cm^{-3} s^{-1}; for $f > g$; $f = 500$ s^{-1}).

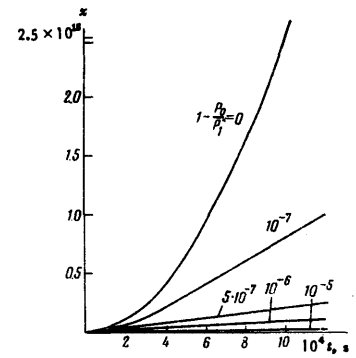

Fig. 11. Dependence of x on t at various values of p_1/p_0 ($n_0 = 10^3$ mole cm^{-3} s^{-1}; $f < g$).

It is possible in principle, however, to have instances where even one active centre is produced very rarely. We encountered such a case in a study, with Ryabinin [19], of the ignition of sulphur. Above the lower limit here ignition took place only rarely, and usually no ignition was observed. When a weak discharge was passed through the cylinder containing the oxygen, however, and the oxygen was then passed into the vessel containing the sulphur, ignition was always observed above the lower limit.

We would remind you that in atomic bombs a neutron source is used for the same purpose.

Since the value of n_0 is always very small (at a pressure $p \leqslant p_1$), the reaction rate is equal to almost zero and conditions for the development of a chain avalanche are not created. At a pressure only slightly greater than p_1 the reaction rate increases rapidly to extremely high values within a fraction of a second.

The first experimental verification of the theory of branched chain ignition was obtained in our Institute by Koval'skii [30] for the example of the oxidation of detonating gas ($2H_2 + O_2$) at 485° and various p_1/p_0 ratios (Fig. 12). From this it was possible to determine the value of f and hence the branching constant [31]. The exponential growth of the avalanche is confirmed up to a degree of conversion of 20–30% (Fig. 12). The curves for high degrees of conversion are distorted because of the decrease in the concentration of the original gases. A complete analysis of

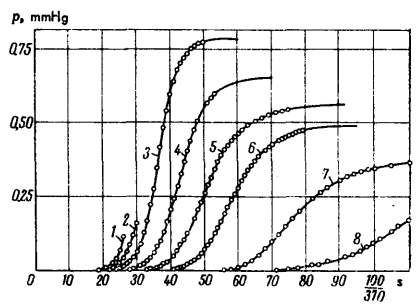

Fig. 12. Kinetics of the oxidation of a $2H_2 + O_2$ mixture at 485° and various initial pressures (mmHg): 1) 8.2; 2) 7.8; 3) 7.4; 4) 7.1; 5) 6.8; 6) 6.4; 7) 6.1; 8) 5.8. [30]

the curves for the development of the chain avalanche was made difficult by the lack of reliable data on the chemical mechanism of the reaction. The experimental verification of the theory became much easier after Lewis[22] put forward his scheme for the oxidation of hydrogen.

When applied to a pressure near the lower limit, this scheme for the oxidation of hydrogen, for which rigorous experimental verification was subsequently obtained, can be written in the form:

(1) $OH+H_2 \rightarrow H_2O+H$,
(2) $H+O_2 \rightarrow OH+O \rightarrow$ chain branching,
(3) $O+H_2 \rightarrow OH+H$,
H+ wall, O+ wall, OH+ wall $\rightarrow$ chain termination.

It is assumed that the chains are initiated by the reaction $H_2 + O_2 \rightarrow 2OH$. The smallest reaction rate (particularly when the mixture contains an excess of hydrogen) is that of the reaction $H + O_2 \rightarrow OH + O - 17$ kcal. This is the only endothermic step. From this it was concluded that in mixtures with an excess of hydrogen over the stoichiometric quantity, the highest concentration in the course of the reaction will be attained by H atoms. By using the method of quasi-steady concentrations for the change in the concentration of H with time, we obtain the expression:

$$\frac{d[H]}{dt} = n_0 + (2a_2 - a_2')[H] = n_0 + 2a_2\left(1 - \frac{a_2'}{2a_2}\right)[H], \qquad (11)$$

where $f = 2a_2 = 2k_2[O_2]$; $g = a_2'$; $n = [H]$; and $(1 - a_2'/2a_2) = (1 - p_1/p_0)$.

We can also write a differential equation for the rate of consumption of oxygen:

$$\frac{d[O_2]}{dt} = n_0 + k_2[O_2][H]. \qquad (12)$$

By solving the system of differential equations (11)–(12), we can calculate the entire course of the reaction from its initiation to complete combustion. I published this work in 1944.[32] Nalbandyan and Karmilova[33] in 1958 repeated Koval'skii's experiments[30] on the study of the value of Δp as a function of t, much more extensively and in much more detail. From these experiments it was possible to determine the constant k_2 for the branching reaction, and then to compare with experiment all the theoretical relationships which I had obtained. The agreement was found to be exceptionally good. Here it was also shown that the ratio $f/g = 2a_2/a_2'$ is in fact equal to p_0/p_1. It was also shown[32] that in the reaction $2H_2 + O_2$ at $p_1/p_0 = 0.5$, the concentration (or partial pressure) of H atoms at 50% consumption of the original oxygen should amount to 30% of that of the original oxygen and hence to 60% of the reacted oxygen, or 30% of the partial pressure of the water formed. Correspondingly, at $p_1/p_0 = 0.25$ the pressure of H atoms at the maximum will amount to 80% of that for the original oxygen, and at $p_1/p_0 = 0.7$ to about 10% of that of the original oxygen (Fig. 13). All these relationships are observed at a temperature of about 500°, when there is almost no equilibrium dissociation of water. This quite surprising result could essentially have been obtained from our theory ten years earlier.

When chain termination is neglected, the result of Lewis' three elementary reactions can be expressed by the following stoichiometric relationship: $H + 3H_2 + O_2 = 3H + 2H_2O +$ + 13 kcal or $3H_2 + O_2 \rightarrow 2H_2O + 2H$. We see that the chemical energy liberated in the formation of water according to

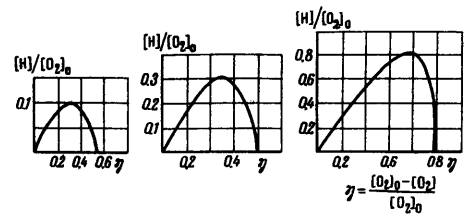

Fig. 13. Dependence of [H] on $\eta = \frac{[O_2]_0 - [O_2]}{[O_2]_0}$ at various values of p_1/p_0.[32]

the reaction $2H_2 + O_2$ is used up in the dissociation of H_2, thus maintaining the rapid development of the chain avalanche. At the end of the reaction, all the H atoms naturally recombine on the wall of the vessel, forming H_2 or H_2O molecules. This is accompanied by the liberation of an additional quantity of energy. A process taking place with the build-up of an atomic H concentration equal to twice the concentration of the original oxygen could in principle be carried out in vessels with a large radius (for example 10 m) with walls treated in such a way that the value of ϵ was very small. Here the pressure p_1 would be negligibly small, of the order of several ten-thousandths of a millimetre, and by carrying out the experiment at a pressure of say 0.1 mmHg, chain termination at the walls and within the vessel by ternary collisions $H + H + M \rightarrow$ $\rightarrow H_2 + M$ could be neglected. Then the rate at which the rapidly-formed atomic hydrogen disappeared as a result of chain termination in the interior of the vessel and at the walls would be so slow that at the end of the reaction we would have in the vessel as many H atoms as water molecules. This would make it possible to use this method of preparing atomic hydrogen for all sorts of reductions, for example, the reduction of oxides. The practical utilisation of this reaction is hindered by the fact that the pressures in the system are too low. An increase in the pressure to 10 mmHg, which would increase the quantity of atomic hydrogen by a factor of 100, would require such rapid rates of flow that the atomic hydrogen could not be prevented from recombining by ternary collisions.

This surprising conclusion regarding the vast relative concentrations of atomic hydrogen was confirmed experimentally by Kondrat'eva and Kondrat'ev[34]. They determined the concentration of free atoms from the increase in temperature recorded by a thermocouple placed in detonating gas burning at a pressure slightly greater than p_1, and confirmed the theoretical conclusion that the concentration of atomic hydrogen reaches 20–30% of the original concentration of oxygen in the mixture. Kondrat'ev's method, however, was nevertheless not quite a direct method of chemical analysis. The theory was subsequently confirmed thanks to an idea of Voevodskii's. In ordinary chain reactions the concentrations of atoms and radicals are too low to permit their detection by the EPR method. In branched chain reactions, however, where these concentrations are incomparably greater, the EPR method can be used successfully, as proved experimentally by Voevodskii and coworkers[35]. The method made it possible to determine not only the quantity of free radicals, but also their chemical composition. In 1960 Voevodskii showed that the concentration of atomic hydrogen does in fact reach the values indicated above.

Subsequently, Kondrat'ev and Nalbandyan[36], using the same method, detected considerable quantities of atomic oxygen in the $H_2 + O_2$ flame; the concentrations were found to be greatest in mixtures poor in hydrogen. Soon afterwards, the same authors[37] were able to record the EPR signals of OH radicals in the hydrogen flame and to determine their concentrations at various compositions of the mixture (Fig. 14). In the stoichiometric mixture the values of [H] reach 10^{16} molecules cm^{-3}, that is, about 1 mmHg. Earlier, it had been assumed (on the basis of the values for the rate constant of the reaction $O + H_2 \rightarrow OH + H$, given by Harteck and Kopsch[38]), that the concentration of O atoms was much smaller, by about 2 orders of magnitude, than that corresponding to the above observations. The value for the rate constant of the reaction $O + H_2 \rightarrow OH + H$, recently determined by Azatyan[39,40] by the method of limits, shows good agreement with the observed concentrations of atomic oxygen. The values of the concentration of OH radicals measured by the EPR method also agree with the value of the rate constant for the reaction $OH + H_2 \rightarrow H_2O +$ + H, determined by Avramenko[41] and Kondrat'ev[42].

The EPR method was also applied to the oxidation of carbon monoxide. Nalbandyan and coworkers[43-47] made a detailed study of rarefied carbon monoxide flames with oxygen in the presence of small quantities of substances acting as hydrogen donors. (Absolutely dry mixtures of CO and O_2 containing no hydrogen donors are incapable of spontaneous ignition.) H_2 and other donors were used as additives. In complete accordance with the chain branching mechanism, the combustion of CO in the presence of H_2 can be represented by the following scheme:

$$H_2+O_2\rightarrow 2OH \quad \text{(chain initiation)},$$
$$OH+CO\rightarrow CO_2+H,$$
$$H+O_2\rightarrow OH+O,$$
$$O+H_2\rightarrow OH+H,$$
$$\left.\begin{matrix} H+\text{wall} \\ O+\text{wall} \\ OH+\text{wall} \end{matrix}\right\} \rightarrow \text{chain termination}.$$

In a rarefied flame of this mixture in the presence of small quantities of added H_2, Nalbandyan and coworkers were able to detect high concentrations of atomic oxygen, hydrogen, and OH radicals, whose concentrations were found to be in good agreement with the OH concentrations previously measured by Kondrat'ev[41,42,48-50] from the electronic absorption spectra. Thus all the types of active centre assumed to be responsible for chain branching in this system were identified.

When small quantities of H_2 were added, O atoms predominated in the flame, and when large quantities of H_2 were added, H atoms predominated in the flame (see Fig. 15, which gives the concentrations of H, O, and OH for the same $CO + O_2$ mixture containing different quantities of added H_2). The concentrations of H and O atoms were always much greater than the concentration of OH radicals[51]. In the Institute of Chemical Physics of the Academy of Sciences of the USSR, Azatyan and coworkers[39,40] put forward a method for determining the rate constants for the reaction of atomic oxygen and hydrogen with the molecules of various substances, making use of the decrease in the lower limit of spontaneous ignition for the combustion of a mixture of CO and O_2 in the presence of small quantities of added H_2 or other hydrogen donors.

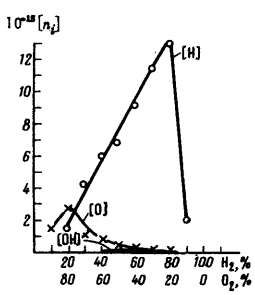

Fig. 14. Dependence of the concentrations of H, O, and OH on the initial composition of the hydrogen–oxygen mixture[37].

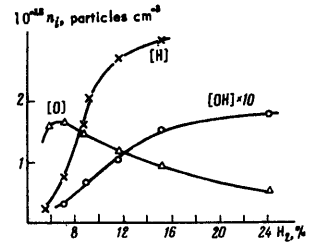

Fig. 15. Dependence of the concentrations of H, O, and OH on the initial concentration of H_2 in the CO flame[51].

This method was used to determine the values of the rate constants for all the fundamental elementary reactions in rarefied flames of hydrogen and carbon monoxide. Using these constants, it was possible to calculate by means of an electronic computer the time dependence of the concentrations of H_2O and OH during the reaction and to compare the results with the experimentally observed (by the EPR method) changes in the concentrations of all the active particles with change in the flow velocity[52]. The flow velocity can be regarded as a quantity corresponding to the reaction time. Fig. 16 gives the calculated (on the left) and experimental (on the right) values of the change in the concentrations of O, H, and OH in the flame for a $CO + O_2 + 6\%$ H_2 mixture, and shows that the curves are of similar shape. The discrepancy of 20% in the absolute values of the concentrations ought to be attributed primarily to the difference in the conditions of reaction in a flow system (in which the experiments were carried out) and the static system assumed for the calculations. The discrepancy is evidently related chiefly to the fact that no allowance was made for the diffusion of atoms in the flow system.

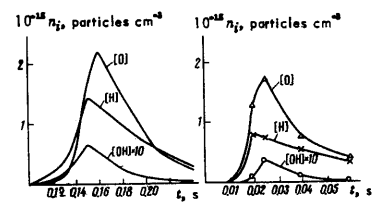

Fig. 16. Comparison of the time dependences of the concentrations of O and H atoms and OH radicals in the $2CO + O_2 + 6\%$ H_2 flame, obtained by calculation (on the left) and by experiment (on the right).[52]

TABLE. $H_2 + O_2$ mixture. p = = 2.96 mmHg, T = 993°K.

	H	O	OH
$10^{-16}(n_i)_{exp}$	6	0.8	0.16
$10^{-16}(n_i)_{theor}$	6.2	0.81	0.15

The calculated and experimental values of the H, O, and OH concentrations for an $H_2 + O_2$ mixture are given in the Table [53] (for the same interval). Such good agreement is probably accidental.

It is important to apply the EPR method to the study of the mechanism of other branched reactions, such as the combustion of phosphorus, sulphur, carbon disulphide, etc. Work in this direction has only begun to develop in our Institute.

I now wish to turn to work, carried out recently in our Institute, which has extended considerably our ideas on branched chain reactions and has shown that the number of reactions with a branched-chain mechanism is much greater than was previously supposed.

As already shown, branching is always associated with utilisation of the energy of the chemical reaction. At an early stage in the development of the chain theory [16,26], I imagined that branching takes place as a result of the formation, in the course of the reaction, of energetically excited particles, with an excess of vibrational or electronic energy, which could give up the excitation energy to molecules of the starting materials, leading to their dissociation into atoms and radicals.

Although these ideas gave a consistent and extremely general explanation for the course of branched chain reactions, the idea that excited particles take part in the branching was in fact left aside and until recently was almost never discussed in the literature.

In fact, according to modern physical theories, the simultaneous transfer of several quanta of vibrational energy when particles collide is extremely improbable.

Although the transfer of energy from electronically--excited molecules is possible, the probability of formation of electronically-excited particles in chemical reactions is generally very low.

Moreover, as we saw for the example of the oxidation of hydrogen, branching in this reaction takes place without excited particles, by the reaction $H + O_2 \rightarrow OH + O$ followed by $O + H_2 \rightarrow OH + H$. Thus it would seem that branching involving excited particles is impossible or unlikely. Nevertheless, in order to explain many phenomena observed in chain reactions, particularly in fluorination, it has in recent years become necessary to return again to the idea that a part in branching is played by energetically-excited particles, products of the exothermic elementary reactions of chain propagation.

An important addition to the old ideas, however, is the observation that the branching takes place not by the transfer of energy from an excited product molecule to a molecule of the original reagent, but by chemical reaction of the excited product molecule with the formation of atoms and radicals.

This chemical reaction may be either unimolecular decomposition of the excited molecule or its bimolecular reaction with a molecule of the original reagent.

I shall explain this with reference to several examples of fluorination, studied in Shilov's laboratory [54] in our Institute.

One of the stages in chain fluorination is the reaction

$$R + F_2 \rightarrow RF + F.$$

This reaction is so exothermic that the heat of the reaction sometimes exceeds the energy of the weakest bond in the RF^* molecule being formed. This molecule may therefore undergo unimolecular decomposition with the formation of atoms and radicals, leading to chain branching. For example, in the reaction of fluorine with methyl iodide, the chain is propagated according to the reactions

$$\text{(a)}\ F + CH_3I \rightarrow HF + CH_2I,$$
$$\text{(b)}\ CH_2I + F_2 \rightarrow CH_2FI^* + F.$$

The energy of the C–I bond in the CH_2FI^* molecule is less than the heat of reaction (b). The CH_2FI^* molecule may therefore dissociate immediately after its formation:

$$CH_2FI^* \rightarrow CH_2F + I$$

and the CH_2F radical reacts further with F_2:

$$CH_2F + F_2 \rightarrow CH_2F_2 + F.$$

When fluorine is mixed with methyl iodide, flames are produced immediately, even at very low pressures of the reagents. The probability of branching is apparently so high that the range of spontaneous reaction extends over all pressures attainable in practice.

The most important proof of this mechanism was provided by the discovery of high concentrations of I atoms in the reaction zone by the EPR method. It was shown that the concentration of I atoms reaches more than 10% of the concentration of original F_2. [55] At the same time there is almost no increase in temperature in the reaction zone (the reaction is carried out at very low pressures).

An interesting feature is that whereas in the gaseous phase the reaction of CH_3I with F_2 takes place very readily, and iodine is liberated in accordance with the proposed mechanism, fluorine does not liberate iodine from methyl iodide in solution in an inert oil. This means that in the reaction there is still in principle an upper limit, produced by loss of energy from the excited CH_2FI^* molecules on collision with surrounding molecules [56].

The kinetics of the reaction of fluorine with methyl iodide were recently calculated theoretically on an electronic computer on the basis of elementary stages including the proposed branching reaction. The data obtained for the composition of the products at different reagent ratios showed good agreement with experiment.

Another type of branching reaction is observed in the addition of fluorine to alkenes. For example, in the fluorination of tetrafluoroethylene, the C_2F_5 radical produced by the addition of an F atom to the alkene may undergo unimolecular decomposition with rupture of the C–C bond according to the reactions

$$F + C_2F_4 \rightarrow C_2F_5^* \rightarrow CF_3 + CF_2.$$

In actual fact, the overall heat of these two reactions is positive and amounts to ~ 20 kcal mole^{-1}, that is, the heat of the first reaction is sufficiently great to ensure subsequent dissociation of the radical. This leads to branching,

since the reaction of CF_2 with F_2 leads to the formation of two new F atoms:

$$CF_2+F_2\rightarrow CF_3+F,$$

$$CF_3+F_2\rightarrow CF_4+F.$$

A flame is readily produced when fluorine is mixed with tetrafluoroethylene. In accordance with the mechanism of a chain-branched reaction, very large concentrations of F atoms were detected in the reaction zone during the fluorination of C_2F_4.

If the excitation energy of the radical formed by the addition of the F atom to the alkene is insufficient to bring about its decomposition, branching may take place as a result of its subsequent reaction with F_2. The two successive reactions lead to the accumulation of sufficient energy for unimolecular decomposition of the resulting molecule, leading to branching.

Study of the gas-phase reactions of fluorine with tetrachloroethylene and dibromoethylene by the EPR method showed that very high concentrations of F and Cl atoms are formed in the reaction zone for the first compound, and very high concentrations of F and Br atoms in the second, confirming the suggestion that these reactions are branched chain reactions.

When the excitation energy is insufficient for unimolecular dissociation of the bond, branching may take place by the bimolecular reaction of an excited molecule of the reaction product with a fluorine molecule. The mechanism of formation of the radicals in the bimolecular reaction of valency-saturated molecules is less usual than unimolecular decomposition of a molecule, so that I would like to remind you of it at this stage.

In 1954, I suggested[29] that the activation energy of the endothermic reaction $RX + IR \rightarrow R + XI + R - q$ is close to the endothermicity q, and that its activation barrier is close to zero.

In reality, examination of the reverse reaction, in which two R radicals attack the XI molecule, indicates that its activation barrier is probably even smaller than that for the reaction $R + XI \rightarrow RX + I$, and we know that the activation barrier for reactions of radicals with molecules usually does not exceed a few kilocalories per mole. From the principle of detailed balance, it follows that the reaction of two molecules with the formation of two radicals will also have a low activation barrier.

These ideas were confirmed theoretically for the simplest reaction of two hydrogen molecules:

$$H_2+H_2\rightarrow H+H_2+H.$$

In addition, special experiments were carried out in our Institute to record radicals directly by the EPR method for those instances where the consumption of energy in the reaction is small.

Molecular fluorine is an example of a molecule for which bimolecular reactions of the type $F_2 + HR \rightarrow F + HF + R$ are particularly favourable, since they do not involve the consumption of a large amount of heat and may even be exothermic. Most chain fluorination reactions are initiated thus[57].

The activation energy of these reactions is apparently always less than the excitation energy of the molecules formed in the exothermic reactions of chain fluorination. Thus the same bimolecular reaction involving the formation of radicals from two molecules may also take place in the branching. The excited molecules of the product may react with F_2 without any additional activation energy, and this makes chain branching possible.

The simplest example is the fluorination of hydrogen. In this case, in the chain analogous to the Nernst chain for the reaction of hydrogen with chlorine: $F + H_2 \rightarrow HF + H$; $H + F_2 \rightarrow HF + F + 98$ kcal; the second reaction is exothermic to the extent of 98 kcal; this is more than twice the energy of the F–F bond.

The reaction

$$F_2+HF\rightarrow F.\,\boxed{.F\ldots H.}\,.F\rightarrow F+HF+F-38\ \text{kcal}, \qquad (I)$$

requires the consumption of 38 kcal, corresponding to the dissociation energy of fluorine. It may be assumed that the greater part of the HF* molecules formed in the elementary act $H + F_2 \rightarrow HF + F + 98$ kcal will carry the greater part of the energy of this reaction, for example, 60 kcal. This is much greater than the energy consumption and corresponds to the activation energy of process (I).

Thus here branching takes place by the reaction of an excited HF* molecule with F_2. The results of experiments confirm this suggestion. It was found that the range of spontaneous reaction between hydrogen and fluorine is bounded by clearly defined upper and lower pressure limits, and this is one of the characteristics of a branched chain reaction[58].

It should be noted that the reaction of fluorine with hydrogen has always appeared puzzling, and different authors have obtained extremely contradictory results.

Thus Eyring and Kassel[59] stated that although a mixture of hydrogen and fluorine explodes readily, they were able to prepare mixtures which were stable at room temperature and a total pressure of the reagents equal to atmospheric pressure.

Others (Grosse and Kirschenbaum[60]) attributed these results to experimental errors and showed that a mixture of hydrogen and fluorine always ignites at room temperature.

Consideration of the mechanism of chain ignition indicates that these contradictions are apparently due to the fact that the first authors worked with mixtures inside the ignition peninsula whereas the others worked outside this peninsula. It should also be noted that chain termination within the interior of the vessel takes place by reaction with oxygen, so that the position of the upper limit depends to a marked extent on the concentration of oxygen impurity in the fluorine.

In all these examples it can be seen that the excited molecules of the product do not transfer energy to the original molecules. At the same time it is this energy which is used directly in the chemical reactions leading to the formation of atoms and radicals which begin new chains, so that it brings about branching in this way. Thus the old ideas of the important part played by excited molecules in branching find application here. In this connection it may be noted that in any exothermic reaction of an atom or radical with a molecule, the molecule of the reaction product initially has considerable vibrational excitation energy. A number of instances have been recorded where the greater part of the energy of the reaction is concentrated in vibrational degrees of freedom of the molecule.

Data on the dissipation of vibrational energy show that this process takes place fairly slowly according to the same principle (of which mention was made earlier) — the low

probability of multi-quantum transitions — and, which is most important, for large vibrational quanta the transfer of even one quantum usually requires 10^3–10^4 collisions.

Even in the light of the above discussion, however, we would not expect that the probability of branching would be close to unity, that is, that the chain branching would be intensive. For a chain avalanche to develop, however, it is sufficient that there be more than one branching in the total length of the chain, that is, that the probability of branching be greater than $1/\nu$. Since the lengths of the main chains in such reactions are very great, at least from hundreds to tens of thousands, this order of probability of branching is sufficient to ensure a mechanism of developing chain avalanche.

The probability of branching is determined to a considerable extent by the energy liberated in the elementary reactions of chain branching. It is therefore not surprising that so many branched chain processes have been discovered in gas-phase reactions of molecular fluorine, for which the elementary reactions are particularly exothermic. We may justifiably say that chain gas-phase fluorination is almost entirely associated with the range of branched chain reactions.

Other branched-chain reactions which have been well studied are those involved in gas-phase oxidation by molecular oxygen. Here also, branching is brought about by chemical energy, as a result of the formation of stable H–O and C–O bonds, the O–O bond being comparatively weak. The elementary processes here are less exothermic than in fluorination, so that in the gaseous phase we have both branched reactions and unbranched (or degenerately-branched) chain reactions.

Branched chain reactions are not restricted to oxidation and fluorination, however. It is known, for example, that the decomposition of NCl_3 to N_2 and Cl_2 is a branched-chain process exhibiting an upper limit[61]. The energy for branching here is undoubtedly provided by the very high bond energy in the N_2 molecule formed (225 kcal mole^{-1}). In this connection, other reactions involving decomposition with the liberation of N_2 ought to be studied. It is possible that the example of NCl_3 is not an exception.

There are other examples of chain reactions where the chain-branching hypothesis explains the observed relationships. Thus clearly defined limiting phenomena are observed in the chlorination of acetylene, according to data obtained by Shtern (in this country) and Porter (in England). It should be noted that a particularly large amount of energy is liberated in the chlorination of acetylene compared with the chlorination of other compounds.

Finally, flashes of cold flame are observed at certain pressures and temperatures in the gas-phase nitration of alkanes, as shown by Shtern[62]. Here also, a unique part is played by the formation, in the course of the elementary exothermic act, of a product which contains an excess of energy and is therefore able to undergo unimolecular decomposition with the formation of radicals.

Thus the liberation of various forms of energy in chain reactions is used to accelerate these reactions, creating the conditions for an explosion. The energy concentrated in individual molecules in the form of vibrational or electronic excitation is used for branching in chain spontaneous ignition.

This principle of the utilisation of the energy of a chain reaction can be examined on a much wider basis and applied to molecules possessing considerable chemical energy. The intermediate formation of molecules, such as peroxides and aldehydes, which are not excited but possess a considerable reserve of chemical energy relative to the final reaction products (for example, CO_2 and H_2O), may give slow branching, as a result of their kinetic instability, a phenomenon which I have named "degenerate branching".

A very large number of gas-phase and liquid-phase oxidations are known to take place by a mechanism involving these degenerately-branched chain reactions.

In conclusion, I would like to report some results on unbranched polymerisation reactions at low temperatures.

In 1960–1961 Enikolopyan, Gol'danskii, and coworkers[63] in the Institute of Chemical Physics of the Academy of Sciences of the USSR, and later other workers[64,65], in other institutes in this country and abroad, showed that in the solid-phase polymerisation of a number of monomers (acrylonitrile, vinyl acetate, methyl methacrylate, formaldehyde, etc.) under the influence of electrons with an energy of 1.5 MeV, the reaction rate is independent of temperature over a wide range of irradiation temperatures (reaching 77°K). The dependence of the initial rate of polymerisation of acrylonitrile on the reciprocal of the temperature is shown in Fig. 17. It can be seen that the rate of polymerisation in the liquid phase decreases with decrease in temperature in accordance with a value for the activation energy E = 3000 cal mole^{-1}, but at the freezing point (m.p. = 355°K) the rate increases by a factor of 25 and subsequently remains unchanged down to 77°K. In other words, the effective activation energy in the solid phase is zero. Generally speaking, on going from the liquid to the solid phase, the rate may increase considerably (acrylonitrile and formaldehyde), decrease considerably (methyl methacrylate), or remain almost unchanged (vinyl acetate)[63]. The striking feature always, however, is that the rate is constant over a wide temperature range in the solid phase, from 77°K to the melting point.

It is now known that many other monomers polymerise in the solid phase with zero activation energy.

Other forms of polymerisation temperature dependence are also known. For example, almost no polymerisation of hexamethylcyclotrisiloxane (HMCTS) takes place in the liquid phase, but the rate of the process increases sharply as the freezing point is approached, reaches a maximum in the solid phase close to this point, and with further decrease in temperature the rate again decreases and gradually reaches a plateau which extends down to 77°K (Fig. 18).

In the polymerisation of phenylacetylene there is no sharp change in activation energy on passing through the melting point (Fig. 19)[63], and with decrease in temperature the reaction rate continues to decrease slowly, showing only a slight tendency to form a plateau close to 77°K.

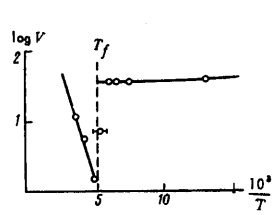

Fig. 17. Temperature dependence of the rate of polymerisation of acrylonitrile[63].

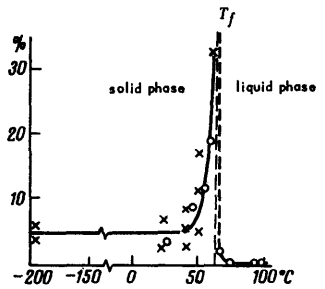

Fig. 18. Temperature dependence of the rate of polymerisation of hexamethylcyclotrisiloxane [63].

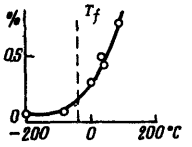

Fig. 19. Temperature dependence of the rate of polymerisation of phenylacetylene [63].

There remained doubts, however, as to whether the polymerisation takes place during the irradiation of the specimen or only during its subsequent treatment (de-freezing and isolation of the polymer). To investigate this problem, Barkalov and coworkers [66] used a special calorimeter to record the thermographic thawing curves as vinyl acetate, which had previously been irradiated at -196°C, was gradually heated. Two heat-liberation peaks were detected, close to the temperature of the phase transformation of vinyl acetate at -129°C and close to the melting point at -93°C. The same experiment was carried out without any irradiation. The thermographic curves obtained in the two experiments practically coincided, showing that no polymerisation takes place under the conditions of thawing. If polymerisation had taken place during thawing, the curves from the two experiments should have been different, because of the additional liberation of the heat of polymerisation in the first experiment.

Barkalov and coworkers [67], using a specially constructed differential thermocouple, made direct measurements of the heat liberated during the irradiation of acrylonitrile at -196°C, and hence the rate of polymerisation and the total quantity of heat liberated. It was found that the rate of polymerisation and the total quantity of heat are very close to those from the kinetic curves measured from the yield of polymer after thawing. This proved that the entire polymerisation took place at low temperature directly under the influence of the beam. Unfortunately, it was possible to carry out only a few of these experiments because of the destruction of the calorimeter.

In France, Bensasson and Dworkin [68], in Magat's laboratory, repeated the experiments with acrylonitrile and recorded the thermographic thawing curve. On the basis of these experiments they concluded that ~30% of the polymerisation takes place at -196°C during the irradiation and that the remaining ~70% takes place close to the phase transformation of acrylonitrile in the range from -140° to -100°C during the thawing.

Recently, Tal'roze and Kritskaya [69], in the Institute of Chemical Physics, carried out experiments on the polymerisation of acrylonitrile under slightly different conditions (a thin film of the frozen monomer was irradiated with electrons with an energy of 2 keV, whose path in the substance was much less than the thickness of the film and amounted to only 0.25 μm), using an extremely efficient adiabatic calorimeter. The measurement of the heat liberation was carried out directly under the beam. The experiments which they carried out in 1964 showed that rapid polymerisation takes place at the temperature of the phase transformation (-135°C) whereas, according to the latest data from the experiments which they continued, no reaction takes place at -196°C.

Thus the three groups of authors obtained contradictory results in the study of the polymerisation of acrylonitrile: the first group concluded that polymerisation takes place entirely at -196°C and not at all while thawing; the second group concluded that polymerisation under the beam takes place only partly at -196°C and partly after irradiation during the thaw, at the phase transformation; and the third group consider that the reaction takes place only at the temperature of the phase transformation and does not take place at all at -196°C. Further studies are obviously necessary in order to reach agreement.

Let us first of all consider the question of why irradiation leads to polymerisation in a solid. Irradiation in a solid (as in a liquid or gas) leads to the production of free radicals, electrons, and ions, which naturally may act as the initial centres for the development of chain polymerisation. In a solid, however, all these particles have a very low mobility (the electrons have a low mobility since they may be captured fairly rapidly by suitable traps). This was confirmed by direct experiments in which the monomers were replaced by substances incapable of undergoing polymerisation. The concentrations of free radicals here could be measured directly by the EPR method. It was found that the concentration of free radicals remains unchanged with time, both at -196°C and also with increase in temperature up to the temperature of the corresponding phase transformation, or, in the absence of such a transformation, up to temperatures comparatively close to the melting point. Under these conditions free radicals recombine rapidly and disappear.

Thus as the temperature of the phase transformation is approached, the mobility of the free radicals increases very rapidly. The same is true of electrons. Buben and Nikol'skii [70] in our Institute observed that specimens previously irradiated at -196° emit light at all phase transformations as the temperature is raised but emit almost no light in the intervals between the phase transformations. This takes place so clearly that they put forward this method (radiothermoluminescence) as an extremely effective and simple method for determining the temperatures of all the phase transformations. It is evident that the electrons captured in various types of trap are liberated and recombine with ions at the temperatures of the phase transformations. An interesting feature is that the phase transformation makes the electrons mobile. It is clear that the sudden rearrangement of the atoms at the phase transformation may create conditions favourable for diffusion processes and for processes of electron transfer.

It is therefore natural that the polymerisation of monomers, initiated by free radicals, ions, and electrons formed on irradiation, will take place particularly readily in the regions of a phase transformation.

It is thus difficult to suppose that polymerisation may take place at temperatures below the phase transformations in solid monomers after irradiation. However, polymerisation directly in the beam can in principle occur at any temperature, no matter how low, since the free radicals, ions, and electrons are produced in a "hot state" so that they may bring about initiation of the growth of the polymer chain. Theoretically, therefore, the possibility of polymerisation at extremely low temperatures is not excluded.

Here, however, it is necessary to make allowance for another feature. If the growth of the polymer chain is to take place rapidly with an activation energy $E = 0$, the monomer molecule being attached must be suitably placed, relative to the terminal radical or ion of the growing polymer chain. In phase transformations, when the molecules can move, this orientation may take place readily. At lower temperatures in the solid, the appropriate orientation takes place with difficulty so that the polymerisation appears to be associated with a fairly high activation energy. In each unit stage in the growth of the polymer chain, however, energy amounting to 14–20 kcal mole^{-1} is liberated. This energy is sufficient to ensure mobility of the neighbouring monomer molecule, that is, to orientate it into the required position. Thus in principle, reaction without activation energy is possible no matter how low the temperature.

Finally, one other important feature must be noted. Polymerisation is accompanied by an increase in the density of the substance, since the distance between the carbon atoms in two neighbouring molecules of the monomer C=C C=C C=C is greater that that in the polymer C–C–C–C–C–C–. Thus the polymer chain developing in the monomer is elongated. In the solid state at low temperatures where there are no phase transformations, the contraction of this chain is very difficult. The chain is frozen in the solid monomer. The elongated molecule may thus be thermodynamically unstable. Polymerisation in the beam is then impossible at low temperature.

It is not excluded that for monomer molecules situated along defects, for example, on the surface of fine crystallites, reaction with contraction of the resulting polymer chain may have a fairly high probability, or at least a probability which is immeasurably greater than that in the bulk. This may be the reason for the so-called "limiting" of the yield of polymer under the beam, observed by Kargin and coworkers[71]. "Limiting" of the yield of polymer is observed from liquid nitrogen temperature to the phase transformation temperature, the maximal yield under the beam being measured in percentages of the total concentration of original monomer (gradually increasing with the temperature of irradiation), whereas Barkalov and coworkers[66] have shown that the "limitation" of the polymer yield is removed by irradiation at the temperature of the phase transformation and above, that is, here the polymerisation may take place throughout the entire volume.

Let us now turn to the most important problem of how the chain propagation reaction in the solid phase can take place with zero activation energy.

Polymerisation processes in the liquid phase, which have been fairly well studied, are of two kinds.

1. Radical Polymerisation

Radical polymerisation occurs under the influence of free radicals A$^{\cdot}$, obtained either by irradiation with light of appropriate wavelength or by the spontaneous decomposition of traces of peroxide mixed with the liquid monomer or its solution:

$$A^{\cdot}+C{=}C \rightarrow A{-}C{-}C^{\cdot},$$
$$A{-}C{-}C^{\cdot}+C{=}C \rightarrow A{-}C{-}C{-}C{-}C^{\cdot}, \text{ etc.}$$

For radical polymerisation in the liquid phase the activation energy of chain growth amounts to 3–5 kcal mole^{-1}. There are no grounds for considering that in the solid this energy can be equal to zero. Radical polymerisation therefore cannot explain the temperature dependence of the reaction rate which we observed, if it were to reflect accurately the course of the reaction under the beam. Closer examination of the suggestion that energy is liberated at the moment a chain grows one unit shows that it cannot explain the fact that the activation energy is equal to zero or the production of long purely energetic polymerisation chains.

2. Ionic Polymerisation

This type of polymerisation takes place in particular under the influence of the acids XI. Ionic polymerisation can be represented schematically:

$$I^{+}+C{=}C \rightarrow I{-}C{-}C^{+}, \quad \text{chain initiation}$$
$$I{-}C{-}C^{+}+C{=}C \rightarrow I{-}C{-}C{-}C{-}C^{+}, \quad \text{chain propagation}$$
$$I{-}C{-}C{-}C{-}C^{+}+C{=}C \rightarrow I{-}C{-}C{-}C{-}C{-}C{-}C^{+}, \text{ etc.}$$

Despite the large number of ionic polymerisation processes, the mechanism of ionic polymerisation is insufficiently clear. It is suggested that the $C{-}C^{+}$ ion is accompanied by a counter-ion Z, so that it is correct to represent the terminal group of the growing polymer in the form $I{-}C{-}C{-}C{-}C^{+}\ Z^{-}$ + C=C. When the next monomeric molecule is attached, the positive charge is transferred to the terminal carbon atom of the polymeric radical formed. The counter-ion moves simultaneously to the same carbon atom $I{-}C{-}C{-}C{-}C^{+}\ Z^{-}$.

In a liquid medium this movement is difficult, particularly if the Z^{-} ion is solvated, and this explains the activation energy (~3000 cal mole^{-1}) for ionic polymerisation. Without these complicating features (the presence of the counter-ion, solvate sheaths, etc.), for example, if the polymerisation took place in a vacuum, the actual process of attachment of a monomer with "overflow" of electrons, and hence the movement of the positive charge along the growing carbon chain, would probably take place without any activation energy. Justification for this suggestion may be provided by the experiments of Tal'roze[72] in the Institute of Chemical Physics and of Stevenson[73] in the USA, who observed various reactions of ions with molecules in a vacuum, in the chamber of a mass spectrometer. It was found that for almost all exothermic reactions of this type the activation energy is zero. Moreover, American[74] and Canadian[75] workers have recently shown that in the ion sources of a mass spectrometer at comparatively high pressures, ionic polymerisation reactions take place to give chains consisting of up to 8 units, with an activation energy almost equal to zero. In solutions, however, ionic reactions always require an activation energy because of the presence of solvate sheaths and interaction with the ions of opposite charge. This might explain the existence of activation energy in the liquid phase and its absence in the solid phase.

In a solid, particularly at low temperature, irradiation with fast electrons or γ-rays, in my opinion, produces a situation which is much closer to the conditions of experiments in the chamber of a mass spectrograph than to the conditions of chain growth in the liquid phase. Here, two features are important. The first is the production, in the solid or in the liquid under the influence of ionising radiation, of secondary electrons with an energy of 10–30 V. These electrons move out from the ion to distances which are considerably greater than the radius of the influence of any existing coulombic forces. They are then captured by an impurity or trap of some sort. The difference between the liquid and the solid (without the phase transformation) is that in the liquid (and also in the phase transformation), the mobility of the ion or the electron combined with the trap is sufficient to ensure rapid approach of the ion and electron with the formation of an ion pair. As we have already noted, the electrostatic forces holding this pair together prevent the growth of the ionic polymer chain without activation. In the solid, however, particularly at low temperature, both the ion and the electron captured by the trap are almost immobile, so that here, as in the chamber of the mass spectrograph at low pressures, the ion may bring about growth of the polymer chain without any activation energy.

A second possibility is that a comparatively fast electron with an energy of ~ 10–30 V geometrically does not go anywhere, but enters the semi-conductivity band and with the charge of the ion forms an electron–hole pair, which may exist for a fairly long period in the form of an exciton, moving in the solid with almost no resistance. The moving particle may then bring about rapid polymerisation. The polymer chain will thus be as it were the track of the motion of the exciton, which is naturally retarded by the necessity for movement of the carbon atoms of the polymer chain, corresponding to hundredths of an Ångström unit. In this instance the rate of movement of the exciton, and the rate of growth of the polymer chain, have values of $\sim 10^5$ cm s^{-1}. Chain termination will be determined by disappearance of the exciton.

As we saw above, until recently all experimental data indicated that the polymerisation of a number of monomers takes place completely or for the most part directly under the beam at low temperatures down to -196°C. Recently, workers in our Institute[76], Abkin[77] in the Karpov Physical Chemistry Scientific Research Institute, and Magat in France began experiments to study polymerisation at liquid helium temperatures. It has already been found that after irradiation at the temperature of liquid helium, the monomers after de-freezing give a polymer in yields close to those observed with irradiation in liquid nitrogen. Here also, however, we are still left with the problem of whether the resulting polymer is produced during thawing.

If polymerisation directly at 4.2°K were firmly established, the only explanation would be the possibility of energetic polymerisation chains, and this would require the introduction of essentially new theories into chemical kinetics, for example, the introduction of the exciton hypothesis. This might open a new page in kinetics.

As we have seen, however, new experiments which contradict this suggestion have recently been carried out. They lead to the conclusion that polymerisation of acrylonitrile under the beam does not take place at -196°C. If future confirmatory experiments by all workers show that this is indeed so, at first sight all this will naturally seem much more trivial. The state of a substance in a phase transformation is analogous to the liquid state or to the state of the solid monomer close to the melting point.

If we think carefully, however, the situation here is not so simple either. Thus in the irradiation of acrylonitrile and formaldehyde, on going from the liquid to the solid monomer, that is, at a temperature only just above the freezing point, the reaction rate in the solid state is greater than that in the liquid state by a factor of 25 for the first and by a factor of 100 for the second. It must be remembered that there are also instances, for example, the radiation polymerisation of HMCTS, when almost no reaction takes place in the liquid phase on irradiation, whereas in the region of the freezing point the rate of conversion immediately reaches very high values, gradually decreasing with further decrease in temperature. Many other similar facts could be cited.

Thus the solid state may in many instances facilitate polymerisation. It is often said that in the solid state intermediate polymeric species may be produced in the form of chains of monomer molecules with correct angular orientation relative to one another, close to that corresponding to the disposition of the C atoms in the polymer chain. In other words, we have as it were the formation of characteristic "polymonomeric" complexes, preceding the polymerisation and facilitating its development after initiation, when one of the monomer molecules is ionised. This situation cannot be realised in a readily mobile liquid monomer. As noted by Kargin[78], in the solid state close to the melting point or in a phase transformation where limited mobility is possible, the most favourable conditions are created for optimal mutual arrangement of the molecules and the production of this type of association. This hypothesis also, however, has not yet been confirmed by direct experiment.

Moreover, another important feature must be noted here. Until now no direct measurements have been made of the rate constant for chain growth at the temperatures of phase transformations (in particular close to the melting point). Thus basically we do not know whether chain growth takes place here with or without activation energy. It must be borne in mind that correct arrangement of the monomer molecules does not in itself eliminate the activation energy, which should then be partly the same as that for the liquid phase (since in the liquid phase the molecules "select" the reaction path corresponding to the lowest activation energy). If the activation energy close to the phase transformations and at the melting point is to be lower than that in the liquid phase, or in the limit equal to zero, we require not only correct arrangement of the monomer molecules, but also the formation of appropriate "polymonomeric" complexes. A fairly wide range of phenomena are now known, in which complex formation may facilitate a reaction considerably, not only as a result of an increase in the pre-exponential term, but also as a result of a decrease in the activation energy. It is possible that on appropriate initiation, almost instantaneous transformation of the "polymonomeric complex" into a polymer chain may occur.

In conclusion I would like to describe some quite different experiments which also indicate, however, that extremely rapid polymerisation processes take place even in the absence of any special chemical chain initiators. Dremin in our Institute has developed an extremely interesting method of studying chemical reactions and phase transformations under the influence of shock waves which are excited using explosives and are propagated through

the solid monomer. Pressures varying from 10 000 to hundreds of thousands of atmospheres are produced in the front of the shock wave. It has been found possible to obtain much information on chemical transformations from the form of the shock front. Dremin has recently extended this method considerably by finding a technique for preserving specimens subjected to the action of the shock wave without allowing their breakdown by the action of the wave. In addition to providing the information obtained by studying the shock front passing through the starting material being studied, this has made possible direct observation of the transformations which occur in it.

A number of results have already been obtained by this method and published. Here, however, I shall mention only the polymerisation processes studied by this method by Barkalov, Gol'danskii, Dremin, Tal'roze, Yampol'skii, and their coworkers[79,80]. It was found that extensive polymerisation of many monomers takes place in the solid state under the influence of a shock wave. Study of the form of the front shows that the polymerisation process takes place in the front of the shock wave in a time interval less than 10^{-8} s. The calculated temperature of the monomer in the shock wave does not exceed 200–300°C. We know that almost no polymerisation takes place at these temperatures in the absence of initiators. We may also note that the yield of polymer remained unchanged when the monomer was cooled to liquid nitrogen temperature, so that we are here dealing with a pressure pulse. Thus the chief role in the polymerisation is played by pressure. The curves giving the form of the shock front indicate that this extremely rapid polymerisation takes place when the pressure in the shock front reaches a value at which the density of the monomer becomes close to that of the polymer under ordinary conditions. This is natural, since at this density the distance between the carbon atoms in the C=C C=C monomer becomes almost equal to the distance between two C atoms in the polymer C–C–C–C. Here, however, the movement of electrons from the C=C C=C groups in the monomer into the C–C–C–C groups in the polymer apparently does not require any activation energy when initiation occurs because the shock wave reduces the marked friction in the specimen.

THE INFLUENCE OF COORDINATION ON THE REACTIVITY OF ORGANOMETALLIC COMPOUNDS

O. Yu. Okhlobystin

CONTENTS

I. Introduction 17
II. Influence of coordination on the physical properties of bonds 18
III. Chemical consequences of coordination 19
IV. Factors which determine the character of coordination 21

I. INTRODUCTION

In attempting to answer the question implied in the title, it must first be recognised, as do Dewar and Thompson [1], that estimates of reactivity generally follow two main directions on the basis of: (a) different charge densities, bond orders, polarisability, etc.; or (b) a different in the energies of the reactants and of the transition state. From the standpoint of strict kinetics, only the second approach is legitimate. All constructs which ignore transition states are incorrect in principle. However, the second approach encounters serious theoretical difficulties [1], and in organometallic chemistry only the first has yet been practical, the approach of coarse correlations, giving only an approximate idea of the comparative reactivity of various compounds. The present work is not an exception in this sense.

The various reactivity series for the metal alkyls [2] are widely recognised as too generalised. It is evident that such series cannot be applied to reactions which differ in nature and in mechanism. In speaking about the comparative reactivity of organometallic compounds in a series of different reactions these reactions must be divided into groups similar in some features which play a decisive part. Practice shows that to a first approximation two types of organometallic reaction must be distinguished — additions to multiple bonds and substitutions. Neglect of these simple considerations necessarily leads to confusion both in the comparative evaluation of the reactivity of different compounds, and also in the evaluation of the influence of different complex-forming media on the activity of the same compound. To avoid this widespread error mainly substitutions will be considered.

Furthermore, following the now commonly accepted point of view, it must be assumed that in most such reactions the breaking of the metal–carbon bonds is heterolytic

for the rather active metals (Li, Mg, etc.). The energy of the heterolytic breaking of a non-ionic bond $A-B \rightarrow A^+ + B^-$ is greater than the energy of its homolytic dissociation, since to bring about such breaking it is necesary to do additional work in polarising the bond[3,4]:

$$D_H = E + I_A - E_B,$$

where D_H is the energy of heterolytic breaking of the bond A–B, E the bond energy, I_A the ionisation potential of A, and E_B the electron affinity of B. Eaborn[4] successfully used this approximation to evaluate the reactivity of different $\rangle$Si–X bonds in heterolytic substitutions of X. The application of this to metal–carbon bonds has apparently not been attempted.

The energy of heterolytic bond-breaking is extremely dependent on the solvolytic capability of the medium. With ionic bonds, solvation is the motive force for the destruction of the lattice during the dissolution of a substance in an ionising medium. With non-ionic, but sufficiently polar, bonds ionisation again cannot be neglected, but the energy of heterolytic breaking of the bond in a strongly solvating medium should obviously be less by some quantity proportional to the solvating ability of the medium, which is connected with the additional polarisation of the bond under the action of the solvent.

With organometallic compounds which contain rather polar bonds (M–C, M–H, M–Cl, etc.) this means that strong solvation should bring about additional polarisation of these bonds. However, the nature of this solvation is important.

Two fundamental types of solvating interaction must be distinguished[5,6]. Firstly, solvation can be a purely electrostatic interaction of the polar molecules of the solvent with molecules of the solute without the formation of any chemical bonds between them. Secondly, solvation can occur through bonds which have a donor–acceptor nature. Finally, there is specific solvation[5]. Electron-deficient cations form coordination complexes with solvents which possess electron-donor atoms; anions tend to form hydrogen bonds using the partially protonated hydrogen atoms of the solvent. In both instances we are concerned with specific solvation. Solvents which do not contain hydrogen atoms capable of forming hydrogen bonds are termed aprotic[5]. They are incapable of the specific solvation of anions but if electron-donor atoms (usually oxygen) are present they form coordination complexes with cations. After the appearance of Parker's review[5], the view became widely accepted that in a polar aprotic solvent medium the nucleophilic activity of anions in bimolecular substitutions (S_N2) of the anion–dipole type is greatly increased.

Among the factors which determine the increase in the reactivity of anions in S_N2 reactions are the following[5-7]: (1) the weak solvation of the anion, which makes it mobile in comparison with a strongly solvated counter-ion: (2) the breakdown of ion pairs (or ionic aggregates) due to the strong solvation of cations with the formation of "free" anions; and (3) the polarisation of a transition state, leading to the separation of the charges.

Most organometallic compounds do not have an ionic structure and do not form independent carbanions in solution. The validity of applying the concepts of the accelerating action of dipolar aprotic solvents on S_N2 reactions of anions to the reactions of organometallic compounds is not so obvious in this connection. It is characteristic that Parker[5] included in his review only certain reactions of alkali enolates having an ionic structure; he did not consider true organometallic compounds.

Tchoubar[6], in referring to the earlier work of Hammett[8], emphasises that an increase in the ionicity of a bond takes place precisely as a result of donor–acceptor interaction and that the characteristics of the medium such as dipole moment, dielectric constant, etc. play only a subordinate part in this increase. The conditions for dissociation into independent ions is here no longer obligatory, however, and Tchoubar in effect did not consider organometallic compounds.

Nevertheless, as will be shown below, the effect of aprotic electron-donor solvents and complex-forming anions in this field of chemistry is pronounced[9] and, with the reservations made at the beginning, of a rather general character.

II. INFLUENCE OF COORDINATION ON THE PHYSICAL PROPERTIES OF BONDS

In the specific solvation of an organometallic cation or of the positive end of a dipole there is a change in the valence state of the metal atom, which is inevitably accompanied by a change in the spatial configuration of the molecule, the interatomic distances, valence angles, etc. Digressing from that, the role which a dipolar aprotic solvent plays in a transition state nevertheless means that coordination facilitates an increase in the ionicity of the bonds in the initial compound. For ionic crystals this principle was formulated and generalised by Pauling[10]. It is supported by many experimental data, most of which relate, unfortunately, to inorganic materials.

A comparison of the quadrupole frequencies of ^{35}Cl in tin tetrachloride (24.296, 24.226, 24.140, and 23.720 MHz) and of the $SnCl_6^{2-}$ anion (15.61–15.73 MHz, depending on the nature of the cation) shows that chlorine is considerably more ionised in the complex anion than in the tetrachloride[11], which is consistent with the Mössbauer spectral data[12]. In the formation of the trimethyltin chloride complex with pyridine the Sn–Cl bond (2.37 Å) is lengthened (2.43 Å), and the complex has a planar configuration of the $(CH_3)_3Sn$ group, while the chlorine and nitrogen atoms are located at the vertices of a trigonal bipyramid[13,14]. The example of dibutyltin dichloride showed that the quadrupole splitting of the γ-transition of ^{119m}Sn depends strongly on the nature of the complex-forming solvent and its mole fraction[15]. It is characteristic that the increase in quadrupole splitting is continued up to a solvent : $(C_4H_9)_2SnCl_2$ molar ratio of 3, that is, even after the formation of an equimolecular complex. The polarisation of the Sn–Cl and Pb–Cl bonds in the formation of complexes of trialkyltin chlorides and trialkyl-lead chlorides with *NN*-dimethylacetamide and *NN*-dimethylformamide, with production of a bipyramidal structure also follows from the infrared and NMR spectra of these complexes[16].

A study of the proton resonance spectra of triethylaluminium, triethylgallium, and their ether addition compounds led Brownstein and coworkers[17] to conclude that in the complexes with ether the metal–carbon bonds were more "antibonding" in comparison with the initial metal alkyls. The decrease in the "electronegativity" of the aluminium atom on going from the trialkylaluminiums to complexes of the $MAlR_4$ type was also noted on the basis of their NMR spectra[18]. It is interesting that the tendency of the aluminium atom in such complexes to coordination is

not exhausted, and when they are dissolved in ether additional coordination with the ether takes place, accompanied by distortion of the AlR_4^- tetrahedron [19].

An increase in the bond length, which is usually associated with an increase in their ionicity [10], also follows from purely structural data. Thus the B–F bond, equal to 1.30 ± 0.02 Å in boron trifluoride is extended to 1.38–1.40 Å in the complexes of boron trifluoride with amines [20]. The bonds of mercury with halogens are lengthened on increasing its coordination number [21].

III. CHEMICAL CONSEQUENCES OF COORDINATION

The marked influence of electron-donor aprotic solvents on the course of various organometallic reactions has been repeatedly noted by many authors; however, the most varied assumptions have been made to explain these observations and until recently there has been no general approach to the appraisal of the role of the complex-forming media. The matter is also complicated by the fact that the same solvent often behaved differently towards different solutes. It is sufficient to mention that the addition of alkyl-lithiums to multiple bonds is often accelerated by complex-forming ethers, which is connected with the increase in the polarity of the C–Li bond in a complex with an ether [22,23], whereas the trialkylaluminium–ether addition compounds add to the alkenes with greater difficulty than the original alkylaluminiums [24]. Grignard reagents give lower yields of addition products with ketones in tetrahydrofuran [25], but they are especially effective in alkylation reactions in tetrahydrofuran [9]. Such behaviour often led to conflicting judgements. It is characteristic, for example, that in the celebrated monograph of Rochow and coworkers [2] it is stated directly that "under the influence of solvation bond polarity is decreased, thanks to the concentration of electrons with the electronegative donor atom of the solvent"†. The authors consider this question in direct association with the decrease in reactivity of the organometallic compounds during a fall in the polarity of the metal–carbon bond. However, analysis of the facts that have been accumulated at present shows this conclusion to be incorrect.

The increase in the polarity of metal–carbon bonds during coordination at the metal atom is confirmed by the acceleration of the heterolytic reactions of substitution and exchange in complex-forming media.

Ziegler [26] notes an increase in the rate of the "normal" Wurtz reaction:

$$RLi + R'X \rightarrow RR' + LiX,$$

in ether in comparison with a hydrocarbon medium and explains this phenomenon by the greater "ionising" ability of the ether. Eastham and Gibson [27] found that the rate of the reaction

$$C_4H_9Li + RBr \rightarrow LiBr + C_4H_9R,$$

is 10^3 times greater in the presence of ether [than in hexane (Ed. of Translation)], which the authors connect with the conversion of the hexameric butyl-lithium into a dimer on coordination with ether. According to Gilman and coworkers, the metallating ability of the alkyl-lithiums is higher in ether than in a hydrocarbon [28] and higher in tetrahydrofuran than in ether [29,30]. Gilman notes that the ease of metallation of fluorene and its analogues by the alkyl-lithiums in various ethers is proportional to the instability of their solutions in the ether concerned, but does not link this effect with a difference in the solvating ability of the solvent.

In recent years it has been found that a sharp increase in the nucleophilic activity of the alkyl-lithiums in substitutions also takes place in the formation of complexes with amines. Thus the complexes of butyl-lithium with *NNN'N'*-tetramethylethylenediamine and 1,4-diazobicyclo[2,2,2]octane metallise not only toluene, but also benzene more readily than butyl-lithium itself [31]; the reaction takes place even at room temperature.

Brown and coworkers [32] explain the increase in the reactivity of alkyl-lithiums in the presence of Lewis bases by a decrease in the degree of association of the initial compound. Actually, these authors showed that in the action of triethylamine on hexameric ethyl-lithium the latter dissociates into three molecules of coordinated dimer. The decrease in the degree of association of alkylmagnesium halides in a strongly solvating medium [33–35] is accompanied by their partial symmetrisation [34].

The general occurrence of a decrease in the degree of association is frequently considered to be the main reason for an increase in the reactivity of organometallic compounds. It is clear, however, that despite their plausibility, these concepts do not satisfactorily explain the nature of the action of the complex-forming media, since solvents capable of coordination markedly increase the reactivity of even those compounds which are monomers themselves (R_2Zn, [36] R_2Cd [37]).

The addition of Lewis bases to organolithium compounds increases their activity also in additions to multiple bonds [22,38–42].

It becomes more and more evident from recent data that the use of strongly solvating solvents accelerates nucleophilic substitutions of organomagnesium compounds. Thus the ease of the "normal" Wurtz reaction:

$$RMgX + R'X \rightarrow RR' + MgX_2,$$

is proportional to the solvating ability of the ether used as the solvent [43]. Whereas in diethyl ether the "normal" Wurtz reaction is brought about only for the allyl, benzyl, and greatly branched tertiary radicals [44], in dimethoxyethane the simplest aliphatic radicals readily undergo it [43].

According to Normant [45] the solvating ability of the medium ("basicity", in the expression of the author) is one of the deciding factors which determine the possibility of Grignard reactions with the halogen derivatives of alkenes and alkynes. The condensation of Grignard reagents with halogenoacetylenes:

$$RMgBr + Br{-}C{\equiv}CR' \rightarrow R{-}C{\equiv}C{-}R' + MgBr_2,$$

takes place only in a medium of hexamethyltriamidophosphate [hexamethylphosphoric triamide (Ed. of Translation)], but in less solvating solvents (ether or tetrahydrofuran) it does not occur. On the other hand, the Wurtz reaction with participation of unsaturated Grignard reagents and propargyl bromides occurs smoothly even in tetrahydrofuran [45].

† Reference 2, page 24 states: "Normally the effect of solvation is to decrease bond polarity by contribution of electrons from the electronegative donor atom of the solvent (the oxygen of ether, etc.) to the metal, but solvolytic dissociation into ion pairs also may occur". (Ed. of Translation).

Whereas a Wurtz reaction between heptynylmagnesium bromide and propargyl bromide catalysed by copper(I) chloride takes place in 115 h at 37° in diethyl ether, it needs only 1.5 h at the same temperature in tetrahydrofuran. The times for the analogous reaction with 1-chloropentyne are 65 h in ether and 1 h in tetrahydrofuran[46].

For the usual Grignard reagents in diethyl ether an exchange of radicals of the type:

$$RMgX+R'X \rightleftarrows R'MgX+RX,$$

is not characteristic and is observed only in certain specific instances. In a medium of the more solvating ethers even the simplest aliphatic and aromatic halides also take part in the exchange reaction[47-49]. The degree of exchange in the system n-$C_5H_{11}MgBr$ + CH_3I (0°, 1 h) in diethyl ether, diethoxyethane, ethoxymethoxyethane, diglyme, tetrahydrofuran, and dimethoxyethane, is respectively 5.7, 6.6, 12.7, 15.8, 17.5, and 38.5%. Aromatic iodides in dimethoxyethane medium exchange 52-75% after 3 h, giving the corresponding arylmagnesium halides[47].

Significantly, the completely unsolvated organomagnesium compounds which are obtainable in hydrocarbon medium[50] react with alkyl halides by a free radical mechanism[51]; the reaction products RMgX + R'X here are the products of the conversion of the free radicals R' and R''. The very nature of the breaking of the C–Mg bond (homolytic or heterolytic) in RMgX + R'X systems is thus determined by the nature of the solvent.

The accelerating action of electron-donor aprotic solvents appears especially clearly in metallating reactions. The simple replacement of ether for tetrahydrofuran makes the formation of Iotsich complexes strongly exothermic and rapid[9]. Metallation by alkylmagnesiums takes place very readily in hexamethyltriamidophosphate[52,53], where fluorene, indene, triphenylmethane, etc. are smoothly metallated. The usual Grignard reagents metallate fluorene only at 130°, but triphenylmethane is not metallated at all. Evidently, hexamethyltriamidophosphate ("hexametapol") $[(CH_3)_2N]_3PO$ is still the best solvent for metallating reactions: other complex-forming solvents are inferior to it in accelerating action[53].

Kinetic data on the metallation of hex-1-yne by ethylmagnesium bromide[33,54] are somewhat contradictory. On the one hand, replacing ether by tetrahydrofuran somewhat accelerates the reaction, but at the same time a reaction which is bimolecular in ether becomes termolecular[33]. However, in the presence of a tenfold excess of the hexyne the rate of its metallation by ethylmagnesium bromide falls with increase in the solvating ability of the ether in which the reaction is carried out[54]. It is possible that this exception from the general rule is due particularly to the presence of a large excess of acetylene, which changes the mechanism of the reaction.

It has been repeatedly noted that many alkylations of element–halogen bonds by Grignard reagents in a medium of tetrahydrofuran take place more rapidly and with better yields of organoelemental compounds than in ether[55-58]. This phenomenon, however, is frequently explained by the greater dissolving power of tetrahydrofuran or the possibility of working at a higher temperature. In reality, these factors hardly seem decisive; the main reason for the accelerating action of tetrahydrofuran is that in relation to a Grignard reagent it is a better complex-forming agent than ether. Really, dialkylthallium halides are alkylated to trialkylthalliums only by organolithium compounds and the usual Grignard reagents (in ether) are unsuitable for this purpose. In tetrahydrofuran the reaction takes place readily even at 0–5°; for example, triethylthallium is thus obtained[9,59]:

$$(C_2H_5)_2TlCl+C_2H_5MgBr \xrightarrow[0-5^\circ]{THF} (C_2H_5)_3Tl.$$

The sterically hindered alkylation of trichlorosilane by 1-naphthylmagnesium bromide in ether does not give any tri-(1-naphthyl)silane[60]: in tetrahydrofuran the latter is obtained with a yield < 30%,[33] and in an even more solvating ether – dimethoxyethane – the reaction proceeds under mild conditions and gives trinaphthylsilane with a yield > 70%:[9]

$$HSiCl_3+3\alpha\text{-}C_{10}H_7MgBr \xrightarrow{\text{dimethoxyethane}} (\alpha\text{-}C_{10}H_7)_3SiH+3MgBrCl.$$

The relatively inactive phenylethynylmagnesium bromide alkylates chlorotrimethylsilane only at 100° (after removal of ether)[60]; however, in tetrahydrofuran, and even more in dimethoxyethane, the reaction is exothermic at room temperature and the yields of trimethyl(phenylethynyl)silane are 47 and 77% respectively[9]:

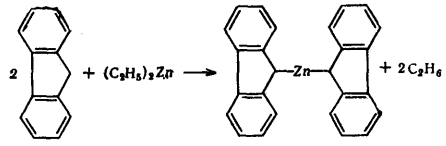
$$(CH_3)_3SiCl+C_6H_5C{\equiv}CMgBr \rightarrow C_6H_5C{\equiv}CSi(CH_3)_3+MgBrCl.$$

In using dimethoxyethane as a solvent phenylmagnesium bromide can be used successfully instead of phenyl-lithium for obtaining pentaphenylantimony[9]:

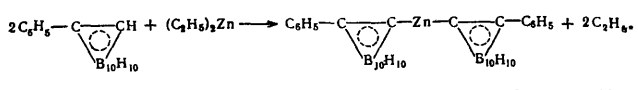
$$(C_6H_5)_3SbCl_2+2C_6H_5MgBr \xrightarrow{\text{dimethoxyethane}} (C_6H_5)_5Sb+2MgBrCl.$$

Recently Ingold[61] reported that in the presence of dimethyl sulphoxide dialkylthallium halides are alkylated even by organomercury compounds.

As already noted, with alkyl-lithiums the coordination at the lithium atom facilitates both substitutions and also addition to multiple bonds. With organomagnesium compounds things are otherwise. Strongly solvated Grignard reagents give worse yields of addition products in reactions with ketones[25] and nitriles[62]; in some other instances only slight influence of solvation was observed[63].



With organozinc compounds even such "classical" dipolar aprotic solvents as dimethylformamide and dimethyl sulphoxide can be used as strongly solvating media. In a non-complex-forming (hydrocarbon) medium diethylzinc hardly metallises phenylacetylene at all, whereas in hexamethyltriamidophosphate the reaction is violent[36]:



$$2C_6H_5C{\equiv}CH+(C_2H_5)_2Zn \rightarrow (C_6H_5C{\equiv}C)_2Zn+2C_2H_6.$$

The complex-forming solvents are arranged in the following series according to their accelerating action on this reaction (under the formula is given the time needed for half the theoretical amount of ethane to be liberated, in seconds)[36]:

$$\underset{\infty}{[(CH_3)_2N]_3PO} > \underset{200}{(CH_3)_2SO} > \underset{270}{(CH_3)_2NCHO} > \underset{7200}{CH_3OCH_2CH_2OCH_3} > \underset{\infty}{n\text{-}C_7H_{16}}.$$

Use of hexamethyltriamidophosphate allows even fluorene and phenylbarene to be readily metallised by diethylzinc:

The influence of electron-donor solvents on the reactivity of diethylcadmium is as perceptible again[37]. The

time for the half liberation of the theoretical amount of ethane in the reaction of diethylcadmium with phenylacetylene is 3 h 50 min in dimethylformamide, 1 h in dimethyl sulphoxide; it is characteristic that the difference in the accelerating action of these solvents for diethylcadmium is more significant than for diethylzinc. Whereas in ether diethylcadmium does not metallate phenylacetylene, in the presence of *NNN'N'*-tetramethylethylenediamine the reaction is almost explosive[37].

It was noted earlier[9] that no sharp distinction can be made between the solvation of an organometallic compound by donor–acceptor interaction with the solvent and the formation of stable complexes of the "reverse onia" type. Actually there are arguments in support of the idea that the reactivity of such complexes is higher than that of the original organometallic compounds[64]. Whereas neither potassium hydride nor butyl-lithium separately metallates alkylbenzenes their complex with one another $K[LiH(C_4H_9)]$ does so readily[65]. The alkylation of element–carbon bonds by trialkylaluminiums takes place more readily when the latter are bound in complexes with ethers or amines[66,67]. This also holds for the metallating ability of complexes of the $MAlR_4$ type in relation to alkynes: whereas trialkylaluminiums (except for triphenylaluminium[68]) add to the triple bond of alkynes the $MAlR_4$ complexes metallate them[69]. The complexes of alkylaluminiums with tertiary amines behave similarly[70].

It is significant that the addition of potassium chloride to unreacted mixtures of trimethylaluminium and silicon tetrachloride leads to the formation of tetramethylsilane[64]. The use, not of alkylaluminiums, but their complexes with alkali metal halides for the synthesis of organometallic compounds allows the process to be made more selective and with greater conversion of the alkyl groups[71,72].

The exchange of labelled mercury in $RHgX + Hg^*X_2$ systems is catalysed by halide anions and acetate ions, which form coordination complexes with the original organomercury compounds[73,74].

In the presence of iodide anions the breaking of Hg–C bonds in organomercury compounds with elemental iodine becomes a heterolytic reaction[75-87]. Beletskaya and coworkers suggested[76] that the decisive step in this exchange mechanism can be the formation of a complex of the organomercury compound with the iodide anion, which leads to the "relaxation" of the Hg–C bond. They later demonstrated the existence of such complexes with phenylmercury(II) chloride during a study on nucleophilic assistance in protodemercuration reactions[79]. The mechanism of assistance in reactions with multicentre transition states, with allowance for the effect of the medium, has also been considered by Dessy and Paulik[7].

It is evident that here the authors are dealing with the reduction of the energy of the heterolytic breaking of a metal–carbon bond under the influence of coordination at the mercury atom.

It has already been shown above that extension of the thesis of an increase in nucleophilic activity of organometallic compounds during complex formation in substitutions to additions can lead to erroneous conclusions. Such an ambiguous effect of coordination also appears in oxidations, carbonations, and some other reactions. Thus the coordination of diphenylmagnesium by ethers facilitates its oxidation by atmospheric oxygen[80], yet the rate of oxidation of a 2-phenylbis(biphenylene)alkylsodium falls sharply as the solvating ability of the solvent is increased[81]. Evidently, the strong specific solvation facilitates carbonation: alkali metal acetylides are smoothly carbonated (under pressure) in dimethylformamide[82] but hardly at all in ether. The carbonation of pentafluorophenylmagnesium halides in tetrahydrofuran gives pentafluorophenylbenzoic acid in 67% yield[83]. The same Grignard reagent in ether does not react with ethylene oxide but in tetrahydrofuran it smoothly forms 2-pentafluorophenylethanol (yield 82%)[84]. However, the information available about the influence of coordination on the ease of addition is clearly insufficient for any generalisations.

Summarising, the following general conclusions can be drawn:

1. Dipolar aprotic solvents form complexes of the donor–acceptor type with organometallic compounds, identical in many respects with the complexes of these compounds with anions ("reverse onia").

2. Both here and elsewhere there is an increase in the polarity of the bonds of a metal with more electropositive partners, including carbon, which lowers the energy of heterolytic breaking of metal–carbon bonds and makes a little-solvated carbanion (or carbanion end of a dipole) exceptionally active in heterolytic exchanges.

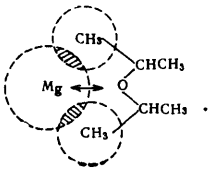
3. The influence of coordination on the course of additions is ambiguous, since here two opposing factors operate: (a) an increase in the nucleophilic nature of the metal–carbon bond; (b) a hindering of complex formation with an unsaturated compound, which prevents the necessary increase in the electrophilic nature of the multiple bond in the transitional state.

IV. FACTORS WHICH DETERMINE THE CHARACTER OF COORDINATION

The extent of the changes referred to above depends on the complex-forming (solvating) ability of the molecules of the donor in relation to a given organometallic compound. The problem of the methods for evaluating this ability is still not completely clear, however. From a comparison of given series of solvating solvents it becomes clear already that in relation to different compounds the different series of solvating abilities agree with one another only in the most general features, while differing considerably in details. It is quite evident, as Hamelin noted[85] for organomagnesium compounds, that interpretation only in terms of the basicity of the donor towards a proton is impossible since there is usually no direct correlation between the basicity of a ligand and its complex-forming ability in most of the examples considered. In relation to trialkylboron compounds the complex-forming ability of different amines ($NH_3 > EtNH_2 > Et_2NH > Et_3N$) is the reverse of their basicity in water ($NH_3 < EtNH_2 < Et_2NH < Et_3N$)[86]; the ability of aluminium hydride to coordinate decreases in the following series of solvents: tetrahydrofuran > Et_3N > > EtOEt.[87] Unlike tetrahydrofuran and dimethoxyethane, the strongly basic triethylamine has no significant accelerating action on the exchange[48,49]:

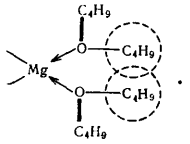
$$RMgX + R'X \rightleftarrows R'MgX + RX$$

Different ethers which differ little in their "basicity", differ markedly in their ability to coordinate with ethylmagnesium bromide[34] and in their accelerating action on the reaction of organomagnesium compounds (see above).



The examples given suffice to show that the basicity alone of a donor in relation to a proton is not a deciding

factor. Because of this, the use of the term "basicity", even with a series of reservations, is undesirable, since it creates the danger of misinterpretation. It is more correct to speak of the complex-forming ability of the donor (corresponding to the solvating ability of a medium) or of the affinity of a ligand for a particular cation or molecule, as is done, for example, by Ahrland and coworkers[88].



The non-correspondence between the proton-basicity of a donor and its coordination capability is due to a combination of factors, which must be considered in greater detail.

From the viewpoint of inductive effects tetrahydrofuran and diethyl ether should be donors of approximately equal strength; the fact that tetrahydrofuran is in reality a better complex-forming agent is usually explained by the absence of steric hindrance in coordination by this solvent[89].

The importance of the steric requirement in coordination has been stated repeatedly. Brown and coworkers[90] distinguish two types of steric hindrance during coordination — *B*- and *F*-strains. In the first the steric hindrances arise because of degree of branching close to the donor atom of the ligand; thus Hamelin[34] explains, for example, the low "basicity" of di-isopropyl ether in relation to a Grignard reagent:

In the second, equivalent to the *F*-strain of Brown and coworkers, solvation is hindered by the general steric hindrance of the ligand molecules arising during coordination[34]:

It is to be expected that the relation between the *B*- and *F*-factors will depend significantly on the dimensions of the metal atom: an increase in its covalent radius should intensify the role of *F*-strain and reduce the influence of *B*-strain. Clearly it is also necessary to consider the obstructions created by the replacing groups at the metal atom.

As well as the steric requirement of the substituents at the atoms of the donor and metal, the electron-donor properties of these substituents must be considered. Depending on the character of the substituent the donor–acceptor properties of the central atom can change within wide limits. Whereas, for example, trimethylantimony is a Lewis base, perfluorotrimethylantimony contains a coordination-unsaturated antimony atom capable of adding pyridine[91]. The feeble donor properties of diphenyl ether are undoubtedly due to the interaction of the unshared electron pairs of the oxygen with the π-electrons of the phenyl rings; in the absence of steric hindrance aryl derivatives of metals form, as a rule, more stable coordination complexes. Among recent studies mention may be made of the work of Noltes and van der Kerk[92], who showed that diphenylzinc forms coordination complexes more readily than dibutylzinc.

The replacement of hydrogen by a methyl group directly at a donor atom of a ligand significantly increases the ability of the latter to coordinate. In its capability for coordination dimethyl ether should significantly surpass diethyl and the higher ethers. This is also facilitated by the favourable steric conditions with the former. Actually, the heat of formation of the ether addition compound $(CH_3)_3Al{-}O(CH_3)_2$ is 19 kcal × × mole^{-1} [93] whereas that for the complex $(CH_3)_3Al{-}O(C_2H_5)_2$ is 11.2 kcal mole^{-1}.[94] An even more marked difference in the solvating ability of dimethyl and diethyl ethers appears in the formation of the naphthalene negative ion from sodium and naphthalene[95]: diethoxyethane has always been found to be a much less suitable solvent than dimethoxyethane[49,96].

A very important factor, which favours coordination, is the bidenticity of a donor and the possibility of forming a five-membered ring. Usually, bidentate ligands give more stable complexes and to a greater measure bring about all those changes mentioned above. Coordination complexes with ligands of this type have also been described for many organometallic compounds — for derivatives of beryllium[97], magnesium[98,99], zinc[100], cadmium[101], and boron and aluminium[24]. It is characteristic that dimethylcadmium with unidentate donors (tetrahydrofuran, pyridine) gives liquid 1 : 1 complexes which dissociate into the components even at low temperature, whereas analogous complexes with *NNN'N'*-tetramethylethylenediamine, 2,2'-bipyridyl, and 1,10-phenanthroline are solid and stable[101]. When the initial organometallic compound is associated (R_2Be, R_2Mg), coordination with bidentate ligands leads to the formation of monomeric complexes to a greater degree than for other complex-forming agents, which must also make a contribution to the general nucleophilic nature of the M–C bond. Thus, dimethylberyllium forms monomeric complexes with dimethoxyethane, *NNN'N'*-tetramethylethylenediamine, etc.[97]; the complex of dimethylmagnesium with this diamine can be distilled[98,99]. Unfortunately in studying the conditions for the formation of such complexes and their stability, most authors do not give any information about the interesting problems of their reactivity in comparison with that of the initial compounds.

Allowance must be made for the fact that the tendency of various metals (as ions or parts of molecules) to complex formation under equally severe conditions also depends on the nature of the donor atom of the ligand[88]. Most acceptor-metals form the most stable complexes when the donor atom belongs to the Second Period of the Periodic System (N, O, F). However, some metals (for example, mercury) give more stable complexes with elements of later periods (P, S, B, etc.). Transition metals such as cadmium, thallium, lead, and bismuth occupy an intermediate position and their affinity for one or another type of ligand depends on the specific conditions, including the nature of their environment. Boron is adjacent to these elements; characteristically[83,102], whereas the activity of the donors in relation to trimethylboron falls in the sequence N > P > As, in relation to borane (BH_3) this sequence alters (N < P ≫ As)‡.

Evidently information on the stability of complexes and on the affinity of ligands for different Lewis acids (including ions and polar molecules) can be used, with some limitations, also for evaluating the change in polarity of bonds and reactivity during coordination.

‡ $(CH_3)_3N$, $(CH_3)_3P$, and $(CH_3)_3As$ were used throughout.

With increase in the atomic number of the metal within the limits of Groups IIb–V there is an increase in the polarisability of the atomic core, which as a whole leads to an increase in the polarisation interaction between the atoms, and consequently to a decrease in the ionicity of the bond. It could evidently be expected that the relatively strong polarisation interaction would also level out to some extent the effect which is brought about by coordination. When the metal atom exhibits sufficiently mobile d-electrons (for example, atoms of metals of type $d^{10}s^2$) and the donor-atom has vacant d-orbitals, the d_π–d_π dative interaction between the atoms of the metal and the donor is an additional factor stimulating the formation of a complex. A consequence of this is, for example, that with increase in the atomic number of the metals in the zinc subgroup there is a rise in the tendency of their compounds to form complexes with derivatives of phosphorus, sulphur, and other elements having vacant d-levels.

It is evident that the reactivity of organocadmium and organomercury compounds will increase under the influence of complex-forming agents containing phosphorus and sulphur to a greater extent than that of the corresponding compounds of magnesium and zinc.

Hence at present it is possible to draw only the following tentative conclusions.

1. The influence of complex formation on the nucleophilic reactivity increases with effective charge at the nucleophilic atom, which, in turn, depends on the relative affinity of the given ligand for the compound concerned.

2. This affinity depends on: (a) the nature of the metal and of the donor atom of the ligand; (b) steric conditions; (c) the bidenticity of the ligand; (d) the inductive effects created by the substituents at the metal and the donor atom; (e) the Lewis basicity of the ligand; (f) factors which at present still cannot be understood. The action of all these factors may not be concordant, which in theoretical respects greatly complicates the problem of the degree and character of the different solvation effects and coordination phenomena.

3. Ideas about complex formation by metal ions (i.e. concepts from the chemistry of complex compounds) can evidently be transferred to complex formation by organometallic compounds, with definite limitations, and this allows a rough *a priori* appraisal to be made.

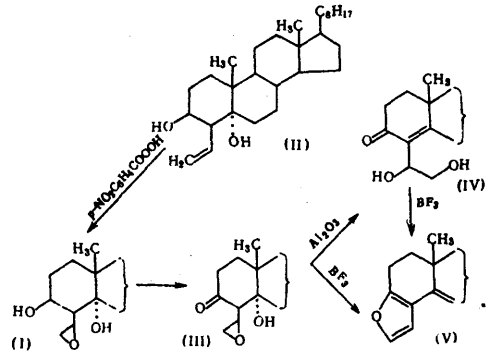
I. INTRODUCTION

In recent years the attention of investigators has been attracted more and more to a series of new, unusual steroidal compounds in which a cyclopentenoperhydrophenanthrene system is condensed with various heterocycles. The increased interest in the compounds of this class is also due to the fact that the number of known steroidal heterocycles isolated from natural sources is increasing each year. An important place among steroid sapogenins is occupied by compounds with a condensed tetrahydrofuran ring. The study of the structure and properties of the alkaloids of the steroid series which show high physiological activity showed that many of them (solanidine, solasodine, tomatidine, conessine, cevine, rubijervine, etc.) are also condensed heterocyclic systems of the steroid series.

The adding on of heterocyclic rings in different positions of a steroid molecule is effected by the usual, well-studied procedures, widely employed in the chemistry of heterocyclic compounds. The initial substances for the preparation of heterocyclosteroids most frequently are ketones, hydroxymethyleneketones, and other accessible derivatives of steroids.

As was to be expected, the addition of heterocycles to steroids often leads to a change in their physiological activity and the appearance of new, interesting biological properties. For example, the fusion of a pyrazole heterocycle to ring A of the steroid nucleus significantly increases the selectivity of its endocrinological activity. Thus 17α-androstano[3,2-c]pyrazole obtained on the basis of 2-hydroxymethylene-17α-methyldihydrotestosterone is 35 times more active than methyltestosterone as an anabolic agent, exhibiting in this one-quarter of its androgenic activity. This observation served as an impetus for the extension of the investigations in the field of synthesis of steroidal heterocycles, and now we know a large number of steroidal pyrazoles and pyrazolines, isoxazoles and isoxazolines, pyrroles and indoles, pyridines and quinolines, thiazoles, triazoles, etc.

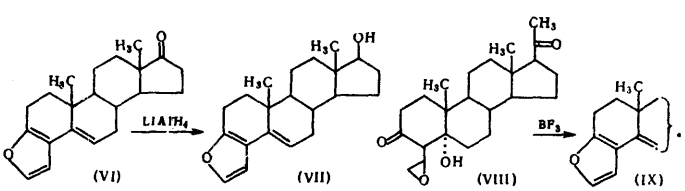
Since the numerous data on the synthesis and properties of the heterocyclosteroids are scattered, this stimulated us to write the present review, in which the main literature published up to the end of 1965 is systematised. It deals with the methods of synthesis and properties of only condensed heterocyclic steroid compounds. The numerous steroid derivatives containing heterocyclic residues are not presented in this review. The authors also do not discuss α-oxides, thio-oxides, lactones, dioxolanes, and other analogous compounds of the steroid series which are described in detail in the literature.



II. STEROIDS CONDENSED WITH FIVE-MEMBERED HETEROCYCLES

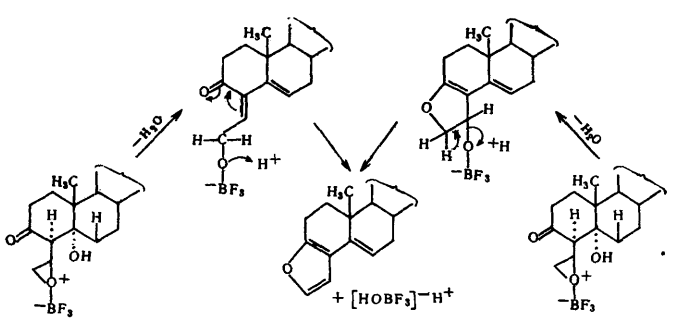
1. Synthesis of Furanosteroids

Compounds with a condensed furan ring are found among the natural alkaloids, the mono-, sesqui-, di-, and tri-terpenoids, and also the steroids.



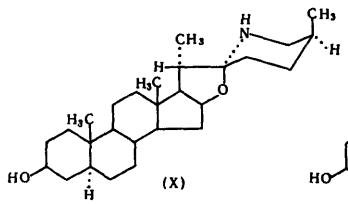
A series of furano-derivatives of cholestane, androstane, and pregnane was recently obtained in good yields by the cyclisation of $\beta\gamma$-epoxyketones of the steroid series in the presence of boron trifluoride–diethyl etherate[1].

Epoxyketols (I) of the cholestane series are obtained from 4β-vinyldiols (II) [2] on reaction with peroxy-acids (for example, p-nitroperbenzoic acid). The reaction proceeds in ether, tetrahydrofuran, or their mixtures:

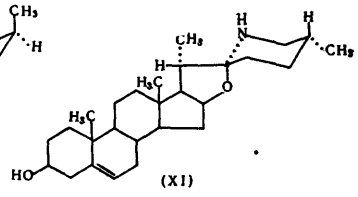


It is noted[1] that the epoxydiol (I) is better converted into the epoxyketol (III) by oxidation with the Jones–Kiliani reagent than by the complex of chromium(VI) oxide with pyridine. The epoxyketol (III) is readily dehydrated in alkaline medium and even during passage through a column of alkaline aluminium oxide it is quantitatively converted into a product with an opened epoxide ring (IV). On treatment with boron trioxide–diethyl etherate, both (III) and (IV) are converted into the furan derivative (V).

By a series of analogous conversions in the androstane series the furanoketone (VI) was obtained, which can then be reduced to the furanotestosterone (VII), and in the pregnane series by treatment of the unpurified epoxyhydroxydiketone (VIII) the corresponding furanoprogesterone (IX) was isolated in 85% yield:



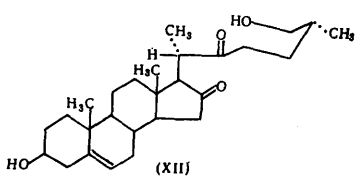
The mechanism of the cyclisation of the furano-derivatives is:



Biological tests showed that the propionate of furanotestosterone (VII) was devoid of androgenic and anabolic activity when administered either subcutaneously or orally[1].

Among the steroidal sapogenins (sarsasapogenin, diosgenin, etc.) an important place is occupied by tetrahydrofuran derivatives in which the heterocycle is condensed with ring D of the steroid in positions 16 and 17. The derivatives which contain the tetrahydrofuran ring are found among the

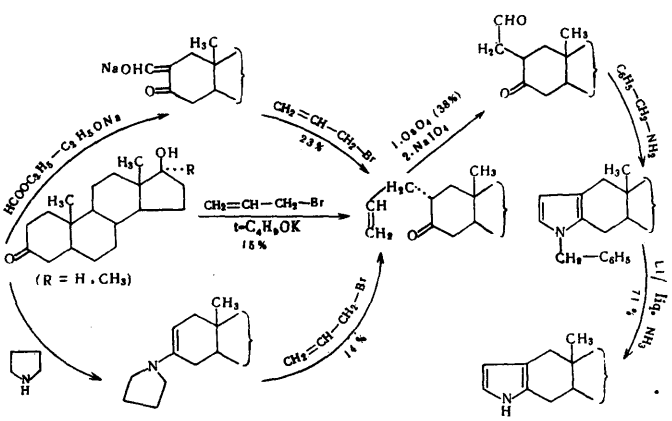
steroidal alkaloids of the tomatidine (X) and solasodine (XI) type[3]:



(X)

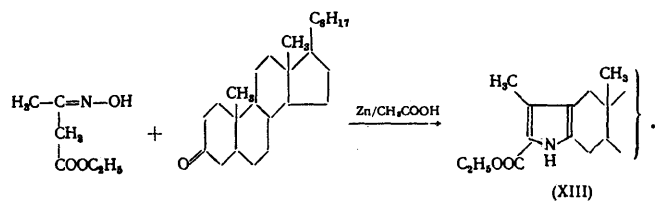
(XI)

The structure and stereochemical configuration of solasodine were confirmed by its synthesis from cryptogenin (XII):[4]



(XIII)

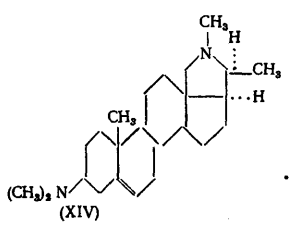
The scope of the present review does not permit dwelling in detail on the chemistry of the steroidal sapogenins and alkaloids, particularly as the problems of the structure and properties of these compounds have received detailed consideration in the literature[3].



2. Pyrrolo-, Pyrrolidino-, and Indolo-Steroids

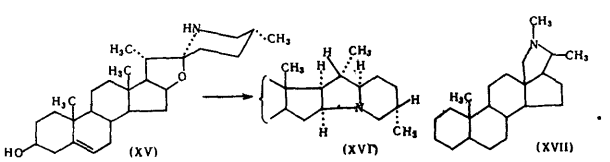
The attachment of a pyrrole ring to the steroid skeleton is effected on the basis of a general method of cyclising 1,4-dicarbonyl compounds by heating them with ammonia or primary amines at 100°. The necessary 1,4-dicarbonyl derivatives of the steroids are obtained by the following scheme[5]:

When an acetoxy-group is present at $C_{(17)}$, the debenzylation in the last stage is accompanied by deacetylation. During the direct allylation of the initial ketone with allyl bromide and potassium t-butoxide, the 4α-allyl derivative is also formed as a side-product, but it could not be converted into the corresponding pyrrole[5].



The Knorr method was also used successfully for obtaining pyrrole derivatives of steroids. By using it in the condensation of cholestan-3-one with the oxime of acetoacetic ester, ethyl 5′-carboxy-4′-methylcholestano[3,2-*d*]-pyrrole (XIII) was obtained[6]:

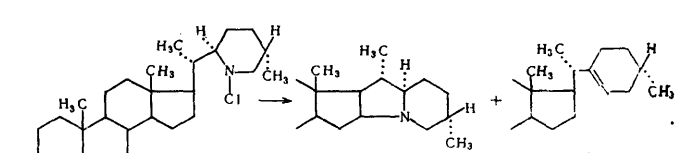
(XIII)



Androst-4-en-3,17-dione was converted analogously into the ethyl ester of 3′-carboxy-2′-methylandrosta-4,16-dien-17-ono[3,2-*d*]pyrrole[6]. However, cholest-4-en-3-one could not be converted into the corresponding pyrrole derivative.

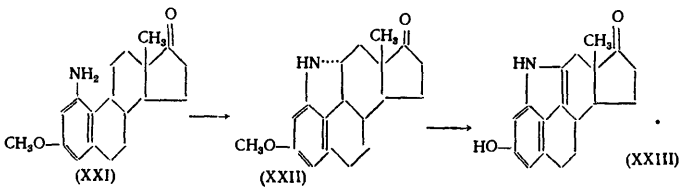
Pyrrolidine derivatives of steroids are also known, mainly among the steroid alkaloids isolated from plant materials. For example, the most widely distributed and most important representative of the alkaloids isolated from the seeds of various species of the Indian shrub *Holarrhena* is conessine (XIV) which was recently synthesised, starting from derivatives of 5α-pregnane or pregn-5-ene[7,8]:

(XIV)



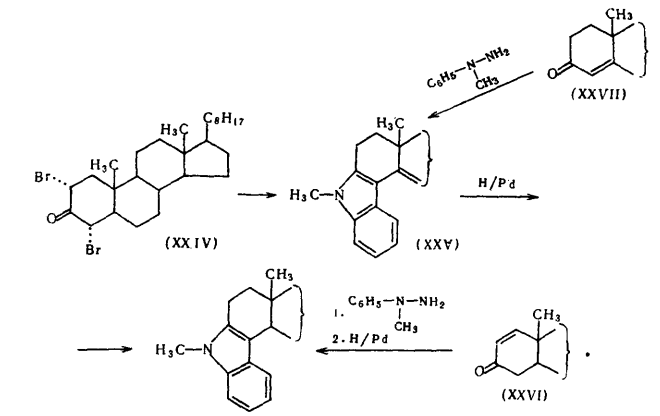
Δ⁵-Tomatidine (XV) formed the basis of a recent synthesis of the steroidal alkaloid solanidine (XVI) which contains a condensed perhydropyrrocoline ring[9]:

(XV) (XVI) (XVII)



As a result of extensive investigations carried out by a large group of French investigators[10-12] it was found that various species of *Apocynaceae* are also rich in steroid alkaloids which are derivatives of conamine (XVII). The latter contains a pyrrolidine ring but pregnane is always the basis of the skeleton and therefore these alkaloids can be used for the industrial production of various pregnane derivatives[13].

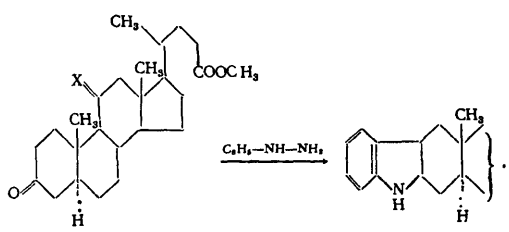
An interesting observation was made during the treatment of *N*-chlorosteroidamines with 5% KOH in methanol: in this the chloroamine (XVIII) gives 57% of the alkaloid demissidine (XIX) and 3.5% of the azomethine (XX); on the other hand the (22 *S*, 25 *R*) isomer (XIX) under these conditions does not form demissidine and is converted into the azomethine in 60% yield[14]:



(XVIII) (XIX) (XX)

Quite recently the synthesis of a new, interesting steroid heterocyclic system was proposed[15]. It appeared that on diazotisation of 1-amino-3-methoxyoestra-1,3,5(10)-trien--17-one (XXI) and subsequent treatment with sodium azide, the 1-azido-derivative is obtained, which on heating in n-hexadecane is converted into indoline (XXII). This, by a series of conventional transformations is converted with high yield into the final product, 3-hydroxy-1,11-imino--oestra-1,3,5(10),9(11)-tetraen-17-one (XXIII):

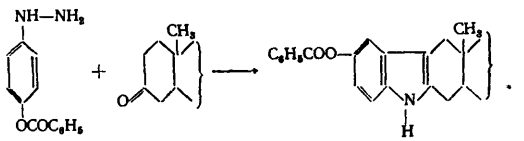
(XXI) (XXII) (XXIII)



In 1937, during the dehydrobromination of 2α,4α-dibromocholestan-3-one (XXIV) with dimethylaniline a compound was obtained[16] which on the basis of subsequent investigations[17] was given the structure (XXV). The structure proposed was confirmed by counter-synthesis from cholest-1-en-3-one (XXVI) and cholest-4-en-3-one (XXVII) and α-methylphenylhydrazine by the Fischer reaction, and also by infrared and ultraviolet spectroscopy[17].

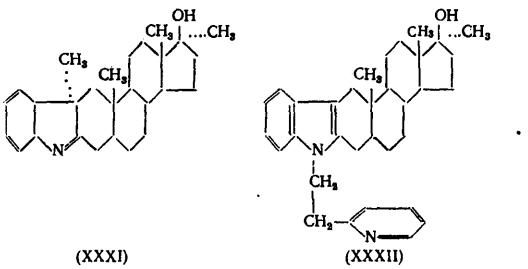
(XXVII) (XXIV) (XXV) (XXVI)

More detailed proof of the structure (XXV) of the compounds obtained has been given recently[18].



The Fischer reaction has also been employed successfully for obtaining other indole derivatives of the steroids. Thus in the reaction of methyl 3-ketocholanate (XXVIII; X = H_2) and its 12-keto-derivative (XXVIII; X = O) with phenylhydrazine in acetic acid the indole derivative (XXIX) was obtained, condensed with the steroid nucleus in positions 2 and 3 of the pyrrole ring[6]:

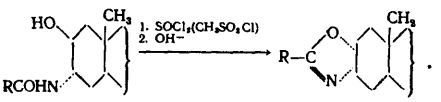
(XXVIII) (XXIX)



where X = H, O.

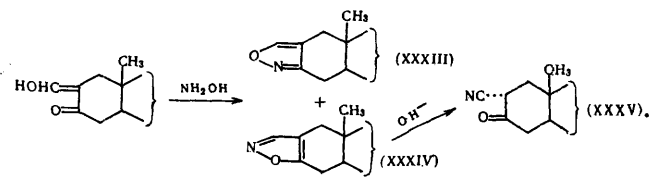
In the search for steroid analogues of 5-hydroxytryptamine and with the aim of investigating them as hypotensive agents, a group of English investigators recently developed a synthesis of androstano[2,3-*b*]-5′-hydroxyindole derivatives from 3-keto-steroids and *p*-benzoyloxyphenylhydrazine (XXX) by the following scheme[19]:

(XXX)



On starting from 17β-hydroxy-2α,17α-dimethylandrostan-3-one and phenylhydrazine, the indolenine (XXXI) was obtained, and the reaction of androstanoindoles with 2-vinylpyridine in dimethylformamide in the presence of sodium gave compounds of the type of (XXXII). Replacing the vinylpyridine by 2-methyl-5-vinylpyridine did not lead to a positive result[19]:

(XXXI) (XXXII)

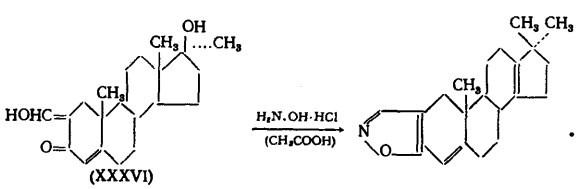


3. Oxazolino-, Isoxazolo-, and Isoxazolino-Steroids

On treating the acyl derivatives of *trans*-amino-alcohols with thionyl chloride or methanesulphonyl chloride and then washing with alkali, various 2′-substituted oxazolinosteroids were obtained[20,21]. For example, 2β-benzoylamino-3α--hydroxycholestane gives cholestano[3β,2β-*d*]-2′-phenyloxazoline, and 2β-hydroxy-3α-benzoylaminocholestane gives cholestano[3α,2α-*d*]-2′-phenyloxazoline[21]:

Owing to their considerable biological activity the methods of synthesis and properties of isoxazole derivatives of steroids have been studied in considerable detail.

Even in 1925 it was shown[22] that in the reaction of hydroxymethylenecyclohexanone with hydroxylamine a mixture of isomeric [2,3-*d*]- and [3,2-*c*]-isoxazoles is formed. The same method is successfully used for the synthesis of steroidoisoxazoles[23]. Usually for this purpose the hydroxymethyleneketosteroid is boiled with hydroxylammonium chloride in alcohol in the presence of sodium acetate. As in the condensation of hydroxymethylenecyclohexanone, the steroid hydroxymethyleneketones also form two isomers (XXXIII) and (XXXIV):[23]



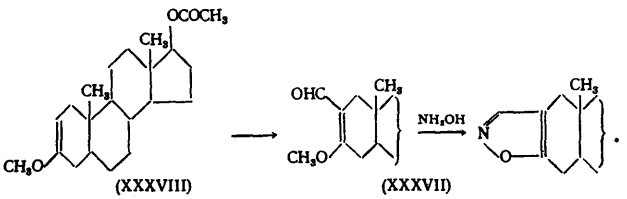
(XXXIII) (XXXIV) (XXXV).

To separate them use is made of the ability of the [2,3-*d*]isoxazoles (XXXIV) to be readily converted into α-cyanoketones (XXXV) on treatment of the reaction mixture with alkali[24]. For example[25], in the reaction of 2-hydroxymethylene-17α--methyldihydrotestosterone with hydroxylamine the reaction product is treated with sodium methoxide, whereupon the [2,3-*d*]-isomer is quantitatively converted into 1-cyano--17α-methyldihydrotestosterone, but the [3,2-*c*]-isomer (XXXIII) is recovered unchanged from the reaction medium in 41% yield calculated on the initial hydroxymethylene-ketone. 2α-Cyanocholestan-3-one could only be made by this means[26]. Hence this process was also shown to be a convenient preparative method for the introduction of the cyano-group into the $C_{(2)}$ of the steroid nucleus, which could not be achieved by a direct path.

It was shown that the rate of formation of (XXXIII) and (XXXIV) is greatly dependent on the pH of the medium, the solvent, and the temperature[27]. This fact is of great importance for the development of a process for the synthesis of [2,3-*d*]isoxazolosteroids, which are of greater interest as regards their biological activity than their [3,2-*c*]-analogues. In a weakly alkaline medium a mixture of isoxazoles is usually formed[28]. Unsaturated steroid hydroxymethyleneketones with a Δ^4 double bond are converted under these conditions only into [2,3-*d*]isoxazoles[25]. The same products are also formed in the presence of a 4,4-*gem*-dimethyl group in the molecule of the initial hydroxymethyleneketone[28].

On carrying out the reaction in glacial acetic acid one isomer (XXXIV) is also formed preferentially.

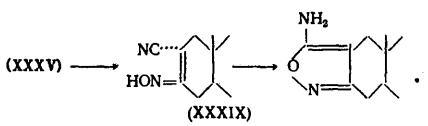
It should be noted that when a secondary hydroxyl is present at $C_{(17)}$ in the molecule of the initial steroid, on carrying out the reaction in acetic acid its acetylation also occurs[28]. When a hydroxymethyleneketone containing a tertiary hydroxyl at $C_{(17)}$ is introduced into the reaction, dehydration with a Wagner–Meerwein rearrangement takes place, as, for example, with 2-hydroxymethylene-17α--methyltestosterone (XXXVI).[29] This behaviour can be avoided if the reaction is carried out in weakly acid medium with the addition of an excess of sodium acetate[28]:



(XXXVI)

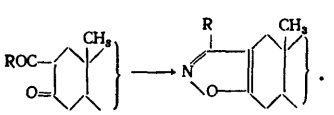
The structure of the products of the rearrangement is shown[29] by the absence of hydroxyl absorption and splitting of the band at 1380 cm^{-1} in the infrared spectrum and by the presence of a singlet in the NMR spectrum at 9.03 τ, the intensity of which corresponds to the nine protons of the three methyl groups[29].

The methyl group which had migrated is ascribed the β-configuration, since it is known[30] that the Wagner–Meerwein rearrangement proceeds without change of configuration.



Cortisone is converted analogously into 2-hydroxymethylenecortisone, which on treatment with hydroxylamine forms 17α,21-dihydroxypregn-4-en-11,20-diono[2,3-*d*]-isoxazole[25].

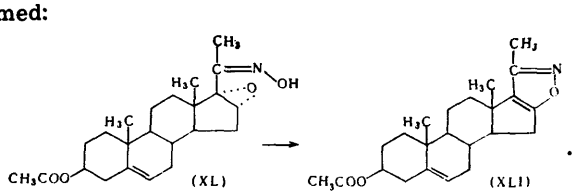
The acetate of 2-formyl-3-methoxyandrost-2-en-17β-ol (XXXVII) — obtained by the formylation of the acetate of 3-methoxyandrost-2-en-17β-ol (XXXVIII) by the Vilsmeier reagent — was recently used for the preparation of [2,3-*d*]isoxazoles[31]:



(XXXVIII) (XXXVII)

It is interesting to note that the 2α-cyanoketones which are obtainable on the basis of [2,3-*d*]isoxazoles can be used for the synthesis of steroido[3,2-*c*]-5′-aminoisoxazoles (XXXIX).[32] Condensation of these compounds is carried out either with hydroxylammonium chloride in a pyridine solution, or with hydroxylammonium acetate in ethanol. The reaction proceeds with the intermediate formation of an oxime:

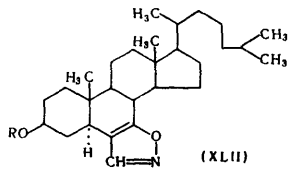
(XXXIX)



Isoxazolosteroids were also synthesised on the basis of corresponding β-diketones. In the condensation of 2-aryl--3-ketosteroids with hydroxylamine [2,3-*d*]isoxazoles are obtained which contain alkyl substituents in position 3 of the isoxazole ring[33]:

where R = CH_3, n-C_3H_7.

To retain the keto-group, it is first either blocked or reduced and the resulting hydroxyisoxazole oxidised with chromium(VI) oxide in pyridine[29].

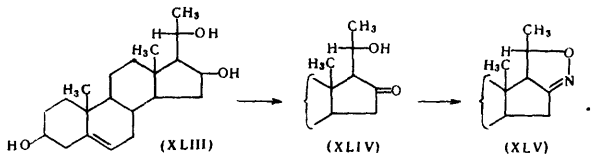


A series of steroidoisoxazoles of a new type was recently obtained[34]. When the oxime of the acetate of 16α,17α-epoxy-3β-hydroxypregn-5-en-20-one (XL) is treated with phosphoryl chloride in pyridine the acetate of androst-5-en-3β-ol[17,16-*d*]-3′-methylisoxazole (XLI) is formed:

The product obtained is saponified with alkali into an alcohol, which in turn is smoothly oxidised after Oppenauer to the 3-keto-derivative.

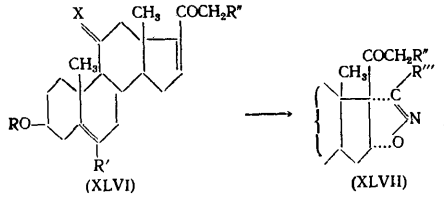
For the identification of the steroidoisoxazoles, use can be made of the fact that the ultraviolet spectra of all the isoxazoles which do not contain a Δ^4 double bond have a band at 227 nm but in the presence of a Δ^4 bond there are bands at 207, 209, and 286 nm.[29] For isoxazoles of the

type (XLII) obtained on the basis of 6-hydroxymethylene--7-ketosteroids, an absorption band appears at 231 nm in the ultraviolet spectrum[29]. In general it can be noted that [2,3-*d*]isoxazoles absorb in the ultraviolet region at greater wavelengths than their [3,2-*c*]-analogues, that is, at 227 ± ± 2 and 222 ± 1 nm respectively[28]:



(XLII)

Attachment of the isoxazoline ring to steroids can also be brought about by condensation of hydroxylamine with steroid ketones of suitable structure.

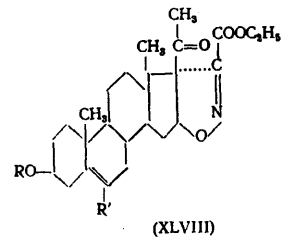


On the basis of 16β,20α-diols (XLIII) selective oxidation gives the corresponding 20α-hydroxy-16-ketosteroids (XLIV), the 16-oximes of which are converted under Beckmann rearrangement conditions (on treatment with tosyl chloride or acetic anhydride in pyridine) into steroido-[16,17-*c*]isoxazolines (XLV) in good yield[35]. The acetate of 3-β-hydroxy-5'-methyl-5α-androstano[16,17-*c*]isoxazoline, a series of Δ⁵-steroido[16,17-*c*]isoxazolines, and also a series of 3-ketoisoxazolines were obtained in this way[35].

Cyclisation proceeds with retention of the configuration at $C_{(20)}$ and the hydrogen atoms at $C_{(17)}$ and $C_{(20)}$ have the *trans* configuration. Evidently, the initial oxime reacts in the *anti*-form; in the opposite behaviour the configuration at the $C_{(20)}$ atom would be the reverse[35]:

(XLIII) (XLIV) (XLV)

The second method of synthesis of steroidoisoxazolines consists in the reaction of αβ-unsaturated ketosteroids with the acid chlorides of hydroxamic acids. This reaction has been well studied earlier in the aliphatic series[36]. To carry out the reaction a catalytic amount of triethylamine is added to a mixture of benzhydroxamic acid chloride and a derivative of 16-dehydro-pregn-5-en-20-one (XLVI) in tetrahydrofuran at 0°. The corresponding steroido[17,16-*d*]--3'-phenylisoxazolines (XLVII; R = C_6H_5) are separated from the reaction medium in ~ 80–90% yield[37]:



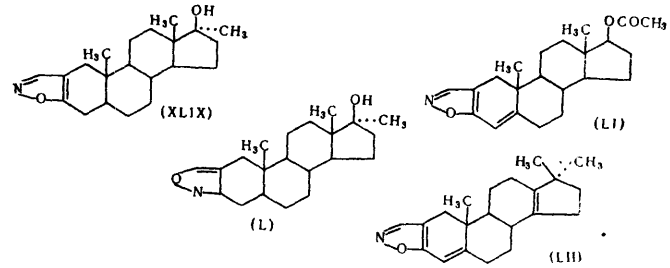
(XLVI) (XLVII)

where R = H, CH_3CO; R' = H, CH_3; R'' = H, OH; R''' = = CH_3, C_6H_5; X = H_2, O.

Saponification of the 3-acetyl derivatives (XLVII; R = = CH_3CO) to the corresponding alcohols and oxidation of the latter after Oppenauer can be used to obtain 3-ketosteroido-isoxazolines[37].

3'-Methylisoxazolines (XLVII; R''' = CH_3) were obtained by the above scheme with a yield of ~ 69–99.8% in the presence of an excess of acethydroxamic acid[37].

The reaction of natural 16-dehydro-20-ketopregnane derivatives with ethyl oxalate nitrile oxide gives isoxazolines of type (XLVIII):[38]



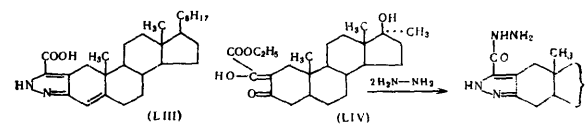
(XLVIII)

where R = H, CH_3CO; R' = H, CH_3.

In the ultraviolet spectrum of all the isoxazolines synthesised the chromophoric group $-N=C-C_6H_5$ appears by three absorption bands at 212, 218, and 262 nm.[37]

The steroidoisoxazoles are a new class of modified steroid hormones which exhibit an interesting physiological activity. It was shown by analogy with steroidopyrazoles that the attachment of an isoxazole ring also brings about interesting changes in the activity of the initial steroids. The most interesting preparation of this class was 17α-methylandrostan-17β-olo[2,3-*d*]isoxazole (XLIX), which in comparison with methyltestosterone exhibits 9.7 times more anabolic, twice the miotropic, and 0.24 times the androgenic activity[28].

Almost the same activity is exhibited by androstan-17β--olo[2,3-*d*]isoxazole[28]. Contrary to the corresponding pyrazoles these compounds are completely devoid of oestrogenic activity[23]. 17α-Methylandrostan-17β-olo[3,2-*c*]-isoxazole (L) was a strong anabolic agent. Two preparations (LI) and LII) were effective anti-tumour agents[30]:

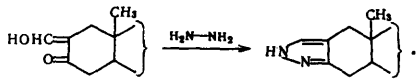


(XLIX) (LI) (L) (LII)

The introduction of additional 4,4-dimethyl- or 6α-methyl--3'-alkyl substituents lead to minimal myotropic activity[28].

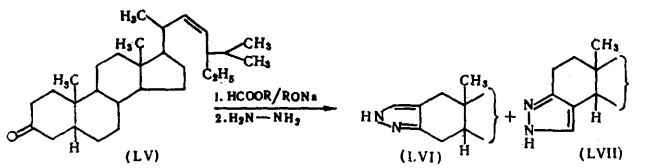
The 19-nor derivatives have the least interest. The completely saturated products always have greater activity than their Δ⁴- and Δ⁴,⁶-analogues[28].

4. Pyrazolo- and Pyrazolino-Steroids



The first steroid pyrazole was 5'-carboxycholest-4--eno[3,2-*c*]pyrazole (LIII), obtained by condensation of 2-oxalylcholestenone with hydrazine[39]. Afterwards certain transformations were performed on 2-oxalyl-17α-methyldihydrotestosterone, which can be obtained from ethyl oxalate, sodium methoxide, and the corresponding 3-keto--steroid[32]:

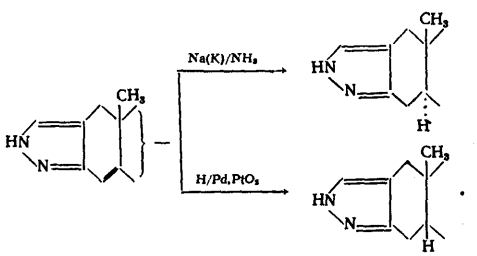
(LIII) (LIV)



It was shown[40] that steroido[3,2-*c*]pyrazoles form a new class of steroid hormones with interesting physiological activity.

The main method of synthesis of the compounds of this class is the condensation of steroidohydroxymethyleneketones with an excess of hydrazine:

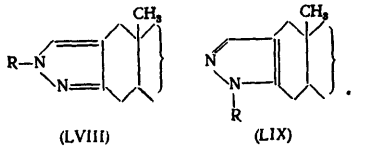
Hydroxymethyleneketones are readily obtained by formylation of the corresponding ketones with ethyl formate in the presence of sodium hydride or ethoxide in benzene or dioxan solution of either saturated or unsaturated ketones[41].



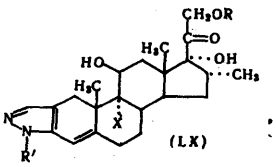
Note that both for A/B-*trans*- and for A/B-*cis*-3-ketosteroids only the 2-formyl derivatives are obtained in good yields (~ 70–90%); these are considerably more stable thermodynamically than the corresponding 4-formyl derivatives[42]. The only exception is 5β-stigmast-22-en-3-one (LV), which on formylation gives a mixture of the 2- and 4-formyl-5β-stigmast-22-en-3-ones, and under the action of hydrazine these are converted into pyrazole derivatives (LVI) and (LVII), readily separable chromatographically[42]:

Partial formylation at $C_{(4)}$ is here the result of the formation of an intermediate derivative with a very low solubility which immediately upon formation undergoes further reversible conversion into the 2-hydroxymethyleneketone[43].

Hence formylation of 3-keto-steroids with subsequent condensation with hydrazine readily gives the corresponding A/B-*trans*- and A/B-*cis*-steroido[3,2-*c*]pyrazoles[43].



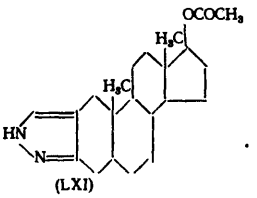
Another path for the production of 5α- and 5β-steroidopyrazoles consists in the selective reduction of readily accessible Δ^4-steroidopyrazoles. It has been shown that in the catalytic hydrogenation over palladium or platinum(IV) oxide the 5β-isomers are obtained[42,43], but in reduction with alkali metals in a mixture of liquid ammonia, tetrahydrofuran, and ethanol only the 5α-isomers are obtained, with yields of 62–76%:[44]



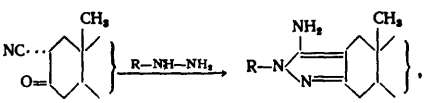
Reduction of the aromatic pyrazole ring during the hydrogenation is not observed[44].

It would be expected that condensation of 2-hydroxymethylene-3-ketosteroids with substituted hydrazines should give, depending on the reaction conditions, mixtures of 1′- and 2′-substituted pyrazoles (LVIII) and (LIX).[45]

However, as was shown for an alkylhydrazine, the substituted nitrogen of which has a more nucleophilic character, only the isomer (LVIII) is obtained, and for phenylhydrazine, in which the β nitrogen atom is more nucleophilic, isomer (LIX) is obtained[46]:

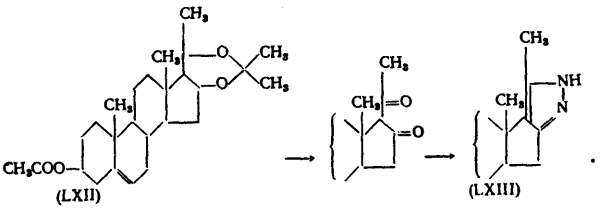


Extensive studies of the steroidopyrazoles were made by Hirschmann and coworkers[47-50]. They synthesised certain 5α-pregn-4-eno[3,2-*c*]pyrazoles (LX) based on cortisol and its 16α-methyl and dihydro-derivatives through their hydroxymethylene derivatives,



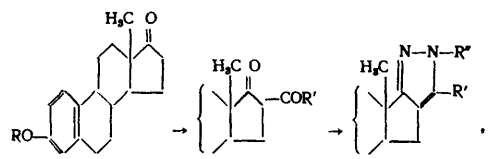
where R = H, CH_3CO; R′ = H, C_6H_5, p-FC_6H_4; X = H, F.

It was recently shown[31] that on treating the acetate (XXXVIII) with hydrazine the corresponding 5α-pyrazole (LXI) is formed:



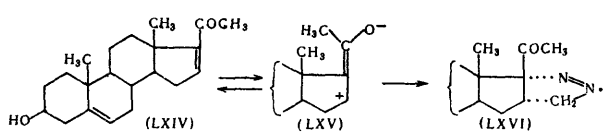
A series of 5′-amino-substituted steroidopyrazoles was obtained by condensation of 2α-cyano-3-ketosteroids with hydrazine[32]:

where R = H, CH_3.



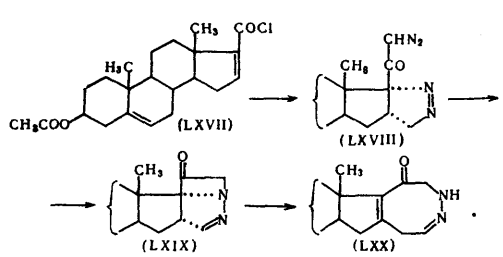
The 16β,20α-isopropylidenehydroxysteroids of type (LXII) are also of interest for the synthesis of the steroidopyrazoles. These are readily converted into 16,20-diketones, which form with hydrazine in ethanol pyrazole derivatives (LXIII), in which the heterocyclic ring is condensed with a steroid component in positions 16 and 17:[51]

Analogous results were also obtained on the basis of 5α-pregnan-3β,16β,20α-triol.[52]

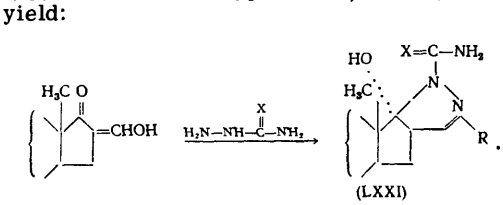


It should be noted that in the Wolff–Kishner reduction of 16α,17-epoxyhydroxypregnenone, in addition to a mixture of difficultly separable diols androst-5-en-3β-olo[16,17-*c*]--5′-methylpyrazole is formed[53].

According to the results of Italian chemists[54], the synthesis of [17,16-*c*]pyrazoles of the androstane and oestrane series is conveniently effected by treatment of 17-ketosteroids with ethyl formate or diethyl oxalate in the presence of sodium hydride or methoxide with subsequent cyclisation with hydrazines of the 16-formyl derivatives obtained:



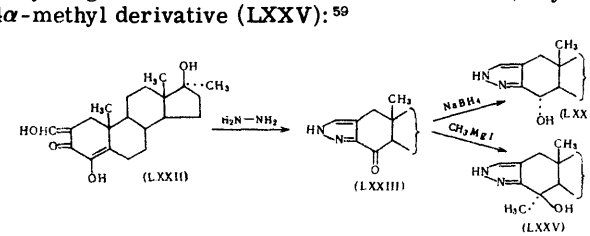
where R = H, CH_3,  ; R′ = H, $CO_2C_2H_5$; R″ = H, CH_3.



It is known that αβ-unsaturated ketones, esters of carboxylic acids, and nitriles add on diazoalkanes to form pyrazolines. This reaction also proved possible in the steroid series. In the reaction of diazomethane with 16-dehydro--20-ketopregn-5-en-3-ol (LXIV) or (LXV), 20-ketopregn--5-en-3-olo[17,16*c*]pyrazoline (LXVI) is formed[55]:

When the acid chloride (LXVII) is reacted with diazomethane, a 21-diazopyrazoline (LXVIII) is formed, evidently as a result of the addition of diazomethane to the unsaturated diazomethyl ketone. The (LXVIII) thus obtained gives with warm acetic acid the compound 3β-acetoxy-16α,17α,21--[3,1,1-(2-pyrazolino)]pregn-5-en-20-one (LXIX).[56,57] When (LXIX) is heated on the steam-bath in acetic acid with a large quantity of sodium acetate, the diazepinone (LXX) is formed in 16% yield. The derivative obtained is successfully methylated and acetylated on nitrogen, but does not form an oxime or semicarbazone at the carbonyl group[56,57]:

When semicarbazide, thiosemicarbazide, and some of its derivatives react with 16-hydroxymethylene-17-ketosteroids, pyrazolines of the type (LXXI; R = H) are formed in high yield:



With 16-ethoxyallyl-17-ketones, the pyrazolines (LXXI; R = $CO_2C_2H_5$) are formed[58].

On heating in a bomb with methyl iodide, 1′-methylsteroido[3,2-*c*]pyrazoles are converted into 1′,2′-dimethylpyrazolium salts, which are stable, high-melting compounds, relatively poorly soluble in water[46].

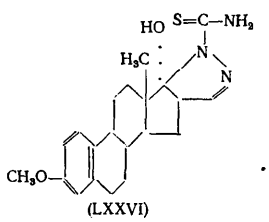
On treating the steroidopyrazoles with acid anhydrides, *N*-acyl derivatives are obtained, which, however, readily lose an acyl group on boiling in aqueous acetic acid. In an attempt to methylate the unsubstituted nitrogen of *N*-acyl pyrazoles the *N*-acyl group is detached and 1′,2′-dimethylpyrazolium salts are formed[46].

Treatment of steroido[3,2-*c*]pyrazoles with potassium cyanate in dilute alcoholic solution with hydrogen chloride leads to the corresponding *N*-carbamoyl derivative[46]. These compounds, like the *N*-acylpyrazoles, are of interest for the temporary protection of the NH group of the pyrazole ring, since the carbamoyl group can also be readily removed on boiling with an excess of hydrogen chloride in aqueous alcohol.

In the presence of a secondary hydroxyl group at $C_{(17)}$ of the steroid pyrazoles it can be oxidised by a mixture of sulphuric and chromic acids in dimethylformamide to the 17-keto-group[46]. To obtain 4-ketoandrostane derivatives, a start is made from 4-hydroxy-2-hydroxymethylene-17α--methyltestosterone (LXXII), which is condensed with hydrazine in ethanol, forming the compound (LXXIII).[59] With the aid of sodium tetrahydroborate, the pyrazole (LXXIII) is reduced to the 4-hydroxy-derivative (LXXIV) and with methylmagnesium iodide is converted into the 4β-hydroxy--4α-methyl derivative (LXXV):[59]

All the androstano[3,2-*c*]pyrazoles have a characteristic absorption maximum in their ultraviolet spectrum at 223 nm (ε ~ 5000), which is displaced in 0.01 *N* alcoholic hydrogen chloride solution to 229 nm (ε ~ 6200). When a conjugated double bond is present the steroidopyrazoles have absorption maxima in the 261 nm region (ε ~ 10 000). The bathochromic shift of the maxima in the acid solution is explained by the protonation of the pyrazole ring, since such a phenomenon is not observed in alcoholic alkali solution[46].

The fusion of a coplanar pyrazole ring to the steroid nucleus leads to substitution of the $C_{(3)}$ oxygen atom by nitrogen which changes the nucleophilic environment in this region. In this there is a change in the distance between the active centres of the steroid molecule at $C_{(3)}$ and $C_{(17)}$, since the length of the C=N bond is ~ 1.4 Å, and the length of the C=O bond in the original ketone is 1.2 Å. This evidently shows some influence of the strength of the bond of the steroid molecule with the chelate receptors and can lead to selectivity in the reaction between the steroid and the receptor[46].

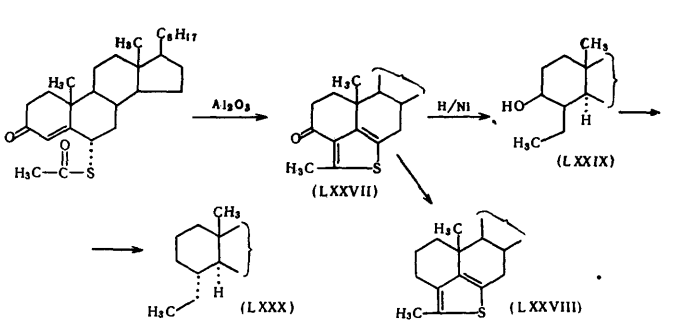


It would also be expected that in this there would be a significant fall in the oestrogenic activity[60], which is in fact observed[46].

The androgenic and anabolic activity drops sharply on the introduction at $C_{(17)}$ of alkyl residues greater in volume

than ethyl and also during *N*-methylation. However, the acylation of the pyrazole nucleus does not alter the activity, probably owing to the lability of the *N*-acyl groups. Activity of the same order is observed in Δ^4- and $\Delta^{4,6}$-steroido[3,2-*c*]-pyrazoles [46].

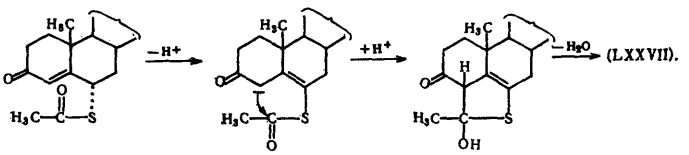
The introduction of substituents into the steroid nucleus has the most influence on the activity of steroidopyrazoles. But whereas the activity of 9α-fluoro-11β-hydroxy-6α--methyl derivatives of 17α-methyltestosteroid is higher than that of 17α-methyltestosteroid itself, the introduction of analogous substituents into the steroido[3,2-*c*]pyrazole molecule appreciably reduces its activity [46]. The activity of 4-methyl- and 19-nor-steroidopyrazoles is greatly diminished and the 4-keto-, 4-hydroxy-, and 4α-methyl--pyrazoles are completely inactive (LXXIII)–(LXXV). [59] The physiological activity mentioned is completely absent from compounds with the pyrazole ring in positions 16 and 17. [54]



The pyrazoline (LXXVI) is an effective hypocholesterinemic agent at very low oestrogenic activity [58], but some pyrazoles of type (LX) were very interesting in their anti--inflammatory activity [49]. The authors assumed that these pyrazoles are active as such and not as a result of biological release of the 3-keto-group:

(LXXVI)

5. Thienosteroids



The first representative of the class of thienosteroids was obtained in 1963 [sic] from 6α-thioacetylcholest-4-en--3-one. [61] During the chromatography of this product on an aluminium oxide column the authors unexpectedly observed that cyclisation occurs with the formation of a thiophene derivative, which on the basis of chemical properties and the ultraviolet and infrared spectra was ascribed the structure (LXXVII). [62] This compound was converted, by a Huan-Minlon reduction, into a thiophen derivative of cholestane (LXXVIII). Catalytic reduction of (LXXVII) over Raney nickel leads to the formation of 4β-ethylcholestan-3β-ol (LXXIX), from which 4α-ethylcholestane (LXXX) is obtained by known methods [62]:

(LXXVII) (LXXIX) (LXXX) (LXXVIII)

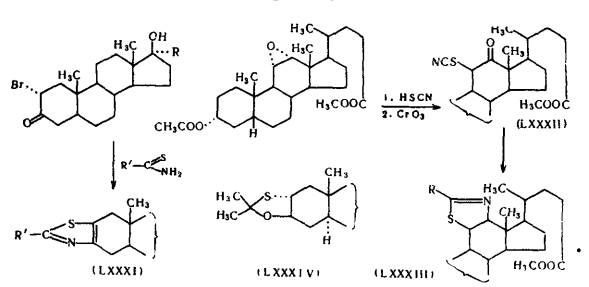
The intramolecular condensation described has also been used with progesterone, testosterone, and their derivatives [62]. Always, derivatives were obtained analogous in structure to the cholestanone derivative (LXXVII).

Probably the reaction includes enolisation of a Δ^4-3-ketone with later formation of an anion at $C_{(4)}$ by the following scheme [62]:

(LXXVII).

Use of different catalysts of a basic character confirms the suggested mechanism. Treatment of 6α-acetylthio-19-nor-testosterone acetate with potassium t-butoxide and trimethylmethanol gives the corresponding 17-hydroxythieno--derivative in 39.5% yield, but on boiling with sodium hydride in toluene the yield of product is increased to 56.6%. [63]

Thienosteroids can be identified by the presence of characteristic absorption bands in the ultraviolet spectrum (220, 268, and 304 nm). [63]

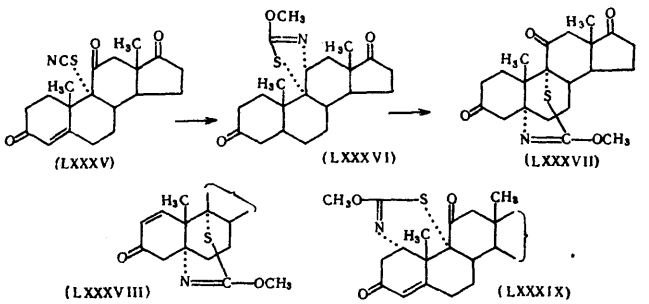


6. Thiazolosteroids

Although methods of synthesising thiazoles have been studied rather thoroughly [64], the addition of this heterocycle to compounds of the steroid series was only accomplished in 1960. [25] Thiazolosteroids were obtained by condensing 2α-bromodihydrotestosterone with thioformamide or thioacetamide in alcoholic solution with the formation of products of structure (LXXXI). [25,65]

In developing this, Doorenbos and Dorn [66] made a detailed investigation of the condensation of 2α-bromo-17α-methyldihydrotestosterone with acid thioamides, thiourea, phenyl- and allyl-thiourea, and thus obtained thiazole derivatives of the general formula (LXXXI).

The addition of the thiazole ring in positions 11 and 12 to acetylmethyl cholanate was achieved by Japanese investigators [67]. These syntheses started from the 11α,12α- and 11β,12β-epoxysteroids, which under the action of thiocyanic acid in ether easily form thiocyanato-compounds. Chromium(VI) oxide in acetic acid oxidises the latter into 12-keto-11β-thiocyanato-compounds (LXXXII). On boiling these compounds with secondary amines in dioxan solution, closing of the thiazole ring takes place with the formation of substituted derivatives of cholano[12,11-*a*]thiazole (LXXXIII).

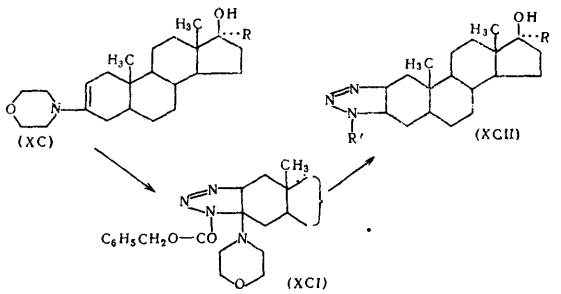


It was also shown [68] that on heating 2α-thiocyanatocholestan-3-one in dioxan containing hydrochloric acid, an oxothioline is formed in good yield (LXXXIV).

(LXXXI) (LXXXIV) (LXXXIII)

On treating 9α-thiocyanatoandrost-4-en-3,11,17-trione (LXXXV) with a water–methanol solution of potassium

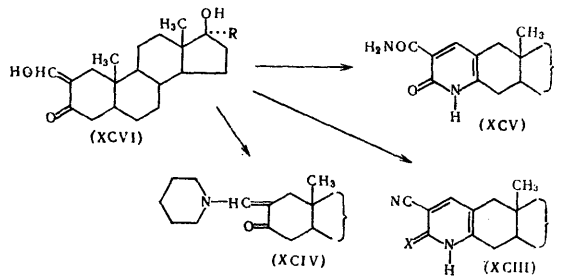
carbonate at ordinary temperature 2′-methoxyandrost-4--eno-3,17-diono[11α,9α-*d*]thiazoline (LXXXVI) is formed in good yield[69]. When the thiazolines thus obtained are boiled or kept for a long time in methanol solution, rupture of the $C_{(11)}$–N bond takes place with formation instead of a $C_{(5)}$–N bond, such as, for example, the conversion of (LXXXVI) into (LXXXVII).[70] The necessary condition for such a type of isomerism is the presence of an αβ-unsaturated keto-system. 1,4-Dienones are also isomerised but considerably more slowly, and this results in the formation of a mixture of (LXXXVIII) and (LXXXIX):



According to the results of biological tests[65], 2′-methyl 17α-hydroxy-17β-methylandrostano[3,2-*d*]thiazole is a strong anabolic agent.

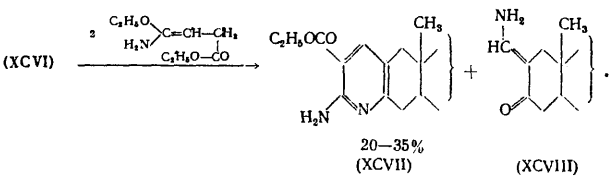
7. Triazolosteroids

The methods of adding a triazole ring to a steroid system have been inadequately studied. Only one method of synthesising compounds of this type has been investigated[71], based on the condensation of enamines[72] of steroid ketones with various azides. In this way, from 3-morpholylenamines of dihydrotestosterone and its 17α-methyl derivative (XC) the corresponding *N*′-carbobenzoxy-3-(*N*-morpholyl)-5α--androstan-17β-olo[2,3-*d*]triazoles (XCI) were obtained. In removing the morpholine ring by reduction with palladium on carbon or lithium tetrahydroaluminate, androstano-[2,3-*d*]triazoles (XCII; R′ = H) were obtained.



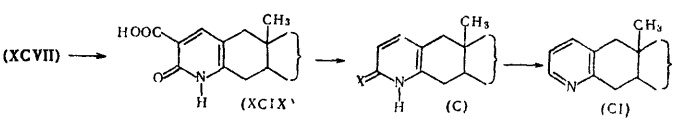
By reaction of dihydrotestosterone with phenyl azide, *N*′-phenyl-5α-androst-2-en-17β-olo[2,3-*d*]triazole (XCII; R = H; R′ = C_6H_5) is obtained, and from the 17α-methyl derivative (XC) the corresponding 17α-methyltriazole (XCII; R = CH_3, R′ = C_6H_5).

III. STEROIDS CONDENSED WITH SIX-MEMBERED HETEROCYCLES



1. Pyridino- and Quinolino-Steroids

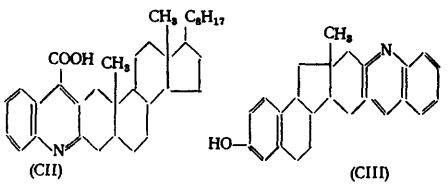
On boiling an ethanol solution of dihydro-2-hydroxymethylenetestosterone and its 17α-methyl derivative with cyanoacetamide in the presence of triethylamine the corresponding 5′-cyanosteroido[3,2-*b*]pyrid-6′-ones (XCIII) are obtained[73]. Triethylamine is necessary for this conversion, because on replacing it by sodium ethoxide reaction does not occur, and in the presence of piperidine only a 2-piperidinomethylene-3-keto-derivative is obtained (XCIV). In the absence of catalyst and solvent at 180° a pyridonocarboxamide derivative (XCV) is formed[73]:



where for (a) X = O, and for (b), X = S; R = H, CH_3.

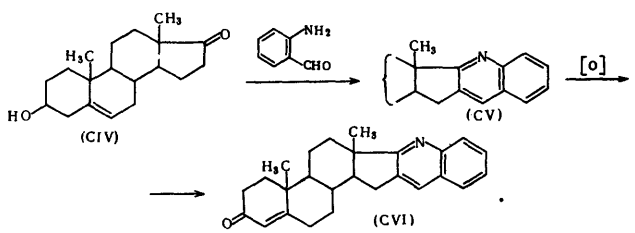
The condensation of (XCVI) with cyanothioacetamide in methanol proceeds analogously both with triethylamine and with piperidine, with the formation of thiopyridones (XCIIIb) in good yield. This condensation does not occur when a Δ^4 double bond is present, although these same Δ^4 compounds condense well with the amide amidine of malonic acid or with ethyl 3-amino-3-ethoxyacrylate, pyridine derivatives (XCVII) being formed[74]. Considerable amounts of 2-aminomethylene derivatives (XCVIII) are formed as side-products during this:

For proof of the structure, the products (XCVII) were hydrolysed into carboxypyridone-derivatives (XCIX), which at 300° in a vacuum were decarboxylated into pyridones (Ca). With phosphorus pentasulphide the latter is converted into thiopyridones (Cb), which can also be obtained by condensation of (XCVI) with cyanothioacetamide. Finally, unsubstituted pyridines (CI) are obtained by treatment with dimethyl sulphate in water–methanol solution of potassium hydroxide with subsequent desulphurisation over Raney nickel[73]:



for (a) X = O; for (b) X = S.

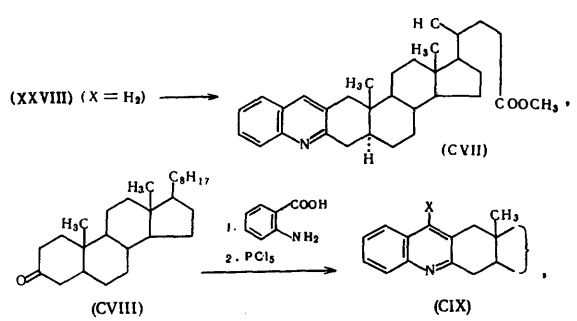
In biological tests compounds of the pyridinosteroid class showed a favourable ratio of activity, although to a considerably weaker degree than testosterone propionate[73].



Evidently the first synthetic representative of the quinolinosteroids are the 4′-carboxycholestano[3,2-*b*]quinoline (CII), 4′-carboxyoestrono[17,16-*b*]quinoline (CIII), and the products of their decarboxylation[75], obtained by condensation of the corresponding steroid ketones with isatin by the

Pfitzinger reaction. It was found[75] that the sodium and potassium salts of these acids exhibit strong haemolytic activity:

(CII) (CIII)



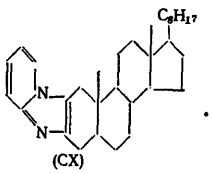
The Friedländer reaction has been used successfully for making steroidoquinolines. For example, condensation of androst-5-en-3β-ol-17-one (CIV) with *o*-aminobenzaldehyde in a basic medium gave androstano[17,16-*b*]quinoline (CV) in 90% yield[76], which is smoothly oxidised after Oppenauer into an αβ-unsaturated ketone (CVI). The quinoline (CV) was also obtained by counter-synthesis from (CIV) by the Pfitzinger reaction[76]:

(CIV) (CV) (CVI)

Analogous conversions were performed in a series of 5,6-dihydro-derivatives of the initial steroids[76].

The methyl ester (CVII) was obtained from the methyl 3-ketocholanate in this way[6]:

(CVIII) (CIX)



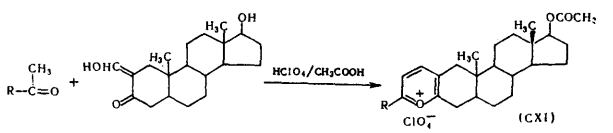
for (CVIII), X = OH; for (CIX), X = Cl.

On heating cholestan-3-one with *o*-aminobenzoic acid, 4′-hydroxyquinoline (CVIII) was synthesised, which on reaction with phosphorus pentachloride or phosphoryl chloride is converted into the 4′-chloro-derivative (CIX).[6]

However, attempts to condense unsaturated ketones (cholestenone, testosterone) with isatin were unsuccessful[75] and also there was no success in obtaining quinolino-[3,4-*b*]steroids from 2,2-dimethylcholestanone even under severe conditions[76].

The absorption of quinolinosteroids in the ultraviolet region is analogous to that for 1,2,3,4-tetrahydroacridine and 2,3-cyclopentanoquinoline. However, for cyclopentanoquinolines of type (CV), as a result of the increased strain of the ring, a feebly hypsochromic shift of the multiplet absorption in the 305–320 nm region is observed[76].

On treatment of 2α-bromo- or 2α-pyridino-3-ketosteroids with hydroxylammonium chloride in pyridine solution steroid compounds of type (CX) are obtained which contain imidazo[1,2-*a*]pyridine rings[77]:

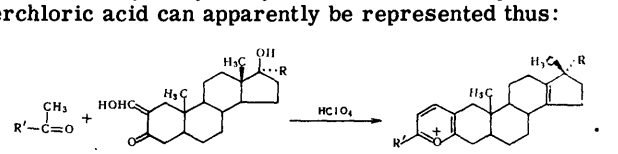


(CX)

2. Derivatives of Steroidopyrylium Salts

In recent years pyrylium salts have attracted the attention of many investigators owing to the high reactivity of the pyrylium cation and the possibility of converting it into various aromatic and heterocyclic compounds[78]. Among the various methods of synthesis of pyrylium salts, that of condensing β-dicarbonyl compounds with methyl and methylene ketones is attractive by its simplicity. Accessible cyclic hydroxymethylene ketones, readily obtainable from cycloalkanes, form pyrylium salts in good yield on condensation with ketones in the presence of perchloric acid[79,80].

It has been shown[81,82] that steroid hydroxymethylene-ketones are also quite convenient starting materials for obtaining steroid compounds with a condensed pyrylium ring:

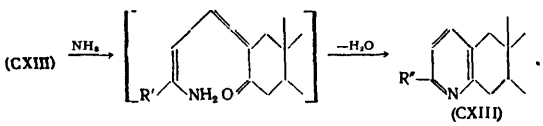


(CXI)

When a mixture of 2-hydroxymethylenedihydrotestosterone with an excess of aliphatic, aliphatic-aromatic, or heterocyclic methyl ketones in glacial acetic acid in the presence of equimolecular amounts of 70% perchloric acid is heated briefly on a water-bath, 6′-substituted 17-acetoxyandrostano[3,2-*b*]pyridylium perchlorates (CXI) are formed[82].

Steroidopyrylium perchlorates exhibit strong fluorescence when irradiated with ultraviolet light and also in solutions.

Under the conditions of the reaction the secondary hydroxyl group of the initial hydroxymethylene ketone is acetylated.

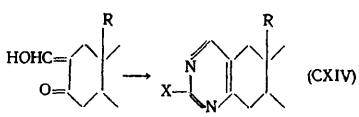


A series of pyrylium derivatives was also obtained on the basis of 2-hydroxymethylene-17α-methyl-[81] and 17α-ethyl--2-hydroxymethylene-dihydrotestosterone[82]. Here, as might be expected, the formation of pyrylium salts is accompanied by loss of the 17β-tertiary hydroxyl with a Wagner–Meerwein rearrangement. Therefore the reaction of the above hydroxymethylene-ketones in the presence of perchloric acid can apparently be represented thus:

(CXII)

The 6′-substituted 17α-alkyl-17β-methylandrost-13--eno[3,2-*b*]pyrylium perchlorates (CXII) which are formed, like other pyrylium salts, react smoothly with ammonia, forming in high yield the corresponding 6′-substituted

steroido[3,2-*b*]pyridines (CXIII). The synthesis of the simplest derivatives of this class by known paths is rather complicated and involves several stages[73] (see p. 33):

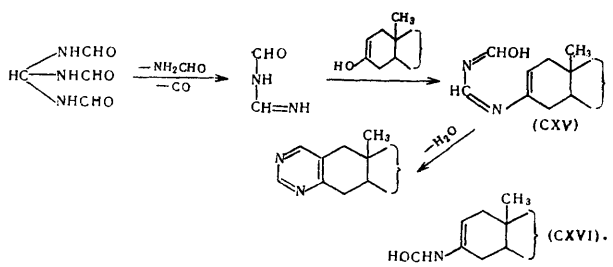


(CXIII)

3. Pyrimidinosteroids

Because many compounds of the pyrimidine series are physiologically active, attempts were made to synthesise condensed pyrimidinosteroids.

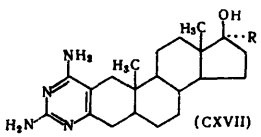
Various pyrimidine bases in the steroid series were obtained by the well studied reaction of condensation of 2-hydroxymethylene-5α-androstan-3-ones with guanidine, urea, and thiourea[32]. 2′-Amino-, 2′-hydroxy-, and 2′-mercapto-androstano[3,2-*d*]pyrimidines (CXIV) were obtained in this way. On treating the mercapto-derivative with Raney nickel it is smoothly converted into the unsubstituted derivative (CXIV; X = H):[32]



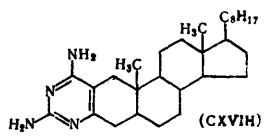
(CXIV)

where R = H, CH_3; X = H, HO, SH, NH_2.

No little interest is also aroused in the synthesis of pyrimidines by the treatment of ketones with trisformylaminomethane in formamide[83]. In this way pyrimidines unsubstituted at C_2' were obtained, identical with the products given by the method described above (CXIV; X = H).



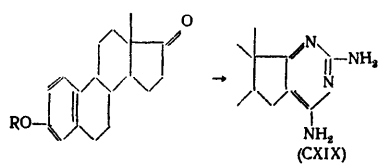
The first stage in the reaction is apparently the formation of a formamidine or formylformamidine which is subsequently cyclised with formation of a pyrimidine derivative by the scheme[84]:



The intermediate compound (CXV) can also be partly decomposed with loss of formamide and formation of a side product (CXVI).

However, the production of pyrimidines in this way is accompanied by low yields. Better results are obtained in the reaction of steroid hydroxymethylene ketones with formamidine or other amidines[25,65,85]. The reaction takes place on prolonged (4–27 h) boiling of an alcoholic solution of a hydroxymethyleneketone, an amidinium chloride, and a base (potassium hydroxide, sodium ethoxide, triethylamine).

Recently a method of synthesising 2′,6′-diaminosteroido-[3,2-*d*]- and 2′,6′-diaminosteroido[17,16-*d*]-pyrimidines[86] was also proposed on the basis of the previously developed condensation of ketones with cyanoguanidine[87]. In this way on the basis of testosterone and its dihydro- and 17α-methyldihydro-derivatives and also cholestan-3-one the corresponding androstano- and cholestano-pyrimidines (CXVII) and (CXVIII) were obtained:

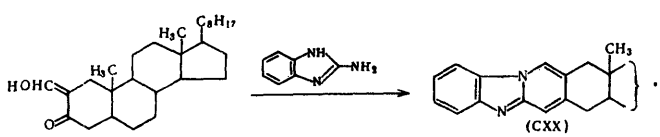


(CXVII)

(CXVIII)

where R = H, CH_3.

Analogous results are also obtained with 17-ketosteroids[86]. Oestrone and its methyl ester are converted into oestra-1,3,5(10)-trien-3-olo[17,16-*d*]-2′,6′-diaminopyrimidines (CXIX):

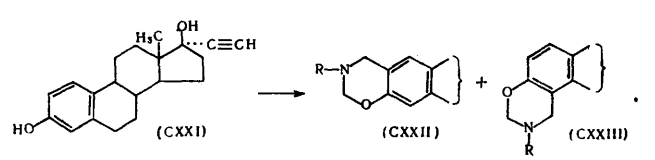


(CXIX)

where R = H, CH_3.

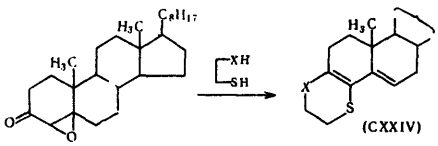
All the diaminopyrimidines obtained exhibit antibacterial activity against certain gram-positive micro-organisms[86], in particular against *Staphylococcus aureus*.

The interesting condensed heterocyclic compound (CXX) was synthesised by condensation of 2-hydroxymethylene-cholestan-3-one with 2-aminobenzimidazole[6]:



(CXX)

4. Dihydro-Oxazinosteroids



As shown earlier[88], dihydro-*m*-oxazines show specific anti-tumour activity and, unlike other carcinostatic agents, are devoid of toxicity. Because of this, the preparation of dihydro-oxazinosteroids was studied.

Condensation of the 17α-ethynyloestradiol (CXXI) with formaldehyde and primary amines gave a mixture of two isomeric oxazines (CXXII) and (CXXIII), which are readily separated chromatographically[89]. Of the preparations obtained, the oxazine (CXIII; R = cyclohexyl) was a good anti-tumour agent. In large doses, all the compounds obtained exhibit oestrogenic action:

Reaction of 4β,5β-epoxy-5α-cholestan-3-one with 2-mercaptoethanol in dioxan in the presence of polyphosphoric acid gives cholesta-3,5-dieno[3,4-*b*]oxathian (CXXIV; X = O) in 78% yield and on reaction with ethanedithiol the dithian

(CXXIV; X = S) is obtained[90,91]. The oxathian (CXXIV; X = O) can to a certain extent be considered as a sulphur analogue of dihydro-oxazines of the type (CXXIII):

(CXXIV)

---o0o---

The information given in the present review shows that the recent rapid developments in investigations of the chemistry of heterocyclic derivatives of steroids are of definite interest in the chemistry of steroids as a whole. It can be hoped that further development of work in this direction will allow new biologically active compounds to be synthesised, which will evidently find use as pharmaceutical preparations.

IV. Thermography and related methods of study 48

I. INTRODUCTION

Thermography[1] — an effective method of chemical study — was until recently comparatively little used in the study of polymers. In recent years, however, a large and increasing number of papers have been published on the use of thermographic methods in the chemistry of macromolecular compounds, and this makes it desirable to review this work and to describe the possibilities and future prospects of this method. The chapter in Ke's book on newer methods of polymer characterisation[2] contains interesting material, but does not exhaust the subject.

In the thermographic method, the change in the temperature of a specimen placed in a heating block is recorded as the latter is smoothly heated (or, less frequently, cooled). Particularly valuable information is obtained by recording the difference in the temperatures of the specimen being studied and a standard substance placed in the same block, or the difference in the temperatures of the specimen and the block itself. The resulting differential curve shows, in the form of peaks or other deviations from a straight line, all the thermal effects and all changes in thermal characteristics leading to more rapid or less rapid increase in the temperature of the specimen relative to that of the standard, within definite temperature ranges. This method is called differential thermal analysis (DTA). This term is being used increasingly as a synonym for thermography.

Usually, both the temperature of the specimen ("simple recording") and the above temperature difference are recorded simultaneously with respect to a time coordinate. At the present time, however, many papers give only differential curves.

Thermographic studies are carried out using photorecording instruments of different designs, for example, the Kurnakov apparatus[3] and its various modifications[4,5]. Recording on electronic potentiometers (recorders) is now widely used. The sensitive elements are usually low-inertia thermocouples, but resistance thermometers and thermistors are sometimes used. A general trend is the reduction of the size of the specimen from the previously used gramme quantities to milligrammes or fractions of a milligramme[6] without decrease in the sensitivity of the analysis and with the production of more highly resolved peaks.

Thermography is one of the basic methods for the phase analysis and thermal characterisation of substances. It also provides a means of studying various transformations taking place in substances, such as the aging of alloys[7]. Thermograms can be used for the quantitative estimation of thermal constants (heat capacity, thermal conductivity[8]), and to determine not only the temperatures but also the heats of phase transformations and chemical reactions: for a given heat transfer coefficient, the heat of the process is proportional to the area of the peak described by the differential curve during the corresponding transformation[9]. Although the theory of thermal analysis is still being developed[10], the thermographic method has provided the basis of a number of methods of determining thermal quantities — methods combined under the heading of thermographic calorimetry[11] — and also as a basis for the production of suitable apparatus[12].

A characteristic feature of the thermographic method is that in some cases different physical and chemical processes (for example fusion, boiling, and endothermic reactions) produce identical effects. It is therefore the task — sometimes not easy — of the research worker to interpret the thermograms obtained. For this purpose it is often necessary to carry out additional experiments in which the substance being studied is subjected to various forms of heat treatment, after which the thermogram is recorded again. The introduction of data obtained by other methods is also extremely useful.

While noting the fact that thermographic methods are comparatively little used in organic chemistry, Ravich[13] correctly points out that this situation has developed both as a result of certain scientific traditions, and also because of the specific features of the materials studied; he refers to the complicated structures of organic substances, and their ability to undergo supercooling, vitrification, the formation of a large number of non-equilibrium systems, etc. A rational explanation of the discrepancies in the data obtained by different workers who apparently studied identical materials can be obtained only by making allowance for the time factor[14]. These features are even more characteristic of polymers.

The applicability of thermographic methods to the study of polymeric materials is related to their tendency to undergo various physical and chemical thermal transformations. The various chemical processes — polymer formation, vulcanisation, thermal oxidation, and degradation — are accompanied by definite thermal effects. The conversion of a polymer from the vitreous state into the highly elastic state is accompanied by a change in the thermal characteristics. Crystallisation, fusion, and polymorphic transformations are accompanied by the liberation or absorption of heat. Fig. 1 gives a schematic thermogram[15] which covers the complete temperature range of existence of a polymer and illustrates the manifestation of most of the above processes. It is naturally a general scheme, to provide guidance in the study of specific thermograms†.

1) vitrification; 2) crystallisation; 3) fusion; 4) oxidation; 5) degradation.

II. STUDY OF STRUCTURAL TRANSFORMATIONS

1. Thermographic Manifestations of Transformations in Homopolymers

In the study of polymers it is necessary to bear in mind the lack of correspondence between the structural and thermodynamic criteria of phase states[16]. X-Ray and crystal-optical methods give the structural characteristics of polymers, whereas thermographic methods give the phase characteristics.

Phase transformations characteristic of polymers include the formation of a crystalline phase from an amorphous phase (crystallisation) and the opposite process — fusion. For polymorphic crystalline polymers, interconversion of the modifications is also observed. The thermograms provide an objective representation of all these processes.

Vitrification. The conversion of vitreous polymers into a highly elastic or viscous-fluid state, and the opposite process, although they are essentially not phase transformations since they occur within a single amorphous phase, are accompanied by a change in a number of the properties of the polymers, including their thermal properties. As a result, despite the absence of the thermal effect characteristic of phase transformations, the thermogram shows a characteristic inflection: a change in the course of the differential curve from that characteristic of a polymer in the vitreous state to that characteristic of a polymer after softening. When the conditions of the experiment are unchanged, the magnitude of the inflection can be used to estimate approximately the quantity of amorphous phase in partly crystalline polymers.

Dudek and Lohr[17] used the thermographic method to study the vitrification temperature of poly(methyl methacrylate) and the influence of small quantities of monomer and plasticiser on this temperature. The vitrification of poly(methyl methacrylate) and atactic polypropylene was

† In all the Figures, as in most thermographic work, values of $\Delta T > 0$ (exothermic effects) are plotted upwards along the axis of ordinates, whereas values of $\Delta T < 0$ (endothermic effects) are plotted in the opposite direction. It should be borne in mind that a number of authors, chiefly foreign, use the opposite sign convention. Where their work has been used in the present review, the thermograms have been redrawn in accordance with the above principle.

studied by Strella [18], who proposed a method for calculating the heat capacity from the difference in the temperatures of the periphery and centre of a cylindrical specimen. This method was discussed and the calculation refined by Haly and Dole [19].

Wunderlich and Bodily [20] used "dynamic differential-thermal analysis", which makes it possible to compare a large number of thermograms recorded at different rates. They showed that for slowly annealed amorphous polystyrene the thermograms in the vitrification range show not simply the jump characteristic of the quenched specimen, but also a peak, which increases with the rate of heating. This method was also used to study the kinetics of the vitrification and softening of polystyrene [21]. Keavney and Eberlin [22], in a study of the vitrification of poly(vinyl chloride), polystyrene, etc., showed that change in the size of the specimen and the rate of heating has no significant influence on the transformation temperature T_g. Murphy [23] used a thermographic method to determine the dependence of the vitrification temperature on the molecular weight of polyacrylonitrile.

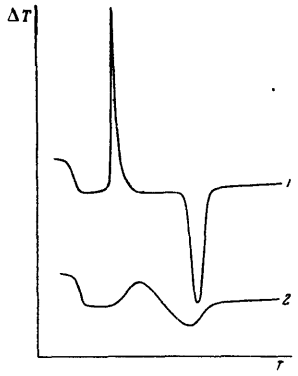

Fig. 2. Characteristic thermograms for an amorphous crystallising polymer: 1) with highly regular structure; 2) with lower regularity.

Crystallisation‡ can be observed on a thermogram if the rate of this process is commensurate with the rate at which the thermogram is recorded [25]. Since the thermogram usually covers an appreciable range of temperatures, the specimen during the experiment may find itself in a temperature range in which crystallisation takes place fairly rapidly; an exothermic effect will then appear on the thermogram. The absence of an effect from a given range does not indicate that crystallisation is not taking place. Thus the thermogram for amorphous natural rubber [26], which crystallises even at room temperature, does not show an exothermic effect in the corresponding range, since the process then takes place extremely slowly.

The intensity of crystallisation depends to a marked extent on the presence of crystalline nuclei in the bulk of the amorphous polymer [27]. Such nuclei may be provided, in particular, by traces of previously formed crystallites, which did not disappear completely when the polymer was converted into the amorphous state before the experiment. Sometimes, when the nuclei are removed completely, an exothermic effect may not appear on the thermogram, or the peak may be smaller and displaced towards higher temperatures.

Let us consider a polymer which is completely amorphous in the original state and which crystallises during the experiment (Fig. 2). The thermograms show a more or less sharp peak, whose area gives information on the integral heat liberation and hence on the total quantity of crystalline phase formed, and whose height gives information on the intensity of the process. A sharp high maximum indicates that all the material capable of crystallising has crystallised in a narrow time and temperature range ("explosively"). An equally sharp peak may be observed at a much higher temperature when the melt is cooled at the same rate. A broad range of intensive crystallisation is thus detected. The optimal temperature apparently lies in the middle of this range.

A high rate of crystallisation can be observed only in polymers with a highly regular structure. Decrease in regularity leads to a decrease in the rate of crystallisation, and the process then covers an appreciable temperature range. Considerable variations are observed in the degree of perfection or size of the resulting crystallites, and this is reflected in the considerable variation in their melting points. The temperatures of crystallisation and fusion of polymers differ considerably: definite melting points correspond to the observed temperatures of formation of crystallites [28]. This is also shown clearly on the thermograms. Illustrative data were obtained by Gray and Casey [29], who subjected polyethylene specimens, which had been converted into the amorphous form, to successive treatments at a series of decreasing temperatures. Each peak on the fusion thermogram corresponded to crystallites formed at a definite temperature (Fig. 3).

Fusion. In a thermographic experiment, crystallisation usually takes place at a continuously increasing temperature, and fusion also takes place continuously, over a wide temperature range. A flat exothermic crystallisation peak (curve *2* in Fig. 2) is often converted directly into an indistinct endothermic fusion minimum.

In many instances imperfect crystallites melt at temperatures favourable for subsequent crystallisation. Thus fusion is accompanied not only by formation of an amorphous phase but also by recrystallisation — the formation of more perfect crystallites melting at higher temperatures.

The dependence of the melting point on the rate of heating is due to two factors. The first of these — recrystallisation — tends to increase the temperature as the rate of heating is decreased, and is observed chiefly at low rates of heating. At rates of heating above a certain limit, the melting point is almost independent of the rate of heating [30] (it should be emphasised that here we are speaking not of

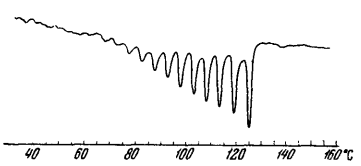

Fig. 3. Fusion of polyethylene crystallised at temperatures successively decreasing by 5 deg. [29]

‡ The crystallisation of polymers is discussed in detail in Mandelkern's monograph [24], but the thermographic method is not dealt with.

equilibrium fusion, but of metastable fusion). At high rates of heating, however, the second factor — superheating produced by kinetic factors — begins to operate in the opposite direction. It is here of interest to note the temperatures of three elements of the thermographic peak: the start, the peak value, and the end. For poly(tetrafluoroethylene)[31] at rates of heating reaching 46 deg min^{-1}, the superheating amounts to 30 deg, and is greater, the greater the molecular weight. The temperature of the start of fusion is independent of the rate of heating. At the intermediate rates used in thermographic studies, the possibility of superheating is small, and usually it is necessary to make allowance for the influence of only the first of the above factors.

The dependence of the temperature of the endothermic fusion peak T_{fusion} on the temperature at which crystallisation took place T_{cryst} (when almost no recrystallisation is observed during fusion) is close to linear (curve *1* in Fig. 4). The limiting melting point T_{lim} corresponding to the equilibrium crystals is characterised by the fact that the temperatures of crystallisation and fusion are equal. It can be found as the point of intersection of the extrapolated straight line giving the above relationship with a line drawn at an angle of 45° from the origin of coordinates ($T_{fusion} = T_{cryst}$). Using this method, Wyckoff[32] found the value 178.4° ± 0.3° for the limiting melting point of polypropylene. On recrystallisation, the curve giving the dependence of the melting point on the temperature of initial crystallisation undergoes a change in character; if the process took place under ideal favourable conditions, the crystallites formed at any temperature would reach the equilibrium state (line *2*). Usually, however, recrystallisation does not proceed to completion in a thermographic experiment, and the actual curve *3* lies between the two limiting straight lines.

Recrystallisation is revealed on the thermograms (Fig. 5) when the rate of this process is comparable to the rate of heating of the specimen during the thermographic experiment. Splitting of the fusion peak may be observed, due to superposition of the endothermic effect of fusion and the exothermic effect of crystallisation. By recording the thermograms at different rates, it is possible to observe a change in the ratios of the low-temperature and high-temperature peaks: the slower the rate of heating, the greater the relative magnitude of the latter. With very rapid heating, recrystallisation cannot take place at all. In this way it is possible to obtain proof that the splitting of the fusion effect is due to recrystallisation during the experiment. Frequently, however, the presence of two endothermic minima on polymer thermograms is due to other factors.

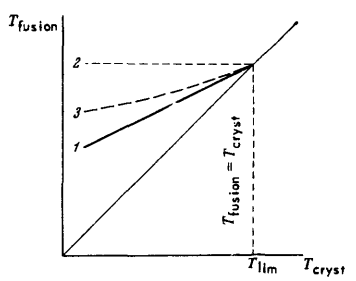

Fig. 4. Dependence of the melting point of a crystalline polymer on the temperature of crystallisation.

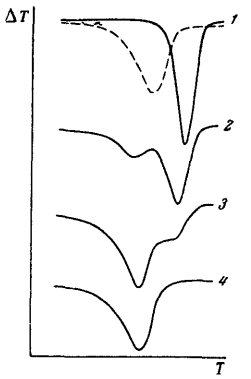

Fig. 5. Characteristic fusion thermograms for polymers in which the crystallites show a wide range of degrees of perfection. The rate of heating increases from 1 to 4; the broken line gives the hypothetical curve for where there is no recrystallisation.

Until now we have considered the thermograms of specimens in which the formation of crystalline phases takes place only during the actual thermographic experiment. Much more frequently, the crystallites in the specimens studied are formed at an earlier stage. The form of the thermogram then depends to a marked extent on the thermal pre-history of the material.

Since the crystallisation of a polymer can take place at a number of different temperatures, the crystallites obtained correspond to different endothermic peaks on the thermograms. For thermal analysis it makes no difference whether they correspond to different structural modifications (as for gutta-percha) or to crystallites of the same modification. This illustrates both the advantages and limitations of the thermographic method. On the one hand, it detects differences in super-molecular formations which cannot be detected even by X-ray diffraction. On the other hand, it cannot indicate whether the presence of two or more endothermic minima is due to differences in structure, recorded by X-ray diffraction, or to differences in the efficiency of aggregation. The existence of several endothermic effects with definite melting points (in the absence of polymorphic transformations) should not be regarded as an indication of the existence of the corresponding number of phases, since the crystallites of each type are not thermodynamically equivalent. Under favourable temperature conditions and over a sufficiently long period, they may all be converted into more stable crystallites with the "limiting" melting point. Thus the presence of these crystallites with different degrees of perfection, giving different peaks on the thermograms, is due not to thermodynamic but to kinetic factors.

Two or several fusion peaks are observed on a thermogram when the crystallisation has been carried out by treating the specimen at several gradually decreasing temperatures. On the other hand, when a specimen has been kept at several successively increasing temperatures, the thermogram shows only one endothermic peak, corresponding to the crystallites formed at the highest of the temperatures. (The previously formed low-temperature crystallites melt and undergo recrystallisation to different extents.)

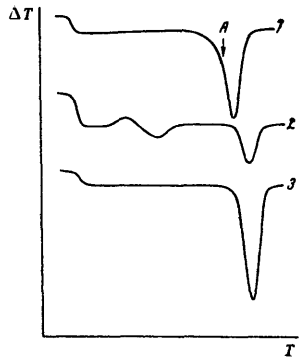

Fig. 6. Thermograms for crystalline polymers (schematic; see text for explanation).

If it can be assumed that the polymer has undergone recrystallisation, but that because of the relatively high rate of the thermographic experiment the process is revealed on the thermograms to only a very slight extent, it is best to treat the specimen in a special experiment for a more or less prolonged period at a temperature close to the melting point of the specimen, and then to verify, by repeating the recording, the efficiency of the recrystallisation process.

When non-equilibrium crystallites are heated for a relatively short period (at a temperature corresponding to point *A* on curve *1* in Fig. 6), only a small quantity of equilibrium phase is formed; the resulting amorphous phase is able to undergo only partial recrystallisation (the rate of crystallisation at this temperature is low), and can be detected in a subsequent experiment (curve *2* in Fig. 6): the thermograms show exothermic effects corresponding to the formation of new non-equilibrium crystallites from this amorphous phase, and the fusion of these crystallites. With increase in the duration of the constant-temperature treatment, the quantity of amorphous phase decreases and the quantity of equilibrium crystallites increases. The area of the peak and the peak temperature on the thermogram approach the limiting values (curve *3* in Fig. 6)[33].

Thus the thermographic method is extremely effective for the direct observation of the processes of crystallite formation and fusion in polymers, and also for phase analysis. It also reveals the thermal pre-history of a polymer specimen.

2. Thermographic Study of Individual Homopolymers

Early experimental results. The fusion and crystallisation of synthetic and natural polymers have been studied by a number of workers. Initially, the procedure used involved the construction of cooling and heating curves from data obtained by periodic temperature measurements (at isolated points). Baker and Fuller[34] and Jenckel and Wilsing[35] used this method to study crystallising polyurethanes and made a number of observations regarding the characteristic features of the fusion process, the dependence of the melting point on the conditions of crystallisation, etc.

The method of differential thermal analysis appears to have been used for the first time by Mikhailov and Klesman[36], who pointed out the characteristic features of the thermograms for two structural modifications of polyamides — crystalline and amorphous. They also undertook quantitative thermographic determinations of the heats of crystallisation and fusion of a polyamide of the polycaprolactam type. Even these early papers revealed the extensive possibilities provided by thermographic methods in the study of polymers, although the authors did not avoid a number of inaccuracies, in particular by attributing the endothermic effects to the conversion of the amorphous polymer from the vitreous state into the highly elastic state and from the highly elastic state into the viscous-fluid state. Subsequently, Mikhailov and Gorbacheva continued their studies of structural transformations in synthetic polyamides and polyesters[37], and studied the influence of the conditions of preparation, drawing, and heat treatment on poly(ethylene terephthalate) and fibres produced from it[38]. The same authors studied the influence of molecular weight (polycapramide and polypropylene), method of preparation — poly(vinyl alcohol) — and form (powder or fibre) (polyacrylonitrile) on the behaviour of polymers when heated[39]. Early work on the thermographic study of polymers includes Coste's work[40] on polyesters and polyamides.

Tolchinskii and coworkers[41] used the thermographic method to study polypropylene. They established the temperature limits of the crystallisation and fusion of the polymer, investigated the dependence of the crystallisation range on the rate of cooling, and estimated the degree of crystallinity of various polypropylene specimens.

Thermographic studies were also carried out by Ke, who examined various methodological features of the thermography of polymers and gave the differential-thermal heating and cooling curves for various grades of polyethylene, polypropylene, their mixtures[42], copolymers, and block-copolymers[43], and also the thermograms for various polyamides[44], polyesters[45], and other materials[46].

Polyalkenes. On the assumption that the heat of crystallisation of polyethylene is close to the corresponding value for hydrocarbons with sufficiently high molecular weight, Ke[42] determined the percentage crystallinity of this polymer by finding the ratio of the area of the peak on its thermogram to the peak area for dotriacontane, whose crystallinity was taken as 100%. The degree of crystallinity of polyalkenes was also determined by other workers. Thus Strella[47] describes the thermographic assembly, calculation procedure, and results obtained for crystalline polyethylene and polypropylene. On the basis of the theory that the heat capacities of the amorphous and crystalline sections of the polymer are additive, he used the experimental values of the deviations on the differential curve to calculate the degree of crystallinity for any temperature within the fusion range.

Wunderlich and Kashdan[49] studied specimens of polyethylene crystallised from the melt and isolated in the form of single crystals from solution. The degrees of crystallinity were compared by measuring the areas and heights of the thermographic peaks. In both instances good agreement with dilatometric data was obtained.

The slight lack of rigour in thermochemical calculations from the magnitude of the thermal effect of fusion is due to the fact that the conditions of the process are not isothermal. Chiu[50] described an assembly containing a heating block with two divisions. In the first of these the specimen is heated in the usual way until the required temperature is reached, after which it is immediately transferred to the second, constant-temperature division of the block, and the isothermal crystallisation curve is recorded.

The problems of the thermographic calorimetry of polymers have been examined by a number of authors[51,52]. The thermographic method has been used to study the kinetics of crystallisation of polypropylene[53] and to determine the temperature dependence[54] of the heat capacity of this polymer§. The crystallisation of polyethylene after partial fusion has been studied[55] and problems associated with the influence of the thermal history on the crystallisation of polyethylene have been investigated[56]. Similar problems have also been examined by a number of other workers[14,29,32,52,53,55]. Some thermodynamic aspects of the crystallisation of polyethylene and its copolymers have also been examined[57].

Baltenas and Igonin[58] found that for polyethylene specimens with different degrees of ordering the application of an external pressure of up to 3000 atm leads to an increase in the fusion range and to an increase in the temperature of the endothermic peak by 65–70 deg. This result shows the importance of the study of polymers under pressure; this aspect of thermographic studies has hardly been touched.

A number of factors influencing the shapes and dimensions of the elements of the fusion thermograms for polymers were studied by Ke[59]; he distinguishes factors which are determined by the characteristic features of the preparation of the specimens (the thermal history) and factors which are related to the characteristic features of the experimental procedure (size of specimen, rate of heating, method of introducing the thermocouples, etc.). Similar studies were made for synthetic fibres by Schwenker and Zuccarello[60]. As pointed out by Ke, the shape of the fusion peak gives information on the size distribution of the crystallites. The thermograms which he gives for random ethylene–propylene copolymers reflect the decrease in the percentage crystallinity and the decrease in melting point produced by introducing propylene units into the chain. The author explains this in terms of the effect of lateral methyl groups. In analogous situations, ethyl groups are even more effective. A similar phenomenon is also observed for copolymers of poly(ethylene terephthalate) and isophthalic acid; increase in the concentration of the latter in the copolymer to 40 mole % leads to complete suppression of crystallisation[45].

The thermograms for different crystallising polymers are in general of the same type. Thus the regular features noted for polyalkenes also characterise the thermograms for other classes of polymer.

Polyamides, polyethers, and polyesters. Inoue[61] studied the crystallisation and fusion of various polyamides, poly(oxymethylene), etc., in addition to polyethylene and polypropylene. A detailed study was made of Nylon-6; experiments were carried out to find how the crystallisation is influenced by the temperature of the melt, which determines the number of crystalline nuclei remaining (Fig. 7*a*). For Nylon-6 with high molecular weight and for poly(oxymethylene), two exothermic peaks are observed, attributable to the break in the rate of crystallisation with change in temperature. When a seed crystal is introduced, the crystallisation is complete at the temperature of the first peak (Fig. 7*b*). DTA data were used to estimate the heats of fusion and crystallisation of various specimens and to calculate their crystallinities.

§ The influence of nuclei on the crystallisation of polypropylene was recently studied by Beck and Ledbetter.[48]

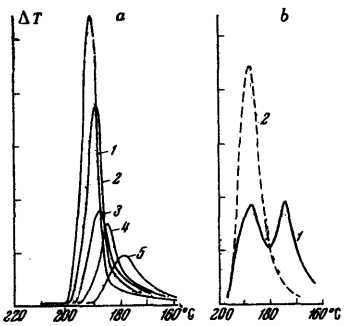

Fig. 7. Dependence of the crystallisation of Nylon-6 on:
a) the initial temperature of the melt: 1) 235°; 2) 245°; 3) 260°; 4) 290°; 5) 320°;
b) the presence (2) or absence (1) of nuclei-forming species.[61]

Gudim[62] used the thermographic method to study physical transformations in caprolactam and polyamide prepared by polymerisation in a vacuum, in an atmosphere of nitrogen, and in air, and also subjected to γ-radiation. The crystallisation and fusion of poly(ethylene terephthalate) were also studied[63]. Differential thermal analysis was used to study the properties of poly-β-propiolactone, prepared by polymerisation in the solid state[64].

The application of the method to organoelemental polymers has also been described[65].

Elastomers. Studies have been made of various forms of natural and synthetic elastomers (natural rubber, gutta-percha, and balata, and various grades of synthetic rubber), in which the fusion of the crystalline phase of the polymers and the conversion of the material from the vitreous state into the highly-elastic state were observed[66,67]. The influence of the rate of heating and the temperature of crystallisation on the melting point of rubber has also been noted[66]. The fusion ranges of the α and β forms of gutta-percha and the influence of the temperature of the melt on their ratio in the polymer were also studied.

Thermographic studies of natural rubber[69], gutta-percha[70], and synthetic chloroprene[71] and divinyl (SKD)[72] rubbers have been made by the authors of the present review. The vitrification, crystallisation, and subsequent fusion of rubbers which had been converted into amorphous forms have been studied, and the optimal crystallisation ranges have been determined. The areas of the peaks on the thermograms have been used to study the kinetics of the crystallisation of natural rubber and the way in which it is influenced by breakdown (milling)[73].

The thermograms of natural rubber show separate fusion peaks for crystallites formed at low temperatures (optimal crystallisation at -25°) and at room temperatures[69]. It has been established that the "high-temperature" crystallites act as nuclei for the low-temperature crystallisation; when the high-temperature crystallites are absent almost no exothermic effect is observed in the region of -25°.

For gutta-percha, cooling curves have been recorded in addition to heating curves. When melts obtained from the α or β forms of gutta-percha are cooled at medium rates, in every instance only the β form crystallises. When

the gutta-percha specimen is annealed at a temperature below the melting point of the β form, only the crystallites of this modification accumulate, whereas when the specimen is kept at a temperature slightly above the melting point of the latter, it is possible to obtain a material which exists almost entirely in the α modification[70].

Two specimens of highly regular divinyl rubber, containing 90% and 81% of the 1,4-*cis*-form, gave thermograms similar to those illustrated in Fig. 2 [72]. The extremely narrow crystallisation range of the first specimen results from the high degree of ordering and uniformity of the crystallites formed.

Recrystallisation processes are readily revealed on thermograms at rates of heating comparable with the rates of these processes. By annealing individual specimens of Nairit [neoprene type (Ed. of Translation)] at various temperatures, it has been possible to observe the increase in the degree of perfection of the crystalline phase and to obtain crystallites in a state close to the equilibrium state[71].

3. Thermographic Manifestation of Polymorphism in Polymers

Some crystallising polymers exist in various crystallographic modifications; we have already mentioned the α and β modifications of gutta-percha. When specimens which have been converted into the amorphous form are heated from low temperatures, the "low-temperature" less perfect form usually crystallises. Subsequently, when these crystals begin to melt, crystallisation of the second "high-temperature" form from the melt may be observed. In clearly defined instances the thermograms show a sharp exothermic effect which as it were separates the two peaks characteristic respectively of the fusion of each crystalline phase (curve *1* in Fig. 8). In less clearly defined instances the exothermic peak may not be so sharp, but the thermograms still show two minima or a "shoulder" on one side of the endothermic peak (curve *2* in Fig. 8). Finally, if the time required for the interconversion of the forms is very much greater than the time taken to pass through the corresponding temperature range in the thermographic experiment, the process is not observed at all on the thermograms. This is the reason for the fact that in the experiments referred to above the conversion of β-gutta-percha into the α form was not observed, whereas at extremely low rates of heating, which are very rarely used in thermographic studies, the thermograms reveal both forms[66,67]. The manifestation of polymorphism on the thermograms of *trans*-polybutadiene was observed by Dannis[68].

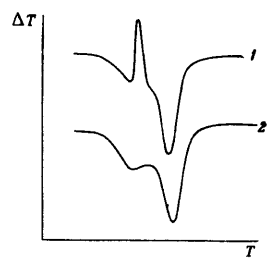

Fig. 8. Characteristic thermograms for polymers exhibiting polymorphism (see text for explanation).

Considerable attention has been paid to the study of the polymorphic transformations in polybut-1-ene, which exists in three modifications: their interconversions have been studied in detail[74]. The metastable tetragonal modification (form II) crystallises from the melt. Form III crystallises from solution. On its thermogram, the endothermic effect of fusion at 94° is converted into a sharp exothermic peak, which corresponds to the transformation of form III into form II. The second endothermic effect at 110° corresponds to the fusion of form II. Annealing of the specimen at appropriate temperatures increases slightly the melting point of each modification[75].

At room temperature, polybut-1-ene is gradually converted from form II into form I [76]; the rate of the conversion of form II into form I is much greater for specimens in the form of films than that for cast specimens[77]. The influence of traces of catalyst (ash) on the rate of the conversion of form II into form I was also studied. This conversion is irreversible[78]. The direct formation of form I during polymerisation has been described[79].

There is lack of agreement as to whether the transformation takes place with the formation of an intermediate melt or by a crystal–crystal scheme.

The phenomenon of polymorphism has been studied by the thermographic method for other series in addition to polyalkenes and dienes. Polyesters formed by adipic acid and *p*-phenylenebisethylene glycol, and also block-polyurethanes based on these materials[80], showed the existence of two polymorphic modifications, described as the α and β forms by analogy with gutta-percha. The heating curve for a polyester specimen which had been converted into the amorphous form and quenched revealed crystallisation of the β form at +12°. It begins to melt at 101–102°, but the exothermic crystallisation of the α form begins at 111°. This is followed by fusion of this form at 152°. The α form is obtained when a melt of the polyester is cooled slowly or when a specimen is subjected to constant-temperature treatment at 120–140°. The corresponding polyurethane which has been converted into the amorphous form crystallises in the β form at a slightly higher temperature and with a smaller thermal effect. The formation of the α form from this melt takes place less intensively, as indicated by the small exothermic crystallisation peak. The results obtained agree with data obtained by X-ray diffraction and infrared spectroscopy.

Of the other polymers, mention may be made of poly(tetrafluoroethylene), on whose thermograms Ke[46] observed two endothermic peaks at 20° and 29°, due to phase transformations in the polymer. The same result was obtained by Slonimskii and Ershova[81].

The thermographic method apparently detects not only the transformation of crystalline phases, but also some transformations in the vitreous state. Thus for polystyrene small thermal effects were observed at about 50°, attributed to hindering of the twisting vibrations of the phenyl groups[82].

4. Structural Transformations in Polymeric Systems

Berg[1], recommending thermography as a method for the phase characterisation of mixtures, points out that it is based on the fact that the temperatures of most phase transformations (and some reactions) are independent of the quantity and quality of the components in the mechanical

mixture. In solutions and alloys, however, the temperatures of phase transformations depend on composition, and thermographic study makes it possible to reveal this dependence. This is also true of polymeric systems, but there are additional considerations, related to the specific features of these materials. The phase analysis of polymeric systems in many instances gives quite definite results. The successful analysis of a mixture of seven polymers has been reported[83].

A random copolymer is a completely homogeneous system, which behaves like a homopolymer, with a characteristic set of properties; it is characterised by a definite vitrification temperature. For crystallising polymers, a decrease in crystallinity is observed on formation of copolymers, due to the non-regularity of the chain. This was examined above for the example of polyethylene containing propylene units. At a certain concentration of co-monomer, crystallisation may be suppressed completely, as mentioned above in connection with studies of polyesters[45]. It has been shown by DTA that polyethylene loses its ability to crystallise at a concentration of any of the co-monomers studied (methyl acrylate, methyl methacrylate, and vinyl acetate) of ~5.5 mole %[84].

Block and graft copolymers exhibit characteristic features which differ from those of random copolymers. In many respects they are similar to physical mixtures of polymers, for which the regular features of the thermograms are determined, as for any two-component or multi-component systems, by the phase equilibria: the presence and nature of ranges of separation into layers and crystallisation.

Systems formed by a polymer with a substance of low molecular weight. When a polymer and an inert filler are completely incompatible, the effects which they produce on the thermograms are completely independent and differ from those of the individual components only in their intensity. When the components are completely soluble (compatible) in the melt, crystallisation may lead to the formation of mixtures of the eutectic type, or solid solutions, and this, in accordance with the general principles of physicochemical analysis, determines the dependence of the melting points on composition.

Polymers which exhibit a limited compatibility with a substance of low molecular weight occupy an intermediate position. For crystalline polymers in these systems, the endothermic fusion peak is displaced usually towards lower temperatures. If the substance of low molecular weight is also crystalline, the thermogram also shows its characteristic fusion peak. This is illustrated in a paper by Ke[85]. The thermogram for a system in which the component with low molecular weight does not crystallise is shown in Fig. 9, and the thermogram for a system in which both components crystallise is shown in Fig. 10.

Polymer–polymer systems are characterised by thermograms which are determined in general by the same regular features. In the examination of mixtures of polymers, which may be obtained from compatible melts, solutions in a common solvent, or by milling, the question of the physical compatibility of the components of the mixture is of the greatest importance. This problem reduces to the determination of whether the system consists of one or several phases. In the first case the thermograms show one vitrification range and one range of crystallisation or fusion, whereas in the second (in principle at least)

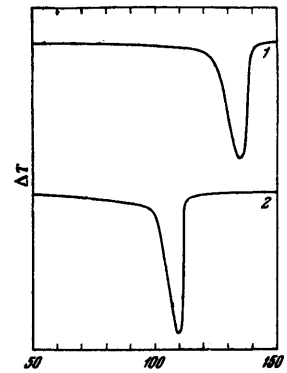

Fig. 9. Fusion of high-density polyethylene: 1) in pure form; 2) containing α-chloronaphthalene.[85]

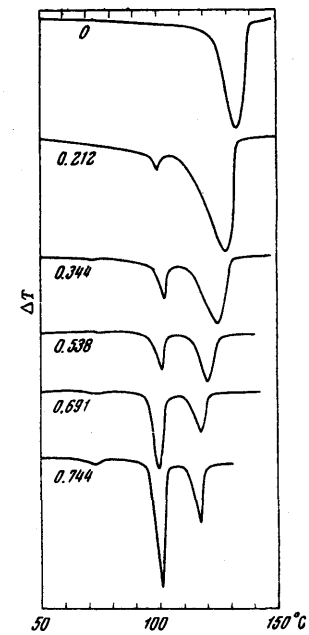

Fig. 10. Influence of phenanthrene on the fusion of high-density polyethylene. The figures next to the curves give the mole fractions of phenanthrene.[85]

the thermograms show several of these elements. Thermography thus provides a method for studying the compatibility of polymers. A study of this type was carried out by Mikhailov and coworkers[86] for the polyethylene–polypropylene system. The authors regarded the formation of two minima on the fusion curve as a criterion of incompatibility. Without objecting in principle to the conclusions reached here, we would point out that the formation of two minima is also observed for homopolymers, for which we cannot speak of compatibility. Thus the presence of several effects is a necessary but not a sufficient sign of non-homogeneity in a system.

Thermograms for the crystallisation of mixtures of the above system were given by Inoue[87]. A noteworthy feature is that the crystallisation of polyethylene and polypropylene takes place in the same temperature range. It

is natural that mixtures of these polymers should show a single crystallisation peak. Nevertheless, these polymers melt at different temperatures, and their non-homogeneous mixtures give separate fusion peaks on the thermograms [86,88].

In other examples the components of the mixtures may have identical melting points, and this feature must always be taken into account in the thermographic analysis of complex mixtures.

Mixtures of high- and low-density polyethylene give a homogeneous melt, but after the latter has solidified, the components melt separately, forming two peaks on the thermograms. An intermediate peak has also been observed [89], and on this basis an equilibrium diagram was constructed for the system, with an extended range of "mixed crystals" [90]. As shown above, however, not every thermal peak need be associated with a separate phase; it may be due to recrystallisation phenomena. A similar view is held by Gray and Casey [29], who consider that the intermediate peak results from annealing. Stafford [83] also studied mixtures of polyethylene with different densities by recording cooling (crystallisation) and heating (fusion) curves. He showed that the DTA method can be used for the quantitative analysis of mixtures.

Inoue [87] studied the crystallisation and fusion of mixtures of polyamides. The degree of crystallinity was determined from the peak areas, and it was concluded that a high degree of crystallinity is attained for the component present in excess. The decrease in the melting point (the peak value) observed for the high-melting component (Nylon-6) was almost imperceptible for the relatively low-melting component (Nylon-11). It should be noted that this last conclusion is not general, since changes in melting points are determined by the relationships between the components, responsible for the form of the fusion diagram of the specific systems.

Block copolymers. The thermograms of block copolymers show features characteristic of each of the polymers forming the blocks. If both are capable of crystallising, and the melting points are different, the thermograms show two separate fusion peaks, as for mechanical mixtures. For the ethylene–propylene block copolymer, Ke [42] showed the dependence of the magnitude of the peaks on the duration of annealing, and from the peak areas he estimated the proportion of each block in the total crystallinity. The same author observed a double exothermic crystallisation peak on the cooling curves, whereas a molten mixture of the corresponding homopolymers, in agreement with Inoue's data [87], gave only one unresolved peak.

Block and stereo-block copolymers with different compositions, obtained from the same components, have been studied [91]. It was found possible to determine the composition of the copolymers from the ratio of the areas of the fusion peaks on the thermograms (Fig. 11). Analogous studies were made by Porter and coworkers [92]. The quantity of crystallites corresponding to each block was found from the heights of the peaks on the thermogram. In spite of the arbitrary nature of this approach, it was found that the ratio of the height of the polyethylene peak to the sum of the heights of both peaks is an almost linear function of the weight fraction for mixtures and copolymers with different compositions. Over a considerable range of change in block ratios, the crystallinity of the copolymer is usually determined by the block present in excess. It is only in the range of comparable ratios that two systems of crystallites are observed simultaneously. This can be illustrated

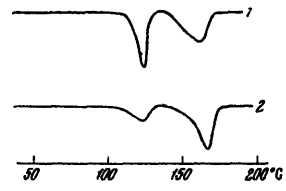

Fig. 11. Fusion of ethylene–propylene block copolymers:
1) 44 mole % ethylene; 2) 13 mole % ethylene. [91]

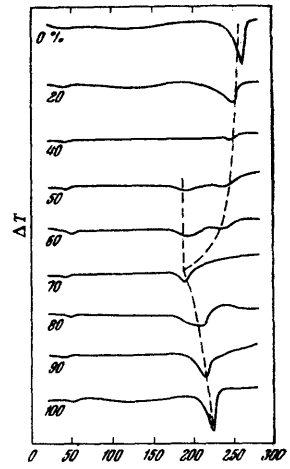

Fig. 12. Fusion of hexamethyleneadipamide–sebacamide copolymers for which a block structure was proposed. The figures next to the curves give the mole percentages of hexamethylenesebacamide. [44]

by an example [44] in which a study was made of poly(hexamethyleneadipamide–sebacamide) copolymers obtained by polycondensation at the phase interface (Fig. 12). The comparatively small displacement of the temperature peaks, shown by the broken line in Fig. 12, indicates, in the opinion of the authors, that the copolymers formed under the reaction conditions are block copolymers (random copolymers, in accordance with Flory's theory, give a much sharper decrease in temperature). The data given in Fig. 12 were used to construct a diagram resembling the eutectic fusion diagrams of binary systems. The "eutectic" composition corresponds to the copolymer containing 70% sebacamide. Block copolymers of the same adipamide with terephthalamide gave a diagram of the non-eutectic type, and this was attributed to the possibility of mixed-crystal formation.

Thermographic studies have been made [93,94] of model block polyesterurethanes, in which one block consisted of an aliphatic polyester and the other consisted of an arylene-containing polyester. The thermogram for a polymer consisting entirely of non-crystallising blocks showed only a jump at the vitrification temperature, after which the differential curve rose very slowly. As the percentage of crystallising blocks was increased, the effect of fusion was

revealed with increasing clarity (the effect is complex due to recrystallisation). In a series of copolymers for which both blocks are capable of crystallising, the regular features observed are similar to those described above for polyamides. In some instances the thermograms were complicated by the phenomenon of dimorphism, characteristic of the polyesters[80].

III. STUDY OF CHEMICAL REACTIONS

1. Thermal Reactions of Polymers

Vulcanisation, isomerisation, and thermal oxidation and degradation are all reactions which can be revealed by thermograms. All these processes are exothermic, except the last: degradation is usually accompanied by absorption of heat. Frequently, it follows one of the other processes (most frequently thermal oxidation) and the exothermic effect is converted into the endothermic effect, just as was observed in the range of crystallisation and fusion of crystals. These effects are observed at much higher temperatures, however, and there is usually no difficulty in distinguishing them. The extent of the exothermic range and the sharpness of the transition from oxidation (or other exothermic process) to degradation is determined by the nature of the polymer, the presence of stabilisers, and the nature of the surrounding atmosphere.

The transformations of phenol–formaldehyde resins were observed by Ravich and coworkers[13]. The exothermic effect at 165° for Resol corresponds to its conversion into Resite, whose thermogram does not show this effect. DTA was used to study[95,96] the vulcanisation of Vibrin-135 — a mixture of poly(glycol maleate) and triallyl cyanurate polymer. The exothermic peak in the range 150–180° corresponds to polymerisation at the double bonds of the polyester and the second allyl group of triallyl cyanurate. The exothermic effect at 300–320° is due to the polymerisation of the third allyl group.

The curing of a large number of commercial products — unsaturated ester resins and epoxide resins — has been studied[97], but the results given are not sufficiently definite. When epoxide compounds react with anhydrides and diamines, an exothermic peak is observed in the range 100–150° (at lower temperatures for the former than for the latter, due to the greater reactivity)[98]. The exothermic peak at 300–400° is considered to be due to the isomeric conversion of the epoxy-groups into carbonyl groups and the start of decomposition.

Unsaturated polyester–styrene copolymers have been studied[99]. The ratio of the exothermic peak areas for specimens cured at room temperature for different periods of time to the peak areas for a specimen studied immediately after preparation provided a measure of the degree of curing (Fig. 13). A similar method was used to study the cure rate of phenol–formaldehyde resins[100]. The rate of vulcanisation of rubber by sulphur has been studied[101] by recording the thermograms for specimens subjected to preliminary partial vulcanisation in a press for different periods of time at 153°. The influence of metal oxides on the vulcanisation of ebonite was also studied[102]. A modification of the thermographic method, which makes it possible to determine the heats of vulcanisation of rubbers, has been proposed[103]. The vulcanisation (under the influence of diamine, benzyl peroxide, or magnesium oxide) of the copolymer of vinylidene fluoride with perfluoroprene

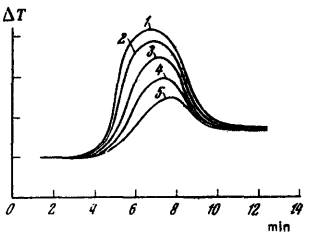

Fig. 13. Polymerisation during the heating of unsaturated polyester–styrene copolymers after hardening for:
1) 2; 2) 3; 3) 4; 4) 5; 5) 6 h.[99]

has been studied, but the thermograms obtained do not appear sufficiently significant[104].

In principle, the thermographic method can also be used to study various polymer-analogue transformations and other reactions taking place with the participation of macromolecular compounds. The thermal effects in the reaction mixtures are studied. Mention may be made of a unique application of the method to study the processes taking place in the water–heat treatment of starch[105,106].

2. Thermal Degradation

Thermographic methods are often used to estimate the thermal stability of polymers. The results of a thermographic experiment differ considerably from the data obtained by prolonged treatment of a polymer at elevated temperatures. This is due to the fact that the thermographic experiment, with its characteristic dynamic temperature conditions, lasts for only a short period and a measurable degree of degradation may be reached at higher temperatures than under the conditions of static tests. Moreover, the shape of the thermogram often depends on the dimensions and shape of the specimen and its degree of dispersion (block or powder), and also on the nature of the surrounding atmosphere. For comparative purposes, however, for example the comparison of a series of specimens, or the study of the influence of stabilisers or other ingredients, the thermographic method can prove extremely useful.

The thermographic method may give information on the mechanism of degradation of polymers. Thus the method has been used to study the degradation of polyethylene (high- and low-density) and polypropylene; it was found that degradation is preceded by oxidation with the formation of hydroperoxides[107]. The thermal behaviour of isotactic polypropylene has also been studied[108]. DTA has been used to investigate the influence of antioxidants on the thermal stability of polyethylene[109].

The thermal transformations of poly(methyl methacrylate), polystyrene, and phenol-formaldehyde resins have been studied[110]; effects associated with degradation of the polymers and secondary decomposition of the breakdown products were observed.

Lee[111] used a variety of methods to study the thermal stability of polycarbonates, and gave the characteristic thermogram for lexan. He considers that the exothermic peak at 300–320° corresponds to oxidation (it almost disappears in an atmosphere of nitrogen), and that the endothermic peak at 340–380° is due to depolymerisation

resulting from reactions such as the separation of hydroperoxides, hydrolysis, the separation of bisphenol, and alcoholysis. The processes of thermal degradation begin at higher temperatures: decarboxylation, dehydration, hydrolysis, dehydrogenation, chain rupture, and the separation of ester (together with possible formation of cross-linkages). With heating in air, these processes correspond to the endothermic peaks at 450–600°. Lee points out that since the initial step in the degradation is oxidation, this process should be inhibited to increase the stability of the polymer, but "pure" degradation may be observed independently of oxidation at higher temperatures. The degradation of block copolymers based on polycarbonate has been studied[112].

Korshak and coworkers studied polybenzimidazoles[113,114] and a number of polyarylates[115], which were shown by thermographic analysis to have a high thermal stability. The temperatures of the start of decomposition of the polyarylates lie in the range 375–465°, and those of the polybenzimidazoles lie in the range 460–520°. Mixed polybenzimidazoles (the diphenyl esters of a mixture of sebacic or terephthalic and isophthalic acids) show a slightly lower thermal stability than the homopolymers. Heat-resistant triazole polymers[116], hexa-allylmelamine polymers, and certain related compounds[117] have been studied.

Studies have been made of the thermal stability, characterised by the temperature where oxidative processes start, for some silicone polymers[118]. Pashchenko[119] has studied organosilicon compounds used as lacquers.

In a study of polymers with inorganic main chains, Andrianov[120] concluded, on the basis of DTA data, that cyclic compounds containing Si, Al, Ti, and Co atoms joined through oxygen have a high stability to elevated temperatures. Opening of the rings takes place above the temperature corresponding to the stability of the organic groups framing the inorganic part of the molecules.

Thermographic methods have been used[121] to study the compatibility of polymethyl methacrylate and octadecylammonium bentonite filler. The latter shows an exothermic effect on the thermogram at 285°, corresponding to the combustion of its organic fraction. This peak is completely suppressed in the presence of 10% poly(methyl methacrylate); the authors regard this as evidence for the compatibility of the polymer and filler.

Studies have been made of the processes taking place when SKN-40 nitrile rubber and phenol–rubber compositions based on it are heated[122]. For SKN-40, an exothermic effect begins at 250°, attributed to rearrangement of the internal structure and the formation of bridges between the molecules. Weight losses are observed above 360° due to oxidative thermal degradation.

The thermal analysis of some polyurethane elastomers[123] and polyester resins[15,124] has been carried out. The stability of a number of fibre-forming polymers has been studied[60] and it has been established that Nylon-6 and polypropylene give only endothermic peaks, indicating depolymerisation, whereas polycarbonate (lexan) and Teflon show both exothermic and endothermic peaks on the thermograms in the degradation range. The thermographic method has been used to study the pyrolysis of wood and its components[125]. DTA has been used to study the influence of inhibitors on the pyrolysis and combustion of α-cellulose[126]. Wood gives an interesting thermogram, which appears as the superposition of the thermograms of its main components — cellulose and lignin. A considerable number of thermograms of natural substances (celluloses, starches, and related compounds) have been published[127]. Studies have been made of the thermal stability and flammability of phenol and epoxide resins used as fillers for paper[128].

It is clear from a large amount of experimental material that the final stage in the recording of the thermograms may be the complete volatilisation of the degradation products (with an endothermic effect), or their combustion (with a sharp exothermic effect), or finally carbon formation, depending on the nature of the polymer and the conditions of the experiment. For an intensive study of the mechanism of degradation it is desirable to combine thermographic methods with study of the change in the weight of the specimen (thermogravimetric studies) and analysis of the decomposition products, for example by chromatography, mass-spectrometry, etc.

3. Reactions of Polymer Formation

A unique application of the thermographic method is in the study of the kinetics and mechanism of the reactions of polymer formation, since these processes involve the liberation of heat.

The thermographic method appears to have been first applied to the study of polycondensation by Brasseur and Champetier[129–131]. In the reaction of ethylene glycol, glycerol, and other polyhydroxy-compounds with phthalic anhydride, the endothermic effect due to fusion (dissolution) of the anhydride is followed by an exothermic maximum due to polyesterification; the water produced at this stage reacts with the excess of anhydride to form the acid. It is only at higher temperatures that the esterification of the dihydroxy- or polyhydroxy-compound by the acid produced leads to the liberation of water; the thermogram then becomes irregular due to the formation of bubbles of water vapour at the thermocouple. If acid is taken at the beginning of the reaction, no exothermic peak is observed on the thermogram.

Thermograms obtained in a study of the formation of phenol–formaldehyde resins[132] showed exothermic effects due to condensation of the original reagents (60–110°) and curing of the resulting resins (168–180°). It is of interest to compare the thermograms recorded at different component ratios (Fig. 14). The thermographic method has been used to study the formation of alkylphenolic resins[133].

The thermographic method has also been used to study the mechanism of polymerisation[134] for triallyl cyanurate and triallyl isocyanurate. Triallyl cyanurate gives peaks at 100° and 160–220°. The first was attributed to the reaction of two of the double bonds, and the second to polymerisation at the third double bond with the simultaneous

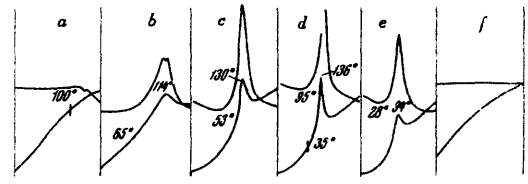

Fig. 14. Action of heat on phenol–formaldehyde mixtures with phenol concentrations (%):
a) 10; *b*) 30; *c*) 58; *d*) 80; *e*) 90.[132]

conversion of cyanurate into isocyanurate. In triallyl isocyanurate all the double bonds are polymerised at the temperature of the first exothermic peak.

The formation of macromolecular compounds by polymerisation under the influence of radiation has been studied. Since the process is exothermic, it has often been studied by measuring the increase in temperature in general [135] and by the thermographic method in particular. In the study of the polymerisation of formaldehyde in the solid state under the influence of γ-rays [136], it was found that at certain temperatures and intensities of irradiation the reaction acquires the character of a thermal explosion. The analogous reaction of acetaldehyde has also been studied [137].

DTA has been used to study the polymerisation, initiated by irradiation, of cetyl methacrylate, *N*-methylsuccinimide, and *N*-vinylcaprolactam in the solid and liquid states [138]. The reaction takes place smoothly or explosively, depending on the conditions. The radiation polymerisation of crystalline trithiane has been studied [139].

Kargin and coworkers [140-142] used the thermographic method to study the polymerisation taking place when certain monomers were heated below their melting points in the presence of magnesium vapour as initiator. They noted that this process takes place at temperatures close to the phase transformations of the monomer and is explosive in character. Thus the thermogram for the acrylonitrile–Mg system shows "spikes" on the differential curve at -165° or -135°. These temperatures correspond to exothermic maxima on the thermogram for pure acrylonitrile.

In the works cited, the thermographic method was used for the direct observation of polymerisation in the solid state, but it has also been used to characterise the polymers obtained [143].

IV. THERMOGRAPHY AND RELATED METHODS OF STUDY

The thermogravimetric method. The method involving the periodic weighing of a specimen kept at a definite temperature is often used to estimate the thermal stability of a polymer and to study the kinetics of its decomposition. The automatic recording of the change in weight in a controlled atmosphere, particularly under vacuum, both under isothermal conditions and with regular increase in temperature, has undoubted advantages [144]. In the latter circumstance the thermal conditions correspond to those used in the thermographic method, so that it is possible to record thermographic and thermogravimetric curves simultaneously; this method is used in the study of minerals [145]. The assembly may also record the linear contraction of the specimens [146] (see also Mashintsev and coworkers [147]). In another successful development [148], the apparatus records not only the simple and differential temperature curves and the weight curve, but also a differential curve characterising the rate of change in weight. This apparatus has been called a derivatograph.

Thermography with recording of the gas liberation. The formation of gas during the thermal degradation and certain other reactions of polymers makes it possible to study these processes from the dynamics of gas liberation. Both manometric [149,150] and volumetric methods can be used. An advantage of the volumetric method over the manometric method is that the pressure is kept constant, so that it does not oppose the reaction. The combination of the thermographic method with automatic recording of the gas liberation was developed for substances with low molecular weights [151], but it can also be applied successfully to polymeric materials. The possibility of carrying out the recording at reduced pressure is extremely valuable [152]. Although this method has not yet been applied to polymers, we would like to point out its promising possibilities. It should be noted that the volumetric and thermogravimetric methods do not always give concordant results. For example, in the degradation of polymers the gases and non-condensing vapours form only one source of the loss in weight; condensing volatile decomposition products do not produce a change in volume.

The combination of thermographic methods with mass-spectrometry is extremely fruitful. Under smooth heating conditions, it is possible to record the thermograms and either to obtain the mass spectrum (with rapid scanning) at various temperatures or to record continuously the ion current — either the total current or the current corresponding to a given ion, for example H_2O^+ (m/e = 18). In one scheme [153] a milligramme specimen is placed in a miniature furnace mounted directly in the ion source of a mass-spectrometer of the time-of-flight type. The decomposition is carried out under the extremely high working vacuum conditions of the instrument (about 10^{-7} mmHg). In another development [154], the gases formed on decomposition pass into the mass-spectrometer along a tube from a removable heating block in which any desired pressure can be maintained. In the latter case, however, retardation of the mass-spectrometric peak relative to the thermographic peak may be observed, the retardation being greater, the higher the pressure and the greater the "dead volume" of the system. This method, which has been tested for substances of low molecular weight, appears quite promising for the study of polymers. The same is true of the combination of thermographic methods with gas chromatography.

Thermography combined with microstructural studies. The thermograms for micro-quantities of a substance can be recorded directly on a microscope slide, heated by a linear programme on a special heated microscope stage [155]. It then becomes possible to make simultaneous observations, to take photographs at intervals, or even to record a cine-film. A correlation is thus established between the structural changes observed in the microscope and the thermal effects on the thermogram. This method, which has been used successfully, in particular, to study the phase structure of triglycerides, also appears promising for the study of polymeric materials. The combination of the widely used microscope observation of structures and their transformations with thermographic characterisation of the polymers appears extremely promising.

Thermographic and thermomechanical methods for studying polymers. Thermomechanical curves [157] are widely used in the study of polymers [158]. The method most similar to the thermographic method is that in which the temperature is altered by a linear programme and the deformation of the polymer takes place under the influence of a continuous load [159]. Automatic recording of the deformation on deformation–time coordinates or, more particularly, deformation–temperature coordinates [160,161] makes it possible to compare the curves obtained with thermograms recorded under the same thermal conditions. An assembly has been described, in which the

specimens used to obtain the thermograms and thermomechanical curves are heated simultaneously in the same block.

The thermomechanical curves for amorphous polymers can be used to determine the temperatures of vitrification and flow. The thermograms give the vitrification point but do not reveal the point corresponding to conversion into the fluid state. The thermomechanical curve records any change in the state of the polymer, if this change is associated with a change in its deformability (under a varying load)[162]. The thermographic method records a change in the state of the substance through its thermal properties, and the thermomechanical method records a change in state through the mechanical properties. In specific instances these methods may show different sensitivities to a change in state, so that the two methods supplement one another.

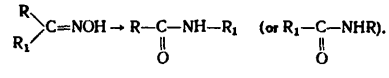
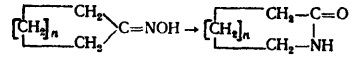
KINETICS AND MECHANISM OF THE BECKMANN REARRANGEMENT OF ALICYCLIC KETOXIMES UNDER THE CATALYTIC ACTION OF SULPHURIC ACID AND OLEUM



M. I. Vinnik and N. G. Zarakhani

CONTENTS

I. Introduction 51
II. Some properties of concentrated aqueous solutions of sulphuric acid 52
III. Some information about the mechanism of ionisation of alicyclic ketoximes in aqueous solutions of strong acids 52
IV. Rate constants of the Beckmann rearrangement of alicyclic ketoximes 53
V. Mechanism of the Beckmann rearrangement of oximes 56
VI. Temperature dependence of the rate constants of the Beckmann rearrangement of alicyclic ketoximes in sulphuric acid and in oleum 62



I. INTRODUCTION

In 1886 Beckmann[1] first carried out the conversion of oximes into acid amides. This reaction is called the Beckmann rearrangement. In the rearrangement of the ketoximes *N*-substituted amides of carboxylic acids are formed:

The Beckmann rearrangement was at first used only under laboratory conditions as a convenient and simple preparative method and as a method for establishing the structure of ketones. This reaction made it possible to synthesise a large number of amides, and also various amino-acids, which either were unknown or were obtained by complex processes of poor efficiency.

Recently the Beckmann rearrangement of a series of cyclic aliphatic ketoximes has attained great importance as an industrial method of obtaining lactams:

The rearrangement of cyclohexanone oxime into ϵ-caprolactam is of special importance. The industrial production of the lactam of ϵ-aminocapronic acid is one of the multi-tonnage processes of contemporary chemical industry. Wallach[2] obtained ϵ-caprolactam from cyclohexanone oxime under the catalytic action of sulphuric acid in 1900. ϵ-Caprolactam is the raw material for the production of one of the most important products of contemporary synthetic chemistry — caprolactam polyamide.

Lactams with a greater number of carbon atoms than ϵ-caprolactam also find application in industry, since they have been used as the basis of syntheses of polyamide resins with different physicochemical and mechanical properties.

The Beckmann rearrangement is an acid–base process and proceeds under the catalytic action of a large quantity of the reagents. The catalysts for this reaction are protic and aprotic acids. Concentrated sulphuric acid is usually employed, but phosphoric acid, phosphorus pentachloride, aryl sulphonyl chlorides, aluminium chloride, hydrogen bromide, and hydrogen fluoride are also used as catalysts. "Beckmann mixture" is an active catalyst for the rearrangement; it consists of a saturated solution of hydrogen chloride in glacial acetic acid, to which is then added ~ 20% acetic anhydride. This reagent is used under conditions when the oxime reacting is insoluble in other solvents.

Because of the great theoretical and practical interest of the Beckmann rearrangement, the literature devoted to an explanation of its mechanism is voluminous. There are

now over six hundred papers on the Beckmann rearrangement of various ketoximes and aldoximes. The most important information on this subject has been surveyed in detail in the review articles of Jones[3], Knunyants and Fabrichnyi[4], Donaruma and Heldt[5], and Zil'berman[6], and in Houben-Weyl[7].

Unfortunately, among the many publications devoted to the study of the mechanism of the Beckmann rearrangement, very few are of a quantitative nature. However, the ideas developed on the basis of synthetic data and also on the structure of the final and intermediate products of the rearrangement are undoubtedly of interest; such data are quite valuable for understanding the mechanism of the reaction.

The present review considers the kinetic data and mechanism of the Beckmann rearrangement of alicyclic ketoximes in aqueous solutions of sulphuric acid and in oleum. Sulphuric acid and solutions of sulphur trioxide in sulphuric acid are effective catalysts of this process; they are used in the industrial manufacture of ϵ-caprolactam. Parameters are known for these solutions which characterise the thermodynamic and catalytic properties used for establishing the mechanism of ionisation of the reagents and the mechanism of the limiting stage of the chemical process.

II. SOME PROPERTIES OF CONCENTRATED AQUEOUS SOLUTIONS OF SULPHURIC ACID

The Hammett acidity function H_0, the thermodynamic activity of the acid a_{HA}, and the thermodynamic activity of the water in the acid a_{H_2O} are quantitative characteristics of the catalytic activity of aqueous solutions of strong acids. It should be noted that in an investigation of the detailed mechanism of chemical reactions in acid media and particularly their early stages, a knowledge of the accurate values of H_0, a_{HA}, and a_{H_2O} of the solution in which the reaction is proceeding becomes particularly important. Fig.1 gives the values of H_0, $a_{H_2SO_4}$, and a_{H_2O} at 25° for concentrated aqueous solutions of sulphuric acid and dilute oleum. The values of $a_{H_2SO_4}$ were taken from Giauque and coworkers[8], the value of H_0 from Vinnik and coworkers[9], and the activity of water from Giauque and coworkers[8] and Vinnik and Ryabova[10].

The ionic and molecular compositions of aqueous solutions of sulphuric acid are also known[11,12]. Information about the equilibrium composition of the solution is needed to explain the mechanism of the physicochemical interaction of the reagent with the medium. The following species are in equilibrium in aqueous solutions of sulphuric acid: undissociated sulphuric acid H_2SO_4, the anions HSO_4^- and SO_4^{2-}, and also the ion pair $HSO_4^-.H_3O^+$ (or the hydrate of the acid $H_2SO_4.H_2O$). Fig. 2 shows the concentration of the ions HSO_4^- and SO_4^{2-}, the undissociated H_2SO_4 molecules, and the ion pairs $HSO_4^-.H_3O^+$ (or the species $H_2SO_4.H_2O$) as a function of the sulphuric acid concentration, after Zarakhani and Vinnik[12]. In dilute aqueous solutions of sulphuric acid, alicyclic oximes undergo hydrolysis. In aqueous solutions of the acid with >85–90% H_2SO_4, oximes are almost completely converted into lactams. As will be shown below, the rate constant of the Beckmann rearrangement increases with the concentration of the acid in the interval 85–100% H_2SO_4. In very dilute oleum the rate constant rises with increase in the concentration of sulphur trioxide in the solution. For these particular solutions the following

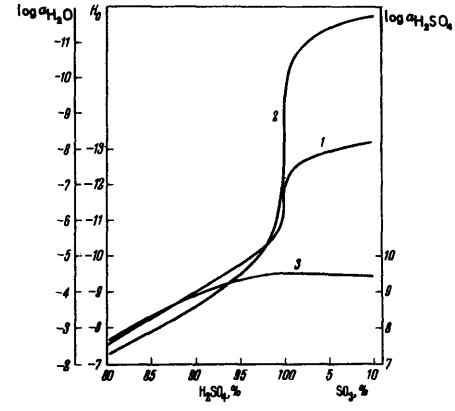


Fig. 1. Thermodynamic activity of water and acid and acidity function of concentrated aqueous solutions of sulphuric acid at 25°:
1) H_0; 2) $\log a_{H_2O}$; 3) $\log a_{H_2SO_4}$.

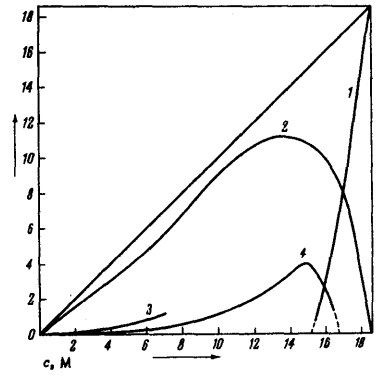

Fig. 2. Concentrations of ions and species in aqueous solutions of sulphuric acid:
1) H_2SO_4; 2) HSO_4^-; 3) SO_4^{2-}; 4) $HSO_4^-.H_3O^+$.

regularities are observed in the change of the parameters listed above. As the concentration of the acid is increased the acidity of the medium rises, the acidity function H_0 falls ($H_0 = -\log h_0$), the thermodynamic activity of the acid rises, and in the range 99–100% H_2SO_4 it is almost constant; the thermodynamic activity of water falls; the concentration of the HSO_4^- anions also decreases.

In oleum, as the concentration of sulphur trioxide is increased the concentration of the $H_3SO_4^+$ and $HS_2O_7^-$ ions rises but the concentration of the HSO_4^- anions falls[10]. The water activity a_{H_2O} also falls[10]. The activity of sulphuric acid $a_{H_2SO_4}$ in oleum falls — on account of the bonding by sulphur trioxide into pyrosulphuric acid and of ionisation, but apparently the decrease is slight.

III. SOME INFORMATION ABOUT THE MECHANISM OF IONISATION OF ALICYCLIC KETOXIMES IN AQUEOUS SOLUTIONS OF STRONG ACIDS

In acid solutions oximes are present in various forms coexisting in equilibrium. This has been shown by kinetic experiments on the hydrolysis of oximes in dilute aqueous

solutions of sulphuric and hydrochloric acids and also from information on the effect of additions of oxime on the acidity of concentrated solutions of sulphuric acid. As the concentration of the acid is increased, the effective rate constant of the hydrolysis of cyclohexanone oxime[13] and cyclopentanone oxime[14] at first rise, reach a maximal value, and then fall sharply. The maximal value of the rate constant of the hydrolysis is observed in extremely dilute solutions of the acid (see Fig. 3). For example, with cyclohexanone oxime the maximal rate constant is reached in 4.65×10^{-3}–6.52×10^{-3} M solutions of hydrochloric acid[15] and in 1.39×10^{-3}–5.2×10^{-3} M solutions of sulphuric acid[13]. The increase in the rate constant of the hydrolysis is connected with the appearance of reactivity in the protonated form of the oxime† $RNOH_2^+$:

$$RNOH + H^+ \rightleftarrows RNOH_2^+.$$

The decrease in the rate constant of the hydrolysis in such dilute solutions of acids can be explained only by change of the protonated form of the oxime into an unreactive form during the hydrolysis of the ion pair $RNOH_2^+.A^-$:

$$RNOH_2^+ + Cl^- \rightleftarrows RNOH_2^+ \cdot Cl^-,$$

$$RNOH_2^+ + HSO_4^- \rightleftarrows RNOH_2^+ \cdot HSO_4^-.$$

Hence from data on the dependence of the rate constant on acid concentration it follows that in aqueous solutions of strong acids alicyclic ketoximes are present in at least three forms: un-ionised RNOH, protonated $RNOH_2^+$, and ion pairs $RNOH_2^+.HSO_4^-$. The ion pair can also be named as a salt of the oxime‡. Calculations based on the data from hydrolysis show that alicyclic ketoximes are very strong bases. For example, cyclopentanone oxime and cyclohexanone oxime are already completely protonated in 0.05 *N* sulphuric acid[13,14] and hydrochloric acid[15] solutions. In more concentrated solutions the protonated form is completely converted into ion pairs. Cyclohexanone oxime in 2.5% H_2SO_4[13] and cyclopentanone oxime in 10% H_2SO_4[14] are found almost completely as the ion pairs $RNOH_2^+.HSO_4^-$. However, owing to the change in the activity coefficients of the ion pairs and protonated species in highly concentrated H_2SO_4 solutions, dissociation of the ion pairs occurs with formation of protonated species $RNOH_2^+$. For example, in 99% sulphuric acid the ion pairs of suberone oxime are completely dissociated and almost all the oxime in solution is present as the ions $RNOH_2^+$.

This conclusion is based on experiments on the influence of additions of oxime on the acidity of sulphuric acid solutions. In highly concentrated sulphuric acid small quantities of the dissolved substance change the acidity of the medium differently according to whether protonated species or ion pairs are formed. A change in the properties of the medium is reflected in the degree of ionisation of indicators used to measure the acidity function.

Water is known to be completely ionised in sulphuric acid solutions with >90% H_2SO_4:[16]

$$H_2SO_4 + H_2O \rightleftarrows H_3O^+ + HSO_4^-.$$

† Here and subsequently the following symbols are used: un-ionised form of oxime, RNOH; protonated form of oxime, $RNOH_2^+$; salt of oxime, $RNOH_2^+.A^-$; dehydrated salt, $RN^+.HSO_4^-$.

‡ The structure of the complex which consists of the protonated form of the oxime and the anion of the acid is unknown. It can be either an ion pair (a salt), or an ester of the oxime and sulphuric acid.

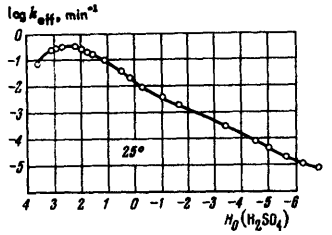

Fig. 3. Variation of the rate constant of the hydrolysis of cyclohexanone oxime with the acidity function H_0 of sulphuric acid.

TABLE 1. Effect of additions of suberone oxime on the ionisation of 2,4,6-trinitroaniline at 25°†.

H_2SO_4 concn., wt. %	Acid taken, g	Oxime added, g	$\log c_B/c_{BH^+}$ of indicator	H_0	H_0^*
99.145	6.684	—	—0.68	—10.64	—
	6.684	0.0868	—0.58	—10.54	—10.56
	6.684	0.281	—0.42	—10.38	—10.40
	6.684	0.413	—0.33	—10.29	—10.32
	6.684	0.544	—0.26	—10.22	—10.23

† H_0^* is the acidity function of a solution of 99.145% H_2SO_4 to which instead of the oxime an equal number of moles of water are added.

When the test substance changes the acidity function of the solution as does an equimolar amount of water, then it is present completely as the protonated form. When ion pairs are formed the change in the acidity function will be less than in the dissolution of the same number of moles of water. This criterion can be used to study the ionisation mechanism in 98–100% sulphuric acid where it is possible to use such small additions of the substance that concentrations can be used instead of activities in the expression for the equilibrium constant. Table 1 gives values of the acidity function for 99.145% acid with addition of suberone oxime. 2,4,6-Trinitroaniline was used as the indicator in measuring the acidity function. Relatively small additions of the oxime (up to 1 M) alter the acidity function of the medium by the same amount as equimolar additions of water. Consequently, oximes are present in these solutions as the protonated species $RNOH_2^+$.

IV. RATE CONSTANTS OF THE BECKMANN REARRANGEMENT OF ALICYCLIC KETOXIMES

In connection with the analysis of kinetic data on the Beckmann rearrangement it is desirable to note which methods are used to determine the degree of conversion of oxime into lactam. In some published works the degree of conversion of oxime into lactam was determined from the quantity of unreacted oxime. Wichterle and Roček, in an investigation of the Beckmann rearrangement of cyclohexanone oxime in oleum[17–19], determined the concentration of oxime in the specimens by a colorimetric method[20], based on the formation of blue 1-chloro-1-nitrosocyclohexane:

$$C_6H_{10}NOH + Cl_2 = 2HCl + C_6H_{10}(Cl)NO.$$

Chlorinated urea was used as the chlorinating agent. Ogata and coworkers[21], who investigated the rearrangement of cyclohexanone oxime in sulphuric and perchloric

acids, determined the unreacted oxime in the form of the 2,4-dinitrophenylhydrazone. The analysis of oximes by their conversion into 2,4-dinitrophenylhydrazones was also done in the work by Pearson and coworkers[22]. Methods based on the isolation of the oxime or on converting it into a coloured compound are laborious and making an analysis with their use requires a relatively large quantity of oxime. These methods can be used for investigating the kinetics of relatively slow processes, since 2–3 min are needed for sampling. To obtain a kinetic curve, not less than ten points are needed and then the time for half-conversion should be ~ 10–20 min.

It is convenient to use a spectrophotometric method for the common determination of oxime and lactam in the reaction mixture. This method is based on differences in the molar absorptivities of the oxime and the lactam in solutions of sulphuric acid and oleum. At 222 nm the molar absorptivity of the oxime is considerably greater than that of the lactam. The spectrophotometric method allows the kinetics of the process to be studied at low oxime concentrations with hardly any effect on the properties of the medium (10^{-3}–10^{-4} M), and here there is no necessity to remove samples and the optical cuvette itself serves as the reaction vessel. Therefore the spectrophotometric method can be used to measure the rate of unimolecular processes which take place relatively rapidly, even those where the time for half-conversion is 30–40 s. Ultraviolet spectroscopy has been used[23-26]. Heldt[27] used a spectrophotometer for measurements in the infrared region of the spectrum to study the kinetics of the Beckmann rearrangement of the esters of oximes with *p*-toluenesulphonic acid. Thanks to this, he succeeded in determining the frequency of the absorption bands of intermediate products of the chemical process.

The Beckmann rearrangement of alicyclic ketoximes is an irreversible process. In experiments where the concentration of the oxime in the acid is low the process is first order relative to the oxime and the unimolecular constant remains unchanged right up to complete conversion of the oxime into the lactam. Tables 2–8 give the available published rate constants for the rearrangement of alicyclic ketoximes in sulphuric acid and in oleum.

The kinetics of the rearrangement of cyclohexanone oxime has been investigated in several works and these data are given in Tables 3–6. We have made experiments at low oxime concentrations[26].

Ogata and coworkers[21] studied the rearrangement of cyclohexanone oxime in relatively dilute aqueous solutions of sulphuric and perchloric acids. The sulphuric acid concentration was varied from 48.4 to 79.1% H_2SO_4 at 90° and from 89.4 to 99.6% at 60°. The perchloric acid concentration was varied within the range 47.4–59.9% $HClO_4$, at 90°. As regards the experiments in 48.4–79.1% H_2SO_4 solutions there is no doubt that under such conditions the oxime did not undergo complete hydrolysis. Since during the course of the experiments the unreacted oxime was determined the rate constants quoted[21] probably reflect the consumption of the oxime in the overall-process, including both hydrolysis and the Beckmann rearrangement. The rate constants obtained[21] for 89.4–99.6% acid cannot be doubted and are given in Table 5. Under identical conditions these constants are less than our values of the constants[26]. Pearson and coworkers[28] determined the rate constants of the Beckmann rearrangement of certain aliphatic and alicyclic ketoximes in 94.5% sulphuric acid. At the same temperature the rate constant for cyclopentanone oxime, cyclohexanone oxime,

and cycloheptanone oxime (suberone oxime) differ somewhat from the data given in Tables 2, 3, and 7. It is impossible to find the precise reason for this discrepancy. It can be assumed that the decrease in the rate constants is connected with the fact that the experiments [28] were made at relatively large concentrations of the oximes (~ 0.1 M). These results are given in Table 6. The same table also gives the rate constants for the Beckmann rearrangement of certain aliphatic ketoximes in 94.5% sulphuric acid. Although in this article the discussion of the Beckmann rearrangement of aliphatic ketoximes is being especially avoided, these figures are nevertheless of interest for a comparison of the reactivity of various ketoximes.

Wichterle and Roček [17-19] investigated the Beckmann rearrangement of cyclohexanone oxime in oleum. This rearrangement is an exothermic process, the ΔH for this reaction in the gas phase being 22 kcal $mole^{-1}$. Since the

experiments were made with a relatively high concentration of oxime (~ 0.5 M), to avoid considerable overheating caprolactam was added to the reactor in addition to the oxime. Table 4 gives the rate constants for the rearrangement which they obtained.

In carrying out the reaction in oleum the rate constant is lowered by a high concentration of the oxime and also by additions of the lactam. The following facts may be quoted as an illustration. The rate constants of the Beckmann rearrangement of cyclohexanone oxime in oleum with 0.025-0.65 wt. % SO_3 at 25° have been determined [26] at ketoxime concentrations varying from 1.7×10^{-3} M to 32.4×10^{-3} M. Such concentrations of the oxime are almost without effect on the rate constant. These results are shown in Table 9. In the same table are given the rate constants for oleum with 1% SO_3, obtained by Wichterle and Roček [18].

In their experiments [18], the oxime concentration was ~ 0.5 M and together with this additions of caprolactam were made (14 g per 15 g oleum). This constant, even at 30°, is much less than the constant at 25° obtained with low oxime concentrations. This shows that additions of large amounts of oxime and lactam significantly lower the catalytic activity of oleum. As already mentioned above, low rate constants are also obtained in aqueous solutions of sulphuric acid in working with relatively large amounts of

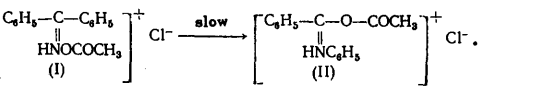
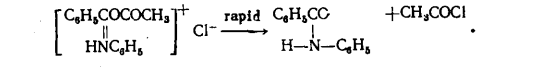
oxime (0.15–0.35 M). This should be taken into account in investigations where the rate constants are determined to provide information about the reactivity of substances of different chemical structure.

V. MECHANISM OF THE BECKMANN REARRANGEMENT OF OXIMES

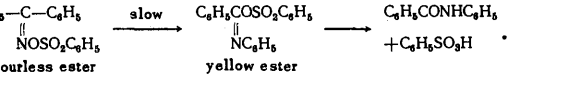


Until recently information on the mechanism of the Beckmann rearrangement of oximes was based on investigations of a preparative nature. Despite the fact that such investigations did not concern alicyclic ketoximes, it is helpful to analyse them, since it would be expected that in some of these conditions the rearrangement mechanism will not differ significantly for different ketoximes.

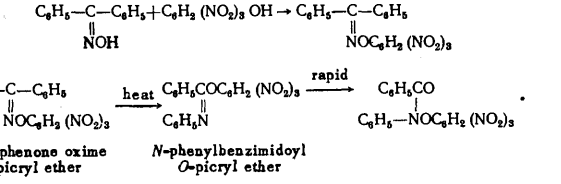
Sluiter[29] considered that not the oximes as such, but their esters, undergo the rearrangement. The exquisite preparative procedures of Kuhara[30] are based on this hypothesis.



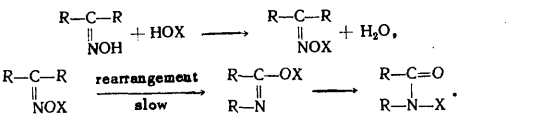
In studying the action of acid chlorides on the Beckmann rearrangement of benzophenone oxime, Kuhara observed that the ester of benzophenone and benzenesulphonic acid is rearranged at a very high rate. Under these conditions the chloroacetate exhibits much less reactivity and the acetate hardly undergoes any rearrangement. Benzophenone oximium acetate undergoes rearrangement on the addition of hydrogen chloride. Kuhara proposed the following mechanism. In the presence of HCl, acyl chlorides are obtained, which rapidly form a complex with the oxime:



The isomerisation of this complex is the limiting stage:



Complex (II) is an addition product of acetyl chloride and benzanilide. It decomposes rapidly with formation of benzanilide:



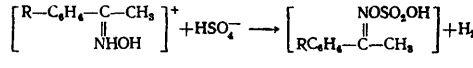
Kuhara showed that the benzenesulphonate which is formed in the reaction of benzenesulphonyl chloride with the sodium salt of benzophenone oxime is colourless. In time, this ester isomerises into another ester, which is yellow. In the presence of moisture (in moist air) the yellow ester is converted into benzanilide:

Chapman[31–34] obtained similar results for the Beckmann rearrangement of benzophenone oxime under the action of picric acid. The oxime and the acid form benzophenone oxime *O*-picryl ether which isomerises on heating into *N*-phenylbenzimidoyl *O*-picryl ether; the latter is rapidly converted into a salt of an anilide.

Chapman considers[31] that the formation of ethers can be explained by the catalytic action of many substances on the process of the Beckmann rearrangement of oximes. In the general example the mechanism can be represented by the following scheme:

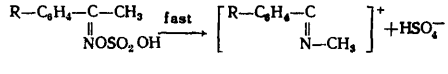
According to Chapman, the chlorides and oxide chlorides of phosphorus and sulphur, aryl sulphonyl chlorides, and, probably, sulphuric acid also act in this way. On carrying out the rearrangement under the action of hydrogen chloride in dichloroethane solution, the kinetic curves for the process have an autocatalytic nature[31]. The action of hydrogen chloride cannot be explained by the mechanism given above. This is also shown by the results of Stieglitz and Peterson[35,36], who showed that *N*-chloro-compounds of the type R–C–R do not undergo the Beckmann rearrangement.
‖
NCl

Pearson and Ball[37] consider that the mechanism for the Beckmann rearrangement proposed by Kuhara and Chapman explains the catalytic action of sulphuric acid in this process.



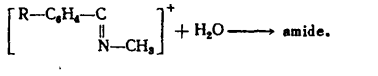
Firstly the oxime and acid form a salt-like complex. This stage is exothermic and in aqueous solutions of the acid it is reversible.

Stage I:



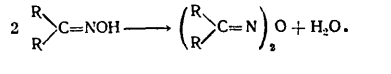
Then the salt-like complex loses water with the formation of the sulphate.

Stage II:



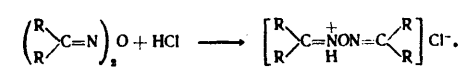
Unlike Chapman, Pearson and Ball assume that the dehydration stage, as a result of which sulphate is formed, is the slowest in the process. The sulphate is rapidly rearranged into a dehydrated ionised form of the amide (stage IIIa).

Stage IIIa:

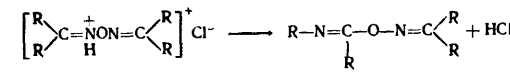


In aqueous solutions the ionised form of the amide rapidly adds on water (stage IIIb).

Stage IIIb:

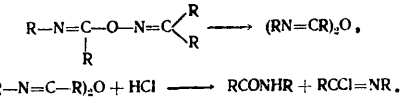


Dehydration of the oxime during the course of the Beckmann rearrangement has been demonstrated in experiments of Brodskii and Miklukhin[38,39]. They carried out the Beckmann rearrangement of benzophenone oxime in ethereal solution under the catalytic action of phosphorus pentachloride at 15°. After the process had ended, the reaction mixture was diluted with water containing an excess of ^{18}O. In the benzanilide obtained, the ^{18}O content was the same as in the water used for the saponification. In acid and neutral media benzanilide does not exchange this oxygen.



Stephen and Staskun[40] proposed another mechanism for the Beckmann rearrangement of ketoximes. In the opinion of these authors, the ketoximes form anhydrides:

Hydrogen chloride adds on to the molecule of the anhydride and forms a salt:



In the salt, according to the authors[40], the symmetry of the anhydride is destroyed, thanks to which it is rearranged into a ketoximimidate:

ketoximimidate

This rearranges into the imidoyl anhydride, which in the presence of HCl is converted into an amide:

This mechanism was proposed to explain the catalytic action of aprotic acids. According to this mechanism the reactive form is formed from the anhydride of the ketoxime. When the conditions are such that the fraction of the oxime present as anhydride is small, the process will be second order in relation to the oxime.

There are still no facts to confirm this conclusion. The authors of this scheme assume that the proton is attached to one of the nitrogen atoms. The possibility of attachment of the proton to the oxygen atom is not excluded.

We will analyse the kinetic demonstrations of the mechanism of the limiting stage of the Beckmann rearrangement of alicyclic ketoximes in sulphuric acid. As shown above, in aqueous solutions of sulphuric acid oximes are found in three forms: the un-ionised form RNOH, the protonated form $RNOH_2^+$, and the ion pairs $RNOH_2^+.HSO_4^-$. It is evident that no one of these forms in isolation is capable of reaction in the Beckmann rearrangement. The un-ionised form is not reactive since this process does not take place without a catalyst. The protonated form is also incapable of reaction in this process, since in solutions of the acid where almost all the oxime is present in this form the rate of the process rises on increasing the acidity of the medium. Under conditions where the rate constant of the Beckmann rearrangement rises the concentration of the ion pairs falls; in solutions with $>99\%$ H_2SO_4 the fraction of ion pairs calculated on the total oxime concentration can be neglected. Consequently, the ion pairs $RNOH_2^+.HSO_4^-$ are not reactive in this process.

In dilute oleum with increase in the SO_3 concentration in the solution the rate constant of the Beckmann rearrangement of cyclopentanone oxime, cyclohexanone oxime, suberone oxime, and cyclododecanone oxime rises to a certain value and then remains constant on further increase of the oleum concentration (Fig. 4).

For unimolecular processes the value of the rate constant is often reached under conditions where all the reagent is present in a reactive form. This form can be either a complex of the reagent with the catalyst or an ionised form produced by interaction of the reagent with the solution containing the catalyst. The ratio of the observed rate constant to the limiting value of the rate constant expresses the ratio of the concentration of the reactive species to the total concentration of the reagent under the given conditions.

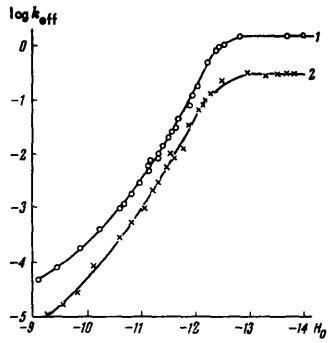


Fig. 4. Variation of log k_{eff} with H_0 in the Beckmann rearrangement of cyclopentanone oxime (2) and cyclododecanone oxime (1) in sulphuric acid and in oleum at 25°.

Judging from this criterion, in aqueous solutions of sulphuric acid right up to 100% H_2SO_4 the fraction of reactive species is low in comparison with the oxime concentration. This makes it possible to find the mechanism of formation of the reactive species from the dependence of the observed rate constants on the thermodynamic activities of the acid and water, and also the acidity of the acid solutions. In this it is understood that the kinetic experiments were made with the same low concentrations of oxime so that their effect on the values of the parameters mentioned could be neglected. The activity of the acid and water and the acidity functions for the range we are interested in are known for 25°. To be able to compare the values of k_{eff} with the quantities mentioned over wide ranges at 25° for relatively dilute solutions the rate constants were extrapolated from higher temperatures. Tables 10–13 give the values of k_{eff} at 25° for cyclopentanone oxime, cyclohexanone oxime, suberone oxime, and cyclododecanone oxime

from published sources[23-26]. In these tables values of H_0, a_{H_2O}, $a_{H_2SO_4}$, and values of $\log k_{eff}a_{H_2O}$ are given for corresponding concentrations of acid and oleum.

As these tables show, $\log k_{eff}a_{H_2O}$ remains constant in the range 91.74–97.18% H_2SO_4 for cyclopentanone oxime and in 85.34–90.3% acid for suberone oxime. Such a dependence can be obtained if two conditions are fulfilled: (a) the reactive form is produced in the dehydration of either $RNOH_2^+$ ions or the species $RNOH_2^+.HSO_4^-$; (b) almost all the oxime in the solution is present in a form which is dehydrated. On the basis of the above considerations the oxime can be present in such solutions as the ion pairs $RNOH_2^+.HSO_4^-$ and the protonated species $RNOH_2^+$. Dehydration of the ion pairs (salt) can be represented by Eqn. (1):

$$RNOH_2^+ \cdot HSO_4^- \rightleftarrows RN^+ \cdot HSO_4^- + H_2O. \quad (1)$$

Dehydration of the protonated species can be expressed by Eqn. (2):

$$RNOH_2^+ \rightleftarrows RN^+ + H_2O. \quad (2)$$

The ion pairs $RN^+.HSO_4^-$ can be considered as an association product of the dehydrated ions RN^+ with the HSO_4^- anions:

$$RN^+ + HSO_4^- \rightleftarrows RN^+HSO_4^-. \quad (3)$$

We will derive an equation for the variation of the observed rate constants k_{eff} on the quantities a_{H_2O}, $a_{H_2SO_4}$, and h_0 for instances when either the ions RN^+ or the ion pairs $RN^+.HSO_4^-$ are capable of reaction. We will use K_c to denote the thermodynamic constant of salt formation:

$$RNOH_2^+ + HSO_4^- \rightleftarrows RNOH_2^+ \cdot HSO_4^-,$$

$$K_c = \frac{a_{RNOH_2^+} \, a_{HSO_4^-}}{a_{(RNOH_2^+ \cdot HSO_4^-)}}, \quad (4)$$

where $a_{RNOH_2^+}$, $a_{(RNOH_2^+.HSO_4^-)}$, and $a_{HSO_4^-}$ are the activities of of the $RNOH_2^+$ cations, the $RNOH_2^+.HSO_4^-$ species, and the HSO_4^- anions. We will draw up the balance equation for the oxime under conditions when the concentration of the reactive species (this can be either the RN^+ ions or the $RNOH_2^+.HSO_4^-$ ion pairs) can be neglected. Such a condition is observed in the Beckmann rearrangement of cyclopentanone oxime, cyclohexanone oxime, suberone oxime, and cyclododecanone oxime in sulphuric acid solutions up to 100% H_2SO_4.

$$C_0 = C_{RNOH} + C_{RNOH_2^+} + C_{RNOH_2^+ \cdot HSO_4^-},$$

where C_0 is the total concentration of the oxime.

As already mentioned, alicyclic oximes have a high basicity. In solutions of acids where the Beckmann rearrangement occurs the relative concentrations of the un-ionised species of the oxime can be neglected:

$$C_{RNOH} \ll C_{RNOH_2^+} + C_{RNOH_2^+ \cdot HSO_4^-},$$

$$C_0 = C_{RNOH_2^+} + C_{RNOH_2^+ \cdot HSO_4^-}. \quad (5)$$

We will express $C_{RNOH_2^+}$ and $C_{RNOH_2^+.HSO_4^-}$ in terms of C_0 and the equilibrium constant K_c:

$$C_{RNOH_2^+} = \frac{C_0}{1 + \frac{a_{HSO_4^-}}{K_c} \cdot \frac{f_{RNOH_2^+}}{f_{(RNOH_2^+ \cdot HSO_4^-)}}}, \quad (6)$$

$$C_{RNOH_2^+ \cdot HSO_4^-} = \frac{C_0}{1 + \frac{K_c}{a_{HSO_4^-}} \cdot \frac{f_{(RNOH_2^+ \cdot HSO_4^-)}}{f_{RNOH_2^+}}}. \quad (7)$$

The activity of the anions of the acid $a_{HSO_4^-}$ is conveniently expressed in terms of $a_{H_2SO_4}$ and h_0:

$$a_{H_2SO_4} = K_{2A} \cdot a_{H^+} \cdot a_{HSO_4^-},$$

where K_{2A} is the thermodynamic constant for the dissociation of the hydrogen sulphate ions:

$$HSO_4^- \rightleftarrows SO_4^{2-} + H^+.$$

At 25°,[41] $K_{2A} = 1.2 \times 10^{-2}$. Since in aqueous solutions of strong acids[42], $a_{H^+} = h_0$,

$$a_{H_2SO_4} = K_{2A} \cdot h_0 \cdot a_{HSO_4^-}; \quad a_{HSO_4^-} = \frac{a_{H_2SO_4}}{K_{2A} \cdot h_0}.$$

We will use K_2 and K_3 to denote the expressions in the activities of the equilibrium constants of the processes of dehydration (1) and (2):

$$K_2 = \frac{a_{(RNOH_2^+ \cdot HSO_4^-)}}{a_{RN^+ \cdot HSO_4^-} \cdot a_{H_2O}}; \quad K_3 = \frac{a_{RNOH_2^+}}{a_{RN^+} \cdot a_{H_2O}}.$$

We will express the concentrations of the $RN^+.HSO_4^-$ species and RN^+ ions in terms of C_0, the equilibrium constants, and the quantities a_{H_2O}, h_0, and $a_{H_2SO_4}$:

$$C_{RN^+} = \frac{C_0 \frac{f_{RNOH_2^+}}{K_3 \cdot f_{RN^+}} \cdot \frac{1}{a_{H_2O}}}{1 + \frac{a_{H_2SO_4}}{K_{2A} \cdot K_c \cdot h_0} \cdot \frac{f_{RNOH_2^+}}{f_{(RNOH_2^+ \cdot HSO_4^-)}}}, \quad (8)$$

$$C_{RN^+ \cdot HSO_4^-} = \frac{C_0 \cdot \frac{1}{K_2 \cdot a_{H_2O}} \cdot \frac{f_{(RNOH_2^+ \cdot HSO_4^-)}}{f_{RN^+ \cdot HSO_4^-}}}{1 + \frac{K_{2A} \cdot K_c \cdot h_0}{a_{H_2SO_4}} \cdot \frac{f_{(RNOH_2^+ \cdot HSO_4^-)}}{f_{RNOH_2^+}}}, \quad (9)$$

where $f_{RNOH_2^+}$, f_{RN^+}, $f_{RNOH_2^+.HSO_4^-}$, and $f_{RN^+.HSO_4^-}$ are the activity coefficients of the ions $RNOH_2^+$ RN^+, and the ion pairs $RNOH_2^+.HSO_4^-$ and $RN^+.HSO_4^-$ respectively.

It is assumed that the rate of the limiting stage is determined by the concentration of the dehydrated species. Therefore with change in the properties of the medium k_{eff} should change by the same equation as the concentration of the reactive species. We will analyse Eqns. (8) and (9). The analysis of these is most convenient with the example of suberone oxime, since it is reliably known that in 99% sulphuric acid it is present completely in the form of the protonated species $RNOH_2^+$. Consequently, for such solutions in Eqn. (8):

$$1 \gg \frac{a_{HSO_4^-}}{K_c} \cdot \frac{f_{RNOH_2^+}}{f_{(RNOH_2^+.HSO_4^-)}}$$

and

$$C_{RN^+} = \frac{C_0}{a_{H_2O}} \cdot \frac{f_{RNOH_2^+}}{K_3 \cdot f_{RN^+}}.$$

It is well known how the ratio of the activity coefficients $f_{RNOH_2^+}/f_{RN^+}$ changes with the sulphuric acid concentration. Since, in the present example we are considering the very narrow range from 99 to 100% H_2SO_4, where it is possible to neglect the relative concentration of the reactive species it can be assumed that $f_{RNOH_2^+}/f_{RN^+}$ is constant. Then

$$\frac{C_{RN^+}}{C_0} = \frac{\text{const}}{K_3 \cdot a_{H_2O}}.$$

If the dehydrated ion RN^+ is reactive, then in the range 99–100% H_2SO_4 for the effective rate constant the equation

$$k_{eff} a_{H_2O} = \text{const} \frac{k_{true}}{K_1}$$

should hold, where k_{true} is the true rate constant.

As Table 12 shows, the quantity $\log k_{eff} a_{H_2O}$ for suberone oxime is not constant in 99.23–100% H_2SO_4. In this range the quantity $\log k_{eff} a_{H_2O}$ falls by a factor of 12. This greatly exceeds the possible change in the ratio $f_{RNOH_2^+}/f_{RN^+}$ in this narrow range.

The quantity $\log k_{eff} a_{H_2O}$ is also not constant in such a narrow range for other oximes (see Tables 10, 11, and 13). Consequently, the limiting stage of the Beckmann rearrangement of alicyclic ketoximes is not the isomerisation of the dehydrated ions RN^+. Since in the sulphuric acid concentration range being considered suberone oxime is almost completely present as the ions $RNOH_2^+$, in Eqn. (9):

$$1 \ll K_{2A} \cdot K_c \cdot \frac{h_0}{a_{H_2SO_4}} \cdot \frac{f_{(RNOH_2^+.HSO_4^-)}}{f_{RNOH_2^+}}$$

$$C_{RN^+.HSO_4^-} = \frac{C_0 \cdot a_{H_2SO_4} \cdot f_{RNOH_2^+}}{a_{H_2O} \cdot h_0 \cdot K_{2A} \cdot K_2 K_c \cdot f_{RN^+.HSO_4^-}}, \quad (10)$$

and in the present instance it can be taken that in the narrow range 99–100% H_2SO_4 the ratio of activity coefficients $f_{RNOH_2^+}/f_{RN^+.HSO_4^-}$ will be almost constant, and

$$\frac{C_{RN^+.HSO_4^-}}{C_0} = \frac{\text{const}}{K_{2A} \cdot K_2 \cdot K_c} \cdot \frac{a_{H_2SO_4}}{a_{H_2O} \cdot h_0}.$$

In the range considered the concentration of the reactive species can be neglected. If the ion pairs $RN^+.HSO_4^-$ are reactive, then:

$$k_{eff} = k_{true} \frac{a_{H_2SO_4}}{a_{H_2O} \cdot h_0} \cdot \frac{\text{const}}{K_{2A} \cdot K_2 \cdot K_c}.$$

In this instance the product $k_{eff} a_{H_2O} h_0 / a_{H_2SO_4}$ will be constant.

On increasing the acid concentration from 99.23 to 100% H_2SO_4 the effective rate constant of the Beckmann rearrangement of suberone oxime rises by a factor of 108. As the results in Table 12 show, in this interval the quantity $k_{eff} a_{H_2O} h_0 / a_{H_2SO_4}$ is almost constant. The scatter which occurs $\left(\log \frac{k_{eff} a_{H_2O} h_0}{a_{H_2SO_4}} = -8 \pm 0.1\right)$ is evidently connected with the error in determining the effective rate constants, the activity of water, the acidity h_0, and also with possible small changes in the ratio $f_{RNOH_2^+}/f_{RN^+.HSO_4^-}$. This quantity is also almost constant in this range for other oximes (see Tables 10, 11, and 13). This suggests the conclusion that the dehydrated ion pairs in this process are reactive. To obtain the complete equation for the dependence of k_{eff} on a_{H_2O}, h_0, and $a_{H_2SO_4}$ it is necessary to add to the balance equation derived above the concentration of the reactive species $RN^+.HSO_4^-$:

$$C_0 = C_{RNOH_2^+} + C_{RNOH_2^+.HSO_4^-} + C_{RN^+.HSO_4^-}.$$

If the $RNOH_2^+$ and $RNOH_2^+.HSO_4^-$ concentrations are expressed in terms of the concentration of the reactive species $RN^+.HSO_4^-$ and the equilibrium constants, we obtain:

$$C_{RN^+.HSO_4^-} = \frac{C_0}{1 + \frac{a_{H_2O} \cdot h_0}{a_{H_2SO_4}} \cdot K_{2A} \cdot K_2 \cdot K_c \cdot \frac{f_{RN^+.HSO_4^-}}{f_{RNOH_2^+}} + K_2 \cdot a_{H_2O} \frac{f_{RN^+.HSO_4^-}}{f_{RNOH_2^+.HSO_4^-}}}.$$

Precise analysis of this equation is difficult, since it is unknown how the activity coefficients in this equation change. There are grounds for assuming that with change in the sulphuric acid concentration over a wide interval (for example, from 85 to 100% acid) the activity coefficients of the ions and species mentioned change considerably. In the present instance the equation includes the ratios

$$\frac{f_{RN^+.HSO_4^-}}{f_{(RNOH_2^+.HSO_4^-)}} \text{ and } \frac{f_{RN^+.HSO_4^-}}{f_{RNOH_2^+}}.$$

There is reason to think that the ratio of the activity coefficients of two ion pairs will depend weakly on the acid concentration. As already mentioned above, in relatively dilute sulphuric acid solutions, where the Beckmann transformation occurs, the relation $\log k_{eff} a_{H_2O} = \text{const}$ is obeyed. Such a relation can be kept if the ion pairs $RN^+.HSO_4^-$ are reactive and the ratio $f_{RN^+.HSO_4^-}/f_{RNOH_2^+}$ is independent of the acid concentration. We assume that this ratio is constant also in more concentrated solutions of the acid.

We will represent $K_{2A} K_2 K_c f_{RN^+.HSO_4^-}/f_{RNOH_2^+}$ by $K_2' K_c'$ and $K_2 f_{RN^+.HSO_4^-}/f_{RNOH_2^+.HSO_4^-}$ by K_2'. Then:

$$C_{RN^+.HSO_4^-} = \frac{C_0}{1 + K_2' K_c' \frac{a_{H_2O} \cdot h_0}{a_{H_2SO_4}} + K_2' a_{H_2O}}. \quad (11)$$

We will write the expression for W, the rate constant of the process:

$$W = k \frac{a^*}{f^*} = k \frac{a_{RN^+.HSO_4^-}}{f^*} = k \frac{C_{RN^+.HSO_4^-} \cdot f_{RN^+.HSO_4^-}}{f^*},$$

where a^* and f^* are the activity and activity coefficient of the activated complex. The activated state is formed from the ion pairs $RN^+.HSO_4^-$. The activated complex and the ion pairs $RO^+.HSO_4^-$ have the same composition; therefore we

will assume that the ratio $f_{RN^+.HSO_4^-}/f^*$ is independent of the composition of the reaction medium:

$$W = k_{true} \cdot C_{RN^+.HSO_4^-} = \frac{k_{true}\, C_0}{1 + K_2' K_c' \frac{a_{H_2O} \cdot h_0}{a_{H_2SO_4}} + K_2' a_{H_2O}}$$

$$\frac{W}{C_0} = k_{eff} = \frac{k_{true}}{1 + K_2' K_c' \frac{a_{H_2O} \cdot h_0}{a_{H_2SO_4}} + K_2' a_{H_2O}}, \qquad (12)$$

Eqn. (12) describes the variation of the effective rate constant k_{eff} of the Beckmann rearrangement of aliphatic ketoximes on the quantities a_{H_2O}, h_0, and $a_{H_2SO_4}$ of aqueous solutions of sulphuric acid and oleum. In solutions where $C_{RN^+.HSO_4^-} + C_{RNOH_2^+} \ll C_{RNOH_2^+.HSO_4^-}$ the following relation should hold:

$$k_{eff} \cdot a_{H_2O} = \frac{k_{true}}{K_2'}.$$

As already mentioned, such a dependence exists for suberone oxime and cyclopentanone oxime. It is not valid for cyclohexanone oxime and cyclododecanone oxime in the sulphuric acid concentration range studied.

As the constants quoted below show, even in 90% acid cyclohexanone oxime is found almost completely as the protonated species $RNOH_2^+$. In 90% acid for cyclododecanone oxime the concentrations of the $RNOH_2^+$ ions and $RNOH_2^+.HSO_4^-$ species are commensurate. Therefore, for these oximes the product $k_{eff}a_{H_2O}$ does not stay constant. For suberone oxime and cyclopentanone oxime, the salt formation constant K_c' can be determined from the kinetic data for solutions of the acid where the relative concentrations of the $RNOH_2^+.HSO_4^-$ species and $RNOH_2^+$ ions are commensurate. If

$$C_{RN^+HSO_4^-} \ll C_{RNOH_2^+.HSO_4^-} + C_{RNOH_2^+},$$

then

$$k_{eff} = \frac{k_{true}}{K_2' K_c' \frac{a_{H_2O} \cdot h_0}{a_{H_2SO_4}} + K_2' a_{H_2O}}. \qquad (13)$$

Eqn. (13) can be transformed:

$$\frac{1}{k_{eff} \cdot a_{H_2O}} = \frac{K_2' K_c'}{k_{true}} \cdot \frac{h_0}{a_{H_2SO_4}} + \frac{K_2'}{k_{true}}.$$

This equation describes the variation of k_{eff} with h_0, $a_{H_2SO_4}$, and a_{H_2O} and allows K_c' and K_2'/k_{true} to be calculated. Fig. 5 shows the variation of $1/k_{eff}a_{H_2O}$ with $h_0/a_{H_2SO_4}$ for suberone oxime.

The salt formation constant K_c' at 25° is 0.29 ± 0.02 for suberone oxime and 0.1 ± 0.02 for cyclopentanone oxime.

The ratio $k_{true}/K_2'K_c'$ is calculated from the variation of k_{eff} on a_{H_2O}, h_0, and $a_{H_2SO_4}$ for acid solutions where

$$C_{RNOH_2^+} \gg C_{RNOH_2^+.HSO_4^-} + C_{RN^+.HSO_4^-},$$

If the limiting rate constants observed in oleum are true rate constants, then in dilute oleum there should be a transitional region where both the reactive form $RN^+.HSO_4^-$ and the ions $RNOH_2^+$ are present in commensurate concentrations.

In that region the effective rate constant should be given by the equation:

$$k_{eff} = \frac{k_{true}}{1 + K_2' K_c' \frac{a_{H_2O} \cdot h_0}{a_{H_2SO_4}}}. \qquad (14)$$

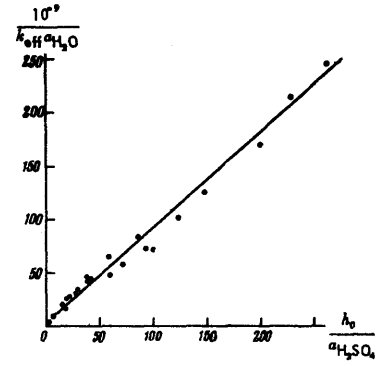

Fig. 5. Variation of $1/k_{eff}a_{H_2O}$ with $h_0/a_{H_2SO_4}$ for the Beckmann rearrangement of suberone oxime in sulphuric acid at 25°.

This equation can be used to calculate the value of k_{true} and $K_2'K_c'$. However, the true constants k_{true} calculated by Eqn. (14) are greater than the limiting values of the rate constants. For example, at 25° the limiting value of k_{eff} is 1.05 min^{-1} for cyclohexanone oxime, and the value of k_{true} calculated from Eqn. (14) is 1.35 ± 0.05 min^{-1}. For cyclopentanone oxime the limiting value of k_{eff} is 0.31 min^{-1} and the calculated value 0.6 ± 0.2 min^{-1}. Consequently, the limiting values of the rate constants in this instance do not correspond with the true values, that is, in solutions where k_{eff} no longer depends on the composition of the medium the reagents are not completely found in the reactive form. This is connected with the fact that in oleum containing 5–11% SO_3 the value of the constant $a_{H_2O}h_0/a_{H_2SO_4}$ (see Table 14) and therefore the degree of conversion of the oxime into the reactive form $RN^+.HSO_4^-$ does not change as the SO_3 concentration in the solution is varied.

Table 15 gives the values of the k_{true}, K_c', K_2', and $K_2'K_c'$ at 25° for four alicyclic ketoximes. K_2' and K_c' could not be calculated separately for cyclohexanone oxime. There are spectroscopic results which support the appearance of a new form of the oxime in the solutions of the acid where the

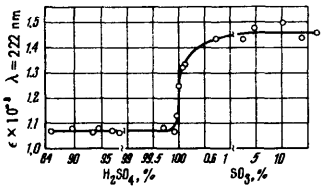
rate constant of the Beckmann rearrangement rises sharply. Fig. 6 shows the dependence of the molar absorptivity of cyclohexanone oxime at λ = 222 nm as a function of the concentration of sulphuric acid and oleum. As Fig. 6 shows, precisely in solutions where the H_2SO_4 concentration is over 99% and also in extremely dilute oleum the molar absorptivity of the oxime at λ = 222 nm rises sharply. This wavelength does not lie at the maximum absorption of the oxime; it is selected because the change in its absorption intensity was determined by the rate of the Beckmann rearrangement. Since this rise occurs in a rather narrow range of acid concentrations (from 99.9% H_2SO_4 to 0.1% SO_3) the possibility of explaining this by the displacement of the absorption maximum is excluded. Such effects are observed during the appearance of new forms of a substance which are distinguished from the other forms by the absorption coefficients at definite wavelengths.

In this way, on the basis of the results described, it follows that alicyclic ketoximes in concentrated sulphuric acid are present as four equilibrium forms: the un-ionised form, the protonated form, ion pairs, and dehydrated ion pairs. The form reactive in the Beckmann rearrangement is the dehydrated ion pair.

The mechanism can be represented as follows:

This mechanism does not differ in principle from that of Kuhara and Chapman proposed for the Beckmann rearrangement in non-aqueous solutions. According to Kuhara and Chapman the reactive form is the ester of the oxime and the acid. The results quoted do not agree with the mechanism proposed by Pearson and Ball[37]. According to them the ion pairs $RNOH_2^+.HSO_4^-$ should be reactive. As already mentioned above, the relative concentration of these falls in the sulphuric acid concentration region where there is a rise in k_{eff}. The limiting stage for the Beckmann rearrangement of alicyclic ketoximes can be either that of ion pair dissociation (rupture at the –N–O– bond) or that of rupture of the $-\overset{\diagdown}{C}-\overset{\diagup}{C}-$ bond of the ring in the $RN^+.HSO_4^-$ species. Since



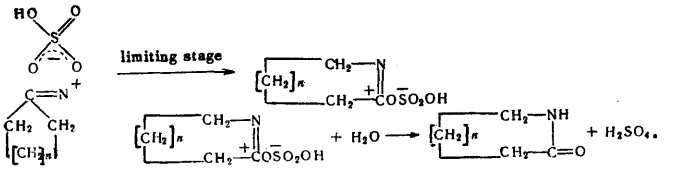


Fig. 6. Variation of the molar absorptivity (ϵ, litre mole^{-1} cm^{-1}) of cyclohexanone oxime at λ = 222 nm with the H_2SO_4 concentration.

the hydrated salt $RNOH_2^+.HSO_4^-$ is in equilibrium with the $RNOH_2^+$ cations, it can be suggested that the salt $RN^+.HSO_4^-$ is also in equilibrium with the products of its dissociation (RN^+ and HSO_4^-). In every instance ionisation, that is, rupture of the bond between nitrogen and oxygen, can proceed much more rapidly than rupture of a $-\overset{\diagdown}{C}-\overset{\diagup}{C}-$ bond and ring. It therefore seems likely that the limiting stage is the breaking of the $-\overset{\diagdown}{C}-\overset{\diagup}{C}-$ bond in the oxime. The breaking of a C–C bond and the formation of a C=N bond can proceed during the transfer of the positive charge from the nitrogen atom to the carbon atom. The HSO_4^- anion apparently assists the transfer of charge. In acids with a low water concentration and in oleum the dehydrated protonated form of the lactam is formed during the rearrangement. Hydration takes place during dilution of the reaction product with water.

Scheme of the limiting stage

In concentrated oleum, dehydrated ion pairs $RN^+.HS_2O_7^-$ can be formed:

$$2\,RNOH + 3\,H_2S_2O_7 \rightleftarrows 2\,RN^+ \cdot HS_2O_7^- + 2H_2SO_4.$$

As noted above, "Beckmann mixture" – consisting of a mixture of acetic acid and acetic anhydride, saturated with gaseous hydrogen chloride – is often used for preparations. Starting from the mechanism of the Beckmann rearrangement in sulphuric acid, the catalytic action of "Beckmann mixture" can be explained. For carrying out the process it is necessary to have an acid medium to bring about ionisation of the oxime. Since oximes are usually strong bases, the hydrochloric acid present in the "Beckmann mixture" is sufficient for this purpose. In the presence of an excess of acetic acid an ion pair (or salt of the oxime) can be formed. For the formation of the reactive form it is necessary that the salt consisting of the protonated form of the oxime and the anion of the acid be dehydrated. Judging from the available data the dehydration proceeds to an appreciable degree at very low activities of water. For example, in sulphuric acid the ion pairs of alicyclic ketoximes are dehydrated to a significant extent in the solutions where the water activity is less than 10^{-5}–10^{-6}. The presence of the anhydride in the mixture allows a low activity of water to be maintained in the solution. The water formed in the dehydration of the oxime in this medium is used up in the hydration of the anhydride and the activity of the water does not increase.

VI. TEMPERATURE DEPENDENCE OF THE RATE CONSTANTS OF THE BECKMANN REARRANGEMENT OF ALICYCLIC KETOXIMES IN SULPHURIC ACID AND IN OLEUM

For the same concentration of sulphuric acid or oleum the rate constants of the Beckmann rearrangement k_{eff} at different temperatures fit the Arrhenius equation:

$$k_{eff} = Ae^{-E_{eff}/RT}.$$

* These quantities were obtained in work where the oxime concentration was ~ 0.5 M and in addition to the oxime a lactam was added (14 g lactam per 15 g oleum).

The activation energy which can be found from the Arrhenius equation depends on the concentration of sulphuric acid in solution. Table 16 gives the values of log A and E_{eff} for the rearrangement of cyclopentanone oxime, cyclohexanone oxime, suberone oxime, and cyclododecanone oxime in solutions of sulphuric acid and in oleum from published data [23-26]. As the acid concentration is raised the activation energy falls. For example, with suberone oxime, E_{eff} = 29.3 kcal mole^{-1} in 87–89% acid and 23.5 kcal mole^{-1} in oleum with 7.5 wt. % SO_3. In solutions where almost all the oxime is in the reactive form the observed activation energy is constant. For example, in the rearrangement of cyclohexanone oxime the activation energy is constant in the range from 99.74% H_2SO_4 to 15.4% SO_3. To explain what the activation energy calculated by the Arrhenius equation represents it is necessary to analyse Eqn. (12) which expresses the dependence of k_{eff} on the quantities a_{H_2O}, $a_{H_2SO_4}$, and h_0. On taking into account the temperature dependence of the constant this equation must be written as:

$$A_{eff}\,e^{\frac{-E_{eff}}{RT}} = \frac{A_{true}\cdot e^{\frac{-E_{true}}{RT}}}{1+\dfrac{B_2 e^{\frac{\Delta H_2}{RT}}\cdot B_c e^{\frac{\Delta H_c}{RT}}\cdot B_{H_2O} e^{\frac{-\Delta H_{H_2O}}{RT}}\cdot B_{h_0} e^{\frac{-\Delta H_{h_0}}{RT}}}{B_{H_2SO_4}\cdot e^{\frac{-\Delta H_{H_2SO_4}}{RT}}} + B_2\cdot B_{H_2O} e^{\frac{\Delta H_2-\Delta H_{H_2O}}{RT}}},$$

where E_{true} and A_{true} are the true activation energy and true preexponential factor, ΔH_2 and ΔH_c the standard changes in enthalpy of the dehydration and dissociation of the ion pair $RNOH_2^+.HSO_4^-$, and B_2 and B_c the entropy multipliers of the equilibrium constants K_2' and K_c'. ΔH_{H_2O}, ΔH_{h_0}, and $\Delta H_{H_2SO_4}$, and B_{H_2O}, B_{h_0}, and $B_{H_2SO_4}$ are the heats and entropy factors which characterise the change in the activity of water, the acidity, and the activity of sulphuric acid with temperature.

In solutions where

$$C_{RN^+.HSO_4^-} \gg C_{RNOH_2^+} + C_{RNOH_2^+.HSO_4^-},$$

$$A_{eff}\,e^{-E_{eff}/RT} = A_{true}\,e^{-E_{true}/RT},$$

and the activation energy and preexponential factor given by the Arrhenius equation will be the true values. In oleum, where the rate constant of the rearrangement does not change, ~ 70% of the total concentration of the alicyclic ketoximes studied are in the $RN^+.HSO_4^-$ form. Therefore, the activation energy and preexponential factor determinable under these circumstances are the true ones.

In relatively dilute solutions of acid§ almost all the oxime is present in the form of the ion pairs $RNOH_2^+.HSO_4^-$:

$$C_{RNOH_2^+.HSO_4^-} \gg C_{RNOH_2^+} + C_{RN+HSO_4^-}.$$

Here:

$$A_{eff}\,e^{\frac{-E_{eff}}{RT}} = \frac{A_{true}\,e^{\frac{-E_{true}}{RT}}}{B_2 e^{\frac{\Delta H_2}{RT}}\,e^{\frac{-\Delta H_{H_2O}}{RT}}},$$

and

$$-E_{eff} = -E_{true} - \Delta H_2 + \Delta H_{H_2O}.$$

Such conditions are observed, for example, for suberone oxime in the range 85.3–90.3% H_2SO_4 and for cyclopentanone oxime in the range 91.74–96.2% H_2SO_4. It now becomes possible to determine ΔH_2 for the oximes mentioned. The values of E_{eff} and ΔH_{H_2O} for 90% sulphuric acid can be used for the calculations. Table 16 gives the values of E_{eff}; ΔH_{H_2O} = 5.0 kcal mole^{-1}. This quantity is calculated from the temperature dependence of the pressure of water vapour over solutions of the acid, which are taken from a handbook [43]. ΔH_2 is -7.0 ± 2 kcal mole^{-1} and -10 ± 2 kcal mole^{-1} for cyclopentanone oxime and suberone oxime respectively. In acid solutions where

$$C_{RNOH_2^+} \gg C_{RNOH_2^+.HSO_4^-} + C_{RN^+.HSO_4^-}$$

$$A_{eff}\,e^{\frac{-E_{eff}}{RT}} = \frac{A_{true}\,e^{\frac{-E_{true}}{RT}}\cdot B_{H_2SO_4}\,e^{\frac{-\Delta H_{H_2SO_4}}{RT}}}{B_2 e^{\frac{\Delta H_2}{RT}}\cdot B_c e^{\frac{\Delta H_c}{RT}}\cdot B_{H_2O} e^{\frac{-\Delta H_{H_2O}}{RT}}\cdot B_{h_0} e^{\frac{-\Delta H_{h_0}}{RT}}}$$

and

$$-E_{eff} = -E_{true} - \Delta H_2 - \Delta H_c + \Delta H_{H_2O} + \Delta H_{h_0} - \Delta H_{H_2SO_4}.$$

This condition is observed for solutions of the acid in the range 99.4–100% H_2SO_4. In connection with the fact that for such solutions the enthalpies ΔH_{H_2O}, ΔH_{h_0}, and $\Delta H_{H_2SO_4}$ are still unknown it seems impossible to calculate the value of ΔH_c. It should be noted that in the intermediate region where the $RNOH_2^+.HSO_4^-$ and $RNOH_2^+$ concentrations are commensurate, in the general example the rate constants at different temperatures should not obey the Arrhenius equation, since the expression for k_{eff} includes the sum of two quantities with exponential factors. However, for a narrow temperature interval the Arrhenius equation is satisfied. The effective activation energy cannot then be presented in the form of a sum of E_{true} and the change in the

§ Here by relatively dilute solutions of sulphuric acid we mean solutions in which the H_2SO_4 concentration is < 90 wt.%.

enthalpies of the equilibrium processes. This is also true where the concentrations of $RNOH_2^+$ and $RH^+.HSO_4^-$ are commensurate.

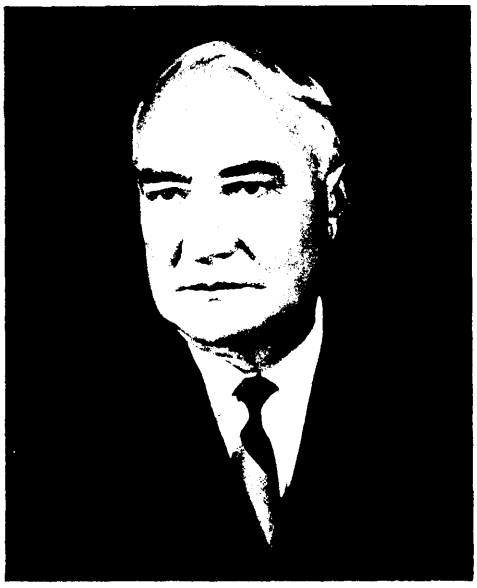

Table 15 gives the equilibrium constants K_2' and K_c', the product $K_2'K_c'$, E_{true}, and A_{true} for the four alicyclic ketoximes, and shows that E_{true} is less for ketoximes with an even number of carbon atoms than for those with an odd number of carbon atoms. This regularity is observed also for the activation energy of the Beckmann rearrangement of the oxime *p*-toluenesulphonates in chloroform[27]. From Heldt's results[27], the activation energies are 27 ± 1.3 and 23.4 ± 1.1 kcal mole^{-1} for cyclopentanone and cyclohexanone oximes and 24.4 ± 1.1 and 21.8 ± 1.2 kcal mole^{-1} for cycloheptanone and cyclo-octanone oximes respectively. For cyclohexanone oxime the preexponential factor is 4×10^{13} s^{-1}. This quantity is close to the normal preexponential factors for unimolecular reactions. For the remaining three oximes the intrinsic preexponential factors are greater than the normal values.

RUSSIAN CHEMICAL REVIEWS
Uspekhi Khimii

February 1967

VALENTIN ALEKSEEVICH KARGIN

Dear Valentin Alekseevich!

The Editorial Board of the journal "Uspekhi Khimii" convey to You their heartfelt greetings on the occasion of your sixtieth birthday and the completion of 45 years of your working life.

As an eminent physical chemist in our country, You have made a great contribution to the development of colloidal chemistry, polymer science, and also Soviet polymer industry. The wide range and depth of the problems of polymer science which You have solved, thereby gaining fundamental new knowledge in this field, have earned You the profound respect of scientists and industrial workers, both in our country and beyond its boundaries.

The Editorial Board of the journal "Uspekhi Khimii" wish You, dear Valentin Alekseevich, good health and new creative successes in your chosen branch of chemical science.

The Editorial Board of the Journal "Uspekhi Khimii"

U.D.C. 541.6:678.43/44

THE SUPERMOLECULAR STRUCTURE OF RUBBERS

V. A. Kargin, Z. Ya. Berestneva, and V. G. Kalashnikova

For a long time polymers were regarded as systems consisting of disordered, entangled, folded molecular chains. Crystallisation was thought to be the only possible ordered process in such systems.

However, a number of studies carried out in recent years failed to confirm these ideas on the structure of polymers. It was shown that, when polymers crystallised, spherulites with well defined boundaries and single crystals, much longer than the molecular chains, were formed. Geometrical considerations alone indicated that such structures could not be formed in a system of entangled molecular chains, and the hypothesis was therefore advanced that even amorphous polymers contain ordered elements [1,2].

The electron microscope studies of Kargin and coworkers showed that polymers with rigid molecular chains in the amorphous state are in fact well ordered systems [3-10]. Supermolecular structures may arise in these systems without a phase transition, the primary elements of these structures being globules or packets of molecular chains.

This ordered arrangement appears to be of a fluctuation type. Quite recently it was found that large structures, with dimensions up to several hundred microns, may arise in rigid-chain polymers [11-13]. Moreover, a number of experimental results indicate the presence of ordered arrangements of molecular chains in polymers melts [14,15]; there is also evidence that packet formations occur in dilute solutions of polymers [16,17].

Examination of the structure of solid polymers would be expected to show that the most disordered arrangement of molecular chains occurs in polymers with flexible molecular chains, known as elastomers, which are most similar in their physical state to liquids. The first X-ray structure studies did in fact show that the structure of rubbers is very similar to the structure of poorly ordered liquids [17]. The establishment of the kinetic theory of high elasticity promoted the development of the idea that elastomers consist of systems of entangled molecular chains [18-28]. However, the correctness of the assumptions made in setting up a model for the structure of rubbers within the framework of the theory of high elasticity has long been the subject of doubt. Thus Treloar noted that it is necessary to take into account intermolecular forces which hold the rubber molecules together at definite points, or even regions, with the formation of a three-dimensional network [29].

Bunn put forward the hypothesis that in rubbers the molecular chains are not arranged in an entirely random manner, but that regions of relative order occur in which the molecules are roughly parallel [30]. The same molecule passes through an ordered region and a completely disordered region.

Moreover, it has been suggested in a number of experimental papers that ordered formations occur in rubbers. Thus, examination of the mechanical properties of thin films of natural rubber showed that these films may contain some kind of structural units with dimensions of about 200 Å. [31]

A study of the dependence of the coefficient of diffusion of macromolecules of synthetic polyisoprene into amorphous natural rubber on the molecular weight of the latter also gave results suggesting that the molecular chains in natural rubber are ordered [32].

Recently it was found that the mechanical properties of films of natural rubber obtained from solutions depend on the initial concentration of the solution, provided that the concentration of the solution is not greater than 1%. [33] At concentrations higher than 1%, association complexes are formed in the solution, and the films obtained from such solutions have a more ordered structure, which is also reflected in their mechanical properties. The formation of some kind of ordered structures has been observed by the dilatometric method in butadiene-styrene rubber obtained by low-temperature polymerisation [24].

Since only structures with short-range order can occur within the limits of the amorphous state, it would be difficult to obtain any kind of results by studying the structure of amorphous rubbers by direct structural methods (for example, X-ray methods).

Investigation of the structure of rubbers by optical methods, and particularly by the methods of electron optics, showed the existence of ordered structures in rubbers. Thus, a study of mixtures of rubberlike polymers by phase-contrast microscopy showed that such systems were heterogeneous [34]. It was shown that in these systems mixing of the rubbers down to molecular dimensions does not occur; the mixture always consists of alternating characteristic structures of varying density with dimensions of the order of one micron.

Finally, in recent years the highly sensitive electron microscope method has been used to study the structure of amorphous rubbers. However, several papers have failed to give definite results of any kind with regard to the processes by which structures are formed in rubbers. Because of the difficulty of preparing rubbers, the workers concerned obtained either completely structureless films [35-37], or a pattern of strands, sometimes forming a characteristic network of threads with spherical or elliptical thickenings of different sizes [37-40]. It is not possible to draw any conclusions as to the structure of rubbers from the torn film rubber patterns obtained in the work reported in these papers.

Later, Shon showed that small spherical particles, 30-55 Å in diameter, could be observed on the surface of films of a number of amorphous rubbers (copolymer of butadiene with acrylonitrile, Buna-K, natural rubber) [41]. The test preparation was obtained by the replica method with preliminary shadowing with iridium. The author concluded that the view that rubber is a system with entangled molecular chains with no microstructure is incorrect, but that, in fact, amorphous rubber consists of more or less spherical particles formed from individual folded molecules. The author developed this point of view in a subsequent paper [42]. It should be noted that the observed size of the particles is at the limit of the resolving power of the replica method used [43]. Consequently, these results cannot be considered reliable. Moreover, it was shown that the occurrence of good rubberlike elastic properties evidently cannot be related to the presence of globular structures [44]. Thus, the graft copolymer of methyl methacrylate and natural rubber has rubberlike elastic properties only when it is isolated from solution under such conditions that the natural rubber chains remain stretched, but the methyl methacrylate chains are twisted. If this is not so (natural rubber chains folded into globules and methyl methacrylate chains stretched), a hard, completely inelastic product is obtained. In the study of organic compounds in the electron microscope it is difficult to obtain images with sufficient contrast, since the scattering power of carbon atoms is low, and the slight differences in density at separate sections of the film do not give the necessary difference in electron densities to provide contrast.

The structure of such polymers can only be evaluated when surface relief is present to provide the differences in thickness that are necessary for contrast. In the examination of crystalline polymers there is a considerable difference between different sections as a result of previous processes associated with the formation of structures, and because the polymer is solid.

Being elastomers, rubbers resemble liquids in their physical state. As they have a low modulus of elasticity, under the action of surface tension forces these systems tend to form spheres, or, in large amounts, they spread over the base, which leads to a smoothing of the relief that reflects the structure of the compounds.

To eliminate these difficulties, special methods of preparing the samples must be used [45]. Different solvents, or mixtures of solvents, can be used to reduce the solubility of rubbers. In this case, as the solvent is evaporated the concentration of the solution increases and, when the critical

concentration is reached, rubber separates from the solution. A poor solvent gives the best conditions for aggregation and the production of ordered structural formations. It is also possible, by the method of stretching films until rupture, to separate isolated structural elements from those that form the film.

The best results were obtained by preparing rubber samples from very dilute solutions at low temperatures [45,46].

Low temperatures promote the ordering process and give better structures for the amorphous state. Rapid cooling of a drop of rubber solution to a temperature below the glass temperature fixes the structure of the rubber in solution. When the solvent is removed at the same temperature, the rubber remains on the film holder in the solid state.

By using dilute solutions, isolated structural elements that may arise in elastomers can be obtained. Light petroleum has been used as a solvent; this gives a low glass temperature. It was shown by this method that amorphous rubbers are not structureless systems, but show a definite degree of order, characterised by the appearance of fibrillar structures about 200 Å in diameter and several microns long. Fig. 1 shows a picture of a sample of SKB rubber obtained under these conditions.

Similar structures were also observed in samples of type SKS-30 butadiene–styrene rubber [45,46]. Since SKS-30 and SKB rubbers have an irregular structure and cannot be crystallised, it is obvious that the structures observed in them are amorphous.

The formation of structures in elastomers at ordinary temperatures has been studied in the following way. The rubber was dissolved in a specially selected solvent and deposited on a film-base as a drop of solution, and the solvent was removed by different methods [45], or preparations were made as films on a water surface. The samples were shadowed with palladium to increase contrast.

The non-crystalline rubbers, SKS-30, SKB, and SKS-85, and also rubbers with a regular structure, such as natural rubber and chloroprene rubber of the "nairit A" type, give a pattern of striated structures in the amorphous state [45,47]. Thus Fig. 2 shows striations, up to about 1000 Å wide, arranged without order over the whole field of vision.

The first impression obtained from this pattern is that the film is made up of folds. For this reason, many workers who obtained similar patterns did not associate them with

Fig. 1. Na-butadiene rubber obtained from a dilute solution in petroleum ether at -75°.

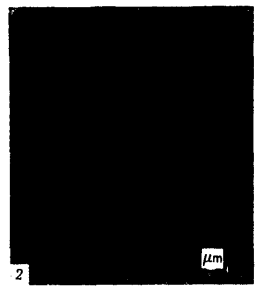

Fig. 2. Film of type SKS-30 rubber.

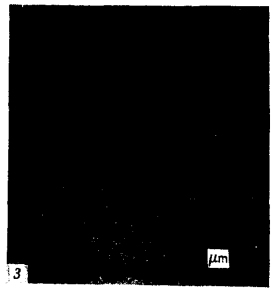

Fig. 3. Film of natural rubber obtained from a dilute solution in chloroform.

the process of structure formation. However, natural rubber gave the clearest striated structure pattern when the polar solvent chloroform was used (Fig. 3) [45,47]. In this case isolated structural elements forming a striated structure in the film can be observed. The presence of isolated structural elements during the preparation of samples at low temperature, and also at ordinary temperatures when a poor solvent is used, indicates that the striated structures observed result from processes leading to the formation of structures in amorphous elastomers.

The microstructure of the amorphous chain has no effect on the nature of the order in rubbers within the limits of the amorphous state. It has been shown that a reduction in molecular weight facilitates the process of structure formation. At low molecular weights the striated structure pattern is much more marked [45].

Up to now the finer features of this type of structure have not been elucidated. The possibility of ordered structures arising in amorphous polymers, and also the possibility of observing an intermediate state when a new phase separates from a homogeneous polymer solution may be imagined in the following way.

Every phase transition occurs abruptly within a very narrow temperature or concentration range. We cannot observe the transition itself because the time in which it occurs is too short compared with the times required for its observation. However, it is well known that, for example, in phase transitions in liquids, when one liquid separates into two phases, the change itself is preceded by the formation of clusters which are sometimes so large that the liquid becomes cloudy near the critical point although it still forms a single phase. The lifetime of these

clusters is also too short for direct observation. But there is no doubt that, given sufficient magnification, if we were able to observe such a liquid over very short periods of time, shorter than the relaxation period of the liquid, we would see the whole picture of the generation of order in the liquid: this would include the formation of clusters, their increase in size, and finally the formation of a dividing boundary and the production of a new phase. This would be the picture that Maxwell's imaginary "demon" would see if he could make observations over sufficiently short time intervals.

We cannot make such observations (which would show us the whole morphology of phase transitions), because ordinary molecules are too small, and their rate of movement is too great for the methods available to us. If we increase the size of the molecules by several orders of magnitude and obtain a corresponding reduction in their rate of movement by using polymeric compounds, we can observe the molecules and their aggregates directly with the electron microscope. The long relaxation time makes it possible to fix virtually any intermediate non-equilibrium state of the system observed, including all stages of a phase transition. By means of polymeric compounds, it is possible to set up a kind of enlarged model of a liquid the motion of whose molecules is greatly retarded, and to observe this model by means of the electron microscope.

Vulcanised chloroprene rubber which has been subsequently rolled until it is again in the soluble state has been studied. Values for the solubility of this rubber can then be easily chosen so that it is soluble in volatile solvents to the limited extent necessary for making preparations.

A 0.1–1% solution of rubber in CCl_4 was deposited on a pyroxylin base. As the drop of solution evaporated, the rubber concentration increased and, when the critical value was reached, two layers were formed, since the rubber preparations under examination were soluble to only a limited extent in this solvent. By regulating the rate of evaporation of the solvent it was possible to fix the different stages of formation of the new phase in the rubber solution.

Figs. 4*a*–4*c* and Fig. 5 show two series of such experiments. The first photograph (Fig. 4*a*) shows pictures of the still homogeneous rubber with typical striated structures. Then clusters arise with no sharp interfaces (Fig. 4*b*). Finally, a boundary begins to form but it is not closed immediately (Fig. 4*c*). Only in the final stage do we see particles of another phase with well marked boundaries typical of colloidal particles (Fig. 5).

Thus, intermediate stages in layer formation with the separation of a new phase can be observed in rubber. It is clear that intermediate and non-equilibrium states can exist for long periods even in elastic polymers, which have the most pronounced molecular mobility of all polymeric compounds, and that processes that are undetectable in low-molecular compounds can be observed when they occur in polymers.

After ordered structures had been found to occur in a number of rubbers, i.e. compounds that exist in a rubberlike state at temperatures roughly between -50°and +50°, it was suggested that the structures observed in rubbers are typical of all compounds that occur in the rubberlike state. In other words, the presence of striated structures is associated with rubberlike properties. It has recently been shown by several workers that isotactic polybutylene [48,49], chlorinated gutta-percha [50], and other compounds with rubberlike properties have a striated structure.

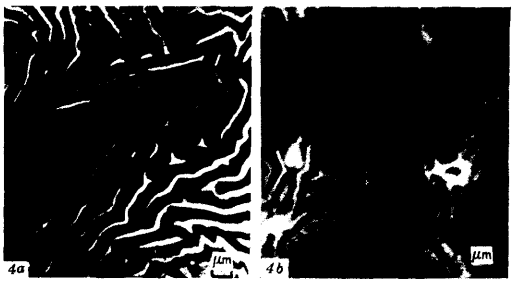

Fig. 4. Film of neoprene W rubber obtained from a solution in chloroform. The solvent was evaporated at room temperature. The film was kept in air for 3 to 5 days. Concentration of initial solution:
a) 0.1%; *b*) and *c*) 1.0%.

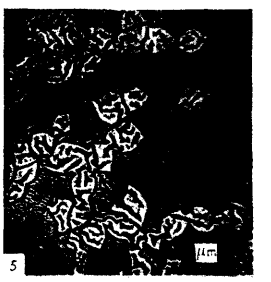

Fig. 5. Film of neoprene W obtained from a chloroform solution. The solvent was evaporated in a desiccator at room temperature over CCl_4. The film was kept for 3 to 6 days.

Thus, striated structures are typical of compounds that exist in the rubberlike state. In this connection it is of interest to examine the structure of fluorinated rubbers, which have a low degree of elasticity. It has been shown that the poor mechanical properties of cured rubber based on fluorinated rubbers are associated with special features in the supermolecular structure of these rubbers [51].

SKF-26 rubber is soluble in a very limited range of solvents — a number of ketones and esters. For this reason, acetone, ethyl methyl ketone, and isopentyl acetate have been used as solvents.

The structure of films is shown in Figs. 6*a* and 6*b*. Fig. 6*a* shows a film obtained from an acetone solution, and Fig. 6*b* a film from an isopentyl acetate solution.

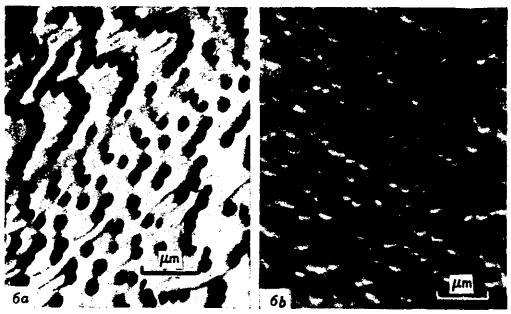

Fig. 6. Structure of films of type SKF-26 fluorinated rubber. The film was prepared:
a) from solution in acetone; *b*) from a solution in isopentyl acetate.

It is very clear that the films contain globular particles, irrespective of the nature of the solvent used; the diameter of the particles is about 1000 Å. A number of molecular chains contained in each globule may be calculated from the formula

$$n = \frac{\pi D^3 N \rho}{GM},$$

where n is the number of molecular chains, D the globule diameter, N the Avogadro number, ρ the density of the rubber, and M the molecular weight.

The mean molecular weight of the sample of rubber examined was 300 000. Calculations show that the globules are aggregates consisting of thousands of molecular chains. The value obtained is an upper limit; if the globule is deformed, this calculation gives high results. It has been found (Fig. 7) that block rubber, the structure of which was studied by the replica method, and also thin films, have globular structures, the size of the globules being the same in both cases.

It should also be noted that a characteristic feature of the structure of SKF-26 rubber is that only part of it is in the globular form; between the globules there is a kind of adhesive, the structure of which has not been elucidated (Fig. 6*a*).

The presence of two structural modifications is most clearly observed when samples are prepared from very dilute solutions (8×10^{-3} wt. % in ethyl methyl ketone).

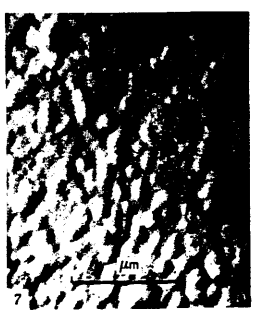

Fig. 7. Angular replica shadowed with palladium from SKF-26 block rubber.

Fig. 8*a* clearly shows an isolated globule and an aggregate of four densely packed globular particles in the neighbourhood of a portion of rubber the structure of which has not been elucidated. Sometimes fibrillar structures (Fig. 8*b*) may be observed in the structureless mass, which suggests that the adhesive may have a fibrillar structure.

The study of the properties of films stretched right up to the onset of rupture has confirmed this hypothesis. Fibrillar structures (Figs. 9*a*–9*c*) are clearly visible in stretched samples; it is clear that stretching reduces the number of globular structures, but the size of the globules does not change, and in the early stages of stretching they are only slightly deformed (Fig. 9*b*).

Sometimes, but not frequently, gradual unrolling of the globules may be observed, as shown in Fig. 9*c*. Obviously, during stretching there is both an abrupt and a gradual unrolling of the globules with the formation of fibrillar structures.

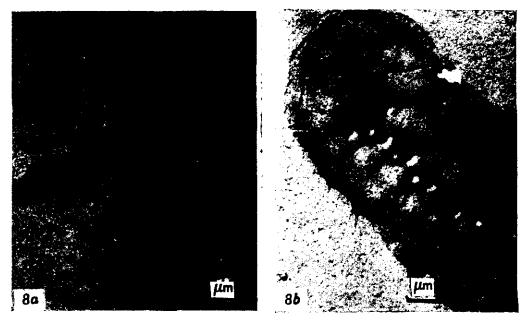

Fig. 8. (*a*) and (*b*) Type SKF-26 fluorinated rubber prepared from a dilute solution in ethyl methyl ketone.

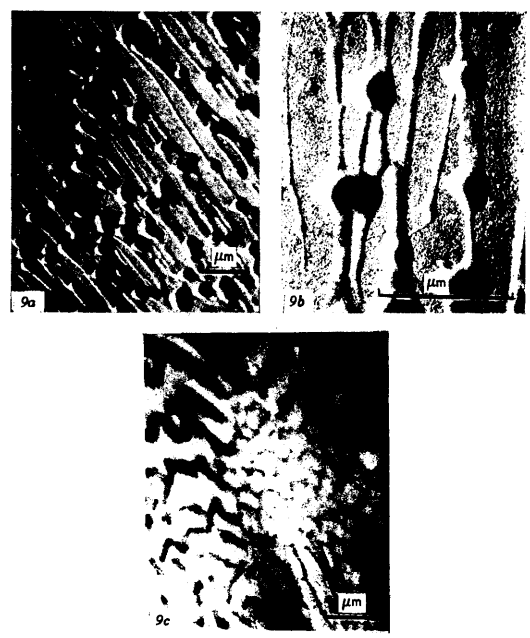

Fig. 9. (*a*, *b*, and *c*) Stretched film of type SKF-26 fluorinated rubber.

The globular structures in SKF-26 fluorinated rubber have the same dimensions of about 1000 Å over a wide range of concentrations of the solutions from which the samples are prepared. It may therefore be assumed that the globular structures arose in these rubbers during polymerisation. The diameter of 1000 Å appears to be the limiting diameter for a stable spherical particle of the fluorinated rubber. When the diameter increases beyond this limit, the globules are rearranged to form linear structures, because, when there are a sufficiently large number of molecules in the globule, the linear arrangement of these molecules may lead to denser packing and may also be more favoured energetically.

Thus, two structural modifications (globular and fibrillar) in equilibrium have been observed in SKF-26 fluorinated rubber. When the rubber is stretched, the globules abruptly unfold and the proportion of the fibrillar form increases. The development of elastic properties is probably associated with the existence of fibrillar formations and the possibility of globules unfolding. The presence of two structural forms in the rubber, with the globular form predominating, is probably responsible for the poor elasticity of this material.

Thus, electron microscope studies have shown that amorphous rubbers are ordered systems containing fibrillar and striated structures, in which globular structures may also occur. The formation of globular structures in rubber of the SKF-26 type leads to a reduction of its elasticity.

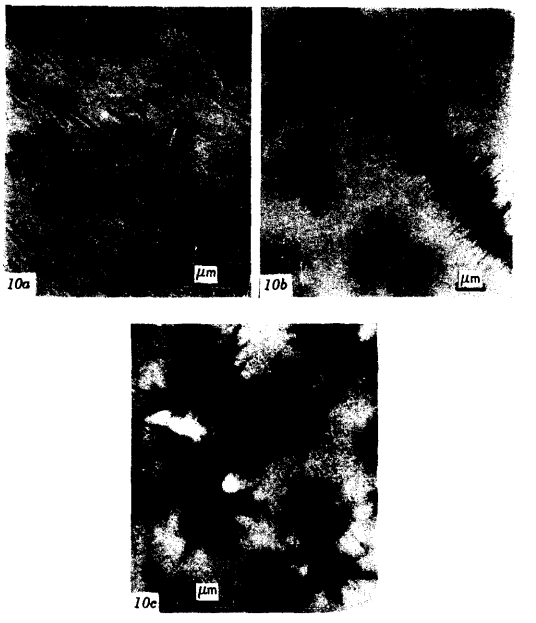

Fig. 10. Film of chloroprene rubber:
a) 1 day after removal of solvent; *b*) 2 days after removal of solvent; *c*) 7 days after removal of solvent.

It has been known for quite a long time that under certain conditions natural rubber, and also other elastomers with a regular structure, can be crystallised [17,27,52-72]. A great many papers have been devoted to the crystallisation of rubbers, and these have been exhaustively reviewed in a number of monographs [19,73,74].

The possibility that large crystalline structures of regular geometric shape may be formed in elastomers has cast doubt on the elastomer model proposed in the kinetic theory of rubberlike elasticity [75,76]. A somewhat modified model has been proposed for the structure of rubbers [76]; however, this does not differ fundamentally from the model of Kuhn, Mark, and Guth and is merely an unsuccessful attempt to set up a new theory for the structure of amorphous rubber which would explain the relative ease with which natural rubber tends to crystallise when the temperature is reduced. Campbell and Allen have made some interesting observations [24]: they used the polarisation microscope to study crystallisation in natural rubber and in polybutadiene obtained by low-temperature polymerisation. It was found that, when fused samples are repeatedly crystallised, the initial spherulite pattern is fully and precisely restored These results indicate that, when rubbers are fused, the molecular chains do not become entangled but a degree of order is maintained similar to that in the crystalline state.

Electron microscope studies of the structure of amorphous and crystalline rubber have shown that, at first, striated structures are observed, the finer structure of which is still not apparent. What part do these structures play in crystallisation? Is the process of crystallisation based on the striated structures present in the amorphous state, or are the crystalline formations the result of an independent ordering process? It has been shown experimentally that, in the initial stage of the crystallisation of polychloroprene (Fig. 10*a*), the striated structures are split into fine fibrillar formations, that is, "acicular" crystalline structures based on the striated structures in the amorphous state are formed in the process of crystallisation [45,46].

Thus, striated structures are the first to be formed, and then fibrillar structures of a different kind are formed. Crystalline fibrillar structures are formed from striated structures already present in the amorphous state. The final stage is the formation of spherulites (Fig. 10*c*).

The whole process of structure formation in elastomers has been observed in polychloroprene rubbers and isotactic polybutylene, which have rubberlike properties.

Figs. 10*a*–10*c* show the separate stages of the crystallisation of polychloroprene rubber. Thus, Fig. 10*a* shows the initial stage of the formation of fibrillar structures, which are later converted into acicular formations (Fig. 10*b*); finally, spherulite structures are formed (Fig. 10*c*).

Isotactic polybutylene shows a similar, but more marked structure formation (Figs. 11*a*–11*c*); here the crystallisation process leads to the formation of single crystals [48]. Fig. 11*a* shows the development of crystalline formations from striated structures. It is clear that the striated structures more or less split into separate fibrils. The further development of order leads to the coexistence of spherulites and crystalline surfaces (Fig. 11*b*), but crystallisation does not yet appear to have occurred throughout the bulk of the material. Further crystallisation leads to the growth and interpenetration of structures (Fig. 11*c*)

It has been shown that the presence of spherulites and lamellar crystalline formations in polymers with flexible chains does not inhibit the development of reversible deformations [49,76].

Thus, for many years the idea was widely accepted that rubbers are systems of entangled molecular chains; this idea arose from the kinetic theory of high elasticity. The correctness of this model was questioned almost as soon as

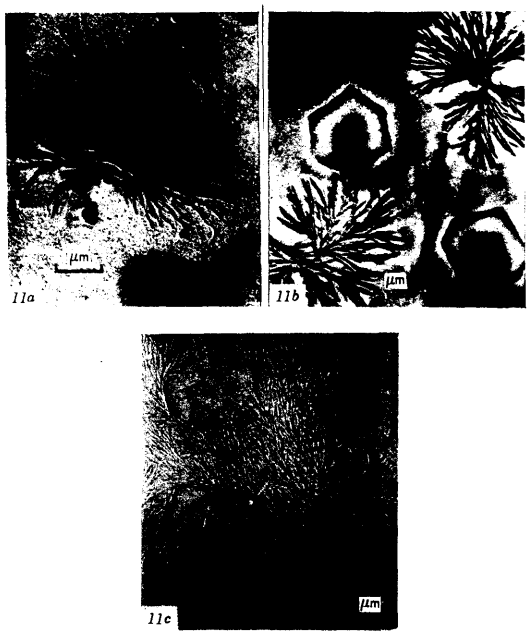

Fig. 11. *a*) Sample of isotactic polybutylene prepared from a dilute solution in toluene at 70° with rapid evaporation of the solvent and subsequent rapid cooling; *b*) and *c*) film of isotactic polybutylene obtained at 85° with subsequent slow cooling.

it had been proposed. In the 1940's experimental results began to appear that indicated indirectly the presence of an ordered arrangement of molecular chains in amorphous rubbers. The use of electron microscopy represented a new stage in the study of the structure of rubbers. By this method, it was shown that amorphous elastomers are not in fact systems of disordered entangled molecular chains, but systems containing well marked fibrillar and striated structures. Compounds in which this kind of structure was observed have good elastic properties.

Striated structures are the first stage in the development of order; these give rise to fibrillar structures, which in turn form more complex secondary molecular structures, spherulites, and crystals.

In the course of conversion into manufactured articles, rubbers are subjected to a number of treatments (plasticising, introduction of ingredients, vulcanisation). It is generally assumed that vulcanised rubber consists of a system of randomly arranged entangled molecular bundles. As with unvulcanised rubbers, the problem of structure formation in vulcanised rubbers is only considered from the point of view of the ability of the rubber to crystallise and of the effect of cross-linking on crystallisation. A certain volume around the cross-links is excluded from the total volume of material capable of crystallising; this is termed the volume "forbidden" to crystallise. The diameter of this volume around each cross-link is about 5100 Å.[77,88] It is assumed[79] that the existence of this volume only prevents the development of crystallisation in the direction along the axis of the molecules; crystallisation in a lateral direction is not limited, and the crystals formed are virtually indistinguishable from the crystals formed in the absence of cross-links. X-Ray structure analysis of crystallised vulcanised natural rubber has shown that the maximum rate of crystallisation of vulcanised rubbers is observed at the same temperature as the maximum for natural rubber[64,78-86], but the rate of crystallisation is inversely related to the thickness of the spatial network[86].

The principles that have been found to apply to vulcanised natural rubbers are also valid for the cured rubbers prepared from natural starting materials that were studied; these include 1,4-*cis*-polyisoprene, 1,4-*cis*-polybutadiene (SKD), and chloroprene rubbers[72,87]. The authors explained the phenomena observed on the basis of a model consisting of entangled molecular chains, with allowance for the effect of the "forbidden space" on crystallisation.

However, a number of experimental results are not in agreement with this model. Thus, melting points of crystals formed in the vulcanisation of natural rubber calculated on the basis of this model differ by one order of magnitude from the experimental results. Calculation shows that 1% cross-linking of chains should lower the equilibrium melting point of the crystallised network of natural rubber by 2–3 deg, whereas in fact the reduction is 20 deg.[80,88]

The hypothesis that crystalline formations have the same structure in vulcanised and unvulcanised rubber is also found to be only a first approximation; the results of X-ray structure analysis show that crystalline formations in vulcanised rubbers are much more defective[80].

On the basis of the X-ray structure analysis of vulcanisates of natural rubber, Lukin and Kasatochkin put forward the hypothesis that two kinds of intermolecular interaction occur in the amorphous vulcanisate[89]. The part of the compound with low molecular interaction is termed "gaseous", and the other part "liquid". The effects observed appear to indicate that the vulcanisate contains regions with different degrees of order. In this case, the greater molecular interaction corresponds to the more ordered regions.

In the vulcanisation of amorphous gutta-percha under different conditions, Kargin and Sogolova obtained products with different mechanical properties and probably with different degrees of order; this indicates that vulcanisates contain ordered formations[90,91].

The use of the electron microscope was a further step in the study of the structure of vulcanisates. Preparations were made by the replica method; these were taken from the tear surface of the vulcanisates or from a previously etched surface.

However, because of purely technical difficulties in the preparation of samples for electron microscope studies, identical results have not been reported. Thus, Lykin and Pechkovskaya observed in their electron microscope studies globular formations on the tear surface of vulcanisates of natural rubbers, but they considered it premature to draw any definite conclusions from this observation[92].

In other papers[93-95] dealing with the structure of vulcanisates of silicone rubbers, the authors conclude that the vulcanisates have globular structures, but the interpretation of the photographs is not unambiguous; they also show marked elongated structures of a fibrillar type.

Andrews and Braden obtained different results[96]. They made electron microscope studies of the structure of natural rubber vulcanisates after the surface had been etched with ozone; they found that the etched surface showed a system of fibrils, 500 Å in length and about 10 μm in diameter. Thus, etching showed that the samples had a heterogeneous structure. The authors explain the presence of this kind

of structure as the effect of strains set up in the samples during vulcanisation. From our point of view, these results indicate that ordered regions exist in the vulcanisates irrespective of the strains.

Electron microscope studies of the structural changes that occur during the vulcanisation of "nairit A" (by radiation, chemical, and thermal methods) gave the following results[45,97]. When chloroprene rubber is irradiated with γ-rays in a vacuum with the formation of a reticular structure, the original morphological pattern of the sample is not destroyed. Comparison of the infrared spectra of the samples irradiated in a vacuum with the spectra of the original samples shows that fairly extensive changes occur in the microstructure of the chain. The cross-linking of chains to form secondary molecular structures in the early stages of the irradiation probably prevents the destruction of these structures on further irradiation. Thus, when irradiated in a vacuum, the sample becomes cross-linked, considerable changes occur in the microstructure of the chain, and there is also probably considerable change to the amorphous state[98], but the type of arrangement of the molecular chains is unchanged.

When vulcanisation is carried out by the thermal method or by means of sulphur monochloride, the structure of the sample is gradually destroyed. Thermal vulcanisation was carried out at 153°, that is, at a much higher temperature than the melting point of rubber. Fig. 12*a* shows the initial structure of "nairit A"; crystalline molecular formations can be seen. Prolonged thermal vulcanisation destroys the structure (Fig. 12*b*). However, when low degrees of vulcanisation are applied, the morphological structures observed in the original rubber reappear with time; these range from amorphous band structures right up to more complete crystalline formations. Fig. 12*c* shows both striated and acicular formations.

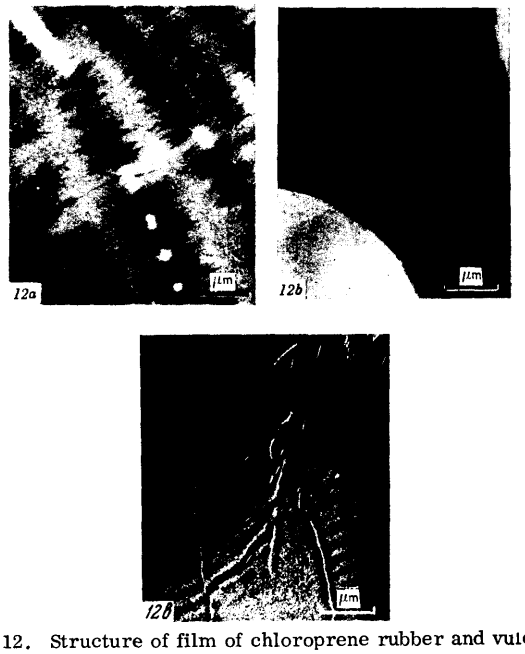

Fig. 12. Structure of film of chloroprene rubber and vulcanisate of type "nairit A" (thermal vulcanisation) in a vacuum: *a*) original rubber; *b*) after vulcanisation at 153° for 10 min; *c*) 9 days after vulcanisation.

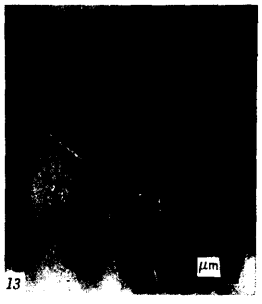

Fig. 13. Film of "nairit A" immediately after vulcanisation in air at 153° for 20 min.

Fig. 14. Film of "nairit A" 16 days after vulcanisation in air at 153° for 20 min.

Fairly large well formed surfaces with a regular geometrical shape (Fig. 13) can be observed immediately after thermal vulcanisation of samples for 20 min. Moreover, crystallisation continues with time and further spiral growth of crystals occurs on the surfaces first formed (Fig. 14). Thus, thermal vulcanisation may give rise to more nearly perfect structures than those in the original rubber.

Determination of the density of the network in portions of a sample has shown that, with vulcanisation for 20 min, cross-linking occurs at sections of the chain averaging 400 Å in length. With this kind of network, it is difficult to imagine how the polymer can crystallise, and in particular how higher structural forms, such as the crystals formed in this case, can arise, if it is assumed that the cross-links are statistically distributed between the individual polymer chains. It is probable that complete destruction of the secondary molecular structure in "nairit A" does not occur even at 153°, and, like any other chemical process, vulcanisation occurs at the boundaries separating these structures without destroying the structures themselves. It is only at high degrees of vulcanisation that bonds of this kind begin to be formed inside the structural elements.

In other words, vulcanisation is heterogeneous; otherwise the rubber would lose its ability to crystallise with the formation of higher structural forms.

In some cases it appears that not only does a vulcanisation network not prevent the formation of structures, but it may in fact promote this process. Thus, a study of carboxyl-containing polymers vulcanised with metal oxides has shown that the vulcanisates have an unusually high stability in unfilled mixtures[99]. However, the network formed is

easily destroyed by solvents; the energy required for destruction of the bonds is 1000–2000 cal mole^{-1}, that is, of the order of the energy of intermolecular interaction. This kind of network is therefore formed without chemical bonds. It has been suggested that basic salts are formed by the interaction between the polymer and the large oxide particles distributed in it; these sections also constitute the nodes of the network formed. The degree of order in these sections is probably much greater than in the remaining bulk of the polymer; this is due to the orienting action of the vulcanising agent. Here, too, large secondary molecular structures may be thinly distributed throughout the vulcanisate.

If the vulcanisation network arises at the boundary of structural formations, when the vulcanised rubber is destroyed elementary structural formations are retained; these are the component parts that make up more complex structures.

Processes of structure formation in disintegrated thermal vulcanisates of sodium-butadiene rubber (SKB) and neoprenes AS and W were studied in the following way. The vulcanisates were mechanically disintegrated to the soluble state in a laboratory rolling mill; they were then dissolved and deposited on a screen in the form of drops of solution. The disintegrated vulcanisates showed more ordered structures than the initial rubber (Figs. 15 and 16). Fig. 15*b* shows a more nearly perfect striated structure than the initial SKB rubber (Fig. 15*a*). Fig. 16*b* shows a spiral growth of crystals instead of the acicular structures of the original neoprene AS (Fig. 16*a*).

The processes of structure formation in disintegrated rubbers are retarded as the vulcanisation time is increased, that is, when the network becomes denser [100].

Thus, it has been shown that, when vulcanisates have been rolled and then brought into solution, secondary molecular structures are formed that differ in character from those of the original rubbers. This confirms that the cross-linking during vulcanisation is effected not between separate molecular chains, but between primary structural elements. On rolling, disintegration of vulcanisates appears to occur at cross-linking positions, the elementary structures being retained. The formation of secondary molecular structures in disintegrated rubbers can only be explained by the formation of a network between the primary structural elements; more complex secondary molecular structures are then formed from these elements, that is, vulcanisation is a heterogeneous process from the structural point of view.

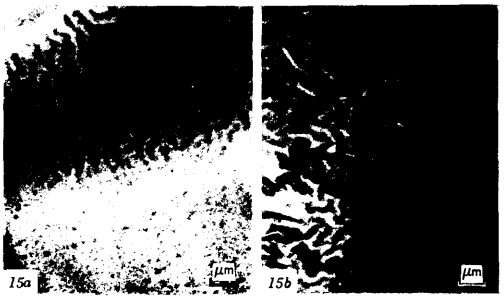

Fig. 15. *a*) Structure of original SKB rubber; *b*) SKB vulcanisate disintegrated to the soluble state by rolling.

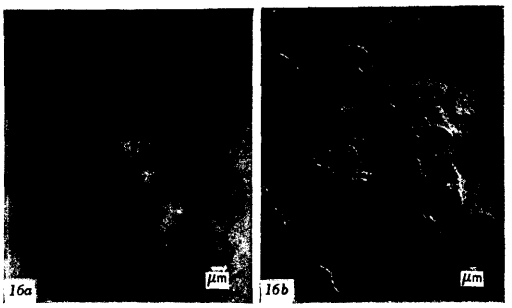

Fig. 16. *a*) Structure of original neoprene AS rubber; *b*) vulcanisate of neoprene AS disintegrated to the soluble state by rolling.

It has also been shown by the replica method that cured rubbers prepared from a number of different raw rubbers are ordered systems; they show structures similar to those observed in the raw rubbers [101]. The cured rubbers with the more ordered structures also have the best mechanical properties [102].

The introduction of low-molecular compounds (water, methanol, nonyl alcohol) increases structure formation in cured rubbers, and this is accompanied by an increase in strength [103].

All this is evidence for the lability of structure in vulcanisates and points to the importance of processes of structure formation in the treatment of rubbers.

Thus, for a long time rubbers were regarded as systems of entangled molecular chains. In the 1940's indirect experimental results began to appear indicating the presence of order in amorphous elastomers. This evidence was obtained both in the study of amorphous rubbers and in the study of special features of the crystallisation of rubbers with a regular structure. The use of electron microscope methods for studying the structure of rubbers and vulcanisates enabled the structure of amorphous rubbers to be elucidated, and the processes of structure formation in crystalline rubbers to be followed. It was shown that amorphous rubbers are ordered systems. Ordering processes occur in these, leading to the formation of striated structures 1000 Å in diameter, fibrillar structures 200 Å in diameter, and globular formations.

Rubberlike properties in elastomers are associated with the presence of striated, fibrillar structures. In studies on the structure of chloroprene rubber and isotactic polybutylene, the whole process of structure formation could be followed; striated structures are first formed in the amorphous state and then crystalline structures develop from these. The striated structures are an expression of pre-crystalline order in elastomers.

Vulcanisates, like rubbers, are ordered systems. Vulcanisation is a heterogeneous process that occurs at the boundaries of the structural elements present in the rubbers.

POLYMERISATION OF CHEMICALLY ACTIVATED MONOMERS†

V.A. Kabanov

CONTENTS

1. Introduction 75
2. Intramolecular effect 76
3. Intermolecular effect 78
4. Simultaneous occurrence of intra- and inter-molecular effects. Macromolecular "matrices" 80
5. Chemical activation in radical polymerisation 85

In a recently published paper Kargin and Kabanov[1] discussed the problem of the polymerisation of complexed and organised monomers, which may be regarded as one of the new developments in the field of macromolecular synthesis. In the present review an attempt is made to develop and justify in greater detail some of the postulates put forward by Kargin and Kabanov.

1. INTRODUCTION

The conversion of a monomer M into a polymer P can be represented by the mechanism

$$M \rightarrow R^* \rightarrow P, \qquad (I)$$

where R^* are activated intermediates (growing chains). However, this mechanism does not reflect the interaction of M, R^*, and P with the medium, which often occurs in real systems. Therefore, extending mechanism (I), one should write

$$M(X)_i \rightarrow R^*(X)_j \rightarrow P(X)_k, \qquad (II)$$

where X represents the species of the medium interacting with the monomer molecules, with the active centres of the growing chains, and with the units of the polymer being formed (i, j, $k \geqslant 0$).

If the chemical interaction of the monomer with the medium results in an increase of the absolute rates of conversion or, when several modes of polymerisation are possible, in a relative increase of the rate of conversion by a particular pathway, chemical activation is said to obtain and the corresponding monomer is chemically activated.

Chemical activation of a monomer may be due to (1) the redistribution of electron density among the intramolecular bonds caused by the interaction between M and X, which we shall call the intramolecular effect or (2) a change in the nature of the intermolecular bonds between the reacting species accompanied by a change in their distribution and mutual orientation (for example, the formation in the system of organised aggregates favouring chain growth), which we shall call the intermolecular effect.

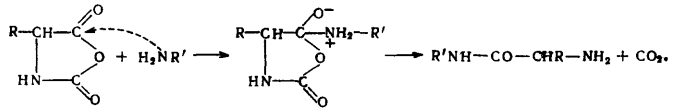
The presence in the systems of species X interacting with the monomer often affects more than just its reactivity. The addition of a monomer molecule combined with a species X to the initial active centre may result in the formation of a new active centre which is also capable of retaining the species X. Hence the possibility arises of a change in the reactivity (for example, activation) of the growing chains and even the possibility of polymerisation mechanisms which are not characteristic of the given monomer in relatively inert media.

Finally, the interaction between the species X, the initial monomer, and the units of the polymer being produced can appreciably alter the free energy of polymerisation. Indeed if the chemical potentials of the macromolecular units and monomer molecules in the presence of X are μ_{px}

† The contents of this article were presented at the International Symposium on Macromolecular Chemistry, Tokyo–Kyoto, September, 1966.

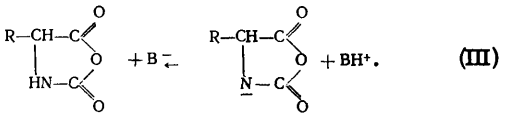
and μ_{mx} respectively, the change in chemical potential on polymerisation is

$$\Delta\mu = u_{px} - \mu_{mx} = \mu_p - \mu_m + \overline{\Delta G}_x = \Delta\mu_0 + \overline{\Delta G}_x. \quad (1)$$



where μ_p, μ_m, and $\Delta\mu_0$ are the chemical potentials of the polymer and monomer and the change in chemical potential in an inert medium. $\overline{\Delta G}_x$ is the difference between the free energies of interaction of X with the polymer units and with the monomer.

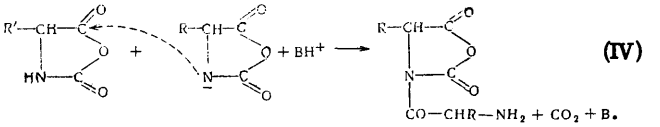
Thus "chemical activation" opens up extensive possibilities of influencing the mechanism and thermodynamics of polymerisation reactions. The above considerations constitute the basis of the approach formulated and developed in recent years by Kargin and his school.



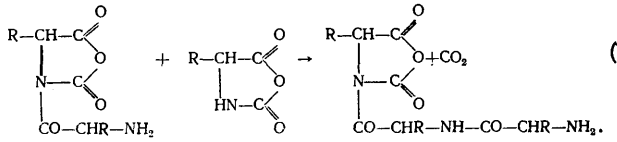
Certain examples, adduced to demonstrate a number of important aspects of the polymerisation of chemically activated monomers, are discussed below.

2. INTRAMOLECULAR EFFECT

A classical example is the polymerisation of *N*-carboxy-anhydrides (NCA) to polypeptides. The mechanism of this reaction has been examined in detail in Szwarc's review[2]. NCA are known to polymerise easily in the presence of bases (amines, alkalis, alkali metal alkoxides, and others). When primary amines are used as initiators, the initiation takes place as a result of the nucleophilic attack by the amino-group on the carbon atom of the carbonyl group of the monomer in position 5:

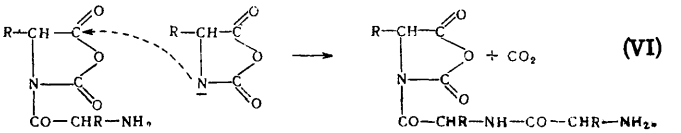


Chain growth takes place similarly, but with participation of the terminal amino-group of the chain being formed. However, this mechanism does not account for the experimental data when polymerisation is initiated by secondary amines or strong bases. Some years ago Bamford and Block[3] proposed another mechanism for the polymerisation of NCA, based on the hypothesis that in the presence of a sufficiently strong base the monomer exists in two forms described by the equilibrium:



(III)

Initiation takes place as a result of the interaction between the "normal" and ionised monomer molecules:

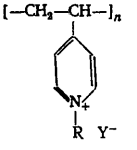


(IV)

This results in the formation of a bifunctional dimer, whose terminal amino-group can attack and add to the "usual" NCA molecule by the mechanism

(V)

At the same time the terminal cyclic group can be attacked by an ionised monomer molecule:

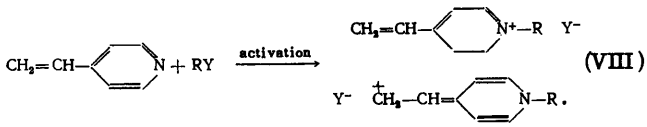


(VI)

Using ^{14}C-labelled initiators, Goodman and coworkers[4] and Scoffone and coworkers[4] confirmed this mechanism and showed that in the presence of tertiary amines and strong bases (in particular sodium methoxide) chain growth takes place mainly by mechanism (VI), i.e. by the addition of ionised NCA molecules, which react significantly faster than the initial molecules. Thus the interaction of NCA with strong bases results in its chemical activation (greatly enhanced nucleophilic character) by mechanism (III). Within the framework of the problem under discussion, the complex mechanism of the polymerisation of NCA must be assigned to one of the simplest limiting cases, since the activator (base) reacts only with monomer molecules and not with the growing chains [in mechanism (II) $i = 1$ and j, $k = 0$]. The alkali-catalysed polymerisation of caprolactam, studied in detail by Wichterle and coworkers[5], takes place similarly.

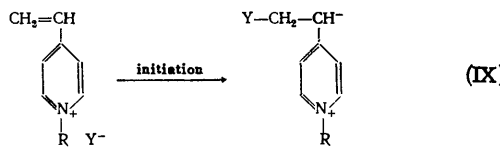
In the example just considered the activation is due to the chemical modification of the individual monomer molecules and not to the intermolecular bond between them, i.e. according to the classification adopted above the activation must be attributed to the intramolecular effect.

Systems in which the activator forms fairly strong bonds with monomer molecules, the active centres of the growing chains, and the units of the macromolecular molecules, i.e. constitutes a component of the polymer, can be assigned to the second limiting case. It has been shown recently[6-10] that in the interaction of 4-vinylpyridine (4-VP) with alkyl halides (Menshutkin reaction) in organic media (benzene, nitrobenzene, acetonitrile, dimethyl sulphoxide, propylene carbonate, and methanol) at -5° and above, instead of monomeric quaternary salts, the products isolated are high-molecular amorphous substances with the general formula



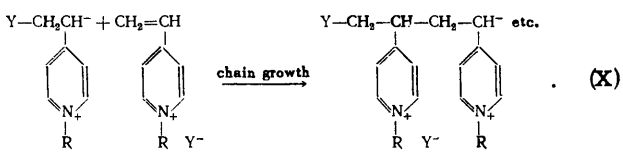
(VII)

which do not contain free pyridine base groups, i.e. spontaneous polarisation takes place. In the presence of an excess of 4-VP the formation of the polymer ceases as soon as the alkyl halide has been used up, and unreacted 4-VP remains in the system. This indicates a close relation between salt formation and polymerisation and that only 4-VP molecules which have undergone the Menshutkin reaction participate in the polymerisation. Strong inhibitors of radical polymerisation (benzoquinone, diphenylpicrylhydrazyl, and *N*-oxides) do not retard the reaction and do not affect the characteristic viscosity of polymers. This means that a radical mechanism of polymerisation can be excluded. When the reaction between 4-VP and ethyl bromide is carried out in acrylonitrile and in styrene, the resulting polymers do not contain nitrile and styrene units respectively, i.e. under the reaction conditions both styrene and acrylonitrile behave as solvents and do not copolymerise with 4-VP. This makes it possible to eliminate the



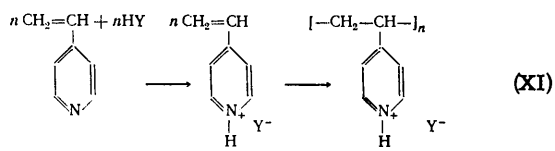
usual anionic and cationic mechanisms. The findings enumerated above necessitated the hypothesis that the polymerisation has a specific mechanism whereby only the molecules of the vinylpyridinium salts formed in the Menshutkin reaction are selectively polymerised. This mechanism was confirmed by detailed kinetic measurements (Aliev, Kabanov, Kargin)[8-10].

The first stage, which is rate-limiting for the process as a whole, is the Menshutkin reaction:



(VIII)

As a result of the appearance of a positive charge on the nitrogen atom in the monomeric salt, the π-electrons of the double bonds are appreciably displaced towards the pyridine ring, this being accompanied by a sharp increase in the electrophilicity of the double bond. The activated monomer now readily combines even with weak nucleophilic agents. The role of such an agent in the initiation reaction is fulfilled by the anion Y^-:



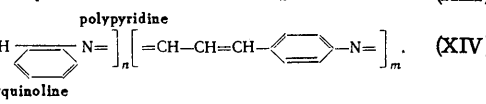
(IX)

[It should be noted that Eqn. (IX) bears a profound analogy to the well known pyridylethylation processes][11,12]. The zwitter-ion produced begins chain growth, by combining with the next molecule of the chemically activated monomer:

(X)

The molecules of 4-VP and other monomers cannot compete with those of the vinylpyridinium salt, in the first place because on addition of any other monomer to the active centre charges of opposite sign, which in the initial active centre interact via the π-bond system of the pyridine ring, would have to be separated, i.e. the energy of the system would increase significantly (loss of conjugation in the zwitter-ion and electrostatic effect). In the example examined the activator itself undergoes chemical reaction, forming a strong bond with the monomer and entering into the composition of the polymeric chain [in mechanism (II) i = 1 and j and k are equal to the degree of polymerisation], and cannot be removed from the polymer after the reaction. However, chemical activation of 4-VP (as well as that of 2-vinylpyridine) occurs also under the action of strong proton acids[6,10,13]. When 4-VP is mixed with sulphuric, nitric, toluenesulphonic, and other acids in benzene, ethyl ether, and other solvents at room temperature, the corresponding salts of poly-4-VP are formed:

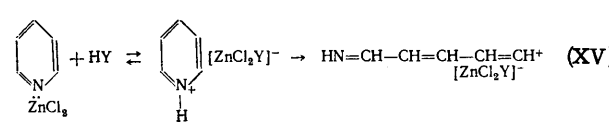
(XI)



The mechanism of the polymerisation is probably largely similar to the one just described, but the subsequent treatment of the system with dilute alkali converts polyvinylpyridinium ions into polyvinylpyridine, i.e. the activator is readily removed from the polymer. It is striking that on addition of strong acids (in particular sulphuric acid) to 4-VP solutions in styrene the 4-VP salt produced immediately polymerises. Neither the excess 4-VP nor styrene are involved in the reaction. Thus the conversion of 4-VP into quaternary salts results in the generation of active centres with exceptional chemical selectivity. By virtue of the unusual nature of the active centres, the growing chains are capable of "selection" from the reaction system and can combine with N-alkylated or protonated monomer molecules.

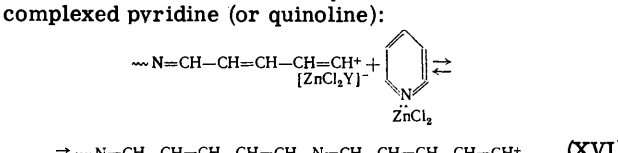
The polymerisation and copolymerisation of complexed aromatic heterocycles (pyridine and quinoline) with ring opening may be regarded, in principle, as a closely related case[14-19]. The polymerisation of the stoichiometric complexes of pyridine and quinoline with zinc chloride has been investigated in detail between 250° and 370°:

(XII)



When melts of the pyridine complexes are heated above 330° and those of quinoline complexes above 250° in the presence of proton-donating initiators (HPO_3, H_2O, and pyridinium or quinolinium chlorides), high-molecular thermostable paramagnetic substances soluble in concentrated mineral acids are produced; their structure may be described by the formulae

(XIII)



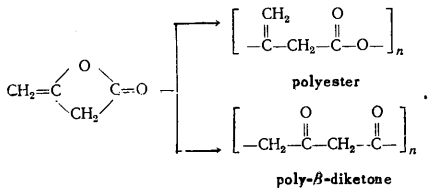
(XIV)

The kinetic role of the complex-forming agent probably consists in the polarisation of the nitrogen–carbon bond in the aromatic heterocycle which facilitates its heterolytic splitting when attacked by an electrophilic agent. Detailed kinetic studies[10,15-17] suggest that the following polymerisation mechanism is the most likely. Initiation in the presence of proton donors can be represented by the mechanism

(XV)

(for simplicity, only one of the pyridine molecules bound to each zinc chloride molecule is shown here). Chain growth occurs as a result of the attack by the carbonium cation on the complexed pyridine (or quinoline):

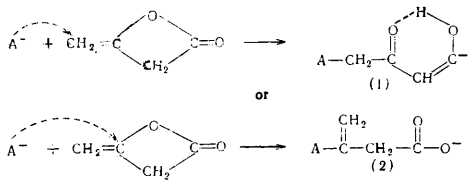
(XVI)



At the end of the reaction the polymer can be separated from the complex-forming agent by reprecipitation with water from concentrated mineral acids.

Chain growth in the polymerisation of aromatic heterocycles is reversible. For this reason, at a given temperature a limiting degree of conversion, determined by the equilibrium concentration of the monomer complex, is established in the system. The study of the temperature

variation of the limiting conversion showed that the polymerisation of pyridine and quinoline complexes is characterised by a lower limiting temperature (for the pyridine complex $T_{1.lim} \simeq 300°$, $\Delta H \simeq 13$ kcal mole^{-1}, and $\Delta S \simeq 19$ e.u., and for the quinoline complex $T_{1.lim} \simeq 240°$, $\Delta H \simeq 12$ kcal mole^{-1}, and $\Delta S \simeq 19$ e.u.). As shown above, these thermodynamic quantities include respectively the differences between the enthalpies and entropies of formation of the complex of the activator with the polymer and with the monomer.

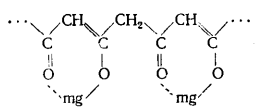


In the absence of complex-forming agents, polymerisation of pyridine and quinoline with ring opening cannot be achieved. Thus chemical activation of these monomers yields new polymers, which cannot be obtained by the usual methods of synthesis. Some years ago polymeric products were obtained by a similar procedure from nitriles by polymerisation at the C≡N bond[10,14,20-26]‡. The starting materials were complexes of nitriles with coordination-unsaturated metal halides.

Chemical reactions of monomers and growing chains with the species derived from the medium can influence the structure of the polymer units. Possibly this effect actually takes place in the polymerisation of diketen initiated by metallic magnesium[27]. It is known that, depending on the nature of the initiating agents and the reaction conditions, diketen can polymerise to a polyester[28] or a poly-β-diketone[29]:

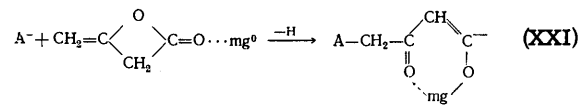
(XVII)

The reaction of diketen with magnesium results in the formation of substances which initiate the anionic polymerisation of diketen (the initiation mechanism has been examined by Shul'gina et al.[27]). A copolymer is then formed, in which the ratio of polyester and poly-β-diketone units is approximately 1 : 1. The structure of each successive unit is determined by the mode of the nucleophilic attack on the vinyl group of the monomer by the growing anion:



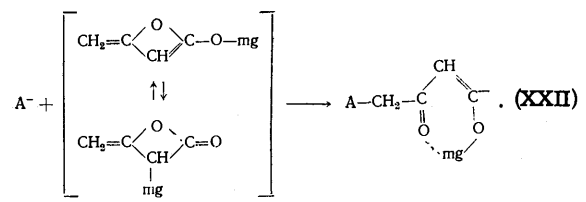
(XVIII)

or



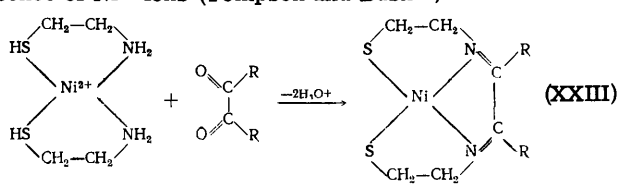
(XIX)

However, when the polymerisation is carried out in the presence of an excess of highly dispersed metallic magnesium (dispersed in the reaction system) hydrogen is evolved during the reaction and a polychelate, not containing ester units, is formed:



(XX)

After treatment with acid, the polychelate is converted into poly-β-diketone (mg represents one equivalent of magnesium). It may be supposed that in this case the polymerisation involves monomer molecules combined with magnesium and the reaction proceeds by one of the following mechanisms:



(XXI)

or

(XXII)

The chelate anion formed is more stable than anion (1) in mechanism (XVIII) and anion (2) in mechanism (XIX). For this reason, the reaction results exclusively in the formation of β-diketone units. In other words, the new monomer obtained in the reaction between diketen and magnesium is chemically activated for the formation of poly-β-diketone. It is noteworthy that in the chemistry of low-molecular compounds there are a number of cases where substances capable of coordinating the starting materials and the final products have a decisive influence on the mode of the chemical reaction (see, for example, Ref. 30). Of the numerous examples available, one may quote the synthesis of Schiff bases from β-mercaptoethylamine and α-diketones in the presence of Ni^{2+} ions (Tompson and Bush[31]):

(XXIII)

The reaction yields a compound with a significantly more stable chelate unit than the initial substance. In the absence of a complex-forming agent, thiazolines and mercaptals are formed instead of the Schiff base. The use of a similar principle in the synthesis of polymers may be of considerable interest.

3. INTERMOLECULAR EFFECT

In all the systems examined so far chemical activation must be regarded as due to an intramolecular effect. Although chemical interaction between the monomer and the species derived from the medium by no means always leads to a redistribution of electron density involving the reaction centres of the monomeric molecules responsible for polymerisation, such interaction can nevertheless lead to a considerable acceleration of polymerisation, i.e. to the activation of the monomer in the broad sense of the word, if it results in a change of the distribution of the reacting species, and (or) orientation of the reaction centres favouring chain growth (intermolecular effect).

An outstanding example is the initiation by benzoyl peroxide of the polymerisation of *p*-methacryloyloxybenzoic acid (MOBA) in the presence of *p*-cetyloxybenzoic acid

‡ The thermodynamic considerations concerning the polymerisation of complexed nitriles presented by Kargin et al.[20] are erroneous.

(COBA), investigated recently by Amerik et al.[32] In dimethylformamide solution MOBA polymerises in accordance with laws characteristic of the usual radical processes (reaction order with respect to the initiator 0.5 and with respect to the monomer 1.1). An equimolar mixture of MOBA and COBA forms smectic liquid crystals in the temperature range 87–133°. The structure of the smectic layer of such a crystal is shown in Fig. 1.

The rate of polymerisation and the molecular weight of the polymer formed in liquid crystals are significantly higher than in solution (at the same monomer concentrations the molecular weight changes from 5×10^4 to 6×10^5). The order of the reaction with respect to the monomer is close to zero. It is quite evident that the formation of hydrogen bonds between MOBA and COBA cannot influence directly the reactivity of the vinyl groups of the monomer. The acceleration of polymerisation and the increase of molecular weight are probably due to the existence in the system of labile monomeric "seeds", which, as shown earlier[33-35], favour the growth of polymeric chains. One cannot exclude the possibility that the "organised" disposition of double bonds in smectic layers can also influence the mechanism of the fundamental chain growth step. In view of this, the observed differences in the temperature variation of the microtacticity of polymers formed in solution and in liquid crystals are of considerable interest (Table 1).

In the polymerisation of MOBA in solution the percentage content of isotactic (i), heterotactic (h), and syndiotactic (s) triads in the polymer varies in the "normal" way [$\Delta(\Delta H^{+}) = 1025$ cal mole^{-1}; $\Delta(\Delta S^{+}) = 0.5$ e.u.]. In the liquid-crystal polymerisation the isomeric composition of the polymer differs significantly and is altogether independent of temperature [$\Delta(\Delta H^{+}) \simeq 0$; $\Delta(\Delta S^{+}) = 0.8$ e.u.]. The above data show at least a difference in the energy relations of the transition states in solution and in the liquid crystal. It

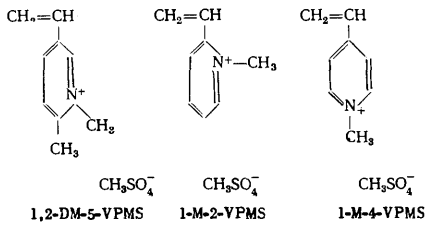
TABLE 1. Temperature variation of the microtacticity of poly-*p*-methoxybenzoic acid (poly-MOBA)[32] measured by the NMR method after the conversion of poly-MOBA into poly(methyl methacrylate).

Polymerisation temperature, °C	In solution			In the liquid crystal		
	i	*h*	*s*	*i*	*h*	*s*
0	6.2	18.8	75.0			
40	7.0	23.3	69.7			
90	8.2	28.8	63.0	8.0	44.0	48.0
110	8.7	30.1	61.2	8.0	45.0	47.0
130				8.0	45.0	47.0

should also be noted that in the absence of COBA at temperatures above 100° the rate of depolymerisation of poly-MOBA is comparable with the rate of its formation. Therefore, when the reaction is carried out in solution, a polymerisation–depolymerisation equilibrium is established, and the yield of polymers does not reach 100%. Polymerisation in the liquid-crystal state at temperatures up to the melting point of the liquid crystals results in complete conversion of the monomer into the polymer. Thus in this case the activator not only influences the kinetics but also the thermodynamics of the polymerisation.



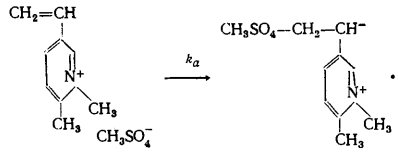
The intermolecular effect is shown "in a pure form" in polymerisation in canal compounds[36,37]. It is known that in the presence of certain organic substances urea and thiourea form tetragonal crystals with tubular channels of molecular diameter, which become filled with molecules of the organic substances. Certain vinyl compounds and dienes become arranged into linear sequences of molecules in such channels and can be rapidly polymerised under the action of accelerated electrons and γ- or X-radiation. When canal compounds of buta-1,3-diene with urea and dimethylbuta-2,3-diene with thiourea are irradiated with electrons, the corresponding crystalline *trans*-poly-1,4-dienes are formed[36,37], although the radiation-induced polymerisation of these monomers in the solid state or in solution always results in irregular polymers of mixed structure. The weak van der Waals interaction with the walls of the channels cannot lead to appreciable redistribution of electron density in the individual monomer molecule. Therefore the chemical effects shown in polymerisation in canal compounds, in particular the sharp increase in the relative rate of 1,4-*trans*-addition of dienes, must be attributed in the first place to the favourable mutual orientation of the double bonds of the initial monomeric sequences, i.e. to an intermolecular effect. Strictly speaking, even if the term "chemical activation" is applicable to the above phenomenon the same stipulations must be made as in the application of the term "chemical compound" to canal compounds.

Pursuing further this approach, one can cite the familiar phenomenon of the sharp increase in the rate of polymerisation in the crystallisation of liquid and vitreous monomers[33-35,38]. It has been shown that the acceleration is closely related to the formation at the interface between the crystalline and amorphous phases of mobile ordered aggregates of monomeric molecules — "labile seeds"[38] — i.e. is also due to an intermolecular effect. However, in this case the factors which lead to the formation of "labile seeds" are physical and not chemical in nature: the concept of "chemical activation" degenerates.

4. SIMULTANEOUS OCCURRENCE OF INTRA- AND INTER-MOLECULAR EFFECTS. MACROMOLECULAR "MATRICES"

In many cases the intramolecular and intermolecular effects occur simultaneously in chemical activation. It was noted above that the quaternary salts of 4-VP and alkyl halides polymerise spontaneously in organic media in statu nascendi. In accordance with the polarisation mechanism examined above, it is to be expected that quaternary salts of vinylpyridines with the double bond in position 5 or 3 and hence polarised to a lesser extent should show a smaller tendency towards spontaneous polymerisation. Indeed in the reaction between 2-methyl-5-vinylpyridine (MVP) and ethyl bromide, methyl iodide, dimethyl sulphate, and others in organic solvents (acetone, ethyl acetate, etc.) polymerisation does not occur: crystalline monomeric salts are precipitated. The salts of 4-VP and 2-VP whose anions exhibit relatively weak nucleophilic properties can also be obtained in a monomeric form in organic solvents at low temperatures. However, all these monomers polymerise spontaneously in concentrated aqueous solutions.

Kargin et al.[7,8,10,39-41] studied this spontaneous polymerisation of 1,2-dimethyl-5-vinylpyridinium methyl sulphate (1,2-DM-5-VPMS), 1-methyl-2-vinylpyridinium methyl sulphate (1-M-2-VPMS), and 1-methyl-4-vinylpyridinium methyl sulphate (1-M-4-VPMS) in water:



1,2-DM-5-VPMS 1-M-2-VPMS 1-M-4-VPMS

It has been established that carbon dioxide, sodium bicarbonate (which is in equilibrium with carbon dioxide), and sulphur dioxide are powerful inhibitors of spontaneous polymerisation. This finding eliminates Shyluk's hypothesis[42] of radical initiation and is in good agreement with the specific anionic mechanism of the polymerisation of 4-VP salts in organic media proposed above. Inhibition can then be regarded as a result of the addition of carbon dioxide or sulphur dioxide to the active centre carbanion.

When these inhibitors are present or specially added, induction periods appear on the kinetic curves. Using 1,2-DM-5-VPMS as an example, it has been shown that the duration of the induction period τ is related to the rate of generation of active centres v_a by the following simple expression characteristic of strong inhibitors:

$$\tau = [\text{inhibitor}]/v_a . \qquad (2)$$

Hence there is a possibility of a direct measurement of v_a. It may be expected that the rate of formation of active centres by reactions of the type of reaction (IX) (see p. 77) will be higher the greater is the polarisation of the double bond in the quaternary salt molecule. Indeed the rates v_a determined from the experimental values of τ and calculated by Eqn. (2) proved to be higher by a factor of 3.5–4 for 1-M-2-VPMS and 1-M-4-VPMS than for 1,2-DM-5-VPMS (in the range 10–35°, k_a for 1,2-DM-5-VPMS varies from 2.8×10^{-7} to 4×10^{-7} min^{-1}). Using 1,2-DM-5-VPMS as an example, the initiation reaction has been shown to be of first order with respect to the monomer, which is in complete agreement with the type (IX) mechanism, i.e.

(IX')

At the same time the kinetic curves for polymerisation in concentrated aqueous solutions (2.5 M and higher) yield satisfactory straight lines when plotted in terms of the equation for first-order reactions (Fig. 2) up to conversions (q) close to one. This means that the overall reaction is also of first order with respect to the monomer. However, the initial rate of reaction $(dg/dt)_0$ falls sharply when the initial concentration of the monomer $[M]_0$ is reduced (Fig. 3), although for a usual first-order reaction this quantity should not be a function of $[M]_0$ at all. At the same time the characteristic viscosities (molecular weights) of the polymers formed were found to decrease appreciably (Fig. 3). The temperature variation of the rate of polymerisation and the molecular weight is also quite unusual. When the temperature is increased, the rate of polymerisation and the characteristic viscosity pass through a maximum (Figs. 4 and 5).

All the attempts to account for all the experimental data using the normal concepts of homogeneous kinetics were unsuccessful. However, the observed relations can be readily explained if it is assumed that in concentrated solutions of monomeric salts ordered aggregates ("labile seeds") are present, whose lifetimes are greater or at least comparable with the time required for chain formation, as happens in liquid crystals. A hypothetical structure of an ordered aggregate is shown in Fig. 6. With this arrangement of the species in the aggregate, the double bonds form "layers" stabilised by hydrophobic interaction. It is suggested that "organised" monomer molecules, which retain sufficient mobility, are readily polymerised when an active centre enters an ordered layer. The electrical

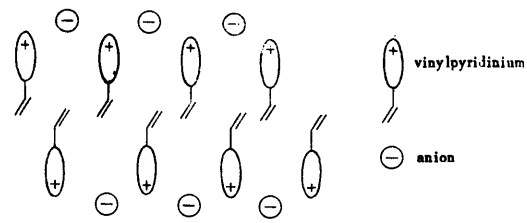

Fig. 6. The hypothetical structure of an organised aggregate in concentrated aqueous solutions of a vinylpyridinium salt.

double layer prevents the access of charged species, in particular H_3O^+ ions, to the growing chain and hence the destruction of carbanions by the addition of protons. Therefore the rate of polymerisation is independent of the pH of the medium between 2 and 9. In contrast to protons, the uncharged carbon dioxide and sulphur dioxide molecules easily reach the active centres and inhibit the process.

On the basis of the independence of the molecular weight of the degree of conversion (which has been shown experimentally and is evidence of the attainment of a steady state), the expression for the rate of polymerisation can be written in the form

$$-\frac{d[M]}{dt} = v_i\bar{\nu}, \qquad (3)$$

where [M] is the concentration of the monomer at any instant, $\bar{\nu}$ the average length of the kinetic chain, and v_i the rate of initiation. The first order of the initiation reaction with respect to the monomer, found experimentally, implies that

$$v_i = \varphi v_a = \varphi k_a[M], \qquad (4)$$

where k_a is the rate constant for the generation of active centres by a reaction of type (IX′) and φ is the initiation efficiency.

Noting that $q = (M_0 - M)/M_0$ and substituting Eqn. (4) in Eqn. (3), we obtain

$$\frac{dq}{dt} = \bar{\nu}\varphi k_a(1-q). \qquad (5)$$

At high values of $[M]_0$ the experimental variation of q with time is described by the equation

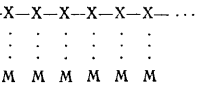
$$-\ln(1-q) = \bar{\nu}\varphi k_a t, \qquad (6)$$

which is obtained by integrating Eqn. (5). If it is assumed that, having attained the boundary of the ordered aggregate the active centre is immediately destroyed by combining with a proton or a water molecule, $\bar{\nu}$ should of course be related to the size of the ordered aggregates. In highly concentrated systems the formation of a macromolecule does not result in the breakdown of adjacent ordered regions.

Therefore $\bar{\nu}$ is independent of the degree of conversion ($\bar{\nu}$ = = const) and the polymerisation kinetics are described by the usual first-order equation. However, dilution of the initial system or a fairly appreciable temperature rise result in a decrease of the size of the ordered regions ("fusion") and the experimentally observed fall of the rate and the molecular weight. The validity of these considerations is confirmed by the sharp decrease of the viscosity of 1,2-DM--5-VPMS solutions on dilution (Fig. 7) and on raising the temperature, which is observed in the same range of concentrations and temperatures as the decrease of the rate and the molecular weight.

One of the causes of the increase of the rate with temperature in the region of lower temperatures must be attributed to the positive temperature coefficient of the initiation reaction ($E_a \simeq 7$ kcal mole^{-1} for 1,2-DM-5-VPMS). Thus the maxima on the rate–temperature curves can be explained by the superposition of two opposed factors — the increase of the rate of initiation and the breakdown of "labile seeds". However, this explanation cannot account for the extremal temperature variation of the molecular weight. Nevertheless, if it is assumed that chain termination occurs not only at the boundaries of the ordered aggregates but also, with a certain probability, within them (for example at water molecules which sometimes penetrate into the hydrophobic regions), then the extremal temperature variation of the molecular weight can also be satisfactorily accounted for. Indeed the maximum average length of the chains which can form under the given conditions ($\bar{\nu}_{max}$) is determined by the average length of the seeds. In the absence of chain transfer, the number-average degree of polymerisation $\overline{DP}$ can be expressed by the formula

$$\overline{DP} = (1-\lambda)\,\bar{\nu}_{max} + \lambda\,\frac{k_p}{k_t}, \qquad (7)$$



where k_p is the chain growth rate constant, k_t the chain termination rate constant within the seed, and λ the fraction of chains which are destroyed before reaching the end of the seed. If the activation energy for chain growth is higher than for chain termination within the seed, then at low temperatures most of the chains are terminated within the seeds ($\lambda \simeq 1$) and $\overline{DP}$ is determined by the ratio k_p/k_t and its temperature variation by the difference between the activation energies for chain growth and termination. In this temperature range $\overline{DP}$ increases with temperature. At high temperatures, where "fusion" takes place and the size of the ordered aggregates decreases, $\bar{\nu}_{max}$ falls and becomes smaller than k_p/k_t. Then most of the chains are destroyed at the edges of the seeds ($\lambda \simeq 0$) and $\overline{DP}$ is determined by the greatly reduced value of $\bar{\nu}_{max}$. In the absence of chain transfer, the rate of polymerisation can be written

$$-\frac{d[M]}{dt} = v_i\left[(1-\lambda)\,\bar{\nu}_{max} + \lambda\,\frac{k_p}{k_t}\right]. \qquad (8)$$

This expression explains the experimentally observed similarity of the variation of the rate of polymerisation and the molecular weight with the reaction conditions§.

Thus the concept of chemical activation of the monomer as a result of an intramolecular effect (polarisation of the double bond in the quaternary salt molecule) proved to be inadequate to account for the relations observed in the spontaneous polymerisation of vinylpyridinium salts in concentrated aqueous solutions. The kinetic data require the additional hypothesis of "labile seeds" which arise as a result of intermolecular interaction in the reaction system, i.e. of an intermolecular effect.

The combination of intra- and inter-molecular effects in chemical activation is closely related to the problem of "matrix" polymerisation. Suppose that the activator species X are chemically bound into long sequences. Then on addition of the monomer, the following system forms:

The monomer and the "matrix" can be chosen so that the reactivity of the monomer M bound to X should be significantly higher than that of free M. Then a chain M_n is formed from activated monomer molecules on each X_n sequence.

The reaction described recently by Furukawa and coworkers[43] may be quoted as an interesting example. In their study of the interaction between acetaldehyde and activated alumina the Japanese investigators observed that the adsorbed monomer polymerises with high yields at -70° to amorphous rubberlike polyacetal. The infrared spectrum of acetaldehyde adsorbed on alumina shows a pronounced bathochromic shift of the absorption band due to the carbonyl group, compared with the liquid monomer (6.4 instead of 5.8 μm), which indicates appreciable polarisation of the C=O bond (intramolecular effect). The authors[43] suggest that on adsorption the acetaldehyde molecules assume an ordered arrangement in the adsorption layer, as shown in Fig. 8 (intermolecular effect). Both factors favour rapid growth of polymeric chains, i.e. lead to the activation of the molecule.

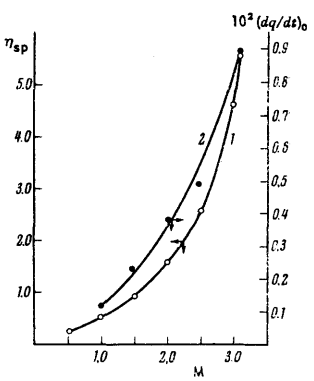


Fig. 7. Variation of the specific viscosity of an aqueous solution (curve 1) and the rate of polymerisation (curve 2) of 1,2-dimethyl--5-vinylpyridinium methyl sulphate with monomer concentration; the viscometric and kinetic measurements were made at 25°.

§ The behaviour of 1-M-4-VPMS in the temperature range 35–40° is exceptional (Fig. 4). Despite the continuing fall of the molecular weight, the rate of polymerisation increases suddenly after passing through a maximum by a factor of nearly six, which corresponds to an effective activation energy of about 70 kcal × × mole^{-1}. As before, the kinetic curves for polymerisation at 40° yield straight lines when plotted in terms of the equation for a first-order reaction (Fig. 2, curve 1). This effect can be attributed to a sudden rearrangement of the aggregates over a narrow temperature range.

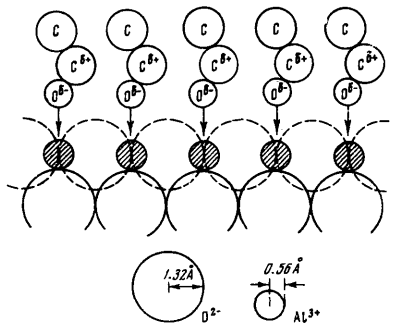

Fig. 8. Acetaldehyde adsorbed on the surface of γ-alumina [43].

The phenomenon of chemical activation of the double bonds of 4-VP in its conversion to the quaternary salt, described above, recently enabled Kargin et al. to achieve polymerisation on macromolecular "matrices" [7,8,10,13,44]. Polystyrenesulphonic acid (PSSA), polyethylenesulphonic acid (PESA), and polyacrylic acid (PAA) were used as the matrices. In all cases an equivalent amount of 4-VP was chemisorbed on the polymeric acids, activated, and polymerised by the mechanism described above. The products were polymeric salts, paired macromolecules of the polymeric acid and polymeric base (Fig. 9). The 4-VP molecules for which there is no room on the "matrices" remain inactive and are not involved in the reaction.

If the degree of neutralisation of the polymeric acid (i.e. the degree of saturation of the "matrix") is close to unity, the polymerisation of 4-VP on the polymeric acids is rapid at room temperature even in dilute aqueous solutions, since the activated monomer species are grouped along the polymeric activator chains regardless of the average concentration. However, the rate of polymerisation greatly depends on the degree of saturation, increasing sharply when the latter approaches unity. The problem of the effect of the degree of saturation of the "matrix" on the rate of the process is cardinal, since it is directly related to the problem of the elucidation of the nature of the interaction between the substrate and activator.

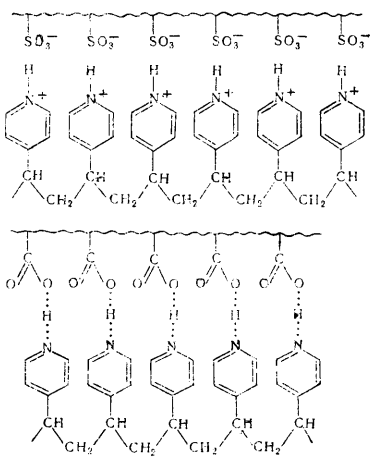

Fig. 9. The structure of the "matrix" polymerisation product.

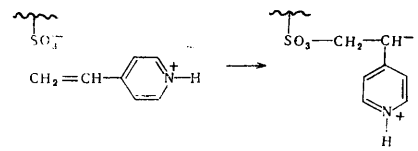
The marked dependence of the rate of polymerisation on the degree of saturation α can be explained on two different hypotheses. The first of these reduces to the following. Suppose that the vinylpyridinium cations formed on neutralisation of the polymeric acid are firmly bound to its units and cannot migrate along the "matrix". The probability of the formation of a continuous sequence of p-activated 4-VP molecules is

$$\omega_p = \alpha^{p-1}(1-\alpha). \qquad (9)$$



The average length of continuous sequences at a given value of α is

$$\bar{\nu} = \sum_1^\infty p\omega_p = \sum_1^\infty p\alpha^{p-1}(1-\alpha) = \frac{1}{1-\alpha}. \qquad (10)$$

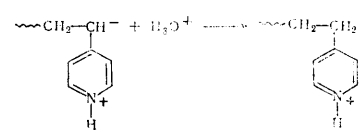
If it is assumed that the length of the kinetic chain is determined by the length of the continuous sequence of activated molecules on the matrix, then, provided that initiation is possible in any unit of this sequence, the initial rate of polymerisation is

$$v_p = v_i\frac{\bar{\nu}}{2} = \frac{v_i}{2(1-\alpha)}, \qquad (11)$$

where v_i is the rate of initiation. Assuming further that the initiation reaction is of first order with respect to the monomer (see above), i.e. takes place by the mechanism

(XXIV)

one can write

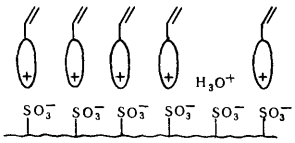


$$v_i = k_i[M] = k_i\alpha[C], \qquad (12)$$

where k_i is the initiation rate constant, [M] the concentration of the monomer, and [C] the concentration of the polymeric acid. On substituting Eqn. (12) in Eqn. (11), we obtain

$$v_p = {}^1/_2 k_i[C]\frac{\alpha}{1-\alpha}. \qquad (13)$$

Eqn. (13) predicts a rapid increase of the initial rate of polymerisation as α approaches unity (v_p tends to infinity when α = 1 because of the simplifying assumption made in the derivation that the "matrices" are of infinite length).



The second possible explanation is based on the assumption that activated 4-VP molecules can migrate within a certain space along the "matrix" and that the length of the kinetic chain for $\alpha < 1$ is related to the probability of the destruction of the active centre by the non-titrated hydronium ions, by the mechanism

(XXV)

In fact the "structure" of the reaction system formed on titration of the polymeric acid with 4-VP cannot ensure

electrostatic protection of the active centre from the non-titrated protons, in contrast to the mechanism adopted for the polymerisation of vinylpyridinium salts in concentrated aqueous solutions (see p. 81). This structure can be represented as follows:

(XXVI)

In the regions where the matrix is not saturated by the monomer, the probability of an encounter between an active centre and hydronium ions, which are held in the vicinity of such regions by the electrostatic interaction with the polymeric anion, is very high. Then the rate of chain termination v_t is given by the equation

$$v_t = k_t n [H_3O^+], \quad (14)$$

where k_t is the termination rate constant and n the concentration of active centres.

The average length of the kinetic chain at low conversions, when the change in the concentration of the activated monomer may be neglected, is given by the expression

$$\bar{\nu} = \frac{k_p n [M]}{k_t n [H_3O^+]} = \frac{k_p \alpha [C]}{k_t [H_3O^+]}. \quad (15)$$

The initial rate of polymerisation is

$$v_p = v_i \bar{\nu} = \frac{k_i k_p}{k_t} C^2 \frac{\alpha^2}{[H_3O^+]}, \quad (16)$$

where k_p is the chain propagation rate constant. Noting that for a strong acid

$$\alpha = \frac{[H_3O^+]_0 - [H_3O^+]}{[H_3O^+]_0},$$

where $[H_3O^+]_0$ is the concentration of hydronium ions in the non-titrated acid, we have finally

$$v_p = \frac{k_i k_p \alpha^2 [C]}{k_t (1 - \alpha)}. \quad (17)$$

Eqn. (17), like Eqn. (13), predicts a very rapid increase in the initial rate of polymerisation when α tends to unity.

In order to decide which of the two hypotheses is correct, it is necessary to "spoil" the "matrices" by titrating them before the addition of 4-VP with any non-polymerisable base, for example alkali. Then if we denote the degree of preliminary neutralisation by β and the overall degree of neutralisation by α as before, Eqn. (13) becomes

$$v_p = {}^1/_2 k_i [C] \frac{\alpha - \beta}{1 - (\alpha - \beta)}, \quad (13')$$

and Eqn. (17) becomes

$$v_p = \frac{k_i k_p (\alpha - \beta)^2 [C]}{k_t (1 - \alpha)}. \quad (17')$$

It follows from Eqns. (13′) and (17′) that the hypothesis of the rigid fixation of vinylpyridinium ions on the polymeric acid macromolecules leads to the theoretical prediction of a higher sensitivity of the rate of reaction to preliminary neutralisation in the range of α values close to unity than the hypothesis of chain termination by hydronium ions.

To decide which of the two kinetic equations describes the real process, two series of experiments were made. In the first series a 0.0119 N aqueous solution of PESA was titrated with 0.076 N aqueous solution of 4-VP to pH 5.6, which corresponds to $\alpha \simeq 0.999$. In the second series the same PESA solution was 50% titrated with the sodium hydroxide solution and then the pH was again brought to 5.6 by the addition of a solution of 4-VP. Thus in the first series of experiments we have $\beta = 0$ and $\alpha = 0.999$ and in the second series $\beta = 0.5$ and $\alpha = 0.999$. The rate of polymerisation was measured spectrophotometrically. It was found that in the solutions where $\beta = 0$ the rate of reaction was 3.6–3.9 times higher than in the solutions where $\beta = 0.5$.

It is now necessary to compare the result with the theoretical predictions. The relative decrease of the rate of polymerisation γ' on the assumption of rigid fixation of the activated monomers can be found by dividing Eqn. (13) by Eqn. (13′):

$$\gamma' = \frac{\alpha (1 - \alpha + \beta)}{(1 - \alpha)(\alpha - \beta)}. \quad (18)$$

On substituting the values of α and β specified in the experiments, we obtain $\gamma' \simeq 1000$, i.e. the rate of polymerisation on the "spoiled matrix" should be lower by a factor of one thousand than on the matrix titrated with 4-VP only. The relative decrease of the rate of polymerisation γ'' on the assumption of migration of vinylpyridinium ions along the polymeric acid molecules and the destruction of active centres by non-titrated protons is obtained by dividing Eqn. (17) by Eqn. (17′):

$$\gamma'' = \frac{\alpha^2}{(\alpha - \beta)^2}. \quad (19)$$

For the values of α and β used, $\gamma'' \simeq 4$, which is in good agreement with experiment.

It is striking that the morphology of the polymerisation products of 4-VP on polymeric acids is closely related to the form of the "matrix" in solution. Electron microscope studies have shown that in the polymerisation in methanol, where the macromolecules are rolled into globules, the polymeric salts form as disordered globular aggregates. In the polymerisation in water, where the matrices are ionised and extended, distinctly fibrillar structures are produced[7,8,10,13]. Thus chemical activation of 4-VP by polymeric acids is indeed due to a combination of intramolecular and intermolecular effects. It must be emphasised that the conversion of 4-VP into vinylpyridinium ions is by itself insufficient to ensure appreciable reaction rates in aqueous media. In dilute aqueous solutions of 4-VP salts and low-molecular acids there is virtually no spontaneous polymerisation. In equimolar mixtures of 4-VP and glacial acetic acid only traces of a polymer are formed in several days. At the same time 50% conversion of the 4-VP salt and PAA into a polymeric salt in 0.092 N solution at 20–50° is attained in 35–3 min (overall activation energy 26.4 kcal mole^{-1}). It may be supposed that in this case too the formation of "labile seeds" from activated monomeric molecules plays a very significant role, since it is difficult to account for the observed acceleration on going from low-molecular to high-molecular activators by the concentration effect alone.

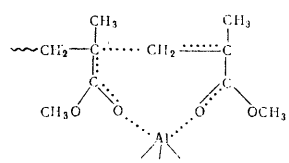
Polymerisation on macromolecular activators still constitutes only a very rough approximation to the synthesis of polymeric chains in living cells. However, it is well known that preliminary chemical activation of the substrate is one of the fundamental principles of biochemical processes.

5. CHEMICAL ACTIVATION IN RADICAL POLYMERISATION

It is known that the properties of free radicals and the rates of radical reactions depend relatively little on the properties of the medium (in particular its polarity). However, this is true only in those cases where the species of the medium are incapable of specific chemical or semichemical interaction with the reacting species. Even relatively weak chemical interaction of the functional groups of the radical or monomer with the medium influences the chain growth rate constants in radical processes.

A systematic study of the role of organic complex-forming agents in radical copolymerisation was recently undertaken by Ryabov, Semchikov, and coworkers[45]. They showed, in particular, that introduction of proton donors into the system styrene (St)–2-VP alters markedly the composition of the copolymers formed on radical initiation, and, what is particularly important, the nature of the composition curves. Table 2 presents the relative activities and their products for the copolymerisation of styrene and 2-VP in the presence of various proton donors taken in ratios of approximately 1 : 1.5 relative to 2-VP. The table also gives the pK values of the complex-forming agents investigated.

In their solid-phase copolymerisation styrene and 2-VP do not exhibit a tendency towards alternation. Over the entire range of relative concentrations the copolymer is slightly enriched in 2-VP. In the presence of proton donors a tendency towards alternation appears, and increases with the acidity of the donor. The authors attribute the observed effect to the positive polarisation of the double bond in the 2-VP molecule, as a result of the formation of a hydrogen bond between the nitrogen atom of the pyridine ring and the complex-forming agent. This conclusion is confirmed to some extent by the application of the Hammett equation and the Q–e scheme to the data obtained.



Strong inorganic complex-forming agents have an even more significant influence on radical polymerisation. In 1958 Bamford et al.[46] showed that the rate of polymerisation of acrylonitrile (AN) in dimethylformamide, initiated by free radicals, increases appreciably on addition to the system of lithium chloride which forms complexes with C≡N groups. A preliminary explanation of this effect was based on the postulated higher reactivity of the complexed chain propagation radicals. Two years later Kargin et al.[47] noted that the rate of the photo-initiated polymerisation of methyl methacrylate (MMA) saturated with zinc chloride increases sharply near the interface between the crystals and the liquid. At the same time Parrot and Monteiro[48] confirmed the results of Bamford and coworkers[46] by their observation of the acceleration of the radical polymerisation of acrylonitrile on addition of lithium chloride, magnesium chloride, and aluminium chloride. Data on the effect of zinc chloride on the polymerisation kinetics and the copolymerisation rate constants for a number of monomers were obtained by Imoto and coworkers[49]. The kinetic measurements of Bamford and coworkers[50] showed that the acceleration of photopolymerisation in the system MMA–$ZnCl_2$ is due to an increase of the chain propagation rate constant: the chain termination rate constant remains virtually unchanged.

TABLE 2. Effect of organic complex-forming agents on the copolymerisation constant of styrene (M_1) and 2-vinylpyridine (M_2).[45]

Complex-forming agent	pK	r_1	r_2	$r_1 \times r_2$
—	—	0.57 ±0.05	1.33 ±0.08	0.758
Ethanol	18	0.486±0.07	0.862±0.08	0.418
Methanol	16	0.426±0.05	0.607±0.06	0.258
Phenol	9.95	0.253±0.06	0.549±0.07	0.139
Acetic acid	4.75	0.16 ±0.04	0.36 ±0.07	0.058

The problem of the mechanisms leading to an increase of the rate of the radical-initiated chain propagation in the presence of inorganic complex-forming agents is at present the subject of detailed studies. The first attempt at a theoretical interpretation of this phenomenon was undertaken by Tazuke et al.[51] by the molecular orbital method. Using the simple LCAO approximation, they calculated the values for the extent of delocalisation S_r^R, regarded as a measure of the reactivity of the monomer, and of the stabilisation energy of the transition state ΔE_{rs} for complexes of various substituted derivatives of vinylpyridine, acrylonitrile, and methyl methacrylate with zinc chloride, and obtained a qualitative agreement between the theory and the kinetic experiments. Such calculations are made essentially to take into account the intramolecular effect of the complex-forming agents. However, in many cases chemical activation probably cannot be explained solely by the intramolecular effect, particularly in solid-phase polymerisation or in polymerisation in concentrated solutions in the presence of stoichiometric or nearly stoichiometric amounts of complex-forming agents.

Some light has been thrown on this problem by the results of Zubov et al.[52], who investigated the solid-phase photopolymerisation of methyl methacrylate in the presence of aluminium chloride and bromide. The kinetic data, the study of the infrared spectra of the complexed monomer, and the ESR spectra of the complexed radicals enabled the authors to put forward certain ideas concerning the mechanism of the acceleration of the polymerisation. It is suggested that, in the presence of low concentrations of inorganic activators (i.e. for monomer : activator ratios significantly lower than the stoichiometric values), the observed acceleration is mainly caused by the intramolecular effect. The hypothetical structure of the activated complex may be represented as follows:

(XXVII)

The unpaired electron of the complex radical, which according to the ESR data spends some time on the aluminium atom (spin density on aluminium about 1%), is transferred to the monomer molecule in the transition state. It is suggested that this fundamental step has a higher probability than the usual radical addition. For this reason, the chain propagation rate constant is higher in the presence of the complex-forming agent. However, the above hypothesis cannot account for the kinetic data obtained when the monomer : complex-forming agent ratios are close to the stoichiometric value. In this case the formation of organised aggregates of complexed methyl methacrylate molecules ("labile seeds"), favouring chain growth, probably

begins to play a significant role, as happens, for example, in certain liquid crystals (intermolecular effect).

Quite recently Nechaev et al. [53] observed the acceleration of the photo-initiated polymerisation of methyl methacrylate in the presence of 4% oleum. It was found that the rate of polymerisation increases with the concentration of sulphuric acid and passes through a maximum. At the molar ratio H_2SO_4 : MMA = 1 the molecular weight is also a maximum (Fig. 10). It may be supposed that in this case the intermolecular effect is one of the causes of the chemical activation of methyl methacrylate.

The intramolecular effect postulates cannot account for the sharp increase in the rate of the radiation-induced photopolymerisation of allyl monomers in the presence of zinc chloride [52]. Allyl acetate (AA) to which an equimolar amount of zinc chloride has been added polymerises 5.5–6 times faster. The rate of polymerisation of allyl alcohol (AAlc) increases by a factor of 24 in the presence of zinc chloride at an allyl alcohol : zinc chloride ratio of 2. Since the double bond in allyl monomers and the unpaired electrons in the corresponding chain propagation radicals are not conjugated with the functional groups participating in the formation of complexes, it is difficult to expect an appreciable change in their reactivity as a result of the addition of zinc chloride. One of the possibilities consists in the activation of the complexed allyl chain transfer radicals. Nevertheless this alone does not fully explain the observed kinetic features. The explanation should probably also be sought in a combination of intramolecular and intermolecular effects.

Radical polymerisation in the presence of complex-forming agents has been recently introduced in polymer chemistry and its further development will probably lead to fundamentally new methods for the control of the rates and the stereochemistry of radical processes. The studies of the chemical activation of monomers in the formation of charge-transfer complexes which have been begun in a number of laboratories are particularly promising.

---oOo---

The problems of the polymerisation of chemically activated monomers may be regarded as part of the general problem of the effect of the interaction between the substrate and the species derived from the medium on the capacity of the substrate to undergo a particular reaction. The

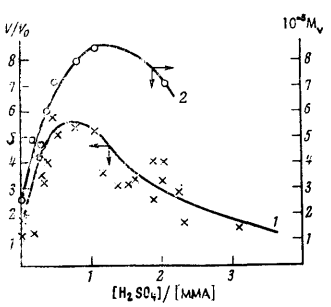


Fig. 10. Variation of the relative rate of polymerisation of methyl methacrylate (curve 1) and the molecular weight of the resulting polymer (curve 2) with the monomer : activator molar ratio at 20°.

averaging simplification associated with the introduction of the macroscopic concept (medium) is always to some extent a consequence of the insufficient knowledge of the investigator of the nature and distribution of the concrete interactions in the reaction system at a molecular level. This averaging simplification is very convenient in analysis and is probably justified in the case of weak interactions, but it involves fundamental limitations in the elucidation of the detailed mechanisms of chemical reactions. The present review deals with systems for which the necessity to formulate the term "interaction with the medium" in a more concrete form is quite evident. The examination of the monomer–activator problem on a somewhat wider scale leads to an important generalisation. Imagine a system in which the number of monomer molecules is somewhat higher than the number of activated molecules. If the activator combines with the units of the polymer being formed as strongly or more strongly than with the monomer molecules, then during the reaction the fraction of the activated monomer decreases continuously. Actually this means that in the initial system part of the less active monomer is replaced by a more active variety. Examples of such systems are quoted above. If the bond between the activator and the polymer chain units is much weaker than that with the monomer, then one activator molecule can be used repeatedly and can facilitate the polymerisation of a large number of monomer molecules: the concept of the "activator" merges with the classical concept of the "catalyst". An example is the polymerisation of *N*-carboxy-anhydrides examined above. Finally, if the activator molecules interact with the growing ends of the chain more strongly than with the average monomer molecules and with the macromolecular units, they will be retained at the end of the chain during its growth and, within the framework of the generally adopted interpretation of catalytic polymerisation processes, the activator may be regarded as a component of the catalytic complex responsible for the chain process. This is precisely what happens in the lithium-induced polymerisation of methyl methacrylate, dienes, etc. in the presence of organic donors (tetrahydrofuran, amines, etc.).

Between these three limiting cases enumerated above, there should be a multiplicity of intermediate situations. A number of deviations from the normal behaviour of catalysts are known. It cannot be excluded that such "deviations" should in fact be regarded as an effect of the general laws governing the characteristics of systems of an intermediate type.

The above discussion is applicable to a wide range of other chemical processes as well as polymerisation. Further progress in this field will probably lead to a general examination of the problem of catalysts, active solvents, modifiers, etc.

I. INTRODUCTION

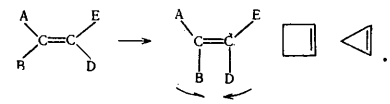
The problem of the dependence of the properties of compounds on the deformation of the angle between the bonds is being studied at present very intensively, both theoretically and experimentally; strained compounds such as bicyclobutane[1], diphenyltetrahedrane[2], cubane[3], and others have been synthesised successfully. Compounds with altered valence angles are characterised by an increased content of internal energy, which changes their physical and chemical properties. Thus the far-reaching analogy in the properties of cyclopropane and olefin derivatives is generally known.

The term "strain", introduced by Bayer[4] in 1885, does not explain the significance of the above processes, which are probably of widely different types. Usually it is understood to imply deformation of the valence angles and the associated deformation of the molecules. Since the angles between the orbitals† of the carbon atoms in various hybrid states are different, there is a possibility of representing certain changes in valence angles as a result of rehybridisation. An idea of this kind was applied for the first time in 1949 by Walsh[5] and also by Coulson and Moffitt[6] to account for the structure of cyclopropane. Nowadays this view has been widely adopted.

The strained double bond is of particular interest. All the substituents at a double bond are in the same plane as the olefinic carbon atoms; the normal C=C–X angle is assumed to be 120° (the angle between the orbitals of the sp^2 hybridised carbon atom[7]). Deviation from this geometry requires an expenditure of energy and the internal energy of molecules containing such a fragment is higher. In real compounds the C=C–X angle almost always differs from 120°, if only because of the breakdown of ideality due to different bond lengths[8] (in ethylene 117° 30'), but the deviation of both valence angles at the double bond by 5° causes an energy increase of only 1 kcal mole^{-1}. Since the concept of strain is largely qualitative, we shall regard a double bond as "strained" when the deviation from the "ideal" geometry is so great that it begins to have an effect on the physical and chemical properties of the compounds containing the given fragment.

A considerable number of original studies dealing with the strained double bond have appeared recently in the literature. However, this problem has not been examined as a whole, and the aim of the present review is to fill this gap.

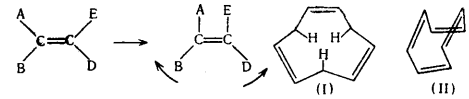
II. TYPES OF STRAIN IN THE DOUBLE BOND



From the formal point of view, the decrease of the valence angle between two bonds of a tetragonal atom can cause the atom to become "olefin-like"; according to Bayer's theory, the double bond may be regarded as a two-membered ring (this description of the double bond is still used, but to a lesser extent than the σ,π-method[8-10]).

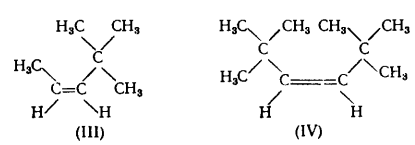
In contrast to the tetrahedral atom, strain in the double bond can occur in different ways, which are non-equivalent as regards the induced rehybridisation of the olefinic carbon atom; these will therefore be considered separately.

If the double bond has four substituents A, B, D, and E, then all types of strain in the double bond can be divided into two groups: those occurring in the ABDE plane and those involving the displacement of any one substituent from this plane.



1. Deformation in the Plane of the Double Bond

The deformation of the valence angles in the plane of the double bond (ABDE) can in turn occur in several ways. One of the possibilities is the decrease of the valence angle as a result of the mutual approach of the groups B and D in the *cis*-position ("cisoid compressive strain"):

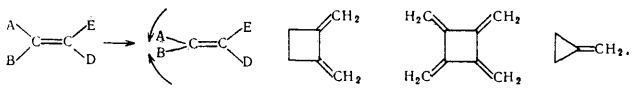


Such strain occurs, for example, in cyclo-olefins with small rings — in cyclobutene or cyclopropene. These examples show that the deformation of the valence angles (considered from a formal standpoint) can become very high. Thus the deviation of the C=C–C valence angle from the normal value in cyclobutene[11] is 26° 06' and in cyclopropene[12] 55° 24'. From the point of view of structural theory, cisoid compressive strain should result in more "acetylenic" character of the double bond; this was apparently foreseen by Bayer[4]. Nowadays it is assumed that such strain should lead to rehybridisation of the olefinic atoms with increase of the *s*-character of the exocyclic bonds (C–H bonds of unsubstituted monocyclic olefins) and the *p*-character of the endocyclic C–C bonds. It is interesting that also from the point of view of Walsh's model of cyclopropene[5] there should be a definite analogy in the properties of acetylene and cyclopropene. Attention will be drawn to this analogy in the properties of strained olefins with cisoid compressive strain and acetylenes in further discussion below.

Another type of strain is the increase in valence angles as a result of the repulsion of the groups B and D in *cis*-position ("cisoid repulsion strain"):

(I) (II)

It would appear that this type of strain should occur in macrocyclic olefins. However, the latter are non-planar and the valence angles are very close to the normal value. Nevertheless in cyclohexene[13,14] the C=C–C angle is already 122°, i.e. slightly higher than the normal value. The increase of the valence angle and hence the strain in the double bond is influenced by the transannular repulsion of hydrogen atoms in cyclic olefins. For example, the C=C–C angle in *cis,cis,cis*-cyclononatriene (I)[15-17] is 124°, due to the repulsion of the mutually non-bonded hydrogen atoms. Cisoid repulsion strain occurs also in cyclo-octatetraene (II), where the C=C–C angle is 126° 46'.[18] The cisoid increase of valence angles can also take place in non-cyclic compounds. An example of this kind is *cis*-t-butylmethylethylene (III)[19] and *cis*-di-t-butylethylene (IV)[19,20]:

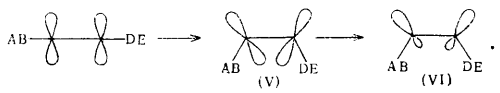


(III) (IV)

† This terminology is used in accordance with the recommendation of the Second Conference on Quantum Chemistry (Vilna, 1962).

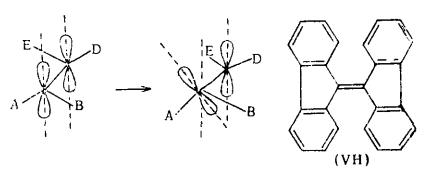
Although there are no literature data for the valence angles in compounds (III) and (IV), measurements of the heats of hydrogenation (see below) undoubtedly indicate a considerable strain of the double bond in compound (III) and particularly (IV).

In the case of cisoid repulsion strain rehybridisation with increase of the *s*-character of the endocyclic bonds and the *p*-character of the exocyclic bonds [in compounds (I)–(IV) these are C–H bonds] should also occur and therefore the changes in bond character should be the opposite of those observed for cisoid compressive strain.



Further, there is a possibility of "unilateral compressive strain" of the double bond in the ABDE plane as a result of the mutual approach of groups A and B:

This type of strain occurs, for example, in dimethylenecyclobutane[21], tetramethylenecyclobutane[22], and methylenecyclopropane[23] molecules. Evidently repulsion strain of this type can also exist in the presence of two bulky groups at one of the carbon atoms of the double bond.

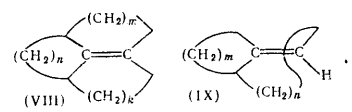


2. Deformation of the Double Bond with Displacement of the Substituents from a Single Plane

The strain of the double bond involving the displacement of the substituents from the ABDE plane can also occur in several ways. Strain in the double bond with displacement of all four substituents below the plane of the double bond ("out-of-plane strain") is possible:

The transition (V) → (VI) should then occur[24]. This is due to the tendency of the olefinic carbon atom to undergo a transition from the sp^2-hybridised state to the sp^3-hybridised state in the presence of such deformation of valence angle. However, examples of compounds of this type are evidently so far unknown. It is also noteworthy that this type of strain in the double bond is to some extent analogous to that in compounds of the type of dehydrobenzene[25].

Another type of strain in the double bond involving the displacement of the substituents from the plane of the double bond is "torsional strain":



Rotation about the double bond entails a decrease of the degree of overlap of *p*-electrons, which is approximately proportional to the square of the cosine of the angle of rotation[7,26]. Dibiphenylene-ethylene‡ (VII) can serve as an example of a compound with torsional strain; in this case the rotation is due to the repulsion of the mutually non-bonded hydrogen atoms in the *peri*-positions. According to Rummens[27], torsional strain cannot be compensated by rehybridisation.

It is noteworthy that torsional strain causes a much greater increase in the energy of the ground state than in the energy of the excited state. This can be illustrated by the results of the calculation of Coulson and Jacobs[28] which show that the order of the double bond in stilbene in the ground state is 1.820 and in the first excited state only 1.436; therefore the difference between the energies of these states should decrease with increase in torsional strain. For the ground N-state of ethylene, rotation by 90° requires the expenditure of 61 kcal mole^{-1}.[29,30]

Thus strain in the double bond can occur in different ways and sometimes it is difficult to decide to which type of strain a particular case should be assigned. In this respect, *trans*-cyclo-octene is interesting. In early studies it was assumed that the double bond fragment in this compound is planar and that the strain in the molecule is due to the deviation of the valence angles from the normal value[31]. However, in subsequent studies involving the investigation of the dipole moment and the infrared spectrum[24] of *trans*-cyclo-octene and also its separation into optical isomers[32,33] it was assumed that torsional strain occurs in this compound and the angle of rotation was estimated[34] as 17° ± 5°.

In addition, in complex polycyclic systems there is a possibility of cases involving the combination of certain types of strain of the double bond, as, for example, in the hypothetical structures (VIII) and (IX):

III. ESTIMATE OF THE STRAIN IN THE DOUBLE BOND

In many calculations of the conformations of cyclic compounds[35–40] and solvolytic reactivity[39,40] it has been shown that the deformation of the angle between the bonds is not localised but extends to other bonds, so that the energy of the system as a whole is a minimum. Therefore, there is no doubt that the deformation of the angle at the double bond entails a certain deformation of the remaining angles. However, as an approximation the overall strain may be regarded as the sum of the different types of strain [angular strain, bond extension, torsional (Pitzer) strain, interaction between mutually non-bonded atoms[41]] and therefore in favourable cases one may speak of the intrinsic strain of the double bond.

The strain can be estimated experimentally from thermochemical data[42]. Thus comparison of the negative heats of hydrogenation of cyclohexene (27.1 kcal mole^{-1})[43] with those of *cis*- and *trans*-but-2-enes (28.5 and 27.5 kcal × × mole^{-1} respectively)[44] shows that the double bond in cyclohexene is unstrained. The heats of hydrogenation of cyclo-olefins are presented in Table 1. In comparing these data, account must be taken of the fact that they may have been obtained under different conditions; however, the error does not exceed 1 kcal mole^{-1}.[42,45]

The negative heat of hydrogenation of compounds with cisoid compressive strain increases with decrease in ring size and is a maximum in cyclopropene[46] (53.9 kcal mole^{-1}).

‡ Better termed 9,9′-bi(fluorenylidene) (Ed. of Translation)].

* Calculated from ΔH°_{form},[44] taking E_{C-H} = 98.7 kcal mole^{-1} and E_{C-C} = 82.6 kcal mole^{-1}.[45]

The double bond in bicyclic bridged systems is also strained. Table 1 shows that the negative heat of hydrogenation of norbornene (X) is very considerable. Similarly $-\Delta H_{hydr}$ for bicyclo[2,2,2]octene[43] (XI) is 28.25 kcal mole^{-1}, that for the first double bond in norbornadiene[43] (XII) is 35 kcal mole^{-1} and that for the first double bond of barrelene[47] (XIII) is as much as 37.6 kcal mole^{-1}.

(X) (XI) (XII) (XIII) (XIV)

Compounds with cisoid repulsion strain can also be considerably strained. Thus the negative heat of hydrogenation of *cis*-t-butylmethylethylene (III) is 30.8 kcal mole^{-1} and that of *cis*-di-t-butylethylene[19] (IV) is 36.2 kcal mole^{-1}. The negative heats of hydrogenation of the *trans*-isomers of these olefins are 26.5 and 26.87 kcal mole^{-1} respectively, i.e. close to the value for the unstrained double bond.

However, direct comparison of the heats of hydrogenation cannot always be used to estimate the strain of the double bond. In fact, the heat of hydrogenation characterises the difference between the heat contents of the olefin and the corresponding paraffin, i.e. the difference between their heats of formation. Therefore, the heat of hydrogenation depends not only on the strain of the double bond but also on the strain in the saturated hydrocarbon which obtains on hydrogenation: the greater the strain of the paraffin, the higher is its heat of formation and the lower the negative heat of hydrogenation. This is clearly seen in the heats of hydrogenation of cyclo-octene, cyclononene, and cyclodecene (Table 1). The decrease of the negative heat of hydrogenation is in this case due to the strain in the corresponding cycloparaffins[31]. Similarly the negative heat of hydrogenation of cyclopentene is lower than that of cyclohexene, despite the fact that the deformation of the double bond is higher in cyclopentene; the explanation is that the strain in cyclopentane is higher than in cyclohexane[48]. The excess strains in cycloparaffins relative to the unstrained cyclohexane are also given in Table 1.

Therefore, the strain of the double bond can be estimated directly from the heats of hydrogenation only when the saturated hydrocarbon is unstrained. Thus it follows from the above data that the strain of the double bond in compound (III) is equivalent to 4.3 kcal mole^{-1} and in compound (IV) to 9.9 kcal mole^{-1}. If the strain in the cycloparaffin is neglected, the lower limit to the strain of the double bond can be estimated. Thus the strain of the double bond in norbornene should not be less than 6 kcal mole^{-1} and in *trans*--cyclo-octene it should not be less than 5.1 kcal mole^{-1}.

It is also possible to estimate the upper limit of the strain of the double bond by a different procedure. The overall strain in the cyclo-olefin relative to cyclohexene is[45]:

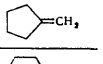
$$E_{strain}\,(\text{olefin}) = \Delta H_{hydr}\,(\text{olefin}) - \Delta H_{hydr}\,(\text{cyclohexene}) + E_{strain}\,(\text{paraffin}).$$

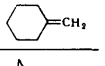
The values calculated for these conditions are presented in Table 1. The overall strain in the olefin [E_{strain}(olefin)] relative to cyclohexene includes the excess strain in the double bond and in other groups. The strain of the double bond can be estimated from data on the excess strain in the paraffin per CH_2 group. If it is assumed that this quantity is the same also for the olefin, then the strain of the double bond can be calculated thus:

$$E_{strain}\,(\text{double bond}) = E_{strain}\,(\text{olefin}) - (n-2)E_{CH_2}\,(\text{paraffin}).$$

The data for cyclopropene, cyclopentene, and cycloheptene calculated in this way are also listed in Table 1. Evidently the results represent the upper limit to the strain of the double bond. It is also clear that such calculation for *cis*-cyclo-octene and higher cyclo-olefins gives somewhat indefinite results, since the strain per CH_2 group in the cycloparaffin is significantly higher than in the *cis*--cyclo-olefin due to the transannular repulsion of hydrogen atoms.

Finally the strain of the double bond in *trans*-cyclo--olefins can be roughly estimated from a comparison of the heats of hydrogenation of the *cis*- and *trans*-isomers. For *trans*-cyclo-octene, such comparison yields 9.2 kcal × × mole^{-1}.





The energy which must be expended to cause the deviation of the valence angle from the normal value may be calculated[8,49] from the equation

$$E = \frac{1}{2}k\alpha^2, \qquad (1)$$

where k is the bending force constant and α the deviation of the angle from the normal value. A large number of semiempirical calculations of the strain energy and of the stable conformations of cycloparaffins have been made[35-38]. Eqn. (1) is also applicable to the calculation of the conformation and strain in cyclo-olefins. It is noteworthy that usually the force constant for the C=C–X angle is higher than that for the C–C–X angle[49,50], which shows that it is more difficult to alter the angle of the sp^2-hybridised atom. The conformation of cyclohexene was in fact calculated in this way[13,14]. The present authors calculated the double bond strain energy for certain cyclo-olefins, the results and the C=C–C angles being listed in Table 1. The bending force constant for the C=C–C angle was taken to be 0.8×10^{-11} erg radian^{-2}, i.e. close to the C–C–C force constant in cyclobutane[51] (for justification of this choice, see Ref. 49).

Critical examination of the limits of applicability of this method among cycloparaffins[49] shows that, whereas for cyclobutane the agreement with experiment is more or less

	—	1665 [64]	1751 [65]	4.3

satisfactory, for cyclopropane such calculation yields a strain energy which is much too high and therefore the method can be applied only in the case of small or at any rate moderate deformations of the valence angle. When the deformation of the angle is considerable, involving the formation of "banana" bonds [51-54], the above method of calculation cannot be used. Calculations on the cyclopropene molecule [12] show that, although formally the angle between the bonds in the methylene group of cyclopropene is 50°48', the angle between the orbitals is 105° 35' and therefore "banana" bonds are formed in this case. Table 1 also shows that the calculated value of 109° for the angle in norbornene [55,56] is somewhat too high and therefore the strain of the double bond should be greater. This finding is also confirmed by spectroscopic data (see below).

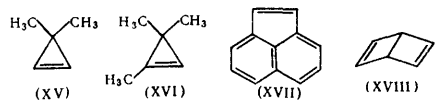
The application of Eqn. (1) to *cis*-di-t-butylethylene (IV), taking into account the strain of the double bond, permits the calculation of the C=C–C angle in this compound, which is found to be 136°.

Finally, the published data on the heats of hydrogenation of certain compounds with unilateral compressive strain (Table 2) show that the strain of the double bond in methylenecyclobutane is not less than 1.6 kcal mole^{-1}, but it is evident that this value is significantly too low because of the strong repulsion of the mutually non-bonded hydrogen atoms and the methyl group in methylcyclobutane. Nevertheless the strain of this bond is smaller than would be expected from the valence angles in this compound.

IV. PHYSICAL PROPERTIES OF THE STRAINED DOUBLE BOND

From the formal point of view, the decrease of the angle between the bonds of the tetragonal carbon atom results in the atom becoming increasingly more "olefin-like". This was probably suggested by Bayer: it is not fortuitous that he examined the problems of the theory of strain in an article dealing with unsaturated compounds [4]. Formally, it is possible to calculate the "strain" in the formation of the double and triple bond in the same way as for cycloparaffins [4,10].

Similarly cisoid compressive strain should cause the bond to acquire "acetylenic character" and, as already stated above, there should be an analogy between olefins with cisoid compressive strain and acetylenes. Such analogy should undoubtedly be reflected in the physical properties of olefins of this type. However, as mentioned above, different types of strain of the double bond may be non-equivalent from the standpoint of the possibility of the compensation of the strain by rehybridisation and therefore strained olefins can exhibit significantly different relations in their physical properties.



1. Nuclear Magnetic Resonance Spectra

As already stated, compounds with cisoid compressive strain should show an increase of the *s*-character of the exocyclic bond. In recent years estimates of the fractional *s*-character of the C–H bond from the spin–spin interaction constant $J(^{13}C-H)$ have been made extensively. A simple relation was proposed in 1959: [67,68]

$$\% S = \frac{J(^{13}C-H)}{5}. \quad (2)$$

The value of $J(^{13}C-H)$ for the carbon–hydrogen bond of an sp^3-hybridised atom is about 125 c/s (125 c/s for methane [67], 123 c/s for cyclohexane [67]), and for acetylenic compounds it is about 250 c/s (248 c/s for methylacetylene [67], 251 c/s for phenylacetylene [67]). For unstrained olefins, $J(^{13}C-H)$ is in the region of 157 c/s (157 c/s for ethylene [69], 159 c/s for benzene [69], 155 c/s for cyclo-octatetraene [69]).

The values of $J(^{13}C-H)$ for certain cycloalkanes and cycloalkenes are presented in Table 3, which shows that $J(^{13}C-H)$ increases with the cisoid compressive strain. This may be attributed to the increase of the *s*-character of the =C–H bond with increasing strain in the double bond. The value of $J(^{13}C-H)$ for cyclopropene is unknown, but for 3,3-dimethylcyclopropene [70] (XV) and 2,3,3-trimethylcyclopropene [70] (XVI) these constants are 220 and 218 c/s respectively and thus the hybridisation of the carbon atoms at the double bonds in these compounds is significantly different from the hybridisation in ethylene.

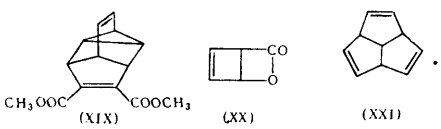
The constants for norbornene (X)[69] (174 c/s), norbornadiene (XII)[71] (168 c/s), and acenaphthylene (XVII)[69] (178 c/s) also show that their double bonds are strained. Possibly the high strain of the double bond in acenaphthylene is in fact responsible for the high heat of polymerisation (24.0 kcal mole^{-1}) of this compound[45].



We may note that the above simple equation gives $J(^{13}C-H)$ = 166.5 c/s for the C–H bond of the sp^2-hybridised atom. Nevertheless the fractional s-character of many compounds has been calculated in this way. This procedure has been criticised[72,73]. It has been shown that in some cases (for example, for halogeno-derivatives) other factors exert a dominant effect[74]. Apparently, only when compounds with similar structures are compared is it possible to make fairly reliable conclusions on the basis of the variation of $J(^{13}C-H)$, provided that it is sufficiently pronounced. Here we must point out that so far $J(^{13}C-H)$ has been almost always determined from proton spectra. Burke and Lauterbur[75] compared the values obtained from proton and ^{13}C spectra for a number of cycloalkanes and found certain discrepancies (the greatest discrepancy was found for cyclodecane: 8 c/s). It is very interesting that their calculation confirmed that the observed values of $J(^{13}C-H)$ derived from carbon and proton spectra deviate in different directions from a certain specified value, assumed to be true. It is quite obscure what happens in olefins and therefore care must be exercised in the interpretation of these data, except perhaps for compounds (XV) and (XVI).

Another explanation of the discrepancy in the values of $J(^{13}C-H)$ is possible. It is known from the work of Mislow[8,76] that the s-character of a bond can be expressed in terms of the "hybridisation parameter" of the bond λ_i^2, so that

$$\% S = \frac{100}{1+\lambda_i^2}. \qquad (3)$$

λ_i^2 can be readily calculated if the geometry of the molecule is known. Such calculation for ethylene (adopting the σ,π-model) yields λ^2 = 2.2 for the C–H bond and λ^2 = 1.7 for the C=C σ-bond. Hence on combining Eqns. (2) and (3) we obtain $J(^{13}C-H)$ = 156 c/s, which is almost identical with the experimental value. Thus in simple olefins C–H bonds have a somewhat enhanced p-character (in the case of ethylene we have $sp^{2.2}$) compared with the requirement for an sp^2-hybridised atom.

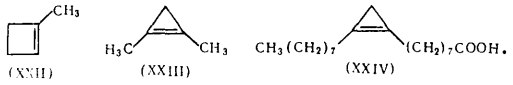
The increase in the s-character of the =C–H bond should be reflected also in the chemical shift of the olefinic proton. The degree of shielding of the proton then decreases and the signals are displaced in the direction of decreasing field. Data on chemical shifts are presented in Table 3. The shift of the signals due to the olefinic protons with increasing cisoid strain has been observed in a fairly large number of examples. Thus τ for olefinic protons is 3.36 for barrelene (XIII)[77], 3.45 for bicyclo[2,2,0]hexadiene (XVIII)[78], 3.47 for the diester (XIX)[79], and 3.27 for the lactone of 3-hydroxycyclobutene-4-carboxylic acid (XX)[80].

(XIX) (XX) (XXI).

2. Infrared Spectra

In the region of =C–H vibrations unsubstituted cyclo-olefins exhibit two frequencies corresponding to symmetrical and asymmetric vibrations[81] (ν^{s}_{C-H} and ν^{as}_{C-H}), which are given in Table 3. The assignment in some studies[62,82] of the frequency 3126 cm^{-1} in the cyclobutene spectrum to ν^{as}_{C-H} is incorrect; this frequency can be readily interpreted as an overtone of the vibrations of the C=C bond[83]. This is also true of norbornene and some of its derivatives[84]. Calculations on the infrared spectrum of cyclobutene showed that the vibration frequency ν^{as}_{C-H} should be 3019 cm^{-1}, i.e. lower than the vibration frequency ν^{s}_{C-H} (3061 cm^{-1})[83].

The ν^{s}_{C-H} vibration frequency of *cis*-but-2-ene, which is 3023 cm^{-1} according to Wiberg and Nist[62] and 3034 cm^{-1} according to Sverdlov and Krainov[85], may be quoted for comparison. An absorption band near 3300 cm^{-1} is characteristic of the ≡C–H bond[81]. It is evident from the data in Table 3 that the ν^{s}_{C-H} vibration frequency increases systematically with decreasing ring size and hence with increasing double bond strain.



The vibration frequency of the C=C bond in unstrained olefins is near 1650–1660 cm^{-1} (1658 cm^{-1} for *cis*-but-2-ene[62]); data for cyclo-olefins are presented in Table 3, which shows that, as the ring size decreases, this band is initially displaced towards lower frequencies, in cyclopentene and cyclobutene, and then the frequency increases again in the case of cyclopropene. This phenomenon occurs also in the spectra of other compounds. Thus, as already pointed out above, the double bond in cyclononatriene (I) is almost unstrained [according to Eqn. (I), E_{strain} for a single double bond is 0.56 kcal mole^{-1}], which is confirmed by the presence of the frequency 1641 cm^{-1}.[15] However, in triquinacene (XXI)[86], which has a geometry similar to that of compound (I), the strain is higher. This is also shown in the infrared spectrum of compound (XXI), which contains the frequencies 3050 and 1613 cm^{-1}.

Comparison of the C=C stretching vibration frequencies shows that the double bond in norbornene is strained approximately to the same extent as the double bond in cyclobutene. The presence of a frequency in the region 1550–1575 cm^{-1} provides a means of ready identification of the double bond in derivatives of this type[84].

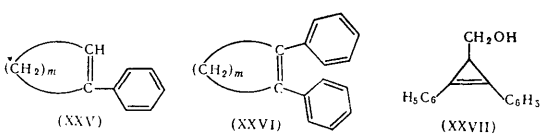
This unexpected decrease of the C=C bond frequency has been explained by a decrease of its force constant[62,82]. However, Sverdlov and Krainov's calculation[83] of the infrared spectrum of cyclobutene showed that the normal value of this force constant can be used. The frequency of the C=C bond depends (for substitution of the same type) on the C=C–C angle. The coefficient of the kinematic interaction of the C=C and C–C bonds is proportional to the cosine of the angle between these bonds. The coefficient is -0.064 for *cis*-but-2-ene, -0.946 for cyclopentene, and -0.009 for cyclobutene; thus the interaction of the coordinates Q(C=C) and Q(C–C) decreases in this series, which results in a decrease of the vibration frequency of the C=C bond. From this point of view, the higher value of this frequency in cyclopropene is reasonable, since the coefficient for the latter compound is 0.054.

It is also interesting to examine the effect of substitution at the double bond on the C=C vibration frequency. In unstrained olefins transition from a *cis*-disubstituted double bond to a trisubstituted double bond causes an increase in frequency from 1650 to 1670–1680 cm^{-1}, i.e. Δ_1 is 20–30 cm^{-1}, and transition to the tetrasubstituted double bond

entails an increase from 1650 to 1680–1690 cm^{-1}, i.e. Δ_2 is 30–40 cm^{-1}. Nevertheless for norbornene derivatives Δ_1 = 60–65 cm^{-1} and Δ_2 = 86–90 cm^{-1},[84] i.e. the frequency increase due to increasing degree of substitution becomes much higher as the strain increases. Similarly, it follows from the infrared spectroscopic data for 1-methylcyclobutene (XXII)[87] that here Δ_1 (relative to cyclobutene) is 70 cm^{-1}.

(XXII) (XXIII) (XXIV).

This relation is shown particularly clearly for cyclopropene derivatives. For 1,3,3-trimethylcyclopropene (XVI)[88] (1768 cm^{-1}), 1,2-dimethylcyclopropene (XXIII)[89] (1898 cm^{-1}), and sterculic acid (XXIV)[90] (1865 cm^{-1}), Δ_1 = 118 cm^{-1} and Δ_2 = 224–257 cm^{-1}.



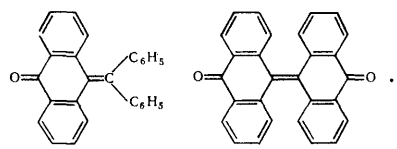
The spectrum of *trans*-cyclo-octene[24] (Table 3) merits special examination. For comparison, the frequencies 3010 and 1650 cm^{-1} in the infrared spectrum of *cis*-oct-4-ene and the frequencies 3027 and 1670 cm^{-1} in the spectrum of *trans*-oct-4-ene may be quoted. Table 3 shows that in the infrared spectrum of *trans*-cyclo-octene the ν^{S}_{C-H} vibration frequency is lower, although this compound is considerably strained. Allinger[24] explained this phenomenon on the grounds of torsional strain in *trans*-cyclo-octene. The presence of a dipole moment (in consequence of torsional strain) explains the appearance of the C=C vibration frequency in the infrared spectrum of *trans*-cyclo-octene, while in the usual symmetrical *trans*-olefins this frequency is forbidden and is observed in Raman spectra.

Thus different relations may obtain in the infrared spectra depending on the different types of strain of the double bond. This can also be illustrated using compounds with unilateral compressive strain of the double bond, the infrared spectroscopic data for which are presented in Table 2. This table also lists the frequencies of the C=O group in the corresponding ketones. It is evident from Table 2 that the frequency of the C=CH_2 bond increases with decreasing ring size, i.e. in conformity with the mode of rehybridisation. The frequency of the carbonyl group in the corresponding ketones varies similarly. For comparison, we may point out that carbon monoxide[91] has an absorption band at 2143 cm^{-1}, while the absorption band of the carbonyl group in keten[92] in the gas phase is 2151 cm^{-1}.

On the other hand, in olefins with unilateral repulsion strain the C=C frequency decreases from 1661 cm^{-1} in 1-ethyl-1-methylethylene to 1644 cm^{-1} in 1-isopropyl-1-methylethylene and 1638 cm^{-1} in 1-t-butyl-1-methylethylene[27], in agreement with the change in hybridisation.

3. Ultraviolet Spectra and Other Properties

There are a few published data on the ultraviolet spectra of certain simple cycloalkenes[62,101] but it is difficult to arrive at any definite conclusions on their basis.



(XXV) (XXVI) (XXVII).

The relations concerning the positions of the absorption bands of derivatives with different functional groups in which the chromophoric group is conjugated with the double bond are also few. Thus Table 3 lists the absorption maxima of the phenyl derivatives of cyclo-olefins of the type of (XXV) and (XXVI). These data show that there is a definite shift of the absorption maximum to the long-wavelength region with increase in the strain of the double bond. There is an indication in the literature of a steady variation in the ultraviolet spectra of unsaturated dicarboxylic acids[102,103], but the available data are incomplete and definite conclusions cannot be arrived at.

Particular interest attaches to an examination of the ultraviolet spectra of olefins with torsional strain of the double bond. As already stated, rotation about the axis passing through the carbon atoms of the double bond causes mutual approach of the energy levels of the ground and excited states. This is evident from Fig. 1, where the potential energy curves for the ground singlet (N) and triplet (T) states and also the excited singlet (V) state for ethylene are plotted schematically; clearly, for those olefins which can give rise to *cis*- and *trans*-isomers, the curves of the type shown in Fig. 1 should be asymmetric.

The ultraviolet absorption band of the usual olefins is due to the $N \rightarrow V$ transition. For an unstrained olefin, this transition is denoted by n_1 in Fig. 1. If the double bond in the ground state is subject to torsional strain and is rotated by an angle φ_1, the ultraviolet absorption maximum in the spectrum of such an olefin is due to the n_2 transition. Hence it is seen that in the presence of torsional strain there should be a bathochromic shift in the ultraviolet spectrum. This has been studied in special detail in the spectrum of dibiphenylene-ethylene (VII)[104]:

(XXVIII) (XXIX).

Eaton and Lin[105] have shown that, on irradiation with ultraviolet light, Δ^2-*cis*-cyclo-octenone isomerises smoothly to Δ^2-*trans*-cyclo-octenone. These workers[106] and also Corey and coworkers[107] obtained in this way the extremely strained *trans*-cycloheptenone, although *trans*-cycloheptene has not so far been isolated[108].

Another very interesting phenomenon, namely thermochromism, is possible for compounds with torsional strain. One of the possible interpretations of this phenomenon was given by Grubb and Kistiakowsky[109], using diphenylmethyleneanthrone (XXVIII), bianthrone (XXIX), and their analogues as examples. A simplified explanation of the phenomenon may be based on Figs. 1 and 2. Torsional strain in

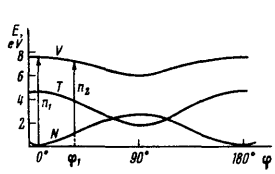


Fig. 1. Potential energy curves as a function of the angle of rotation about the double bond in ethylene; data of Mulliken and Roothaan[29] and Burnell.[30]

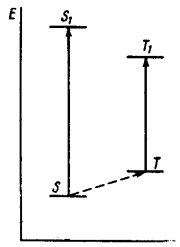

Fig. 2. Schematic representation of the electronic transitions in compounds of the type of (XXVIII), according to the data of Grubb and Kistiakowsky.[109]

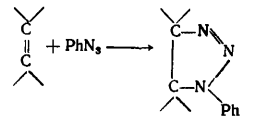
systems of the type of (XXVIII) is so much greater than the energy of the ground singlet state that thermal excitation of the molecules to the lower triplet level becomes possible (Figs. 1 and 2). Therefore triplet–triplet transitions can occur in the absorption spectrum of such a compound (Fig. 2). If the excited triplet level is below the excited singlet level, a bathochromic shift occurs. When diphenylmethyleneanthrone (XXVIII) is heated, the colour changes from yellow to red, the colour change being fully reversible as the temperature is varied.

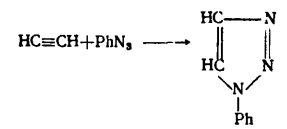
This explanation of thermochromism has been confirmed by quantum-mechanical calculations[110], and also by the study of the temperature variation of paramagnetism. A more rigorous and detailed examination of thermochromism and also other views on this problem have been described by Woodward and Wasserman[111] and Day[112].

Hoijtink[113] showed that the half-wave potential in the polarographic reduction of dibiphenylene-ethylene (VII) is intermediate between the experimental potentials for systems with planar and perpendicular disposition of aromatic rings.



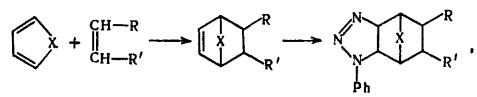
V. CHEMICAL PROPERTIES OF STRAINED OLEFINS

The strain of the double bond is clearly shown not only in physical but also in chemical properties of olefins. These compounds are characterised by high rates of reactions typical of normal olefins. However, reactions characteristic of strained olefins only and also the changes in the stereochemistry of the reactions under the influence of molecular strain are of greatest interest; these will be examined in the present section.



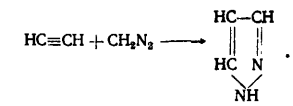
1. Addition Reactions

Addition to the double bond is accompanied by a change in the hybridisation of the carbon atoms — from the sp^2- to the sp^3-hybrid state. The valence angle then decreases from 120° and 109.5°. Therefore, according to the concept of *I*-strain[114], addition should take place readily with compounds having cisoid compressive strain, unilateral compressive strain, and out-of-plane strain. Compounds with torsional strain should also be very reactive, due to the decrease in the degree of overlap of *p*-electrons. The tendency to undergo addition can be inferred from the heat of hydrogenation. Strained olefins react particularly readily by a molecular mechanism involving the formation of cyclic polycentric transition states. 1,3-Dipolar addition and diene synthesis are the most characteristic examples of reactions of this kind.

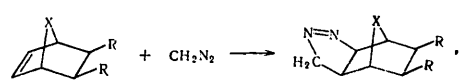


A widely known specific reaction of strained olefins is the reaction with phenyl azide, resulting in the formation of triazolines:

This reaction was investigated in detail by Alder and Stein[115,116] and is widely used nowadays as a kind of "test" for the strained double bond. Unstrained olefins, without electron-acceptor groups, do not undergo this reaction or undergo it with considerable difficulty. According to Dimroth and Fester[117], acetylene reacts with phenyl azide to form phenyltriazole:



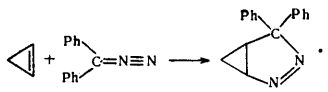
This reaction has been particularly widely used for the identification of diene synthesis adducts of the cyclopentadiene and furan series, since the resulting norbornene and 7-oxabicyclo[2,2,1]heptene contain strained double bonds[118–120]:



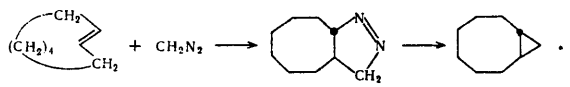
where X = CH_2 and O.

Trans-cyclo-octene reacts extremely vigorously with phenyl azide, while addition to the *cis*-isomer takes place only on standing for several weeks[121]. *Trans*-cyclononene and *trans*-cyclodecene also react with phenyl azide[122–124], while the *cis*-isomers do not react (earlier it was believed erroneously that *trans*-cyclodecene does not give a phenyltriazoline derivative).

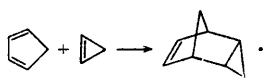
Diazomethane does not usually add to the double bond without electron-acceptor substituents[125]. However, Pechmann[126] showed that acetylene readily reacts with diazomethane to form pyrazole:



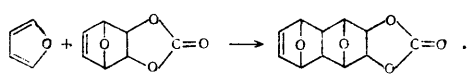
Bearing in mind the analogy between the properties of acetylenes and olefins with cisoid compressive strain, it might have been expected that the latter will also react with diazomethane. Indeed, Zefirov et al. showed that norbornene and also derivatives of 7-oxabicyclo[2,2,1]heptene readily combine with diazomethane to form the corresponding Δ^2-pyrazolines[127,128]:



where X = CH_2 and O.

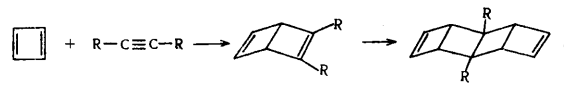


Paul et al.[129] found that cyclobutene also readily combines with diazomethane, but cyclopentene reacts with difficulty, and cyclohexene almost does not react at all (yield 2%). Wiberg and Bartley[130] discovered that cyclopropene readily reacts with diphenyldiazomethane as follows:

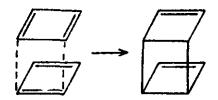


Trans-cyclo-octene also reacts with diazomethane with formation of pyrazoline, which is readily converted into *trans*-bicyclo[6,1,0]nonane under the action of ultraviolet light[131]:

Olefins with cisoid strain of the double bond readily undergo the diene synthesis reaction. For example, cyclopentadiene reacts with cyclopropene at 0°,[130] while the reaction with ethylene requires an elevated temperature and pressure[132]:



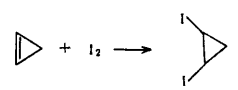
Strained olefins of this type undergo diene synthesis even with relatively unreactive dienes. It has been noted in a number of studies[133,134] that, by virtue of its aromatic nature, furan is an unreactive diene and can react only with very active dienophiles such as maleic anhydride, acetylenedicarboxylic esters, and fumaronitrile. The diene synthesis reaction of furan with dienophiles without electron-acceptor groups takes place under very severe conditions and with a low yield (5% in the case of ethylene[135]) or not at all. However, furan reacts fairly smoothly with bicyclic olefins having a strained double bond[136]:



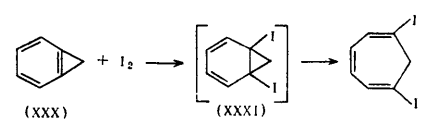
Nowadays diene synthesis with furan is often used for the identification of unstable strained olefins, such as, for example, *trans*-cycloheptene[108], benzocyclobutadiene[137], *trans*-cyclo-octenone[105], and *trans*-cycloheptenone[106]. We may note that compounds of the type of dehydrobenzene are also usually identified by the formation of an adduct with furan[138].

Trans-cyclo-octene also readily undergoes diene synthesis. Ziegler and coworkers[124,139] showed that the reaction of this compound with hexachlorocyclopentadiene takes place easily at 0°, while the *cis*-isomer reacts only on heating to 100°. It is interesting that *cis-trans*-cyclo-octa-1,5-diene readily combines with one mole of hexachlorocyclopentadiene; the second mole adds only on heating.

Strained olefins also readily undergo cyclo-addition reactions. For example, cyclobutadiene reacts with acetylene derivatives to form "Dewar benzene" derivatives[140] and then unusual polycyclobutane derivatives called "pterodactylodienes"[141]:



However, in general the reactions of cyclobutadiene can be treated in two ways: as simple cyclo-addition and as a Diels–Alder reaction. The formation of the *syn*-dimer only[140] in the dimerisation of cyclobutadiene is evidence in favour of the second hypothesis (this should be the effect of Alder's rule of "maximum accumulation of double bonds"):



Both possible dimers, *syn*- and *anti*-, were obtained in a pure form by Nenitzescu and coworkers[142,143] by dihalogenation of dichlorocyclobutene.

Iodination of olefins under usual conditions is as a rule reversible; it is well known that the iodide ion is a good 1,2-dehalogenating agent[144]. For this reason, 1,2-di-iodo-derivatives are obtained by photochemical low-temperature iodination of olefins[145]. However, cyclopropene combines with iodine under the usual conditions in carbon tetrachloride solution[130]:

We may note that under these conditions acetylene also combines with one mole of iodine[146]. In 1965 Vogel and coworkers[147] obtained an extremely strained hydrocarbon — benzocyclopropene (XXX) (a substituted system of this type had been obtained earlier[148]), which exhibits reactivity unusual for aromatic compounds. In particular, compound (XXX) combines with iodine in carbon tetrachloride solution, 1,6-di-iodocycloheptatriene being formed together with *o*-iodobenzyl iodide. The authors explain the formation of this compound by the addition of iodine to the "cyclopropene" double bond with formation of the di-iodo-intermediate (XXXI), which then undergoes the Cope rearrangement[149]:

(XXX) (XXXI)

The infrared spectrum of compound (XXX) has an intense band at 1666 cm^{-1}, whose origin is not altogether clear; we may note further that $J(^{13}C-H)$ for the methylene group in compound (XXX) is 178 ± 2 c/s.

The kinetics of reactions involving the addition of diethylaluminium hydride[124] and hexachlorocyclopentadiene[124] to cyclic olefins and also the reduction of the latter by di-isopentylborane[150] and di-imide[151] have now been investigated; these data are presented in Table 4, which shows that, with increasing cisoid strain, the rate of addition increases too. However, an increase of rate has also been observed for cyclo-olefins having rings of moderate

TABLE 4. Relative rates of addition and complex formation reactions for simple cyclo-olefins.

Ring size	Relative rate of addition				Relative complex formation constant	
	of di-imide	of di-iso-pentyl-borane	of hexa-chloro-cyclopenta-diene	of diethyl-aluminium hydride	in water at 25° (Refs. 58 and 153)	in ethylene glycol at 40° (Ref. 66)

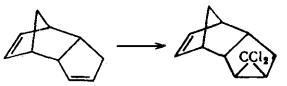
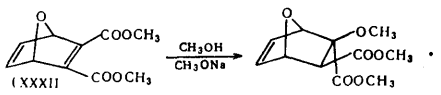
* Data of Garbisch et al.[151]

** Data of Wiberg and Bartley.[130]

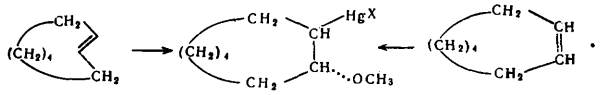


size, with a maximum in the case of cyclo-octene, although these olefins do not have strained double bonds.

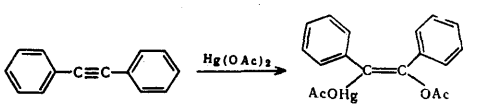
Garbisch[152] developed a method of calculation for steric interactions in cyclo-olefins which he applied successfully in an examination of the tautomeric conversions of hydroxymethylene ketones. The application of this type of calculation to reduction with di-imide yielded a satisfactory calculated value of the reaction rate[151]. The success was due to the fact that the polar effects in the reduction with di-imide are very small and the rate of addition is determined by the energy which must be expended in order to change the geometry of the molecule so that a planar transition state arises ("stereotorsional control").



The impression might be created that the increase of molecular strain in all cases results in an acceleration of the rate of addition. However, this is not so. It has been established that norbornene reacts with dichlorocarbene with considerable difficulty[154], a rearrangement product of dichlorocyclopropane being formed:



The relative inertness of the norbornene bond is clearly evident in the reaction of dicyclopentadiene from which a monoadduct at the cyclopentene double bond is obtained[155]:

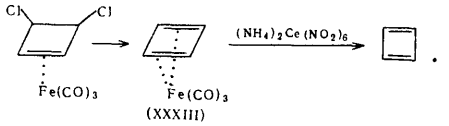


The reason for the retardation of the carbenoid reaction is unknown. We may note, however, that although almost all the "normally" accelerated reactions are of the electrophilic addition type with respect to carbenes, a nucleophilic mechanism cannot be excluded. Nucleophilic addition to a strained double bond has been almost not investigated at all. Thus Zefirov and coworkers[156] showed that nucleophilic addition of methanol to the diester (XXXII) takes place in the normal way without the homoallylic participation of the second double bond:

Finally, the stereochemical aspect of the reactions involving addition to strained olefins must be considered. A number of investigators have shown that the addition of mercury salts to olefins such as norbornene[157-160] or derivatives of 7-oxabicyclo[2,2,1]heptene takes place as *cis*-addition, while hydroxymercuration of unstrained olefins is a *trans*-addition reaction. One of the reasons adduced for the anomalous *cis*-addition is the strain of the double bond in olefins undergoing such addition[160]. Indeed, Sokolov et al.[161] showed that the hydroxymercuration of *trans*-cyclo-octene takes place as *cis*-addition and that of *cis*-cyclo-octene as the normal *trans*-addition:

Burnell[30,162] showed that *trans*-addition reactions at double and triple bonds take place more readily in a twisted conformation. At the same time, such a transition state is difficult to achieve in rigid strained olefins and in the presence of weak electrophilic agents the reaction may take place by a molecular mechanism. In this connection, it is interesting to note that, as shown by Nesmeyanov and coworkers[163,165] and Drefahl[164], the acetoxymercuration of tolane also takes place as *cis*-addition by the mechanism

The reaction with dimethylacetylene does not involve a single pathway[166].



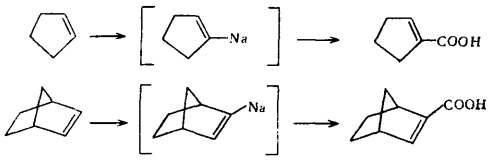
In view of the analogy between the properties of acetylenes and olefins with cisoid compressive strain, in those cases where the stereochemical course of the addition reaction at a double bond is anomalous it would also be useful to investigate the stereochemistry of the addition of the same agent to a triple bond; very little work has been done on this problem.

2. Complex Formation

Lucas and coworkers[167,168] showed that olefins are capable of forming a number of complexes with heavy metal ions and in particular with silver ions. Complexes of this type are formed as a result of the overlapping of the free *s*-orbital of the metal ion and the π-bond of the olefin; the additional stabilisation may be due to the overlapping of the filled *d*-orbitals of the metal and the antibonding π-orbitals of the olefin[6,169,170]. The complexes of silver ions with olefins have been most thoroughly investigated; the instability constants for olefins with unilateral compressive strain are listed in Table 2 and those for olefins with cisoid compressive strain in Table 4. It is evident from Table 4 that in aqueous solutions there is a small but definite increase in the stability of the complexes with increase in the strain of the double bond. Complexes of cyclopropene and also of *trans*-cyclo-olefins are particularly stable. For example, *trans*-cyclo-octene can be extracted from pentane with an aqueous solution of silver nitrate, this being used for its preparative separation from the *cis*-isomer[171]. Data obtained by gas–liquid chromatography on ethylene glycol with added silver nitrate[66] (Table 4) show that the relations which obtain in this case are somewhat different, namely *cis*-cyclo-octene gives a significantly more stable

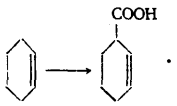
complex than cyclohexene. The high stability of the complex with norbornene and the extremely high stability of the complex with *trans*-cyclo-octene are striking. There is no correlation between the stability of the complexes of olefins with unilateral compressive strain (Table 2) and the magnitude of the double bond strain itself.

Complex formation is often used for the isolation of unstable olefins. In this connection the history of the attempts made over a period of many years to synthesise cyclobutadiene, which has played an important role in the theory of aromaticity [172], is of interest. Particularly intensive studies have been carried out during the last ten years in the laboratories of Nenitzescu [142,173] and Criegee [174]. The principal idea followed in these studies was stabilisation of cyclobutadiene by formation of a π-complex with a metal. It proved possible to obtain a complex of tetramethylcyclobutadiene with nickel chloride [174]. Only in 1965 was cyclobutadiene synthesised by Pettit's group [140,175], by oxidative decomposition of its iron carbonyl compound (XXXIII), which exhibits the properties of an aromatic system:



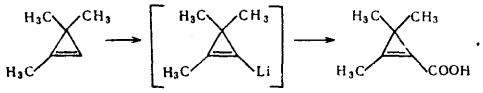
(XXXIII)

According to the calculation performed in 1965 by Dewar and Gleicher [176], cyclobutadiene should have a singlet ground state and its instability should be due to considerable angular strain.



3. Substitution Reactions at the Double Bond

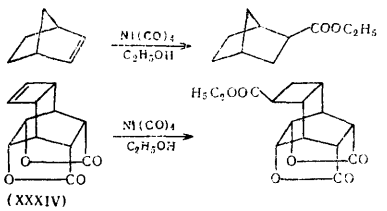
The greater *s*-character of the C–H bond in olefins with cisoid compressive strain results in increased acidity of the hydrogen atoms, similar to that which obtains on going from ethane to ethylene and then to acetylene. The increased acidity of the hydrogen atoms in cyclopropene derivatives has been observed in a number of investigations [88,130]. However, the most convincing data were obtained by Schröder [177] in a study of the base-catalysed deuterium exchange in cyclic olefins. It was found that t-butylacetylene and trimethylcyclopropene readily exchange the hydrogen at the multiple bond even at -20°, the exchange rate constant ratio for these compounds being 1 : 5000. Other cyclo-olefins exchange hydrogen under significantly more severe conditions. Thus bicyclo[3,2,0]heptene slowly exchanges hydrogen even at 110° and rapidly at 139°; cyclopentene exchanges hydrogen at 160°, while *cis*- and *trans*-di-t-butylethylene do not exchange hydrogen at 190°. Norbornene exchanges hydrogen more rapidly than cyclopentene.



The hydrogen at the double bonds of cyclo-olefins can be substituted by a metal. For example, the action of pentylsodium on norbornene or cyclopentene results in the formation of an organosodium derivative of the cyclo-olefin [178,179], which has been identified by conversion into the corresponding acid:

Cyclohexene yields a $\beta\gamma$-unsaturated acid under these conditions [180]:

Closs and Closs [88] showed similarly that trimethylcyclopropene is readily metallated with butyl-lithium:



Trimethylcyclopropene reacts with ethylmagnesium bromide similarly as compounds containing a labile hydrogen atom, i.e. with formation of ethane [181]. It is interesting that trimethylcyclopropene forms a fairly stable copper derivative, whose structure, however, has not so far been established [181].

It should be noted that the more pronounced *s*-character of the exocyclic bond in olefins of this type results in a more pronounced electron-acceptor effect in such compounds than in unstrained olefins. Closs and Closs [182] showed that the dissociation constant of trimethylcyclopropenecarboxylic acid is 4.5 times higher than that of *cis*-crotonic acid.

In conclusion we must consider the reaction of unsaturated compounds with nickel carbonyl. Reppe and Kroper [183] showed that this reaction proceeds smoothly with acetylene derivatives having a hydrogen atom at the triple bond, acids being formed:

$$R{-}C{\equiv}CH \xrightarrow{Ni(CO)_4} R{-}CH{=}CH{-}COOH.$$

Ordinary olefins enter into this reaction with difficulty — cyclohexene, for example, yields cyclohexenecarboxylic acid only under very severe conditions. However, Cookson and coworkers [184] showed that norbornene and also the adduct (XXXIV) readily react with nickel carbonyl:

(XXXIV)

The authors explained this course of the reaction by the strain of the double bonds in the reactants.

---oOo---

The above data show that strained olefins exhibit special characteristics both in their physical and chemical properties. Olefins with cisoid compressive strain of the double bond have been most thoroughly investigated. Under favourable conditions it proved possible to calculate the magnitude of the strain in cyclo-olefins and even the rate constants for addition reactions at the double bond. However, many problems have still been little investigated and remain obscure; this applies especially to olefins with other types of strain of the double bond. A detailed quantum-mechanical examination of the problem of strained double

bonds has not been made either. It is still not clear to what extent various types of strained double bonds are chemically equivalent. In this respect olefins with out-of--plane strain are particularly interesting, since, apart from the ease of addition reactions, the rigid structure of certain cyclo-olefins of this type should pre-determine the *cis*-addition of any reagent. There is no doubt that the study of strained cyclo-olefins can lead to the discovery of fundamentally new reactions and also to a deeper understanding of the stereochemical aspects of the known addition reactions.

IV. The role of the metal and solvent in radical-anio' disproportionation and reduction equilibria 107

I. INTRODUCTION

The chemistry of the organometallic compounds of the alkali metals is developing fairly rapidly. The adducts of alkali metals with aromatic hydrocarbons have attracted much attention because of their unusual structure [1,2] and because they have found wide application in polymer chemistry [3-7] and in synthetic organic chemistry [5,8,9]. The reactions involving the addition of alkali metals to aromatic hydrocarbons were first investigated by Schlenk [10,11], who established, in particular, that in ethyl ether sodium readily adds to anthracene and phenanthrene but not to naphthalene and biphenyl. However, Scott observed [12] that these hydrocarbons react rapidly and quantitatively with sodium when the solvent is 1,2-dimethoxyethane. Subsequently the adducts of benzene and its homologues with alkali metals were obtained in this solvent [13,14].

Scott [12] noted an appreciable electrical conductivity of the solutions of the adducts, indicating their ionic nature. Hückel and Bretschneider [15], who studied the reactions of alkali and alkaline earth metals with aromatic hydrocarbons in liquid ammonia, suggested that the hydrocarbon is converted into an anion by capturing electrons from the metal atom. Weissman and coworkers [16] showed that solutions of aromatic organosodium compounds in tetrahydrofuran exhibit strong paramagnetic absorption and concluded that the aromatic anion is at the same time a paramagnetic species; it has therefore been called a radical-anion ($Ar^{\cdot-}$). The reaction of an aromatic hydrocarbon (Ar) with an alkali metal can be represented by the equation

$$Ar + M \rightleftarrows Ar^{\cdot-}M^{+}. \quad (1)$$

Laitinen and Wawzonek [17] and Hoijtink et al. [18] obtained radical-ions in the electrolytic reduction of hydrocarbons (see also the reviews of de Boer [2] and Hoijtink [19]). The reaction with polycyclic hydrocarbons proceeds further - a second electron adds to the radical-anion and a doubly charged anion (dianion) is formed.

Measurements of the magnetic susceptibility of the solutions of the adducts of anthracene and phenanthrene with sodium [20] showed that, on more prolonged contact between the solution and the metal surface, the paramagnetic compound formed initially ($Ar^{\cdot-}M^{+}$) is converted into a diamagnetic product as a result of the reaction

$$Ar^{\cdot-}M^{+} + M \rightleftarrows Ar^{2-}2M^{+}. \quad (2)$$

Addition of the hydrocarbon to a solution of its dianions results in the appearance of paramagnetism due to the reaction

$$Ar^{2-}2M^{+} + Ar \rightleftarrows 2Ar^{\cdot-}M^{+}. \quad (3)$$

This is an equilibrium reaction and therefore the dianion can be formed not only by the reduction of the radical-anion, but also by the disproportionation of two radical-anions. Recently the possible addition of three electrons to the decacycline molecule has been observed [21].

The properties of radical-anions have been extensively studied by electron spin resonance and electron spectroscopic methods. The ESR spectra were studied by Weissman and coworkers [22-26] and other investigators [27-29]. The

principal studies on the electronic absorption spectra were carried out by Hoijtink and his school[30,31] (see also Refs. 1 and 2). The interpretation of the spectra within the framework of the molecular orbital method[32-36] leads to the conclusion that the electron in the radical-anion occupies the lowest antibonding orbital of the aromatic molecule. The bond with the metal ion is achieved by the coulombic interaction of the entire π-electron system of the radical-anion. The electronic structure of the adducts of alkali metals with aromatic hydrocarbons has been recently discussed in detail in de Boer's review[2].

The problem of the effect of the solvent and metal on the equilibria in the formation and dissociation of adducts has not so far been elucidated adequately, despite its great importance, in particular for the understanding of anionic polymerisation and other organic anionic reactions. This led us to write the present review on the above problem.

II. SOLVATION OF CATIONS IN ADDUCT FORMATION REACTIONS

The positions of equilibria (1)–(3) involving a particular hydrocarbon depend greatly not only on the nature of the metal but also on the solvent, the latter showing different effects on different metals. This was shown qualitatively by Schlenk[10,11] and Scott[12]. Thus, in contrast to lithium, sodium does not react with naphthalene and biphenyl in ethyl ether, but in methyl ether adducts are formed. Potassium interacts with naphthalene and biphenyl even in octane and toluene[37]. The equilibrium concentrations of the radical-anions of benzene[38] formed in the reaction with lithium and potassium in 1,2-diethoxyethane, are higher by approximately two powers of ten than in the reaction with sodium, and the relative concentrations of toluene radical-anions[38] are 100 in 1,2-dimethoxyethane, 30 in 1-ethoxy-2-methoxyethane, and 3 in 1,2-diethoxyethane. Pudovik and Muratova[39] showed that a red dilithium derivative of naphthalene (the solution of naphthalene radical-anions is green) forms in dimethoxymethane and in dioxan. According to Garst's data[40], the nature of the solvent and the metal is important in radical-anion disproportionation reactions.

The pronounced dependence of equilibrium (1) on the nature of the metal and solvent can be explained by an examination of the energy balance in the formation of radical-anions[4]:

$$\Delta H = L + I - E_{Ar} - S_{M^+} - S_{Ar^-} - Q, \qquad (4)$$

where ΔH is the enthalpy of the reaction, L the heat of sublimation of the metal, I its ionisation potential, E_{Ar} the electron affinity of the aromatic hydrocarbon, S_{M^+} and S_{Ar^-} are the heats of solvation of the metal cation and the radical-anion, and Q is the energy of the coulombic interaction of the ions. The electron affinity of the aromatic hydrocarbons (in electron-volts) increases in the sequence[41] benzene (-0.54), biphenyl (0.41), naphthalene (0.65), phenanthrene (0.69), anthracene (1.19). The heats of sublimation and the ionisation potentials of alkali metals and the radii (r) of their cations are presented in Table 1.

The larger is the sum $L + I$ the less vigorous should be the reaction of the metal. In fact, Table 2 shows that the yields of biphenyl radical-anions do not vary with the metal in the same way in different solvents[42]. This is due to the large contribution to the energy of reaction (1) by the heat of solvation of the cations, which is markedly influenced by the solvent.

TABLE 1. Constants of alkali metals[43].

Metal	L, kcal mole^{-1}	I, eV	r, Å
Li	32.2	5.39	0.78
Na	23.4	5.14	0.98
K	18.9	4.34	1.33
Rb	18.0	4.18	1.49
Cs	16.3	3.89	1.65

TABLE 2. Relative concentrations of biphenyl adducts.

Solvent	Li	Na	K
1,3-Dimethoxypropane	100	7	30
1,2-Diethoxyethane	45	15	65
Tetrahydrofuran	100	45	30
Tetrahydropyran	80	10	6

Approximate calculation shows[44] that the heats of solvation do indeed constitute an appreciable fraction of the heat of reaction (1), as a result of which the formation of the hydrocarbon radical-anion in electron-donor solvents is in most cases exothermic. Solodovnikov[29] estimated the heat of reaction of benzene with potassium in 1,2-dimethoxyethane from the temperature variation of the intensity of the ESR signal due to the benzene radical-anion. In the temperature range 233–273°K the heat of reaction is about 20 kcal mole^{-1}.

The temperature variation of the equilibrium constant (K) for the reaction of sodium with biphenyl in certain ethers and their mixtures with n-heptane has been investigated spectrophotometrically[42,45,46]. The enthalpies (ΔH) and entropies (ΔS) of reaction were calculated from the results by the method of least squares using the equation $\ln K = -\Delta H/RT + \Delta S/R$. The values of K_{273}, ΔH, and ΔS and also the temperature range in which these parameters were determined are listed in Table 3. The equilibrium constants were determined without taking into account the activity coefficients. However, this does not prevent a comparison of the effects of solvents (with similar dielectric constants and dipole moments — see Table 5) on the thermodynamics of the formation of the adduct.

The data in Table 3 show (cf. Nos. 1 and 19) that the variation of ΔH when the reaction is carried out in different solvents is as much as ~ 25 kcal mole^{-1}. This confirms what has been said above about the importance of the contribution of the heat of solvation to the energy of the reaction. The absolute values of ΔH, obtained under comparable conditions, decrease in the series dimethyl ether of diethylene glycol > 1,2-dimethoxyethane > 1-ethoxy-2-methoxyethane > 1,2-dimethoxypropane > tetrahydrofuran > 1,2-diethoxyethane > 1,3-dimethoxypropane > tetrahydropyran.

As a result of the ordering of solvent molecules in the solvation shells of the ions, the entropy of the system decreases and the entropy of reaction ΔS is negative. The degree of ordering is higher the more stable is the solvate and therefore on changing the solvent the absolute values of ΔH and ΔS vary in unison, the effects of their variation on the free energy of reaction ($\Delta F = \Delta H - T\Delta S$) cancelling out, so that the variation of the latter is 1–2 kcal mole^{-1}.

Thermodynamic data have also been obtained spectrophotometrically for the reaction of sodium with naphthalene in 1,2-diethoxyethane [45] and for the reaction of sodium with 4-ethylbiphenyl and *N*-ethylcarbazole in tetrahydrofuran [47].

The above thermodynamic data give an idea of the relative solvating power of a number of ethers. More detailed information about its variation with the structure of the solvent molecules can be obtained from Table 4, which gives the relative equilibrium concentrations of sodiobiphenyl (C_{sb}) and sodionaphthalene (C_{sn}) formed at room temperature in the presence of a sodium mirror of large area at the same concentrations of hydrocarbon solutions (arbitrarily defined as 100) in 31 ethers and acetals [42,48]. The values of C_{sb} were determined at the same time by electron spin resonance, the results agreeing satisfactorily with the spectrophotometric measurements (the values of C_{sb} in Table 4 are averages of the results of both methods). If biphenyl was quantitatively converted into the adduct in ethereal solution, i.e. C_{sb} = 100, the ether was diluted with n-heptane and the value of C_{sb} in Table 4 refers to an equimolar mixture of the ether and n-heptane. The last column of Table 4 lists the shifts ($\Delta\nu_{OD}$) of the stretching vibration frequency of the OD bond in the infrared spectrum of deuteriomethanol CH_3OD on formation of the hydrogen bond with the oxygen atom of the ether [49]. According to Gordy [50], $\Delta\nu_{OD}$ is a measure of the electron-donor properties (basicity) of the ethers.

The results in Table 4 may be compared with independent data on the effects of solvents on the spectra of the adducts or the electrical conductivity of their solutions, which according to a number of workers [51-54] also reflect the effect of the solvation of the alkali metal cation. According to these studies, the variation of the solvating power of the ethers (1,2-dimethoxyethane > tetrahydrofuran > tetrahydropyran, methyltetrahydrofuran > 1,4-dioxan) is the same as the sequence corresponding to the decrease of C_{sb} and C_{sn} in these solvents (Nos. 4, 23–26 in Table 4).

TABLE 4. Effect of the structure of solvent molecules on the equilibrium concentrations of the adducts of sodium with biphenyl (sb) and naphthalene (sn) and on the electron-donor properties of the ethers [48,49].

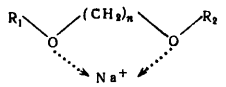
From this point of view, comparison of the results of Shatenshtein et al. [48] and those of Garst et al. [55] is of greatest interest. The latter worker observed that the position of the principal band in the absorption spectrum of the ketyl of sodiobenzophenone depends on the solvent. From the standpoint of the postulate of the ionic nature of ketyls [56,57],

the author explained the shifts of the absorption band by the variation of the interionic interaction due to the differences in the degree of solvation of the Na^+ cation in different solvents. According to McClelland's theoretical findings[57], the band is displaced more towards the red region of the spectrum the higher is the solvating power of the solvent. Then it follows from the data of Garst et al.[55] that the degree of solvation of the Na^+ cation decreases in parallel with C_{sb} and C_{sn} in the same solvents (Table 5).

The phenomenon of cation solvation cannot be explained if solvation is regarded as a purely electrostatic ion–dipole interaction. This is shown by the data in Table 3 on the thermodynamics of the formation of biphenyl radical-anions in different solvents taking into account their polar properties, by the absence of correlation between other parameters reflecting the differences in the solvating power of the solvents and their dielectric constants and dipole moments (see Table 5).

The results can be readily interpreted if the solvation is regarded as complex formation, i.e. a process of the donor–acceptor type. This approach enabled Izmailov[63] to explain the characteristic features of the hydration of alkali metal cations. The electron donors are oxygen atoms which have unshared electron pairs and the cation is the acceptor which provides vacant electron orbitals. The number and direction of the donor–acceptor bonds are determined by the multiplicity and type of hybridisation of the free orbitals of the cations. The probable vacant orbitals in Li^+, Na^+, and K^+ are $2s2p$, $3s3p$, and $4s4p3d$, the type of hybridisation of which is sp^3, sp^3, and sp^3d^2 respectively according to Eyring et al.[64] Thus in the solvation of Na^+ the oxygen atoms of the ligand must be located at the vertices of a tetrahedron with the cation at its centre. The greatest contribution to the heat of solvation comes from the energy of formation of the donor–acceptor bond between the cation and the solvent molecules. The secondary solvation of the cations takes place by ion–dipole interaction, whose energy makes a smaller contribution to the total solvation energy.



The above considerations hold also in the solvation of alkali metal cations by ethers. The more pronounced are the electron-donor properties of the oxygen atom of the given ether, the higher is the solvation energy and at the same time the stronger is the hydrogen bond formed between the ether molecules and CH_3OD. Therefore one should expect a correspondence between the relative concentrations C_{sb} and C_{sn} and $\Delta\nu_{OD}$ in the ether series. However, according to the data in Table 4 there is no such correlation. For example, the electron-donor properties of ethylene glycol ethers increase on substituting one or both CH_3 groups in 1,2-dimethoxyethane by alkyl groups with a larger number of carbon atoms, as a result of the higher inductive effect ($+I$) of such substituents, but the solvation of the Na^+ ion is then weakened. The inductive effect of the oxygen atom is of the opposite sign ($-I$) and therefore, as the methylene bridge separating the oxygen atoms in glycol ethers becomes longer, the latter become stronger bases, and yet the most stable solvate is formed by 1,2-dimethoxyethane. These discrepancies can be explained by the fact that steric factors, which play an important role in the solvation of the cation, have virtually no effect on the formation of the hydrogen bond.

TABLE 5. Comparison of the relative concentrations C_{sb} and C_{sn} with the position of the principal band (λ_{max}, nm) in the spectrum of sodiobenzophenone and the dielectric constants (DC) and dipole moments (μ) of the solvents*.

Solvent	C_{sb}	C_{sn}	λ_{max}	DC$_{25}$°	μ
Dimethyl ether of diethylene glycol	—	—	704	7.25[58]	—

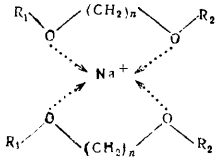
* The superscript numbers indicate the references to work from which the values of the dielectric constants and dipole moments have been taken.

The nature of the steric hindrance may be deduced using the glycol ethers as an example. Studies of the formation of complexes of titanium tetrafluoride[65] or tin tetrachloride[58] with ethers containing two oxygen atoms show that the latter are capable of forming two bonds with an acceptor. The dipole moment of the complex $SnCl_4.2C_2H_5OC_2H_4OC_2H_5$ corresponds to the octahedral model with *cis*-disposition of the oxygen atoms. It may be supposed that the reaction of the ethylene glycol ether with Na^+ ions involves the formation of a chelate complex:



The postulate of the chelate complexes of alkali metals was put forward by Sidgwick[66] as early as the 1920's. Since then it has often been used[59,67–69] to account for the high solvating power of 1,2-dimethoxyethane in various anionic organic reactions.

The structure of the methylene bridge is of great importance for the formation of a stable solvate. The atomic grouping characteristic of ethylene glycol ethers $[-O(CH_2)_2O-]$ must be regarded as the most favourable. For example, even in 1,2-dibutoxyethane the values of C_{sb} and C_{sn} are higher than in 1,3-dimethoxypropane and other dimethyl ethers of higher glycols. This feature of the steric hindrance is associated with the stability of the *cis*-conformation of the molecule, which is necessary for the formation of the chelate. As the number of CH_2 groups freely rotating relative to one another increases, the transition of the molecule to this conformation becomes increasingly difficult. The occurrence of free rotation about all the C–C and C–O bonds in glycol ether molecules was confirmed[61] by the agreement of the experimental dipole moments with those calculated theoretically on the basis of this hypothesis. Free rotation accounts also for the decrease of the solvating power of ethylene glycol ethers with increase in the size of alkyl side-groups, since the possibility of the screening of oxygen atoms by the latter then increases. We have seen (Table 3) that steric hindrance in the solvation of the metal ion is clearly reflected in the values of the thermodynamic parameters for the formation of the adduct.

It is interesting to note that the stability of the complexes of stannic chloride with glycol ethers[58] as well as the values of C_{sb} or C_{sn} (Table 4) decrease in the following sequence when the number n of methylene groups is reduced: $2 > 3 > 4 > 1$. At the same time the change in the

length of the alkyl groups of glycol ethers affects the formation of complexes with stannic chloride less than the solvation of Na^+ ions, since the stability of the stannic chloride complexes with 1,2-diethoxyethane and 1,2-dibutoxyethane is almost the same. This is not surprising, since usually the more intense is the interaction the smaller is its sensitivity to structural factors.

The data on the thermodynamics of the reaction of sodium with biphenyl also made it possible[45,46] to arrive at certain conclusions concerning the mechanism of the solvation. Thus if the solvent is an ethylene glycol ether or its mixture with heptane, the relation between $\log K$ and $1/T$ is represented by two straight lines of different slopes, and ΔH and ΔS each have two different values, depending on the temperature range in which the reaction has been carried out in the given solvent (Table 3, Nos. 2, 3, 5–12, Fig. 1). This can be explained by a stepwise mechanism of the solvation of the sodium ion. Since its coordination number is four[63] and ethylene glycol ether molecules are capable of forming simultaneously two donor–acceptor bonds each, there are two types of chelate complex — with one (see above) and two ether molecules:

Decrease of temperature favours the formation of coordination-saturated solvates. The absolute values of ΔH and ΔS then increase. Szwarc[70] also concluded that two 1,2-dimethoxyethane or four tetrahydrofuran molecules are involved in the solvation of the sodium ion. The temperature corresponding to the break in the $\log K - 1/T$ linear plots must be regarded as the temperature corresponding to the conversion of one type of solvate into another. It falls with increasing steric hindrance in the solvation: 1,2-dimethoxyethane (303°K) > 1-ethoxy-2-methoxyethane (283°K) > 1,2-diethoxyethane (258°K). The above temperatures were determined for a mixture of ether with heptane[46].

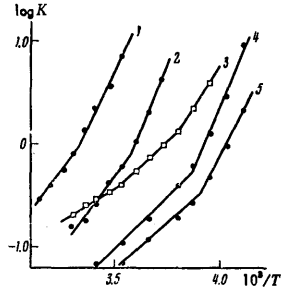


Fig. 1. Variation of $\log K$ for the formation of sodiobiphenyl with $1/T$; solvent: 1) 1,2-dimethoxyethane–heptane; 2) 1-ethoxy-2-methoxyethane–heptane; 3) tetrahydrofuran–heptane; 4) 1,2-diethoxyethane; 5) 1,2-diethoxyethane–heptane.

In contrast to glycol ethers, each tetrahydrofuran molecule can form only one donor–acceptor bond with the cation. It proved possible to demonstrate three solvation steps, of the possible four, on the basis of the temperature variation of the logarithm of the equilibrium constant for the reaction of sodium with biphenyl in a mixture of tetrahydrofuran with heptane (Table 3, Nos. 16–18, Fig. 1). The breaks in the straight line occur at 283°K and 263°K. Judging from the literature data[52] obtained by different methods, the Na^+ cation is fully solvated in tetrahydrofuran only at 200°K. The formation of the coordination-saturated complex (solvate) of the cation is accompanied by a weakening of the coulombic interaction between the ions. Therefore the increment of ΔH for the reaction when the temperature is reduced does not correspond to an additional heat of solvation but to the difference between the latter and the decrease of the coulombic interaction energy.

The hypothesis of the stepwise mechanism of solvation in tetrahydrofuran was put forward by Medvedev, Gantmakher, and coworkers[71] to explain the effect of added ethers on the frequency shift in the spectrum of diphenylalkyl-lithium. It was assumed that two stages in the solvation of the cation in the ion pair are possible — with one and two molecules[72]. The stepwise character of the solvation of lithium alkyls with ether containing one and two oxygen atoms is also reflected in the kinetics of the reaction of butyl-lithium with butyl bromide[73]. The solvation of organic anions by ethers as a result of donor–acceptor interaction is unlikely; the interaction between the solvent and the radical-anion is more probably of a coulombic type. The energy of the solvation of the radical-anion should then be approximately of the same order of magnitude as the energy of the secondary solvation of the cation. Consequently the effect of the solvent on the formation of radical-anions is determined mainly by the solvation of the cation, particularly if account is taken of the fact that differences in the polarity of ethers are only slight.

III. THE ROLE OF CATION SOLVATION IN ADDUCT IONIC DISSOCIATION EQUILIBRIA

The study of the ionic dissociation of adducts in ethereal solutions makes it possible to confirm and extend the above postulates concerning the solvation of cations. Table 6 lists the molar conductances of sodionaphthalene (I — 0.0023 M; II — 0.004 M) multiplied by the viscosity of the solvent[42,45]. Evidently $\Lambda\eta$ decreases by a factor of almost 600 on going from the dimethyl ether of diethylene glycol to tetrahydropyran, although the dielectric constants of the solvents differ little. The sequence of the values of $\Lambda\eta$

TABLE 6. Products of the viscosity and molar conductance of sodionaphthalene solutions at 293°K ($\Lambda\eta$, $cm^2\ \Omega^{-1}\ cP$).[45]

Solvent	$\Lambda\eta$ I	$\Lambda\eta$ II	DC$_{20°}$
Dimethyl ether of diethylene glycol	6.2	5.8	7.25
1,2-Dimethoxyethane	3.3	3.3	6.96
1-Ethoxy-2-methoxyethane	0.77	0.4	5.77
Tetrahydrofuran	0.59	0.44	7.31
1,2-Diethoxyethane	0.09	0.03	4.89
Tetrahydropyran	—	0.01	5.4

corresponds to the solvating power of the solvents (cf. Table 5), since a decrease of the degree of solvation favours ion association. The latter is in general pronounced in ethereal solutions and the adduct is largely present in the form of ion pairs. This follows from the determination of the approximate values of the dissociation constants K_d for the lithium, sodium, and potassium derivatives of naphthalene, calculated[42] by the method of Fuoss and Kraus[74] from measurements of the concentration dependence of the molar conductances (Table 7).

The dissociation constants of the adducts and certain other organometallic derivatives of alkali metals determined by other workers[52,75-79] in tetrahydrofuran solution are also of the order of 10^{-6}–10^{-7} M (Table 8).

The degree of dissociation of lithionaphthalene in 1,2-dimethoxyethane and tetrahydrofuran and also of sodionaphthalene in 1,2-dimethoxyethane at 293°K and a concentration of the order of 0.002 M is approximately 0.1. Under these conditions the value of $\Lambda\eta$ for sodionaphthalene solutions in the dimethyl ether of ethylene glycol is larger only by a factor of two than in 1,2-dimethoxyethane (Table 6), i.e. even in a solvent with a higher solvating power than 1,2-dimethoxyethane the concentration of ion pairs is still high. Dilution of the solution of sodionaphthalene in 1,2-dimethoxyethane to 10^{-4} M increases somewhat the degree of dissociation — approximately to 0.3.

These findings contradict Hoijtink's assertion[51] that sodionaphthalene is completely dissociated in 1,2-dimethoxyethane into free solvated ions. Hoijtink's view was shared by Weissman[52] and a number of other workers[53,54], who investigated the ESR of the radical-anions.

In the ESR spectrum of the sodionaphthalene solution in tetrahydrofuran there is additional splitting, which is absent from the spectrum of the 1,2-dimethoxyethane solution[52]. The intensity of the splitting decreases as the temperature is reduced. At 200°K it almost completely vanishes and the spectrum becomes identical with that of the solution in 1,2-dimethoxyethane. Similar observations were made for solutions of sodionaphthalene in methyltetrahydrofuran, tetrahydropyran, and dioxan[52].

The additional splitting in the ESR spectrum is due to the interaction of the unpaired electron of the radical-anion with the nucleus of the Na^+ cation. Such interaction cannot take place when the ions are free. Therefore Atherton and Weissman[52] suggested that in 1,2-dimethoxyethane the adduct is completely dissociated, while in other ethers it is present mainly in the form of ion pairs. The absence of the additional splitting from the spectrum of the tetrahydrofuran solution at 200°K and below this implies, in view of these investigations, that sodionaphthalene is also completely dissociated under these conditions. The increase of the degree of dissociation as the temperature is reduced can be explained[51] by the increase of the dielectric constant of the solvent. Rowlands and coworkers[81] also observed an additional splitting in the ESR spectra of the radical-anions

TABLE 7. Dissociation constants ($10^6 K_d$, mole litre^{-1}) of naphthalene adducts at 293°K.

* The discrepancy between the values of K_d in Refs. 76 and 80 is due to the different methods of calculation used, the results of the measurements being almost identical. In our view, there is no point in resorting to the more accurate method of calculation, as in Ref. 76, since Λ_∞ is evaluated by extrapolation over a long section of the experimental $\Lambda C - \sqrt{C}$ curve.

of pyrazine and pyridazine (obtained by reaction with sodium) in tetrahydrofuran solution, but not in 1,2-dimethoxyethane. Like Atherton and Weissman[52], they failed to observe the interaction of the unpaired electron with the nucleus of the potassium ion. According to Hush and Rowlands[36], this is due to the insufficient resolving power of the instruments, since examination of the spectroscopic data with the aid of the molecular orbital method leads to the conclusion that in tetrahydrofuran there is powerful ion association of the adducts of naphthalene and anthracene with lithium, sodium, and potassium. Later studies confirmed the validity of this view to some extent. In particular, splitting was observed in the ESR spectra of potassiobiphenyl[82] in tetrahydropyran, dihydropyran, and tetrahydrofuran (quoted in the order of decreasing degree of association) solutions, while the solution in 1,2-dimethoxyethane gave rise to the spectrum of the "free" radical-anion.

Data on the effect of the solvent and the cation on the ion association were obtained also by other investigators using the ESR method. Fraenkel and coworkers[54] showed that the degree of association of cyclo-octatetraene radical-anions with a cation decreases in the following order (the cation and the solvent are indicated): Na^+, tetrahydrofuran > Na^+, dimethoxyethane ≥ Li^+, tetrahydrofuran > Li^+, dimethoxyethane. On the basis of similar experiments, de Boer and Mackor[53] concluded that lithio-, sodio- and potassio-pyracene are completely dissociated into ions in 1,2-dimethoxyethane and completely associated in methyltetrahydrofuran at temperatures in the range between 300° and 180°K. The spectrum of the "free" radical-anion in tetrahydrofuran solution appeared at 183°K in the presence of K^+ and at 193°K in the presence of Na^+, while in the presence of Li^+ it was observed at all the temperatures. Evidently these results[52-54,81,82] are fully consistent with the postulates concerning the relative solvating power of the solvents and the variation of the degree of solvation with the radius of the cation. The contradiction between the conclusion that total dissociation of adducts in ethereal solutions is possible, which was arrived at on the basis of ESR spectroscopic studies, and the results obtained by conductimetric measurements[42,46] can be resolved by means of the hypothesis that two types of ion pairs exist — in contact (I) and separated (II)[46,76,80]. In the latter type the ions are separated by a layer of solvent molecules (Sl)[83,84]. Equilibrium in the dissociation of ion pairs into free solvated ions can be represented by

$$\underset{\text{(I)}}{Ar^-M^+} \overset{\Delta H_1}{\underset{Sl}{\rightleftharpoons}} \underset{\text{(II)}}{Ar^-|Sl|M^+} \overset{\Delta H_2}{\underset{Sl}{\rightleftharpoons}} \underset{\text{(III)}}{Ar^-_{Sl} + M^+_{Sl}} \qquad (5)$$

The position of the equilibrium depends on the type of the adduct, the solvent, and the concentration of the solution and temperature†.

Geske and Maki[86] and McClelland[57] note that the interaction of the unpaired electron with the nucleus of the cation is possible only in the ion pairs in contact, while in separated ion pairs this is prevented by the layer of solvent molecules. Hence the ESR spectra provide information about the concentration of the ion pairs in contact but not about the degree of dissociation of adducts into free ions[46,76].

The idea of the existence of two types of ion pairs has been used recently also to account for other phenomena in solutions of organometallic compounds of alkali metals. Thus Hogen-Esch and Smid[78] observed a change in the spectrum of fluorenylsodium solution in tetrahydrofuran at low temperatures. This phenomenon cannot be attributed to the formation of free ions, since the dissociation constant is very low — 4×10^{-5} M at 203°K. Therefore they concluded that a decrease of temperature is accompanied by the conversion of the ion pairs in contact into separated ion pairs, which have a different spectrum. According to Smid[75], separated ion pairs exist at room temperature in tetrahydrofuran solution of lithionaphthalene and ion pairs in contact in solution of sodionaphthalene in the same solvent.

Similar postulates were introduced recently by Szwarc[87,88] into the chemistry of living polymers to account for the effect of the solvent on the polymerisation kinetics. In his view, the active centres for the chain propagation of living polystyrene in tetrahydrofuran are separated ion pairs and in dioxan ion pairs in contact. Therefore in the first case the rate of polymerisation is about 200 times higher than in the second (the counter-ion is Li^+). Szwarc's explanation is satisfactorily consistent with McClelland's conclusion[57] that ion pairs in contact exist in solutions of metal adducts of benzophenone and anthracene in dioxan.

The mechanism of the dissociation of ion pairs represented by Eqn. (5) also explains satisfactorily[42,76,80] the shape of the curves for the temperature variation of the molar conductance of the adducts of aromatic hydrocarbons with alkali metals in ethereal solutions (Fig. 2). $\Lambda-T$ curves of similar shape were obtained by Hoijtink and coworkers[89,90] and Buschow[91] in studies on solutions of adducts of polyacenes in methyltetrahydrofuran. In particular, it was found that, as the temperature is reduced, the conductance of the lithium adducts falls rapidly, that of sodium adducts passes through a maximum, and that of potassium adducts increases slowly (in the case of potassiopentacene there is a maximum approximately about 220°K). The authors[89-91] explained these results by the increase of the dielectric constant of the solvent as the temperature is reduced, as a result of which the equilibrium in the dissociation of ion pairs is displaced towards free ions, and Λ increases. The simultaneous increase in the viscosity of the solvent lowers the mobility of the ions and results in a fall of Λ. Thus the shape of the $\Lambda-T$ curve is determined by the competing effects of two factors: the changes in the degree of dissociation and in viscosity.

† Recently Szwarc[85] examined quantitatively the problem of equilibria involving the participation of ions and ion pairs. He discussed the effect of the solvent on the degree of solvation, mobility, and association of ions, the structure of ion pairs, etc.

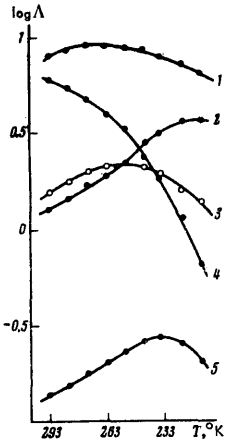

Fig. 2. Variation with T of log Λ for sodionaphthalene solutions; solvent: 1) 1,2-dimethoxyethane; 2) tetrahydrofuran; 3) 1-ethoxy-2-methoxyethane; 4) dimethyl ether of diethylene glycol; 5) 1,2-diethoxyethane.

In conformity with the results of spectroscopic studies, Hoijtink and Buschow concluded that the effect of viscosity begins to influence Λ when the dissociation equilibrium is almost completely displaced to the right. They assert that lithium adducts are present in solution in the form of free ions even at room temperature, while complete dissociation of sodium and potassium adducts occurs at the temperature corresponding to the maximum value of Λ. However, when the effect of viscosity is removed by multiplying Λ by η, it is found that in almost all cases the conductance, and hence the degree of dissociation, increases continuously as the temperature is reduced, down to 213°K (Fig. 3). Comparison of the quantities $\Lambda_T\eta_T$ and $\Lambda_{293}\eta_{293}$ shows that at 213°K too the degree of dissociation is still far from unity. On this basis, one may conclude[80] that below a certain temperature, determined by the properties of the system under investigation, the effect of the increase in the viscosity of the solvent begins to influence Λ more than the increase in the degree of dissociation. Thus this, at first sight unusual phenomenon, can be rationally explained by taking into account the equilibria represented in Eqn. (5).

The heat of dissociation of ion pairs in contact into free ions $\Delta H'_d = \Delta H_1 + \Delta H_2$ is higher than the heat of dissociation of separated ion pairs $\Delta H''_d = \Delta H_2$. Hence it follows that the rate of change of the logarithm of the dissociation constant with $1/T$, which is $-\Delta H_d/R$, will be higher in the dissociation of ion pairs in contact. Probably it is because of this that at relatively high temperatures, when the concentration of ion pairs in contact is much higher than that of separated ion pairs, the effect of dissociation on Λ is more pronounced than the effect of viscosity, and Λ increases as the temperature is reduced. At lower temperatures, when the concentration of ion pairs in contact becomes insignificant and the increase of K_d is slower, viscosity has the dominant effect on Λ, and the latter falls, i.e. the $\Lambda-T$ curve passes through a maximum.

The above explanation presupposes that the temperature corresponding to the maximum value of Λ is the temperature at which one type of ion pairs is converted into the

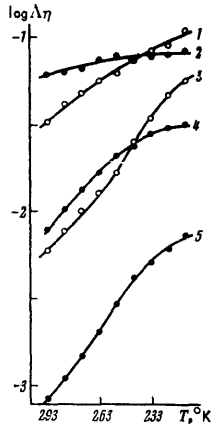

Fig. 3. Variation with T of $\log \Lambda\eta$ for sodionaphthalene solutions; solvent: 1) 1,2-dimethoxyethane; 2) dimethyl ether of diethylene glycol; 3) tetrahydrofuran; 4) 1-ethoxy-2-methoxyethane; 5) 1,2-diethoxyethane.

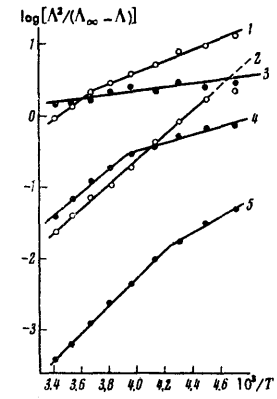

Fig. 4. Variation with $1/T$ of $\log [\Lambda^2/(\Lambda_\infty - \Lambda)]$ for sodionaphthalene solutions; solvent: 1) 1,2-dimethoxyethane; 2) tetrahydrofuran; 3) dimethyl ether of diethylene glycol; 4) 1-ethoxy-2-methoxyethane; 5) 1,2-diethoxyethane.

other. The temperature (°K) of the transition of the sodionaphthalene ion pairs in contact into separated ion pairs falls with decrease in the solvating power of the solvent: dimethyl ether of ethylene glycol (> 293°) > 1,2-dimethoxyethane (273°) > 1-ethoxy-2-methoxyethane (253°) > 1,2-diethoxyethane (235°) > tetrahydrofuran (213°). The analogy with the temperature of conversion of one type of solvate of the sodium cation into another (p. 104) is striking. Possibly the formation of a coordination-saturated solvate is accompanied by the formation of separated ion pairs.

The existence of equilibrium between ion pairs in contact and separated ion pairs is confirmed by the calculation of the heats of dissociation (ΔH_d) of the adducts[42]. If the molar conductance at infinite dilution at any one temperature and the variation of Λ and η with temperature are known, it is possible to estimate approximately the variation of K_d as the temperature is reduced. Approximate values of ΔH_d were calculated from the slopes of the linear plots of $\log K_d$ against $1/T$. In agreement with the above explanation of the shape of the $\Lambda - T$ curves, the values of ΔH_d differ, depending on whether the molar conductance Λ increases or decreases as the temperature is reduced. In the first case $\Delta H_d \simeq$ -6– -9 kcal mole^{-1} and in the second $\Delta H_d \simeq$ -1.5– -4 kcal mole^{-1}. The higher value of ΔH_d is due to the dissociation of the ion pairs in contact. The available literature data on the heats of dissociation of adducts are close to those given above. Weissman[52] found from ESR spectroscopic data ΔH_d = -7.6 kcal mole^{-1} for sodionaphthalene in tetrahydrofuran and Smid[78] obtained from conductivity data ΔH_d = -8 kcal mole^{-1} in the range 298–253°K (ion pairs in contact) and ΔH_d = -1.5 kcal × × mole^{-1} below 253°K (separated ion pairs) for fluorenylsodium in tetrahydrofuran. Two values of ΔH_d correspond to the $\Lambda - T$ curves which pass through a maximum, and, as was to be expected, the lower value occurs at lower temperatures, where separated ion pairs predominate. Graphically this is reflected in a break in $\log K_d - 1/T$ plots (Fig. 4). The temperatures corresponding to the breaks and to the maximum values of Λ are approximately the same[80].

Ether	Break, °K	Maximum, °K
1,2-Dimethoxyethane	~273	~273
1-Ethoxy-2-methoxyethane	253	253
1,2-Diethoxyethane	235	238

The above considerations concerning the mechanism of the dissociation and the state of the adducts of aromatic hydrocarbons with alkali metals in ethereal solutions are in good agreement with the data on the solvating power of ethers of different structures. There is also agreement between the conclusion that two types of ion pairs exist (in contact and separated) and that the solvation of cations proceeds by a stepwise mechanism. It follows from the results of the study of the electrical conductivity of the ethereal solutions of naphthalene adducts that the interionic interaction, which determines the position of the dissociation equilibrium, depends significantly on the conditions of cation solvation.

IV. THE ROLE OF THE METAL AND SOLVENT IN RADICAL-ANION DISPROPORTIONATION AND REDUCTION EQUILIBRIA

The adduct of sodium and naphthalene, which is widely used to initiate anionic polymerisation[3–7], has a green colour whatever the ether in which it is formed; the green colour (absorption maxima at 365 and 810 nm) is due to the presence of naphthalene radical-anions. The reaction of naphthalene with lithium is different. In 1,4-dioxan and 1,2-diethoxyethane[45,92] the green colour of the radical-anions is appreciable only in the first instants after the solution of naphthalene comes into contact with the metallic lithium mirror (its preparation has been described by Petrov et al.[93]). A stable red colour is then obtained due to the appearance in the spectrum of a broad band at wavelengths near 550 nm. On addition of an excess of naphthalene to the red solution in the absence of lithium, this maximum disappears and the spectrum is then characteristic of the naphthalene radical-anions (Fig. 5). The above

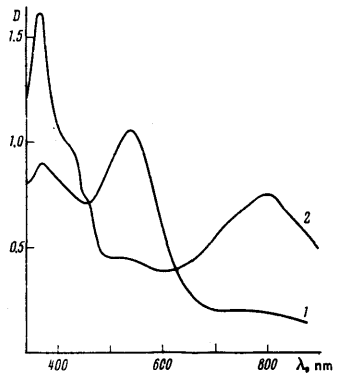

Fig. 5. Spectra of naphthalene–lithium adducts in 1,2-diethoxyethane:
1) in the presence of an excess of lithium; 2) in the presence of an excess of naphthalene.

phenomena have been interpreted[45,92] as evidence for the formation of naphthalene dianions. Their formation in the initial instants, when the solution still contains an appreciable amount of naphthalene, suggests that under these conditions they are formed as a result of the disproportionation of radical-anions [equilibrium (3)].

In tetrahydrofuran and 1,2-dimethoxyethane the green colour of the naphthalene radical-anions persists until reaction (1) involving the formation of radical-anions reaches completion. Only then does the colour of the solution change, and the broad band in the region of 550 nm appears in the spectrum. This means that in this case equilibrium (3) is displaced to the right and the dianions are produced preferentially by the reduction of radical-anions according to Eqn. (2).

Hoijtink and Buschow[94] were the first to describe the spectrum of the naphthalene dianions, which were obtained by the reaction of naphthalene with lithium in methyltetrahydrofuran. They noted that the dianions, which are very reactive, are readily protonated by the solvent at room temperature, forming the carbanions ArH^-:

$$C_5H_{10}O + Ar^{2-}2M^+ \rightarrow ArH^-M^+ + C_5H_9O^-M^+. \quad (6)$$

For this reason, it was impossible to obtain the spectrum of the dianions without the superposition on the latter of the spectrum of the carbanions, which absorb in the wavelength range 350–500 nm.

Smid[75] quotes the spectrum of the solution of the products of the reaction of lithium with naphthalene in tetrahydrofuran (absorption maximum of the dianions at 555 nm), which is of a very similar form to that measured by Shatenshtein et al.[92]

Henrici-Olivé and Olivé[95-98] studied the properties and the preparation of solutions of naphthalene dianions in tetrahydrofuran. They investigated the reactions of lithium and sodium with naphthalene in dimethoxyethane and tetrahydrofuran by measuring the magnetic properties of the solutions of the resulting adducts. They observed that in tetrahydrofuran in the presence of an excess of lithium the concentration of the paramagnetic adduct is much lower than the initial concentration of the hydrocarbon, while the active alkalinity (determined by titration with propyl alcohol) is 1.5 times greater than the alkalinity corresponding to the complete conversion of naphthalene into radical-anions (in 1,2-dimethoxyethane and also with sodium in tetrahydrofuran such phenomena were not observed). Hence Henrici-Olivé and Olivé concluded that, in the presence of an excess of lithium in tetrahydrofuran, dianions are formed together with radical-anions. According to these investigators[96], about 90% of the naphthalene is converted into dianions in 5 h (ratio of the number of lithium gramme-atoms to the number of moles of naphthalene 4.5; concentration of naphthalene 0.15–0.2 M). The colour of the solution gradually changes from green to dark violet. As was to be expected, the addition of an excess of naphthalene to the solution of the dianions results in the restoration of the green colour and an increase in the paramagnetism of the solution.

There exists a definite relation between the state of the adduct in solution and the mode of formation of the dianions, namely the disproportionation of the radical-anions occurs more readily in those solvents where the adducts are present predominantly in the form of ion pairs in contact, since, according to Garst[77], the powerful interionic attraction in such pairs favours the disproportionation reaction, compensating the energetically unfavourable repulsion of electrons in the dianions. On the other hand, if the adduct (lithionaphthalene) is present in solution in the form of separated ion pairs, the electrostatic interaction between the ions is weaker and the disproportionation virtually does not occur. The reduction of the radical-anions as well as their formation according to Eqn. (1) are favoured by solvents with a higher solvating power, in which separated ion pairs are present.

The problem of the disproportionation reactions has been considered in greatest detail by Garst[75,79,100] from the above standpoint. In the study of the effect of the solvent on the radical-anion disproportionation equilibrium it was found that the disproportionation constant (K_{disp}) of sodiotetraphenylethylene[99] increases in the series dimethyl ether of diethylene glycol $\simeq$ 1,2-dimethoxyethane $<$ tetrahydrofuran $<$ 1,4-dioxan, ethyl ether. The following sequence of solvents as regards their effect on the disproportionation constant of sodiostilbene has been obtained[100]: tetrahydrofuran $<$ methyltetrahydrofuran $<$ 1,4-dioxan. After comparing these data with the shifts in the spectra of sodiobenzophenone ketyl as a function of the solvent[55], Garst concluded[99] that a decrease in the degree of solvation of ions (mainly the cations) favours the displacement of the equilibrium in the direction of the formation of dianions. When the temperature is reduced, the degree of solvation of the cations increases, and the interionic attraction weakens, as a result of which the equilibrium should be displaced towards the formation of radical-anions, as is observed experimentally. The increase of the constant K_{disp} for the radical-anions of tetraphenylethylene in tetrahydrofuran with increase in the radius of the cation (at room temperature) observed by Garst and Zabolotny[77] and Ewans and Tabner[101] does not contradict this explanation either, since the interionic interaction in the above solvent increases in the series of cations $Li^+ < Na^+ < K^+$. At the same time Garst et al.[99] observed that in methyltetrahydrofuran, whose solvating power is lower than that of tetrahydrofuran, K_{disp} for stilbene radical-anions decreases in the opposite sense compared with tetrahydrofuran, i.e. with increase in the radius of the cation. Garst[77] believes that this reversal of the reactivity of metals is caused by competition between interionic interaction and solvation. If the reaction is performed in a solvent which solvates cations to a high degree, then the

solvation effect predominates as the radius of the cation increases, and K_{disp} falls, while in a weakly solvating solvent the effect of interionic interaction prevails and K_{disp} increases with the radius of the cation. Thus the dianion formation reactions also convincingly demonstrate the close relation between the phenomenon of cation solvation and interionic interaction (see also Refs. 102 and 103).

It must be emphasised that the above relations involving the effect of the solvent and the nature of the alkali metal on the formation and ionic dissociation of the adducts of alkali metals with aromatic hydrocarbons are of a more general significance, since they apply to a considerable extent to the entire field of organic anionic reactions. To illustrate this postulate, one may refer to the reviews published in this journal[104,105] and to the work carried out in our laboratory[73,106-111] on a series of anionic reactions in ether solvents.

MODERN IDEAS ON THE SUPERMOLECULAR STRUCTURE OF CELLULOSE

V.I.Sharkov

According to modern ideas, cellulose macromolecules form long, unbranched, elastic threads, consisting of D-glucopyranose residues linked by β-glucoside bonds in the 1,4-position.

Since each glucopyranose residue contains alcoholic hydroxy-groups, the cellulose molecule with a degree of polymerisation of 1000 contains 3000 hydroxy-groups. These groups screen the adjacent units in the cellulose macromolecule, and are responsible for rigidity and elasticity; they also determine the nature of the bonds between the macromolecules. The way in which the cellulose macromolecules are mutually arranged in natural and synthetic fibres and in films has an important effect on the strength, stretch, elasticity, hygroscopicity, reactivity, solubility, capacity to undergo wet grinding, ability to take dyes, and many other properties of these fibres.

Unfortunately, we still know very little about the supermolecular structures that are responsible for these properties of cellulose. Nevertheless, it is in this field that we must look for an explanation of processes that lead to the preparation of ultra-strong cellulose fibres, highly reactive celluloses, and other materials of great industrial importance.

Numerous electron microscope studies of natural cellulose fibres carried out in the last 10–15 years have shown that these have a fine fibrillar structure, the diameter of the elementary fibrils varying from 70 to 150 Å, depending on the origin of the preparation [1-5]. However, it has recently been shown that, in an aqueous medium, the microfibrils of some samples of natural cellulose can be cleaved by ultrasonic vibrations into smaller microfibrils with a diameter of about 35 Å. [6,7]

The structure of artificial cellulose fibres depends on a number of factors, the most important being the degree to which they are drawn [8,9]. The more the hydrocellulose fibres are drawn during their formation, the more well defined is their fibrillar structure. X-Ray and electron diffraction studies of natural fibrils suggest that these are made up of macromolecules, arranged parallel to and along the fibril [1,4].

Ranby and other workers have shown that, when natural or regenerated cellulose is subjected to mild heterogeneous hydrolysis, the microfibrils do not react in a uniform manner along the main axis [10,11]. It would appear that the microfibrils are constructed of continuously alternating sections that differ in the rate at which they are hydrolysed. After the readily hydrolysable sections have been dissolved, the microfibrils are broken up by ultrasonic vibrations into short spindle-shaped fragments. The average length of the cellulose macromolecules in these particles, or "micelles", as Ranby calls them, measured in the electron microscope, is about the same as the average length of cellulose residues determined by viscosimetric, diffusion, or sedimentation methods.

This made it possible to evaluate the length of the sections of the cellulose macromolecule that are difficult to hydrolyse from a knowledge of the average degree of polymerisation of the residue after hydrolysis (limiting degree of polymerisation), which was determined from the viscosity of solutions of nitrates or copper complexes [12-22]. The size of the sections of the microfibrils that are difficult to hydrolyse is not constant and depends on the origin of the cellulose sample. Thus, observations with the electron microscope have shown that, after mercerisation or regeneration of cellulose from solution, the length of the microfibrils that are difficult to hydrolyse is reduced by a factor of 2–4. [10,11]

Studies on the limiting degree of polymerisation have shown that there is a great difference in supermolecular structure between natural and artificial cellulose fibres. The limiting degree of polymerisation of wood cellulose is 400, [23] but in cord fibres of viscose origin this value varies between 40 and 20.

It is interesting that, in the preparation of ultra-strong fibres, the degree of polymerisation decreases instead of increasing, as might be expected [24,25]. A similar phenomenon is observed in the decomposition of viscose in a precipitation bath with an increasing content of salts [26]. This example shows that in nature cellulose is formed with large sections that are difficult to hydrolyse, but in the preparation of artificial hydrocellulose fibres these sections are 1/10 to 1/20 the size of the natural sections.

Studies carried out in recent years have shown that the readily hydrolysable sections of cellulose macromolecules undergo oxidation [27], thermal decomposition [18,28], enzymic hydrolysis [29], and alcoholysis [30] much faster than the other sections.

Using the electron microscope, Hess and coworkers showed that, after treatment with iodine, the microfibrils are not uniformly stained, and alternating dark and bright sections are formed [31]. In size the bright sections were similar to Ranby's micelles that were difficult to hydrolyse. It was concluded that the dark sections containing iodine are readily accessible amorphous components of cellulose.

Similar lack of uniformity in these microfibrils was observed by Manly, who subjected the fibrils to preliminary treatment with an aqueous solution of uranyl acetate or phosphotungstic acid [7]. After this treatment, the microfibrils of the Valonia algae showed the presence of a "bead-like" structure, with individual oval-shaped beads, 175 Å wide and 200 to 400 Å long. Dark coloured connective tissue was present between these formations. The microfibrils of ramie, cotton, and wood cellulose 35 Å in diameter, obtained after vigorous treatment of larger microfibrils with ultrasonic vibrations, also had a bead-like structure. Manly has suggested that this periodicity along the microfibril axis might be due to the formation of the fibril from a band folded into a spiral. However, sufficient evidence to support this has not been obtained, because the measurement is at the limit of the resolving power of modern electron microscopes, and the use of ultrasonic vibrations might lead to further profound structural changes.

It has been shown that the easily hydrolysed fraction of cellulose is hydrolysed 50–60 times more rapidly than the fraction that is difficult to hydrolyse [32]. But there is no sharp transition between these two fractions; this has led some workers to suggest that there is an intermediate mesomorphic cellulose fraction that is hydrolysed at a rate between the rates for the two extreme fractions [14].

It has recently been shown that the density of the cellulose fraction that is difficult to hydrolyse is much greater than that of the easily hydrolysable fraction, and this density varies with the type of cellulose [33,34].

It was also found that the rate of heterogeneous hydrolysis or alcoholysis of the fraction difficult to hydrolyse decreased as the density increased [33,34]. Measurement of the true specific gravity of cellulose during hydrolysis showed that the easily hydrolysed fraction becomes somewhat more dense and its reactivity decreases [35]. This effect is due to the rupture during hydrolysis of strained sections of the macromolecule with the formation of a denser structure.

The increase that occurs in the density of cellulose in the presence of water has been studied from several points of view. It has been shown that cellulose regenerated from its derivatives, for example, the acetate [36] or the xanthogenate [26], generally forms a loose low-density structure that readily undergoes ethanolysis and hydrolysis. When moistened with water, these types of cellulose rapidly become more dense and less reactive.

An especially large density effect was observed when loose cellulose obtained by dry grinding in special mills was moistened with water [37-40].

In recent years the use of alcoholysis [30,35,38-42] and dioxanolysis [35,43] instead of hydrolysis has facilitated studies on the increase in density of reactive cellulose. This change in methods of cleaving cellulose has to a great extent reduced its tendency to increase in density and so has limited the distorting effect of density increase on the quantitative determination of the portion of cellulose that reacts easily [35,38] and also of the maximum degree of polymerisation [44]. As the same time the use of hydrolysis and

alcoholysis in the investigation of various cellulose samples enabled a quantitative study to be made of the spontaneous increase in density that occurs when cellulose is cleaved in polar liquids[23-35].

As mentioned above, the cellulose macromolecules in natural and artificial microfibrils form alternating dense and loose sections along the main axis; this variation appears to be due to the tendency of the long cellulose macromolecules to undergo mutual orientation when highly swollen structures are dehydrated and their orientation is destroyed. The sections of the macromolecule between the dense, oriented sections must cause mutual lack of uniformity in the arrangement of the chains, and this must be reflected in the formation of looser, less oriented, structures in these sections, which are therefore more accessible to reagents. It is quite possible that the size of the oriented and of the loose sections along the microfibril depends on the initial orientation of the macromolecules produced under the conditions of formation of the sample. The greater the orientation in the initial swollen sample, the greater will be the tendency to form dense, highly oriented (crystalline) sections instead of sections with a loose (amorphous) structure, and vice versa.

Studies on the limiting degree of polymerisation of various cellulose samples have shown that the size of the dense, oriented, and more reactive sections depends on the method and conditions of regeneration of the cellulose[26]. Thus, for example, the presence in the precipitation bath of sodium sulphate, zinc sulphate, and especially of modifiers, promotes the preparation from viscose of cellulose with a large number of loose sections and small dense, oriented sections. The double-bath method of regenerating cellulose enhances this effect still further.

On the other hand, stretching increases the proportion of the less reactive fraction by increasing the proportion of oriented sections in the macromolecules[35]. This effect is still further increased by the swelling of hydrocellulose fibres, for example, in aqueous alkali[44]. Thus, the size of the dense and loose sections in cellulose depends on the origin of the cellulose and can be controlled within certain limits.

A study of the stability of fluctuations along the microfibrils of cellulose is of great interest. Recently this process has been elucidated using a method in which hydrogen of the hydroxy-groups in cellulose is exchanged for deuterium or tritium.

It had previously been shown that, when cellulose is immersed in heavy water, the hydrogen of the hydroxy-groups in the loose sections of the molecule is readily exchanged for deuterium[45,46].

Under these conditions, the hydrogen of the hydroxy-groups of the dense sections is not exchanged. To determine the mobility of this equilibrium, Sepall and Mason[47,48] repeatedly moistened cellulose samples with deuterium oxide or tritium oxide, drying them after each immersion. They found that, after 100 to 200 treatments, virtually all the hydrogen atoms of the cellulose hydroxy-groups had been exchanged for deuterium or tritium; the proportions of dense and loose sections of the macromolecule remained constant. With a single treatment, deuterium and tritium became inaccessible after penetrating into the densely packed sections of the macromolecule and were not exchanged for ordinary hydrogen.

According to Sepall and Mason, this observation indicates that fluctuations in the macromolecules in the microfibrils are not constant, and when the cellulose is alternately moistened with water and dried, the dense and loose sections in the microfibrils can be displaced along the fibril axis. It is interesting that the rate of replacement of hydrogen in the densely packed sections increases with the degree of swelling of the cellulose and with the temperature of the water.

Thus, the periodic increases in density in the bundles of cellulose macromolecules described above are not stable.

The nature of the bonds between adjacent macromolecules is of particular interest from the point of view of the supermolecular structure of cellulose. As early as 1926, Slonsler and Dore and then Higgins and Park advanced the hypothesis, on the basis of analogies with other compounds containing hydroxy-groups, that the hydroxy-groups of adjacent cellulose macromolecules form hydrogen bonds. But it was not until 1940 that Ellis and Butt[49] showed by means of infrared spectroscopy that all the hydroxy-groups of cellulose are in fact linked by hydrogen bonds. This conclusion was later confirmed by many workers and it is now fully accepted.

It must, however, be borne in mind that a small proportion of the hydroxy-groups, situated on the external and internal surfaces of cellulose fibres or films, must remain free for reasons of geometry. Direct estimation of these free groups with CH_3MgI in ethyl ether by Tserevitinov and Chugaev's method shows that the number of free hydroxy--groups in cellulose fibres accessible to the Grignard reagent is 5% of the total number of groups[50]. The remaining hydroxy-groups appear to be linked by intramolecular or intermolecular hydrogen bonds. The energy of these bonds varies from 2–3 to 6–7 kcal $mole^{-1}$, and it depends on the spacing between the groups and on steric hindrance.

The closer are the hydroxy-groups of adjacent cellulose macromolecules the stronger are the hydrogen bonds between them. For this reason, the thermodynamic method should be the best method for evaluating the bonding energy of adjacent molecules in a unit volume of cellulose. Unfortunately, such methods are not yet available, and the strength of the hydrogen bonds must therefore be measured by an indirect method. Infrared spectra are most generally used for this purpose.

The vibrations of free alcoholic hydroxy-groups correspond to an absorption maximum at 3570–3580 cm^{-1}. When hydrogen bonds are formed between the hydroxy-groups, absorption bands appear in the 3550–3000 cm^{-1} region, and the stronger the hydrogen bond the greater is the deviation from the absorption band of free hydroxy-groups. Examination of the spectra obtained shows that cellulose preparations give a broad set of absorption bands in the hydrogen--bond region[51]. This indicates the presence of hydrogen bonds of different strengths, which are responsible for the properties of the given type of cellulose. It is therefore possible to characterise the hydrogen bonds between the macromolecules by measurements based on indirect properties, such as the ability of certain reagents to penetrate deeply into the cellulose and rupture these bonds.

The most widely used and the simplest method of this kind is the determination of the absorption of water from air at a definite relative humidity. The ratio of the amount of moisture absorbed by the cellulose to the amount of moisture absorbed under the same conditions by cotton cellulose is termed "accessibility". It has been shown that the value of this accessibility depends on the structure of the cellulose and is independent of the relative humidity of the air[52].

Since, in air of low relative humidity, absorption of water is due to binding by alcoholic hydroxy-groups of the cellulose on the accessible surface of the sample, the quantity of water absorbed is a measure of the area of this surface. Here it must be borne in mind that water molecules that penetrate into the capillaries of the cellulose can break weak hydrogen bonds and penetrate into the depth of the cellulose, causing it to swell. Thus, it should be noted that the term "accessibility", measured by absorption of moisture, refers not only to the surface of the dry sample, but also to the surface that is formed as a result of swelling[53-57].

X-Ray studies have shown that water is absorbed by the loose part of the cellulose and does not penetrate deeply into the tightly packed sections of the macromolecules.

Methods of measuring the swelling of cellulose and in particular its dissolution are widely used in determining the intensity of intermolecular interaction in cellulose. These methods are based on the hypothesis that the most weakly bound macromolecules are the first to pass into solution. For the differential evaluation of the strength of the hydrogen bonds, methods are used in which the cellulose preparations under test are treated with solvents of gradually increasing dissolving power. This enables an arbitrary spectrum of bond strengths to be determined for different cellulose preparations[58].

However, the increase in the solubility of cellulose when its degree of polymerisation is reduced must be taken into account; intermolecular interaction is obviously no less decisive.

The methods to be considered here include those based on the swelling and dissolution of cellulose in ethylenediamine and its complexes, in cuprammonium solution, in solution of iron tartrate complex, in aqueous solutions of alkalis, sodium zincate, quaternary ammonium bases, calcium thiocyanate, chloral hydrate, zinc chloride, concentrated sulphuric acid and phosphoric acids, etc.[59-67].

Important results have also been obtained by measuring the rate of reaction of cellulose under heterogeneous conditions. Thus, for example, Nickerson and Troitzsch and other workers[68,69] used a method in which cellulose was partially formylated with formic acid of different concentrations at different temperatures.

In 1953 the present author in collaboration with Korol'kov and Garmanova[70] used the oxidation of cellulose with nitrogen dioxide, in the gaseous state or dissolved in carbon tetrachloride, for this purpose; this method was also used later by Roseveare and Spaulding[71]. Hydrolysis, ethanolysis, etc. may also be mentioned here.

Attempts have been made to evaluate the strength of the bonds between the macromolecules by measuring the amount of heat evolved in the mercerisation of cellulose by alkali solutions of increasing concentration[58], and also from the changes in the X-ray diffraction pattern of cellulose (as a result of the transition from cellulose I to cellulose II) after treatment with such solutions[72,73], and by measuring the rate of decrease of the degree of polymerisation of cellulose subjected to mild hydrolysis[74], etc. By means of these methods, data were obtained characterising the degree of lateral order in the whole mass of cellulose, that is, in the dense and loose regions.

To determine the degree of lateral order in the dense sections alone, some workers treated the cellulose in two stages; the first consisted of mild hydrolysis or ethanolysis to destroy loose regions, and in the second stage the residue was dissolved in aqueous solutions of sodium hydroxide of increasing concentration[75,76].

The methods enumerated above have been used to evaluate the heterogeneity of the energy of the lateral bond in various cellulose preparations and the variations have been represented on histograms. These methods have recently been used to characterise cellulose.

However, the heterogeneity of cellulose fibres due to their different anatomical structure must also be taken into account, and also heterogeneity due to compounds associated with cellulose which affect its solubility and tendency to swell.

The elucidation of the phase diagram of cellulose is of particular interest. At present the most widely held view is that cellulose consists of two phases, an amorphous and a crystalline phase; the amorphous phase is identified with the loose, readily accessible portion of cellulose, and the crystalline phase with the dense, oriented portion, which has a low reactivity. Such an interpretation applied to a polymer is usually associated with the presence of an interface between the two phases. It should, however, be noted that the presence of this interface has still not been demonstrated, and it is unlikely that such an interface exists. In this connection, many workers consider that cellulose may be partly in the mesomorphic or transition state; this state is characteristic of the boundary region between the amorphous and crystalline sections. Mark, in a typical statement, classifies cellulose as a stereoregular polymer, the rigidity of these polymers being due to the rigidity of the glucopyranose rings themselves and to strong intermolecular bonds[77]. When the molecules are arranged parallel to one another, these bonds promote the formation of crystal-like packets or aggregates. The terms "crystallite" and "crystallisation" are used with reference to certain regions within the cellulose system that show a state of three-dimensional order similar in some respects to the order in crystals of ordinary low-molecular compounds, such as sucrose, maleic anhydride, etc. However, the crystalline regions in cellulose do not have the regular shapes characteristic of ordinary crystals. They are much smaller and they are much more defective. Here the crystalline regions are linked with the non-ordered, amorphous regions by chains passing through both regions. Thus, there is no sharp boundary between the ordered (crystalline) regions, in which the molecules are arranged parallel to one another, and the non-ordered (amorphous) sections. Many workers share the view that cellulose is a single-phase crystalline system with a large number of dislocations[78]. In isolated sections of such a structure, the incidence of defects may be so great that the compound in these sections can be regarded as amorphous. In natural microfibrils highly oriented and poorly oriented sections regularly alternate along the length of the fibril, forming a bead-like structure. As mentioned above, the proportions in which these sections are present depend on the origin of the sample.

The alternation of sections differing in orientation is also found in regenerated cellulose, which does not have a microfibrillar structure, but here the regularity is less marked.

The variations mentioned in the structure of cellulose are similar among themselves and are based on the general idea that defect crystalline structures are present in cellulose.

Numerous X-ray structure studies on cellulose, especially those carried out in recent years[79-81], have definitely confirmed that cellulose contains three-dimensionally ordered regions with unit cells of fixed dimensions.

The degree of mutual orientation of cellulose macromolecules, measured by X-ray diffraction, varies within wide limits in different samples of cellulose. According to Ranby's studies, this orientation reaches a high degree in animal and bacterial cellulose and gradually decreases in cotton, and particularly in wood cellulose (Fig. 1).[82] Crushing and, in particular, dry grinding reduces the degree of orientation of natural cellulose[39,83,84].

The degree of orientation of highly stretched hydrocellulose fibres is much greater than that of isotropic fibres. However, the intensity of interaction (hydrogen bonds) between the macromolecules of natural and regenerated cellulose differs greatly, as is indicated by variations in the tendency to swell and to dissolve. The interaction between the macromolecules in natural fibres is much stronger than that in artificial fibres. For example, the solubility of natural cellulose in 10% aqueous sodium hydroxide solution generally does not exceed 10–20%, but under the same conditions regenerated cellulose in the form of fibres or films dissolves to the extent of 40–90%.

The energy of the interaction of macromolecules in "polynose" fibres is much greater than that in ultra-strong cord fibres. The difference in the packing of macromolecules is also displayed in a number of other properties. For example, natural cellulose has a higher density (1.55–1.60) than hydrocellulose fibres or films (1.495–1.530),[35] and it is hydrolysed[85-86] and ethanolysed[33] more slowly.

The special features of the supermolecular structure of cellulose mentioned above confirm that modifications of this structure exist with high bond energy (natural fibres) and low bond energy (hydrocellulose fibres). Each modification may show a different degree of mutual orientation of its macromolecules. The X-ray diffraction patterns of these two basic types of cellulose are different, which indicates a difference in the spatial arrangement of the macromolecules in a three-dimensional lattice. These two types of cellulose have been named cellulose I and cellulose II.

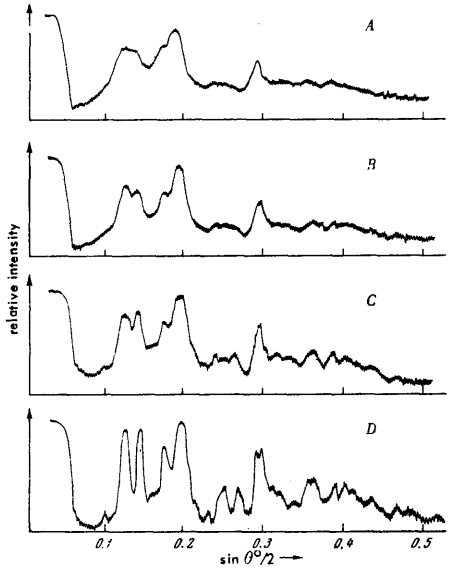

Fig. 1. X-Ray powder diffraction patterns of natural cellulose of different origins:
A) wood cellulose; *B*) cotton cellulose; *C*) animal cellulose (tunicine); *D*) cellulose from valonium algae[82].

It should be noted that this division of cellulose according to the strength of the side bonds and the structure of the unit cell is somewhat arbitrary, since cases are known in which there is a relatively strong side bond in cellulose II (for example, in "polynose" fibres).

At present, cellulose III and cellulose IV[87-88] are also known, the latter being formed from cellulose II by heating. In older papers reference was made to the conversion of cellulose II into cellulose I under these conditions, but this has not been confirmed by later studies[87,88]. A new, fifth modification of cellulose (cellulose X) has recently been described[89,90].

The unit cell of natural cellulose, or cellulose I, has been most studied[89,91-96]; this cell is monoclinic and has the following dimensions: a = 8.35 Å; b = 10.3 Å; c = 7.9 Å; angle β = 84°; volume 672 Å^3.

Wellard[97], who recently studied a large number of different natural celluloses, showed that the dimensions of their unit cells vary within comparatively narrow limits. Mercerised natural and highly oriented regenerated cellulose have the monoclinic cell of cellulose II with the following dimensions: a = 8.02 Å; b = 10.3 Å; c = 9.03 Å; angle β = 62.8°.[91-96,98-100]

Cellulose III is obtained by treating natural cellulose with non-aqueous liquid ammonia[101,102] or ethylamine[103]. Its unit cell has the following dimensions: a = 7.74 Å; b = 10.3 Å; c = 9.90 Å; angle β = 58°.

Cellulose IV, which is obtained by heating cellulose II in water or glycerol at high temperatures[87], has a unit cell of the following dimensions: a = 8.12 Å; b = 10.3 Å; c = 9.03 Å; angle β = [value omitted in Russian original (Ed. of Translation)].

Cellulose X, a new modification that has been little studied, was obtained by the regeneration of natural cellulose from its solutions in 40.3% hydrochloric or 85% phosphoric acid[89,90].

It is of interest to note that cellulose III is the only modification that can be converted into the initial natural cellulose I; up to now celluloses II, IV, or X have not been converted into cellulose I.[104]

All these modifications of cellulose give different X-ray diffraction patterns (Fig. 2); this appears to be due to differences in the configurations of the unit cells[91-96].

Thus, polymorphism is observed in cellulose. It is of interest that cellulose I is the only cellulose formed in nature, and has not yet been prepared in the laboratory.

The crystalline nature of cellulose has been demonstrated in different samples by studies on double refraction[105,106], magnetic anisotropy[107], fluorescence[108], and the piezoelectric effect[109-111].

The crystalline structure of highly oriented cellulose is indicated by the splitting (dichroism) of the absorption bands in the infrared spectra[112], and also by the X-ray diffraction patterns of true crystals of oligosaccharides obtained by the

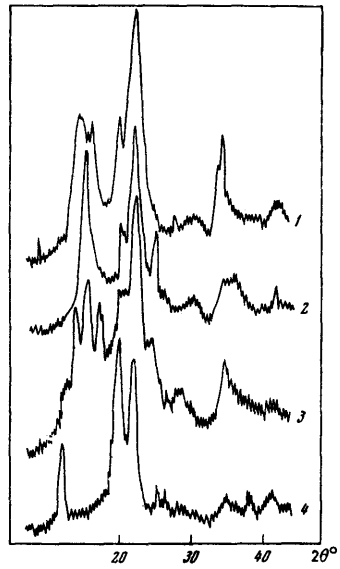

Fig. 2. X-Ray powder diffraction patterns of various modifications of cellulose:
1) cellulose I; 2) cellulose IV; 3) cellulose X; 4) cellulose II; the absorption intensity is plotted on the ordinate and the double angle (2θ) on the abscissa.[96]

extensive cleavage of cellulose (from cellulose to cellohexaose). In the latter case, after acetolysis of the cellulose and subsequent chromatography on a celite column, well crystallised oligosaccharides with a degree of polymerisation between 2 and 7 were separated[113]; these were identified after saponification. Oligosaccharides with a degree of polymerisation of 4 or more showed X-ray diffraction patterns virtually identical with the patterns of cellulose II. Thorough chromatographic separation of the oligosaccharides ensured that compounds of longer chain length did not appear in these fractions. Thus, typical crystals of higher oligosaccharides of cellulose obtained from aqueous solutions gave X-ray diffraction patterns characteristic of one of the modifications of cellulose that is also only formed in the presence of water (cellulose II).

The X-ray diffraction method, which shows the presence of regions of varying degree of orientation in cellulose, is widely used for the qualitative and quantitative evaluation of the extent to which cellulose occurs in the crystalline form[95,114-117].

It should, however, be noted that this method of quantitatively evaluating the crystallinity of cellulose is to a large extent arbitrary and should be used with great caution. For example, comparison of the X-ray diffraction patterns of hydrocellulose fibres[118] before and after removal of the easily hydrolysed (amorphous) fraction showed that the fibres contained virtually the same amount of "crystalline" fraction, although the proportion of the crystalline fraction would be expected to increase greatly after hydrolysis. It has been reported in other papers, however, that a slight increase in the proportion of crystalline fraction is observed when various celluloses are subjected to mild hydrolysis[119].

Various physical and chemical methods have been used in determining the degree of crystallinity of cellulose. Some of these are based on the removal of the amorphous fraction by hydrolysis with dilute acids[120-125], or by oxidation with periodic[26] or chromic[126] acids. In other methods the degree of crystallinity is determined from the absorption of water[127,128], from the rate of exchange of hydroxy-group hydrogen atoms for deuterium[45,46], or tritium[47,48], from the density of the crystalline and amorphous sections[106,129], from the heat of wetting[130], from the absorption of iodine from aqueous solutions[131,132], and from the exchange of hydroxy-group hydrogen atoms of the amorphous sections for thallium in solutions of thallium ethoxide[133], or for sodium in solutions of sodium in liquid ammonia[134].

Methods based on differences in the rate of esterification of the amorphous and crystalline fractions of acetylation[135] or formylation[136-138] form a separate group.

It should be noted that none of these methods gives a clear idea of the degree of crystallinity; they merely indicate the density of packing, the degree of orientation, and the strength of intermolecular bonds; this must be taken into account in the evaluation of the results obtained. Thus, at present we have no reliable methods for determining the degree of crystallinity of cellulose.

This is obviously due, firstly, to the absence of a clear boundary between the crystalline and non-crystalline sections, and, secondly, to the failure of many workers to distinguish properly between "crystalline" and "dense" sections; not all densely packed sections and sections difficult of access can be regarded as crystalline.

Of the methods enumerated above, the X-ray diffraction method appears to be the most suitable for determining the crystallinity of celluloses, but even this method must be used with great caution.

Another point of view on the phase state of cellulose is based on the hypothesis that it has an amorphous structure. Kargin is the founder of this theory in the Soviet Union. Over a period of many years, he and his students have systematically supported and advocated the theory that cellulose is an amorphous polymer with an anisotropic structure[139-149]. He considers that clear X-ray diffraction patterns obtained on a number of vegetable fibres have been incorrectly evaluated by some workers as providing proof of the crystalline structure of the polymer. According to Kargin and coworkers, it is necessary to distinguish between the elements of order responsible for the mutual arrangement of the chains and the order that arises on crystallisation of the polymer[146]. In the latter case additional bonds are formed without substantial change in the order of the arrangement of the macromolecules, but the proportion of these bonds is not great compared with the degree of order in oriented samples.

To determine the phase composition of cellulose, Kargin and coworkers used a method based on the dependence of the interference width on the wavelength of the beam used in systems with long-range order. For this purpose, they studied the interference obtained by the reflection of X-rays (wavelength 1.54 Å) and an electron beam (wavelength 0.05 Å). Since they found no such dependence, they concluded that cellulose has an amorphous structure.

Unfortunately, the electron diffraction method as applied to cellulose has serious disadvantages, and for this reason the results obtained have been criticised by some workers[81].

Evidence in favour of the amorphous structure of cellulose is also provided by the change that occurs in the X-ray diffraction pattern of an isotropic viscose film when the latter is stretched. It has been shown that, when signs of

a high degree of orientation of the film appeared in the X-ray patterns, there were no new interferences that could be ascribed to the crystallisation of the cellulose [141]. These experiments confirm that no phase transition from the amorphous to the crystalline state occurs, provided that these two states show different interferences, which has not yet been confirmed.

In this respect, the changes in X-ray interferences in natural and highly oriented, artificial cellulose fibres that have been subjected to dry grinding are interesting. Under these conditions, it is characteristic that the interferences in the natural cellulose entirely disappear (Fig. 3) without new ones appearing [39,83,84], although the cellulose retains most of its properties (transition to the amorphous state). When ground cellulose from highly oriented viscose fibre is treated with water, the initial X-ray diffraction pattern of the fibre is partly restored.

In developing the theory of the amorphous structure of cellulose, Kargin et al. attempted to change the second-order transition temperature of cellulose, that is, the transition point at which it changes from the vitreous to the highly elastic state, by the introduction of plasticising additives [145]. Under these conditions, the amorphous polymers show a reduction of the second-order transition temperature. Experiments in which triethylphenylammonium hydroxide was added as a plasticiser to cellulose confirmed that this transition temperature is reduced; it was therefore concluded that cellulose always exists in the vitreous state.

By measuring the integral heats of solution in triethylphenylammonium hydroxide of cellulose fibres with differing degrees of orientation, Mikhailov and Fainberg attempted to show that these fibres undergo a phase transition [150]; no appreciable difference in the heats was observed. This was interpreted as demonstrating that cellulose was amorphous in all the samples examined.

In 1962 these workers determined the heat capacity of isotropic and highly oriented cellulose fibres and observed no appreciable difference; this was also interpreted as proof that cellulose is amorphous [151].

The experimental results mentioned above obtained by Kargin and his students led them to conclude that cellulose fibre is a body that is solid in its state of aggregation but liquid in its phase state, with oriented anisodiametric molecules. Therefore, cellulose fibre is an anisotropic liquid phase the equilibrium state of which corresponds to a completely disoriented structure. Under normal conditions this process [attainment of equilibrium (Ed. of Translation)] is inhibited by the existence of a fixed structure [144].

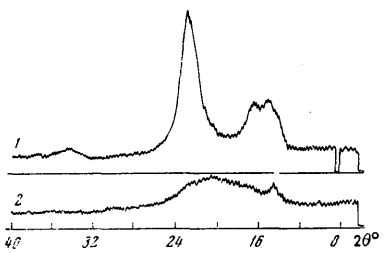

Fig. 3. X-Ray powder diffraction patterns of natural cotton cellulose before (1) and after (2) dry grinding.[39]

In later work Kargin and coworkers studied the supermolecular structure of viscose ultra-strong cord fibres and observed that these contained "ordered structural forms", which, however, were not internally perfect [152]. This indicated that cellulose undoubtedly shows a high degree of order. This interpretation that cellulose has an amorphous structure with a high degree of order agrees with the interpretation previously advanced that in amorphous cellulose the unfolded chains form packets (clusters), with isolated macromolecules passing through several packets.

These considerations are largely in agreement with modern views on cellulose accepted by advocates of both the crystalline and the amorphous hypotheses. The differences between the advocates of the two hypotheses appear to be mainly differences in terminology, the physical interpretations being very similar.

Now the main question in dispute is what name should be given to the "packet", which is recognised by all: should it be regarded as a crystal or as a highly oriented amorphous formation? Discussions in Soviet journals have shown that at present this question cannot be unambiguously answered because of the absence of reliable methods of investigation [78,154-159].

A final decision can probably only be reached by a study of an artificial cellulose crystal, with well defined boundaries, that can be assigned to a definite crystallographic system. If such a crystal had a diffraction pattern and other properties similar to those of highly oriented natural and regenerated cellulose, this would indicate that cellulose has a crystalline structure; on the other hand, if these properties were different, the crystallinity of cellulose would not be demonstrated. In this connection, work on the preparation of crystals of linear polysaccharides is of great importance; these polysaccharides include amyloses [160,161], inulin, mannan [162-164], xylan [164-167], and in particular cellulose [167]. Plane orthorhombic crystals of cellulose have been obtained by the slow saponification of low-molecular acetylcellulose in a dilute solution of alkali.

X-Ray and electron diffraction studies on these crystals have shown that they consist of a system of parallel plates in which the macromolecules are arranged perpendicular to the plane of the plate. The thickness of the plate varies over a range of 100 Å, i.e. it is much smaller than the length of the cellulose molecule from which the crystal is formed. It has been shown that amylose has a similar laminar-crystalline structure [160]. This phenomenon, which is characteristic of many crystallisable high polymers of linear structure [169-172], is also encountered in cellulose [167,168]. This crystalline structure of linear polymers can be explained if it is assumed that at the edge of the crystal the polymer chain turns through an angle of 180° to re-enter the lattice. Thus, the crystals described above are formed by the folding of long macromolecules in a plane perpendicular to the plane of the plate.

Manely has now obtained acetylcellulose crystals of similar structure [168-173]. When these crystals were saponified in an aqueous medium, cellulose that had a polycrystalline structure with folded macromolecules was obtained [174].

X-Ray diffraction studies on Ranby's cellulose crystals showed the presence of interferences in the same positions and of the same intensity as those found with highly oriented hydrocellulose fibres (cellulose II); no new interferences were noted (Fig. 4).

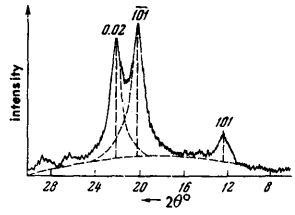

Fig. 4. X-Ray diffraction pattern of crystalline cellulose II powder.[167]

It is interesting that up to 50–60% of all the hydroxy--groups in these crystals are readily exchanged for deuterium in heavy water, that is, they behave in the same way as the groups in ordinary cellulose. Like ordinary hydrocellulose fibres and films, cellulose crystals obtained at a temperature of 30–90° form cellulose II, but those obtained at 120–150° form cellulose IV. The paper by Wolfrom and Dacons[113] mentioned above also provides evidence for the existence of cellulose crystals; these workers showed that, in the crystalline state, the products of the partial hydrolysis of cellulose — from cellotetraose to celloheptaose — gave X-ray diffraction patterns typical for cellulose II.

Whistler made a similar observation for linear xylan molecules[175], the only difference being that here the lowest compound to give a pattern similar to that of crystalline xylan was the hexasaccharide.

These examples show that crystalline formations in cellulose II give X-ray diffraction patterns similar to the patterns for oriented regenerated cellulose. If these formations are regarded as polymer (cellulose) crystals — and there are sufficient grounds for this assumption — we must recognise that similar crystalline structures are present in fibres and films of regenerated cellulose. Obviously, this conclusion can also be extended to natural fibres.

Since macromolecules with a folded structure were found to occur in the interior of various polymers of a crystalline nature, it must be assumed that similar formations can occur also in the interior of regenerated cellulose. It is assumed that in natural microfibrils the macromolecules are arranged longitudinally, but in the microfibrils of regenerated cellulose folded and unfolded macromolecules are present in various proportions.

How the packets or crystalline formations made up of folded macromolecules form sufficiently strong fibres is still obscure. It has been suggested that one end of some macromolecules enters one packet while the other end enters another packet, and in this way a mutual bond is formed along the fibre[172].

In contrast to this view, some workers regard the microfibrils as tubes formed from a solid band folded spirally in which the cellulose macromolecules are arranged perpendicular to the axis of the band in the folded state, as in crystals[160]. It should, however, be noted that these hypotheses need to be critically evaluated.

On the basis of the experimental work cited here, natural and highly oriented regenerated cellulose can be regarded as linear polymers made up of alternate highly oriented and poorly oriented sections. The highly oriented sections are similar in structure to the crystalline formations characteristic of a number of linear polymers.

I. INTRODUCTION

A characteristic feature of modern chemical processes, occurring at high rates at high temperatures and pressures in multiphase systems, is their great complexity. This complexity is shown in the large number and wide variety of the parameters determining the course of the processes and the large number of internal relations between the parameters and their mutual influence, the change in one parameter entailing a non-linear change in others. The complexity is enhanced by the occurrence of feedback between the parameters and also by the development of competing modes of the process, whereby the course of the latter is altered.

The complexity of a chemical process makes it necessary to understand it in terms of *models*, i.e. systems which reflect the individual aspects of the phenomena in a given process, restricted to the required conditions. Models are represented in terms of a definite mathematical notation, which establishes the relation between the parameters of the process, using both theoretical methods and experimental data. In their analysis and use, such models are usually divided into separate blocks, purely chemical phenomena, determined by classical chemical kinetics, being considered separately; blocks taking into account mass and energy transfer during the chemical reaction are distinguished. In this connection it has become usual to distinguish the micro- and macro-kinetics of chemical processes. This subdivision is of course to a certain extent arbitrary, but it makes

possible an accurate quantitative estimate of various aspects of a complex chemical process, so that it constitutes, in consequence, the scientific basis of industrial chemical processes.

The modern concept of macrokinetics was introduced by Frank-Kamenetskii [1], who also indicated the problems and the scope of this concept. Subsequently macrokinetics were formulated as a special branch of chemical kinetics and became the basis for the calculation of the parameters of chemical reactors and industrial chemical processes. Ten years after the appearance of Frank-Kamenetskii's paper, a special Symposium of the European Federation of Chemical Engineers devoted to the problems of macrokinetics was held in Amsterdam in 1957. [2] With the advent of computer techniques, the macrokinetics of chemical processes have entered a new stage of development — there is now a possibility of mathematically modelling chemical processes, their optimisation, and control [3-5]. The problems of macrokinetics have been further considered in Levich's papers [6].

Microkinetics deal with reactions in a chemical process at the molecular level on a scale not exceeding the mean free path of the molecules. Molecular friction (viscosity), molecular heat transport (thermal conductivity), and molecular matter transport (molecular diffusion) are also included among phenomena on the scale of molecular interactions.

In the study of processes at two levels, the state of liquid media becomes important. The mixing of liquids is called microscopic if it is restricted to the mixing of individual molecules; such a state of the liquid is called a micro-state [7,8]. Classical chemical kinetics are based on kinetic equations corresponding to micro-states.

Macrokinetics are concerned with the study of the interactions in a chemical process at the level of molecular aggregates on the scale of eddies, drops, or gas bubbles, i.e. on the scale of the so-called macro-particles. The mixing of liquids is regarded as macroscopic if it occurs on interaction between macro-particles. Consequently such a liquid state is referred to as macroscopic.

Examination of macro- and micro-mixing is important for heterogeneous systems, since one of the phases in such systems usually behaves as a liquid in a macro-state. For example, the solid phase in liquid–solid systems may be interpreted as a liquid in a macro-state, since each species of the solid constitutes a definite molecular aggregate. The disperse phase in liquid–liquid systems may serve as another example. Segregation in such systems increases with the surface tension.

Homogeneous systems behave as liquids in a micro-state, except for very viscous liquids or systems in which very rapid reactions take place. In the latter two cases the time required for the homogenisation of the system may prove to be appreciable compared with the rate of reaction and therefore the latter is limited by the mixing process.

The principal problem in macrokinetics is to establish the laws governing the transport of matter and energy on the macroscopic level under real conditions of chemical processes. The problem reduces to determining the distribution of concentrations and temperatures in the reactor as a function of the organisation of the reactant streams, heat inflow or outflow, and the effect of diffusion. For example, in contact-catalytic processes in a stationary catalyst bed one examines on the macroscopic level the distribution of temperatures and concentrations in the radial and axial directions in the bed under the usual non-isothermal and non-adiabatic conditions. On the microscopic level under these conditions, one examines the distribution of heat and concentrations within the catalyst particle (and within its pores).

Evidently, in the examination of a chemical process as a whole micro- and macro-kinetics constitute a single unity. However, this does not mean that the problems involved in the study of macrokinetics cannot be of independent interest, by virtue of the specificity of the scale of the objects examined and the specificity of the laws which obtain on macroscopic levels.

Accordingly, the study of chemical processes in industrial reactors comprises two aspects. Under laboratory conditions, the microkinetics of the process are investigated, whereby the reaction mechanism is established and the kinetic equations are derived. Using an experimental reactor of the chosen design, the parameters of the models which determine the macrokinetics of the process are established — the coefficients of longitudinal and radial mixing, the flow conditions, the coefficients of mass and heat transfer, etc. are determined. The micro- and macro-kinetic parameters are then combined into a complete mathematical model from which graphical and numerical relations between all the process parameters may be obtained by the method of mathematical modelling (the principle is that the deformation of the model is not studied using an actual physical model, as in physical modelling, but directly on the mathematical model itself using electronic computers) and the optimum conditions may be found (using the familiar optimisation methods). Thus the study of macrokinetics constitutes the basis of the modern analysis of industrial chemical processes. The mathematical models of chemical processes, taking into account the phenomena of energy and mass transport, which are superimposed on purely chemical phenomena in order to emphasise the importance of and necessity for the study of the problems of the macrokinetics of chemical processes, are examined below.

II. MATHEMATICAL MODELS OF ISOTHERMAL IDEAL REACTORS

It has become customary to examine the operation of real reactors by comparing them with ideal models. Usually the analysis is based on two extreme models: the ideal plug flow model and the ideal backmix flow model. The possibility of choosing such models was first pointed out by Kirillov [9], who gave a quantitative treatment of the elutriation phenomenon. Quantitative estimates of the course of chemical processes in the above models have been made [10,11].

The ideal plug flow model corresponds to the state in which the components are continuously introduced into the reactor and removed from it (Fig. 1); longitudinal and transverse mixing of the medium particles is then completely absent. The residence time of all the particles in the reactor is the same and equal to the ratio of the volume of the reactor to the volume flow rate of the liquid. The composition of the liquid and the reaction rate vary from point to point along the length of the reactor. The relation between the residence time in the reactor and the rate of reaction is established on the basis of the material balance of the reactor.

The following notation will be used: V_A is the influx of reactant A in kmole s^{-1}, V_r the reaction volume in litres, x_A the conversion defined as $x_A = (c_{A_0} - c_A)/c_{A_0}$, c_{A_0} and

c_A are the initial and final concentrations of reactant A in kmole litre^{-1}, and w_{r_A} is the rate of reaction (the rate of conversion of reactant A) in kmole s^{-1}.

For a steady stream and a constant reactor cross-section, one can write, in accordance with Fig. 1,

$$V_A - (V_A + dV_A) + (-w_{r_A})dV_r = 0 \qquad (3)\dagger$$

whence

$$-dV_A + (-w_{r_A})dV_r = 0.$$

Bearing in mind that $V_A = V_{A_0}(1 - x_A)$ and $dV_A = -V_{A_0}dx_A$, we obtain after substitution in Eqn. (3), separation of variables, and integration:

$$\frac{V_r}{V_{A_0}} = \int_0^{x_A} \frac{dx_A}{w_{r_A}}. \qquad (4)$$

On introducing the concentration c_{A_0}, defined as the number of kilomoles per unit volume and the volume per second V_s (in litre s^{-1}), one can write

$$V_{A_0} = c_{A_0}V_s. \qquad (5)$$

Evidently the ratio V_r/V_s, which has the dimensions of time, is the residence time τ_n of the reactant in the reactor, and therefore one can write

$$\tau_n = \frac{V_r}{V_s} = c_{A_0}\int_0^{x_A} \frac{dx_A}{w_{r_A}} \text{ (seconds)}. \qquad (6)$$

In the general case for a reaction of an arbitrary nth order the rate of reaction w_{r_A} can be written thus:

$$-w_{r_A} = kc_A^n = kc_{A_0}^n(1-x_A)^n. \qquad (7)$$

After substitution of Eqn. (7) in Eqn. (6), we obtain

$$\tau_n = \frac{V_r}{V_s} = c_{A_0}\int_0^{x_A} \frac{dx_A}{kc_A^n} = \frac{1}{k}c_{A_0}^{1-n}\int_0^{x_A} \frac{dx_A}{(1-x_A)^n} \text{ (seconds)}. \qquad (8)$$

Tubular reactors with a large tube length : diameter ratio (longitudinal mixing may be neglected) with a turbulent flow of liquid or gas (radial mixing may be neglected in view of the planar velocity profile in turbulent motion) are based on the ideal plug flow model. The plug flow model also fits a periodic reactor, but with respect to the time coordinate and not the length coordinate.

The ideal backmix flow model corresponds to the state in which it is assumed that the components are continuously introduced into and removed from the reactor (at the same rate); the mixing of the medium particles in the reactor is so complete that the concentration of each component is the same throughout the volume.

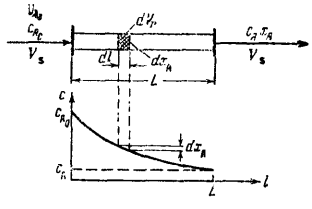

Fig. 1. The structure of the ideal plug flow reactor model.

According to the material balance equation for this model, we have

$$V_s(c_{A_0} - c_A) = (-w_{r_A})V_r. \qquad (9)$$

By analogy with Eqn. (6), the residence time of the reactant in the reactor τ_n' can be represented by the expression

$$\tau_n' = \frac{V_r}{V_s} = \frac{c_{A_0} - c_A}{(-w_{r_A})} = \frac{c_{A_0} - c_A}{kc_A^n} = \frac{1}{k}c_{A_0}^{1-n}\frac{x_A}{(1-x_A)^n}. \qquad (10)$$

Comparison of the conversions in ideal plug flow and ideal backmix flow models of the reactor for the same residence time and a first-order reaction with $k = 1$ yields the curves in Fig. 2. It follows from the graph that in an ideal backmix flow reactor the conversion x_A is lower than in an ideal plug flow reactor. Thus a conversion of 0.85 in an ideal plug flow reactor can be attained in 19 min while in an ideal backmix flow reactor the time required is 57 min.

We may note that, when the reaction medium passes through the plug flow reactor, the conversion increases along the length of the reactor and, since for simple reactions the rate decreases with conversion, the average rate is between the maximum value at the inlet to the reactor and the minimum value at the outlet. When the reaction medium passes through the backmix flow reactor, the conversion at each point in the reactor corresponds to the conversion at the outlet and the average rate is equal to the low value at the outlet from the reactor. Consequently, when the two reactor models are compared under isothermal conditions for the same conversion at the outlet, the average reaction rate in the plug flow reactor is always higher and therefore the required volume of a reactor of this type is smaller.

The model of the reactor affects not only the conversion but also the distribution of the reaction products. We shall examine as an example the decomposition of a component A which can occur in two ways [12]:

$$a_1A \xrightarrow{k_1} R \text{ (desired product)}$$
$$a_2A \xrightarrow{k_2} S \text{ (undesired product)}$$

at rates defined by Eqns. (11) and (12):

$$w_{r_R} = \frac{dc_R}{d\tau} = k_1c_A^{a_1} \qquad (11)$$

$$w_{r_S} = \frac{dc_S}{d\tau} = k_2c_A^{a_2}. \qquad (12)$$

On dividing Eqn. (12) by Eqn. (11), we obtain the ratio of the rates of formation of products S and R:

$$\frac{w_{r_S}}{w_{r_R}} = \frac{k_2}{k_1}c_A^{a_2-a_1}. \qquad (13)$$

It follows from Eqn. (13) that only by varying the concentration c_A is it possible to change the product concentration ratio c_S/c_R, since the kinetic parameters k_1, k_2, a_2, and a_1 are constant for a given system at a given temperature.

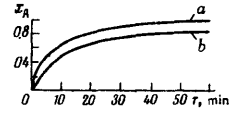

Fig. 2. Conversion in ideal plug flow (curve a) and ideal backmix flow (curve b) models.

† Eqns. (1) and (2) are missing in the Russian original (Ed. of Translation).

Their influence on the distribution of products is shown as follows.

1. If $a_1 > a_2$, i.e. the reaction order for the desired product is higher than the reaction order for the undesired product, then $a_2 - a_1$ is negative. According to Eqn. (13), to obtain relatively high yields of the desired product R, it is necessary to have a high concentration of the reactant A (c_A) in the reactor, which can be achieved in one of the following ways: (a) by using an ideal plug flow reactor, where the concentration c_A decreases gradually from initial high values; (b) by increasing the total pressure in gas-phase systems or by eliminating inert impurities, whereby the concentration of the reactant at the inlet to the reactor is increased; (c) by eliminating the product recycle flow.

2. If $a_1 < a_2$, i.e. the reaction order for the desired product is lower than for the undesired product, the preferential formation of the product R requires lower concentrations of the reactant, which is achieved by one of the following procedures: (a) by using an ideal backmix flow reactor in which the concentration of the reactant rapidly attains the minimum value corresponding to the outlet; (b) by introducing a recycle flow, whereby the inlet concentration and the concentration of reactant A in the reactor are reduced; (c) by reducing the pressure or increasing the concentration of inert gases in gas-phase systems. All these measures necessitate a large reactor. In this case the optimum design is achieved by comparing the economic balance of the cost of removal of the undesired product and the large capital outlay required for larger plant.

3. If $a_1 = a_2$, i.e. both reactions are of the same order, Eqn. (13) becomes

$$\frac{w_{r_S}}{w_{r_R}} = \frac{dc_S}{dc_R} = \frac{k_2}{k_1} = \text{const} \qquad (14)$$

i.e. the distribution of products is constant for a given rate constant ratio k_2/k_1 and independent of the type of reactor. The ratio of the products may be varied by changing the ratio k_2/k_1 in the following way: (a) by changing the temperature conditions of the process, when the activation energies for the two reactions differ from one another; (b) by using a selective catalyst.

Fig. 3 shows the variation of the relative yield of the intermediate product R with the kinetic parameters and the type of reactor [12] for the consecutive reaction

$$A \xrightarrow{k_1} R \xrightarrow{k_2} S.$$

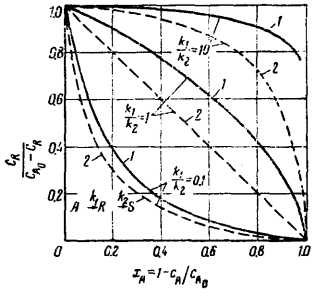

Fig. 3. Relative yield of the intermediate product in ideal plug flow (curve 1) and ideal backmix flow (curve 2) reactors for various conversions of the starting material.

On the basis of Fig. 3, we may conclude firstly, that the yield of the intermediate product R in the plug flow reactor is always higher than in the backmix flow reactor, and, secondly, that for high k_1/k_2 ratios the conversion is high, and vice versa for low ratios, i.e. under these conditions recycle flow should and should not be used respectively.

The distribution functions for the products of parallel consecutive reactions can be very conveniently and rapidly analysed by analogue computers. Structured assembly schemes have been proposed for the solution of problems of this kind by analogue computer; typical chemical reactions have been examined and the optimum yields of products have been calculated [13].

III. MATHEMATICAL MODELS OF ISOTHERMAL NON-IDEAL REACTORS

1. General Postulates

In contrast to the ideal reactors examined above, in non-ideal reactors the distribution of the reacting particles of the medium along the stream and along the stream cross-section is non-uniform. For this reason, in such reactors account must be taken of the transverse and longitudinal mixing of the medium particles. The distribution function of concentrations with respect to time is used as one of the characteristics in the operation of non-ideal reactors. A second characteristic is the state of segregation of the particles, i.e. a distinction must be drawn between processes at a micromixing level (at a molecular level) and processes at a macromixing level (the level of molecular aggregates). The level corresponding to the state of the system is defined by the so-called degree of separation of the system or the degree of segregation I introduced by Danckwerts [7]. The concepts of the "concentration at a point" and the "age of the liquid at a point" are introduced in connection with the concept of the degree of segregation. They denote the concentration, or age, averaged over a very small space compared not only with the system as a whole but also compared with the dimensions of the molecular aggregates and yet large enough to contain many molecules.

If the age of a molecule is defined as the time τ elapsed from the instant when the molecule entered the system, the variance of the age of all the molecules of the system, i.e. the average square of the deviations of the molecular ages from the average age, may be calculated:

$$\text{Var}\,\tau = \overline{(\tau - \bar{\tau})^2}, \qquad (15)$$

where $\bar{\tau}$ is the average age of all the molecules present in the system at a given instant; the overall bar over the symbols denotes an average value for all the molecules.

If the average molecular age at each "point" is denoted by τ_p, the variance of the age may serve as a measure of the degree of separation. The variance is

$$\text{Var}\,\tau_p = \overline{(\tau_p - \bar{\tau})^2}, \qquad (16)$$

where the overall bar denotes averaging over all the points.

If mixing takes place at a molecular level, the average age of all the molecules at each point is the same and equal to the average in the system and the variance of the age at different points is then zero.

If mixing takes place at a macroscopic level, i.e. the system is completely separated (segregated), the variance

of the age at different points in the system is equal to the variance of the age of all the molecules, i.e.

$$I = \frac{\mathrm{Var}\,\tau_p}{\mathrm{Var}\,\tau} = 1. \qquad (17)$$

For any other degree of separation, I will be less than unity:

$$I = \frac{\mathrm{Var}\,\tau_p}{\mathrm{Var}\,\tau}\,\frac{\overline{(\tau_p - \bar{\tau})^2}}{(\tau - \bar{\tau})^2} < 1. \qquad (18)$$

The limiting value $I = 0$ corresponds to the state of maximum mixedness, a concept introduced by Zwietering[8].

For a system in which the distribution of residence times is equal to the distribution in an ideal backmix flow model, I may be between zero (mixing at a molecular level) and unity (complete segregation). In a system corresponding to the ideal plug flow model, where there is no mixing of the stream particles, the degree of separation attains the maximum value $I = 1$.

We shall determine the effect of the level of mixing, or the state of the system, on the conversion in the reactors. Consider two arrangements of two reactors corresponding to two extreme models: the ideal plug flow and ideal backmix flow models connected in series (Fig. 4). The difference between the two schemes consists in the fact that in scheme *a* mixing takes place at a later stage and in scheme *b* at an earlier stage. The overall distribution of residence times in both reactor arrangements will be the same — the usual delta-function (see below) is obtained for the plug flow zone and an exponential function for the backmix flow zone.

If these two systems are regarded solely as different types of flow apparatus without chemical reaction, designed, for example, to lower the temperature and concentration variation in a steady stream of liquid, their effects will be completely the same. The difficulty in the study of chemical reactors arises from the fact that usually the mixing of the elements of the liquid takes place at the same time as the chemical reaction. Although the overall mixing in both systems is the same, the mixing in the second scheme takes place at an earlier stage of the chemical reaction, while in the first scheme the mixing occurs at a later stage. This, of course, leads to different yields of the products in the systems. If the reaction is isothermal and of an order greater than unity, a higher conversion will be attained in the first arrangement of apparatus. According to what has been said above, the plug flow reactor *1* corresponds to a higher degree of segregation than the backmix flow reactor *2* ($I_1 > I_2$).

On the basis of these considerations a different treatment of the effect of the level of mixing is also possible. Imagine a reactor with complete segregation, consisting of a long tube in which there is a piston-type stream or ideal plug flow, with a large number of closely packed lateral outlets (Fig. 5*a*). The stream flowing through these lateral outlets is controlled in such a way that the total distribution of residence times in the system is equal to the given distribution which is being investigated. It is assumed that the volume of the lateral outlets is insignificant. A very short section along the length of the tube may be regarded as a point in this system. Clearly the distribution of the ages at each point is extremely narrow and there is no mixing in the system, except for the mixing in the common outlet. Thus the mixing of molecules with different ages is achieved as late as possible, i.e. at point *A* (Fig. 5*a*).

A second imaginary flow system, with maximum mixing, can be obtained, by simple flow reversal, from the first flow system which is completely segregated. We then have many inlets and one outlet (Fig. 5*b*). It is assumed that mixing in the radial direction is ideal and that the flowing liquid is scattered immediately throughout the length of the tube. As soon as it enters the system, each molecule mixes with other molecules which will leave the system simultaneously. Thus mixing of the molecules occurs as soon as possible. This state is defined as the state of "maximum mixedness" — it is the opposite of the concept of total segregation[8].

Summarising the above findings, we arrive at the following most important conclusion: for a complete analysis of the operation of a chemical reactor, it is necessary to know (1) the reaction kinetics, (2) the response function of the system or the residence time distribution curve, (3) the properties of the system, i.e. the presence of macro- and micro-systems, and (4) whether mixing takes place during early or late stages.

In terms of classical kinetics, chemical reactions are considered at a microscopic level and consequently systems to which such kinetics are applied are microsystems.

The following conclusions may be made on the basis of the work of Danckwerts[7] and Zwietering[8]: (1) allowance for the degree of segregation and maximum mixedness is important only in homogeneous systems, since heterogeneous systems are always completely segregated, i.e. are always in a macrostate; (2) the degree of segregation and maximum mixedness must be taken into account only in stirred-flow tank reactors, since the streams in reactors operating on the total plug flow principle are always completely segregated; (3) in first-order reactions in homogeneous systems in stirred-flow tank reactors the conversion is independent of the level of mixing; the reaction rate is higher for the completely segregated state in reactions of an order greater than unity and lower in reactions of an order smaller than unity; (4) a plug flow reactor always

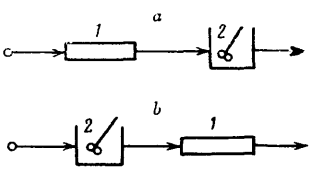

Fig. 4. Effect of the positioning of reactor models on the mixing level:
1) ideal plug flow; 2) ideal backmix flow.

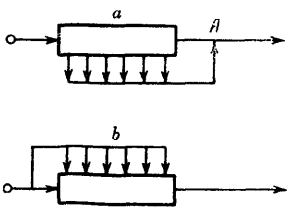

Fig. 5. Mixing in later (*a*) and earlier (*b*) stages.

gives a higher conversion than backmix flow reactors, both at the level of minimum and maximum segregation.

As mentioned above, to estimate the degree of non-uniformity of the distribution of the medium particles and hence the concentrations of the reactants in reactors, the corresponding distribution function is found by a statistical treatment of the experimental data on the variation of the concentration at the outlet from the reactor as a result of perturbations at the inlet, i.e. a cybernetic method is used to analyse the transmission of the signal through the test object.

Usually in the analysis of the distribution function for concentrations in reactors three types of perturbation (or, correspondingly, three types of input signal), differing in the mode of introduction of the tracer at the inlet, are used: step perturbation (step signal), pulse input signal (delta-function), and sinusoidal perturbation (frequency response) (Fig. 6).

At the outlet from the reactor the corresponding output signal (the time variation of tracer concentration at the outlet), whose form depends on the hydrodynamic conditions of the streams in the reactor, is obtained. The time parameter can be conveniently represented in the dimensionless form $\theta = \tau/\overline{\tau} = V_s\tau/V_r$, where τ is time in general and $\overline{\tau}$ the residence time of the tracer in the reactor, equal to the ratio of the volume of the reactor V_r filled with liquid to the volume of liquid V_s flowing in 1 s.

Step perturbation — *F* curve. In step perturbation the concentration of the tracer at the inlet reaches abruptly a constant value c_0. The distribution of the concentrations c at the inlet is then obtained in the form of the so-called *F*-curve, ranging from zero to $c/c_0 = 1$ (Fig. 6*a*).

Delta-function — *C* curve. In the case of pulse tracer injection (delta-function) the so-called *C* curve, shown in Fig. 6*b*, is obtained at the outlet.

Sinusoidal perturbation (frequency response). When the rate of injection of the tracer is varied harmonically, a sinusoidal curve, with a modified amplitude and phase angle, is obtained at the outlet (Fig. 6*c*).

The statistical distribution function for the tracer in the case of pulse perturbation can be written in the form (*C* curve)

$$C = \int_0^\infty \tau C(\tau)\, d\tau. \qquad (19)$$

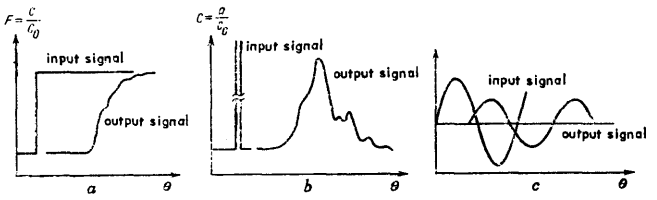

Fig. 6. The types of perturbation (input and output signals) used in the determination of the type of reactor model:
a) stepwise perturbation (*F* curve); *b*) delta-function (*C* curve);
c) frequency-response curves.

The residence time distribution function $C(\tau)$ characterises the fraction of the substance (tracer) in the exit stream which remained in the system for a time smaller than τ. The average residence time $\overline{\tau}$ is determined from the relation

$$\overline{\tau} = \frac{\int_0^\infty \tau C(\tau)\, d\tau}{\int_0^\infty C(\tau)\, d\tau} \simeq \frac{\Sigma \tau c}{\Sigma c}. \qquad (20)$$

The distribution function $C(\tau)$ is put in the form

$$C(\tau) = \frac{1}{\tau}\frac{c}{c_0} = \frac{c_0}{\Sigma c\, \Delta\tau}\ (s^{-1}), \qquad (21)$$

where $\Delta\tau$ is the sampling interval.

The dimensionless residence time θ is

$$\theta = \frac{\tau}{\overline{\tau}}.$$

When the average residence time is known, the *C* curve may be characterised by the equation

$$C = \frac{c}{c_0} = \overline{\tau} C(\tau). \qquad (22)$$

The variance or scatter of the quantity under consideration about the mean (for a continuous distribution), for a finite number of equidistant points (equal sampling intervals), is defined by the formula

$$\sigma^2 = \frac{\Sigma x_i^2 f(x_i)}{\Sigma f(x_i)} - \left[\frac{\Sigma x_i f x_i}{\Sigma f(x_i)}\right]^2. \qquad (23)$$

Thus when the variance is expressed in units of time, i.e. σ_τ^2 has the dimensions $(\text{seconds})^2$, we have

$$\Sigma f(x_i) = \Sigma c_i;\ \Sigma x_i f(x_i) = \Sigma \tau_i c_i;\ \Sigma x_i^2 f(x_i) = \Sigma \tau_i^2 c_i;$$
$$\sigma_\tau^2 = \Sigma \tau^2 C(\tau)\Delta\tau - (\overline{\tau})^2.$$

The following expression holds for the variance in dimensionless units:

$$\sigma^2 = \frac{\sigma_\tau^2}{(\overline{\tau})^2} \qquad (23a)$$

or for the *C* distribution of the dimensionless time θ we have

$$\sigma^2 = \frac{\Sigma \theta^2 C}{\Sigma C} - 1 = \Sigma \theta^2 C \Delta\theta - 1. \qquad (23b)$$

The relation between the distribution functions for step and pulse perturbation is given by

$$C = \frac{dF}{d\theta};\quad F = \int_0^\theta C\, d\theta.$$

Since $C(\tau)d\tau$ characterises the fraction of the substance in the exit stream with the ages τ and $\tau + d\tau$, on multiplying this quantity by the concentration c_A of the reactant remaining in the element of stream with the age $\tau + d\tau$, we can determine the average concentration $\overline{c}_A$ of the unreacted reactant leaving a real reactor:

$$\overline{c}_A = \int_{\tau=0}^{\tau=\infty} c_A C(\tau)\, d\tau. \qquad (24)$$

Eqn. (24) is valid only for linear processes in which the output signal is directly proportional to the input signal and which therefore have the property of additivity. Bearing in mind that for first-order reactions the concentrations are related by the expression

$$c_A = c_{A_0} e^{-k\tau}$$

we can write, in conformity with Eqn. (24),

$$\bar{c}_A = c_{A_0} \int_0^\infty e^{-k\tau} C(\tau)\, d\tau. \qquad (25)$$

Thus if information is available about the kinetics of the chemical reaction, we can determine by Eqn. (25) the conversion in a non-ideal reactor from the distribution curve $C(\tau)$ obtained experimentally for the given type of reactor.

Frequency response. The frequency response is obtained when the variation of the amount of tracer added is periodic (Fig. 6) at a definite frequency; the variation of tracer concentration at the inlet and outlet is then characterised by sinusoidal curves mutually displaced in amplitude and phase. The use of the method of frequency response for the analysis of reactors has been described by Kramers and Alberda [14] and has been developed by Mayer and Rippel [15]. Frequency analysis permits the replacement of time functions with the aid of the Laplace operator method. The Laplace operator is defined by the expression

$$F(p) = \int_0^\infty e^{-p\tau} f(\tau)\, d\tau. \qquad (26)$$

In this method the time function $f(\tau)$ describing the behaviour of the reactor is replaced by the so-called transfer function $F(p)$. The latter is the ratio of the output function $F_{outp}(p)$ transformed by the Laplace method to the Laplace input function $F_{inp}(p)$:

$$F(p) = \frac{F_{outp}(p)}{F_{inp}(p)}. \qquad (27)$$

If the transfer function is set up over a wide range of frequencies, it is possible to obtain a frequency response diagram which is then compared with the known frequency response diagram for ideal reactor models. Table 1 presents typical transfer functions for ideal reaction models and first-order reactions. By combining different models, it is possible to estimate the transfer function for a real reactor.

Consider an ideal backmix flow reactor in which a first-order reaction takes place. The following notation is introduced: V_s is the space velocity, c_{inp} the concentration of the reactant at the inlet, c_{outp} the concentration of the reactant at the outlet, k the reaction rate constant, and V_r the volume of the reactor. The material balance equation can be written in the form

$$V_s c_{inp} - V_s c_{outp} - k c_{outp} V_r = V_r \frac{dc_{outp}}{d\tau}. \qquad (28)$$

After Laplace transformation, we have the equation

$$V_s c_{inp}(p) - V_s c_{outp}(p) - k c_{outp}(p) V_r = V_r c_{outp}(p)\, p, \qquad (29)$$

where p is a Laplace operator.

The following expression for the concentrations of the reactant at the inlet to, and outlet from, the reactor can be obtained from Eqn. (29):

$$\frac{c_{outp}(p)}{c_{inp}(p)} = \frac{\frac{V_s}{V_r}}{\left(\frac{V_s}{V_r} + k + p\right)}. \qquad (30)$$

On introducing the time constant $V_r/V_s = T$, we obtain the equation

$$\frac{c_{outp}(p)}{c_{inp}(p)} = \frac{1}{T\left(\frac{1}{T} + k + p\right)} \qquad (31)$$

or

$$\frac{c_{outp}(p)}{c_{inp}(p)} \frac{1}{Tp + Tk + 1}. \qquad (32)$$

The relation obtained describes a state which varies with time, i.e. a non-steady state. Since usually c_{outp}/c_{inp} is measured in the steady state where p is close to zero, Eqn. (32) can be reduced to the form

$$\frac{c_{outp}(0)}{c_{inp}(0)} = \frac{1}{Tk + 1}. \qquad (33)$$

When Eqn. (33) is compared with the transfer function for the total backmix flow reactor (see Table 1), it is seen that the equation for first-order reaction kinetics in the steady state can be obtained from the transfer function on replacing p by the rate constant k. This opens up the possibility of assessing the process kinetics from the frequency response.

Two models based on the ideal reactor concept are used to analyse the operation of real reactors with non-linear systems. These models are the plug flow model with longitudinal or radial mixing (dispersion model) and the model with total mixing in individual tanks joined together in series, but without mixing of the contents of the different tanks (the tanks-in-series model).

TABLE 1. Typical transfer functions for ideal reactor models with first-order reactions.

Type of reactor	Transfer function	Remarks
Ideal backmix flow	$\frac{1}{T_1 p + 1}$	$T_1 = V_r/V_s$; V_r is the reactor volume and V_s the space velocity of the liquid
Ideal plug flow	e^{-pT_d}	$T_d = L/w$ is the transport lag, L the reactor length, and w the linear flow rate of the liquid
N ideal backmix flow reactors of equal volume in series (staged reactors)	$\frac{1}{(T_1 p + 1)^n}$;	
N ideal backmix flow reactors of unequal volume in series	$\frac{1}{(T_1 p + 1)(T_2 p + 1) \ldots (T_n p + 1)}$;	$T_1 = V_{r_1}/V_s$ $T_n = V_{r_n}/V_s$
Ideal plug flow and ideal backmix flow reactors in series	$\frac{e^{-pT_d}}{T_1 p + 1}$	

2. The Dispersion Model

As stated above, this model is based on the plug flow model with longitudinal and radial mixing. The coefficient of longitudinal or radial mixing D_L is analogous to the molecular diffusion coefficient in Fick's diffusion equation:

$$\frac{\partial c}{\partial \tau} = D_L \frac{\partial^2 c}{\partial l^2}. \qquad (34)$$

In the theory of mass transport [16] the coefficient D_L is also called the coefficient of turbulent diffusion or of eddy transport, which describes its physical nature. For this reason, the model can also be called the *eddy model*.

The equation for the transport of the substance at a macroscopic level in a steady stream with allowance for

longitudinal mixing and chemical reaction takes the following form on the basis of the law of the conservation of matter:

$$w\frac{dc_A}{dl}-D_L\frac{\partial^2 C_A}{\partial l^2}+kc_A^n=0. \quad (35)$$

Eqn. (35) is normally used in a dimensionless form. For this purpose, we put $z = l/L$ and $\tau = L/w = V_r/V_s$, where L is the length of the reactor, w the linear flow rate across the total cross-section, V_r the reactor volume, and V_s the space velocity of the stream. On multiplying all the terms of Eqn. (35) by τ, we obtain

$$\frac{dc_A}{dz}=\frac{D_L}{wL}\frac{\partial^2 c_A}{\partial z^2}+k\tau c_A^n=0. \quad (36)$$

Introducing the conversion $x_A = (c_{A_0} - c_A)/c_{A_0}$, we obtain

$$-\frac{dx_A}{dz}+\frac{D_L}{wL}\frac{\partial^2 x_A}{\partial z^2}+k\tau c_{A_0}^{n-1}(1-x_A)^n=0. \quad (37)$$

In order to solve the above equation, it is necessary to know the value of the coefficient D_L, which is determined independently or from the experimental concentration distribution curve with respect to time, considered above for homogeneous and heterogeneous systems.

Usually the coefficient of longitudinal or radial mixing is determined in the dimensionless form D_L/wL, as in Eqn. (37), which is the reciprocal of the Peclet number $Pe = wL/D_L$. The choice of the linear dimension L, which is the determining dimension, is important. The dimensionless parameter D_L/wL varies from zero for an ideal plug flow stream to 1 for a total backmix flow stream.

Homogeneous systems. The distribution curves examined above, together with the values of the parameter D_L/wL, make it possible to determine the real reactor model, however much it may differ from ideal reactor models.

Fig. 7 shows C and F curves for a closed vessel corresponding to different values of the dimensionless parameter D_L/wL, in which the determining dimension L has been assumed to be the distance from the stream inlet to the stream outlet in the closed vessel. Levenspiel and Smith [17] and also Van der Laan [18] found from the C curve the relations between the variance σ^2 and the dimensionless parameter D_L/wL. For low deviations from ideal plug flow, which often obtain in tubular reactors, the C curves approximate closely to the normal Gaussian distribution and the relation between the variance and D_L/wL is represented by the equation

$$\sigma^2 = 2\frac{D_L}{wL}. \quad (38)$$

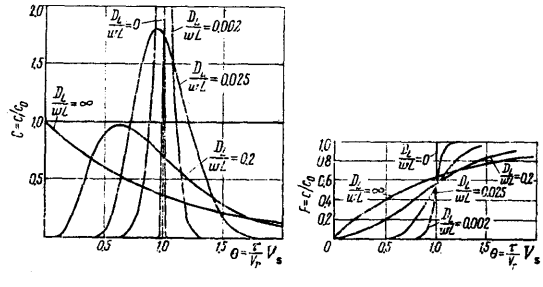

Fig. 7. Variation of output curves (C and F) with D_L/wL and θ.

When $D_L/wL < 0.01$, the maximum error associated with the use of Eqn. (38) is less than $5(D_L/wL)$, i.e. 5% when $D_L/wL = 0.01$ or 0.5% when $D_L/wL = 0.001$.

Table 2 presents different ways of using the dispersion models in homogeneous reactions under isothermal conditions [19].

Heterogeneous systems. In view of the importance of heterogeneous gas–solid systems for the analysis and calculation of the parameters of contact-catalytic processes, a large number of studies have been made [14,34-40] on the quantitative relation between the Peclet number for longitudinal ($Pe_L = d_p w/D_L$) and radial ($Pe_R = d_p w/D_R$) mixing and the Reynolds number Re in such systems. The particle diameter d_p is used as the determining dimension in the Peclet and Reynolds numbers, and the linear velocity of the liquid (gas) w is referred to the total cross-section of the apparatus. The results of these investigations are represented schematically in Fig. 8.

Fig. 8 shows that under turbulent conditions in gases and liquids the radial number Pe_R for mass transport is close to 12 (curve A), which agrees with Baron's theoretical calculations [41]. The Peclet number for longitudinal mixing in gases is approximately 2, which is also consistent with theoretical calculations [34,41], but differs from the experimental values for liquids. At low Re numbers, the "radial" and "longitudinal" Peclet numbers deviate from 2 and 12. In this case molecular diffusion has a significant influence.

Solution of the general form of the equation for the dispersion model. Because of its non-linearity, Eqn. (37) can be solved for specified boundary conditions only by numerical methods using computers.

TABLE 2. Different modes of utilisation of dispersion models.

Reaction order	Type of reaction	Type of flow	Mode of diffusion [dispersion]	References

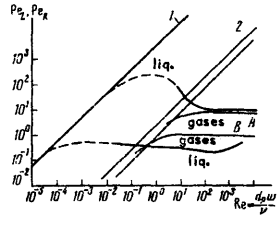

Fig. 8. Variation of the longitudinal (Pe_L) and radial (Pe_R) Peclet numbers with the Reynolds number Re:
1) molecular diffusion of liquids; 2) molecular diffusion of gases; A) radial diffusion; B) longitudinal diffusion.

The analytical solution of Eqn. (37) has been achieved only for first-order reactions. The following expression was obtained:

$$\frac{c_A}{c_{A_0}} = 1 - x_A = \frac{4a \exp\left(\frac{1}{2}\frac{wL}{D_L}\right)}{(1+a)^2 \exp\left(\frac{a}{2}\frac{wL}{D_L}\right) - (1-a)^2 \exp\left(-\frac{a}{2}\frac{wL}{D_L}\right)}, \quad (39)$$

where

$$a = \sqrt{1 + 4k\tau\left(\frac{D_L}{wL}\right)}.$$

The numerical solution of Eqn. (37) for first- and second-order reactions was achieved by Levenspiel and Bischoff[30] and by Fan and Bailie[28]. Levenspiel and Bischoff presented their solution in the form of graphs for different values of Pe_L, in which the ratio of the real reactor volume (taking into account longitudinal mixing) to the ideal plug flow reactor volume is plotted against the fraction of the unreacted reactant $c_A/c_{A_0} = 1 - x_A$. They concluded that for low conversions longitudinal mixing does not have much effect and the difference in the volumes of the ideal and real reactors is insignificant. It should be borne in mind that the dispersion model yields reliable results for comparatively small deviations from the ideal plug flow model and therefore the graphs described above can be used only for relatively low values of the parameter D_L/wL.

Effect of radial mixing. The effect of radial mixing is shown when the ratios of the tube diameter to particle diameter are low. Radial mixing is significantly influenced by the radial temperature profile, which leads to non-uniformity in conversion. A logical consequence of the radial gradient is a high rate of heat flow to and from the walls of the reactor. In principle, radial transport is an entirely desirable phenomenon for the elimination of hot spots along the reactor axis. The rate of radial diffusion may be increased by choosing a suitable ratio of tube diameter to particle diameter and a suitable temperature of the walls of the cooled reactor.

3. The Tanks-in-Series Model

The tanks-in-series model is based on the concept of the subdivision of the apparatus (reactor) into separate tanks. Within each tank ideal mixing takes place but there is no mixing between different tanks.

The relation between the C curve distribution and the number of tanks N is defined by the expression

$$C = \frac{c}{c_0} = \frac{N\theta^{N-1}}{(N-1)!} e^{-N\theta}, \quad (40)$$

where

$$\theta = \frac{\tau}{V_r/V_s}.$$

The relation between the number of tanks N and the variance σ^2 is

$$\sigma^2 = \frac{1}{N} = 2\frac{D_L}{wL} - 2\left(\frac{D_L}{wL}\right)^2\left(1 - e^{-\frac{wL}{D_L}}\right) \quad (41)$$

or Eqn. (38) can be used with adequate accuracy for practical calculations:

$$\sigma^2 = \frac{2}{N} = 2\frac{D_L}{wL}.$$

Assuming total mixing of the gas within the free volume of a monolayer of catalyst particles in the direction of the stream, the number of total backmix flow tanks is evidently L/d_p. The relation between the number of such tanks N and longitudinal macrodiffusion D_L, the length of the catalyst bed, and the gas flow rate w is

$$N = \frac{Lw}{2D_L}. \quad (42)$$

When $N = L/d_p$, then $wd_p/D_L = 2$ and the reactor operates as staged total backmix flow tanks.

Fig. 9, which has been constructed on the basis of Carberry's data[40] for a first-order reaction under isothermal conditions, shows the variation of the ratio of the conversion in a stationary bed x_{mix} and the conversion x_{plug} in a reactor without mixing (total plug flow reactor) with the product of the first-order reaction rate constant k and the duration of contact τ. Similar relations have been obtained for non-isothermal and non-adiabatic conditions[42,43].

The relation between the Pe_L number for a plug flow reactor and the number of tanks (or the number of staged reactors) is shown clearly in Fig. 10, based on the data of Trambouze[44].

4. Mixed Models

Apart from the plug and backmix flow streams examined above, additional phenomena occur in real reactors, such as stream circulation, their by-pass flow, cross-over streams, and stagnant zones. The model of the streams in a real reactor is then set up by means of different combinations of ideal backmix flow and plug flow models, stagnant zone models (concentration assumed to be constant),

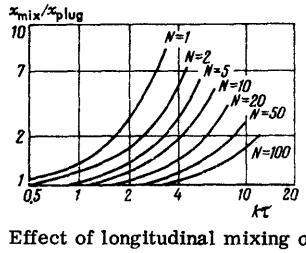

Fig. 9. Effect of longitudinal mixing on first-order processes.

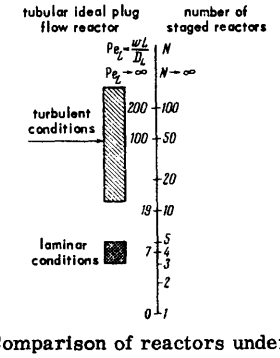

Fig. 10. Comparison of reactors under different hydrodynamic conditions.

etc. Subsequently the output concentration curves for a real reactor are compared with curves constructed on the basis of the proposed combination of models [5]. Table 1, quoted above, is very useful for this purpose.

The simplest mixed reactor models were examined in Levenspiel's monograph [12] and treated systematically by Wen and Chung [19]. The stagnant zone method of calculation, which gives better results than Levenspiel's method, has been described recently [45].

IV. EFFECT OF THERMAL PARAMETERS ON CHEMICAL PROCESSES

The distribution of temperatures in a stream (along the axis t and for radius R) in the presence of a chemical reaction can be represented in the following form, in conformity with the law of conservation of energy:

$$\frac{\partial t}{\partial \tau} = -w\frac{\partial t}{\partial l} + D_{Lq}\frac{\partial^2 t}{\partial l^2} + \frac{D_{Rq}}{R\partial R}\left(R\frac{\partial t}{\partial R}\right) + \frac{w_r(\pm \Delta H)}{c_p\gamma},$$

where $\partial t/\partial\tau$ is the rate of change of temperature with time. If in the system under consideration the heat of chemical reaction evolved is entirely consumed in changing the heat content of the system, the reactor used under such conditions is referred to as an adiabatic reactor. The temperature of the reaction mixture, defined by the ratio $T_a = (\pm\Delta H)c_{A_0}/\gamma c_p$, is then called an adiabatic temperature.

Depending on the model, the following heat balance equations hold for adiabatic reactors:

for a backmix flow reactor

$$V_s\gamma c_p(t_e - t_i) = V_s(c_e - c_i)(\pm\Delta H), \quad (43)$$

for a plug flow reactor

$$V_s\gamma c_p dt = w_r(\pm\Delta H)\,dV_r. \quad (44)$$

The following heat balance equations hold for a polytropic reactor, depending on its model:

for a backmix flow reactor

$$V_s\gamma c_p(t_e - t_i) = V_s(c_e - c_i)(\pm\Delta H) - \alpha F(t_e - t_x), \quad (45)$$

for a plug flow reactor

$$V_s\gamma c_p dt = w_r f(\pm\Delta H)dz - \alpha F'(t - t_x)dz = V_s(\pm\Delta H)dc - \alpha F'(t - t_x)dz. \quad (46)$$

The following notation is used in the above equations: w_γ is the rate of change of concentration due to the chemical reaction, w the linear flow rate, V_s the space velocity of the reaction mass, D_{Lq} and D_{Rq} are the coefficient of longitudinal and radial heat transport, γ is the specific gravity, c_p the specific heat at constant pressure, ΔH the heat of reaction (the plus sign corresponds to an endothermic reaction and the minus sign to an exothermic reaction), t_i and t_e are the initial and final temperatures of the reaction mass, c_i and c_e the initial and final concentrations of the reactants, α is the coefficient of heat transfer from the reaction mass to the cooling agent, t_x the temperature of the cooling agent, F the heat exchange surface area, F' the heat exchange surface area referred to unit length, and f the cross-sectional area of the stream in the reactor.

Isothermal reactors are relatively infrequently used in large-scale processes because of the high cost of the heat-exchange equipment. Therefore adiabatic or polytropic industrial reactors are usually designed.

Cholette and Blanchet [46] made a theoretical comparison of the conversion in an adiabatic plug flow reactor with that in a backmix flow reactor (for a microstate). The comparison yielded the same results for both endothermic and isothermal reactions, i.e. the plug flow reactor proved to be superior to the backmix flow reactor. For exothermic reactions at low conversions, the backmix flow reactor proved to be more convenient than the plug flow reactor, but at high conversions the opposite was true.

The above estimate of the average reaction rates provides an explanation of these findings. The rate of endothermic reactions decreases with the conversion as a result of the consumption of the reactants and the decrease of the temperature of the system. Since the average rate of reaction in the plug flow reactor, where it assumes a value which is the average of the maximum rate at the inlet and the minimum rate at the outlet, is always higher than the average rate in the backmix flow reactor, it follows that in the presence of heat exchange too the plug flow reactor is always preferable to the backmix flow reactor.

The rates of most exothermic processes initially increase with the conversion, as a result of the increasing temperature of the system, but at high conversions they fall due to the consumption of the reactants. Under conditions of increasing rate, the average reaction rate in the backmix flow reactor is always higher than in the plug flow reactor. However, after the attainment of a certain conversion, somewhat higher than that corresponding to the maximum rate, the average rates in both reactor models become identical and at higher conversions the plug flow reactor again becomes more advantageous.

The variation of the conversion with the residence time in plug flow and backmix flow reactor models (at two levels) is shown in Fig. 11 for endothermic reactions and in Fig. 12 for exothermic reactions. In the graphical construction of the conversion profiles, use was made of the temperature variation of the reaction rate based on the Arrhenius equation, and temperature was eliminated by setting up the heat balance for an adiabatic reactor (with subsequent analytical or numerical solution), the following conditions being assumed: $ER/T_0 = 40$ and $T_a/T_0 = 0.1$, where $T_a = (\pm\Delta H)c_{A_0}/\gamma c_p$ is the adiabatic temperature and T_0 the initial temperature.

Comparison of the segregated state with mixing at the molecular level for endothermic reactions (Fig. 11) shows that the highest conversion is attained for reactions of any order in the segregated state. The difference between this result and the result considered for isothermal conditions,

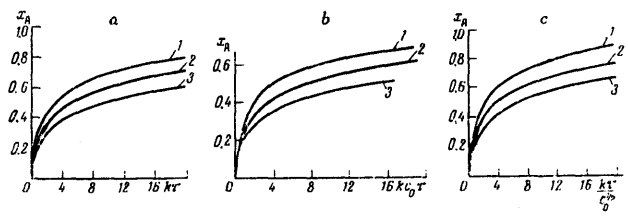

Fig. 11. Dependence of the conversion on the reactor model and the mixing level for endothermic reactions of different orders: *a*) first-order reactions; *b*) second-order reactions; *c*) reactions of order 1/2;
1) plug flow reactor; 2) backmix flow reactor (macromixing); 3) backmix flow reactor (micromixing).

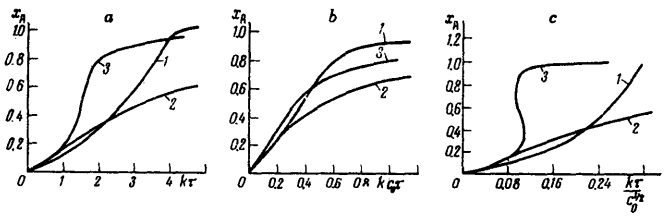

Fig. 12. Dependence of the conversion on the reactor model and the mixing level for exothermic reactions of different orders: *a*) first-order reactions; *b*) second-order reactions; *c*) reactions of order 1/2:
1) plug flow reactor; 2) backmix flow reactor (macromixing); 3) backmix flow reactor (micromixing).

where the order of the reaction has a significant influence, is due to the mode of variation of the reaction rate. In an endothermic system the rate decreases with increasing conversion, both due to the disappearance of the reactants and the decrease of the temperature of the system. In the systems examined above the temperature effect was greater than the compensation due to the order of the reaction.

Comparison of the segregated state with mixing at a molecular level for exothermic reactions (Fig. 12) leads to the opposite conclusion — the highest conversion corresponds to mixing at a molecular level. This is because in exothermic systems the initial rate increases with conversion due to the increasing temperature of the system.

Combinations of reactor models have been considered by Cholette and Blanchet[46]. It was shown that for exothermic reactions a combination of plug flow and backmix flow (at a molecular level) reactors is sometimes more satisfactory than the individual reactor models. Douglas notes[47] that some of Spencer's calculations[48], based on the dispersion model, have shown that the optimum conversion is attained at a certain finite non-zero value of the mixing parameter, i.e. for a hypothetical case intermediate between the plug flow and backmix flow reactor models. These findings can be explained by considering the variation of the average reaction rate in the two systems.

Denbigh[49] showed that the plug flow reactor is always preferable in cases where the rate of reaction decreases with increasing conversion. On the other hand, the backmix flow reactor is more advantageous when the rate increases during the reaction. Therefore, for exothermic reactions whose rate passes through a maximum as the conversion increases, the optimum model is the backmix flow reactor under conditions of increasing rate and the plug flow reactor under conditions of falling rate.

Aris[50] made a quantitative estimate based on the above postulates and showed that, for a reaction of the type A → products,

$$w_r = kc_{A_0}(1-x_A) = c_0^n\left(A\exp\frac{-E/RT_0}{1+\frac{T_a}{T_0}x_A}\right)(1-x_A)^n; \qquad (47)$$

the condition corresponding to the maximum reaction rate w_r is $\partial w_r/\partial x_A = 0$ and the required conversion x at the outlet may be obtained by a combination of backmix flow reactors. The following equation then holds:

$$n\left(1+\frac{T_a}{T_0}x_A\right)^2 = (1-x_A)\frac{E}{RT_0}\frac{T_a}{T_0}. \qquad (48)$$

It has been shown that the best model for reversible gas-phase reactions may be obtained by setting up a decreasing temperature profile[51] which can be attained by by-passing a cold feed. Aris[51] examined by-pass schemes with two and three adiabatic reactors and also other optimum schemes.

A comparative assessment of reactor models can be conveniently made by comparing the slopes $dx_A/d\tau$ of $x_A-\tau$ curves, i.e. by differentiating the material balance equations for reactors under different heat-exchange conditions[47]. On the basis of Eqn. (47), we have for the plug flow reactor

$$c_{A_0}^{1-n}\frac{dx_A}{d\tau} = k(1-x_A)^n. \qquad (49)$$

After appropriate substitutions, the material balance equation for the backmix flow reactor yields the expression

$$c_{A_0}^{1-n}\frac{dx_A}{d\tau} = k(1-x_A)^n\left[\frac{1-x_A}{1+(n-1)x_A - x_A(1-x_A)\frac{1}{k}\frac{dk}{dx_A}}\right]. \qquad (50)$$

Comparison of Eqns. (49) and (50) shows that the slope of the $x_A-\tau$ curve for the backmix flow reactor differs from the slope of the curve for the plug flow reactor by the factor

$$\left[\frac{1-x_A}{1+(n-1)x_A - x_A(1-x_A)\frac{1}{k}\frac{dk}{dx_A}}\right]. \qquad (51)$$

Under isothermal conditions we have

$$\frac{dk}{dx_A} = 0,$$

and the factor (51) reduces to the form

$$\left[\frac{1-x_A}{1+(n-1)x_A}\right]. \qquad (52)$$

Since the above factor is always less than unity, the slope of the curves for the total backmix flow reactor is always smaller than the slope for the plug flow reactor and therefore under isothermal conditions the plug flow reactor is always preferable to the backmix flow reactor.

Under endothermic conditions we have

$$\frac{dk}{dx_A} = \frac{d}{dx_A}\left[A\exp\left(\frac{-E/R}{T_0 - T_a x_A}\right)\right] = -\frac{k\frac{E}{RT_0}\frac{T_a}{T_0}}{\left(1-\frac{T_a}{T_0}\right)^2}. \qquad (53)$$

On substituting Eqn. (53) in Eqn. (51) and assuming that the factor (51) is always less than unity, i.e. that the slope of the $x-\tau$ curves for the backmix flow reactor is always smaller than the slope of the curves for the plug flow reactor, we obtain the inequality

$$-n\left(1-\frac{T_a}{T_0}x_A\right)^2 < (1-x_A)\frac{E}{RT_0}\frac{T_a}{T_0}. \qquad (54)$$

Since the left-hand side of this expression is always negative and the right-hand side is always positive, the factor (51) is indeed smaller than unity. Therefore for endothermic reactions a plug flow reactor will always give a higher conversion per unit volume.

For exothermic reactions, we have the equation

$$\frac{dk}{dx_A} = \frac{d}{dx_A}\left[A\exp\left(\frac{-E/R}{T_0 + T_a x_A}\right)\right] = \frac{k\frac{E}{RT_0}\frac{T_a}{T_0}}{\left(1+\frac{T_a}{T_0}x_A\right)^2}. \qquad (55)$$

It follows from Fig. 12 that the slopes of $x-\tau$ curves for the backmix flow reactor are higher than the slopes of the

curves for the plug flow reactor at low conversions, are equal at a certain intermediate conversion, and lower at high conversions. Therefore on substituting Eqn. (55) in expression (51), we should obtain a factor greater than unity at low values of x and smaller than unity at high values of x:

$$\frac{(1-x_A)\left(1+\frac{T_a}{T_0}x_A\right)^2}{[1+(n-1)x_A]\left(1+\frac{T_a}{T_0}x_A\right)-x_A(1-x_A)\frac{E}{RT_0}\frac{T_a}{T_0}} \begin{matrix} > 1 \text{ small } x \\ = 1 \text{ intermediate } x \\ < 1 \text{ large } x \end{matrix} \quad (56)$$

or

$$n\left(1+\frac{T_a}{T_0}x_A\right)^2 \lessgtr (1-x_A)\frac{E}{RT_0}\frac{T_a}{T_0}. \quad (57)$$

It is evident from formula (57) that at high conversions the right-hand side approaches zero (when x_A tends to unity). At a very low conversion ($x \simeq 0$) the following inequality can be obtained from formula (57):

$$n < \frac{E}{RT_0}\frac{T_a}{T_0}. \quad (58)$$

The inequality (58) is valid for the majority of exothermic systems. It is noteworthy that, if this relation does not hold, the rate of reaction decreases with increasing conversion and the plug flow reactor is more advantageous than the backmix flow reactor.

To determine the optimum combination of reactor models, consider the graphical method based on the construction of a conversion profile [46,47,52]. On the basis of Fig. 12, characterising the conversion profile for individual reactor models, one constructs a conversion curve for exothermic reactions in the backmix flow reactor (Fig. 13, curve *1*) which gives the steepest possible curve. If a system comprising a combination of two reactor models (backmix flow–plug flow) is proposed, a second curve for the plug flow reactor must be constructed (curve *2*). The point A corresponding to the highest slope of the curve for the backmix flow reactor is selected. The line AB, parallel to the curve for the plug flow reactor along the section CD, is drawn from point A. The line AB characterises the conversion which obtains for the combination of the two reactors. However, this profile does not yield the optimum system, because evidently best conditions can be achieved if the system includes a larger backmix flow reactor and a smaller plug flow reactor. Similarly if the conditions of the backmix flow reactor correspond to those at point G and a profile is constructed for the combined system, better conditions can be attained in a system with a smaller backmix flow reactor. Therefore under the conditions at point

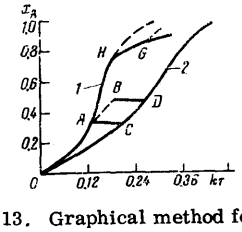

Fig. 13. Graphical method for the construction of combined reactor models:
1) backmix flow reactor (micromixing); 2) plug flow reactor.

H (the point corresponding to equal slopes of the curves) the optimum reactor combination is obtained.

Thus the following conclusions can be arrived at on the basis of the above considerations: the ideal plug flow reactor is always more advantageous for isothermal and endothermic conditions, while for exothermic conditions a combination of reactor systems is more suitable. The optimum temperature profile for complex reactions has been examined by Bilous and Amundson [53]. Slin'ko [54] calculated optimum temperature profiles for contact-catalytic reactors.

V. THERMAL STABILITY OF CHEMICAL REACTORS

The concept of the stability of systems was first formulated by Lyapunov [55]. A system is regarded as stable if after the removal of any perturbation it returns to the previous state. When thermal stability of chemical reactors is considered, perturbations can arise in the system in exothermic processes due to the different mode of heat supply and heat removal. The thermal stability of chemical reactors has a significant effect on the temperature and concentration profiles in the reactor and also provides information which can be used in the selection of the automatic reactor control system.

Assuming that the heat gained by the reactor is evolved in the chemical reaction, i.e.

$$dQ_{\text{infl}} = w_r \Delta H\, dV_r = k_0 e^{-E/RT} c_{A_0}^n (1-x_A)^n \Delta H\, dV_r \quad (59)$$

and the heat loss is determined by the heat content change in the system and by an external heat exchanger,

$$dQ_{\text{outfl}} = V_s \gamma c_p\, dt + \alpha F' (t - t_x)\, dz \quad (60)$$

it is readily seen that the relation between the heat gained and the temperature of the system is exponential, while that between the heat lost and the temperature of the system is linear, i.e. in an exothermic reaction the rate of heat gain is much faster than the rate of its loss and can result in an undesirable increase in the temperature of the system. This fact was pointed out at one time by Semenov [56] and Frank-Kamenetskii [57]. Under endothermic conditions, the problem of stability does not arise.

The necessary condition for the stability of the reactor with respect to heat is

$$\frac{dQ_{\text{outfl}}}{dT} \geqslant \frac{dQ_{\text{infl}}}{dT}. \quad (61)$$

It follows from the heat-exchange conditions in different reactor models examined earlier that the stability conditions also depend on the reactor model and the degree of conversion in the system.

A characteristic feature of the temperature profile of a tubular plug flow reactor with an external heat exchanger is that the reaction volume is proportional to the square of the diameter, while the surface area of the heat exchanger is proportional to the diameter. Therefore in tubes of large diameter the instability is more pronounced than in tubes of small diameter.

As the process proceeds in a plug flow reactor, the temperature initially rises fairly rapidly and the rate of heat loss also increases. The maximum temperature is attained at the point where the local rate of heat loss is equal to the rate of heat supply as a result of the reaction. With increasing conversion, the reaction rate falls, which leads to

a decrease of the temperature in the reaction zone, the temperature approaching that of the cooling agent. Only for a reaction of zero order, whose rate is independent of concentration, does the temperature in the reactor remain constant at the maximum value until the reaction is complete. It should be borne in mind that, with the exception of autocatalytic reactions and reactions with an induction period, the maximum reaction rate at a given temperature is the initial rate, i.e. the rate at the inlet to the reactor, where in fact there is a risk of a sharp rise of temperature.

The stability criteria can be found directly from the balance equations examined previously. According to Eqns. (10) and (49), the following expression is valid for an exothermic first-order reaction in an ideal backmix flow reactor of fixed volume:

$$x_A = k\tau(1-x_A). \tag{62}$$

The requirement for stability is[61] that the derivative of the left-hand side of Eqn. (62) with respect to x_A should be greater than the derivative of the right-hand side, representing the heat gain. Then, in conformity with Eqn. (55), we have the inequality

$$1 > -k\tau + \tau(1-x_A)\frac{k\frac{E}{RT_0}\frac{T_a}{T_0}}{\left(1+\frac{T_a}{T_0}x_A\right)^2}. \tag{63}$$

Using Eqn. (62), the product $k\tau$ can be eliminated from the last expression and the stability criterion is obtained in the form[47]

$$\frac{\left(1+\frac{T_a}{T_0}x_A\right)^2 - x_A(1-x_A)\frac{E}{RT_0}\frac{T_a}{T_0}}{(1-x_A)\left(1+\frac{T_a}{T_0}x_A\right)^2} > 0. \tag{64}$$

We may note that when the stability condition is defined by the inequality (64), the inequality (57) becomes unambiguous.

If condition (64) is satisfied for all conversions, the so-called global stability obtains. The relations between the parameters E/R, T_a, and T_0 can then be found. For this purpose, it is necessary to know the values of x_A at which condition (64) is minimised.

Let

$$h = \left(1+\frac{T_a}{T_0}x_A\right)^2 - x_A(1-x_A)\frac{E}{RT_0}\frac{T_a}{T_0} > 0. \tag{65}$$

The value of x_A for which h is a minimum can be found from the condition $\partial h/\partial x_A = 0$:

$$x_{A_{min}} = \frac{\frac{E}{RT_0}-2}{2\left(\frac{T_a}{T_0}+\frac{E}{RT_0}\right)}. \tag{66}$$

On substituting Eqn. (66) in Eqn. (65), we obtain

$$h_{min} = \frac{\frac{E}{RT_0}\left[1+\frac{T_a}{T_0}\left(\left[1-\frac{1}{4}\frac{E}{RT_0}\right)\right]\right.}{\frac{T_a}{T_0}+\frac{E}{RT_0}}. \tag{67}$$

The stability of the ideal backmix flow reactor has been analysed by Van Heerden[58], who was the first to show that several stable states are possible. Bilous and Amundson[59] made a quantitative analysis of stability criteria on the basis of the equation for the non-steady state. Aris and Amundson[60] analysed the stability of the ideal backmix flow reactor without a regulator and also with a proportional regulator, which enhanced the stability. The results of the analysis were presented in the form of phase diagrams in terms of dimensionless concentration–temperature coordinates. The stability of the ideal plug flow reactor has also been analysed by Van Heerden[58].

The stability conditions for a semicontinuous reactor with a stirrer, taking into account the residence time of the reaction mass in the reactor, were formulated by Kafarov and Eremenko[61]. They also indicated scaling methods for reactors of different dimensions, with maintenance of stability conditions, which is very important in industrial practice.

Simchen[62] obtained a solution in the form of the transcendental equation $\exp(-E/RT) = a(T - T_w)$ (where a is a constant depending on the physical parameters of the system) for temperatures corresponding to the points of intersection of the heat gain and heat loss lines, taking into account the temperature of the reactor walls T_w.

The maximum permissible temperatures for a given conversion and selectivity in stirred reactors for parallel and consecutive reactions have been examined by Westerterp[63]. The practical difficulties encountered in the attempts to attain the required process temperature were demonstrated, using the synthesis of phthalic anhydride as an example. Liu Shean Lin and coworkers[64,65] analysed the stability of adiabatic and non-adiabatic reactors with a stationary catalyst bed. The mathematical model was reduced to an examination of the behaviour of the individual particles immersed in the gas stream, when the resistance to heat and mass transport is concentrated on the surface of the particles. An irreversible first-order reaction in the absence of longitudinal and radial gradients of gas flow rates was considered. The balance equations were solved numerically by the response curve method and a graphical interpretation of the solutions was given. The following findings were obtained for the adiabatic reactor. In the initial sections of the bed the stable state is attained relatively rapidly, compared with the output from the bed. At low temperatures the difference between the temperatures and concentrations in the gas and solid phases is almost negligible. These are kinetic conditions, since at low temperatures the chemical reaction is very slow. When the temperature of the particles is relatively high, the chemical reaction is accelerated and heat is rapidly evolved. The process becomes diffusion-dependent. A considerable difference between the concentrations and temperatures in the gas and solid phases then arises.

At a relatively low temperature of the gas at the inlet, the chemical reaction virtually does not take place via the bed and the concentration and temperature profiles are planar. On raising the gas temperature at the inlet, the conversion increases rapidly, becoming almost complete at a certain temperature (the temperature gradient in the bed is then almost zero). The higher is the concentration (partial pressure) of the component at the inlet to the bed the higher is the temperature of the exit gas and the chemical reaction is completed over a relatively short length of the bed. Different profiles are possible for the same temperature and concentration at the inlet and the system may be unstable, depending on the existence of local steady states and their multiplicity for individual particles.

If each particle along the axis of the bed had only one steady state, the reactor would be stable and there would be unique concentration and temperature profiles for all the initial temperatures and particle concentrations.

Due to the heat transmitted via its walls, in a non-adiabatic reactor there is instantaneous radial heat and mass transport in the reactor itself. The temperature within the bed can then be lower than the temperature of the inflowing gas and therefore under non-steady conditions the state of the particles may be different than in the adiabatic reactor. The temperature profile changes sharply as a result of slight change in the temperature of the gas at the inlet. The temperature and concentration profiles vary markedly with the coefficients of heat transfer from the particles in the bed to the gas and from the gas to the reactor walls. Furthermore, as in the adiabatic reactor, there is a possibility of the occurrence of non-unique temperature and concentration profiles, depending on the presence of a multiplicity of states for individual particles. The stability of the system is affected by the initial conditions, such as the initial temperature of the particles of the bed, the temperature of the inflowing gas, and the partial pressure of the reactant. These findings[64,65] agree with earlier investigations[66-68]. Barkelew analysed the stability of reactors with a stationary bed by introducing empirical dimensionless parameters[69].

The stability of contact-catalytic reactors was analysed in the widely recognised work of Boreskov[3], Slin'ko[54], Beskov[70], and others. In these studies the stability conditions were formulated, whereby it is possible to calculate the maximum permissible tube diameters in contact-catalytic apparatus for various synthetic processes. It has been shown that the contact-catalytic unit, consisting of two stable reactors, can have unstable states. The problems of the optimisation of the contact-catalytic apparatus for industrially important processes such as the oxidation of sulphur dioxide, ethylene, methanol, and others were also developed in these investigations.

Kafarov et al.[71] provided a mathematical foundation for the stability criterion. Approximate stability conditions were found[72] for a non-continuous ideal backmix flow reactor with regulation of the coolant temperature and the rate of reactant injection and also for the load period of a semi-continuous reactor with regulation of the coolant temperature. One of the possible ways of increasing the stability of the process in chemical reactors, consisting in setting up an automatic control system for the coolant temperature in the refrigerator and for the rate of injection of reactants as a function of the temperature of the reaction mass, was demonstrated.

Using Lyapunov's method, a number of investigators[60,73-75] analysed the stability of a reactor in the presence of non-continuous perturbations and various control systems. Hoftyzer and Zwietering[76] investigated the stability and control of the ethylene polymerisation process and established that, for certain versions of the set up, there are five possible solutions corresponding to stable states. The stability of chemical reactors for two-phase systems, taking into account the possibility of regulation, was investigated by Schmitz and Amundson[77]. Later Amundson and co-workers[78,79] developed mathematical methods for the analysis of the stability of tubular reactors.

VI. EFFECT OF DIFFUSION PARAMETERS ON CHEMICAL PROCESSES

Depending on the effect of *diffusion macrofactors*, chemical processes can be divided into (1) chemical processes under "kinetic" conditions, (2) chemical processes under diffusion-dependent conditions, and (3) chemical processes under mixed conditions.

A characteristic feature of chemical processes under kinetic conditions is that the rate of the chemical reaction itself is slowest, limiting the rate of the process as a whole, while the flow rates of the streams and their physical properties do not influence the process appreciably. In chemical processes under diffusion-dependent conditions the rate of diffusion of reactant to the reaction zone is rate-limiting and depends on the flow rates of the streams and their physical properties. A characteristic feature of processes occurring under mixed conditions is that the rates of chemical reaction and diffusion are comparable.

The possibility, in principle, of isolating the rate-limiting stage is based on the fact that in many cases a complex process consists of several consecutive stages. The slowest rate is rate-limiting. The methods available for the determination of the rate-limiting stage of the process, i.e. of determining whether diffusion-dependent or kinetic conditions predominate, are as follows[80].

1. Determination from the temperature coefficient of the overall rate of the process. If on changing the temperature by 10 deg the overall rate of the process changes by a factor of 2-3, then, as a rule, the chemical reaction itself is the rate-limiting stage. On the other hand, if a 10 deg temperature change entails a change in the rate of the process by a factor of less than two, mass exchange is the rate-limiting stage. In intermediate cases the reaction takes place under mixed diffusion-dependent and kinetic conditions.

2. Determination from the apparent order of the reaction. If the order is not unity, the rate-limiting stage is the chemical reaction. However, if the order is unity, the question of the rate-limiting stage remains open, since the mass exchange process is also directly proportional to the concentration.

3. Determination from the variation of the overall rate of the process with its hydrodynamic conditions. If the rate of the process is independent of the hydrodynamic conditions, the rate-limiting stage is either mass exchange or simultaneously mass exchange and the chemical reaction (i.e. the reaction takes place under mixed diffusion-dependent and kinetic conditions).

Under diffusion-dependent conditions the rate of the reaction, like the diffusion coefficient, varies relatively little with temperature but changes with the flow rate of the gas stream, like the Nusselt diffusion number[16], i.e. is proportional to the gas flow rate raised to the power of 0.4-0.5 for outside flow and to the power of 0.8 for turbulent motion in inside flow.

Under diffusion-dependent conditions the rate of reaction in no way depends on the concrete features of its chemical mechanism; the rates of a wide variety of reactions differ only because of differences in the diffusion coefficients of the reactants and in the case of reversible reactions because of differences in the equilibrium conditions. All the reactions under diffusion-dependent conditions are of first order with respect to the reactant concentration at a constant total pressure. The order of the reaction with respect to the total pressure differs from the order with respect to the concentration.

Diffusion-dependent conditions obtain at high reaction rates and low rates of diffusion, i.e. at high temperatures, high pressures, and low gas flow rates. On the other

hand, at low temperatures, low pressures, and high gas flow rates, kinetic conditions obtain. In the intermediate region mixed diffusion-dependent and kinetic conditions obtain, where the effect of both diffusion and reaction kinetics is significant. The effects of chemical reactions and diffusion can be taken into account quantitatively (using the additivity principle) and simultaneously only for linear systems, i.e. first-order reactions. The solution of non-linear problems usually reduces to finding a rate-limiting stage in the process.

Examination of the model of the contact-catalytic chemical process from the standpoint of transport phenomena shows that the process takes place simultaneously at microscopic and macroscopic levels. Axial and radial dispersion of heat and mass between the particles, transport of heat and mass between the phases, and transport within the particles take place. Much work has been done in recent years on the study and analysis of transport phenomena in contact--catalytic processes. Since these studies cannot be considered here, the reader is referred to two detailed reviews on this topic [40,81] and also to recent monographs [82,83].

The studies of chemical processes on free surfaces in gas–liquid, vapour–liquid, and liquid–liquid systems have been attracting increasing attention in recent years. The so-called "extractive" reactions, involving the addition of an immiscible solvent to a homogeneous system during chemical reaction in order to remove a side-product or the required product, have been finding increasing application in chemical industry. The chemical process and extraction are carried out continuously [84-87]. A similar principle is used in the application of absorption and fractionation [88]. The effect of mixing on the chemical reaction in liquid–liquid and gas–liquid systems, which is important under these conditions, has been studied by a number of investigators [89-93]. It has been shown that, in a reaction system with mixing, physical equilibrium between the phases may not be attained.

In the construction of mathematical models of chemical processes in two-phase systems, usually one of two possible models is adopted for each phase: the model with centralised parameters and the model with distributed parameters. The model with centralised parameters includes one independent variable, namely time. In models with distributed parameters the variation of variables with time and space is considered, which leads to partial differential equations. The mixing process in homogeneous systems can be described by the model with centralised parameters with an accuracy which is satisfactory for practical purposes. In heterogeneous systems the model with centralised parameters can be applied to the continuous phase and the model with distributed parameters to the disperse phase. In contact-catalytic processes with a solid phase, the catalyst may be regarded as a disperse phase. On the other hand, if the disperse phase is a liquid, the occurrence of internal circulation, coalescence, and redispersion permits the assumption of ideal mixing within the limits of each drop and therefore the model with centralised parameters may be applied to both phases.

However, in a disperse phase account must be taken of the scatter of the values of the dependent variables, i.e. of the presence of a definite distribution of the medium particles (drops) with respect to the residence time (the "age"). If, on the other hand, the drops coalesce and undergo redispersion at a very high rate, the distribution may be evened out. This is most likely for two liquid phases and less likely if the disperse phase is a gas. In practical calculations, it is usually assumed that there is no definite distribution in the disperse phase.

In the construction of mathematical models, one of the following schemes is adopted: (1) the rates of heat and mass transport between the phases are high and the rate of conversion is rate-determining or (2) the rates of transport at the interface are high and therefore the system is in physical equilibrium. According to the second scheme, mass transport is rate-determining, i.e. under these conditions the rate of reaction is so high that the course of the process as a whole is determined by the rate of transport of the reactants. The reactants and the reaction products in the reacting phase are in chemical equilibrium and their concentration in this phase is defined by an equilibrium constant. In intermediate cases the concentrations do not correspond to equilibrium relations and the temperatures of the phases are not the same, and therefore it is then necessary to take into account all the rates of the process.

Various combinations of the above models are possible in cases where the reactions take place at different rates in one or two phases. For example, the reaction may be so fast in one phase that the reaction components are in chemical equilibrium, and the overall rate of reaction is then determined by the conversion in the second phase. More complex situations can also arise in the presence of consecutive, parallel, and other complicated reactions. A number of problems of this kind have been examined in the work of Schmitz and Amundson [77] (quoted previously), who investigated the conditions of stability and control in reactors with stirred two-phase systems. A number of studies on the attainment of conditions corresponding to the occurrence of reactions on free surfaces in liquid-phase systems have been made by Abramzon and coworkers [94]. The studies on chemical reactors for gas–liquid systems have been reviewed by Teller [95].

The effect of circulation on chemical processes and calculations on circulation systems have been described in Nagiev's monograph [96]. Calculations on contact-catalytic processes taking into account circulation are quoted in Orochko's monograph [97] and in a number of later papers of Zinov'eva and Orochko [98]. They also consider the effect of heat and mass transport on chemical reactions.

The general method for the construction of mathematical models for complex chemical reactions which allow the calculation, with the aid of analogue computers, of the kinetic characteristics of reactions of any order taking into account the non-isothermal conditions of the process, and also the calculation of the parameters of reactor control systems, has been described by Biryukov and Kafarov [99]. They also described the ideas underlying the element-by-element calculation by analogue computers of the parameters of various models of industrial chemical reactors [100-102].

GAS CHROMATOGRAPHY IN CATALYTIC STUDIES

L. Ya. Gavrilina and D. A. Vyakhirev

CONTENTS

I. Introduction 135

II. Qualitative and quantitative analysis of the products of catalytic processes 135

III. Catalytic processes in a microreactor (radiochromatography). The study of catalytic reactions under chromatographic conditions 138

IV. Gas-chromatographic study of the physicochemical properties of catalysts 139

I. INTRODUCTION

The development of gas chromatography opens up wide possibilities in the study of catalytic processes. Gas chromatography makes it possible to obtain in a relatively short time information about the composition of the starting materials and products in catalytic processes, facilitates tests on catalysts, and greatly simplifies the experimental technique. A number of examples have been described of the successful use of gas chromatography in the analysis of the products of catalytic processes such as hydrogenation [1-5], dehydrogenation [6-8], isomerisation [9-12], dealkylation [13-15], oxidation of organic and inorganic substances [16-18], polymerisation [19-21], and reactions of organosulphur compounds derived from petroleum [22-24] and of other substances.

In many cases the method in which the catalytic reaction is performed in a flow microreactor attached directly to a chromatographic column proved very fruitful [25-29]. The use of labelled atoms in radiochromatography has been an effective means of studying the mechanism of catalytic processes [28,30,31].

Considerable interest attaches also to catalytic reactions under chromatographic conditions [30-33], whereby it is possible to obtain rapidly new, valuable data on the mechanism and the kinetics of the process and on the properties of the catalyst and their variation with time.

Finally, gas chromatography is a rapid method for the determination of the isotherms and heats of adsorption, the specific surfaces of catalysts, and their surface structure, acidity, and catalytic activity [34-39].

II. QUALITATIVE AND QUANTITATIVE ANALYSIS OF THE PRODUCTS OF CATALYTIC PROCESSES

The study of the majority of catalytic processes is impossible without qualitative and quantitative analysis of the initial materials and the reaction products. In these studies gas chromatography often proves to be the most effective analytical method both in laboratory tests and in the control of industrial processes [40-44].

The methods of analysis of the products of catalytic processes must as a rule meet very stringent requirements, particularly if the reactions are fast and rapid analysis is necessary. For this reason, the shortening of the duration of analysis while maintaining adequate capacity for separation and adequate precision is one of the principal requirements which must be satisfied by a gas-chromatographic method. In many catalytic processes very complex mixtures of substances of different types are obtained, the concentrations of the individual components varying between very wide limits [6,40,41,45]. It is very difficult to separate such mixtures and to analyse them qualitatively and quantitatively.

On the other hand, the determination of trace impurities in the starting materials or the catalytic reaction products is no less complex a problem [46]. The total analysis of the products is frequently interfered with by the presence in the latter of unstable or reactive compounds, substances tending to polymerise, and also water [16,47-49]. It is therefore often necessary to perform extensive preliminary experiments in order to find the most favourable conditions for the chromatography of such mixtures.

Qualitative analysis. Qualitative analysis in gas chromatography is usually concerned in the first place with

the determination of the retention time (or volume)[50-54]. Several methods are known for the identification of chromatographic peaks, based on the measurement of these quantities: (1) determination of the relative retention volumes of the substances being analysed and the pure compounds, in relation to some standard, on several liquid phases; (2) the use of the variation of the logarithm of the retention volume of the given substance with the number of carbon atoms, which is linear within a homologous series; (3) determination of the relation between the logarithm of the retention volume and the factor $Z = T_b/T$, where T_b is the boiling point of the substance and T the column temperature; (4) the use of retention indices (the Kováts method).

Until recently the first method was most frequently employed. A large number of tables and individual data on the relative retention volumes of substances of a wide variety of classes of various liquid phases and adsorbents have been published[50-54]. However, the use of these data is difficult because different workers have used different substances as standards and have made measurements at different temperatures, as a result of which the data are often inconsistent[55].

More reliable results are provided by plots of the logarithms of the retention volumes against the number of carbon atoms or against the boiling points of substances within a single homologous series at a given column temperature. Extensive experimental data on the identification of the homologues of various classes of organic compounds on eighteen liquid phases have been presented by Tenney in the form of such graphs[56].

Zhukhovitskii and Turkel'taub[53] proposed to use the relation between the logarithm of the retention volume of a given substance and the factor Z, defined as the ratio of the boiling point of the substance and the column temperature. For members of a single homologous series, this relation is approximately linear. The identification reduces to finding the boiling point of the test substance from the plot and comparing it with tabulated data. An advantage of this method of identification is that it permits measurements at different temperatures, which is inevitable when the mixture contains components with sharply different boiling points.

Recently the retention indices proposed by Kováts[57-61] have been receiving an increasing amount of recognition. This method of qualitative identification is based on the use of the familiar relation between the logarithms of the retention volumes and the number of carbon atoms in straight-chain paraffins, the logarithms of the retention volumes of such straight-chain paraffins being adopted as an index I scale. In this scale the retention indices for straight-chain hydrocarbons are assumed to be equal to the number of carbon atoms multiplied by one hundred and the indices of other substances, which have intermediate values, are found from the formula

$$I = 100\frac{\ln V_R - \ln V_{R(n\text{-}C_n)}}{\ln V_{R(n\text{-}C_{n+1})} - \ln V_{R(n\text{-}C_n)}} + 100n,$$

where V_R is the true retention volume of the test substance (i.e. the retention volume corrected for the dead space in the column), $V_{R(n\text{-}C_n)}$ the true retention volume of a straight-chain paraffin with n carbon atoms, and $V_{R(n\text{-}C_{n+1})}$ the true retention volume of a straight-chain paraffin with $n + 1$ carbon atoms; we have

$$V_{R(n\text{-}C_n)} \leqslant V_R \leqslant V_{R(n\text{-}C_{n+1})}.$$

The method of expressing the retention volumes in the form of indices has a number of advantages, the most important of which are as follows.

1. The standard is not a substance selected at random but the homologous series of straight-chain hydrocarbons, which enhances the precision of the determination of the indices, and the latter can be reproduced in other laboratories with greater reliability.

2. The difference between the retention indices for a single substance on two liquid phases, polar and non-polar, characterises its chemical nature, which facilitates the qualitative analysis. At the same time, this difference can serve as a quantitative characteristic of the polarity of the chosen liquid phase.

3. When literature data on the retention indices are available, qualitative analysis without pure substances is possible, which is of considerable interest in the analysis of multicomponent mixtures of unknown composition[61].

4. The Kováts indices vary with temperature much less than the simple relative retention volumes, which facilitates the use of literature data obtained at different temperatures[62].

The system of Kováts indices is probably the most universal and the most promising, as evidenced by the fact that an increasing number of investigators have used them in their studies. At the present time tables of retention indices are being compiled for substances of different classes on a wide variety of liquid phases[58,60,63]. In the determination of the retention indices it is essential to exclude as far as possible the effect of adsorption on the solid support, which is particularly pronounced in the chromatography of polar substances[64,65]. In this connection the work carried out to find new supports and to improve the properties of the commonly used inert supports merits attention[66-84]. The technique of liquid phase deposition also has an important role[85].

In the study of new catalytic processes, whose products consist of complex mixtures of unknown composition, it is desirable to check the results of identification based on the retention time or volume by another independent method. Infrared spectroscopy and mass-spectroscopy have found very wide application recently in the analysis of fractions emerging from gas-chromatographic columns[1,86-99]. The combination of gas chromatography with nuclear magnetic resonance is of considerable interest. For example, using this combination of methods, it proved possible to identify the products of complex catalytic processes, such as the condensation of isobutene with formaldehyde[45] and others[100,101]. Examples of the application of polarography in the analysis of fractions eluted from the chromatograph have also been described[102].

In the analysis of complex mixtures preparative gas chromatography, in which considerable advances have now been made[103-107], may prove very useful. Frequently in the identification of chromatographic peaks use is made of chemical reactions specific to pure substances or classes of substances, which are carried out either with the initial mixture to extract or convert a number of products or with fractions collected at the outlet from the chromatograph[108-112]. A method of carrying out such reactions directly in the injector containing the test sample in the vaporised state has been described[109,110].

Chemical reactions can also be conveniently performed in a reactor connected to the chromatograph and the carrier

gas source. The reactor is filled with a suitable reagent or catalyst and maintained at a specified temperature, the reactants being introduced with the carrier gas. For example, in the qualitative analysis of substances of different classes the latter may be catalytically hydrogenated to the corresponding hydrocarbons, which are more readily identified [113-116].

Dravert and other investigators [117-121] extended the range of reactions which can be carried out in a microreactor — they converted the starting material into ethers, saturated and unsaturated hydrocarbons, etc. They showed that this method (which they called reaction chromatography) is not only a means of qualitative analysis but can also be used for quantitative determinations. In many cases it leads to a simplification of the chromatographic process, particularly if the mixture to be analysed contains high-boiling polar substances (for example, alcohols, glycols, acids, hydroperoxides, etc.) [122,123].

A number of workers [124-126] have used pyrolysis with subsequent chromatographic analysis of its products for the qualitative identification of the components of complex mixtures and the analysis of complex organic substances and polymers. The resulting chromatograms are compared with the chromatograms of the pyrolysis products of the substances which are expected to be present. The chromatogram of the pyrolysis products of a compound constitutes a characteristic spectrum, resembling the mass spectrum. The ratios of the peak intensities (heights) may serve as a qualitative characteristic of a given substance.

The literature on reaction chromatography, including pyrolysis, has been reviewed by Berezkin and Gorshunov [127].

Quantitative analysis. Quantitative analysis in gas chromatography is based on the calculation of chromatograms. There are several methods of calculation, depending on the parameters of chromatographic peaks used [53,128]. In practice, the peak area is normally employed as the parameter in the calculation. A number of methods have been described for the determination of peak areas [53,129-134]. In order to obtain accurate quantitative results, it is important to choose the most suitable method for each particular case, depending on the magnitude and shape of the chromatographic peaks. It should also be noted that the use of integrators greatly facilitates the measurements and yields accurate results when all the peaks in the chromatogram are fully separated, regardless of their shape [135-137]. When the separation is incomplete, quantitative analysis based on a detailed study of the shape of the peaks and the mode of their superposition is possible. Several methods for the calculation of incompletely resolved peaks have been described [134,138].

The ratio of peak areas is usually not the same as the ratio of the concentrations of the mixture components. In the first place, this is due to the different sensitivities of the detector to different substances and in the second place to the non-linearity of the detector response. The effect of these factors on the results of quantitative analysis can be taken into account by means of calibration against pure substances and artificial mixtures. Usually three methods of calibration are employed: the method of absolute calibration, the method of internal normalisation (taking into account the coefficients of the sensitivity of the detector to different components), and the internal standard method. The applicability of a particular method depends on the qualitative composition of the mixture to be analysed, on the concentration ratios of its components, on the properties of the detector (the range of linearity, sensitivity, etc.), and certain other factors. This problem has been adequately treated in monographs on gas chromatography [53,54,128] and in the recently published review of Andreev et al. [134], where molar correction coefficients for substances of different classes and detectors of different types have been tabulated.

In the analysis of the products of catalytic processes, both under laboratory and industrial conditions, the problem of the choice of the correct method of sample injection into the chromatograph frequently arises, since it determines the quality of the separation and the reproducibility of the quantitative results [53,139]. At the present time gaseous samples with accurately specified volumes can be most readily introduced by means of dosimetric taps of different designs [128,140-142]. For this reason, an attempt is often made to meter out the liquid samples in the vapour phase. The problem then reduces to the design of sampling taps which would remain gas-tight at an elevated temperature (to prevent the condensation of the mixture components) and which would ensure the required reproducibility of the metering [142-144]. When such taps are present, vaporised mixtures of products of catalytic processes can be analysed directly at the outlet of the reactor without preliminary condensation and trapping, which greatly shortens the duration of the analysis and simplifies the experimental method.

Liquid and solid samples are usually introduced by means of microsyringes, micropipettes, sealed tube breaking devices, and certain other procedures [54,145-147]. All these methods have a number of disadvantages which must be taken into account in the experiments to reduce their effects. Among all the devices, microsyringes are preferred [148]. Reactive substances are introduced in sealed tubes [145].

Let us now consider briefly the methods of accelerating gas-chromatographic analysis, since frequently the duration of the study of a catalytic process is determined by the rate of analysis of its products. The problem of the acceleration of chromatographic separation is indissolubly linked to the efficiency of the column, the selectivity of the liquid phase or the adsorbent, and also the retention time. In many cases involving a high degree of separation the duration of analysis may be shortened by decreasing the proportion of liquid phase, by increasing the temperature of the column and the flow rate of the carrier gas, and by using as the latter hydrogen or helium which have low viscosities [149,150].

The separation of multicomponent mixtures over a wide range of boiling points of the components is greatly improved if the column temperature is increased during the analysis, which is achieved by temperature programming [151-153] and by a chromathermographic technique [53,154,155]. To shorten the duration of analysis, it is convenient to use surface-porous adsorbents and carriers, with pores only at the surface itself, for example porous glasses [156], glass microbeads which have been etched or covered by a layer of a highly dispersed substance [75,157], and other materials. The analysis can be greatly accelerated by decreasing the column diameter [158] and by employing capillary chromatography [53].

Apart from reducing the time of separation, chromatography at reduced pressures provides more favourable separation conditions. It is then possible to reduce considerably the column temperature (since the volatility of the components increases), which enhances the selectivity of the liquid phase and analysis of thermally unstable substances becomes possible [159-161]. Reaction gas chromatography may be used for

the same purpose, whereby high-boiling polar substances can be converted into readily volatile compounds [117-119].

A number of workers have attempted [162,163] to calculate theoretically the minimum time for analysis in capillary and packed columns. Examples of the separation of multicomponent mixtures during the periods of the order of one minute have been given. The chromatograms are recorded with the aid of an oscilloscope [150].

III. CATALYTIC PROCESSES IN A MICROREACTOR (RADIOCHROMATOGRAPHY). THE STUDY OF CATALYTIC REACTIONS UNDER CHROMATOGRAPHIC CONDITIONS

The advantages of the gas-chromatographic method of analysis are most fully shown in the study of catalytic processes in a microreactor attached directly to the separating column of the chromatograph. Either inert gases or gaseous starting materials (H_2, O_2, and others) are used as the carrier gas. The remaining starting materials are introduced into the reactor periodically and are transferred by the carrier gas through a layer of catalyst into the chromatographic column, where the products and the unreacted components of the initial mixture are separated. By carrying out the process in a microreactor, it is possible to investigate over a short period the activity and selectivity of a large number of catalysts while varying various parameters (temperature, space velocity, pressure, etc.) [28,29,164-166].

Catalytic processes in a microreactor are as a rule fast and analysis of the products is the rate-limiting stage in the investigation of reactions and catalysts. For this reason, gas chromatography, which is one of the fastest analytical methods, is the most convenient in this case. In the study of catalytic processes in a microreactor, it is essential to exclude possible analytical errors due to, for example, the sorption of substances on the catalyst, the non-identity of the conditions obtaining in the calibration and in the analysis, the inadequacies in sample injection, etc. It is essential to achieve satisfactory reproducibility of the quantitative chromatographic analysis, since in each experiment it is possible to obtain only one chromatogram. At the present time the system comprising a chromatograph with a microreactor is widely used in the study of both the catalysts themselves [167] and various catalytic processes: hydrogenation and dehydrogenation [25,26], oxidation [27,168], cracking [28], polymerisation [19], and others.

In the study of the molecular mechanism of reactions, tracer atoms and radiochromatography may prove very useful. The essential feature of radiochromatography is the addition to the initial mixture of one of the components which is radioactively labelled. The products of the catalytic reaction are separated and analysed in a chromatograph with two detectors connected in series, for example a katharometer and a radiometric cell. Comparison of the chromatograms obtained with the aid of the two detectors shows which products can be obtained from the substance labelled with a radioactive isotope [28,169]. If a labelled substance, which according to the postulated possible mechanisms of the process is an intermediate, is added to the starting materials, then, by measuring the specific activity of the final products, it is possible to investigate the mechanism and kinetics of the individual stages of the reaction (Neiman's method) [170-172]. Such investigations are usually performed using a microcatalytic apparatus, since the study of the process in a microreactor requires only small amounts of the starting materials. Of course, the results obtained in a microreactor cannot describe the process as a whole. The selectivity of the catalyst may change on going to larger apparatus. It is also possible that under conditions obtaining in the microreactor optimum operation of the catalyst is not always achieved and therefore caution must be exercised in approaching the problem of catalyst selection on the basis of such data alone. However, microcatalytic apparatus with chromatographs can be used successfully in the study of the mechanism of catalytic processes.

Catalytic reactions under chromatographic conditions are more specific. This method is used in the study of both various types of reaction and of the changes in the catalysts during the experiments (exploitation, poisoning, and regeneration) [30-33,173,174]. A microreactor with a catalyst is also used in catalytic reactions under chromatographic conditions. The starting material is introduced as a separate sample (pulse) into the reactor and is transferred by the inert carrier gas or by a gaseous reactant to a layer of catalyst. The reaction products and the starting materials are separated on the catalyst itself and are analysed at the outlet from the reactor by means of a suitable detector.

The conditions of catalytic reactions in pulse chromatography differ from those usually encountered. Thus under chromatographic conditions the intermediate and final products are separated from the starting materials and therefore the interactions between them and the reverse reactions are almost completely excluded. The conversion then increases sharply. In those cases where any one product is not separated from the starting material on the catalyst, it is possible to investigate the process with the latter inhibited by its products and to assess the effect of such inhibition.

Furthermore, under chromatographic conditions the reactants are freed from impurities (except for the impurities present in the carrier gas), which may be catalyst poisons, inhibitors, promoting agents, or initiators. The effect of these impurities can also be investigated [173].

The characteristic features of the chromatographic conditions make it impossible to use this method to investigate the reactions of two or more starting materials in an inert carrier gas, since, as a result of the chromatographic separation of the initial mixture, the reactant molecules do not meet either in the gas phase or on the catalyst surface.

The chromatographic conditions can be conveniently used for reactions of the type

$$A \rightleftarrows B + C,$$

which are fairly fast but have low equilibrium constants [32]. However, an example of reactions of the type

$$A + B \rightarrow C + D.$$

under chromatographic conditions has been described [175]. One of the starting materials is then either continuously passed through the catalyst in the stream of the carrier gas or introduced as a pulse, mixed with other components. Probably in this case the starting materials are not separated in the reactor and therefore reaction between them is possible.

Roginskii and coworkers made a theoretical analysis of heterogeneous catalytic reactions of various orders under conditions of ideal linear chromatography and derived

equations for the rate constants and the activation energies for first-order reactions, which they used in the study of the dehydrogenation of cyclohexane to benzene on a number of catalysts [33]. They showed [176] that the rate constants for the reaction can be determined not only from the degree of conversion at various carrier gas flow rates but also from the shape of the product output curve obtained at a single carrier gas flow rate, on the assumption that under the experimental conditions the adsorption isotherm of the product on the catalyst is linear.

The use of radioisotopes and of an additional radiometric detector provides in this case too an effective means of determining the mechanism of the process when the latter is carried out under chromatographic conditions. For example, confirmation has been obtained of the absence of the reverse reaction in the dehydrogenation of cyclohexane on a platinum catalyst in an inert carrier gas [31] and in the dehydrogenation of butenes to divinyl under chromatographic conditions [177].

The results of the study of a catalytic process under chromatographic conditions provide additional information both about the process itself and about the state of the catalyst. The possible advantages of these conditions in industry have not so far been considered. The possibility that in some processes pulse conditions may prove effective cannot be excluded.

IV. GAS-CHROMATOGRAPHIC STUDY OF THE PHYSICOCHEMICAL PROPERTIES OF CATALYSTS

In heterogeneous catalysis chemical processes are accompanied by adsorption. Therefore the study of the adsorption properties of catalysts constitutes a very important problem. The main characteristics of adsorbents are their structural properties (specific surface, porosity, i.e. quantities which are independent of the properties of the substances adsorbed) and their properties determined by the nature of the adsorbent–adsorbate system (adsorption energy, adsorption isotherm, and others).

Since in gas chromatography the retention time (volume) and the shape of the peak due to a given substance depend on the properties of the adsorbent and the substance adsorbed, it was natural to consider the reverse problem: to investigate on the basis of chromatographic data the properties of adsorbents and catalysts with the aim of reducing the time required for chromatographic investigations. It was found that, with certain assumptions, it is possible to establish a mathematical relation between the specific retention volume of a given substance and the specific surface of the catalyst [36] and between the shape of the chromatographic peak and the adsorption isotherm [178], while the temperature variation of the retention volume makes it possible to determine the heat of adsorption [39]. A chromatographic method for the determination of the activity of certain catalysts has also been described [37].

In most of the studies dealing with the determination of the surface area of adsorbents and catalysts by gas chromatography, use is made of the relation, derived by Wilson, between the form of the chromatographic curve and the form of the adsorption isotherm in the absence of complications associated with the kinetics of the adsorption and longitudinal diffusion (conditions of equilibrium chromatography) [35,179-181]. On the basis of chromatographic data, it is possible to obtain adsorption isotherms on catalysts at different temperatures and to determine the absolute specific surface of the catalyst. Either adsorption–desorption curves or display chromatograms are then employed.

However, more accurate results are given by Nelsen and Eggertsen's thermal desorption method [34,182,183], in which the conditions of equilibrium chromatography are not required, this being particularly important in the study of finely porous adsorbents and catalysts. This method constitutes the basis of gas-chromatographic sorption meters [184,185].

By using as adsorbates substances of different molecular size, it is possible to estimate the nature and distribution of the pores with respect to radius [186]. A method has also been described for the determination of the relative surface area, based on the determination of the specific retention volume V_g at low concentrations, which is proportional (within the limits of experimental error) to the specific surface S_g: [36,187-189]

$$S_g = AV_g \qquad (1)$$

where A is a proportionality coefficient, which depends on the nature of the adsorbent–adsorbate system and on temperature. Eqn. (1) has been tested on a large number of catalysts [36]. The method is recommended for the measurement of the variation of the catalyst surface during its operation and also for rapid estimates of the surface areas of adsorbents and catalysts of the same chemical type.

Kiselev and coworkers [190,191] suggested that the retention volume of a given substance, referred to unit area of the adsorbent, be used as a characteristic of adsorbent–adsorbate systems:

$$V_s = \frac{V_g}{S_g},$$

where V_s is independent of the adsorbent surface area and reflects mainly the properties per unit surface.

The gas-chromatographic method can also be used to investigate chemisorption. Adsorption isotherms and isochores have been obtained for hydrogen on a number of metals and the kinetics of its chemisorption have been studied [192]. Such data may be useful in the investigation of hydrogenation catalysts.

The gas-chromatographic method has also proved an effective means for the investigation of catalysts with acid properties. Thus the total number of acid centres and the strength of their acidity under conditions obtaining in the operation of the catalyst can be found from the amount of chemisorbed ammonia (or an organic base), which can be readily obtained from a frontal chromatogram [183,193]. The effect of surface acidity on the adsorption of hydrocarbons and on catalyst activity has also been investigated with the aid of gas chromatography [38,193,194].

Misono et al. [38] proposed a gas-chromatographic method for the simultaneous determination of the distribution of acid centres with respect to the strength of their acidity and catalytic activity under conditions obtaining in the operation of the catalyst. The method consists in the determination of the retention volume and the heat of adsorption of benzene (a weak base) on the catalyst at different surface coverages of the latter with pyridine (a strong base). From these data, it is possible to construct the curve representing the distribution of the acid regions with respect to the strength of their acidity in terms of the benzene heat of adsorption scale, assuming that pyridine blocks such regions, starting with the most acid ones. If instead of benzene a reactant is admitted to the catalyst, it is possible to investigate, on the basis of the reaction products corresponding to different degrees of poisoning of the acid

centres by pyridine, the activity and selectivity of the catalyst in relation to different types of reaction, depending on the acid strength.

The results obtained in the study of the distribution of acid centres with respect to their acid strength obtained by the above method have been confirmed qualitatively by an indicator method. The advantage of the chromatographic technique is that the determination of the acidity is performed under the conditions of the catalytic process itself. Furthermore, the colour of the catalysts, which interferes with indicator measurements, is without importance in the chromatographic method.

The application of gas chromatography in the determination of the heat of adsorption is based on the fact that, under conditions of ideal chromatography (when the isotherm is linear), the logarithm of the retention volume of the given substance is proportional (after certain necessary corrections) to the free energy of adsorption, and the heat of adsorption can be found from the slope of the linear plot of the logarithm of the adsorbate retention volume against the reciprocal of absolute temperature[39,195,199]. It is assumed that the effect of diffusion and of the finite rate of mass exchange is slight and may be neglected[199]. A chromatograph designed specially for the measurement of heats of adsorption has been described[200]. While it cannot replace the more reliable and detailed calorimetric technique, the chromatographic method permits rapid, simple, and fairly accurate determination of the heat of adsorption.

Comparison of the heats of adsorption determined by both methods shows good agreement in most cases. The discrepancy between the results is mainly due to the different surface coverages used in the two methods[39,198]. Since gas chromatography is highly sensitive, it permits the determination of the heat of adsorption at surface coverages so low that there is no interaction between the adsorbed molecules even when they are capable of association. On combining this method with some other, applicable to higher coverages (for example the calorimetric method), it is possible to determine the energy of association in the adsorption layer. The energy of the hydrogen bond between molecules of alcohols adsorbed on the surface of graphitised carbon blacks has been determined in this way[201,202].

The chromatographic method makes it possible to extend the range susceptible to investigation to temperatures of 300–500° and to measure the heat of adsorption under conditions close to those in a catalytic reaction. These advantages are lacking in the calorimetric method and in the method involving the calculation of isosteric heats from adsorption data, which are usually employed[197,199]

1. Reactions with inorganic compounds 148

2. Reactions with organic compounds 148

V. Uses 154

I. INTRODUCTION

The rapid development of investigations into the preparation and chemistry of perchloryl fluoride $FClO_3$† has made it available not only for study, but also for practical applications.

The marked difference between the exceptionally stable $FClO_3$ and the other unstable oxide fluorides of chlorine has made it of special interest. The high symmetry of its molecule and the great similarity in electronegativities of fluorine and the ClO_3 group explain the stability of perchloryl fluoride and its chemical behaviour as a two-centre electrophilic substance. It is still the only reagent for perchlorylation (introduction of the ClO_3 group) at carbon in organic compounds and at the same time it exhibits the properties of a selective fluorinating agent. The oxidative dimerisation and oxofluorination which can be effected with the aid of $FClO_3$ are reactions of independent interest. The fact that the perchloryl fluoride molecule is made up of atoms of the most electropositive elements determines its behaviour as a strong oxidant.

The available literature on the properties of this compound has been very inadequately surveyed. Brief reviews in Japanese[1] and Chinese[2] have been published, but these dealt with only a small part of the literature. A Russian review[3] which recently appeared was principally devoted to the selective fluorination of steroids.

In the present review we aim to cover as completely as possible the literature on the production, physical properties, and reactions of perchloryl fluoride in the period from 1950 to mid-1965.

II. PRODUCTION OF PERCHLORYL FLUORIDE

Perchloryl fluoride was first obtained by Engelbrecht and Atzwanger[4] in 1952 by the electrolysis of a saturated solution of sodium perchlorate in anhydrous hydrogen fluoride, with a current efficiency of 10%.

A year earlier, Bode and Klesper, who investigated the action of elemental fluorine on potassium chlorate, reported the production of a compound of composition $FClO_3$,[5] which in reality was a mixture of chloryl fluoride $FClO_2$, chlorine, and perchloryl fluoride[6,7]; the last can be isolated in yields of up to 45%.[8] The fluorination was carried out in the solid phase using fluorine diluted with nitrogen at temperatures up to 50°C. The use of efficient cooling (-25°C) and strict control of temperature in working with undiluted fluorine, supplied at a low rate, allowed the yield of $FClO_3$ to be increased to 60%.[9]

† Better written ClO_3F (Ed. of Translation).

In addition to perchloryl fluoride, several gaseous products are formed in the reaction of potassium chlorate with fluorine: Cl_2, $FClO_2$, O_2, Cl_2O_6, and FCl.[8,9] To free $FClO_3$ from impurities it is passed through alkaline solutions of reductants and then condensed at liquid oxygen temperature. This method seemed so effective (after the treatment the proportion of impurities did not exceed 1.5%) that it was used without significant changes in all subsequent work on the preparation of perchloryl fluoride.

Note that both methods (electrochemical and the fluorination of chlorates by fluorine) have several drawbacks: the need to work with special metal apparatus, the difficulty of temperature control in solid-phase fluorination, low yields, etc.

Replacement of elemental fluorine by other fluorinating agents (ClF_3, BrF_3, SbF_5) did not give positive results: the yield of perchloryl fluoride was too low, and the main reaction products with potassium chlorate were $FClO_2$ and Cl_2.[8] Only the use of perchlorates instead of chlorates led to the development of convenient methods of making $FClO_3$.

When potassium perchlorate is heated (70–120°) in an excess of antimony(V) fluoride, perchloryl fluoride is formed in 50% yield. Other metal perchlorates (sodium, barium, magnesium) or perchloric acid can be used in this reaction[10].

Of other reactions, that of perchlorates with fluorosulphonic acid has been studied in greatest detail[11-17]. This method of obtaining $FClO_3$, which was proposed in 1956 by Barth-Wehrenalp[11], is now evidently the simplest and most convenient. Solutions of potassium perchlorate in fluorosulphonic acid are heated at various temperatures. Liberation of perchloryl fluoride starts at 50°, the reaction goes to completion with the temperature gradually rising to 85° or 110°. The yields of perchloryl fluoride vary within the range 50–80%[11-13]. If necessary the fluorosulphonic acid can be regenerated for reuse[12]. The great convenience of the method is that the reaction can be carried out in the usual glass apparatus; moreover the initial substances are available and cheap.

Unfortunately the mechanism of the process has been little studied. The initial suggestion[11] that the compound $(ClO_2)_2S_3O_{10}$ was formed as an intermediate was disproved after a more critical consideration[15,16]. It is now thought more probable that there is an acid–base reaction, expressed by the equation:

$$3\,HSO_3F + KClO_4 \rightleftarrows ClO_3^+ + 3\,SO_3F^- + H_3O^+ + K^+,$$

and the formation of $FClO_3$ is considered to be the result of the thermal decomposition of this equilibrium mixture[15].

With the aim of increasing the yield of perchloryl fluoride in the reaction of potassium perchlorate with fluorosulphonic acid the influence of various fluorine-containing additions was studied: BF_3, HF, SbF_3, and other metal fluorides[17]. Thus, the addition of 5–25 parts SbF_3 per 100 parts fluorosulphonic acid increases the yield of $FClO_3$ to 90% and over. Addition of BF_3 and HF also increases the yield to 85%. Unfortunately, the introduction of these has a bad effect on other aspects of the reaction: SbF_3 hinders the regeneration of fluorosulphonic acid, and BF_3 and HF require pressure for carrying out the reaction. Zinc, aluminium, silver, and lead fluorides, on the other hand, decrease the yield of perchloryl fluoride[17].

The highest yield of perchloryl fluoride (97%) was achieved with a mixture of fluorosulphonic acid and SbF_5 as fluorinating medium. Potassium, sodium, lithium, magnesium, barium, calcium, and silver perchlorates and perchloric acid itself undergo the reaction. Commercial reagents are used and their additional purification is not necessary; unlike all the previous methods the preparation of perchloryl fluoride by this method can be carried out at room temperature. At high temperature (100–135°) the reaction time is 1–10 min in all, which allows the process to be carried out continuously in a packed column. The purity of product obtained after the usual purification reaches 98% and over, air and carbon dioxide being present as trace impurities[18,19].

III. PHYSICOCHEMICAL PROPERTIES OF PERCHLORYL FLUORIDE

The physical and physicochemical properties of perchloryl fluoride have now been studied rather fully (see Table 1).

Under ordinary conditions perchloryl fluoride is a colourless gas with a characteristic sweetish odour. On cooling to -46.8° it condenses to a colourless liquid, which solidifies at -147.75°.

Unlike other compounds of fluorine with oxygen and chlorine (F_2O, $FClO_2$, $FClO_4$, ClF_3, etc.), perchloryl fluoride exhibits exceptional thermal and hydrolytic stability. Dry perchloryl fluoride is almost stable on heating to 500°[20] and is not hydrolysed in the slightest by water even on heating to 250–300°.[8] Perchloryl fluoride does not explode on detonation, but it forms explosive mixtures with certain organic substances[20], which must be taken into account in working with it.

Addition of an inhibitor is not needed for storing $FClO_3$ in either the liquid or the gaseous states. Dry perchloryl fluoride does not corrode most common metals[20]. It does not react with stainless steel, copper, or aluminium[21,22]; of organic materials, Kel-F oil — poly(chlorotrifluoroethylene)[22] — and ethylene–propylene rubber[23] are chemically rather stable towards it. Moist perchloryl fluoride reacts appreciably with vacuum grease and with mercury[24].

TABLE 1.

Physicochemical properties of perchloryl fluoride	Reference
Boiling point −46.68°C	24
Melting point −147.75°C	24
Density of liquid at 20°C 1.434 g ml^{-1} *	27
Critical parameters:	
temperature 95.17°C	27
pressure 53.0 atm	27
density 0.637 g ml^{-1}	8
molar volume 161 cm^3	8
Trouton's constant 21.97	8
Heat of vaporisation	
at boiling point 4.6 kcal $mole^{-1}$	24,27
at 25°C 3.5 kcal $mole^{-1}$	29
Viscosity of liquid:	
at −80°C 0.62 cP	29
at 0°C 0.219 cP	
at +60°C 0.139 cP	
Heat capacity of the liquid at 50°C 0.29 cal g^{-1} deg^{-1}	29
Density of the solid at −190°C 2.19 g cm^{-3}	31
Heat of fusion 916 cal $mole^{-1}$	24
Surface tension at −55.6° 21.3 dyn cm^{-1}	28
Ratio C_p/C_v at 24°C 1.12 ± 0.01	32
Entropy at 25° 66.51 e.u.	24

* It appears that the authors have used an equation for the liquid density as a function of temperature obtained in the range 131°K to 234°K[27] and has used this to give the figure quoted for density at 20°C! (Ed. of Translation).

Perchloryl fluoride is sparingly soluble in water, rather more soluble in organic solvents. Under ordinary conditions (25°, 760 mmHg) its solubility varies within the range 1.5–5.5 g litre^{-1}. The highest solubility is in dioxan, nitrobenzene, and dimethyl formamide [1,25,26].

Empirical equations have been obtained for the temperature dependence of vapour pressure [8,24,27], the density of the liquid [8,27], and the viscosity of the liquid [28]. Detailed information has been published on the heat capacity of liquid perchloryl fluoride at various temperatures [24,29,30], its surface tension [28], and viscosity [28,29].

Structure and Spectra

A compound of composition $FClO_3$ can have one of two structures:

(A) (B)

On the basis of the vibrational spectra, perchloryl fluoride was ascribed structure (B), having the chlorine as central atom and symmetry of type C_{3v}. [33,34] In fact, on comparing structures (A) and (B), the first should have the structure of a triangular pyramid and the second a tetrahedron with the chlorine atom at the centre. Structure (A) could not have symmetry of a type higher than C_s, whereas structure (B) corresponds to a symmetry of type C_{3v}. Accordingly, structure (A) would correspond to the presence of nine main bands active in the infrared region, and structure (B) to six bands. In the observed spectrum of $FClO_3$ there are only six main frequencies (see Table 2), which supports structure (B). The absence of a microwave spectrum for perchloryl fluoride is also considered as confirmation of the C_{3v} model [35].

The infrared spectrum of $FClO_3$ has also appeared in other papers [8,36]. The assignment of the frequencies, made on the basis of a comparison with the spectra of ClO_4^- and FCl, [33] was confirmed by investigation of the Raman spectra [37,38] (see Table 2) and of the high-resolution infrared spectrum in the 525–625 cm^{-1} region [34].

Some correlations with the infrared spectra of perchloryl fluoride have also been made. Thus, Sharp [39] notes a significant similarity in the infrared spectra of $FClO_3$ and FSO_3^-, which is isoelectronic with it; Robinson [40] found a linear relation between the frequencies of the symmetric and asymmetric stretching vibrations of the $-PO_2$ and $-ClO_2$ groups which is also suitable for many oxygen ligands.

TABLE 2. Vibrational spectra of perchloryl fluoride*.

Raman spectrum (Ref.37)	Infrared spectrum (Ref.33)	Assignment of frequencies
410 v.s.	405	ν_6 (e) rocking
549 s.	549	ν_3 (a_1) deformation ClO_3
587 m.	589	ν_5 (e) deformation ClO_3
695—724 m.	704	ν_2 (a_1) stretching $^{37}Cl-F$
	714	ν_2 (a_1) stretching $^{35}Cl-F$
1061 v.s.	1061	ν_1 (a_1) stretching Cl—O
1312 w.	1315	ν_4 (e) stretching Cl—O

* s strong; vs very strong; m medium; w weak.

The values of the frequencies here depend regularly on the electronegativity of the groups connected to the central atom.

The dipole moment of perchloryl fluoride is very low [35]; its accurate value of 0.023 ± 0.003 D was determined by using specially sensitive apparatus [41].

From measurements of the vapour pressure, heats of fusion and vaporisation, and the phase transformation temperatures, the entropy of perchloryl fluoride as an ideal gas at the boiling point has been calculated [24] to be 60.17 e.u. From the table of thermodynamic properties [42] this quantity was found to be 62.59 e.u. (interpolation). For a crystal with disordered arrangement of the F and O atoms at 0°K the difference in these quantities should be $R \ln 4 = 2.75$ e.u. The fact that the observed difference is slightly less than this value shows that there is a high degree of disorder in the arrangement of the fluorine and oxygen atoms in the perchloryl fluoride crystal [24].

Tallman and coworkers [31,43] give X-ray diffraction data and the density of crystalline perchloryl fluoride at liquid air temperature. From these data the authors assume that crystalline perchloryl fluoride has a tetragonal cell ($a = b = 7.66$ Å, $c = 5.31$ Å). The ^{19}F-NMR spectra of perchloryl fluoride have been discussed [44–46]. According to the interpretations in References 44 and 46 the observed spectra are the sum of $F^{35}ClO_3$ and $F^{37}ClO_3$ spectra, in each of which there is spin–spin interaction of the fluorine nucleus with the nucleus of the corresponding Cl isotope (both isotopes have spin $I = \frac{3}{2}$). The F–Cl spin–spin interaction which is observed extremely rarely in spectra here becomes observable, apparently owing to the low rate of relaxation of the chlorine nucleus, which is in turn due to the highly symmetrical environment of the chlorine atom (that is, the anomalously low constant of the quadrupole interaction of the chlorine nuclei). The very high chemical shift (320 p.p.m. to lower fields relative to CF_3CO_2H lines) shows the extremely low negative charge on the fluorine, in other words, the high degree of covalency of the F–Cl bond in the $FClO_3$ molecule. The fact that the electronegativities of fluorine and the ClO_3 group are close to one another is also confirmed by the absence of a dipole moment from $FClO_3$. [41]

The mass spectrum of perchloryl fluoride has been studied [47–49]. The potentials for the appearance and the relative intensities of the negative [47,49] and positive [49] ions in the mass spectrum have been determined. On the basis of these potentials hypothetical values have been advanced for the ionisation energies of the radicals obtained in the breakdown of the $FClO_3$ molecule, and the heat of formation of perchloryl fluoride has been estimated to be -5.3 ± 4 kcal × × mole^{-1} (in good agreement with the -5.12 ± 0.68 kcal × × mole^{-1} from another study [50]) and the dissociation energies of the bonds to be $D_{(O_3Cl-F)} = 60$ kcal mole^{-1} and $D_{av(Cl-O)} = 57$ kcal mole^{-1}. [49]

IV. REACTIONS OF PERCHLORYL FLUORIDE

As noted above, perchloryl fluoride exhibits high thermal stability and considerable stability to hydrolysis. Appreciable thermal decomposition of perchloryl fluoride is observed only at temperatures of ~500°C. Gatti and coworkers [51,52] studied the kinetics of thermal decomposition of perchloryl fluoride at 470–500°C over a wide pressure interval (5–1000 mmHg) by the equation

$$2FClO_3 \rightarrow 2ClF + 3O_2.$$

They found that the reaction is unimolecular and completely homogeneous (in quartz); the activation energy is 58.4 ± 2 kcal mole^{-1}.[52] The application of a dimensionless molecular transfer equation, based on similarity theory, to chemical kinetics, in particular for the example of thermal decomposition of perchloryl fluoride, allowed the main kinetic characteristics of the process (rate and activation energy) to be obtained without employing any assumptions about the mechanism[53].

1. REACTIONS WITH INORGANIC COMPOUNDS

Perchloryl fluoride does not react with dilute aqueous solutions of alkalis or thiosulphate, nor with solid alkalis[8,13].

Even at 250–300° the hydrolysis of $FClO_3$ is very slow. Quantitative hydrolysis is brought about by concentrated alkali solutions at the same temperature, according to the equation:

$$FClO_3 + 2\,NaOH \rightarrow NaClO_4 + NaF + H_2O.$$

However, in an alcoholic solution of potassium hydroxide perchloryl fluoride is readily split at 25°C with the formation of a precipitate of $KClO_4$, and KF is left in solution. This reaction can be used for the quantitative determination of $FClO_3$.[1]

The reaction of $FClO_3$ with sodium and potassium starts only at ~300°C, although it proceeds rather vigorously[8].

All these results led initially to perchloryl fluoride's being considered a chemically inert substance but, as appeared subsequently, this does not correspond with reality. Perchloryl fluoride is capable of reacting vigorously with several inorganic and organic compounds at moderate temperatures and even on cooling below 0°C.

Perchloryl fluoride reacts rather easily with liquid ammonia or its aqueous solutions[8,54] by the equation:

$$FClO_3 + 3\,NH_3 \rightarrow NH_4F + NH_4NHClO_3.$$

The reaction takes place quantitatively in a few hours. Sodium amide greatly accelerates the reaction in liquid ammonia. From the ammonium salt perchloryl amide, which could not be isolated pure, the silver, caesium, and potassium salts have been obtained: $AgNHClO_3$, $CsNHClO_3$, Cs_2NClO_3, $KNHClO_3$, K_2NClO_3, which are derivatives of the unstable amide of perchloric acid, $H_2N{-}ClO_3$. These salts, especially in the dry form, are sensitive to impact, friction, and the action of a flame.

Perchloryl fluoride oxidises potassium iodide. The reaction proceeds quantitatively on shaking for 4–5 h a solution of KI in 0.1 *N* acid with perchloryl fluoride[8]:

$$FClO_3 + 8\,I^- + 6\,H^+ \rightarrow Cl^- + F^- + 4\,I_2 + 3\,H_2O.$$

In his review Nakanishi[1], in referring to published data[55], states that oxidations involving $FClO_3$ depend to a considerable extent on the reaction temperature, the pH of the medium, and the concentration of the reagents. At high temperatures many reactions proceed explosively. For example, a mixture of $FClO_3$ and H_2S in certain proportions explodes at 150°. With a dilute mixture the rate of reaction at this temperature is low and the reaction is:

$$3\,FClO_3 + 4\,H_2S \rightarrow 4\,SO_2 + 3\,HF + 3\,HCl + H_2O.$$

Reaction with hydrogen chloride in the gas phase at 200–300° proceeds with the formation of chlorine by the equation:

$$FClO_3 + 7\,HCl \rightarrow HF + 4\,Cl_2 + 3\,H_2O.$$

2. REACTIONS WITH ORGANIC COMPOUNDS

In reactions with organic compounds $FClO_3$ behaves as either an oxidant or a two-centre electrophile which, depending upon the conditions, can be used for the introduction of either fluorine or the ClO_3 group.

Fluorination

The reaction of perchloryl fluoride which has been studied best is the fluorination of organic compounds at a carbon having a mobile hydrogen atom. These include compounds with a methylene or methine group activated by one or more electronegative groupings (ketone, alkoxycarbonyl, aldehyde, nitrile, etc.). A necessary condition for the fluorination is the presence of an equimolar amount of a base (usually an alkali metal alkoxide) or the introduction into the reaction of a previously prepared metal derivative of the compound being fluorinated.

Carbonyl compounds. Inman and coworkers[56,57] effected the first fluorinations of compounds with an active methylene group by the action of perchloryl fluoride. They found that ethyl and phenyl malonates react smoothly with perchloryl fluoride in the presence of bases, giving the corresponding monofluoro-substituted esters with yields of over 70%:

$$RCH(COOC_2H_5)_2 \xrightarrow{FClO_3} RCF(COOC_2H_5)_2.$$

The fluorination of malonic esters proper does not stop at the stage of the monofluoro-derivative but leads to the exclusive formation of the difluoromalonate even when there is insufficient base‡. The authors' explanation for this is that the monofluoromalonate ester, which is evidently a stronger acid§ than malonic, undergoes the fluorination more rapidly.

‡ After this review had been written there appeared a paper by Gershon and coworkers[124] describing a more detailed investigation of the action of perchloryl fluoride on malonic ester. It was found that in this reaction in addition to the difluoromalonate there are several other products, including the monofluoromalonate. The qualitative and quantitative composition of the mixture depends on the solvent and the ratio of the reactants.

§ We do not think that this conclusion of the authors is sufficiently well founded. It was recently established[125,126], for fluoronitroalkanes, that the introduction of a fluorine atom in the α position to an electron-acceptor substituent (the nitro-group) does not increase, but, on the contrary, greatly lowers the acidity of the compound. In accordance with this, fluoromalonic ester should be a weaker, not a stronger, acid than malonic ester. On the other hand the ease of fluorination is evidently determined more by the nucleophilic nature of the compound being fluorinated than by its acidity.

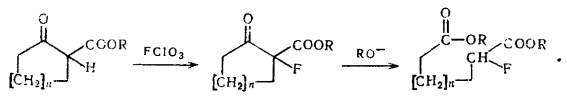
Perchloryl fluoride reacts readily with β-keto-esters [57-59], α-substituted keto-esters giving the monofluoro-derivatives [58,59], but acetacetic ester giving the difluoro-derivative exclusively [57]:

$$CH_3COCHCOOR' \xrightarrow{FClO_3} CH_3COCFCOOR'$$
$$\quad\quad R \quad\quad\quad\quad\quad\quad R$$
$$CH_3COCH_2COOC_2H_5 \xrightarrow{FClO_3} CH_3COCF_2COOC_2H_5$$

A side-reaction here is the removal of the acetyl group, which is facilitated by an excess of the base and raising the temperature. Thus, in the fluorination of the ethyl ester of 2-acetyl-5-methylhex-4-enoic acid two compounds were isolated: the expected fluorination product (I) and its diacetylated analogue (II) [58]:

$$(CH_3)_2C=CHCH_2\underset{\underset{COCH_3}{|}}{CH}COOC_2H_5 \xrightarrow{FClO_3} (CH_3)_2C=CHCH_2\underset{\underset{COCH_3}{|}}{CF}COOC_2H_5 + (CH_3)_2C=CHCH_2CFHCOOC_2H_5$$
(I) 65% (II) 10%

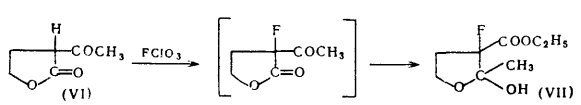
The acetyl group is even more readily detached from fluorinated acetyl diesters. Thus, in the presence of bases fluorination of esters of type (II) leads to the formation of a deacetylated compound as the main product — a monofluoromalonic ester — and only a little of fluorination product (IV) [59]:



$$R'CCH(COOC_2H_5)_2 \xrightarrow{FClO_3} R'CCF(COOC_2H_5)_2 \xrightarrow{ROH,RO^-} R'COOR + CHF(COOC_2H_5)_2$$
(III) (IV)

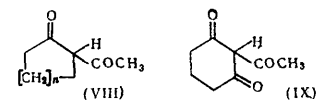
In the fluorination of esters of tricarboxylic acids an ethyloxalyl group can be removed [60,61].

The property of the α-fluoro-α-alkyl-β-keto-esters to lose an acetyl group under the action of bases or an alkoxycarbonyl group in OH-catalysed hydrolysis was used for a directed synthesis of several esters of α-fluorocarboxylic acids [59] and α-fluorinated ketones [58]:



$$RCFCOCH_3 \quad (COOR') \xrightarrow{RO^-} RCFHCOOR' \quad (OH^-) \rightarrow RCFHCOCH_3$$

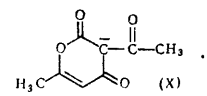
Cyclic β-keto-esters react with perchloryl fluoride like the acyclic esters [62], but not all the fluoro-compounds which are obtained (V) are stable:



(V)

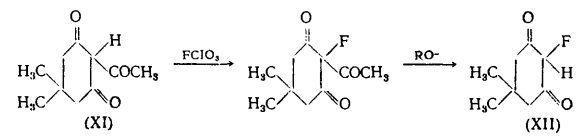
Thus the fluorination product (V; n = 1) could not be isolated, as it underwent a series of changes, leading to ring opening. The most stable fluorination products were compounds with larger rings (V; n = 2, 3) or bicyclic systems. Under the action of alkaline agents compounds of type (V) are readily hydrolysed and decarboxylated, forming cyclic α-fluoroketones [62,63].

On reaction with perchloryl fluoride, lactones of type (VI) also give unstable fluoro-derivatives which undergo a series of transformations under the conditions of the reaction [59,64]. Thus, the final result of the fluorination of lactone (VI) was the formation of (VII) [59]:



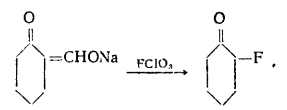
(VI) (VII)

Cyclic β-diketones (VIII) and triketones (IX) also react with $FClO_3$; the regularity in the formation of fluorination products for them is the same as for cyclic β-keto-esters — ring opening, deacetylation [62]:



(VIII) (IX)

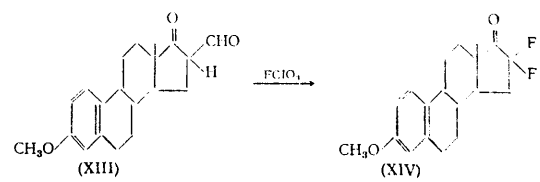
The less nucleophilic nature of the anions of tricarbonyl compounds (in comparison with dicarbonyl compounds) leads to a decrease in the reactivity towards perchloryl fluoride, and the reaction is slow.



Anions which are still more resonance-stabilised such as (X), generally do not react with perchloryl fluoride [62].

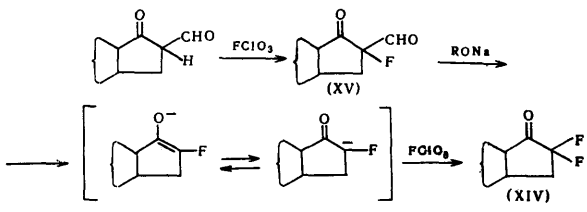
(X)

In the example of tricarbonyl compounds reacting with $FClO_3$ mention must be made of the side-reaction, which can occur in the fluorination of other compounds. When the reaction leads to the formation of compound (XII), which is a stronger acid than the original compound (XI), the former can displace the latter from its salts. Then the compound being fluorinated (XI) is partly recovered unchanged, which leads to a fall in the yield of the desired reaction product:



(XI) (XII)

α-Formylated cyclic ketones behave analogously to α-acetylketones in reaction with perchloryl fluoride: the fluorination is accompanied by loss of the formyl group and sometimes the difluoro-derivative is formed. Fluorination of sodium 2-oxocyclohexylidenemethoxide leads to the formation of 2-fluorocyclohexanone in 40% yield [65]:



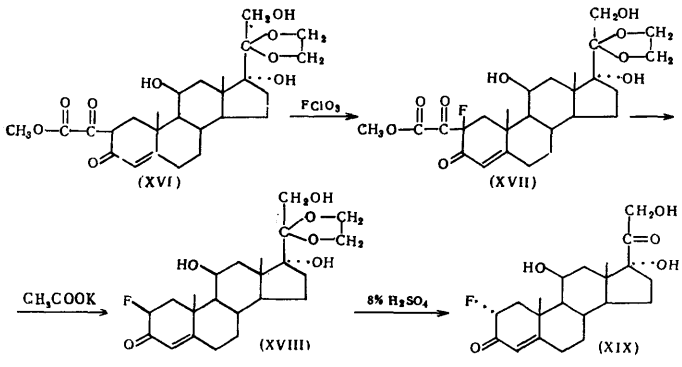
Dipole moment measurements have established the equatorial conformation of the fluorine in the 2-fluorocyclohexanone obtained. This compound serves as a standard for finding the conformation of the α-fluoroketones of the steroidal series.

The fluorination of the α-formylated cyclic ketones has been used successfully to obtain fluorinated analogues of certain steroids¶. Thus, the 3-methyl ether of 16-formyl-oestrone (XIII) reacts with $FClO_3$ in t-butyl alcohol to give at once the 3-methyl ester of 16,16-difluoro-oestrone (XIV) in the presence of a large excess of sodium butoxide [67]:

(XIII) (XIV)

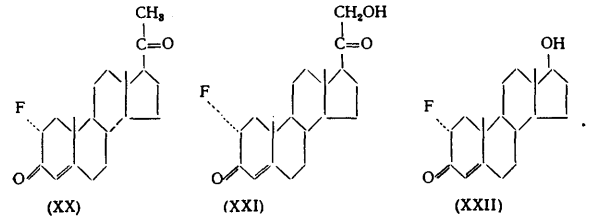
¶ Methods of obtaining fluorosteroids have been reviewed in detail. [66]

The authors assume that the monofluoroformyl derivative (XV) is formed as an intermediate, which subsequently reacts with the base and perchloryl fluoride to give the $\alpha\alpha$-difluoroketone (XIV):



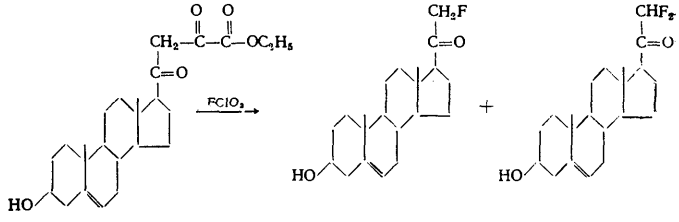
Proof of the proposed scheme was given by the isolation of the monofluoroketone (XV) corresponding to the first stage of the reaction[68].

Monofluoroketones of the androstane series were obtained by an analogous reaction in benzene; the 2-formyl--2-fluorosteroids formed on fluorination were treated with a base to remove the formyl group. For example: 2-fluorotestosterone, 2α-fluoro-17β-hydroxyandrostan--3-one, etc. were obtained in this way[69].



The introduction of fluorine into positions 6α 9α, and 12α of hydrocortisone leads to highly active glucocorticoids. The reaction of $FClO_3$ with the sodium salts of the enol forms of β-dicarbonyl compounds is very convenient for obtaining fluorinated steroidal hormones. This method evidently allows fluorine to be introduced into any methylene or methyl group of the steroid capable of alkylation with the formation of a β-dicarbonyl system. In turn the acylation is conveniently effected by the introduction of an alkoxalyl group[70,71] which is readily detached after fluorination.

For the synthesis of 2α-fluorohydrocortisone, 20-ethyleneketalhydrocortisone was treated with methyl oxalate and sodium methoxide in benzene. The ethyleneketal was taken to prevent methoxalylation at position 21. The 2-methoxalylhydrocortisone-20-ethyleneketal (XVI) which was obtained reacted with perchloryl fluoride[72,73]:



After removal of the methoxalyl group from (XVII) the substance (XVIII) was obtained in 43% yield. The yield of the desired 2α-fluorohydrocortisone (XIX) from (XVIII) was 73%.

2α-fluoroprogesterone (XX) was obtained analogously (44% yield calculated on the initial ethyleneketal), 2α-fluorodeoxycorticosterone (XXI) (25%), and 2α-fluorotestosterone (XXII) (20%)[72]:

A series of fluoro-substituted steroids containing fluorine in positions 2 and 21 has been obtained by the reaction of $FClO_3$ with alkoxalylated steroids[25,72-76]. Most authors consider the conformation of the 2-fluoro-3-keto-derivatives of steroids which are obtained to be equatorial (2α) from measurements of the dipole moments and by analogy of the optical rotatory dispersion curves with those for other halogeno-substituted compounds for which the conformation has been established[65,72,74,78].

Both monofluoro- and difluoro-derivatives were obtained by the fluorination of the 21-ethoxylalyl derivatives of 20-keto-steroids[72]:

An interesting example of fluorination by perchloryl fluoride has been described[77]. It was shown that steroids with the $-\overset{\overset{O}{\|}}{C}-CF_2H$ group are capable of being fluorinated by perchloryl fluoride in the presence of bases, giving a trifluoro-derivative with the $-\overset{\overset{O}{\|}}{C}-CF_3$ group.

Fluorination of tetracyclines with perchloryl fluoride has also been described[79].

Nitriles and nitro-compounds. Compounds with a methylene group activated not only by carbonyl groups but also by other electronegative substituents (the nitrile group and the nitro-group) are fluorinated by perchloryl fluoride.

Substituted malonodinitriles[80] and phenylacetonitriles[81] give fluorinated products with $FClO_3$ in the presence of bases. It has been proposed to use as bases the alkali metals, and their hydroxides, hydrides, amides, and alkoxides[81]:

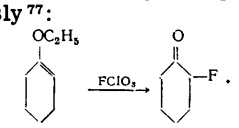
$$RC(CN)_2H \xrightarrow{FClO_3} RC(CN)_2F.$$

The sodium salts of secondary nitro-compounds (2-nitropropane, 2-nitrobutane, and nitrocyclohexane) are fluorinated by perchloryl fluoride in methanol, forming a fluoronitro-compound in 36-42% yield — Eqn. (1). The fluorination is accompanied by side-reactions: by oxidation and by oxidative dimerisation, as a result of which ketones — Eqn. (2) — and vicinal dinitro-compounds — Eqn. (3) — are formed[82]:

$$R_2C{=}NO_2^- + FClO_3 \rightarrow R_2CFNO_2 + ClO_3^- \quad (1)$$

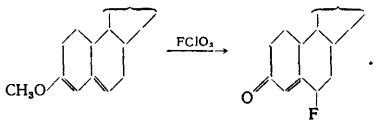
$$R_2C{=}NO_2^- + FClO_3 \rightarrow R_2C{=}O + [HNO_2] + HClO_3 + F^- \quad (2)$$

$$2\,R_2C{=}NO_2^- + FClO_3 \rightarrow \underset{\displaystyle NO_2\ \ NO_2}{R_2C{-}CR_2} + F^- + ClO_3 \quad (3)$$



In the fluorination of primary nitro-compounds appreciable quantities of fluoronitroalkanes (3–5%) could not be obtained; mainly oxidation products are formed here — aldehydes (32–55%). Salts of such nitro-compounds as nitromalonic ester, α-nitro-α-phenyl acetophenone, etc., which have other electronegative substituents in the α position to the nitro-group are converted into the corresponding α-fluoronitro-compounds in high yields (80%)[83].

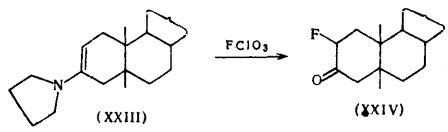
Oxidative dimerisation, which is observed as a side-reaction in the fluorination of nitroalkanes, is sometimes the main reaction. Thus, in an attempt to fluorinate acylamidomalonates with perchloryl fluoride in the presence of sodium ethoxide oxidative dimerisation products were obtained exclusively[84]:



$$2\,RNH{-}CH(COOC_2H_5)_2 \xrightarrow{FClO_3} RNH{-}C(COOC_2H_5)_2{-}C(COOC_2H_5)_2{-}NHR$$

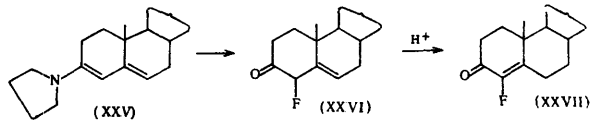
where R = HCO, CH_3CO.

Ethers of enols readily react with perchloryl fluoride in pyridine, forming α-fluoro-ketones in high yields. Thus 2-fluorocyclohexanone was obtained from 1-ethoxycyclohexene; the reaction with steroids having the same structural fragment — an ethoxy-group at a double bond — proceeds analogously[77]:



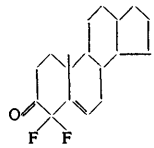
In the presence of two conjugated double bonds the fluorine enters position 6 of the steroid nucleus[77,85]:

Esters of enols (for example, acetates) react like ethers; the reaction takes place in an inert organic solvent, on adding weakly basic nucleophilic agents (water, pyridine)[86,87]. The reactivity of enol acetates with two conjugated double bonds is higher than with one double bond[88]; the latter react much more slowly[89,90].



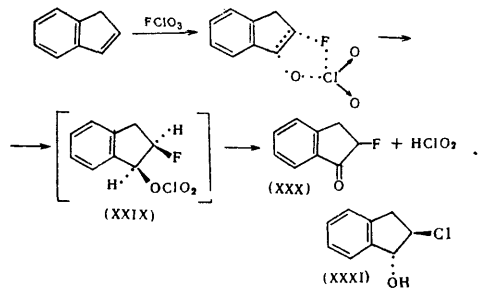
Enamines and enamides. The replacement of oxygen by nitrogen in steroid derivatives, that is, the use of enamides (acetylated enamines) instead of enol acetates considerably facilitates the fluorination. 3β-acetoxy-17-acetaminoandrosta-5,16-diene reacts with $FClO_3$ in pyridine at room temperature within 3 min, the yield of 3β-acetoxy-16α-fluoroandrost-5-en-17-one reaching 70% (against 45% after 20 h from the corresponding enol acetate)[90,91]. A sharp rise in reactivity of enamides compared with enol acetates agrees with the greater ability of the nitrogen atom to give electrons to a double bond, which should facilitate reaction with the electrophilic fluoride of the perchloryl fluoride[90,91].

Enamines are rather reactive in relation to $FClO_3$ but often give a mixture of different reaction products in ratios which depend on the fluorination conditions. Pyrrolidylenamine of cholestan-3-one (XXIII) gives 2α-fluorocholestan-3-one (XXIV) in 72% yield after passing $FClO_3$ into a benzene solution of (XXIII) for 30 s:[92]



(XXIII) (XXIV)

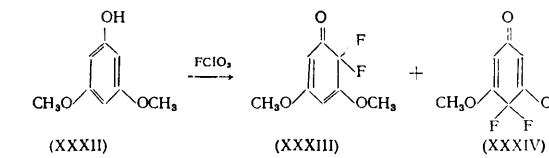
Pyrrolidylenamines of steroids with two conjugated double bonds (XXV) in methanol and dimethylformamide react with $FClO_3$ to form monofluoro-substituted compounds of general formula (XXVI), the isomerisation of which in strongly acid medium leads to (XXVII)[93,94]:



(XXV) (XXVI) (XXVII)

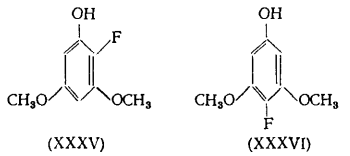
In ether enamines of type (XXV) give mainly 4,4-difluoro-3-keto-Δ^5-steroids (XXVIII)[95,96]:

(XXVIII)



Oxofluorination. Compounds having a cyclic double bond conjugated with an aromatic nucleus, are capable of entering with perchloryl fluoride into the reaction termed oxofluorination, the final result of which is the formation of α-fluoroketones. For example, indene reacts in this way. In this reaction $FClO_3$ acts as a two-centre electrophile which attacks the 2–3 double bond of indene. As a result of this, according to the authors' hypothesis[97], a *cis*-fluoro-chlorate (XXIX) is formed as an intermediate, which is converted into the final α-fluoro-ketone (XXX) by loss of the acid $HClO_2$. This acid apparently takes part in the formation of the *trans*-2-chloroindanol (XXXI) which is isolated from the mixture in considerable quantity:

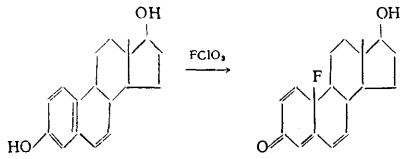
(XXIX) (XXX) (XXXI)



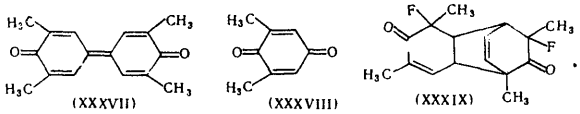
The products of oxofluorination are also formed by the action of perchloryl fluoride on the ethers of enols and enamines, as already mentioned above.

Phenols react with $FClO_3$, forming products of *C*-fluorination in which the fluorine usually enters the *ortho*- and *para*-positions. The molecule acquires a quinoidal structure. When perchloryl fluoride acts on 3,5-dimethoxyphenol (XXXII) in pyridine or dimethylformamide a mixture of two isomeric difluoro-compounds (XXXIII) and (XXXIV) is formed:

(XXXII) (XXXIII) (XXXIV)



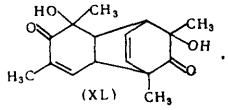
Paper chromatography of the reaction mixture allows the fluorophenols (XXXV) and (XXXVI) to be detected; they may be precursors of the final compounds (XXXIII) and (XXXIV) respectively:



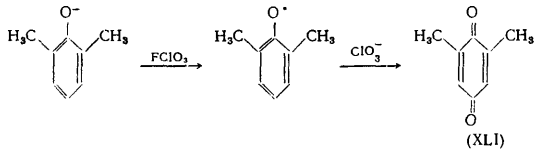
(XXXV) (XXXVI)

Reactions with 2- and 4-chloro-3,5-dimethoxyphenols give predominantly *gem*-chlorofluorodienones, the reduction of which with zinc in acetic acid leads to fluorophenols [98,99].

10β-fluorinated steroids are formed by the action of $FClO_3$ on steroidal phenols. In dimethylformamide the yields are higher than in dioxan [100,101]:



The reaction of perchloryl fluoride with phenols was studied in greater detail for 2,6-dimethylphenol [102]. As a result of the reaction of sodium 2,6-dimethylphenate a mixture of products was obtained, the composition of which depended on the solvent used. In media of low dielectric strength (pentane, dioxan, toluene) quinones (XXXVII), (XXXVIII), and a fluorination product in the form of a dimer (XXXIX) are formed:

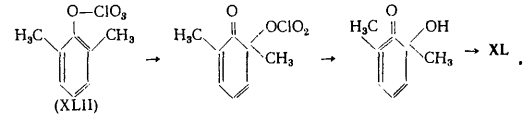


(XXXVII) (XXXVIII) (XXXIX)

In polar solvents (ethanol, dimethylformamide) instead of the dimer (XXXIX) a dimer of analogous structure (XL) is obtained:

(XL)

The authors explain the formation of quinones by the oxidation of the phenate anion to a radical and its subsequent conversion:

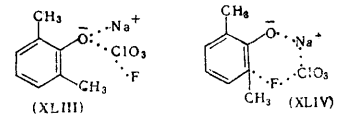


(XLI)

2,6-dimethylphenol itself in toluene does not react with perchloryl fluoride; in dimethyl formamide the reaction is very slow and a mixture of dimethylquinone (XLI) and 2,6-dimethyl-4-chlorophenol is formed. The formation of the latter can be explained by the action on 2,6-dimethylformamide of hypochlorous acid, which in turn is formed at the end of a sequence of redox changes:

$$FClO_3 \rightarrow ClO_3 \rightarrow HClO_2 \rightarrow OClH.$$

The definite influence of the medium on the formation of dimers (XXXIX) and (XL) prompted the authors [102] to suggest that these compounds are the products of the attack of a two-centre nucleophile — dimethylphenate — on perchloryl fluoride, which plays the part of a two-centre electrophile.

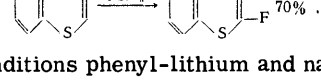


As a result of the attack by oxygen of the phenate ion on the chlorine of the perchloryl fluoride and subsequent intramolecular oxidative disproportionation of compound (XLII), the dimer (XL) is formed:

(XLII)

Were the nucleophilic centre the *ortho*-carbon atom of the phenate ion, then its attack by fluorine would lead finally to the dimer (XXXIX). The reaction of perchloryl fluoride at the carbon or oxygen of the phenate can be compared with the known *O*- or *C*-alkylation of phenates.

The transition state can be either (XLIII) or (XLIV):



(XLIII) (XLIV)

The greater solvation of the cation favours the transition state (XLIII) which leads to the intermediate formation of the ester of perchloric acid (XLII) and then to the dimer (XL). Qualitatively similar results are observed in the alkylation in polar media, when, in accordance with the Ingold hypothesis, the phenate anion reacts at the oxygen and the ion pair at the carbon [103]. Here the more strongly solvating medium facilitates a shift in the equilibrium to the side of an increase in the number of ions (including the phenate anion), which leads, finally, to an increase in the yield of the dimer (XL).

On the other hand the quasicyclic structure of the transition state (XLIV) favours the loss of $NaClO_3$ owing to the electrostatic attraction between the Na^+ group and the ClO_3 group. The gain in energy of the C–F bond compared with F–Cl is also the driving force of the process.

The fact that carbanions usually react with perchloryl fluoride at the fluorine but heteroatomic anions (and amines) at the chlorine, is explained by the authors in the following way: *C*-fluorination is energetically quite a favourable process, whereas the low polarisability (in comparison with the mesomeric carbanions) of the heteroatomic anion and the high electron density at the hetero-atom leads to the repulsion of the *p*-orbital of fluorine and of the hetero-atom (nitrogen or oxygen) [102].

As yet the only example of the fluorination of heterocyclic compounds has been described by Schuetz and coworkers [104]. It was shown that in the presence of butyl-lithium thiophen and some of its derivatives are fluorinated by perchloryl fluoride in position 2:

Under these conditions phenyl-lithium and naphthyl-lithium give an extremely small quantity of fluoro-derivatives. With phenyl-lithium perchlorylbenzene could be isolated from the products of the reaction.

Oxidative fluorination. An interesting, but little studied reaction of $FClO_3$ is that with oximes. Perchloryl fluoride in pyridine is capable not only of fluorinating oximes at carbon, but also of simultaneously oxidising the oxime group to a nitro-group. Since, however, very few substances have been studied it is therefore uncertain how general this reaction is (so-called oxidative fluorination).

The dimethyl ester of oximinomalonic acid forms with perchloryl fluoride in dimethylformamide an oxidative fluorination product in 70% yield:

$$(CH_3OOC)_2C{=}NOK \xrightarrow{FClO_3} (CH_3OOC)_2C\begin{matrix}NO_2\\F\end{matrix}.$$

In the reaction potassium chlorate and chloride are formed. It is interesting that chloronitromalonic ester was isolated as a side-product, the quantity of which rose as the chloride ion accumulated[83]. In this respect the reaction differs from fluorination at an "active methylene" group, which is not sensitive to the presence of foreign ions[57].

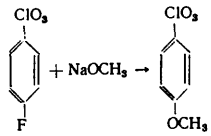
The reaction could not be extended to other oximes, for example, the ethyl ester of α-oximino-β-ketobutyric acid† and the ethyl ester of oximinocyanoacetic acid. Some oximes under the action of $FClO_3$ undergo a Beckmann rearrangement of the second kind. Thus, on treating the sodium salt of α-benzil monoxime (XLV) with perchloryl fluoride it forms a mixture of benzil monoxime benzoate (XLVI) and benzonitrile:

$$\underset{\text{(XLV)}}{2\,C_6H_5C(=O)C(=N{-}O)C_6H_5} \xrightarrow{FClO_3} \underset{\text{(XLVI)}}{C_6H_5C(=O)C(=N{-}O{-}C(=O)C_6H_5)C_6H_5} + C_6H_5CN.$$

Oximes which do not contain electronegative substituents (acetophenone, benzophenone) are converted into the original ketones under the action of perchloryl fluoride[83].

The possibility of using perchloryl fluoride as an oxidant in analysis has been studied[105]. It was shown that in non-aqueous media at room temperature the aldehyde group is very stable to the action of perchloryl fluoride but the amino- and mercapto-groups undergo complex redox conversions.

Perchlorylation



In the presence of a Friedel–Crafts catalyst (usually $AlCl_3$) perchloryl fluoride reacts with aromatic compounds by a type of electrophilic substitution, giving perchlorylaromatic compounds, for example, perchlorylbenzene[106,107]. In the absence of a catalyst the reaction does not take place, but at the same time a complex of the catalyst with perchloryl fluoride was not obtained in the absence of the reagent. Possibly the reaction proceeds through a transition state in which all three components are combined. By analogy with the electrophilic acylation of benzene by Friedel–Crafts, the authors propose the following mechanism for the reaction[107]:

$$FClO_3 + AlCl_3 \rightarrow [FClO_3 \cdot AlCl_3] \rightarrow ClO_3^+ AlFCl_3^-$$
$$C_6H_6 + ClO_3^+ \rightarrow C_6H_5ClO_3 + H^+$$
$$H^+ + AlFCl_3^- \rightarrow HCl\uparrow + AlFCl_2.$$

† The author probably means sodioethyloximinoacetoacetate (Ed. of Translation).

Benzene derivatives (fluorobenzene, phenol, 1,2,3-trifluorobenzene, xylene, etc.) react with perchloryl fluoride. However, the perchlorylation of nitrobenzene and some other aromatic compounds with electronegative substituents could not be carried out.

Perchlorylaromatic compounds are stable in vacuum and steam distillation but can be detonated under severe impact or by a high temperature. They are stable in acid or neutral media but are hydrolysed in strongly alkaline solutions, forming the phenate and chlorate ions. The reaction of halogeno-substituted perchlorylaromatic compounds with alkoxides (and some other reactions with nucleophiles) takes place with retention of the perchloryl group in the nucleus[108], for example:

Reductants such as lithium tetrahydroaluminate, tin(II) chloride in hydrochloric acid, and zinc in hydrochloric acid, do not reduce the ClO_3 group[107], but on a palladium catalyst perchlorylaromatic compounds are readily hydrogenated according to the equation[109]:

$$R{-}C_6H_4{-}ClO_3 + 4\,H_2 \xrightarrow[CH_3COOH]{Pd} RC_6H_5 + HCl + 3\,H_2O.$$

A large number of derivatives are obtained from perchlorylbenzene by the usual methods; they include 4-chloro-, 4-methylthio-, and pentachloro-perchlorylbenzene and 3-perchlorylanilinium chloride. Perchlorylbenzene and its homologues are sulphonated by concentrated sulphuric acid and are nitrated in the *meta*-position by sulphuric–nitric mixture. Azo-, azoxy-, and hydrazo-3-perchlorylbenzenes are also obtained. The infrared spectra of substituted perchlorylbenzenes have been studied[106,107].

Only brief mention has been made of the perchlorylation of alkoxide anions by perchloryl fluoride[56]. With sodium trifluoroethoxide in trifluoroethanol $FClO_3$ gives trifluoroethyl perchlorate and sodium fluoride:

$$F_3CCH_2ONa + FClO_3 \rightarrow F_3CCH_2OClO_3 + NaF.$$

With the less acidic alcohols the reaction does not stop at the stage of the formation of an ester of perchloric acid, but proceeds further by the equation:

$$RO^- \xrightarrow{FClO_3} ROClO_3 \xrightarrow{RONa} ROR + NaClO_4.$$

Thus, sodium ethoxide in ethanol reacts with perchloryl fluoride to give diethyl ether and sodium perchlorate[56].

As already noted, perchloryl fluoride and ammonia give a mixture of ammonium fluoride and the ammonium salt of perchloramide[8,54]. Attempts to carry out an analogous reaction with amines did not lead to the desired result. Perchloryl fluoride reacts with pure amines, usually explosively or forming a complex mixture of oxidation products, usually of the anil type. Aminolysis of perchloryl fluoride by aniline, phenylhydrazine, isopropylamine, isobutylamine, etc. led to the formation of spontaneously explosive solid or liquid substances of unknown structure[110].

Only recently[111] an amine was perchlorylated at the nitrogen. On passing $FClO_3$ into an aqueous solution of piperidine, *N*-perchlorylpiperidine was obtained in 70% yield. This is an unstable liquid, readily hydrolysed by alkalis and highly explosive:

A review has been published[112] part of which is devoted to a consideration of the preparation and properties of perchlorylorganic compounds.

Toxicity

With reference to preliminary tests made on animals, Engelbrecht and Atzwanger[8] characterise perchloryl fluoride as "moderately toxic" 7–8 degrees in Carpenter and coworkers' classification, and give numerical values for LC_{50}: 2000–4000 parts per million in exposure for 4 h. The toxicity of perchloryl fluoride is close to the toxicity of chlorine but without its irritating action[20]. Its odour is detectable in a concentration of 10 parts per million, which is considerably below the permissible concentration on prolonged action. Gall[114] mentions that the toxicity of perchloryl fluoride is low and it does not damage the skin. It was also noted[115] that monkeys can breathe air containing 40 parts per million perchloryl fluoride for a long time but at 200 parts per million slight toxic action is observed.

V. USES

As perchloryl fluoride is a comparatively new substance its possible practical uses are still insufficiently studied. The prospects of using perchloryl fluoride as an oxidant have been considered more than any others. The spectra of flames of some fuel gases with perchloryl fluoride as oxidant have been studied[116] and the rate of flame in mixtures of methane with air on adding perchloryl fluoride has been measured[117]. Schmauch and Servass[115,118] note that the flame of the combination $H_2 + FClO_3$ is readily controlled, has a low background, and can be used with success as a source of excitation in flame photometry.

As an oxidant for rocket propellents[29] liquid perchloryl fluoride in combination with dimethylhydrazine or hydrazine has a specific impulse of 274 s (combustion chamber pressure 42 atm), whereas liquid oxygen with the American fuel JP-4 gives 272 s. In a hybrid, solid–liquid system, perchloryl fluoride gives the same specific impulse as dinitrogen tetroxide, that is, 246 s.[119]

The use of perchloryl fluoride as an oxidant for the high-temperature cutting of metals has been proposed[120].

The possibility of using perchloryl fluoride in other fields is at the discussion stage. There are several patents on its use as a heat transfer medium in refrigeration[121], and as an insecticide–fungicide[122]. The polymerisation of ethylene in the presence of perchloryl fluoride under a pressure of hundreds of atmospheres and a temperature of the order of 200°C has been reported[123].

Thanks to the ability to intensively absorb slow electrons[47] perchloryl fluoride can find application as a gaseous insulator, the dielectric properties of which are better than those of SF_6 and hardly deteriorate on irradiation by γ-rays[21].

Perchloryl fluoride is at present the only agent for obtaining perchlorylaromatic compounds. The latter can find a use for obtaining explosive substances, dyes, and pharmaceutical preparations (3-perchlorylacetanilide, and 4-fluoroperchlorylbenzene exhibit pharmacological potential)[2,106].

COMPLEX HALIDES IN VAPOURS AT HIGH TEMPERATURES

G.I.Novikov and F.G.Gavryuchenkov

CONTENTS

I. Introduction 156

II. Complex halides in vapour form 156

III. Increase in the thermal stability of complex halides on vaporisation 159

IV. Connection between complex formation and dimerisation of compounds in the vapour state 161

I. INTRODUCTION

The extremely rapid development of high temperature chemistry makes necessary the systematic study of the properties of substances in the vapour state. The antiquated ideas about vapour as a medium barren of processes and compounds are now undergoing considerable changes. It is becoming more and more evident that in the variety of forms and peculiarities of their interaction a vapour is often comparable with condensed phases.

Problems of vaporisation and the chemistry and structure of complex molecules in vapour-phase media at high temperatures have repeatedly formed the subject of discussions in monographs and articles. In this connection mention must be made of the works of Margrave [1,2], Searcy [3], Kireev [4], Glemser [5], Novikov [6], Drowart and Goldfinger [7], and some others. They give many examples of polymerisation and complex formation by oxides and halides in vapour form, producing compounds of the hydrate type, salts of oxo-acids, oxide halides, and complex halides. In all the examples considered reference is made only to compounds which exist in the form of neutral molecules, but it may be assumed that in ionised vapour the variety of species will be even greater, since compounds non-existent in the form of neutral molecules can be made stable by addition or loss of electrons and the formation of ionic molecules. Unfortunately, the quantitative physicochemical characteristics of complex vapour-phase molecules — not only ionised but also neutral — are known in very few instances.

The vapour-phase double or complex halides, mainly of the type $MM'X_n$, where M is an alkali metal, M' a metal of another group, and X a halogen are better studied in this respect than other compounds. The review given below will be restricted to these forms alone and will not be concerned with compounds of the type $BeAlCl_5$,[8] In_xCl_y,[9] $SiBCl_5$,[10] etc., which have been studied less extensively.

The practical importance of investigations in the region defined above is obvious, since under industrial conditions many metals are obtained either by electrolysis of molten salt mixtures (including salts of the alkali metals), or by metallothermic reduction of halides.

The study of complexes in vapour form is of great theoretical interest above all for the further development of the chemistry of coordination compounds.

II. COMPLEX HALIDES IN VAPOUR FORM

The simplest representatives of complex compounds of the type $MM'X_n$ in the vapour state are the mixed dimers of alkali metal halides.

As already mentioned, the alkali metal halides exist in vapours in the form of a collection of monomeric, dimeric, and some more complex molecules. However, the relation between the monomer and various polymeric forms is such that for most purposes only dimerisation need be considered and the more complex forms are essential only for lithium halides [11-13].

The stability of the vapour forms of the dimers of the alkali metal halides falls from Li to Cs, as is shown by the data [14] given in Table 1.

In the interaction of dimeric molecules of the various alkali metal halides the constituent parts can be interchanged as a result of which mixed dimers are obtained. Thus data have been given for the reaction [15]:

(1) $(Li_2F_2) + (Na_2F_2) = 2(NaLiF_2)$ $\Delta H^\circ_{1000} = 0.$

The results of a mass spectrometric investigation [16] of equilibria in the disproportionation by stepwise replacement are known:

(2) $(CsRbF_2) = {}^1/_2(Rb_2F_2) + {}^1/_2(Cs_2F_2)$ ΔH°_{904} 1.3 kcal mole^{-1},
(3) $(RbKF_2) = {}^1/_2(K_2F_2) + {}^1/_2(Rb_2F_2)$ ΔH°_{980} 1.4 kcal mole^{-1},
(4) $(KNaF_2) = {}^1/_2(Na_2F_2) + {}^1/_2(K_2F_2)$ ΔH°_{925} 1.5 kcal mole^{-1},
(5) $(NaLiF_2) = {}^1/_2(Li_2F_2) + {}^1/_2(Na_2F_2)$ ΔH°_{1173} 2.3 kcal mole^{-1},
(6) $(RbLiF_2) = {}^1/_2(Li_2F_2) + {}^1/_2(Rb_2F_2)$ ΔH°_{985} 3.0 kcal mole^{-1}.

In the mass spectrometric analysis of the composition of the vapour over LiCl–MCl mixtures [17] (M = Na, K, Rb, Cs) the ions $LiCl^+$, Li_2Cl^+, M^+, MCl^+, M_2Cl^+, and $LiMCl^+$ were observed in the molecular beam. The ion $LiMCl^+$ could be a fragment of molecules of mixed dimers. Analogous results were obtained by Novikov and coworkers [18], but in addition the ion Cs_2LiCl^+ was observed, which the authors took to be a fragment of a molecule of the mixed trimer Cs_2LiCl_3. Thermodynamic characteristics have also been given [18-21] for the disproportionation of the following mixed dimers:

		ΔH°_T, kcal mole^{-1}	t, °C
(7)	$(RbNaCl_2) = {}^1/_2(Rb_2Cl_2) + {}^1/_2(Na_2Cl_2)$	5.8	800
(8)	$(RbKCl_2) = {}^1/_2(Rb_2Cl_2) + {}^1/_2(K_2Cl_2)$	0	800
(9)	$(CsLiCl_2) = {}^1/_2(Cs_2Cl_2) + {}^1/_2(Li_2Cl_2)$	7.0	650—900
(10)	$(CsNaCl_2) = {}^1/_2(Cs_2Cl_2) + {}^1/_2(Na_2Cl_2)$	5.2	650—900
(11)	$(CsKCl_2) = {}^1/_2(Cs_2Cl_2) + {}^1/_2(K_2Cl_2)$	2.7	650—900

TABLE 1. Thermodynamic characteristics of the process $(M_2X_2) = 2(MX)$.

		Li	Na	K	Rb	Cs
Fluorides	ΔH°_{1000}, kcal mole^{-1}	61.5	56.9	49.6	43.9	39.2
	ΔS°_{1000}, e.u.	34.0	31.6	32.4	29.4	30 5
Chlorides	ΔH°_{1000}, kcal mole^{-1}	52.1	48.5	44.5	41.7	39.0
	ΔS°_{1000}, e.u.	32.1	29.0	28.4	28.1	28.0

It should be noted that the substitutions (2)–(11) are exothermic and the thermal effect is the greater the further apart the alkali metals, that is, the greater the difference in properties of their compounds. With increase in this difference the molecule of the mixed dimer becomes less and less symmetrical; the halogen atoms become more and more displaced towards one of the alkali metal atoms, which thus acquires the function of complex formation. To compare the mixed and true dimers as regards stability in the vapour state we will examine the thermodynamic scheme:

Scheme 1

$(M_2X_2) = 2(MX)$	ΔH_1°	$\Delta S_1^\circ \simeq 30$ e.u.
$(M'_2X_2) = 2(M'X)$	ΔH_2°	$\Delta S_2^\circ \simeq 30$ e.u.
$(MM'X_2) = {}^1/_2(M_2X_2) + {}^1/_2(M'_2X_2)$	ΔH_3°	$\Delta S_3^\circ \simeq 0$
$(MM'X_2) = (MX) + (M'X)$	ΔH_4°	ΔS_4°

It is easy to see that:

$$\Delta H_4^\circ = {}^1/_2(\Delta H_1^\circ + \Delta H_2^\circ) + \Delta H_3^\circ$$
$$\Delta S_4^\circ = {}^1/_2(\Delta S_1^\circ + \Delta S_2^\circ) \quad 30 \text{ e.u.} \qquad (B)$$

Hence the change in entropy during the dissociation of simple and mixed dimers is approximately the same, but the enthalpy of dissociation of the mixed dimer (ΔH_4) is greater than the arithmetic mean of the enthalpies of dissociation of the simple dimers by the quantity ΔH_3. Consequently in stability the mixed dimer will approximate to the more stable of the simple dimers, that is, the dimer which has the strongest M–Cl bond.

Since the stability of the dimers falls from Li to Cs (that is, with increase in the ionic radius), in the mixed dimer the ion with the smaller radius will function as the complex-forming atom.

We shall now consider the vapour-phase double compounds formed by the alkali metal chlorides with the dichlorides of some other metals.

The formation of a vapour-phase complex species was first proposed by the investigators of the BeF_2–NaF binary system[22], since this was the most rational explanation for unusual observations on the pressure and composition of the vapour. From the location of the maximum on the curve for the partial pressure of NaF calculated by the Duhem–Margules equation (without allowance for the pressure of the double species) the composition of the complex was found to be $NaBeF_3$. Berkowitz and Chypka[23] observed the analogous compound of beryllium and lithium fluorides (more correctly the ion $LiBeF_2^+$) in a mass spectrometric investigation of the composition of the vapour in the BeF_2–LiF system. For the process:

(12) $(LiBeF_3) = (LiF) + (BeF_2)$

they obtained the value $\Delta H^\circ_{900} = 53$ kcal mole^{-1}.

Many papers only qualitatively justify the assumption of a double compound in the vapour, although the experimental results sometimes allow the composition of the vapour to be calculated.

Among such studies is an investigation of the $BeCl_2$–NaCl and $BeCl_2$–KCl systems[24], the study of the BeF_2–NaF system[22] mentioned above, the work of Barton and Bloom[25] (who studied the formation of double compounds by lead and cadmium chlorides), an article with data on the KCl–$MgCl_2$ system[26], and work on the pressure and composition of the vapour in the $CaCl_2$–KCl and KCl–$SrCl_2$ systems[27]. The formation of $KCoCl_3$, $KNiCl_3$, K_2CdCl_4, and $KZnCl_3$ in the vapour has been proposed[28,29].

Novikov and Kuz'menko[30,31], using published data[22,24,26,27], calculated the thermodynamic characteristics of the dissociation processes of some double chlorides, namely:

	T, °C	ΔH°_T, kcal mole^{-1}	ΔS°_T, e.u.
(13) $(NaBeF_3) = (NaF) + (BeF_2)$	900	52±2	21±3
(14) $(NaBeCl_3) = (NaCl) + (BeCl_2)$	720	54±5	23±2
(15) $(KBeCl_3) = (KCl) + (BeCl_2)$	720	48±5	24±2
(16) $(KMgCl_3) = (KCl) + (MgCl_2)$	1080	58±5	31±2
(17) $(KCaCl_3) = (KCl) + (CaCl_2)$	1100	63±3	30±2
(18) $(KSrCl_3) = (KCl) + (SrCl_2)$	1100	67±17	32±13

The decrease in stability of the double compound $KM'Cl_3$ in the sequence Sr–Be was attributed by the authors[31] to the mutual repulsion of the ligands, the force of which rises in the order Sr–Be.

The change in the stability of the double chlorides along the alkali metal series can be seen in the example of the compounds $MFeCl_3$, the thermodynamic characteristics of the dissociation of which have been given[23,28]:

		ΔH°_T, kcal mole^{-1};
(19)	$(LiFeCl_3) = (LiCl) + (FeCl_2)$	43.0
(20)	$(KFeCl_3) = (KCl) + (FeCl_2)$	34.7
(21)	$(CsFeCl_3) = (CsCl) + (FeCl_2)$	24.7

Obviously, the stability of the double compounds falls from Li to Cs, that is, in the same sequence as the stability of the dimeric alkali metal chlorides.

We shall now consider the thermodynamic characteristics of the vapour-phase complexes in the MCl–$M'Cl_3$ and MF–$M'F_3$ systems.

As in the above examples, the formation of vapour-phase double compounds by the elements of Periodic Groups I and II, the information concerning the compounds of type $MM'X_4$ relate mainly to the fluorides and chlorides.

A large number of investigations have disclosed the formation of volatile double compounds in MCl–$AlCl_3$ and MF–AlF_3 systems.

The existence of the compound $NaAlF_4$ has been shown by X-ray analysis[32] of the condensate obtained on vaporisation of a melt with equimolecular amounts of NaF and AlF_3. An investigation of the condensate obtained by passing an inert gas over AlF_3–NaF melt led Howard[33] to conclude that the volatile compound $NaAlF_4$ existed.

The existence of $NaAlF_4$ in the vapour was confirmed by investigations of the pressure and composition of the vapour in the AlF_3–NaF system made by Vetyukov and coworkers[34] and also Ginsberg and Böhme[35].

Porter and Zeller[36], in studying the AlF_3–LiF system mass spectrometrically, observed two double compounds in the vapour: $LiAlF_4$ and $Li_2Al_2F_8$ (or Li_2AlF_5). These authors calculated the thermodynamic characteristics of the equilibrium:

(22) $(LiAlF_4) = (LiF) + (AlF_3)$ $\Delta H^\circ_{1000} = 73$ kcal mole^{-1}; $\Delta S^\circ_{1000} = 37$ e.u.

As regards the analogous systems of aluminium and alkali metal chlorides, mention must be made of the studies of Naryshkin[37], Plotnikov and coworkers[38], Morozov and coworkers[39,40], and Grothe[41].

An approximate value of the ΔH°_{T} for the equilibrium

(23) $(NaAlCl_4) = (NaCl) + (AlCl_3)$

is ~ 50 kcal mole^{-1}, given by Dewing[42]; this equilibrium was studied in detail by Galitskii[43] with the aid of a combination of tensimetry and analysis of the condensates. He obtained the thermodynamic characteristics:

$$\Delta H^{\circ}_{970} = 49.2 \pm 2 \text{ kcal mole}^{-1}; \Delta S^{\circ}_{970} = 28.9 \pm 2 \text{ e.u.}$$

In the same work[43] data are given for the equilibria:

(24) $(NaFeCl_4) = (NaCl) + (FeCl_3)$ $\Delta H^{\circ}_{970} = 51.6 \pm 2,5$ kcal mole^{-1}; $\Delta S^{\circ}_{970} = 28.9$ e.u.

(25) $(Na_3CrCl_6) = 3(NaCl) + (CrCl_3)$ $\Delta H^{\circ}_{1180} = 139.0 \pm 10$ kcal mole^{-1}; $\Delta S^{\circ}_{1180} = 74.0 \pm 7$ e.u.

(26) $(K_3CrCl_6) = 3(KCl) + (CrCl_3)$ $\Delta H^{\circ}_{1180} = 132.0 \pm 10$ kcal mole^{-1}; $\Delta S^{\circ}_{1180} = 76.0 \pm 7$ e.u.

These results are quite interesting although in the last two examples the correctness of the formula selected for the double compound seems doubtful.

Richards and Gregory[44] investigated the $FeCl_3$–NaCl system by a flow method, passing the vapour of $FeCl_3$ over solid NaCl. For the equilibrium:

(27) $[NaCl] + (FeCl_3) = (NaFeCl_4)$

they obtained the following thermodynamic characteristics:

$$\Delta H^{\circ}_{723} = 3.7 \pm 1 \text{ kcal mole}^{-1}; \Delta S^{\circ}_{723} = 6.5 \pm 1.5 \text{ e.u.}$$

When the equilibrium is recalculated for NaCl vapour, we obtain:

$$\Delta H^{\circ}_{723} = 51.3 \pm 1 \text{ kcal mole}^{-1}; \Delta S^{\circ}_{723} = 29.5 \pm 1.5 \text{ e.u.},$$

that is, values very close to those obtained by Galitskii[43].

Cook and Dann[45], after analysing vapour pressure data for MCl–$FeCl_3$ systems, concluded that vaporisation of the compounds $NaFeCl_4$ and $KFeCl_4$ was possible.

As can be concluded from the above examples, the vapour-phase double compounds of aluminium and iron have the formula $MM'X_4$ in the great majority of instances.

French investigators, in studying the AlF_3–NaF system by the flow and boiling point methods[46], suggested the existence of a heavy vapour-phase molecule, $Na_5Al_3F_{14}$, but this is very improbable. In preferring the form $MM'X_4$ for the vapour phase double compounds of alkali metal chlorides with the trichlorides of other elements we are convinced by the tensimetric and mass-spectrometric investigations of the MCl–$LnCl_3$ systems, where Ln is a rare-earth element (r.e.e.). In the mass-spectrometric analysis of the composition of the vapour over mixtures of the chlorides KCl–$ErCl_3$,[47] NaCl–$LnCl_3$ (Ln = Nd, Er, Y)[48], LiCl–$NdCl_3$,[48] and CsCl–$NdCl_3$ and CsCl–$ErCl_3$,[49] in addition to the ions corresponding to the simple chlorides, the ion $MLnCl_3^+$ has been recorded; this is a fragment of the double chloride molecule $MLnCl_4$.

The thermodynamic characteristics of the dissociation of the complex:

(28) $(MLnCl_4) = (MCl) + (LnCl_3)$

were calculated, starting from the values of

$$K_{equil} = \frac{P_{MCl} P_{LnCl_3}}{P_{MLnCl_4}}$$

for various temperatures. The necessary partial pressures of the components of the vapour were found strictly by the method proposed by Novikov and Gavryuchenkov[50] for the systems $ErCl_3$–KCl,[50] $LaCl_3$–NaCl,[51] NaCl–$NdCl_3$,[48] CsCl–$NdCl_3$ and CsCl–$ErCl_3$,[49] and with some assumptions for the $ErCl_3$–NaCl [52] and KCl–$LnCl_3$ systems[53] (Ln = La, Ce, Pr, and Nd). To calculate the composition of the vapour in these systems we used data on the saturated vapour pressure obtained by tbe boiling point method[54], and information on the gross composition of the vapour obtained by analysis of the condensates.

Table 2 gives the values of the thermodynamic characteristics of the dissociation of $MLnCl_4$, taken from the works cited above[48-53]. It suggests that the stabilities of the r.e.e. chloro-complexes are similar. Along the alkali metal series Na–K–Cs their stability changes in the same sequence as for the dimers of the alkali metal halides. As shown above, there is the same change in stability for the double halides of type $MM'X_3$.

The data are still insufficient to decide reliably how the stability of the $MM'X_4$ double chlorides changes with the nature of the complex-forming element, but since $NaLaCl_4$ is more stable than the corresponding aluminium double chloride by almost 20 kcal mole^{-1} and the double chlorides of boron decompose at ~ 300° without passing into the vapour[55], it can be taken that in the sequence B–Al–La the stability of the double chlorides will increase.

Let us now consider the formation of vapour-phase double compounds of the elements of Periodic Group IV.

The halides of elements in the quadrivalent state have less tendency to form stable double compounds in vapour form than those of elements in a bivalent or tervalent state.

Thus Flengas and Ingraham[56], who studied the behaviour of K_2TiCl_6 in heating, found that this compound, without passing into the vapour, decomposes according to the scheme:

(29) $[K_2TiCl_6] = 2[KCl] + (TiCl_4)$ $\Delta H^{\circ} = 26.4$ kcal mole^{-1}; $\Delta S^{\circ} = 33.3$ e.u.

Just as in the systems CsCl–$TiCl_4$ and RbCl–$TiCl_4$,[57] NaCl–$ZrCl_4$,[58-60] KCl–$ZrCl_4$,[59] and CsCl–$ZrCl_4$,[61] so also in the analogous systems with $HfCl_4$ [61,62] the double compounds do not pass into the vapour, but decompose to form $ZrCl_4$ or $HfCl_4$ vapour.

$ThCl_4$, which is even less volatile, can form a rather stable vapour-phase double chloride[63] with potassium chloride:

(30) $(KThCl_5) = (KCl) + (ThCl_4)$ $\Delta H^{\circ}_{1280} = 49.3 \pm 3$ kcal mole^{-1}; $\Delta S^{\circ}_{1280} = 28.0 \pm 3$ e.u.

TABLE 2. Values of ΔH°_{T}, kcal mole^{-1}, and ΔS°_{T}, e.u., for the dissociation of compounds in the vapour phase.

Compound		Ln				
		La	Ce	Pr	Nd	Er
$NaLnCl_4$	ΔH°_{1400}	69.8	—	—	61.3	63.0
	ΔS°_{1400}	32.8	—	—	32 6	34.0
$KLnCl_4$	ΔH°_{1350}	61.4	61.0	59.3	59.3	59.5
	ΔS°_{1350}	32.6	32.6	32.6	32.6	32.6
$CsLnCl_4$	ΔH°_{1300}	—	—	—	57.2	58.0
	ΔS°_{1300}	—	—	—	29.8	30.8

The authors[63] based the calculation for this system on the pressure and gross composition of the vapour. The form of the compound is determined by analogy with the form of the double fluoride in the $NaF-ZrF_4$ system. The latter system was investigated in detail by Sidorov[64,65]. As a result of the mass spectrometric study of the composition of the vapour in the $NaF-ZrF_4$ system he found that the compound corresponds to the formula $NaZrF_5$ and the value of ΔH_T° was calculated for the process:

(31) $(NaZrF_5) = (NaF) + (ZrF_4)$ $\Delta H^\circ_{1170} = 64.4$ kcal mole^{-1}.

Sense and coworkers[66,67] give for this process very similar values for the thermodynamic characteristics:

$$\Delta H^\circ_{1300} = 67 \text{ kcal mole}^{-1};\ \Delta S^\circ_{1170} = 29 \text{ e.u.}$$

and also suggest the formation of volatile fluorides in the ZrF_4-MF systems (M = Li, Rb).

Comparison of the data for the $NaCl-ZrCl_4$ [58-60] and $NaF-ZrF_4$ [64-67] systems indicates that double compounds of fluorides are more stable than the analogous compounds of chlorides, and this conclusion can evidently be taken as general.

Reverting to the complex chlorides, it is interesting to compare the stability of the double compounds of Groups I, II, III, and IV. Table 3 gives the values of the thermodynamic characteristics of the dissociation of some vapour-phase double compounds.

The choice of the elements in Table 3 is not fortuitous. From their position in the Periodic Table, K, Sr, La, and Th are diagonal analogues, which permits a comparison of the thermodynamic properties of monotypical compounds of these elements.

On comparing the quantities in Table 3, it is seen that there are extrema in the stability characteristics of the vapour-phase double chlorides of the type $KMCl_n$ as n goes from 2 to 5.

Extrema occur because the stability of the vapour-phase double compounds is influenced by at least two opposing tendencies: on the one hand, increase in the charge of the nucleus of the atom of the complex-forming element in the series K–Sr–La–Th, on the other, an increase in the coordination number, and consequently a rise in the repulsion energy of the ligands (Cl) for one another.

The increase in stability of the compounds $MM'Cl_n$ on going down the groups of the Periodic Table which we noted earlier becomes understandable from this point of view, since the coordination number here remains unchanged, whereas the size of the atom of the complex-forming element increases, and consequently the energy of repulsion of the ligands falls.

It is also interesting to note that double compounds which are stable in the vapour are formed when the chlorides reacting have similar volatility. On the other hand, if one of the chlorides has much greater volatility than the other, then the degree of association and the energy of complex formation in the vapour are much less. This can be illustrated by the examples quoted above for reactions in the systems $KCl-M'Cl_4$ (M' = Ti, Zr, Hf, Th). At the same temperature the saturation vapour pressures of titanium, zirconium, and hafnium chlorides are respectively 10^{12}, 10^7, and 10^8 times the vapour pressure of KCl. As already noted, these chlorides do not form volatile double compounds. On the other hand, $ThCl_4$, which has a saturation vapour pressure almost the same as that of KCl, forms the stable vapour-phase compound $KThCl_5$.

TABLE 3.

Equilibrium	ΔH°_T, kcal mole^{-1}	ΔS°_T, e.u.	Reference
$(KKCl_2) = (KCl) + (KCl)$	44.5	28.4	9
$(KSrCl_3) = (KCl) + (SrCl_2)$	67	32	25
$(KLaCl_4) = (KCl) + (LaCl_3)$	61	33	47
$(KThCl_5) = (KCl) + (ThCl_4)$	49	28	56

In conclusion we shall refer to the problem of the vaporisation of ammonium double halides. The facts given above show that double chlorides of the type $MM'Cl_n$ are rather involatile compounds, but stable in the vapour. On the other hand, double chlorides based on ammonium chloride are thought by many authors to be readily volatile.

Thus, Morozov and Toptygin[68], in studying the $AlCl_3-NH_4Cl$ system by the flow method, supposed that the compound NH_4AlCl_4 volatilises without decomposition and found its boiling point to be 402°. In the same system results obtained[69] by a static method indicate that the composition with 50 mole % has maximal boiling point.

Investigators of the $NH_4Cl-FeCl_3$ system[70] found that the compound $FeCl_3.NH_4Cl$ not only exhibits a congruent melting point, but also boils without decomposition and the boiling point of the melt with 50 mole % composition is maximal, as in the $NH_4Cl-AlCl_3$ system.

Li[71] states that $(NH_4)_2SnCl_6$ sublimes at 412°, whereas the alkali metal hexachlorostannates decompose without entering the vapour.

Note that in all the studies mentioned above there is no direct proof of the existence of double chlorides of the type $NH_4M'Cl_x$ in vapour form.

The conclusion that the ammonium double chlorides vaporise (or sublime) without decomposition is usually based on the fact that the condensate obtained in the vaporisation has the same composition as the initial compound. However, when the double compound is formed by ammonium chloride and a rather volatile chloride ($AlCl_3$, $FeCl_3$, $SnCl_4$, etc.) the composition of the condensate and the original compound will be the same even if the compound dissociates completely in the vapour but then is formed again on condensation, as happens in the vaporisation of NH_4Cl. When the double compound is formed by ammonium chloride and another relatively more involatile chloride, then such behaviour is impossible and the composition of the condensate will not correspond to the composition of the compound, as for example, in the $NH_4Cl-ZnCl_2$ and $NH_4Cl-CdCl_2$ systems[70]. Such behaviour by ammonium salts is easy to explain qualitatively. It is well known that the stabilisation of such forms is connected with the formation of the NH_4^+ ion. On transfer to the vapour the degree of ionicity of the bonds in the molecules drops sharply, which in ammonium compounds should lead to marked weakening of them.

Hence there is still no single opinion concerning the formation of ammonium double chlorides in vapour form.

III. INCREASE IN THE THERMAL STABILITY OF COMPLEX HALIDES ON VAPORISATION

To determine whether strengthening or weakening of bonds in complex chlorides occurs on vaporisation it is obviously necessary to compare their stability in relation

to dissociation into simple chlorides in the condensed and vapour states.

The dissociation of double chlorides in these states of aggregation can be related to one another by the following scheme:

Scheme 2

$[MM'Cl_{n+1}] = [MCl] + [M'Cl_n]$	ΔH_1°;	ΔS_1°
$[MCl] = (MCl)$	ΔH_2°;	ΔS_2°
$[M'Cl_{n+1}] = (M'Cl_n)$	ΔH_3°;	ΔS_3°
$[MM'Cl_{n+1}] = (MM'Cl_n)$	ΔH_4°;	ΔS_4°
$(MM'Cl_{n+1}) = (MCl) + (M'Cl_n)$	ΔH_5°;	ΔS_5°

$$\Delta H_5^\circ - \Delta H_1^\circ = (\Delta H_2^\circ + \Delta H_3^\circ) - \Delta H_4^\circ,$$
$$\Delta S_5^\circ - \Delta S_1^\circ = (\Delta S_2^\circ + \Delta S_3^\circ) - \Delta S_4^\circ.$$

According to Scheme 2, bond strengthening in the compound on passing into the vapour is determined by the difference in the thermodynamic characteristics of the first and last processes and appears as the result of the competition of the volatility of the double chloride (ΔH_4°) and of the dissociation products (ΔH_2° and ΔH_3°).

The quantities ΔS_2°, ΔS_3°, and ΔS_4° vary little for the different halides; therefore the difference ($\Delta S_2^\circ + \Delta S_3^\circ$) - ΔS_4° can be taken as constant at ~ 25 e.u. At 1000–1300°K such a change in entropy will correspond with a change in free energy of 25–30 kcal mole^{-1}, that is,

$$\Delta G_5^\circ - \Delta G_1^\circ = (\Delta H_5^\circ - \Delta H_1^\circ) - (25-30)T.$$

Consequently, the strengthening of the double compounds will take place if (ΔH_5° - ΔH_1°) ≥ 25–30 kcal mole^{-1}. From the relation

$$\Delta H_5^\circ - \Delta H_1^\circ = (\Delta H_2^\circ + \Delta H_3^\circ) - \Delta H_4^\circ$$

it can be concluded that the quantities ΔH_2, ΔH_3, and ΔH_4 (that is, the volatility characteristics of the simple and double chlorides) determinine the strengthening or weakening of binding in the double compound on passage into the vapour and, consequently, also the possibility of its existence. Let us examine this question by specific examples.

In the first example we will examine the vapour-phase double chlorides of the r.e.e. and potassium.

For the dissociation of these compounds:

(32) $$(KLnCl_4) = (KCl) + (LnCl_3),$$

where Ln = La, Ce, Pr, Nd, and Er, very similar thermodynamic characteristics have been proposed[50-53].

$$\Delta H_{1350}^\circ = 60 \text{ kcal mole}^{-1};\quad \Delta S_{1350}^\circ = 32.6 \text{ e.u.}$$

In the same studies the following characteristics have been proposed for the sublimation of the double chloride:

(33) $$[KLnCl_4] = (KLnCl_4)\ \Delta H_T^\circ = (60—70) \text{ kcal mole}^{-1};\ \Delta S_T^\circ = 41 \text{ e.u.}$$

Hence in the example under consideration both the double chlorides and their dissociation products are of low volatility. Thus, for $LnCl_3$ (ΔH_S° = 75–65 kcal mole^{-1}, ΔS_S° = = 45–42 e.u.)[72] and for KCl (ΔH_S° = 53.3 kcal mole^{-1}, ΔS_S° = = 33.3 e.u.)[14], the value of ΔH_4° according to Baev's estimate[73] is ~ 4–6 kcal; therefore the difference (ΔH_2° + ΔH_3°) - ΔH_4° will here be greater than the quantity ~ 55 kcal mole^{-1}, which ensures strengthening of the bonds in the complex during vaporisation.

We will consider a second, frequently encountered, example that occurs when the double compound and one of the dissociation products is of low volatility but the other is volatile.

The two chlorides of different volatility KCl and $TiCl_4$ (ΔH_e = 9.6 kcal mole^{-1}) form a compound K_2TiCl_6, which, as is well known[56], decomposes above 300°:

(34) $$[K_2TiCl_6] = 2[KCl] + (TiCl_4) \qquad \Delta H_{920}^\circ = 26{,}4 \pm 1.3 \text{ kcal mole}^{-1};\quad \Delta S_{920}^\circ = 28{,}5 \pm 2.3 \text{ e.u.}$$

This process proceeds without noticeable appearance of potassium chloride in the condensate† which could serve as an indication of the formation of the double compound in the vapour to even a slight extent. We will compare this reaction with the hypothetical appearance in the vapour of $KTiCl_5$ (by analogy with $NaZrF_5$):[55]

(35) $$[K_2TiCl_6] = [KCl] + (KTiCl_5).$$

Let the experimentally imperceptible equilibrium in the vapour:

$$(KTiCl_5) = (KCl) + (TiCl_4),$$

be characterised by the value ΔS° = 28 e.u., like the analogous process of the dissociation of $KThCl_5$:[63]

$$\Delta H_{610}^\circ = 27 \text{ kcal mole}^{-1}.$$

Let us draw up Scheme 3:

Scheme 3

		ΔH kcal mole^{-1}	ΔS, e.u.
(a)	$[K_2TiCl_6] = 2[KCl] + (TiCl_4)$	ΔH_1°=26.4	ΔS_1°=33.3
(b)	$[KCl] = (KCl)$	ΔH_2°=50.2	ΔS_2°=32,6
(c)	$(KTiCl_5) = (KCl) + (TiCl_4)$	ΔH_3°= (≤32)	ΔS_3°= (28)
(d)	$[K_2TiCl_6] = [KCl] + (KTiCl_5)$	ΔH_4° (≥45)	ΔS_4°= (38)

From the experimental data on the vapour pressure of ($TiCl_4$) over $[K_2TiCl_6]$ 1 atm is reached at 798°K. Let us suppose that the condition of near involatility of the double compound at this temperature corresponds to a $KTiCl_5$ pressure ≤ 10^{-4} atm. Starting from this value at ΔS_4° = = 38 e.u. we find for equilibrium (*d*) $\Delta H_4^\circ \geq 45$ kcal mole^{-1}, whence for equilibrium (*c*) we obtain $\Delta H_3^\circ \leq 32$ kcal mole^{-1}. If on the basis of these quantities we calculate ΔG_T° of stabilisation according to Scheme 2, we obtain ΔG_T° = = 28 - $T \times 28 \times 10^{-3}$ kcal mole^{-1} from whence it follows that in the vapour $KTiCl_5$ has enhanced stability only up to 1000°K, when its volatility is negligible, whereas under these conditions the decomposition of $[K_2TiCl_6]$ with formation of ($TiCl_4$) has already ceased.

† In the analogous NaCl–$ZrCl_4$ system Korschunov and Gregory[60] note a little NaCl in the condensate but explain this by entrainment of dust. According to their results the only process is:

(36) $$[Na_2ZrCl_6] = 2[NaCl] + (ZrCl_4)\quad \Delta S_{610}^\circ = 28 \text{ e.u.}$$

The following example, in which a rather difficultly volatile compound decomposes on heating to give two readily volatile compounds, is encountered comparatively rarely. An example is the equilibrium:

$$(37)\qquad [NH_4Cl] = (NH_3) + (HCl) \qquad \begin{matrix}\Delta H^\circ_{298} = 42.4 \text{ kcal mole}^{-1},\\ \Delta S^\circ_{298} = 68.4 \text{ e.u.}\end{matrix}$$

The values ΔH° = 9.4 kcal mole^{-1} and ΔS° = 3.1 e.u. have been proposed[74-76] for the dissociation of ammonium chloride in the vapour:

$$(38)\qquad (NH_4Cl) = (NH_3) + (HCl).$$

Combining these two equilibria, for the sublimation of ammonium chloride we obtain ΔG° = 33 000 - 37T, from which at T = 620°K the saturated vapour pressure of $NH_4Cl \simeq 0.3$ mm, whereas at this temperature its dissociation pressure reaches 1 atm.

These examples lead to the following conclusions.

1. A double compound can be present in vapour in appreciable quantities if the thermodynamic characteristics of its volatility are close to the analogous quantities for the dissociation products.

2. The lower the volatility of the dissociation products (that is, the greater ΔG°_2 and ΔG°_3 in Scheme 2), the more stable the initial compound in the vapour state (the greater ΔG°_5) and the more it is stabilised on transfer to the vapour (the greater the difference ΔG°_5 - ΔG°_1).

On the other hand, if we write the balance equation compiled according to Scheme 2 in the following form:

$$\Delta G^\circ_5 + \Delta G^\circ_4 = \Delta G^\circ_1 + \Delta G^\circ_2 + \Delta G^\circ_3,$$

then we see that in each specific instance the sum ΔG°_5 + + ΔG°_4, that is, the sum of the characteristics of stability and volatility of the double compound, will be constant. This signifies that the greater the volatility of the double compound (the less ΔG°_4), the greater its stability in the vapour state (the greater ΔG°_5).

IV. CONNECTION BETWEEN COMPLEX FORMATION AND DIMERISATION OF COMPOUNDS IN THE VAPOUR STATE

In considering the vapour states of complex compounds formed by the halides of the alkali metals with those of the elements of Periodic Groups II, III, and IV, it is noted[7,48-52] that their stability alters along the series of alkali metals symbathically with the stability of the dimeric alkali metal chlorides. The same symbathic nature is observed in the change in stability of the complex chlorides and dimeric molecules of chlorides of complex-forming elements.

For example, the heats of dissociation of the $KMgCl_3$ and $KBeCl_3$ molecules[30] are 58.0 and 48.0 kcal mole^{-1}, but those of the dimers[77,78] Mg_2Cl_4 and Be_2Cl_4 are 39.2 and 23.0 kcal mole^{-1} respectively. Hence the molecule of the complex chloride as it were inherits the properties of the dimeric molecules of the initial chlorides. The vapour-phase complex chlorides, like the vapour-phase dimers of the simple chlorides, are usually formed by two molecules, for example, $KMgCl_3$, $NaAlCl_4$, $MLnCl_4$, $KThCl_5$, etc., that is, in form these are substituted dimers, formed not by the same, but by different molecules.

Complex chlorides composed of more than two molecules of simple chlorides are encountered very rarely; just as in the vaporisation of pure chlorides the vapour consists mainly of monomeric and dimeric molecules, but trimers and higher molecular weight polymers are usually observed in much smaller proportions.

The formation of molecules of complex chlorides can be represented as a substitution:

$$(39)\qquad (M_2Cl_{2n}) + (M'_2Cl_{2m}) = 2(MM'Cl_{n+m}).$$

When the reacting dimers have similar properties the heat of substitution is close to zero, for example[16,20]:

$$(40)\qquad (Rb_2Cl_2) + (K_2Cl_2) = 2(RbKCl_2)\quad \Delta H^\circ \simeq 0$$
$$(41)\qquad (Na_2F_2) + (K_2F_2) = 2(NaKF_2)\quad \Delta H^\circ = -2.9 \text{ kcal mole}^{-1}.$$

On going to the double compounds of the alkali metal chlorides with the chlorides of the elements of Periodic Groups II and III the difference in properties of the simple chlorides rises, and there is a corresponding increase in the ΔH° of the substitution. For example[30,43]:

$$(42)\qquad (Na_2Cl_2) + (Al_2Cl_6) = 2(NaAlCl_4)\quad \Delta H^\circ = -27 \text{ kcal mole}^{-1}$$
$$(43)\qquad (Na_2Cl_2) + (Be_2Cl_4) = 2(NaBeCl_3)\quad \Delta H^\circ = -22 \text{ kcal mole}^{-1}.$$

According to Scheme 1 considered above, in its stability to dissociation into simple chlorides a double chloride either approaches the more stable dimer or surpasses it, depending on the heat of substitution. In this connection the concentration of the double chloride in the vapour is either greater than that of each of the dimers or approximately the same as the more stable of the dimers. To illustrate this position we will consider Scheme 4:

Scheme 4

$[MCl_n] = (M_2Cl_{2n})$	ΔH_1	ΔS_1
$[M'Cl_m] = (M'_2Cl_{2m})$	ΔH_2	ΔS_2
$MM'Cl_{n+m}] = [MCl_n] + [MCl_m]$	ΔH_3	ΔS_3
$MM'Cl_{n+m}) = {}^1/_2(M_2Cl_{2n}) + {}^1/_2(M'_2Cl_{2m})$	ΔH_4	$\Delta S_4 \simeq 0$
$[MM'Cl_{n+m}] = (MM'Cl_{n+m})$	ΔH_5	ΔS_5

$\Delta H_5 = {}^1/_2(\Delta H_1 + \Delta H_2) + (\Delta H_3 - \Delta H_4)$
$\Delta S_5 = {}^1/_2(\Delta S_1 + \Delta S_2) + \Delta S_3$

Usually $\Delta H_4 > \Delta H_3$; therefore the enthalpy of sublimation of the complex chloride (ΔH_5) is less than the arithmetic mean of the heats of sublimation of the dimers ($\frac{1}{2}\Delta H_1 + \frac{1}{2}\Delta H_2$). At the same time the change in the entropy of sublimation of the complex chloride is greater than the arithmetic mean of the entropies of sublimation of the dimers by the quantity ΔS_3, since $\Delta S_4 \simeq 0$ as the entropy of a reaction proceeding without change in the number of moles of gas.

In this connection the sublimation of a complex chloride can be energetically more favourable than the sublimation of dimers and therefore its concentration in the vapour is significant even when the dimerisation of one of the chlorides is experimentally imperceptible.

From this point of view the existence in the vapour of a complex chloride can indicate the possibility of dimerisation of the simple chlorides which form it.

When the thermodynamic characteristics of the dissociation of a complex chloride (ΔH°_1 and ΔS°_1) are known, for

example, for $KM'Cl_{n+1}$, then the energy‡ of dimerisation of a chloride MCl_n can be calculated by the method already proposed[6]. The thermodynamic Scheme 5 is drawn up:

Scheme 5

$(KM'Cl_{n+1}) = (KCl) + (M'Cl_n)$	ΔH_1°	$\Delta S_1^\circ \simeq 30$ e.u.
$(KM'Cl_{n+1}) = {}^1/_2(K_2Cl_2) + {}^1/_2(M_2Cl_{2n})$	ΔH_δ°	$\Delta S_\delta^\circ \simeq 0$
${}^1/_2(K_2Cl_{2n}) = (KCl)$	$\Delta H_2^\circ = 22.3$ kcal mole^{-1}	
	$\Delta S_2^\circ = 14.2$ e.u.	
${}^1/_2(M_2Cl_{2n}) = (MCl_n)$	${}^1/_2\Delta H_{dim}^\circ = \Delta H_1^\circ - \Delta H_\delta^\circ - \Delta H_2^\circ$	
	${}^1/_2\Delta S_{dim}^\circ = \Delta S_1^\circ - \Delta S_2^\circ$	

On the basis of many comparisons in this work[6] values for ΔH_δ° from 14 to 22 kcal mole^{-1} are proposed, depending on the position of the element in the Periodic System. The energies of dimerisation for the chlorides calculated in that work agree satisfactorily with the available experimental data. For the dimerisation of the alkaline earth metal chlorides, processes which have not been studied, the following values for the energies have been evaluated: 45, 50, and 42 kcal × × mole^{-1} for $CaCl_2$, $SrCl_2$, and $BaCl_2$ respectively. Although these values are rather high, and this shows the stability of the dimeric molecules in the vapour, they do not contradict the well-known monomeric nature of calcium, strontium, and barium chlorides in the vapour. The fact is that in the range 1000–1500°K the vapour pressure of the alkaline earth metal chlorides is low (1–20 mmHg) and consequently the degree of association should also be small.

In the general form the expression for the degree of association of the species in the saturated vapour has the form[6]:

$$\alpha = \frac{1}{1 + 0.5\exp\left(-\frac{\Delta S^\circ_{sub} - \Delta S^\circ_{diss.dim}}{R}\right)\exp\left(\frac{\Delta H^\circ_{sub} - \Delta H^\circ_{diss.dim}}{RT}\right)},$$

from which it follows that the value of α is determined by the difference in the thermodynamic characteristics of sublimation (vaporisation) and the dissociation of the dimer and also by the temperature.

This means that the degree of association in the vapour is determined not solely by the characteristics of stability of the dimeric molecules. High values of ΔH° for the dissociation of dimers can go with very low degrees of association in the vapour and contrariwise. Examples of this are $FeCl_3$ and KCl. The former is almost completely dimerised in the vapour at the boiling point ($\alpha = 1$) whereas the latter has the value $\alpha \simeq 0.04$ at the same temperature, although the dimer Fe_2Cl_6 is less stable than K_2Cl_2 ($\Delta H^\circ_{diss.dim}$ = 31.6 and 44.5 kcal mole^{-1} respectively)[14,79].

It follows that instances when experiment does not disclose dimeric (or polymeric) molecules cannot always be proof of the instability of the latter, but is evidence only of the insufficient sensitivity of the method. In this respect the following example is instructive. An investigation of the vapour-phase chlorides of the rare-earth elements by electron diffraction[77] showed that they are monomers but in a mass spectrometric analysis of the vapour of the same chlorides[81] ions of the $Ln_2Cl_5^+$ type are observed, that is, fragments of a dimeric molecule.

‡ Strictly "enthalpy of dimerisation" (Ed. of Translation).

Judging by the thermodynamic characteristics of the dissociation:

$$(Ln_2Cl_6) = 2(LnCl_3) \quad \begin{matrix}\Delta H^\circ_{1000} \simeq 40 \text{ kcal mole}^{-1} \\ \Delta S^\circ_{1000} \simeq 30 \text{ e.u.}\end{matrix}$$

the dimeric molecules are completely stable, but since at 1000°K the vapour pressure of the r.e.e. chlorides is very low ($\sim 10^{-3}$ mmHg) the vapour contains only 0.1–1% of dimeric molecules and therefore it is impossible to detect them by electron diffraction.

---o0o---

As the above material shows, the contemporary state of the problem of vapour-phase complex halides is to a significant degree on the level of the accumulation of facts. Attempts to generalise and make recommendations run into difficulties on account of the absence of information about structures and the nature of the bonds in these compounds, even without mentioning the inadequate thermodynamic study and the complete absence of data on the kinetics of the formation and breakdown of complex vapour-phase species. However, although the facts are few, their treatment is already of practical and theoretical importance.

I. INTRODUCTION

Depending on the electronic nature of the breaking of old bonds and the formation of new bonds, all substitutions can be classified into three groups: nucleophilic substitutions S_N, electrophilic substitutions, S_E, and homolytic substitutions S_R.

In distinction from the nucleophilic and homolytic substitutions, which have been well studied, the mechanism of electrophilic substitution at a saturated carbon atom was a blind spot in organic chemistry even a decade ago. However, the intensity of the study of the mechanism of this type of reaction is now increasing rapidly.

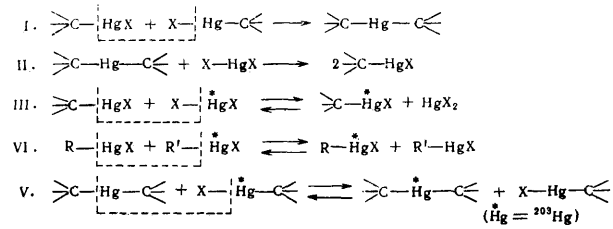
The reason for this, in addition to interest in the S_E reactions for their own sake, is apparently that as a result of discussion between Ingold and Sven† ideas about the mechanism of nucleophilic substitutions, and in particular S_N1 reactions, were greatly complicated. In this connection there was a natural tendency for a series of great chemists to switch to a study of the mechanism of electrophilic substitutions to try to transfer the regularities thus found to the mechanism of nucleophilic substitution.

To compare ideas about the mechanism of S_E reactions, the first essential is a combined study of their stereochemistry and kinetics, as it is in many other instances.

In distinction from nucleophilic and homolytic substitutions, here above all arises the difficulty of selecting suitable subjects for study, especially as regards stereochemistry. Few such subjects are known as yet.

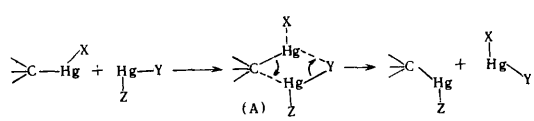
From 1955 until now Cram (a survey of his work has appeared[3]) has completed a great series of works on the study of the stereochemistry of the reaction for the breaking of a carbon–carbon bond under the action of substances which are proton donors:

As a result interesting facts were obtained on the chemistry of carbanions but in most instances Cram was unable to study the kinetics of the reaction.



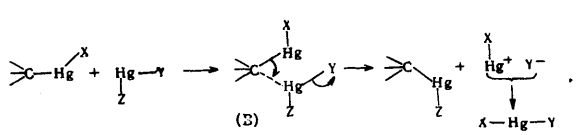
Evidently the most suitable subjects for studying the mechanism of electrophilic substitution at a saturated carbon atom should be organometallic compounds, owing to the definite nature of the polarisation of the metal–carbon bond:

$$^{(+)}M-C^{(-)}.$$

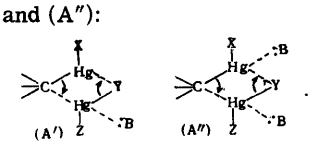


Of all the organometallic compounds, organomercury compounds are the most convenient: they are stable under ordinary conditions but sufficiently reactive, easily prepared, purified, and identified. Therefore, in recent years the most significant progress has been made in studying S_E reactions of organomercury compounds.

2. BIMOLECULAR ELECTROPHILIC SUBSTITUTION (S_E2) AT A SATURATED CARBON ATOM



Study of the kinetics and stereochemistry of the electrophilic substitution at a saturated carbon atom of types I–V:



led to the conclusion that in non-polar and low-polar solvents the above reactions pass through the stage of formation of a cyclic four-membered transition state of type (A)[4–7]‡:

(I) X = Y = Hal, Z = Alk; (II) X = Alk, Y = Z = Hal; (III) X = Y = Z = Hal; (IV) Z = Alk, X = Y = Hal; (V) X = = Z = Alk, Y = Hal. The bases for taking such a structure of the transition state are: bimolecular reactions (kinetics of the second order overall and first order with respect to each of the components) proceed with strict retention of the stereochemical configuration, that is, the newly entering metal atom strictly takes the place of that leaving[8–11]; finally, the open transition state of type (B) is improbable in non-polar and low-polar solvents, because it would lead to the intermediate formation of the ions§ HgX^+ and Y^+:

Naturally, with a solvent in whose molecules there are atoms with unshared electron pairs (pyridine, dimethylformamide, ammonia) one or both of the mercury atoms in the transition state should be solvated or even bound by a coordination bond with solvent molecules — the transition states (A′) and (A″):

† The problems have been reviewed.[1,2]

‡ S_E2 reactions which proceed through a stage of a cyclic transition state are often denoted by the symbol S_Ei.

§ It is quite probable that S_E2 reactions proceed through transition state (B) in polar solvents.[12,13]

For the reactions of one-alkyl isotopic exchange (III) and symmetrisation (I) such coordination has been shown experimentally. Thus the isotopic exchange of α-ethoxycarbonylbenzylmercury(II) bromide with mercury(II) bromide in dimethylformamide is really the reaction of R–Hg–X and a complex of HgX_2 with dimethylformamide[14]:

$$R{-}HgX + \overset{*}{H}gX_2\cdot C_3H_7ON \rightleftarrows R{-}\overset{*}{H}gX + HgX_2\cdot C_3H_7ON .$$

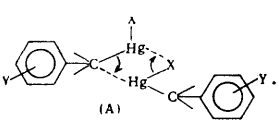
Undoubtedly, when the reaction is carried out in pyridine[6,15] the active reagent is $HgX_2.C_5H_5N$, not free HgX_2. The symmetrisation of the same substance under the action of ammonia in chloroform:

$$2R{-}HgX + 2NH_3 \rightarrow R_2Hg + HgX_2\cdot(NH_3)_2,$$

proceeds through the preliminary stage of the formation of a complex of the organomercury compound with ammonia, evidently by scheme 1¶:

Scheme 1

(a) $R{-}HgX + NH_3 \overset{\text{fast}}{\rightleftarrows} R{-}HgX\cdot NH_3$



(b) $2R{-}HgX\cdot NH_3 \xrightarrow{\text{slow}} R_2Hg + HgX_2\cdot(NH_3)_2\}\ S_E2.$

Here the S_E2 reaction proceeds through the transition state of type (A").

It is easy to see, however, that general conclusions about the mechanism of the S_E2 reactions at a saturated carbon atom, made in considering the transition state (A). whether or not involving solvation or coordination of mercury atoms, will be identical†, because the transition state (A) will not differ significantly from transition state (A").

The main feature of all these transition states is a four-membered ring (A). This very feature is also responsible for symmetrisation with reactions (II)–(V) and determines the corresponding theoretical conclusions made on the basis of an independent study of S_E2 reactions of all five types. Therefore in judging subsequently the characteristic features of the symmetrisation we will consider for clarity a four-membered cyclic transition state (A), so to speak, "in the pure aspect", having, of course, in mind, that in reality either one or both of the mercury atoms are coordinated to molecules of ammonia.

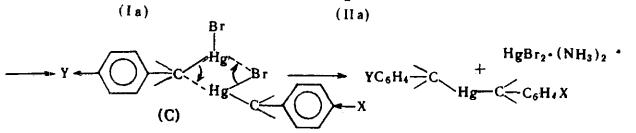
In studying the influence of structural factors on the rate of symmetrisation of a series of substituted α-ethoxycarbonylbenzylmercury(II) bromides it was concluded that in transition state (A) the breaking of the old C–Hg bond plays a more important part than the formation of the new one[5,6]:

(A)

The values of the rate constants for second-order reactions k_2 are given in Table 1.

The influence of substituents Y on this reaction obeys the Hammett equation. Clearly the order of the influence of the substituents is reversed in comparison with typical

TABLE 1.



Y	*p*-NO_2	*p*-I	*p*-Br	*m*-Br	*o*-Br	*p*-Cl	*p*-F	H	*p*-CH_3	*m*-CH_3	*o*-CH_3	*p*-C_2H_5	*p*-$(CH_3)_2CH$	*p*-$(CH_3)_3C$
k_2, ml mole^{-1} s^{-1}	17 730	670	540	1445	426	470	148	110	34	71	32	41	42	28

* The constant k_2 was calculated assuming that Hammett's equation is applicable to this series (ρ = 2.85).

S_E2 reactions‡. This feature can be interpreted in the same way, that in consequence of the specific properties of the given organomercury compounds used (high lability of the C–Hg bond), the S_E2 reaction being studied is in the boundary region close to the region of S_E1 reactions unknown until recently (see p. 167).

Since in the transition state (A) not only the old C–Hg bond but also the old Hg–Br bond is broken it is natural to assume that such a type of transition state will be attained more easily for reactions between molecules of different types (Ia) and (IIa):

$$\underset{\text{(Ia)}}{YC_6H_4CH(HgBr)COOR} + \underset{\text{(IIa)}}{XC_6H_4CH(HgBr)COOR} \xrightarrow{2NH_3}$$

(C)

The electron-withdrawing substituent Y should facilitate the breaking of the old C–Hg bond in transition state (C), and the electron-donating substituent X, should facilitate the breaking of the old Hg–Br bond. Therefore such a type of "cosymmetrisation" should be faster than the symmetrisation of either of the two pure substances. Experiment completely confirmed this. Finally, by use of radioactive mercury ^{203}Hg it was shown[24] that a mercury atom from the original molecule (Ia) with a substituent Y preferentially transfers into the complex $HgBr_2.(NH_3)_2$ but an atom of mercury from molecule (IIa) with a substituent X goes into the organomercury compound formed, as can be predicted by starting from the transition state (C):

$$\underset{\text{(Ia)}}{YC_6H_4{-}\overset{COOC_2H_5}{\overset{|}{C}}H{-}\overset{*}{H}g{-}Br} + \underset{\text{(IIa)}}{XC_6H_4{-}\overset{COOC_2H_5}{\overset{|}{C}}H{-}Hg{-}Br} \xrightarrow{2NH_3}$$

$$\longrightarrow YC_6H_4{-}\overset{COOC_2H_5}{\overset{|}{C}}H{-}Hg{-}\overset{COOC_2H_5}{\overset{|}{C}}H{-}C_6H_4X + \overset{*}{H}gBr_2\cdot(NH_3)_2$$

where Y = Br, X = H; Y = H, X = CH_3; Y = Br, X = CH_3.

Hence the above cyclic transition state in the S_E2 reactions of organomercury compounds can now be considered adequately proved§.

Note that the work of Dessy and coworkers[28] has suggested the possibility of a more complex transition state in S_E2 reactions at a saturated carbon atom than that proposed by Reutov[4-7] and Ingold[29]. However Dessy's work was not confirmed when checked[30].

¶ The basis for the scheme is given and discussed elsewhere.[16-20]

† Jensen and Rickborn's views on this[20,21] are based on a misunderstanding and are erroneous (see Reutov[22]).

‡ Note that such an "anomalous" influence of substituents is observed in the reaction of esters of α-bromomercuriarylacetic acids with I_2/CdI_2 in toluene.[23]

§ The field of the reactions of organometallic compounds proceeding through an analogous cyclic transitional state, which has been studied, includes some bimolecular electrophilic substitutions of hydrogen, halogen, and metal for metal at saturated, alkene, and aromatic carbon atoms.[18,25-27]

3. SYMMETRISATION OF ORGANOMERCURY COMPOUNDS WITH THE AID OF DIPHENYLMERCURY

Diphenylmercury was proposed[31] as a symmetrising agent for organomercury compounds with a labile C–Hg bond:

$$(C_6H_5)_2Hg + 2R{-}HgX \rightarrow R_2Hg + 2C_6H_5{-}HgX\downarrow,$$

where R = CH_3COCH_2, ClCH=CH, or $ArCH{=}COOC_2H_5$.

Three possible reaction schemes were considered:

Scheme 1

(a) $2R{-}HgX \rightleftarrows R_2Hg + HgX_2$
(b) $(C_6H_5)_2Hg + HgX_2 \rightarrow 2C_6H_5{-}HgX\downarrow$

Scheme 2

(a) $R{-}HgX + (C_6H_5)_2Hg \rightarrow C_6H_5{-}Hg{-}R + C_6H_5HgX\downarrow$
(b) $C_6H_5{-}Hg{-}R + R{-}HgX \rightarrow R_2Hg + C_6H_5HgX\downarrow$

Scheme 3

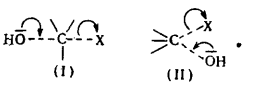
(a) $R{-}HgX + (C_6H_5)_2Hg \rightarrow C_6H_5{-}Hg{-}R + C_6H_5HgX\downarrow$
(b) $2C_6H_5{-}Hg{-}R \rightleftarrows (C_6H_5)_2Hg + R_2Hg.$

Jensen and Miller[32] thought the last two schemes equally probable. However, on using esters of α-bromomercuriarylacetic acids (R = $ArCHCOOC_2H_5$) labelled with ^{203}Hg it was shown[33] that the reaction mechanism corresponds to scheme 2, but not 1 or 3.

It is easy to see (scheme 2) that both stages of the reaction are completely analogous to the three-alkyl isotopic exchange of organomercury compounds discovered earlier[10,11,34].

4. STEREOCHEMISTRY OF THE S_E2 REACTIONS

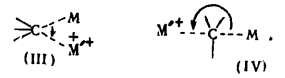
All the S_E2 reactions at a saturated carbon atom yet studied by the example of organomercury compounds proceed with strict retention of the stereochemical configuration.



Examples of this are the symmetrisations[8,9] considered above, the three-alkyl isotopic exchange (p. 164, reaction of type V) discovered by Reutov and coworkers[10,11] and somewhat later independently by Ingold and coworkers[34].

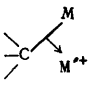
Such a reaction of symmetrical organomercury compounds with a mercury halide (p. 164, reaction II) was studied by Ingold and coworkers[35] and by some others.

The S_E2 rule has been formulated[6], according to which bimolecular electrophilic substitutions at a saturated carbon atom proceed with retention of the configuration.



It is important to attempt to answer the following natural question: is the S_E2 rule, which has been developed on the basis of a study of reactivity of only organomercury compounds, generally applicable?

The inversion of the configuration in S_N2 reactions at a saturated carbon atom is known to be due to the fact that of the two possible transition states (I) and (II), the first is energetically more favourable.



(I) (II)

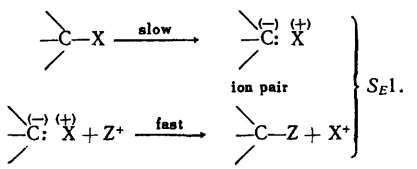
In a similar fashion, of the two possible transition states (III) and (IV) in S_E2 reactions, state (III) should apparently be more preferable in energetic respects — without even speaking about the stabilisation which is often possible on account of the formation of type (A) rings (see p. 164):

(III) (IV)

By analogy with π-complexes it could be suggested that transition state (III) comes about from the preliminary formation of a σ-complex (V):

(V)

However, unlike the π-complexes, there is still no experimental proof of the existence of such σ-complexes. On the other hand it is difficult to oppose the hypothesis that the formation of transition state (III) precedes the attack by the cation on the C–M bond in the sense of a hypothetical σ-complex (V).



As for spatial factors, they are not very favourable for the retention of configuration for organomercury compounds because of the large covalent and van-der-Waals radii of the mercury atom. Hence the spatial factor which hinders reaching transition state (III) probably cannot change the stereochemical result even for extremely large M and M′.

On the basis of the above it can be suggested that the rule of the retention of configuration in S_E2 reactions can be of a rather general character¶.

5. UNIMOLECULAR ELECTROPHILIC SUBSTITUTION AT A SATURATED CARBON ATOM

Of the four possible mechanisms of heterolytic substitution at a saturated carbon atom (S_N2, S_N1, S_E2, and S_E1) the S_E1 type remained undiscovered until the most recent time.

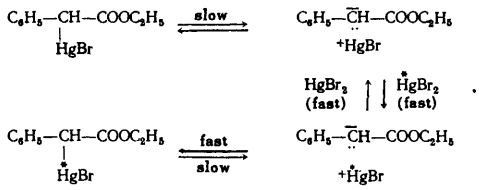
In the general form the S_E1 mechanism can be expressed as follows:

In the first, slow stage the reaction proceeds by ionisation of the C–X bond with formation of a carbanion (part of an ion pair). In the second, rapid stage of the reaction the ion pair reacts with the electrophilic reagent (Z^+), forming the final compound.

The hope of realising the S_E1 mechanism appeared in connection with the results of stereochemistry and kinetics of symmetrisation of esters of α-bromomercuriarylacetic acids under the action of ammonia.

As noted above, the nature of the influence of the structural factors on the rate of the S_E2 reactions being considered showed that in the transition state (A) the breaking of the old C–Hg bond played a more important part than the formation of the new bond[4,6].

¶ A known instance of the inversion of configuration in an S_E2 reaction of 5-norbornene-2-boronic acid with $HgCl_2$ is explained by the exchange of the boronic acid residue for the HgCl residue being a transannular (and not the usual) electrophilic substitution[36]. Winstein[37] described a similar example.

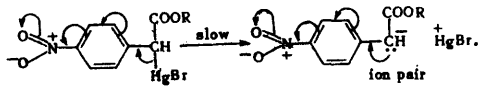


This conclusion, which is unusual for bimolecular reactions, shows that this reaction is close to the boundary region between S_E2 and S_E1 reactions (for the latter, as stated earlier, the stage of ionisation of the old bond is the most important stage)†.

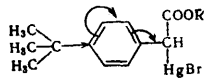
It can be hoped that when the reactions (for the same esters of α-bromomercuriarylacetic acids) are carried out in a solvent with a high ionising ability the S_E1 mechanism will be effected.

Such an attempt, which was crowned with success, was made for the isotopic exchange:

$$RR'R''C{-}HgBr + {}^{*}HgBr_2 \rightleftarrows RR'R''C{-}{}^{*}HgBr + HgBr_2 .$$



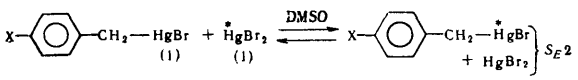
The isotopic exchange in pyridine, dimethylformamide, and ethanol is an S_E2 reaction[15,16]. However, when dimethyl sulphoxide (DMSO), which exhibits high ionising ability, is used as the solvent the kinetics and mechanism of the reaction immediately change. The reaction is first order with respect to the α-bromomercuriarylacetate ester and zeroth-order to the mercury(II) bromide. Hence an S_E1 type of reaction was discovered for the first time[38].



The influence of substituents X in the *para*-position of the benzene ring on the rate of isotopic exchange was studied. The experimental results for substituted α-ethoxycarbonylbenzylmercury(II) bromides at 30° are given in Table 2.

Electron-donating substituents (t-butyl) decrease, but electron-accepting substituents (I, NO_2) increase, the rate of reaction.

Such an order of influence agrees with the predictions about the S_E1 mechanism: electronegative substituents should facilitate breaking of the carbon–mercury bond and stabilise the carbanion, which is formed (as part of an ion pair) as a result of the slow stage of ionisation of the organomercury compound:



The action of the electropositive substituents will be opposing:

(hence the slow rate of ionisation and consequently of the overall reaction as a whole)‡.

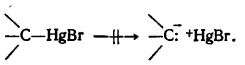
In studying the isotopic exchange in DMSO of benzyl organomercury compounds (less reactive in S_E reactions than esters of α-carboxybenzylmercury(II) bromides) it was found[44] that the reaction takes place by a bimolecular, not a unimolecular, mechanism:

where X = $(CH_3)_2CH$, CH_3, H, Cl, or F, that is, just as when quinoline is used as solvent[45]§.

TABLE 2.

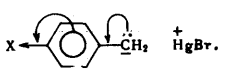
Compounds p-XC_6H_4–CH(HgBr)–$COOC_2H_5$	X		
	$(CH_3)_3C$	I	NO_2
$\frac{k_X}{k_H}$ (DMSO, 30°)	0.71	1.31	4.04

† Note that esters of α-bromomercuriarylacetic acids, like other α-mercurated oxo-compounds, exhibit an extremely labile C–Hg bond, and tend to ionise to a greater extent than the usual alkyl and aryl organomercury compounds.



‡ Ingold and coworkers[39] repeated the work of Reutov and coworkers[38,40] and confirmed completely the results about the S_E1 mechanism in the isotopic exchange of α-ethoxycarbonylbenzylmercury(II) bromide with $^{203}HgBr_2$ in DMSO. In addition, they could not reproduce the results of our work[40] in 70% aqueous dioxan, where kinetics of the first order with respect to the organomercury compound and zeroth order in $^{203}HgBr_2$ were observed also (and consequently, an S_E1 mechanism). According to Ingold's results, which he himself considers preliminary, overall second-order kinetics was observed (first in R–HgX and first in $^{203}HgX_2$). Recently Reutov and Sokolov again repeated the work with 70% aqueous dioxan and reproduced their experimental results published earlier[40,41]. The reason for the above differences in the work with dioxan are still not completely clear to the two groups of investigators. This problem, however, no longer is of principal significance, since both Reutov and Ingold[42,43], "agree qualitatively and quantitatively in principle: the S_E1 mechanism is clear in studying the isotopic exchange of α-ethoxycarbonylbenzylmercury(II) bromide with $HgBr_2$ in DMSO" [Ingold's actual words[43] are: "We are agreed, qualitatively and quantitatively, about the fact of main interest; namely that, in anhydrous DMSO, the substitution in α-ethoxycarbonylbenzylmercury(II) bromide by $^{*}HgBr_2$ is of first order in the organo-mercuric salt and of zeroth order in the mercuric salt and hence must have the S_E1 mechanism" (Ed. of Translation)].

§ It is interesting that allylmercury(II) bromide reacts extremely rapidly with $HgBr_2$:

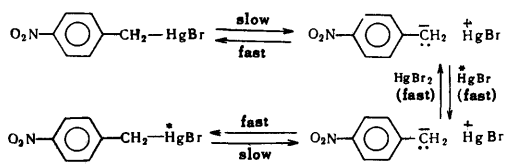


$$CH_2{=}CH{-}CH_2{-}HgBr + {}^{*}HgBr_2 \rightleftarrows CH_2{=}CH{-}CH_2{-}{}^{*}HgBr + HgBr_2 .$$

The isotopic equilibrium is established almost instantaneously at room temperature in various solvents: DMSO, quinoline, acetone, toluene.

Evidently, despite the high ionising ability of DMSO it is here insufficient to ionise the strong C–Hg bond to form an ion pair:

It is natural to assume that the probability of the existence of an S_E1 mechanism of this reaction in DMSO should rise when the carbanion formed as a result of the ionisation exhibits a greater stability owing to the delocalisation of the negative charge, for example, due to structural factors:

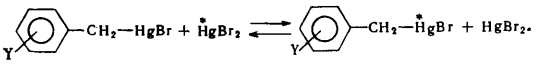


The most suitable subject for the accomplishment of an S_E1 mechanism should be substituted benzylmercury(II) halides with strongly electronegative substituents in the benzene ring. Experimental verification confirmed this prediction.

The kinetics of the isotopic exchange of *p*-nitrobenzylmercury(II) bromide with radioactive mercury(II) bromide in DMSO was studied. As expected, the reaction was of first order overall (first order in organomercury compound and zeroth order to mercury bromide).

Hence an S_E1 reaction of the type being considered was achieved also for benzyl systems, wholly directed by using structural factors and the ionising ability of the solvent[46].

The reaction mechanism can be expressed as follows:



The influence of the halogen X in the compounds $YC_6H_4-CH_2-Hg-X$ on the rate of the S_E1 and S_E2 reactions of isotopic exchange has been studied. It was found that the influence of X is the same in the two instances. The rate of isotopic exchange rises in the sequence: Cl < Br < I.

Such a regularity is understandable, because the more electronegative halogen by induction influence should decrease the effective negative charge on the carbon atom and retard the S_E2 reaction all the same. On the other hand a more electronegative halogen should hinder heterolytic breaking of the C–Hg bond to form a carbanion (retardation of the S_E1 reaction).

Ingold and coworkers[47] described one more example of S_E1 reaction: interaction of di-s-butylmercury with diethylallyl bromide in dimethylformamide, which takes place with racemisation. However, the conclusion about an S_E1 mechanism here seemed erroneous, since no allowance was made in the work for oxidation of the organomercury compound proceeding under the action of atmospheric oxygen[78].

6. ANIONIC CATALYSIS OF ONE-ALKYL ISOTOPIC EXCHANGE

The isotopic exchange of benzylmercury(II) halides with $^{203}HgX_2$ seemed convenient for studying characteristic peculiarities of anionic catalysis discovered by Ingold and coworkers[48] for one-alkyl isotopic exchange:

As shown above, this isotopic exchange takes place in quinoline and dimethyl sulphoxide (with the exception of when Y = NO_2) as an S_E2 reaction:

k_2 (quinoline) = 0.13 litre mole^{-1}h^{-1}; k_2(DMSO) = 0.37 litre mole^{-1}h^{-1}.

In the presence of potassium bromide the isotopic exchange is appreciably faster. For example, at concentrations $[HgBr_2] = [R-HgBr] = 0.06$ M the rate constant of the reaction¶ rises in the following manner as [KBr] is increased[44]:

[KBr], M	0	0.06	0.12	0.18
10^2k_2, litre mole^{-1}h^{-1}	37	148	1444	2139.

The influence of the nature of substituent Y situated in the *para*-position of the benzene ring is opposite for the unactivated reaction and for a reaction catalysed by additions of KBr[44]. Table 3 gives the half-exchange periods $\tau^{1/2}$ in minutes for various $YC_6H_4-CH_2-HgBr$ at [KBr] = = 0, 0.09, and 0.12 M (in DMSO at 70°).

From Table 3 it is evident that in a non-catalysed S_E2 reaction the substituents are arranged in the following sequence as regards accelerating influence:

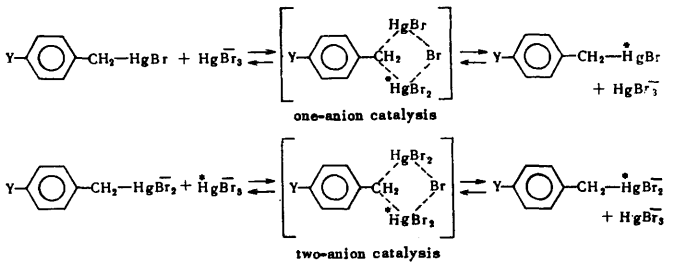
Cl, F < H < CH_3, $(CH_3)_2CH$.

With isotopic exchange in the presence of KBr the picture changes sharply. In addition to strong acceleration of the reaction there is a change in the influence of the substituent, to the contrary order[44]:

$(CH_3)_2CH < CH_3$, H < F < Cl.

The influence of additions of KBr can be explained by the complexes $HgBr_3^-$ and $R-HgBr_2^-$ being formed in the system:

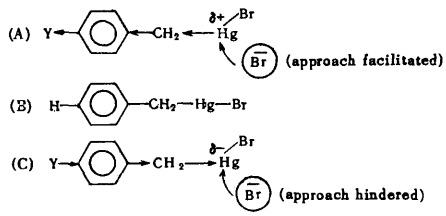
[(a) $HgBr_2 + Br^- \rightleftarrows HgBr_3^-$; (b) $RHgBr + Br^- \rightleftarrows RHgBr_2^-$],



and these complexes are capable of undergoing isotopic exchange. Evidently the second complex should be formed with greater difficulty (that is, at higher KBr concentrations).

TABLE 3.

[KBr], M	$[HgBr_2]$, M	$[YC_6H_4CH_2HgBr]$, M	$\tau^{1/2}$, min for Y =				
			Cl	F	H	CH_3	$(CH_3)_2CH$
0.00	0.06	0.06	1140	1140	1020	780	780
0.09	0.06	0.06	24	35	45	45	50
0.12	0.06	0.06	10	18	25	25	30



¶ At high potassium bromide concentrations (for example, $[KBr]/[HgBr_2] \geq 2$) k_2 is not maintained sufficiently satisfactorily. This can be explained either by a salt effect or by the fact at relatively high KBr concentrations the reaction can proceed in parallel by the S_E2 and S_E1 mechanisms.

Hence for this isotopic exchange it is evidently necessary to allow for there being two parallel reactions:

If two-anion catalysis is stronger than one-anion catalysis, then the rate of reaction should depend directly on the concentration of the complex $R-HgBr_2^-$. It is evident that substituent Y should affect the ease of formation and consequently also the concentration of this complex.

From this point of view it is understandable why in isotopic exchange catalysed by KBr there is the reverse order of influence of substituents in comparison with the non-catalytic reaction. Naturally the electronegative substituents, which draw off the electron density from the mercury atom, should facilitate the formation of a complex with a bromide anion (in comparison with unsubstituted benzylmercury bromide) (see A):

On the other hand, for the electron-donating substituents the formation of a covalent bond of the bromide anion with a mercury atom should be hindered (see B)†.

For isotopic exchange by mechanism S_E1 in the presence of KBr it would be expected that of the two complex formation processes (a) and (b):

$$\text{(a)}\quad HgBr_2 + Br^- \rightleftharpoons HgBr_3^-$$
$$\text{(b)}\quad RHgBr + Br^- \rightleftharpoons RHgBr_2^-$$

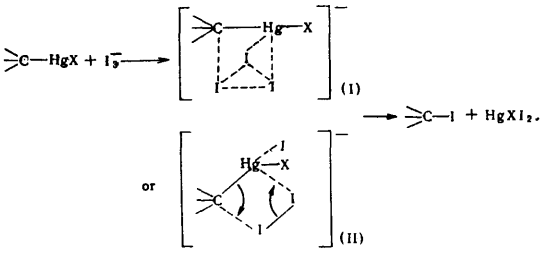
only the second, (b), will affect the rate of the reaction, because the ionisation of the C–Hg and $R-HgBr_2^-$ bonds should proceed more readily than in R–HgBr.

The S_E1 mechanism, which is catalysed by KBr, can be represented as follows:

$$R-HgBr + Br^- \xrightarrow{\text{fast}} R-HgBr_2^-$$
$$R-HgBr_2^- \underset{\text{fast}}{\overset{\text{slow}}{\rightleftharpoons}} \bar{R}: \quad HgBr_2$$
$$HgBr_2\ (\text{fast}) \uparrow\downarrow {}^*HgBr_2\ (\text{fast})$$
$$R-{}^*HgBr_2^- \underset{\text{fast}}{\overset{\text{slow}}{\rightleftharpoons}} \bar{R}: \quad {}^*HgBr_2$$

† In principle the possibility of the anion $HgBr_4^{2-}$ (instead of $R-HgBr_2^-$) also participating in two-anion catalysis must be considered. The results of a study[44] of the influence of substituents Y on the reaction rate support the anion $R-HgBr_2^-$, at least for the benzylmercury bromides mentioned above.

Experiment confirms[49] the above hypothesis of the effect on the reaction rate for only the process of formation of the complex $RHgBr_2^-$.

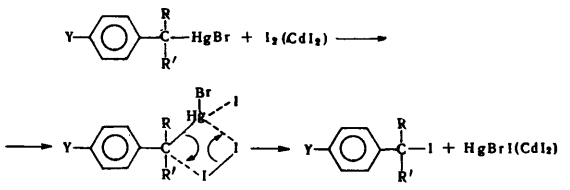


Study of the S_E1 reaction of isotopic exchange of *p*-nitro-benzylmercury(II) bromide with $^*HgBr_2$ in DMSO showed that the reaction rate changes significantly with the KBr concentration. The rate of exchange rises significantly even at KBr concentrations somewhat less than the $^*HgBr_2$ concentration. Thus at [KBr] = 0.05 M, ([$HgBr_2$] = 0.06 M, [RHgBr] = 0.03 M), the rate of exchange increases by a factor of 8. This fact evidently shows that even at KBr concentrations less than the $HgBr_2$ concentration the formation of $RHgBr_2^-$ in the system also takes place to some extent in addition to the formation of $HgBr_3^-$. Naturally a further rise in the KBr concentration rapidly increases the $RHgBr_2^-$ concentration, which should lead to a sharp acceleration of the reaction. At [KBr] = 0.09 M the initial isotopic exchange rate is 47 000 times greater than that in the absence of KBr.

7. HALODEMERCURATIONS

The reaction of benzylmercury halides with iodine in the presence of an excess of cadmium iodide is second-order overall (first with respect to each of the components) in methanol, ethanol, butanol, 70% aqueous dioxan, acetonitrile, dimethylformamide, and dimethylsulphoxide[50-52]. Proof was obtained that I_3^- participates in the reaction (compare Winstein and Traylor[53]):

This S_E2 reaction evidently proceeds through a transition state of type (I) or (II)[52]:



The influence of substituent Y in the benzene ring is shown in Table 4 (k_2 in litre mole^{-1} s^{-1}, in absolute methanol at 19°).

It was noted earlier that the nature of the influence of structural factors on the rate of symmetrisation of esters of α-bromomercuriarylacetic acids shows that in the cyclic four-membered transition state of type (A) the breaking of

TABLE 4.

Y	H	CH_3O	CH_3	F	Cl	Br	NO_2
para	—	8.33	1.93	0.84	0.71	—	instantaneous
meta	0.75	—	0.83	0.42	—	0.46	—
ortho	—	—	1.75	0.22	0.23	—	—

the old C–Hg bond is the determining factor. This conclusion is confirmed also for the reaction of α-bromomercuriarylacetic esters with iodine in the presence of cadmium iodide[23]. The reaction was studied in absolute toluene with additions of 1.5 vol.% methanol:

with R = $CO_2C_2H_5$, R′ = H.

The values of the rate constants for a second-order reaction given in Table 5 show that the sequence of the influence of substituents is here analogous to the sequence of the influence for the symmetrisation.

Halodemercuration is somewhat less sensitive to the influence of substitutents (ρ = 2.3) than symmetrisation.

Hence the S_E2 mechanism for the iodination of these compounds is also in a boundary region adjoining the region of reactions which take place by an S_E1 mechanism. This example is again evidence of the arbitrary nature of the division of mechanisms of substitutions into two extreme types.

The reaction of $Ar-CH_2-HgX$ with halogens in the presence of CdX_2 or NH_4X also are S_E2 reactions[54-58].

The reaction of benzylmercury(II) halides with iodine and bromine in the absence of CdX_2 in non-polar solvents (for example, in carbon tetrachloride) is photochemical‡ and proceeds by a radical-chain mechanisms[59,60]. However, small additions of H_2O, ROH, or R_2O in the reaction mixture (0.25 vol.%) alter the kinetics of the reaction of organomercury compounds with bromine (but not with iodine), and consequently also the mechanism itself[62]. For example, irradiation no longer affects the reaction rate. The kinetics of the reaction becomes second-order (first in each of the reagents).

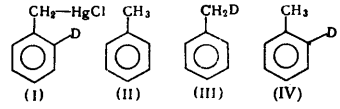
It is natural to assume that this result is due to the formation of a complex of bromine with oxygen-containing molecules and the subsequent participation of this complex in an S_E2 reaction as a donor of electrophilic bromine§:

where R = R′ = H, CH_3, C_2H_5, n-C_3H_7, n-C_4H_9; R = CH_3, C_2H_5, $(CH_3)_2CH$, $(CH_3)_3C$, R′ = H.

The rate constants for certain reactions in the presence of additions are given in Table 6.

Table 6 shows that the effect of oxygen-containing compounds on the reaction rate can be compared with the "coordination capacity" and electron-donor properties of these compounds.

8. PROTODEMERCURATION



Some features of protodemercuration were studied by the example of benzyl organomercury compounds.

It was shown[63] that in alcohol and dioxan the reaction of benzylmercury chloride (BMC) with hydrogen chloride:

proceeds by an S_E2 mechanism.

In studying the reaction with DCl in dioxan under the conditions of pseudounimolecularity — $[BMC]_0$ = 0.25 M, [DCl] = 2.5 M — it was shown[64] that as the reaction proceeds substances (I), (II), (III), and (IV) appear in the reaction mixture¶:

After the reaction had finished, the reaction mixture naturally contained only compounds (II), (III), and (IV).

TABLE 5.

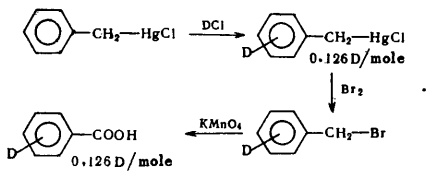
Y	p-NO_2	p-Br	p-I	p-Cl	p-F	H	m-CH_3	p-$(CH_3)_2CH$	p-$(CH_3)_3C$
k_2, litre mole^{-1} s^{-1}	615*	79.3	43.6	33.4	14.1	10.1	7.1	4.5	3.5

* The reaction is very fast when Y = NO_2, therefore here the constant was calculated assuming that Hammett's equation is applicable to this series.

TABLE 6.

Addition	H_2O	CH_3OH	C_2H_5OH	i-C_3H_7OH	n-C_4H_9OH
k_2, litre mole^{-1} s^{-1}	9.46	3.43	2.73	1.46	1.17

Addition	$(CH_3)_2O$	$(C_2H_5)_2O$	$(C_3H_7)_2O$	$(C_4H_9)_2O$
k_2, litre mole^{-1} s^{-1}	2.44	1.68	0.94	0.87



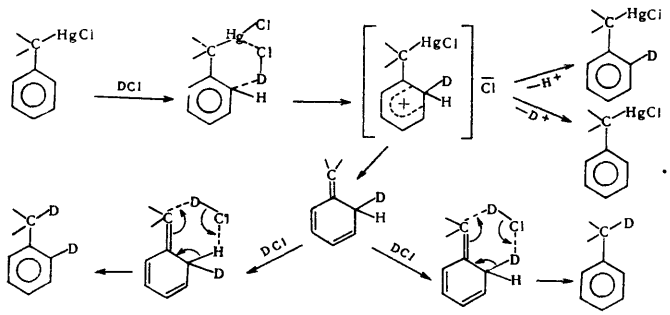
‡ The kinetics, stereochemistry, and mechanism of the homolytic replacement of a mercury atom (connected to a saturated carbon atom) by halogen have been studied by the example of $CH_3CH(HgBr)CH_2CH_3$ with bromine in CCl_4.[61]

§ The reason for the higher reactivity of the $R_2O.Br_2$ complexes in S_E2 reactions compared with Br_2 is given in the section "internal catalysis" (p. 171).

¶ Special experiments showed that the toluene formed does not undergo isotopic exchange with the DCl under the reaction conditions.

From the results given it follows first that BMC undergoes isotopic exchange with the DCl. This is evidently the deutero-exchange observed in organometallic compounds of the transition metals.

That the deuterium was present only in the BMC nucleus was shown as follows:



To determine the position of the deuterium in the BMC nucleus it was reduced with $LiAlH_4$ in toluene.

Infrared spectroscopy then showed that dueterium is in practice present only in the *ortho*-position (k_o/k_p = 25 : 1).

Table 7 gives the mass spectra of toluenes isolated at different amounts of conversion of BMC.

Taking all this into account, the mechanism of this rather complex reaction of BMC and DCl can evidently be rather satisfactorily represented by the following scheme [64]:

Bearing in mind the high lability of the C–Hg bond in the dibenzylmercury (DBM) molecules it could be calculated to provide the first example of an S_E1 reaction at a saturated carbon atom in the protolysis of organometallic compounds:

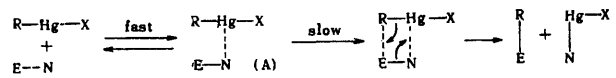
$$(C_6H_5{-}CH_2)_2Hg + HCl \longrightarrow C_6H_5{-}CH_3 + C_6H_5{-}CH_2{-}HgCl.$$

In fact it was shown that in DMSO the reaction proceeds by a first-order dependence and on replacing HCl by DCl the kinetic isotopic effect is absent [65]. This shows that with an overall first-order dependence the reaction has first-order dependence on DBM and zeroth-order on the acid.

TABLE 7.

BMC converted, %	Mass-spectrum of toluenes		
	d_2	d_1	d_0
25	36.4	51.2	12.4
50	36.2	50.2	13.5
70	37.9	48.0	14.0

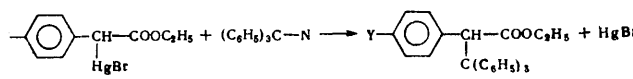
The simplified mechanism can be represented by the scheme:



$$(a) \qquad (C_6H_5{-}CH_2)_2Hg \underset{}{\overset{\text{slow}}{\rightleftharpoons}} C_6H_5{-}\bar{C}H_2{:}\overset{+}{H}g{-}CH_2{-}C_6H_5$$

$$(b) \qquad \underset{\text{ion pair}}{C_6H_5{-}\bar{C}H_2{:}\overset{+}{H}g{-}CH_2{-}C_6H_5} + HCl \xrightarrow{\text{fast}} C_6H_5{-}CH_3 + Cl{-}Hg{-}CH_2{-}C_6H_5.$$

It is interesting that this reaction is also first-order in a series of other solvents: dimethylformamide, aqueous (5%) acetonitrile, tetrahydrofuran, butanol. The probable reason is the high lability of the C–Hg bond and also the formation in the reaction of a rather stable ion pair. Some features of the reaction remain inexplicable, for example, the rise in the rate constant k_1 with increase in the HCl concentration.



9. "INTERNAL CATALYSIS" IN S_E REACTIONS OF ORGANOMERCURY COMPOUNDS

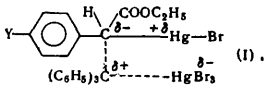
In all S_E reactions of non-symmetrical organomercury compounds there is acceleration under the action of nucleophilic catalysts. Nucleophilic catalysis, which can be regarded as "external", has been mentioned above (the catalysis of isotopic exchange of organomercury compounds with bases, anionic catalysis, etc.). However, in many instances the catalytic action is connected with the preliminary formation of the complex R–HgX with E–N† of type (A), evidently in the pre-kinetic stage of the reaction. This can be termed "internal nucleophilic catalysis" or "internal nucleophilic assistance". Only after the formation of complex (A) is there the slow stage of the reaction — the formation of a new C–E bond:

The idea of "internal nucleophilic catalysis" in bimolecular electrophilic substitutions has been developed in several papers [66–69].

For example, the mechanism of the triphenylmethylation of ethyl α-bromomercuriarylacetates in dichloroethane has been studied:

where N = Br^-, $HgBr_3^-$, $HgBr_3^-$, ClO_6^-, $SnHal_6^-$.

When N = ClO_4^- there is not reaction, since the formation of a complex of type (A) is impossible. Reaction also does not occur with the strongly ionised compound $2(C_6H_5)_3C^+SnHal_6^{2-}$. The use of a weaker Lewis acid — mercury(II) bromide — even allows the alkylation to be carried out — by the complex $(C_6H_5)_3C^{\delta+}\ldots HgBr_3^{\delta-}$ — although the reaction is slower than for $(C_6H_5)_3C$–Br itself; with the latter it was shown spectrophotometrically that the reaction proceeds through the intermediate formation of the complex $RHgBr.(C_6H_5)_3CBr$.



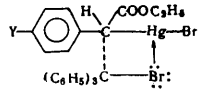
Apparently, in the above reactions the structures of the transitional compounds are different, which is confirmed by the diffferent influence of the substituents Y in the *para*-position of the benzene ring of the organomercury

† E denotes the electrophilic and N the nucleophilic, part of the molecule.

compound. Thus the reaction of mercurated ester with $(C_6H_5)CBr.HgBr_2$ is accelerated by electron-donating and retarded by electron-accepting substituents:

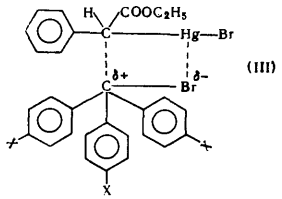
$$C_3H_7,\ C_2H_5 > C_6H_5 > H > F > Cl > Br > I > NO_2.$$

This is evidently connected with the significance of electrophilic attack on a carbon atom — transition state (I):



(I).

In the reaction of organomercury compounds with trityl bromide itself the influence of substituents Y is the reverse:

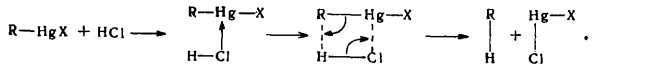


$$NO_2 > Hal > H > Alk.$$

The inversion of the influence of the substituents is evidently due to the influence on the reaction rate of the strength of the bond formed between the bromine and the mercury atom — transition state (II). Here it is possible that the determining factor will be the breaking of the old carbon–mercury bond, and not the formation of the new carbon–carbon bond, that is, the reaction mechanism approximates to the S_E1 type:

(II).

The fact that reaction does not occur when completely ionic compounds are used — for example, $(C_6H_5)_3C^+ClO_4^-$ — shows that in any alkylations of the type being considered one can scarcely expect realisation of a completely open structure of transition state (I) and that some fraction of coordination of $HgBr_3^{\delta-}$ with the mercury atom should occur, although less than for structure (II). That both factors — electrophilic attack at a carbon atom and nucleophilic coordination with the mercury atom — are important is also demonstrated by the influence of substituent X in the molecule of the electrophilic agent — transition state (III):



(III)

where X = CH_3, H, NO_2.

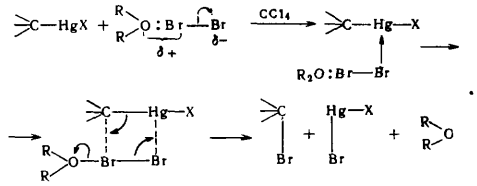
For example, the alkylation rate decreases on going from trityl bromide to tritolylmethyl bromide, that is, on reducing the positive effective charge on the carbon atom. However, a decrease in the effective negative charge on the bromine atom of the triarylmethyl bromide also hinders reaction. It was shown that tri-(*p*-nitrophenyl)methyl bromide, in which the carbon–bromine bond is more covalent than in trityl bromide generally does not alkylate a mercurated ester. Hence for trityl bromide there is an optimal combination of conditions which is responsible for the good alkylating ability of this substance. These results are good illustrations of the necessity for nucleophilic coordination in reactions of organomercury compounds‡.

An analogous regularity can be demonstrated by the example of the protolysis of organomercury compounds.

Reutov and coworkers [63] and Dessy and coworkers [71] showed that the rate of protolysis of organomercury compounds by hydrogen chloride decreases on raising the concentration of water in the solvent. This phenomenon is connected with the fact that at low water concentrations a rise in its concentration is accompanied by an increase in the solvation of HCl and its deactivation, but at higher water concentrations there is a simultaneous ionisation of the HCl, which also hinders the reaction. In addition to the other arguments (the absence of reaction with strong acids incapable of coordination with mercury, for example, $HClO_4$), this observation confirms the hypothesis that the reactant is not the solvated proton but the molecular form HCl, most probably its ion pair. In this it is possible that the nucleophilic coordination of chlorine with mercury occurs in the pre-kinetic stage and then is accompanied by electrophilic attack of hydrogen on carbon:

Naturally, as a result of this, a cyclic transition state is realised in the reaction. Possibly the formation of such a structure of a transition state is an important factor facilitating the strict retention of the stereochemical configuration in reactions of the S_E2 type.

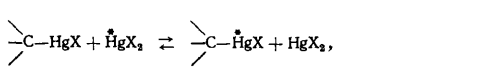
It can be hoped that the conception of internal nucleophilic association will be quite helpful in organoelemental chemistry. Even now much of what was incomprehensible earlier has received a simple and natural explanation§ from the standpoint of this conception.



For example, it was not understood earlier why the complexes of bromine with ethers $R_2O.Br_2$ are more effective reagents in S_E2 reactions with organomercury compounds than free [62]bromine (see p. 170).

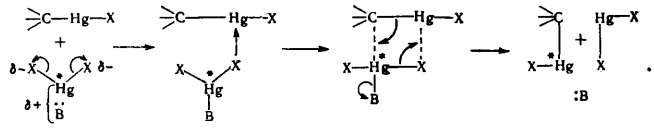
Taking into account the necessity for internal nucleophilic association this is easy to understand: in the complex $R_2O.Br_2$ the electron density at one of the bromine

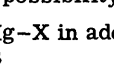
‡ The part of nucleophilic coordination in the reactions of organomercury compounds of the aromatic series is evidently less significant. Thus in the triphenylmethylation of arylmercury bromides for both the complex $(C_6H_5)_3CBr.HgBr_2$ and the free $(C_6H_5)CBr$ the transition states probably have an open structure [70].



§ "External nucleophilic catalysis" in S_E reactions also receives steady attention from this standpoint. Allowing for this phenomenon we will reconsider some generally accepted positions. For example, the widely accepted view that symmetrical organomercury compounds R_2Hg are more reactive than the organomercury salts RHgX is true only for non-catalytic reactions. Under catalytic conditions (when R_2HgX^- and $RHgX_2^-$ really react) the reactions of fully substituted organomercury compounds and of organomercury salts are accelerated but for the latter compounds the acceleration is considerably greater. As a result under catalytic conditions the organomercury salts react more rapidly than symmetrical organomercury compounds.

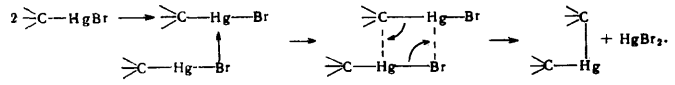
atoms is higher than on the bromine atoms in the Br_2 molecule. Hence the greater capability to coordination with mercury atoms:





The S_E2 reaction becomes so fast that the competing process — photochemical, free-radical reaction — is suppressed.

In reactions of monoalkyl isotopic exchange:

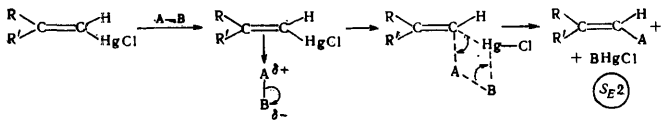


the catalytic action of bases can be explained by the greater tendency of the halogen atoms in $B.\overset{*}{H}gX_2$ complexes to nucleophilic association:

Finally the possibility of the formation of complexes of the type  in addition at a considerable excess of a base must be considered. Here the internal nucleophilic association will be hindered but reaction by an S_E1 mechanism will simultaneously be facilitated.

When the necessity of nucleophilic association is borne in mind it is not surprising that halodemercuration (p. 169) by the S_E2 mechanism takes place easily under the action of the nucleophilic reagent I_3^-,[50-52] etc.

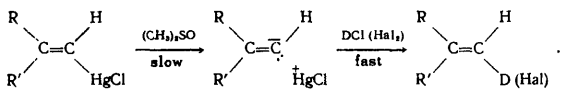
We note, finally, that in the previously considered symmetrisation of organomercury compounds it seems completely possible that the formation of a four-membered cyclic transition state also precedes nucleophilic coordination of a bromine atom with mercury in the pre-kinetic stage:



10. THE REACTIVITY OF ORGANOMERCURY COMPOUNDS OF THE ALKENE AND AROMATIC SERIES

As is well known, in general the mechanism of substitutions in saturated, alkene, and aromatic carbon atoms differs significantly.

However, in organomercury compounds it is impossible not to note in the S_E reactions a known similarity due to a general, extremely characteristic replaceable group (HgX, sometimes HgR).



The S_E2 reactions of alkene and aromatic organomercury compounds in low-polar solvents apparently also proceed through a cyclic four-membered transition state[72-77].

For example, the S_E2 reaction of *cis*- and *trans*-β-chlorovinylmercury(II) chlorides and the *cis*- and *trans*-isomers of styrylmercury halides proceed with retention of the configuration[72-74,77]; their mechanism can be represented by the scheme:

(I) R=Cl, R′=H; (II) R=H, R′=Cl,
(III) R=C_6H_5, R′=H; (IV) R=H, R′=C_6H_5

It is interesting that the S_E1 reaction at an alkenic carbon atom also proceeds with retention of the geometrical configuration[73,74]:

The mechanism of protolysis and halodemercuration of aromatic organomercury compounds also has several similar features[75,76] with the mechanism of the same reactions in the aliphatic series.

PROGRESS IN THE CHEMISTRY OF 2-PYRONES

N. P. Shusherina, N. D. Dmitrieva, E. A. Luk'yanets, and R. Ya. Levina

CONTENTS

I.	Introduction	175
II.	Methods of synthesis of 2-pyrones	175
III.	Chemical properties of 2-pyrones	183

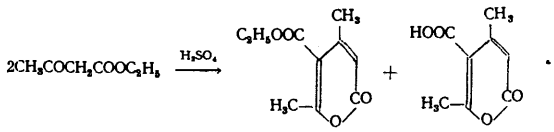
I. INTRODUCTION

Many physiologically active compounds contain an α-pyrone ring in their molecule. They include the bufadienolides — heart glycosides of plant and animal origin (bufotalin, cinobufagin, scilliroside, etc.[1-11]), individual representatives of 2-pyrones[12-15] (paracotoin, yangonin, hispidin) which exhibit antibiotic and fungicidal action[16].

In this connection investigations have appeared in the last decade devoted to the development of general methods of synthesis of 2-pyrones, and also the isolation of individual representatives of 2-pyrones from plants and the establishment of their structure.

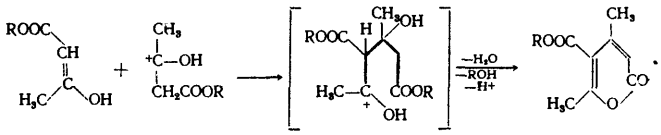
Derivatives of 2-pyrone were used recently for the synthesis of colchicine[17,18], barrelene[19], and other difficultly accessible compounds.

The present review gives an account of the principal literature on methods of synthesis and the reactivity of 2-pyrones†, indicating the progress in the chemistry of these heterocyclic compounds‡.



II. METHODS OF SYNTHESIS OF 2-PYRONES

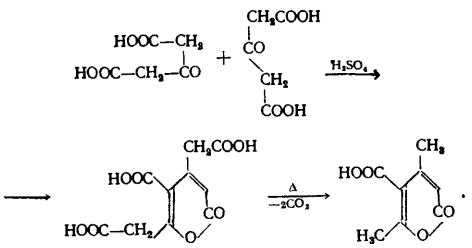
The known methods of synthesis of 2-pyrones can be divided into two types: synthesis from compounds with an open chain of carbon atoms, and from compounds which already contain a six-membered lactone ring.



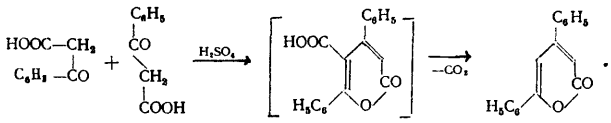
1. CONDENSATION OF β-KETO-ACIDS, β-ALDEHYDO-ACIDS, AND THEIR ESTERS

Condensation in the Presence of Acid Catalysts

One of the longest known methods of synthesis of 2-pyrones is the intermolecular condensation of acetoacetic ester under the action of concentrated sulphuric acid[23] or hydrogen chloride[24-27].

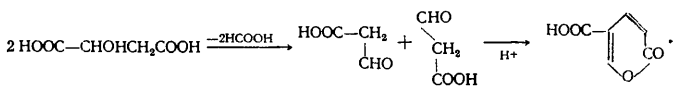


This synthesis of isodehydracetic (2,4-dimethyl-2-oxopyran-5-carboxylic) acid§ and its ester was later studied in detail by Wiley and Smith[28]. According to their suggested mechanism, one molecule of the acetoacetic ester reacts in the enol and the other in the keto- (protonated) form[28]:



Homologues of isodehydracetic acid and its ester exhibiting bactericidal activity were synthesised in a similar manner[14].

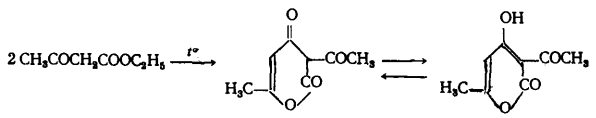
Dibasic β-keto-acids behave analogously in this reaction[34,35]:



When isodehydracetic acid is heated with concentrated sulphuric acid to 160–170° it is decarboxylated into 4,6-dimethylpyran-2-one[23,36].

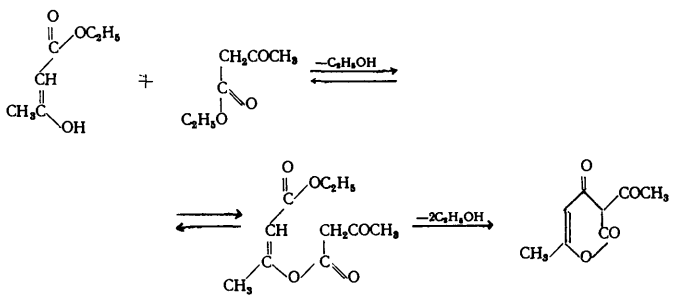
Isodehydrobenzoylacetic acid is decarboxylated even at room temperature, therefore the final product of the condensation of benzoylacetic acid is 4,6-diphenylpyran-2-one[37]:

The synthesis of coumalic acid (2-oxopyran-5-carboxylic acid) by heating malic acid with concentrated sulphuric acid and zinc chloride (quantitative yield) apparently proceeds through the stage of formation of a β-aldehydo-acid (the semi-aldehyde of malonic acid), which, like the β-keto-acids, undergoes intermolecular condensation[38,39]:



† The literature on the chemistry of the coumarins (benzo[*b*]pyran-2-ones), which exhibit specific properties, is not discussed here.

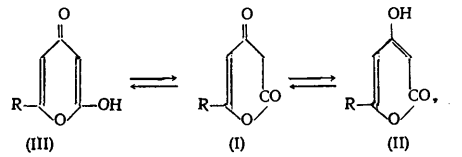
‡ Cavalieri's review[20] on the chemistry of the pyrones, published in 1947, is out of date. The information about the 2-pyrones given in the monographs edited by Elderfield[21] and by Grignard[22] are also restricted to 1947.



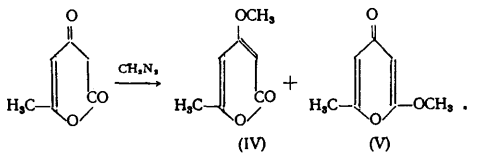
§ Isodehydracetic acid can serve as the starting point for the synthesis of various compounds which are not readily accessible[29,30]; its derivatives are also interesting because of their physiological activity.[31-33]

Condensation in the Presence of Basic Catalysts

Among the thermal decomposition products of acetoacetic ester a substance[40] which received the name dehydracetic acid was observed; later it was ascribed the structure 3-acetyl-6-methylpyran-2,4-dione, which can be found in equilibrium with the tautomeric 3-acetyl-4-hydroxy--6-methylpyran-2-one[41]:

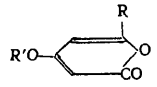


Arndt and coworkers[42-44] suggested that during the pyrolysis a vinyl ester is first formed, which then cyclises into dehydracetic acid (the part of catalyst is played mainly by the walls of the glass reaction vessel):



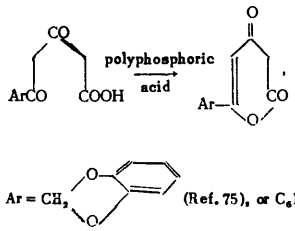
Esters of other β-keto-acids gave in this way alkyl-[45,46], cycloalkyl-[47,48], and aryl-substituted dehydracetic acids[49,50] (some of these compounds exhibit high antibactericidal activity[45,46]).

A notable feature of the compounds of the dehydracetic acid type is their ability when heated with sulphuric acid¶ to lose an acyl group and form 6-substituted pyran--2,4-diones (I)[41-43,52-54]. It is suggested that the latter may exist in two enolic forms — 4-hydroxypyran-2-one (II) and 2-hydroxypyran-4-one (III)[55,56]:



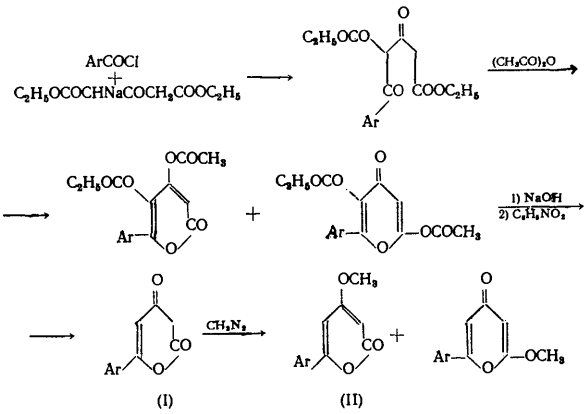
Actually, as infrared and ultraviolet spectra have shown, pyrandiones (pyronones) exist in the form of the 4-hydroxypyran-2-one (II), or the 2-hydroxypyran-4-one (III), or as an equilibrium mixture of (II) and (III), depending upon the substituents, the state of aggregation, and the solvent[57-59].

In the methylation of 6-methylpyran-2,4-dione (and also its analogues) two esters (IV) and (V) were isolated, corresponding to the two possible enol forms[58-65]:



Note that the pyronone nucleus enters into the composition of many physiologically active compounds isolated from plants: yangogin (VI)[66,67], anibine (VII)[68-71], 4-methoxyparacotoin (VIII)[68,70,72], 5,6-dehydrokawain (IX)[72], and hispidin (X)[73,74]:

where R′ = CH_3, R = *p*-$CH_3OC_6H_4CH{=}CH$ (VI); 3-C_5H_4N (VII); 3′,4′-$(CH_2O_2)C_6H_3$ (VIII); $C_6H_5CH{=}CH$ (IX); R′ = H, R = 3′,4′-$(HO)_2C_6H_3CH{=}CH$ (X).

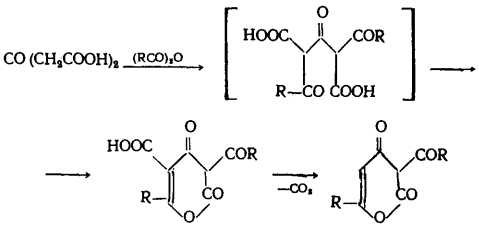


2. INTRAMOLECULAR CYCLISATION OF αδ- AND βδ-DIKETO--ACIDS

Intramolecular dehydration of βδ-diketo-acids leads to the formation of pyran-2,4-diones. Thus the cyclisation of δ-aryl-βδ-diketovaleric acids under the action of polyphosphoric acid (PPA) gives 6-arylpyran-2,4-diones:

where Ar = CH_2 (Ref. 75), or C_6H_5 (Ref. 76).

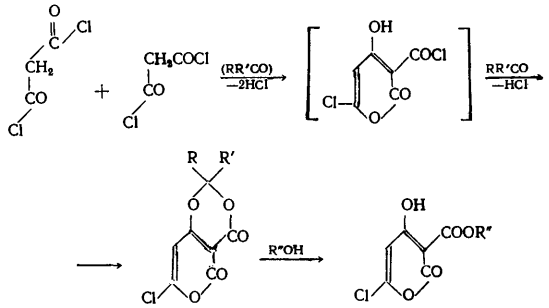
The cyclisation of the corresponding ester of a βδ-diketo-acid is the principle of a method by which Borsche first synthesised yanganolactone (I) and from it yangonin (II)†[67]:



where Ar = *p*-$CH_3OC_6H_4CH{=}CH$.

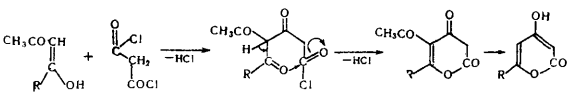
The cyclisation of βδ-diketo-acids into pyran-2,4-diones sometimes takes place very easily even under conditions

¶ Under the action of hydrohalogen acids dehydracetic acid and its analogues are converted into 2,6-disubstituted 4-pyrones.[41-43,51]



† For the structure of yangonin, see Chmielewska and coworkers.[77,78]

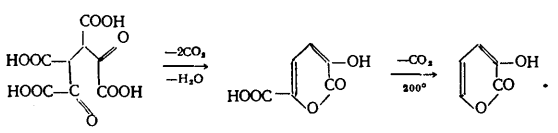
for obtaining the βδ-diketo-acids themselves (for example, under the action of acid anhydrides into acetonedicarboxylic acid[79-81]):



where R = CH_3, C_2H_5, C_3H_7.

Among the conversions of this type must be included the synthesis of 2-pyrones based on malonyl dichlorides‡ and its monoalkyl derivatives. Thus malonyl dichloride itself (in the presence of ketones, which act as weak bases) undergoes the following series of conversions[82]:

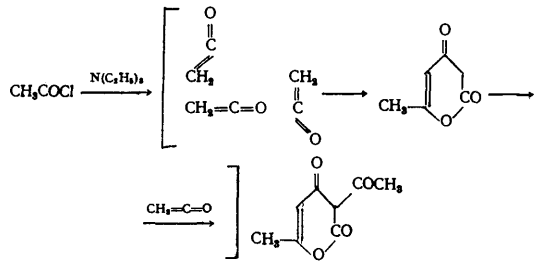
In the condensation of malonyl dichloride with acetylacetone, the pyronone isomeric with dehydracetic acid and containing an acetyl group at position 5 is formed[84]. The asymmetric β-diketone gives in these conversions the isomer corresponding to the preferential direction of the enolisation[84]:



where R = CH_3, C_6H_5.

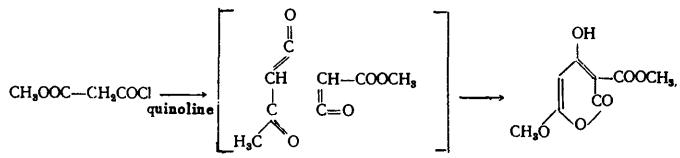
Esters of β-keto-acids (acetoacetic and benzoylacetic esters) behave similarly in reacting with malonyl dichlorides[85,86].

Hence the condensation of malonyl dichloride and its alkyl derivatives with β-dicarbonyl compounds — apparently proceeding through the stage of formation of acid chlorides corresponding to βδ-diketo-acids (type IV) — can serve as a general method of synthesis of 4-hydroxypyran-2-ones (pyran-2,4-diones).



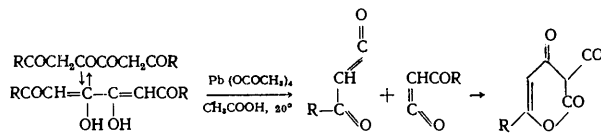
Unlike the βδ-diketo-acids, the αβ-diketo-acids (αα'-dioxalylsuccinic[87,88] and αβ-dioxalylpropionic[89] acids) are cyclised into derivatives of 3-hydroxypyran-2-one, for example:

‡ The condensation of malonyl dichloride in the presence of thiourea with the formation of compounds of the pyronone series has been described, but the precise structure of the products has not been established.[83]

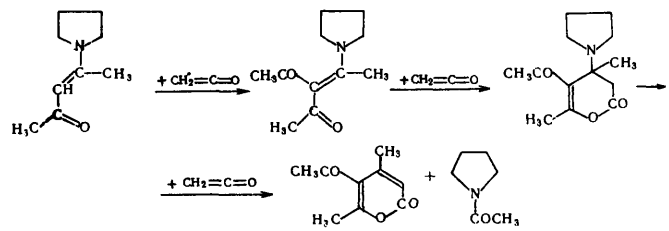


3. KETENS IN THE SYNTHESIS OF 2-PYRONES

2-Pyrones are formed by the action of tertiary amines on the halides of certain acids[90-92]. To explain the nature of the reactions it is assumed that initially ketens are formed, the cyclisation of which also leads to the formation of the corresponding 2-pyrones Thus the formation of dehydracetic acid from acetyl chloride is apparently the result of the trimerisation of keten into pyran-2,4-dione which is acylated further by another molecule of keten in the free 3-position[90]:

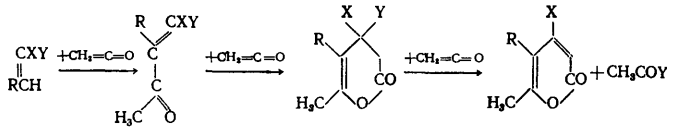


Under the same conditions propionyl chloride forms a homologue of pyran-2,4-dione (trimer of methylketen)[91].



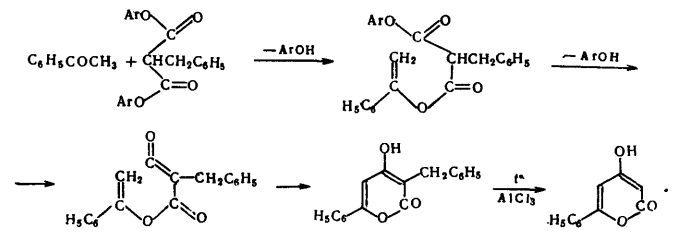
The conversion of methyl chloroformylacetate into a derivative of 2-pyrone evidently proceeds through the intermediate formation of the corresponding keten, which then dimerises[92]:

The action of lead tetra-acetate in acetic acid on 1,3,4,6-tetraketones gives compounds of the dehydracetic acid type; the process can be represented as the dimerisation of an acylketen formed as an intermediate in the splitting of the tetra-ketone[93]:

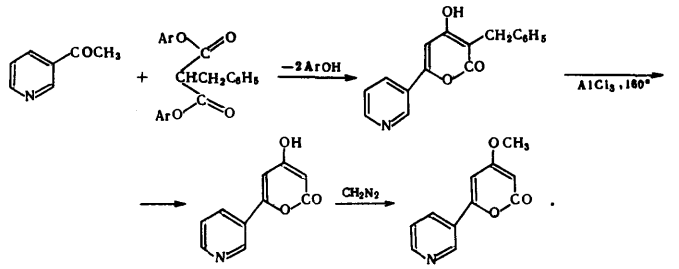


Another possibility of using keten in the synthesis of 2-pyrones consists in its reaction with enamines of carbonyl compounds. Thus, the reaction of the enamine of acetylacetone with keten evidently proceeds as follows[94]:

An ester of isodehydracetic acid is obtained analogously from the enamine of acetoacetic ester, and 1-methyl-3-oxocyclohexano[*c*]pyran from the enamine of cyclohexanone[94].



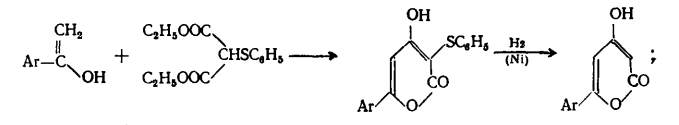
The reaction of keten and its homologues with *NN*- or *ON*-acetals of keten proceeds by the same scheme[95,96]:



where X = NR'_2, Y = NR'_2, OAlk.

4. THERMAL CONDENSATION OF ESTERS OF SUBSTITUTED MALONIC ACIDS WITH KETONES

It was recently found that the thermal condensation of benzylmalonic esters with ketones which can be enolised can serve as a method for the synthesis of compounds of the 2-pyrone series§, for example[99]:

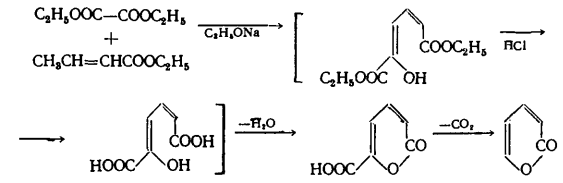


Use of various aliphatic–aromatic[99] and cyclic[100] ketones in this reaction gave (after debenzylation) 4-hydroxypyran-2-ones with a free 3-position[53]. On starting from 3-acetylpyridine, anibine (4-methoxy-6-pyrid-2-yl-pyran-2-one) was obtained by the same method in good yield[101]:

However, 4-methoxyparacotoin (see p. 176) could not be obtained in this way since the ammonium chloride used for debenzylation destroys the piperonyl residue[101].

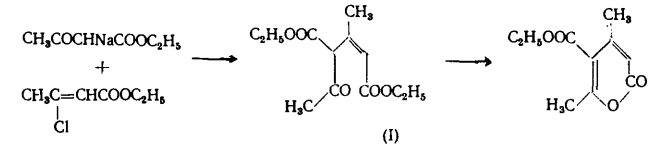
It was subsequently shown that ethyl esters of malonic acids can be used successfully in this reaction instead of the less readily available diaryloic esters[102,103].

A variant of this method is the use of the diethyl phenylthiomalonate[104,105]:



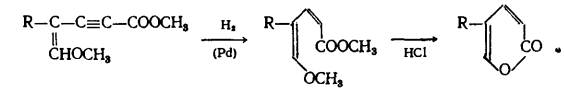
4-hydroxyparacotoin — Ar = 3′,4′-$(CH_2O_2)C_6H_3$ — was obtained in this way.

§ Thermal condensation of malonic esters with phenols is a well-known method of obtaining derivatives of 4-hydroxycoumarin.[97,98]



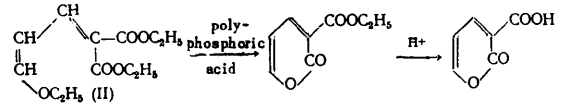
5. CYCLISATION OF αβ-UNSATURATED δ-KETO-ACIDS AND THEIR DERIVATIVES

An important method of synthesis of 2-pyrones is the cyclisation of unsaturated δ-keto-acids and their derivatives, which are often converted into pyrones even under the conditions of their production[106–109]; for example:



The linear homologues of crotonic ester (RCH_2–CH=$CHCO_2C_2H_5$) give 5-alkyl-2-oxopyran-6-carboxylic acid[110], the thermal decarboxylation of which leads to 5-alkylpyran-2-ones[110,111].

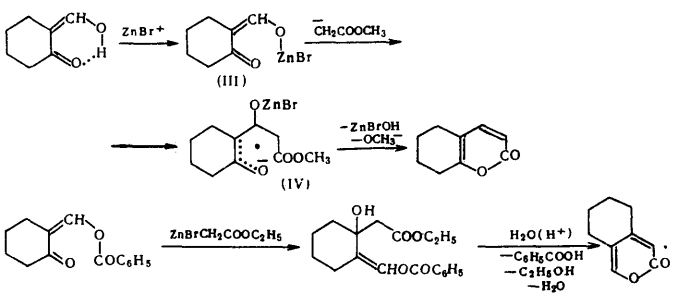
Anschütz and coworkers[112] synthesised ethyl isodehydracetate from the ester of the corresponding unsaturated keto-acid (I):



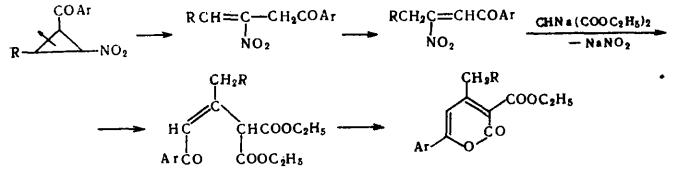
Sometimes αβ-unsaturated keto-acids or their derivatives are so easily cyclised into the corresponding 2-pyrones that their formation in any of these reactions can only be conjectured[113–116].

Attempts to obtain 2-pyrones by cyclisation of αβ-unsaturated δ-aldehydo-acids did not give positive results[110]; however, by using their enol esters for this purpose¶, Panizzi and Nicoletti[117,118] prepared 5-alkyl-substituted 2-pyrones (in poor yield)[117,118]:

In analogous fashion, diethyl 3-ethoxyallylidenemalonic acid (II) is cyclised into ethyl 2-oxopyran-3-carboxylate[119]:

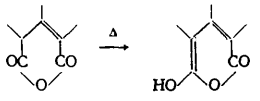


The cyclisation of the ester of the corresponding unsaturated keto-acid can also explain the formation of cyclohexano[*b*]pyran-2-one in the reaction of hydroxymethylenecyclohexanone and methyl bromoacetate (by the Reformatsky reaction).

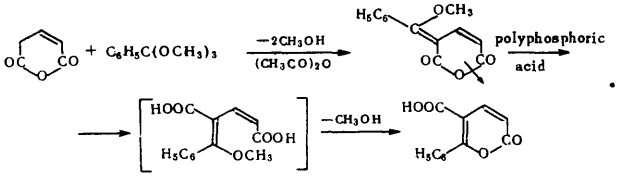


The salt of the enolate (III) gives the condensation product (IV) at the hydroxymethylene group so that only one of the two possible isomers is formed — cyclohexano[*b*]-pyran-2-one[120]. The other isomer, cyclohexano[*c*]pyran-3-one, is obtained on using 2-oxocyclohexylidenemethylbenzoate in this reaction, for which the formation of a salt

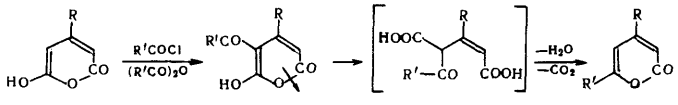
¶ Obtained by three-stage synthesis from methoxyacetonitrile.



of type (III) is prevented and the reaction proceeds at the carbonyl group[121]:

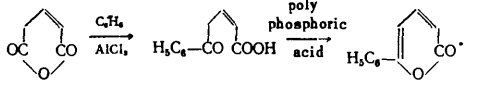


The intermediate formation of esters of $\alpha\beta$-unsaturated δ-keto-acids is also presumed in the production of 2-pyrones by condensation of 1-aroyl-2-nitrocyclopropanes† with bis-(ethoxycarbonyl)methylsodium[122-124]:



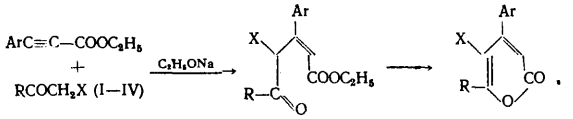
Several methods have recently been proposed for the preparation of 2-pyrones from anhydrides of glutaconic acids, which are characterised by an easy conversion into the isomeric 6-hydroxypyran-2-ones[125,126]:

These methods are also based on the cyclisation of the $\alpha\beta$-unsaturated δ-keto-acids and their derivatives which are formed as intermediates, for example[127]:



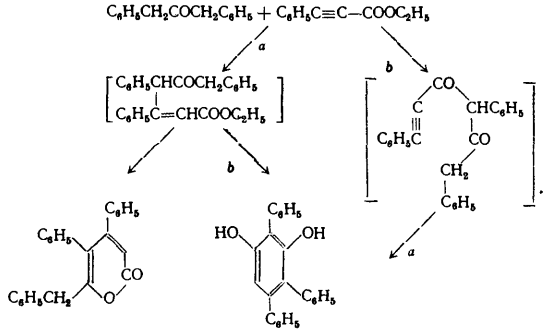
The action of acylating agents on β-methyl- and β-aryl--glutaconic anhydrides gives 5-acyl derivatives, from which it is easy to obtain 6-alkyl-4-methyl-[128-131], 6-alkyl--4-aryl-[132,133], and 4,6-diaryl-pyran-2-ones[134] (with ring opening and recyclisation with participation of the acyl group)[128]:

As a result of such conversions 3,5-diacylated glutaconic anhydrides give 3-acylpyran-2-ones[134].



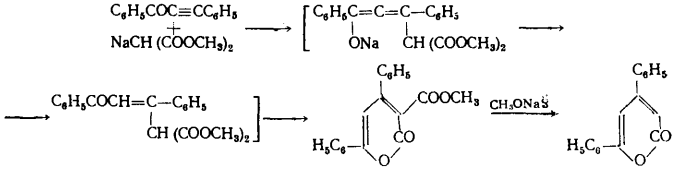
Another path for the use of anhydrides of glutaconic acids consists in their acylation of aromatic compounds; the unsaturated keto-acids thus formed are cyclised further into 6-arylpyran-2-ones, for example[127]:

This method was used with β-substituted glutaconic anhydrides to give a series of 4,6-diarylpyran-2-ones[135-137] and 6-aryl-2-oxopyran-4-carboxylic acids[138].



6. CONDENSATION OF $\alpha\beta$-ACETYLENE ACIDS AND KETONES WITH COMPOUNDS CONTAINING AN ACTIVE METHYLENE GROUP

The condensation of esters of propiolic acids with compounds having an active methylene group — benzyl ketones (I)‡[142-144], ω-alkoxy and ω-aryloxyacetophenones (II)[145], esters of β-keto-acids (III)[146-148], β-diketones (IV)[149] — is widely employed for the synthesis of 2-pyrones; their formation is the result of the dehydration of the $\alpha\beta$-unsaturated δ-keto-acids which are formed as intermediates:

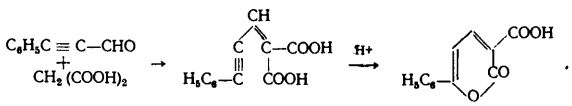


(I) X = C_6H_5; (II) R = Ar, X = OR'; (III) X = $COOC_2H_5$; (IV) X = COR'

Ketones with two active methylene groups form, in addition to the corresponding 2-pyrones, derivatives of resorcinol, the formation of which is explained by the successive occurrence of Michael (*a*) and Claisen (*b*) condensations[150]:

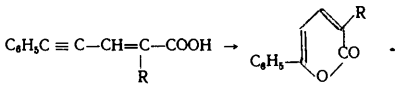
To obtain 2-pyrones use is also made of condensation of ketones of the acetylene series with compounds containing a labile hydrogen atom[151-154], for example[151]:

When the second component in this reaction is methyl α-cyanopropionate, 3-methyl-4,6-diphenylpyran-2-one[156] is obtained.



† Under these conditions the corresponding acylnitrocyclopropanes give not only the corresponding 2-pyrones but also appreciable quantities of resorcinol derivatives.[124]

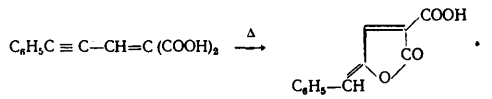
‡ With aliphatic, aliphatic–aromatic, and cyclic ketones the condensation takes place with the formation of derivatives of 4--pyrone.[139-141]



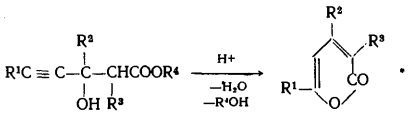
§ It was later shown that the product of the reaction of either 3--carbethoxycarbonyl-6-methyl-4-phenylpyran-2-one[153] or 5-acetyl--6-methyl-4-phenylpyran-2-one[148] with sodium ethoxide is not, however, 6-methyl-4-phenylpyran-2-one.[155]

7. CYCLISATION OF ALKEN-2-YN-4-OIC ACIDS

2-Pyrones can be obtained by the cyclisation of dibasic enynoic acids [109,157] (formed in the condensation of aldehydes of the acetylene series with malonic acid [158-161]) under the action of acidic reagents, for example [109]:



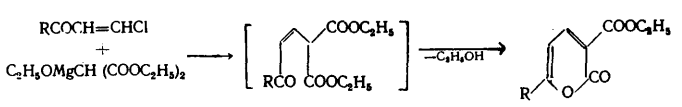
Monobasic enynoic acids are also cyclised in acid media [161-166] or on heating in the presence of mercury sulphate [160], into the corresponding 2-pyrones:



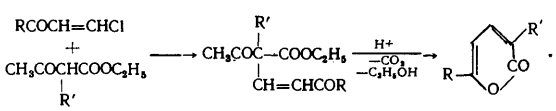
where R = H, or Ar.

However, both types of these acids can also be cyclised (on heating) in another direction — with formation of five-membered unsaturated lactones (derivatives of protoanemonin) [109,162,165], for example:

The cyclisation of enynoic acids forms the basis of a recently proposed method for the production of 4,6- and 3,4,6-substituted 2-pyrones from esters of 3-hydroxy-alkyn-4-oic acids [155]:

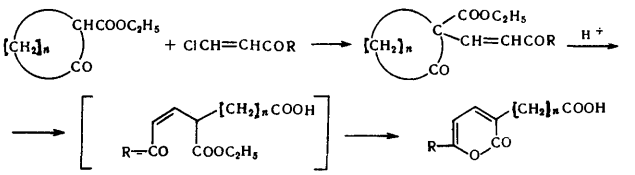


8. 2-CHLOROVINYL KETONES IN THE SYNTHESIS OF 2-PYRONES



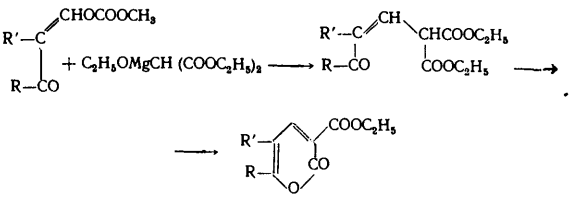
Kochetkov and coworkers used 2-chlorovinyl ketones for making 2-pyrones; these ketones have been widely used in the preparation of other heterocyclic compounds [167].

The reaction of 2-chlorovinyl ketones with substances having a labile α-hydrogen atom leads to the formation of $\beta\gamma$-unsaturated δ-keto-acids, which are readily cyclised into the corresponding 2-pyrones.



The use in this reaction with 2-chlorovinyl ketones of bis(ethoxycarbonyl)methylmagnesium ethoxide [168,169]:

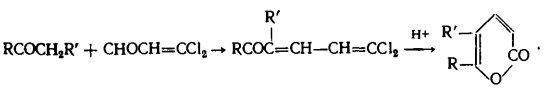
mono-substituted acetoacetic esters [170,171]:



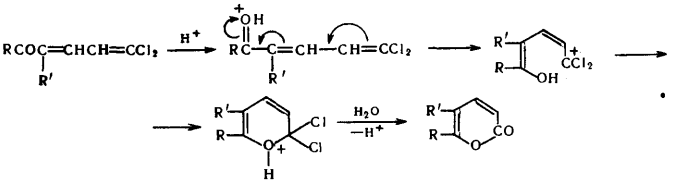
and also esters of cyclic β-keto-acids [170,172]:

can serve for the preparation of 3,5-disubstituted 2-pyrones.

Analogues of 2-chlorovinyl ketones have been used in this reaction: 2-alkoxyvinyl ketones [173] and *O*-alkoxycarbonyl derivatives of the enol forms of β-dicarbonyl compounds [174]; for example:



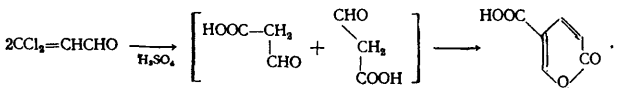
9. $\alpha\beta$-UNSATURATED $\beta\beta$-DICHLOROALDEHYDES AND $\beta\beta$-DICHLOROKETONES IN THE SYNTHESIS OF 2-PYRONES



2,2-Dichloroacryladelhyde, which is readily obtainable from the telomer of carbon tetrachloride and vinyl ethers [175,176]:

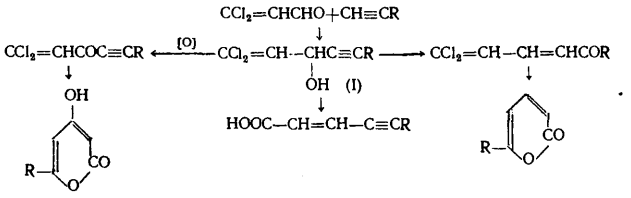
was the basis of Zakharkin and coworkers' development of a new synthesis of 2-pyrones, the first stage of which is the condensation of dichloroacrolein with alkyl aryl ketones (R = Alk, R′ = Ar) [163,164,177-179] with acetoacetic ester (R = CH_3, R′ = $CO_2C_2H_5$) [177-179], pyruvic acid (R = = CO_2H, R′ = H) [180] under the action of hydrogen chloride [177], metallic sodium [163], or barium hydroxide [164,178]:

The authors put forward the following mechanism for the cyclisation of the 3,3-dichloroallyl diketones which are formed as intermediate [177]:



The chloroacetal CCl_2=CH–CHClOR or the telomer $CCl_3CH_2CHClOR$ [181], formed as an intermediate in the preparation of 2,2-dichloroacrylaldehyde, can be used in this reaction instead of the latter.

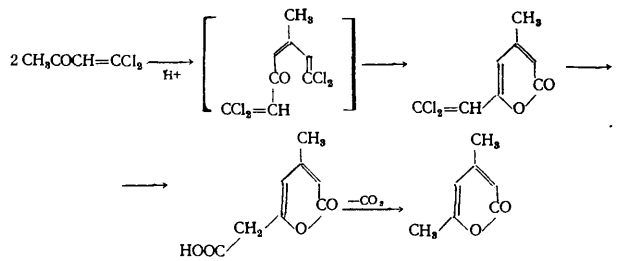
The use of 2,2-dichloro-1-methylacrylaldehyde allows derivatives of 2-pyrone with a methyl group in position 3 to be obtained [179].



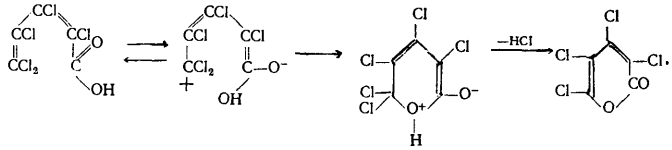
Cyclic β-diketones react with 2,2-dichloroacrylaldehyde [182] or trichloroacrylaldehyde [183,184] to form the corres-

ponding 2-pyrones (without isolation of the intermediate condensation products).

The intermolecular condensation of 2,2-dichloroacrylaldehyde leads to coumalic acid (apparently through the stage of the formation of formylacetic acid)[180]:

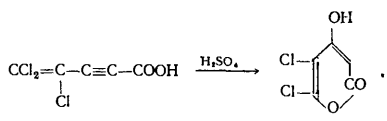


2,2-Dichloroacrylaldehyde was used to make 2-pyrones in another way. On its reaction with the metal derivatives of monosubstituted acetylenes, methanol derivatives (I) were obtained, which were subsequently converted into 2-pyrone derivatives[163,164,178,186]:



This method was used to prepare paracotoin (6-piperonylpyran-2-one)[164,178] and 3-methyl-6-phenylpyran-2-one[164].

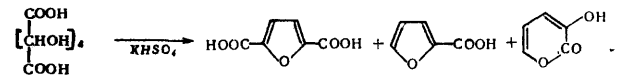
2-Pyrones were also obtained by using 2,2-dichlorovinyl ketones, whose intermolecular condensation takes place by the scheme given above for 2,2-dichloroacrylaldehyde[185]:



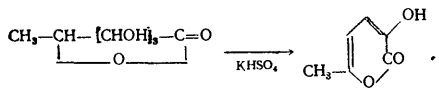
10. CYCLISATION OF POLYCHLORODIENOIC ACIDS

Roedig and Märkl[187] showed that polychlorodienoic acids are cyclised into polychloropyran-2-ones¶ on heating to 180–200°[187,188] or on heating their acid chlorides with concentrated sulphuric acid to 50°:[189]

ω-Bromoperchloropenta-2,4-dienoic acid[187] and perchloropenta-2,4-dienoic acid[190] behave similarly.

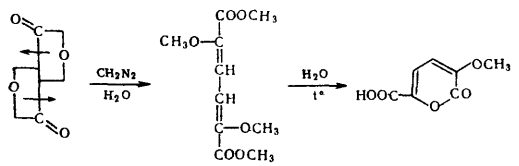


It is interesting to note that trichlorovinylpropiolic acid is converted into 5,6-dichloro-4-hydroxypyran-2-one on standing with concentrated sulphuric acid[191]:



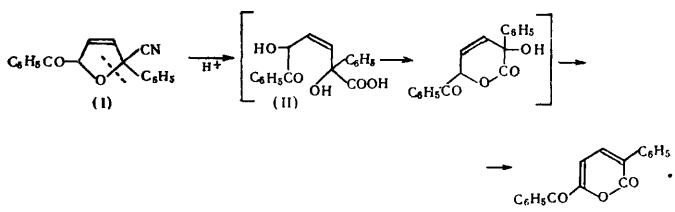
¶ The chlorine atoms in positions 4 and 6 of 2-pyrones are readily replaced by hydrogen on reduction with zinc and acetic acid.[187,190]

11. POLYHYDROXY-COMPOUNDS IN THE SYNTHESIS OF 2-PYRONES

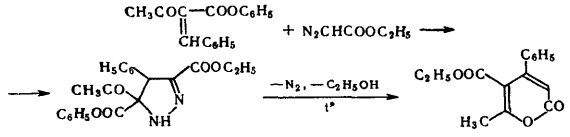


In the dry distillation of mucic acid, in addition to pyromucic (and dehydromucic) acid, an acid isomeric with it is formed, termed isopyromucic acid[192], which, as Chavanne showed[193–198], is 3-hydroxypyran-2-one. A better yield of isopyromucic acid is obtained on heating mucic acid with potassium hydrogen sulphate[198–200] (isopyromucic acid can be separated from pyromucic and dehydromucic acids by making use of their different acidities[201]:

Similarly, 3-hydroxy-6-methylpyran-2-one is formed in the distillation of rhamnolactone[202–204]:



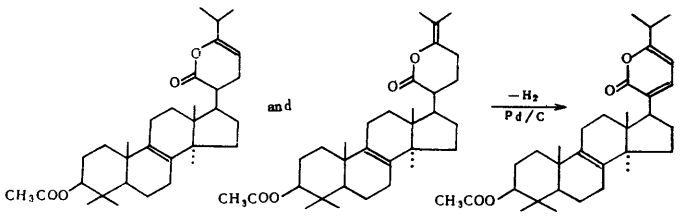
The action of moist diazomethane on the dilactone of mannosaccharic acid gives methyl 2,5-dimethoxymuconate, which is converted on boiling with water into 3-methoxy-2-oxopyran-6-carboxylic acid[105]:



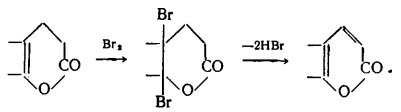
3-Hydroxypyran-2-one and its derivatives are also formed on distilling other polyhydroxy-compounds[198,206].

12. FIVE-MEMBERED HETEROCYCLIC COMPOUNDS IN THE SYNTHESIS OF 2-PYRONES

The conversion of some compounds of the 2,5-dihydrofuran and pyrazoline series into derivatives of 2-pyrones has been described. Thus, in the hydrolysis of substituted 2,5-dihydrofuran (I) the corresponding 2-pyrone is formed — through the intermediate stages of opening of the furan ring with subsequent cyclisation and dehydration of the dihydroxyketo-acid (II) which is formed[207]:



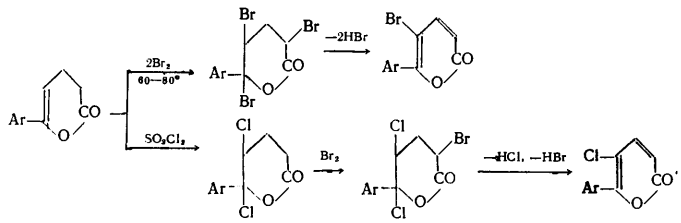
Another example of such a reaction is also well known[208]. The conversion of substituted pyrazolines into the corresponding 2-pyrones has been described[209,210], for example:



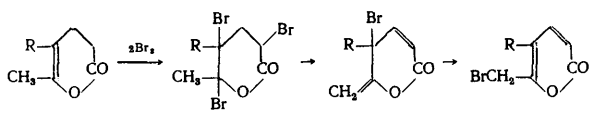
13. δ-LACTONES IN THE SYNTHESIS OF 2-PYRONES

Recently the catalytic dehydrogenation of triterpenoidal δ-enol-lactones into the corresponding 2-pyrones was described[211,212]:

This exhausts the literature on the direct dehydration of δ-lactones.

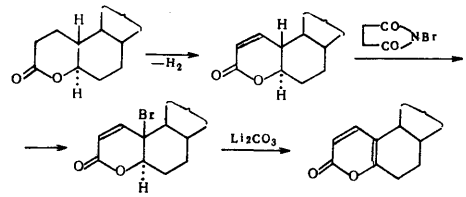


In recent years the indirect dehydration of δ-enol-lactones into 2-pyrones has been developed extensively. Shusherina and coworkers have carried out the conversion of δ-enol-lactones into 2-pyrones by brominating the former and then dehydrobrominating the dibromides which are formed (during their distillation)[213,214]:

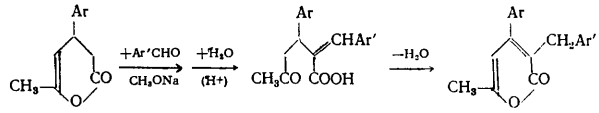


The reaction can serve as a preparative method for obtaining cycloalkano[*b*]- and 5,6-dialkyl- (or 5,6-alkylaryl-) -pyran-2-ones[213,215,216].

The chlorination of δ-enol-lactones (by the action of sulphuryl chloride) with the subsequent dehydrochlorination of the dichlorides was used for the same purpose[217,218].



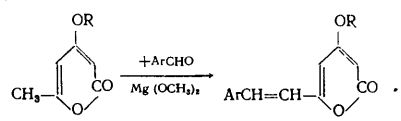
The halogenation of 6-aryl-3,4-dihydropyran-2-ones at the double bond and at the α-methylene group and subsequent dehydrohalogenation is a preparative method for the synthesis of 6-aryl-5-halogenopyran-2-ones[219,220]:



The same series of conversions for 5-alkyl- or 5-aryl- -3,4-dihydro-6-methylpyran-2-ones leads to the production of monohalides of another type — 6-bromomethylpyran- -2-ones, the formation of which is apparently the result of a rearrangement of the intermediate, allyl bromide[221]:

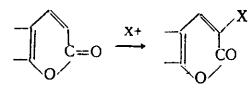
Recently, by the example of steroidal compounds, a method was developed for making 2-pyrones from saturated δ-lactones by partial dehydrogenation in positions 3 and 4 of the lactone ring and subsequent bromination in the allyl position followed by dehydrobromination of the monobromide formed[222]:

What is in principle another method of converting 3,4-dihydropyran-2-ones with an aryl group in position 4† into 2-pyrones has been described — their condensation with aromatic aldehydes and subsequent cyclisation (with isopropenyl acetate) of the α-benzylidene-δ-keto-acids which are formed[223]:



14. PRODUCTION OF 2-PYRONES FROM COMPOUNDS WHICH ALREADY CONTAIN THE PYRONE RING

Reactions of 2-pyrones which take place with retention of the pyrone ring can be used for converting one type of 2-pyrone into another and serve for the production of pyrones of a given structure.



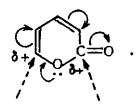
Thus, decarboxylations (see above) are widely used for going from oxopyrancarboxylic acids to 2-pyrones devoid of functional substituents[19,39]. For example, 6-phenylpyran-2-one can be obtained by decarboxylation of all the isomeric 2-oxo-6-phenylpyrancarboxylic acids[115,127,138,160]. The reduction of certain 2-pyrone derivatives is also used for this purpose — 4-chloropyran-2-ones[48], 3-chloromethylpyran-2-ones[224], 5-bromopyran-2-ones[218,219], and 6-bromomethylpyran-2-ones[221].

Homologues of 2-pyranones can be obtained by methylating the pyrone ring with methyl iodide in the presence of potassium hydroxide[225] or with diazomethane[226,227].

The alkyl groups of certain derivatives of 2-pyrone exhibit the ability to undergo condensation with aromatic aldehydes[86,228]. Thus the condensation of esters of 4-hydroxy-6-methylpyran-2-one with corresponding aldehydes gives yangonin[59] and hispidin[229]:

An electrophilic substitution of 2-pyrones recently completed allows derivatives of 2-pyrones with a functional substituent in the 3-position to be obtained[230-235]:

where X = NO_2, SO_3H, SO_2Cl, CH_2Cl.

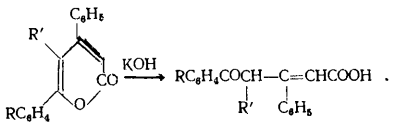


† When there is not an aryl group in position 4, then unsaturated lactones with one double bond in the ring and the other in the exocyclic position are formed.

III. CHEMICAL PROPERTIES OF 2-PYRONES

2-Pyrones exhibit an unusual combination of properties, of which the best known is their ability as unsaturated lactones to react with various nucleophilic reagents. The ability of 2-pyrones to enter into diene synthesis has been much less studied. The electrophilic substitutions of 2-pyrones which characterise these heterocyclic systems as aromatic have been investigated only recently.

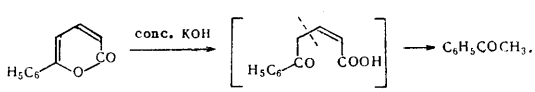
1. REACTION OF 2-PYRONES WITH NUCLEOPHILIC REAGENTS



Nucleophilic reagents whose action on 2-pyrones is accompanied by ring opening attack the pyrone ring in position 2 or 6‡, which agrees with the representation of the electron density distribution in the α-pyrone ring:

In which of these directions any particular reagent will react is apparently determined mainly by the thermodynamic stability of the addition products which are formed[236].

Hydrolysis

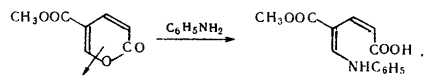


Under the action of aqueous or alcoholic solutions of alkalis the pyrone ring is broken and unsaturated δ-keto-acids are formed[68,72,73,120,135,137,144,145,242,243§]; for example[145]:

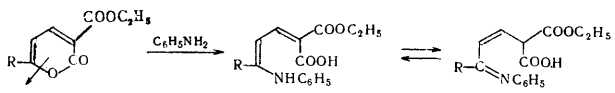
The production of unsaturated δ-keto-acids as hydrolysis products can be considered as the result of the addition of water to the α-pyrone ring at the 1,2- or 1,6-bonds.

In individual instances the unsaturated keto-acids are very easily cyclised (on acidifying the salts) into the original 2-pyrones[225].

Hydrolysis of 2-pyrones with concentrated alkali is frequently accompanied by subsequent hydrolytic splitting¶ of unsaturated keto-acids[20,26,39,68,142,243,247]; for example[246]:



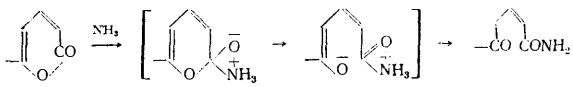
Examples are known of great stability in the α-pyrone ring under hydrolysis conditions. Thus, 3,5-di-t-butylpyran-2-one could be hydrolysed only by prolonged heating with alkali at 150° (in glycerol solution)[243].



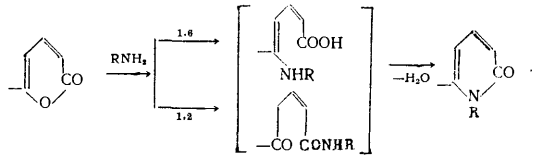
Reaction with Ammonia and Amines

Unlike hydrolysis, the addition of ammonia or amines to 2-pyrones can lead to different reaction products, depending on whether the 1,2- or the 1,6-bond of the α-pyrone ring is broken.

Pechmann and Welsh[248] showed that in the reaction of methyl coumalate with aniline δ-anilino-γ-methoxycarbonylsorbic acid is formed, that is, primary amines are attached at the 1,6-bond of the α-pyrone ring:



Such a presentation of the way 2-pyrones react with ammonia and primary amines is also confirmed by the results of Kochetkov and Kudryashov[249], who obtained 2-ethoxycarbonyl-5-phenyliminoalkadienecarboxylic acids by the reaction of 6-alkyl-3-ethoxycarbonylpyran-2-ones with aniline:



where R = CH_3, C_3H_7, C_5H_{11}.

A second possible direction of the reaction of 2-pyrones with ammonia and amines has also been discussed in the literature[187,251,252]; it is accompanied by breaking of the 1,2-bond of the α-pyrone ring and leads to the production of amides of unsaturated δ-keto-acids; it is suggested that the reaction starts here with attack of the carbonyl group of the 2-pyrone[251]:

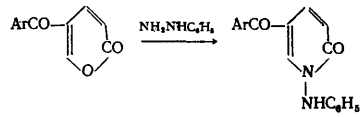
However, such a course of the reaction has not been confirmed.

Usually the action of ammonia and primary amines on 2-pyrones gives 2-pyridones, the formation of which can be considered, in the light of the above data, to be the result of the dehydration of addition products which are formed initially:

The conversion of 2-pyrones into pyridones under the action of ammonia occurs both in the cold[35,123,124,151,187,247,248,253-255], and on heating[112,113,144,145,256,257]; instead of ammonia, ammonium acetate is sometimes used[107,110,189,258-260,266].

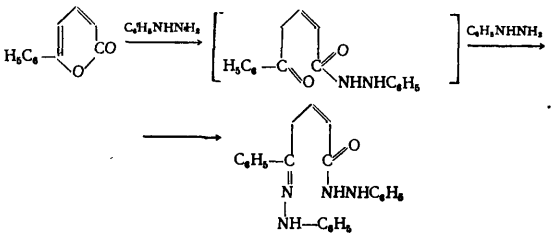
The production of *N*-substituted pyridones[187,248,250,256,259,261-265,267] by the action of primary amines on 2-pyrones (in the cold or on heating) is often used for confirming the structure of 2-pyrones.

---



‡ Saturated and unsaturated γ and δ lactones also react with nucleophilic reagents along these two directions[237,238] but usually under milder conditions than for pyrones.[239-241]

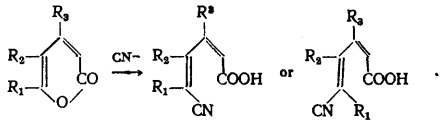
§ The action of alkali metal alkoxides on 2-pyrones leads to the formation of esters of unsaturated δ-keto-acids.[126,151,246]



¶ Therefore the hydrolysis of 2-pyrones is not used for their identification in distinction from the hydrolysis of δ-enol-lactones, (3,4-dihydropyran-2-ones).[244,245]

The reaction of 2-pyrones with phenylhydrazine leads either to *N*-substituted pyridones or to the amides of δ-keto--acids.

Thus, 5-aroylpyran-2-ones readily react with phenylhydrazine to give the corresponding *N*-aminopyridones[256]:



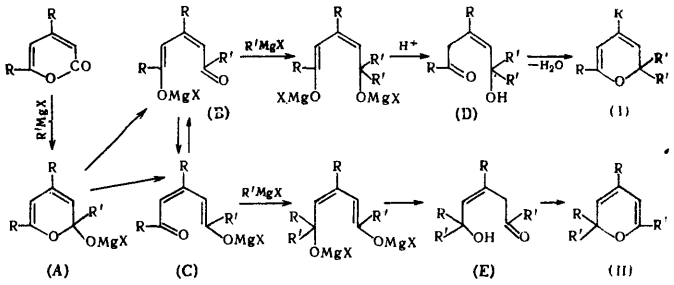
where Ar = C_6H_5, *p*-$CH_3C_6H_4$, *p*-ClC_6H_4, *p*-BrC_6H_4, whereas 6-phenylpyran-2-one forms the phenylhydrazide of the corresponding unsaturated δ-acid (isolated as the phenylhydrazone)[225]:

The reaction of 2-pyrones with hydrazine, hydroxylamine, and semicarbazide leads to the formation of *N*-substituted pyridones[144,145,257,268]†.

Reaction with Sodium Cyanide

Recently Vogel[270] carried out a new reaction of opening the α-pyrone ring at the 1,6-bond under the action of the cyanide ion, which leads to the formation of mononitriles of unsaturated acids of the muconic acid type:

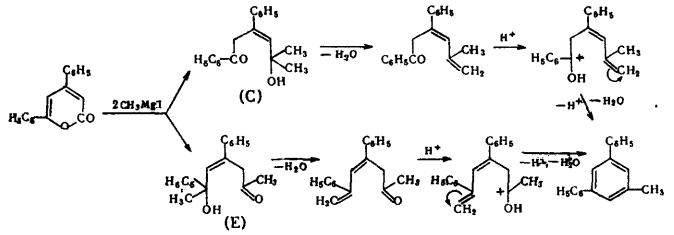
The stereochemical directionality of this astonishingly easy reaction (it ends after 5–10 min in the cold) can be controlled by choice of solvent.



Reaction with Grignard Reagents

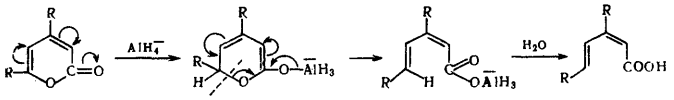
The reaction of pyrones with organomagnesium compounds is quite complicated. Gompper and Christmann[271], who first studied this reaction, ascribed to the compounds obtained the structure of pyrans (I):

(I)



It was shown later[272] that pyrans of structure (II) can also be formed which is explained[273] by the existence of an equilibrium between the two forms of enolates, (B) and (C), which are formed from the initial addition product (A):

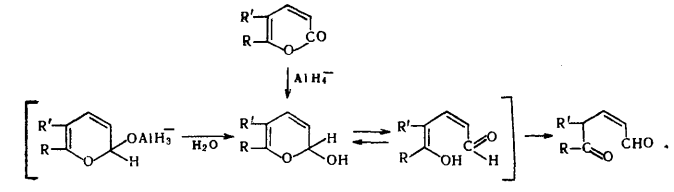
(A) (B) (C) (D) (E) (I) (II)



When the pyrone is taken in excess at R or R′ = Ar then aromatic hydrocarbons are formed in 60–80% yield[95,274].

Apparently, the keto-alcohols (D) and (E) are dehydrated initially into doubly-unsaturated ketones, which are cyclised subsequently by a Prins type of intramolecular reaction[275], for example:

Reduction by Hydro-Complexes of Metals



Hydro-complexes of metals react with 2-pyrones to reduce these to unsaturated acids[276–278] (or under more severe conditions — to unsaturated alcohols[211,212,277,278]), the formation of which is explained, apparently, by the addition of an aluminium hydride anion at the carbonyl group of the 2-pyrone and the hydride ion at position 6 and by subsequent opening of the ring at the 1,6-bond:

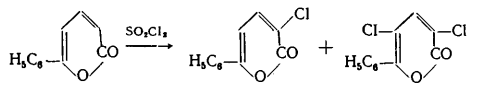
Hence the final result of this conversion is the hydrogenolysis of the 1,6-bond of the α-pyrone ring‡.

† Wiley and coworkers[269] showed that the action of hydrazine on ethyl isodehydracetate takes place anomalously with the formation of 3-methylpyrazol-5-one.

‡ However, in other instances during the reduction of 2-pyrones by lithium tetrahydroaluminate hydrogenolysis of the 1,2-bond of the α-pyrone ring takes place with formation of unsaturated δ-keto--aldehydes[279] or of the products of their further reduction — unsaturated 1,5-diols[280,281]; for example[279]:

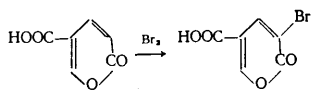
The ease of reduction depends both on the structure of the initial 2-pyrone and on the activity of the metal hydro-complex used. Thus, coumalic acids are reduced at even 0–10° by such mild agents as sodium or lithium tetrahydroborate [277,278].

Sodium or lithium tetrahydroborate very readily reduces 4-methoxy-6-methylpyran-2-one, being converted into the corresponding unsaturated acid; the action of lithium tetrahydroaluminate forms a further reduction product — an unsaturated alcohol [278]. 4,6-Dimethylpyran-2-one is reduced to an unsaturated acid only by lithium tetrahydroaluminate [277,278].



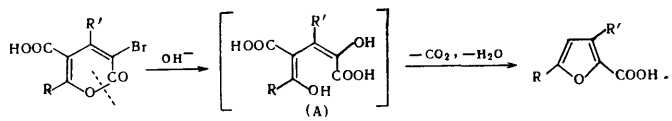
2. ELECTROPHILIC SUBSTITUTIONS IN THE 2-PYRONE SERIES

In accordance with the polarisation of the bonds of the α-pyrone ring it must be expected that the attack of electrophilic reagents will be directed to the third or fifth carbon atom of the ring.



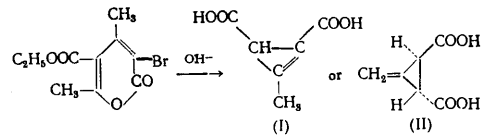
(a) Halogenation

Chlorination. The action of chlorine on coumalic [254] and isodehydracetic [26] acids gave the corresponding monochloro-substituted acids. The position of the chlorine atom was shown by the conversion of one of them (chlorocoumalic acid) into the known 3-chloropyridine [254].

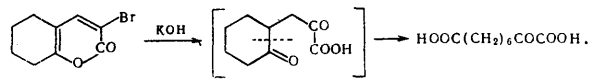


It was recently shown that the chlorination of 2-pyrones takes place very readily under the action of sulphuryl chloride [282]. Thus, under its action 6-phenylpyran-2-one is converted even in the cold into a mixture of mono- and di-chloro-derivatives:

Bromination. Bromination is one of the most studied substitutions of 2-pyrones. Under the action of bromine replacement of one or two (depending on the reaction conditions and the structure of the initial pyrone) hydrogens of the α-pyrone ring takes place. Thus, during the bromination of isodehydracetic [23,26,31,33] and coumalic [28,248,256,253] acids and their esters the corresponding monobromo-derivatives were obtained, for example [248]:



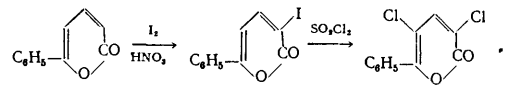
To prove the position of the bromine atom, Feist [26,283,284] used the alkaline hydrolysis of these bromo-substituted 2-pyrones; the hydroxy-acids which are formed as intermediates in the opening of the pyrone ring are cyclised into the corresponding α-furancarboxylic acids, the formation of which is possible only when the bromine atom in the initial bromopyrones is in position 3:



Conversion into α-furancarboxylic acids was used to establish the structure of the bromination products of other 2-pyrones [37,209,247,285–287]. However, examples have been described of the anomalous behaviour of bromopyrones under the action of alkalis.

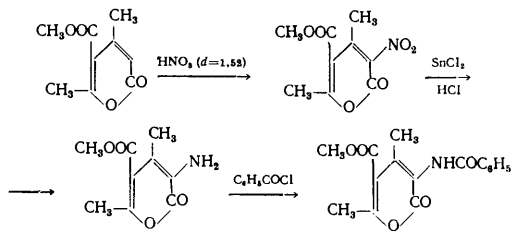
Thus, in the alkaline hydrolysis of the ethyl ester of brominated isodehydracetic acid [112] a substance was isolated [26,284] which is best known in the literature as Feist's acid, for which two structures were proposed later — 2-methylcyclopropene-1,3-dicarboxylic acid (I) [27] and *trans*-3-methylenecyclopropane-1,2-dicarboxylic acid (II) [288]:

Bottini and Roberts [292] supported structure (II) on the basis of a study of NMR spectra.



Another example, which illustrates the anomalous behaviour of bromopyrones in reacting with alkali is the formation of α-ketoazelaic acid from 3-bromo-5,6,7,8-tetrahydrochromen-2-one [289]:

In the bromination of 2-pyrones in which positions 3 and 5 are free, the bromine enters the 3 position in the cold [37,128,129,185,191] and on heating into the positions 3 and 5 with the formation of dibromopyran-2-ones [290,291].

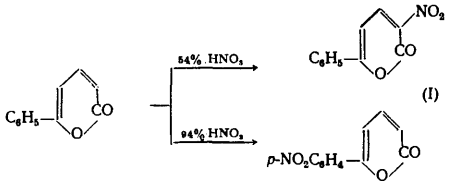


Hardly anything has been published on the reactivity of bromopyran-2-ones. Pechmann [254] described an unsuccessful attempt to replace the bromine atom in bromopyrones by the action of various nucleophilic reagents, showing at the same time the exceptional inertness in these reactions of the bromine connected to the α-pyrone ring.

Iodination. It was recently shown, by the example of 6-phenylpyran-2-one, that under conditions of oxidative iodination (118°, in the presence of concentrated nitric acid) iodine enters the pyrone ring to form 3-iodo-6-phenylpyran-2-one, the structure of which was confirmed by conversion into the well-known 3,5-dichloro-compound§ [282]:

(b) Nitration

The nitration of 2-pyrones was first carried out by Angeli [293], by the example of methyl isodehydracetate; the structure of the reaction product was shown much later [294] by the reduction of the nitro-group and the subsequent benzoylation of the amine formed:



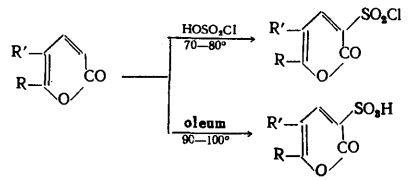
§ The iodination of 3-hydroxypyrone by iodine in the presence of yellow mercury oxide has been described [198], but the structure of the monoiodopyran-2-one thus obtained has not been established.

In other studies it was assumed, by analogy with brominations, that the nitro-group enters the 3-position [33,231,295].

Ciamician and Silber [225] obtained 3-nitro-6-phenylpyran-2-one on nitrating 6-phenylpyran-2-one with 70% nitric acid¶; its structure was recently shown by Zakharkin and Sorokina [246] who converted it into α-amino-δ-phenylvaleric acid. On the basis of this the authors [246] drew the general conclusion that the nitration of 6-phenylpyran-2-one by nitric acid takes place only in the pyrone ring.

However, Shusherina and coworkers [296] showed that by varying the nitric acid concentration 6-phenylpyran-2-one can be selectively nitrated. Thus, when 94% nitric acid is used the nitro-group only enters the benzene ring but with 54% nitric acid only in the pyrone ring:

(I)

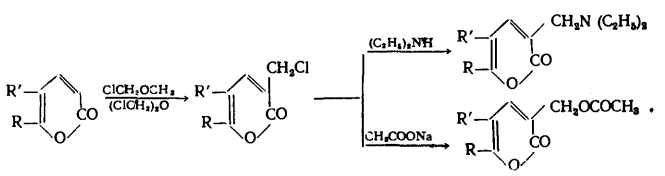


(II)

This feature of the behaviour of 6-phenylpyran-2-one is evidently explained by the greater stability of the oxonium complex in more concentrated acid, which should lead to a decrease in the reactivity of the α-pyrone ring as regards the electrophilic substitutions [296].

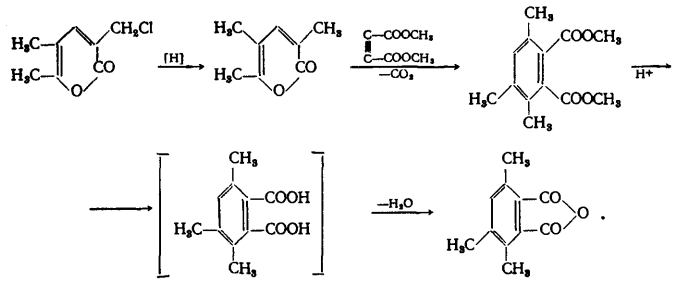
In the nitration of 6-phenylpyran-2-one [290] and isomeric methylphenylpyran-2-ones [231] with nitrating mixture, the nitro-group enters only the benzene ring.

(c) Sulphochlorination and Sulphonation



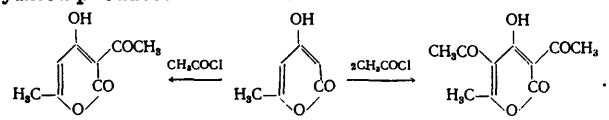
Shusherina and coworkers first effected the sulphochlorination [232] (yield 30–50%) and sulphonation [233] (yield ~ 50%) of 5,6-disubstituted pyran-2-ones:

where R = R′ = CH_3; or R = CH_3, R′ = C_3H_7, C_4H_9.



(d) Chloromethylation

2-Pyrones are chloromethylated in position 3 under the action of a mixture of mono- and bis-chloromethyl esters or of formalin saturated with hydrogen chloride. The chloromethylpyran-2-ones obtained (yield 35–41%) readily undergo exchange reactions [234,235]:



¶ The authors of the present article have shown that in addition to 3-nitro-6-phenylpyran-2-one under these condicitions 6-*p*-nitro-phenylpyran-2-one is also formed (ratio 8 : 1). [290]

The position of the chloromethyl group was shown by converting 3-chloromethyl-5,6-dimethylpyran-2-one into a homologue of phthalic anhydride with a known position of the substituent [224]:

(e) Acylation

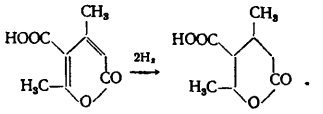
As yet the Friedel-Crafts reaction has been accomplished only for hydroxypyran-2-ones. Thus in the acylation of 4-hydroxy-6-methylpyran-2-one acyl chlorides of carboxylic acids form a mixture of the mono- and di-acylated products [54,85,291,298]:

4-Hydroxy-6-methylpyran-2-one is an example of a compound which has been formylated [297] by a mixture of carbon monoxide and hydrogen chloride in the presence of trifluoroacetic acid, but the structure of the products of the reaction has not been shown.

From the reactions considered in this section it has long been known that for pyrones halogenation and nitration are not typical of an electrophilic substitution, since they can proceed either by an ionic or by a radical mechanism. Possibly this is why 2-pyrones were not considered to be aromatic systems until recently.

The suggestion that 2-pyrones were of aromatic character was made recently by Mayer [300], who drew this conclusion on the basis that 2-pyrone is an isoelectronic analogue of tropone:

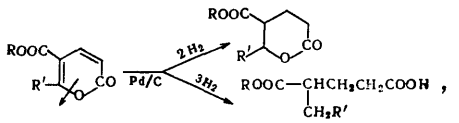
Such typical electrophilic substitutions as sulphuration, sulphochlorination [232], chloromethylation [235], and nitration with nitrating mixture [231] which have been performed for pyrones confirm Mayer's hypothesis and allow this class of heterocyclic compounds to be placed among non-benzenoid aromatic systems.



The conclusion about the aromatic nature of 2-pyrones and also about the similarity of 2-pyrones with tropones was confirmed recently [301,302] by Sheinker and coworkers from a study of the intensity of the absorption bands of the carbonyl group in the infrared spectra of 2-pyrones.

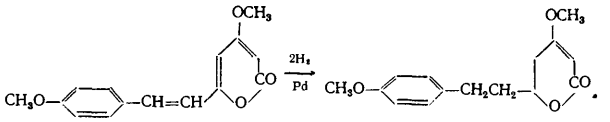
3. REACTION OF ADDITION AT THE DOUBLE BONDS OF THE α-PYRONE RING

A characteristic of the 2-pyrones is reactions which involve compounds with a system of conjugated double bonds — catalytic hydrogenation and diene synthesis.



(a) Catalytic Hydrogenation

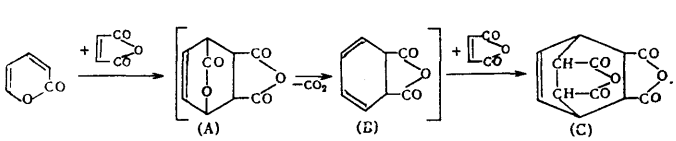
2-Pyrones easily add on hydrogen at the double bonds to form lactones — tetrahydropyran-2-ones, for example[303]:



Hydrogenation catalysts which have been used for 2-pyrones are: palladium on carbon[129,303], barium sulphate[170,304], and also palladium black[305].

In addition to the addition of hydrogen at the multiple bonds of the α-pyrone ring, under catalytic hydrogenation conditions hydrogenolysis of the 1,6-bond is observed, leading to the formation of acids[226,303] (sometimes as the main product of the reaction):

where R = R′ = H and CH_3.



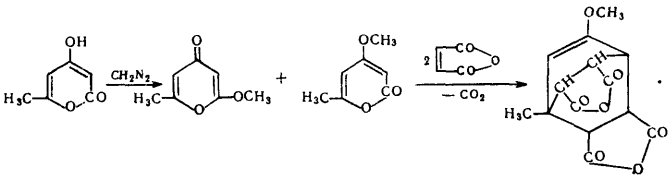
Selective hydrogenation (in the 5,6 position) of the α-pyrone ring has been achieved under certain conditions[305-307]. Thus yangonin gave 5,6-dihydro-4-methoxy--6-(*p*-methoxyphenethyl)pyran-2-one, the narcotic action of which is connected specifically with the absence of a double bond in the 5,6 position of the α-pyrone ring[307]:

Catalytic hydrogenation was used to prove the structure of certain natural compounds containing an α-pyrone ring — scillaren A[8], cinobufagine[6], bufotalinin, and marinobufagin[308].

(b) Diene Synthesis

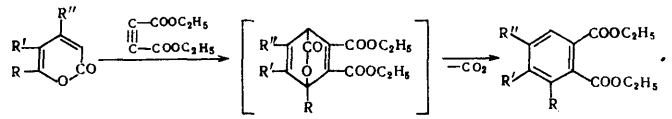
A distinctive property of 2-pyrones is their ability to undergo the diene synthesis. On studying the reaction of 2-pyrone and methyl coumalate with maleic anhydride, Diels and Alder[309] showed that a mono-addition product (A)† is formed at 110°, which is decarboxylated at 130–140° into the 1,2-dihydrophthalic anhydride (B); the latter reacts with another molecule of maleic anhydride, forming a bridging addition product (C):

(A) (B) (C)



It was subsequently found that apart from the temperature the essential factor determining the course of the reaction is the structure of the 2-pyrone. Thus 5-alkylpyran-2-ones[110,117] like the pyrones studied by Diels and Alder[309] form mono-addition products with maleic anhydride at 110°, whereas 5,6-dialkylpyran-2-ones under these conditions give only the di-addition products[213].

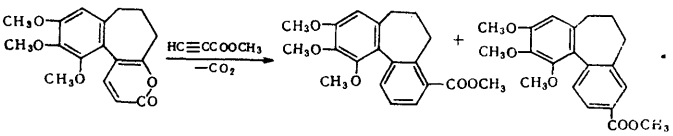
Di-addition products are also formed by 5,6-dialkyl--substituted 2-pyrones containing bromine[230] or acetoxy or chloromethyl groups[224,234,235] in position 3. With polychloropyrones[311] the course of the diene synthesis depends on the number of chlorine atoms in the α-pyrone ring. Thus 3,4,5,6-tetrachloropyran-2-one forms only a di-addition product, whereas the 3,5,6-trichloro- and 3,5-dichloro-pyran-2-ones give mono- and di-addition products.



The presence in the 3 position of the α-pyrone ring of such electronegative substituents as a nitro-, sulpho-, or carboxyl group[123,231] completely deactivates the diene system of the 2-pyrones, making it incapable of undergoing the diene synthesis.

The formation of crystalline di-addition products with maleic anhydride‡, which usually occurs with excellent yields and is accompanied by the characteristic liberation of carbon dioxide, can serve as an excellent method for the identification of 2-pyrones[120,138,208,213,215].

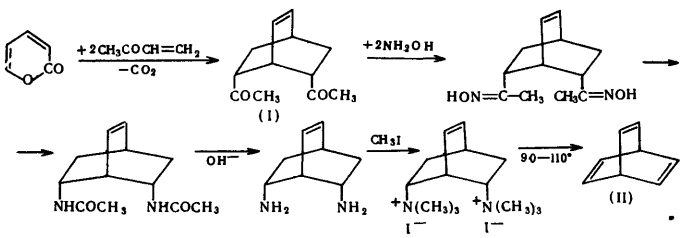
Bu′ Lock and Smith[59] used this reaction to demonstrate the structure of the product of the methylation of 4-hydroxy--6-methylpyran-2-one, which was a mixture of the methoxy--derivatives of the corresponding γ- and α-pyrones, of which only the latter reacted with maleic anhydride:



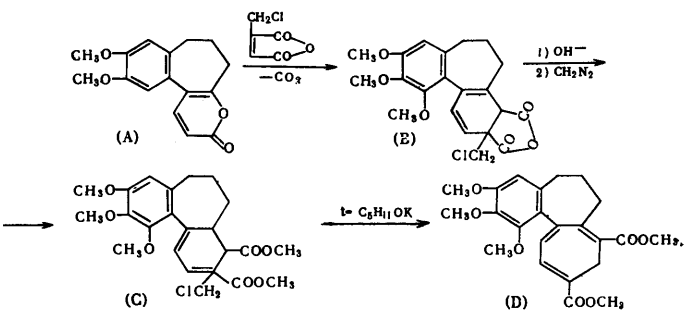
The use of diethyl butyndioate[59,312,313] as a dienophile in reaction with 2-pyrones has been described; the reaction is accompanied by the evolution of carbon dioxide and leads to the formation of the corresponding esters of phthalic acid:

This reaction was used to obtain difficultly accessible derivatives of phthalic acids[18,314].

Methyl propiolate reacts with substituted 2-pyrones to give both possible reaction products — the corresponding esters of the *ortho*- and *meta*-substituted benzoic acids[18]:

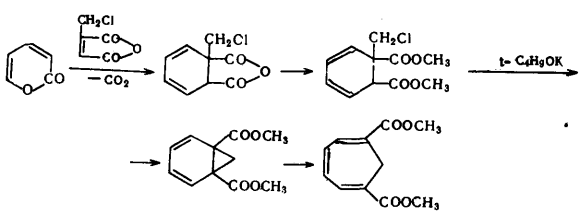


The ability of 2-pyrones to undergo the Diels–Alder reaction has recently been used in organic synthesis. Thus one of the isomeric di-addition products of 2-pyrone with



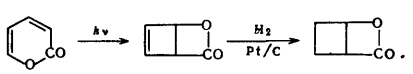
† The endo-configuration of the addition product (A) was recently confirmed by measurement of its dipole moment.[310]

‡ The formation of di-addition products was also observed in the reaction of 2-pyrones with acrylonitrile[246] and *N*-phenylmaleimide.[95]

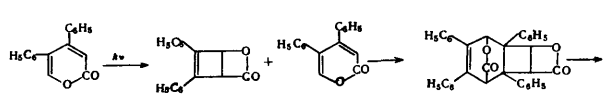


methyl vinyl ketone (I) was used in the synthesis of barrelene, bicyclo[2,2,2]octa-2,5,7-triene[19]:

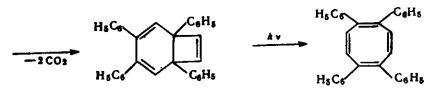
The diene synthesis of the tricyclic 2-pyrone (A) with chloromethylmaleic anhydride was used to synthesise the ester (D) having the colchicine carbon skeleton[17,18]:



The analogous reaction of coumalin with 2-chloromethylmaleic anhydride can be used for the preparative production of cycloheptatriene-1,3-dicarboxylic acid[315]:



4. PHOTOISOMERISATION OF 2-PYRONES



It was recently shown[316] that under the action of ultraviolet light 2-pyrone isomerises into a β-lactone condensed with a cyclobutene ring (the yield is almost quantitative); the structure of the β-lactone was confirmed by the formation of an addition product with isobenzofuran and also by hydrogenation into the corresponding saturated β-lactone:

This interesting reaction was recommended by the authors for the preparation of compounds of the cyclobutane series.

The example of 4,5-diphenylpyran-2-one showed[317] that the β-lactone formed initially undergoes a diene synthesis with the original pyrone under the conditions of the reaction to form an addition product, which on further irradiation is converted into the tetraphenylcyclo-octatetraene:

The published work on the reactivity of 2-pyrones shows that the long-held view of the 2-pyrones as doubly-unsaturated six-membered lactones does not exhaust all the peculiar properties of this heterocyclic system. Now it is also recognised to possess aromatic properties, which should be ascribed to the 2-pyrones on the basis of their recently discovered ability to undergo typical electrophilic substitutions.

The variety of chemical properties of the α-pyrone ring which is apparent in their capability for photoisomerisation, to diene synthesis, and also to react with various nucleophilic reagents (for example, the Grignard reagent, potassium cyanide), allows 2-pyrones to be widely used in organic synthesis for obtaining difficultly accessible compounds of the cyclobutane, cyclo-octatetraene, cycloheptatriene, and pyran series, derivatives of muconic acid, etc.

These results acquire greater importance in that 2-pyrones themselves, thanks to the many methods of preparation developed in recent years, have become available.

HYDROGEN BONDS AND π-COMPLEXES IN RADICAL LIQUID-PHASE REACTIONS

A. L. Buchachenko and O. P. Sukhanova

CONTENTS

1. Introduction 192
2. Hydrogen bonds in radical reactions 192
3. π-Complexes in radical reactions 197
4. Polar factors and specific interactions in radical liquid-phase reactions 200

1. INTRODUCTION

The investigation of the influence of the solvent on the kinetics of radical liquid-phase reactions is of considerable importance for the theory of reactivity. The interaction of a reacting species with solvent molecules alters the electronic structure and reactivity of the species. From a knowledge of this interaction it is possible to obtain important information about the factors influencing the reactivity of the reacting species. There is, moreover, another practical aspect of this problem, associated with the choice of solvent and the improvement of technological processes.

The strongest specific interactions exerting a significant influence on the kinetics and sometimes also the mechanism of liquid-phase radical reactions are those revealed in hydrogen bonds and π-complexes. The aim of the present review is to examine the part played by these interactions in kinetics and to reveal their nature and mechanism, that is to analyse the structural-kinetic aspect of specific interactions.

2. HYDROGEN BONDS IN RADICAL REACTIONS

The problem of the part played by hydrogen bonds in the kinetics of chemical reactions was first raised by Emanuel'.[1] A later review[2] examined a large amount of material on the influence of hydrogen bonding on the kinetics and mechanism of many reactions (chiefly ionic). Numerous studies carried out since that time have confirmed conclusively that the manifestation of hydrogen bonding is one of the fundamental characteristics of liquid-phase kinetics. Much of the mechanism by which hydrogen bonding affects the rate of radical reactions is not yet clear, however.

It is first of all important to know whether a reaction takes place through equilibria involving the association of the reacting species by hydrogen bonding and if so, which of the constants of the multi-stage equilibrium are important. It is possible that the reaction involves not only free non-associated molecules, but also solvates, so that hydrogen bonding is also manifested in the activated complex. The coordination number of the solvated complex is then always of considerable importance.

Physical methods of study (X-ray diffraction, electron diffraction, infrared spectroscopy, nuclear magnetic resonance, etc.) make it possible to obtain extensive thermodynamic information on the structure of the solvates, their coordination numbers, and the equilibrium constants for a large number of classes of substances. This material has been collected in a number of reviews and monographs[3-5]. Different methods often give contradictory information on the structure of solvates, but even if the structure of the associated forms is fairly well known, it is difficult to estimate the part which they play in kinetics: for this, kinetic analysis of the influence of association on the reaction rates is necessary.

In radical reactions, each of the participants in the reaction — the molecule and the radical — may be associated. Let us consider first the influence of association of the molecules on the rate of their reactions.

In the study of the decomposition of hydroperoxides, which are the primary products of the oxidation of most organic and many inorganic compounds, it has been established that at sufficiently high concentrations of the hydroperoxide, its decomposition obeys the kinetic equation for a first-order reaction and apparently proceeds according to the scheme

$$2\mathrm{ROOH} \rightarrow \mathrm{R\dot{O}_2} + \mathrm{H_2O} + \mathrm{R\dot{O}}. \qquad (1)$$

This has been observed in the decomposition of ethyl linoleate[6], cyclohexyl[7], tetralin[8], n-decyl[9], t-butyl[10], and cumene hydroperoxides.

It was assumed that the hydroperoxide molecules are associated by hydrogen bonding to form dimers[6,11], and that their decomposition to give radicals is thereby facilitated considerably. The association of hydroperoxides was in fact confirmed by physical methods[7,12], but kinetic proof of the preferential participation of the associated hydroperoxide in decomposition according to scheme (1) was given only recently in papers by Denisov[10,13]. An analogous effect of increase in the rate of decomposition is brought about by intramolecular hydrogen bonding in acyl hydroperoxides[1].

The decomposition of hydroperoxides is also facilitated by the presence of other substances capable of undergoing association with the hydroperoxide molecules by hydrogen bonding, for example alcohols[14], organic acids[15], etc. This phenomenon was studied in detail[16] for the decomposition of n-decyl hydroperoxide in the presence of hexanoic acid. It is assumed that the decomposition scheme is

$$\mathrm{ROOH} + n\,\mathrm{R'COOH} \overset{K}{\rightleftarrows} (\text{associate}) \overset{k}{\rightarrow} \dot{\mathrm{R}}\mathrm{O} + \dot{\mathrm{O}}\mathrm{H} + n\,\mathrm{R'COOH}. \qquad (2)$$

It was shown that the coordination number n of the associate, that is the number of molecules of acid in the complex with the hydroperoxide, is equal to 2; the equilibrium constants K and the constants k for the decomposition of the complex to form radicals were also determined. The activation energy for the decomposition of the hydroperoxide in the associate (16.1 kcal mole^{-1}) was found to be much less than that for the decomposition of the hydroperoxide in the absence of the acid (23.8 kcal mole^{-1}). All these facts indicate that hydrogen bonding occurs in the elementary stages of the decomposition of the hydroperoxides to form radicals. A detailed analysis of the mechanism of decomposition involving hydrogen bonding, from the viewpoint of the heats and activation barriers of the elementary reactions, was given by Berezin[17].

In radical substitutions (in particular, in the most extensively studied reactions involving hydrogen atom abstraction), the presence of associates of molecules reacting with one another or with solvent molecules by hydrogen bonding means that both free molecules and their associates may take part in the reaction, at different rates. Kinetic proof for this differentiated participation is given in a number of papers.

Thus Berezin's work[17,18] on the oxidative decarboxylation of decanoic acid according to the scheme

$$\mathrm{RCOOH} + \mathrm{r}\dot{\mathrm{O}}_2 \rightarrow \mathrm{r\,OOH} + \mathrm{RC}\!\!<\!\!\begin{matrix}\dot{\mathrm{O}}\\ \mathrm{O}\end{matrix}$$
$$\mathrm{RC}\!\!<\!\!\begin{matrix}\dot{\mathrm{O}}\\ \mathrm{O}\end{matrix} \rightarrow \dot{\mathrm{R}} + \mathrm{CO}_2 \qquad (3)$$

where rO_2 represents the peroxide radical of the hydrocarbon rH in which the decarboxylation takes place, established convincingly that only monomeric non-associated acid molecules take part in the reaction (3), the acid dimers formed by hydrogen bonding being quite inactive.

Study of the reaction of diethyl phosphite with the tri-t-butylphenoxyl radical[19] showed that the effective rate constant for the reaction in benzene increases considerably with decrease in the concentration of phosphite. Kinetic analysis of this dependence showed that the free tri-t-butyl phenoxyl reacts much more rapidly with the monomeric form of the phosphite than with the associated form, the coordination number of which is two. Thus here also the monomeric molecules are found to be much more active than the molecules associated to form dimers.

Hydrogen bonding is revealed most clearly in the kinetics of radical reactions with strongly associated molecules such as alcohols and phenols. The analysis of these reactions has now yielded a sufficiently clear picture of the mechanism and nature of the kinetic influence of hydrogen bonding.

Berezin[17,20] showed that the rate constant for the reaction between the methyl radical and t-butyl alcohol with a tritiated hydroxyl group according to the scheme

$$\dot{\mathrm{C}}\mathrm{H}_3 + (\mathrm{CH}_3)_3\,\mathrm{COT} \xrightarrow{k_{OT}} \mathrm{CH}_3\mathrm{T} + (\mathrm{CH}_3)_3\,\dot{\mathrm{C}}\mathrm{O} \qquad (4)$$

depends to a marked extent on the concentration of the alcohol in n-heptane; with increase in the alcohol concentration, the reactivity of free methyl with respect to the hydroxyl group decreases sharply. This agrees with the idea that only monomeric t-butyl alcohol molecules react with methyl radicals. Detailed kinetic analysis showed that the associates apparently have a cyclic structure; it was also possible to determine the thermodynamic characteristics of the association equilibrium. This work confirmed earlier qualitative observations that associated hydroxyl groups in alcohols are unreactive[21].

The association of phenols has an analogous influence on the reactivity of their hydroxyl hydrogen atoms with respect to methyl radicals[17]; the same is true of the reactions of phenols and amines with peroxide radicals[22]. The hydroxyl hydrogen of alcohols is also comparatively inert with respect to hydrogen atom abstraction[23].

The influence of the medium on the kinetics of the reactions of nitrophenols with the stable tri-t-butylphenoxyl radical, involving the removal of hydroxyl hydrogen, has also been studied[24,25]. For o-nitrophenol, the rate constants for this reaction and the activation energies are quite independent of the nature of the solvent in which the reaction takes place (benzene, hexane, acetone, or methanol), but for m-nitrophenol the medium has a marked influence not only on the rate constants but also on the activation energies (Table 1). A linear relationship between the logarithms of the pre-exponential terms and the values of the activation energy, that is a compensation effect, is observed. The compensation effect is apparently due to the influence of the medium; this influence is localised and is determined by the interaction between the reaction centre and the solvent. The dielectric properties of the solvent have no significant influence on the reaction rate constants even for such dipolar species as the phenoxyl radical and phenol; this follows from the data for o-nitrophenol. This also indicates, in particular, that the reacting radical is not solvated (apparently because of steric hindrance). Comparison of the results for o- and m-nitrophenols indicates that the hydroxyl hydrogens of o-nitrophenol do not form hydrogen bonds with the solvent because of the steric hindrance created by the nitro-group and also because of the strong intramolecular hydrogen bond. When the acetone or alcohol is diluted with inert solvents (heptane), the

TABLE 1. Pre-exponential factors k_0 and activation energies E for the reaction of m-nitrophenol with tri-t-butylphenoxyl.

Solvent	k_0, cm^3 s^{-1}	E, kcal mole^{-1}
Benzene	$8\cdot10^{-16}$	10.2
Acetone	$5\cdot10^{-14}$	14.7
Methanol	$6\cdot10^{-13}$	17.3

m-nitrophenol associates are broken down, yielding the more reactive molecules of the monomeric phenol and a corresponding increase in the effective rate constant[25].

The reaction of a radical with a molecule capable of undergoing solvation can be represented in the following general form:

$$\begin{aligned} \dot{R} + XOH_0 &\xrightarrow{k_0} RH + X\dot{O} \\ \dot{R} + XOH_S &\xrightarrow{k_S} RH + X\dot{O} \\ XOH_0 + nS &\overset{K}{\rightleftarrows} XOH_S \\ X\dot{O} + \dot{R} &\xrightarrow{k_1} XOR \end{aligned} \qquad (5)$$

where $\dot{R}$ represents any reacting radical (for example $\dot{C}H_3$, tri-t-butylphenoxyl, or the peroxide radical), and XOH_0 and XOH_S the reacting molecules of a phenol or alcohol with a free hydroxyl group or with a hydroxyl group solvated by n solvent molecules respectively. This scheme assumes that the radical reacts with the free and solvated molecules with the respective constants k_0 and k_S, and also that solvation equilibrium is established.

With the condition that $k_1 \gg k_0$ and $k_1 \gg k_S$, analysis of scheme (5) leads to the following expression for the rate of disappearance of $\dot{R}$ radicals:

$$-\frac{d[\dot{R}]}{dt} = 2\,\frac{k_0 + k_S K[S]^n}{1 + K[S]^n}[\dot{R}][XOH]_\Sigma,$$

where $[XOH]_\Sigma$ denotes the total concentration of reacting molecules of the phenol or alcohol, and [S] the concentration of solvating molecules. The effective rate constant is given by the expression

$$k_{eff} = \frac{k_0 + k_S K[S]^n}{1 + K[S]^n} \qquad (I)$$

and depends on the concentration [S].

Relationship (I) was analysed for the example of the reaction of tri-t-butylphenoxyl with m-nitrophenol in mixtures of acetone or alcohol as solvating solvents with an inert solvent (heptane)[25]. At low degrees of dilution with heptane, that is with the condition that $K[S]^n \gg 1$, Eqn. (I) can be transformed into

$$k_{eff} = \frac{k_0}{K[S]^n} + k_S\,. \qquad (II)$$

By differentiating expression (II) with respect to the concentration [S] and taking logarithms, we obtain the equation

$$\log\left|\frac{dk_{eff}}{d[S]}\right| = \log\frac{k_0 n}{K} - (n+1)\log[S]. \qquad (III)$$

From Eqns. (II) and (III) and the experimental dependence of the effective constant k_{eff} on the concentration of solvating solvent [S] it is possible to determine the coordination number n and to calculate the values of k_0/K and k_S.

Fig. 1 shows the dependence of k_{eff} on the concentration of acetone in its mixtures with heptane, and also the logarithmic form of this dependence, which satisfies Eqn. (III). The slope of the straight line *2* gives $n = 1$ and the intercept on the axis of ordinates gives the value $k_0/K = 1.7 \times 10^{-3}$ s^{-1}. From Eqn. (II) we then obtain $k_S = 1 \times 10^{-26}$ cm^3 s^{-1} (at 22°). The coordination number n is also equal to unity for the reaction in methanol.

If the reacting molecule undergoes association not with the molecules of the medium but with other similar molecules, the reaction can again be described by a scheme

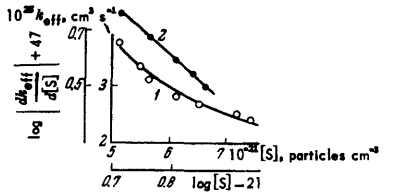

Fig. 1. Dependence of k_{eff} on the concentration of acetone in its mixtures with heptane (curve 1) and its logarithmic transform (straight line 2) [according to Eqn. (III)] for the reaction of m-nitrophenol with tri-t-butylphenoxyl.[25]

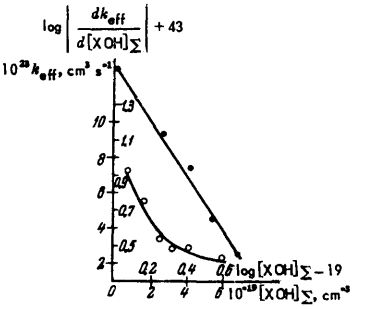

Fig. 2. Dependence of k_{eff} on the concentration of m-nitrophenol and its logarithmic transform [according to Eqn. (IV)] for the reaction of m-nitrophenol with tri-t-butylphenoxyl.[25]

similar to scheme (5), and the corresponding analysis gives the equation

$$\log\left|\frac{dk_{eff}}{d[XOH]_\Sigma}\right| = A + \left(\frac{1}{n} - 2\right)\log[XOH]_\Sigma, \qquad (IV)$$

where A is a constant. From Eqn. (IV) and the data given in Fig. 2 it follows that for the self-association of m-nitrophenol the coordination number $n = 2$.[25]

It should be noted that the coordination number of the solvate complex in the thermodynamic sense denotes the number of solvating molecules present in the complex. The coordination number n appearing in the kinetic equations has its kinetic significance, which does not coincide with the thermodynamic concept. It denotes the number of reactive molecules or groups liberated or held in the elementary equilibrium step of hydrogen bond rupture and formation. Thus in the kinetic equations we cannot use the coordination numbers obtained by physical methods, although in certain particular cases the absolute values of the kinetic and thermodynamic coordination numbers may coincide.

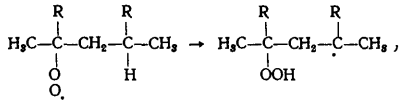
As already noted, in the associates of m-nitrophenol with solvent molecules the value of the kinetic coordination number is unity. This means that only the association of one solvent molecule is significant for kinetics; further association and further growth of the solvate sheath are not significant. In the self-association of m-nitrophenol[25] or diethyl phosphite[19], however, the kinetic coordination number is equal to two, that is two reaction centres take part in the act of complex formation. Thus the reactions of the radicals with the solvated molecules are not elementary reactions, but involve at least three elementary acts: the reaction of the radical with the free non-solvated molecule,

the reaction with the solvate, and the solvation equilibrium. The effective rate constants naturally depend on the concentration of reacting molecules (self-association) or the degree of dilution by an inert solvent (solvation by the solvent). These dependences indicate the existence of specific interactions between the reagents and the molecules of the medium, and they can often be used to investigate the detailed mechanism.

An extremely significant fact in kinetics is that a reaction centre solvated by hydrogen bonding is completely unreactive [18-20] or, strictly speaking, so little reactive that $k_S \ll k_0$. [25]

One reason for this is probably steric hindrance of the reactive group in the solvate. This suggestion alone is obviously insufficient, however, since the distance corresponding to the hydrogen bridge is fairly large and often cannot prevent a reaction by steric hindrance alone. It is clear, for example, that in the reactions of a hydrogen atom, the lack of reactivity of associated hydroxyl groups [23] cannot be attributed entirely to steric effects. Another reason is apparently that the formation of a hydrogen bond in a complex of the type A–H... B leads to partial transfer of charge from the donor B to the acceptor molecule [26] and an increase in the polarity of the reacting bond A–H. This is indicated by the increased intensity of the stretching vibrations of the A–H bond in the infrared spectra, and also by the dipole moments of the complexes and the dielectric properties of substances containing hydrogen bonds [26-29]. The important contribution made by the structure with charge transfer $A^-...H...B^+$ in the complex with hydrogen bonding is also indicated by the linear relationship between the displacement of the stretching and bending vibration frequencies in the hydrogen bridge [30] and by experimental results on NMR chemical shifts on the ^{14}N nucleus of pyridine taking part in hydrogen bonding with methanol [31].

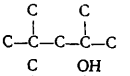
Moreover, there are grounds for assuming that the hydrogen atom in the complex A–H... B is positively charged relative to an ordinary hydrogen atom which is not forming a hydrogen bond, the electron density deficit amounting to 15–20%. This is indicated by electron diffraction data [32], and also by calculation of the NMR chemical shifts (in the one-electron approximation) [33]. It is true that the question of the degree of ionicity of the hydrogen atom is still open [26], but from the kinetic viewpoint the polarisation of the A–H bond in the complex A–H... B is apparently the chief factor leading to the sharp decrease in its reactivity.

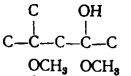


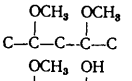
Hydrogen bonding manifests itself not only in the kinetics of radical substitutions, but also in additions across a double bond. Thus *ortho*-substituted *N*-phenylmethacrylamides, whose molecules do not show intermolecular interaction by hydrogen bonding, are polymerised much more rapidly than their *meta*- and *para*-isomers, whose molecules are associated [34].

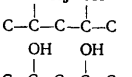
Until now we have been considering the association of reacting molecules. Let us now consider the influence of association of the radicals on the rate and mechanism of radical reactions. Here two cases are possible: firstly, when the radical forms hydrogen bonds with molecules with which it does not react, and secondly when hydrogen bonding by the radical precedes formation of the activated complex, that is the radical is solvated by the molecule or group with which it reacts. As shown below, the kinetic manifestations of these two possibilities are fundamentally different.

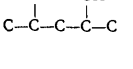
In a study of the decomposition of acetyl peroxide [35] it was shown that the acetyl radicals are more stable in acetic and propionic acids than in aliphatic solvents. This stabilisation of the decomposition of the acetyl radical was attributed to hydrogen bonding between the radical and the acid molecule.





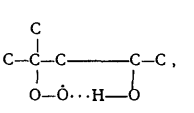






The retarding influence of added water on the oxidation of cyclohexanone was noted by Denisov [36], who showed that this phenomenon is due chiefly to a decrease in the rate constant for chain propagation. This decreased activity of the peroxide radical was assumed to be due to solvation of the radical by water molecules. The proposed kinetic scheme, according to which solvated and non-solvated radicals take part in chain propagation with different rate constants, shows satisfactory agreement with the experimental data. In this paper Denisov formulated clearly for the first time the idea that the participation of radicals in hydrogen bond formation was quite reasonable, and the kinetic consequences of this participation. Subsequent work fully confirmed these ideas.

Thus Rust and Youngman [37], in a study of the oxidation of 2,4-dimethylpentane and 2,4-dimethoxypentane, showed that in these hydrocarbons oxidation proceeds very intensively through intramolecular attack by the peroxide radical on the tertiary C–H bond in the γ-position:



(6)

where R represents a methyl or methoxy group. If one or both of the methyl or methoxy groups are replaced by hydroxyl groups, however, the ability of the hydrocarbons to undergo intramolecular attack by the peroxide radical disappears almost completely. This is effectively illustrated by the scheme given below.

Hydrocarbon	Proportion of products of intramolecular attack, %
	95
	<1
	60–70
	<7.5
	<1

The absence of intramolecular attack (6) in the hydroxyl-containing molecules indicates unambiguously that the peroxide radical forms an intramolecular hydrogen bond of the following type:

which decreases its reactivity with respect to the intramolecular attack at the C–H bond and even leads to a change in the direction of the attack, that is to a change in the oxidation mechanism.

In a number of studies of hydrocarbon oxidation, measurements have been made of the ratios of the constants $k_1/\sqrt{k_2}$ for the reactions of peroxide radicals:

$$\dot{RO}_2 + RH \xrightarrow{k_1} RO_2H + \dot{R}$$
$$\dot{RO}_2 + \dot{RO}_2 \xrightarrow{k_2} O_2 + \text{stable products},$$

in various solvents. It was found that the ratio $k_1/\sqrt{k_2}$ is much smaller in solvents capable of solvating the $\dot{RO}_2$ radical by hydrogen bonding than in inert solvents. This was observed by Howard and Ingold[38] for the oxidation of tetralin and cumene in acetic acid and t-butyl alcohol, by Hendry and Russell[39] for the oxidation of alkenes and arylalkyl hydrocarbons in ethanol and acetic acid, and by Denisov[40] for the oxidation of isopropyl alcohol in methanol and water. These phenomena can be explained on the basis of the theory that the reactivity of the $\dot{RO}_2$ radical is decreased by solvation.

The most convincing proof of solvation of the peroxide radical was obtained by Zaikov and coworkers[41], who measured not only the ratios $k_1/\sqrt{k_2}$, but also the actual constants k_1 and k_2. They showed that solvation of the peroxide radical (in the oxidation of methyl ethyl ketone in aqueous solutions) decreases its reactivity with respect to both chain propagation and disproportionation; the solvate is much less reactive than the free radical, and the coordination number of the solvate is equal to unity. The kinetic data were also used to determine the heat of solvation of the $\dot{RO}_2$ radical.

Walling and coworkers[42-44] studied the competition between two reactions of the t-butoxyl radical — decomposition (7) and substitution (8):

$$(CH_3)_3CO\cdot \xrightarrow{k_{decomp}} (CH_3)_2CO + CH_3\cdot \qquad (7)$$
$$(CH_3)_3CO\cdot + RH \xrightarrow{k_{subst}} (CH_3)_3COH + R\cdot \qquad (8)$$

and the influence of solvents on the quantitative ratio of the products of these reactions. They showed that in a solvating solvent such as acetic acid the difference in the activation energies of reactions (7) and (8), equal to (E_{decomp} - E_{subst}), decreases sharply relative to the value in the gaseous phase or in inert solvents. This effect was attributed to the influence of solvents (and in particular hydrogen bonds) on the activated complex of reaction (7), which is thereby facilitated, with a corresponding decrease in the activation energy E_{decomp}, and hence in the difference (E_{decomp} - E_{subst}). In view of the observation of Levy and Szwarc[35] that the acetyl radical is stabilised by hydrogen bonding, however, it is difficult to suppose that in the present instance hydrogen bonding will facilitate the decomposition of the $(CH_3)_3C\dot{O}$ radical. It appears more probable that hydrogen bonding by the t-butoxyl radical hinders the substitution (8), leading to an increase in E_{subst} and hence to the experimentally observed decrease in the difference (E_{decomp} - E_{subst}). This interpretation explains the results obtained[42-44] and does not contradict the ideas developed by Denisov[36] and confirmed in other work.

The kinetic effects associated with the localised specific interactions between the reacting molecules and radicals and the solvent molecules must apparently be related for the most part not to the activated complex but to the original state, since the lifetime of the activated complex is much less than the characteristic durations of these specific interactions. This remark naturally does not refer to such universal interactions as the dipole–dipole interaction, manifested in the dependence of reaction rates on the dielectric constant of the medium. An example is provided by the detailed work of Zaikov, Maizus, and Emanuel'[45,46] on the influence of the medium on the rate of oxidation of hydrocarbons, alcohols, and ketones, and also by the work of Hendry and Russell[39] on the oxidation of alkenes and arylalkyl hydrocarbons in various solvents.

Thus in all cases when the radical forms hydrogen bonds with those molecules with which it does not react, the result is a decrease in its reactivity in the main reaction; the reaction consists of the ensemble of elementary acts of chain propagation (with the participation of the non-solvated radical and the solvate) and equilibria of radical solvation.

If, however, the radical forms a hydrogen bond with the molecule with which it subsequently reacts, this association facilitates the reaction considerably. Effects of this type were observed by Szwarc and Smid[47] for the decomposition of propionyl and benzoyl peroxides in acetic and trifluoroacetic acids. The ethyl radicals obtained by decomposition of the $C_2H_5C(=O)O\cdot$ radical react with the acids at the C–H or C–F bond. In the decomposition of benzoyl peroxide, the $PhC(=O)O\cdot$ radicals are relatively stable with respect to decomposition and react with the acids at the O–H bond, leading to the formation of $CH_3C(=O)O\cdot$ and $CF_3C(=O)O\cdot$ radicals, which subsequently decompose readily. The final gaseous products were methane and trifluoromethane respectively. Energetically, however, the reaction of the benzoyl radical at the O–H bond in the acid is much less favourable than the reaction at the C–H bond. This anomalous behaviour of the benzoyl radical is due to the characteristic features of its structure, namely its ability to form a hydrogen bond with the hydroxyl hydrogen. This hydrogen bonding precedes the formation of the activated complex and facilitates the reaction.

Analogous effects were observed by Berezin and coworkers[17,18] in a study of the oxidative decarboxylation of acids. In these studies the rate of the reaction of peroxide radicals at the O–H bond in acids was found to be greater by a factor of 13 than the rate of their reaction at the C–H bonds, although energetically the first reaction is less favourable (by almost 12 kcal), so that its rate should have been less than that of the second reaction by a factor of almost 50. Here also, the unusual behaviour of the peroxide radical is apparently due to hydrogen bonding.

Although there are very few papers on the kinetic manifestation of hydrogen bonding involving radicals, there is no doubt that radicals take part in such bonding. Proof for this is provided by the large number of papers on the study of the EPR spectra of radicals in various solvents. It has been shown that the relaxation time and hyperfine splitting in the EPR spectra of radicals depends to a marked extent on the nature of the medium in which the radicals are found[48-52]. This effect is naturally due entirely to the properties of the medium and is regarded by a number of authors[52,54] as a solvation effect. Solvation alters the properties of the unpaired electron, its state, the distribution of its spin density, and hence the reactivity of the radical.

A simple model has been proposed[53] for the solvation of radicals. It was suggested that the changes in the splittings in the spectrum are due entirely to the redistribution of the π-electron spin density of the unpaired electron, and

that this density is influenced by the ligand which is solvating the radical and altering the electronegativity of the atom to which it is attached. Calculations by the molecular orbital method with allowance for the corresponding changes in the Coulomb integrals give the correct sign and magnitude for the observed effects.

Analysis of the EPR spectra of the nitrogen of the stable 2,2,6,6-tetramethylpiperidine *N*-oxide radical[55] showed that in solvating solvents (alcohol, water, or glycerol) the spin density of the unpaired π-electron on the nitrogen atom in the $>\dot{N}-O$ fragment increases by 3–4% relative to its value for inert solvents.

A detailed study of hydrogen bonding with the participation of an unpaired electron was made[56,57] for the example of aliphatic *N*-oxide radicals. It was shown that the changes in the EPR spectra are not related to the dielectric properties of the medium as a whole, but are due chiefly to hydrogen bonding. There is an increase in the constant for the isotropic splitting on the nitrogen as a result of the increase in spin density and possibly a change in bond hybridisation, leading to an increase in the proportion of the *s*-state in the wave function of the unpaired electron. There is a simultaneous decrease in the *g*-factor, the change showing a fairly good correlation with the displacement of the $n-\pi^*$ absorption band of the radical towards shorter wavelengths[58]. Thus the participation of the unpaired electron in hydrogen bonding leads to a significant change in its electronic state.

The same papers[56,57] describe a study of the dynamics of the equilibrium for the solvation of radicals according to the scheme: $R_0 + nS \overset{K}{\rightleftarrows} R_S$, where R_0 and R_S represent respectively "free" radicals and radicals solvated by molecules of the solvent S. The frequency of hydrogen bond formation and rupture was found to be much greater than the difference in the constants for the isotropic hyperfine interaction for the free and solvated radicals, that is the characteristic time required for equilibrium to be established is much less than 2×10^{-7} s. The value of the coordination number *n* for water is equal to unity, and the energies of the hydrogen bonds involving participation of the unpaired electron in the *N*-oxide radicals amount to 4 ± 2 kcal mole^{-1} on the average and do not differ greatly from the energies of ordinary hydrogen bonds. This apparently means that although the state of the unpaired electron in the hydrogen bond does indeed change, the main contribution to the bond energy is made by the donor–acceptor interaction of all the remaining electrons.

Hydrogen bonds involving other radicals, including intra-radical hydrogen bonds, have also been studied[57]. In none of these cases was it possible to obtain hyperfine splitting on the hydrogen atom taking part in hydrogen bonding, because of the short relaxation time for the solvation equilibrium. For strong hydrogen bonds, however, for example in the anion-radicals of naphthazarin and quinizarin[59] this splitting was apparently obtained. Further evidence of this was also provided by data on the scalar paramagnetic relaxation in NMR[60,61], associated with the appearance of an unpaired electron on the hydrogen atom in the hydrogen bridge; the constants for the hyperfine interaction on this hydrogen atom are about 10^4–10^6 s^{-1}. An interesting feature is that the paramagnetic oxygen molecule (triplet ground state) is also solvated by solvent molecules[62].

From the kinetic viewpoint, the formation of a hydrogen bond between the radical and the molecule with which it subsequently reacts may have two effects. Firstly, the formation of this complex may lead to an increase in the entropy of activation of the reaction, since the original state becomes a complex which subsequently undergoes monomolecular decomposition:

$$\dot{R} + HA \rightleftarrows \dot{R}\cdots H-A \rightarrow RH + \dot{A}.$$

Secondly, the participation of the unpaired electron in hydrogen bonding may lead to electronic perturbation of the reacting A–H bond in the complex $\dot{R}\ldots H-A$. Since the unpaired electron is delocalised over the A–H molecule, this complex as a whole can be regarded as a radical; it is possible that exchange or magnetic interactions play an important part in the complex. The idea of these interactions was put forward by McConnell[63] to explain the paramagnetic catalysis of polymerisation and *cis–trans* isomerisation. Berlin and Blyumenfel'd[64] developed this idea to explain the effects of "local activation". These ideas can also apparently be used in radical reactions. Here the reactivity of various radicals and molecules can be explained in terms of exchange interactions in the activated complex, the charge and spin densities at the reactive centre of the radical, etc. At least the kinetic manifestation of hydrogen bonding between radicals and reacting molecules can be readily explained on the basis of these ideas.

3. π-COMPLEXES IN RADICAL REACTIONS

In addition to the influence of hydrogen bonds, another characteristic feature of liquid-phase radical reactions is the influence of the aromaticity of the medium. This has been noted in many papers and is usually attributed to π-complex formation by the molecules and radicals.

According to Mulliken's classification[65], π-complexes are one of the forms of donor–acceptor complexes, in which the donors and acceptors are molecules with labile π-electron clouds (they are also called charge-transfer complexes — CTC). The main interaction in these complexes is between the filled electronic orbitals of the donor and the vacant orbitals of the acceptor.

π-Complexes have now been fairly well studied by physical methods. Electronic transitions between the filled orbitals of the donor and the vacant orbitals of the acceptor in the complex lead to the appearance of new absorption bands in the ultraviolet and visible range, so that spectrophotometry is most widely used to study the structure and properties of these complexes. Not only molecular complexes, but also complexes involving atoms[66–68] and radicals[69–71] have been studied.

The formation of π-complexes, leading to partial transfer of charge within the complex, should alter the electronic structure of the species and their reactivity. This effect should be shown particularly clearly in the kinetics of liquid-phase reactions, in view of the characteristic features of the liquid state.

There are extremely few papers devoted to the kinetic manifestation of π-complexes. We shall examine first π-complex formation by molecules taking part in reactions.

Alder and Leffler[72] observed that the aromaticity of the medium has a marked influence on the decomposition of phenylazotriphenylmethane. The values of the enthalpy and entropy of activation in various solvents were determined with high accuracy and it was shown that there is a linear relationship between them, that is a compensation effect is

observed. Aromatic solvents yield higher values for the enthalpy of activation and higher entropies, the increase in enthalpy on going from cyclohexane to aromatic solvents corresponding approximately to the heats of solvation of the molecules. This suggests that the activation of the decomposition requires preliminary desolvation. Evidence supporting this hypothesis was found by the authors[72] in the parallelism in the changes in the entropies of activation and entropies of fusion of the solvents. If we regard the breakdown of the π-complexes (desolvation) as fusion of the solvate sheath, this parallelism is readily understood. Thus the decomposition of the phenylazotriphenylmethane molecules to form radicals apparently involves consecutive desolvation and decomposition, but the participation of solvates in decomposition is not excluded.

A similar influence of the aromaticity of the medium was also observed in the decomposition of symmetrical diphenylazoethane and bisazomethylpropionitrile[73]. Ziegler did not observe these effects, however, for the decomposition of hexaphenylethane. This is apparently due to steric hindrance and the inability of the phenyl rings of hexaphenylethane to form π-complexes.

Let us now consider π-complex formation by atoms and radicals. Their ability to take part in π-complex formation with a donor is determined by their electrophilic nature (electron affinity) (see Table 2).

The problem of π-complexes involving an $R\dot{O}_2$ radical with a fairly high electron affinity has been very widely discussed for a long time. This discussion was begun in a paper by Boozer and Hammond[74] who put forward a mechanism for the inhibition of oxidation involving a π-complex of the peroxide radical:

$$R\dot{O}_2 + InH \rightleftarrows [RO_2^{\cdot}\cdots InH]$$
$$R\dot{O}_2\cdots InH] + R\dot{O}_2 \rightarrow ROOH + RO_2In.$$

This scheme was subsequently confirmed by Thomas[75] and Denisov[13]. Denisov made a detailed analysis of the conditions under which this mechanism should be revealed kinetically, and showed the limits of its influence.

Zaikov and coworkers[45], Ingold[76], and Russell[39], however, found that the dependence of the rate of oxidation on the dielectric constant of the medium obeys satisfactorily the Kirkwood–Onsager relationship, and no anomalies were observed for the rate of oxidation in aromatic media. Another extremely contradictory paper was published by Thomas[77], in which it was concluded that the $R\dot{O}_2$ radical forms a complex with trialkylamines. Direct experiments using the EPR method to detect π-complexes of the cumene peroxide radicals with a strong donor such as the pyridine molecule did not give positive results: the equilibrium for π-complex formation is displaced considerably towards the free radical[78], whereas even for the iodine molecule (electron affinity only 54.6 kcal mole^{-1}) the complexes with pyridine are extremely stable.

TABLE 2. Electron affinity of various radicals (kcal mole^{-1}).

Radical	Electron affinity	Radical	Electron affinity
$\dot{Cl}$	88.2	$\dot{O}H$	50
$\dot{F}$	83.5	$\dot{C}Rh_3$	48
$\dot{Br}$	81.6	$Ph\dot{O}$	27
$\dot{I}$	74.6	$\dot{C}H_3$	25
$H\dot{O}_2$	70		

Physically, it is extremely difficult to suppose that in the complex $[R\dot{O}_2\ldots InH]$ the interaction involves only π–π interaction and not hydrogen bonding. It might be possible to agree that a π-complex exists if it is assumed that the hydrogen bond between the peroxide radical and the inhibitor molecule InH is fairly weak, but there are as yet no serious grounds for this, rather the reverse: such bonds should be stable[36,37]. Thus at present it is fairly difficult to reach an unambiguous conclusion regarding the existence of π-complexes of $R\dot{O}_2$ with aromatic molecules.

All reactions involving the addition of atoms and radicals to aromatic systems with the formation of σ-complexes do of course involve the formation of intermediate π-complexes. This is apparently the case for the "attachment" of H atoms and $\dot{C}H_3$ radicals to aromatic molecules[79], phenylation[80], hydroxylation[81], and the reactions of peroxide radicals[82]. It is not always possible, however, to detect the intermediate π-complexes as kinetically independent species; this is determined chiefly by the competing reactions of decomposition of the π-complex and its conversion into the σ-complex.

π-Complex formation by the chlorine atom in the chain photochlorination of hydrocarbons has been studied in most detail by Russell[83–85]. In the chlorination of 2,3-dimethylbutane, isobutane, and other branched hydrocarbons the chlorine atom attacks the tertiary C–H bond only four times more readily than the primary bond. In the presence of aromatic solvents this rate ratio increases to 50–300, that is, tremendous selectivity is observed in the reactions of atomic chlorine. The dielectric properties of the medium are of almost no significance, and the order of selectivity (with respect to solvents) shows good correlation with the order of the basic strength of these solvents. This behaviour of the atoms cannot be attributed to the reactions of "hot" atoms and their "cooling" in the aromatic solvents, since the chlorination chains are fairly long, and almost no difference is observed in the rate constants for the gaseous and liquid phases. The most natural assumption is that the $\dot{Cl}$ atom forms a π-complex with the aromatic molecule and that this complex is much less reactive and hence more selective than the free atom. Analogous effects were observed by Russell[86] in the photochlorination of arylalkyl hydrocarbons.

To explain the regular kinetic features of photochlorination, Russell put forward a scheme involving the reaction of the free $\dot{Cl}$ atom and its π-complexes with coordination numbers x equal to one and two, and also π-complex formation equilibria between the $\dot{Cl}$ atoms and one or two aromatic molecules. This scheme does not show sufficiently good agreement with the experimental data[85]. Moreover, it is found that the heat of formation of the complex with x = = 2 is almost 4 times that for the complex with x = 1, which is physically unlikely. Despite the unsatisfactory kinetic analysis, however, there is no doubt that the π-complex is in fact formed and that its selectivity is high.

Berezin and coworkers[87] found that the aromaticity of the medium has a marked influence on hydrogen atom abstraction by the methyl radical from toluene and cyclohexane. The ratio of the rate constants for hydrogen atom abstraction from the aromatic molecule and from cyclohexane decreases sharply with increase in the concentration of benzene or toluene in the mixtures with cyclohexane. This effect at first sight reproduces qualitatively the results obtained by Russell, but it is much more difficult to interpret, since studies were made of the ratio of constants, each of which may depend in different ways on the aromaticity of the medium.

The lack of reactivity in the π-complexes of the t-butoxyl radical in reactions involving the removal of a hydrogen atom can apparently be attributed to the decrease in the ratio k_{subst}/k_{decomp} [see Eqns. (7) and (8)] in aromatic solvents[88-91].

Kinetic data on the influence of aromatic molecules on the rate of recombination of iodine atoms in the gaseous phase were examined by Porter and Smith[92] in terms of complexes with charge transfer between the iodine atoms and the aromatic molecules; the energies of these complexes amount to 1.7–2.4 kcal mole^{-1}. The formation of π-complexes between iodine atoms and hexamethylbenzene in the liquid phase in carbon tetrachloride has been proved spectrophotometrically and kinetically[93]; the equilibrium constant for π-complex formation at room temperature is 2.7 litre mole^{-1}.

A detailed study has been made of the π-complexes of stable aromatic N-oxide radicals and their kinetic manifestation in the removal of a hydrogen atom from 2,6-di-t-butylphenol, which is incapable of undergoing solvation[94]. It was first shown that the rate constants for the reaction of the diphenylnitrogen oxide radical with 2,6-di-t-butylphenol are much smaller in benzene and ethylbenzene than in heptane, the activation energies and pre-exponential terms increasing in the aromatic solvents. Analogous relationships were also observed for substituted diphenylnitrogen oxide radicals.

The kinetic scheme for the reaction of free nitrogen oxide radicals R_0 and their π-complexes R_S with 2,6-di-t-butylphenol PhOH can be represented in general form as follows:

$$\begin{gathered}\dot{R}_0 + PhOH \xrightarrow{k_0} RH + Ph\dot{O} \\ \dot{R}_S + PhOH \xrightarrow{k_S} RH + Ph\dot{O} \\ \dot{R}_0 + nS \underset{}{\overset{K}{\rightleftharpoons}} \dot{R}_S\end{gathered} \qquad (9)$$

where n, the coordination number of the π-complex, shows how many molecules of the solvent S must solvate the radical in order to produce a significant change in its reactivity. The scheme assumes reaction by the free radical and the π-complex, and also π-complex formation equilibrium. Analysis of scheme (9) leads to expression (I) for the effective rate constant k_{eff} for disappearance of the radicals. In an experimental investigation of the dependence of k_{eff} on [S], a study was made of the rate of disappearance of radicals in solvent mixtures, namely in benzene diluted with heptane[94]. The kinetic analysis is here similar to the analysis carried out for hydrogen bonding (see p. 194).

Fig. 3 shows the dependence of k_{eff} on [S] and its transformation into an equation similar to Eqn. (III) for the reaction of dianisylnitrogen oxide with 2,6-di-t-butylphenol at 60°; the value of n obtained from the slope of the straight line is equal to unity. Similar relationships were obtained for various temperatures. The equilibrium constant for π-complex formation by dianisylnitrogen oxide with benzene has the form

$$K = 3.3 \times 10^{-26} \exp(6400 \pm 2000/RT)\ cm^3. \qquad (10)$$

The numerical values of K obtained by the kinetic method show good agreement with the values of K obtained spectrophotometrically[95]; the energy of the bond in the π-complex, determined kinetically, coincides with the bond energy found independently from thermochemical data[96]. This confirms that the kinetic scheme (9) is correct.

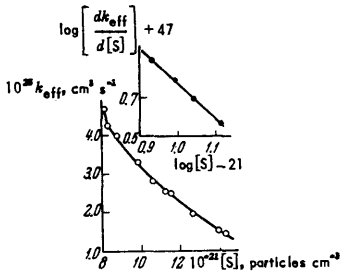


Fig. 3. Dependence of k_{eff} on the concentration of benzene in heptane and its logarithmic transform [according to Eqn. (III)] for the reaction of dianisylnitrogen oxide with di-t-butylphenol.[94]

It is extremely significant that the values of k_S are smaller by an order of magnitude than the values of k_0, that is the π-complex is much less reactive than the free radical; for kinetics, the association of the radical with only one solvent molecule (n = 1) is significant. Further association and further growth of the solvate sheath have no significance, apparently because the first solvating molecule produces the greatest perturbation in the electronic structure of the radical.

The removal of a hydrogen atom from ethylbenzene by various stable N-oxide radicals has been studied[97]. For the reaction of dianisylnitrogen oxide with ethylbenzene, the rate constant increases when the ethylbenzene is diluted with n-decane. This means that the π-complex of the radical with ethylbenzene has a low activity, and no reaction takes place within the complex. This confirms the analogous conclusion reached by Russell[83] for the Cl atom in a π-complex.

The low reactivity of the π-complex is not a general feature. It has been shown[94] that the π-complexes of dianisylnitrogen oxide with pyridine and its derivatives have a high reactivity and react with a smaller activation energy than the free radical. This effect is not due to the influence of the dielectric constant of the medium, since in dichloroethane, whose dielectric constant ϵ is close to that of pyridine, the rate constants and activation energies are almost the same as those in heptane. Thus the reactivity of the π-complex may depend on whether the radical behaves as a donor or an acceptor in the complex.

The problem of whether electron transfer in the π-complex of the radical involves the unpaired electron or includes other lower-lying electrons is of particular interest. Direct measurements, by the NMR method, of the constants for the hyperfine splitting due to delocalisation of the unpaired electron on the molecules of the medium solvating the radical showed that if such delocalisation does in fact take place, it is extremely slight[99]. Studies of the dynamic nuclear polarisation on a number of radicals in aromatic solvents also showed that the degree of delocalisation of the unpaired electron on the ligand in the π-complex is extremely slight[100-102]. There is apparently only slight transfer of charge in the π-complex. The kinetic effects produced by this transfer are fairly large, however.

A compensation effect was observed[97] in the removal of a hydrogen atom from ethylbenzene by aromatic N-oxide radicals. The fact that the radicals for which this effect was observed have extremely similar structures makes it

impossible to attribute the effect to structural differences in the radicals. The origin of the compensation effect must therefore be sought not in the reactivity of the radicals themselves, but in their specific interactions with the medium.

It is apparently a general feature that the compensation effect in liquid-phase radical reactions is usually not observed when the reaction is in fact an elementary reaction. When the reaction is complicated by specific interactions between the reacting species and the solvent molecules (hydrogen bonding, π-complexes), the compensation effect is usually observed. It can be shown that the compensation effect is to be expected when the measured kinetic constants are made up of the rate constants for a number of elementary acts[98].

4. POLAR FACTORS AND SPECIFIC INTERACTIONS IN RADICAL LIQUID-PHASE REACTIONS

As noted above, contradictory experimental facts have been published on the kinetic manifestation of polar factors associated with electrostatic dipole–dipole interactions between the reacting species.

It has been shown in a whole series of papers that the dielectric constant of the solvent has a marked influence on the rate of the radical reactions involved in the oxidation of ethanol and methyl ethyl ketone[45,46,103,104], and alkenes and arylalkyl hydrocarbons[39,76,105], and also the rate of decomposition of t-butyl peroxyformate[106]. In all these examples, the dependence of the reaction rate on the dielectric constant obeys the Kirkwood–Onsager relationship and indicates that the dipolar character of the transition state in these reactions is greater than the dipolar character of the initial reagents.

The dielectric constant of the solvent has absolutely no influence, however, on the rates of the reactions of chlorine atoms with hydrocarbons[85], or of phenoxyl and N-oxide radicals with phenols[24,94], or on the rate of the copolymerisation of styrene with methyl methacrylate or of α-methylstyrene with maleic anhydride[107,108], where it would seem that the strongest polar effects should be revealed. In these examples, as shown above, an important part is played by specific localised interations of the donor–acceptor type.

The latter influence chiefly the initial state of the system, whereas the polar factors exert their chief influence on the activated complex of the reaction. The greater or lesser part played by the polar factors is apparently determined by the electronic structure of the activated complex. The course of the radical reaction $\dot{R} + HX \rightarrow RH + \dot{X}$ can in fact be represented by two schemes:

$$\dot{R} + HX \begin{cases} \xrightarrow{(1)} [\dot{R}\cdots H\cdots X] \rightarrow RH + \dot{X} \\ \xrightarrow{(2)} [R^{(-)}\overset{(+)}{H}X] \rightarrow R^- + H^+ + \dot{X} \rightarrow RH + \dot{X}. \end{cases}$$

Route (1) involves the slow movement of a proton from X to R in the potential field created by rapid electronic motion. Route (2) assumes the transfer of charge from HX to R with the formation of R^- and the cation-radical $\dot{HX}$, which subsequently decomposes to a proton and the radical $\dot{X}$. This reaction path assumes that the charges in the activated complex are separated in time and space; a consequence of this separation is the polarisation of the activated complex and the dependence of the rate on the dielectric constant. The fundamental difference between these routes is that in one case the limiting stage involves the movements of nuclei whereas in the other case electron transfer takes place. Route (2) naturally does not require complete transfer of the electron in the activated complex; only partial transfer, with partial charge separation in the complex, is sufficient.

The realisation of a given form of activated complex depends on the polarity of the medium, which either facilitates the separation of charges or hinders it, and also on the properties of the reacting species — the ionisation potential of the molecule HX and the electron affinity of the radical $\dot{R}$.

This interpretation of the form of the activated complex enables us to look for the possibility of acid–base catalysis of radical reactions. It has in fact been possible to observe examples of both base catalysis (the decomposition of t-butyl peroxyformate in the presence of pyridine)[106] and acid catalysis[109].

Thus the relative part played by polar factors and specific interactions is determined by the form of the activated complex, and its electronic structure.

In conclusion it should be noted that the study of specific localised interactions and polar factors and the part which they play in the kinetics of radical liquid-phase reactions is enriching considerably our knowledge of electronic interactions in the activated complex. The need for further intensive studies in this direction and their undoubted success are obvious.

THE CHEMISTRY OF HOT HYDROGEN ATOMS WITH 1-3 eV ENERGY AND OF EXCITED RADICALS

A. P. Shvedchikov

CONTENTS

I. Introduction 202
II. Formation of hot hydrogen atoms during photolysis of HI and HBr, and their reactions 202
III. Formation and reactions of excited radicals obtained by photolysis of alkyl halides and other compounds 204
IV. Formation of vibrationally excited alkyl radicals by the addition of atomic hydrogen to alkenes 205
V. Reactions between hot H* atoms obtained by photolysis of HI and ethylene 205

I. INTRODUCTION

Many investigations [1-10] of the chemistry of hot tritium atoms produced by the nuclear reactions $^6Li(n,\alpha)T$ and $^3He(n,p)T$ (recoil energy of the T atoms 2.7 and 0.2 MeV respectively) have shown that these atoms can efficiently take part in chemical reactions when slowed down to energies comparable to those of chemical interaction: in particular, they can take part in transfer and substitution reactions proceeding without activation energy

$$T^* + RH \rightarrow HT + R^\cdot \quad (1)$$
$$T^* + RH \rightarrow RT + H \quad (2)$$

For thermal hydrogen atoms the activation energy of reaction (1) is 9-12 kcal mole^{-1}; reaction (2) is not known to occur with thermal H atoms.

Hot T atoms can add on to the double bond of alkenes, giving excited radicals [6,10], and they can also replace individual atoms or even groups of atoms in complicated molecules [1,7]: when this happens the intermediate products can be used in an excited state, and the decomposition mechanisms will be determined by a number of factors (degree of excitation, efficiency of transfer of the excitation energy, etc. [7,8]).

It should be noted that the formation of fast atoms and of excited molecules and radicals is not confined to processes accompanying nuclear transmutations, but it occurs also in radiolysis, photolysis, and even in thermal reactions at high temperatures.

To explain various anomalies in the behaviour of atoms and radicals, many workers in the field of kinetics have put forward the concept of an abnormally high reactivity for the hot hydrogen atoms and radicals obtained in the radiolysis of hydrocarbons and in the photolytic decomposition of excited molecules.

The majority of workers believe that the primary act in the radiolysis of hydrocarbons is fissure of the C-H bond.

The energy excess $E_{excit} - D_{C-H}$ (where D is the dissociation energy of the C-H bond) apportions itself between R and H in inverse proportion to the masses, and is carried away mainly in the form of kinetic energy by the H atom [11].

Hot H* atoms with a kinetic energy of the order of several electron-volts are reactive at low temperatures as well as at ordinary temperatures [12-14]. Armstrong [14] has demonstrated experimentally the existence of hot hydrogen atoms in his study of the low-temperature radiolysis of HCl at -78° and -196°. These atoms are produced by the decomposition of an excited HCl* molecule ($HCl^+ + e \rightarrow HCl^* \rightarrow H^* + Cl$). Radiation yields G of 4.0 and 2.4 respectively were measured for the formation of hot and of thermal H atoms.

The concept of hot H* atoms has been invoked many times in work on the liquid-phase and gas-phase radiolysis of hydrocarbons [15-17]. Reactions between highly excited H* atoms and C_2H_4 molecules have also been detected mass-spectrometrically [18].

However, a quantitative interpretation of reaction schemes involving hot atoms during radiolysis presents serious difficulties, because of the presence of various competing reactions, of the unknown energy spectrum of the hot atoms, etc.

The most convenient route for the preparation of H* atoms is through photochemical reactions, in particular the photodissociation of the hydrogen halides HI and HBr.

II. FORMATION OF HOT HYDROGEN ATOMS DURING PHOTOLYSIS OF HI AND HBr, AND THEIR REACTIONS

Kondrat'ev and coworkers had shown [19], as long ago as in 1934, that the reactivity of H atoms obtained by the photolysis of HI is essentially dependent on their kinetic energy.

Hydrogen iodide has a continuous absorption spectrum in the ultraviolet region, beginning at 3850 Å. [20,21] The maximum extinction coefficient ϵ lies in the region of 2500 Å, and has a value of $\sim 2 \times 10^{-19}$ cm^2 per molecule [20]. Since ϵ_{HI} is high in the region of 2500 Å, and most of the radiation with λ = 2537 Å is absorbed in the first centimeter of optical path at atmospheric pressure, the experiments are usually made at lower HI pressures (~ 10-30 mmHg).

The most commonly used sources of ultraviolet radiation are low-pressure cadmium or mercury resonance lamps of type Hanovia SC 2537 (or lamps type PRK-2 or PKR-4, made in the Soviet Union). For experiments at λ = 1849 Å these lamps are fitted with a Suprasil window [22,23], and with a filter of lithium fluoride irradiated with X-rays or γ-rays,

which transmits ~ 50% of the light with λ = 1849 Å but almost completely suppresses the light of wavelength λ = 2537 Å.

The H* atoms formed in the photolytic decomposition of HI* have a kinetic energy of

$$E_{H^*} = [E_{h\nu} - D_{HI} - E_{I^*}] \times \frac{127}{128} \quad (I)$$

where $E_{h\nu}$ is the energy of the impinging quantum, D_{HI} the dissociation energy of HI, equal to 71 kcal mole^{-1}, and E_{I^*} the electronic excitation energy of an iodine atom to the $I^2P_{1/2}$ state, equal[24] to 21.8 kcal mole^{-1}. Thus, for λ = 3130, 2537, and 1849 Å the energy of hot H* atoms is 20, 41, and 82 kcal mole^{-1} respectively (0.9, 1.8, and 3.6 eV) if the I atom is in the $I^2P_{3/2}$ ground state.

During photolysis of HBr the spectrum of the first formed H* atoms lies in a narrower range of energies, because the first excited state of the bromine atom is 0.4 eV above the ground state[22,24]. In the photolysis of HBr the energy of tne H* atoms is lower than in the photolysis of HI (since the mass of Br is smaller than that of I), and hence the spectrum of H* atoms is narrower and lies in the range 2.5–2.9 eV at λ = 1849 Å. The use of HBr for the production of H* atoms with ~ 3 eV energy also has some other advantages as compared with HI: 1) HBr absorbs weakly in the region of λ = 2537 Å, so that photolysis can be carried out without a filter; 2) the extinction coefficient of Br_2 at λ = 1849 Å is considerably lower than that of I_2; 3) HBr is chemically more stable than HI.

The quantum yield of hydrogen, Φ_{H_2}, during photolysis of HI in the region of λ ≃ 2500 Å is unity, and is independent of temperature between -78° [23] and 190°.[25] The temperature independence of Φ_{H_2} can be explained by a reaction scheme involving hot H* atoms:

$$HI \xrightarrow{h\nu} H^* + I(^2P_{1/2} \text{ or } {}^2P_{3/2}) \quad (3)$$
$$H^* + HI \rightarrow H_2 + I \quad (4)$$
$$H^* + I_2 \rightarrow HI + I \quad (5)$$
$$I + I + M \rightarrow I_2 + M. \quad (6)$$

Chain branching does not take place, because the reaction

$$I + HI \rightarrow I_2 + H \quad (7)$$

is endothermic by 35 kcal mole^{-1}. It has been shown[26] that even $I^2P_{1/2}$ atoms hardly ever undergo transfer reactions of the type (7). The steady-state rate of formation of H_2 and I_2 is

$$\frac{d(H_2)}{dt} = \frac{d(I_2)}{dt} = \frac{I_a}{1 + \frac{k_5}{k_4}\frac{(I_2)}{(HI)}} \quad (II)$$

where I_a is the number of photons absorbed in 1 sec. At low extents of reaction, when the ratio I_2/HI can be treated as constant, the quantum yield of hydrogen Φ_{H_2} is

$$\Phi_{H_2} = \frac{(H_2)_{fin} - (H_2)_{init}}{\int_0^t I_a\,dt} \simeq \frac{1}{1 + \frac{k_5}{k_4}\frac{(I_2)}{(HI)}}. \quad (III)$$

It is evident from Eqn. (III) that $1/\Phi_{H_2}$ is a linear function of the ratio I_2/HI, whose slope gives the ratio k_5/k_4. Schwarz and coworkers[27] examined the photolysis of HI at λ = 2537 Å and found that the ratio k_5/k_4 is 3.8 and does not vary with temperature. Addition of inert moderators (Ne, Ar, He, etc.) results[25] in a decrease of k_4/k_5 from 0.25 to 0.014, and an activation energy $E_4 - E_5 = 4.5 \pm 0.8$ kcal mole^{-1} appears[27].

These results on the effect of temperature and of added inert moderators are difficult to explain in terms of classical kinetics unless the concept of hot atoms is adopted. Thus, the temperature independence of Φ_{H_2} is readily explained if the enhanced reactivity of hot H* atoms is ascribed to the excess kinetic energy of these atoms, which is higher than or equal to the threshold energy required for any particular reaction. The addition of inert moderators to the system causes thermalisation of the hot H* atoms. If we assume that inhibition involves an elastic collision mechanism, the average energy loss per collision, $\Delta\overline{E}/E$, is

$$\frac{\Delta\overline{E}}{E} = \frac{2m_1m_2}{(m_1+m_2)^2} \quad (IV)$$

where m_1 and m_2 are the masses of the colliding atoms. $\Delta\overline{E}/E$ reaches a maximum for $m_1 = m_2$, and therefore He is a more efficient moderator than Ar. The slowing down of H* on HI molecules is a slow process. If He is added, however, the slowing down of H* atoms becomes fast, the probability of reaction (4) decreases, and the ratio k_4/k_5 also decreases. Further experimental confirmation of the reactions of hot H* atoms formed in the photolysis of HI and HBr can be found in the papers of Martin and Willard[22,23] and by Carter and coworkers[28] on the photolysis of HI–RH and HBr–RH mixtures and of their deuterated derivatives at λ = 2537 and 1849 Å, where RH = H_2, CH_4, C_2H_6, C_5H_{12}.

In this case, in addition to reactions (3)–(6), the following reactions occur:

$$D^* + DI \rightarrow D_2 + I \quad (8)$$
$$D^* + RH \rightarrow HD + R^\cdot \quad (9)$$
$$D^* + DI \rightarrow D + DI \quad (10)$$
$$D^* + RH \rightarrow D + RH \quad (11)$$
$$D^* + M \rightarrow D + M \quad (12)$$
$$D + DI \rightarrow D_2 + I \quad (13)$$
$$D + RH \rightarrow HD + R^\cdot \quad (14)$$
$$R + DI \rightarrow RD + I \quad (15)$$

where D* is a hot deuterium atom and D is a slowed deuterium atom. Since the activation energy of (14) is large (~ 7–12 kcal mole^{-1} for thermal hydrogen atoms), it may be assumed that at high concentrations of RH the formation of HD occurs mainly by reaction (9). Then

$$\frac{D_2}{HD} = \frac{k_8}{k_9}\frac{[DI]}{[RH]} + \frac{k_{11}}{k_9} + \frac{k_{12}}{k_9}\frac{[M]}{[RH]} \quad (V)$$

and in the absence of the moderator M we have the linear relationship

$$\frac{D_2}{HD} = \frac{k_8}{k_9}\frac{[DI]}{[RH]} + \frac{k_{11}}{k_9}. \quad (VI)$$

The intercept on the y-axis of the plot of D_2/HD against DI/RH corresponds to k_{11}/k_9, and the slope corresponds to k_8/k_9.

From the slope and the intercept we can, with appropriate assumptions, evaluate the mean probability of reaction per collision in the hot region and the mean energy loss per collision with a hydrocarbon molecule during the thermalisation. Table 1 gives the results of Carter and coworkers[28] and of Martin and Willard[22] for k_8/k_9 and k_{11}/k_9 in the photolysis of DI–RH and HBr(DBr)–RH(RD) mixtures, and also the mean reaction probabilities per collision and the mean energy losses per collision.

The increase of the D_2/HD ratio with increase of wavelength λ, or with addition of an inert moderator, as well as the lack of temperature dependence, is evidence that hot H* atom reactions occur during photolysis of HI.

TABLE 1. Efficiency of slowing down and probability of hot reactions in the DI–RH and HBr(DBr)–RH(RD) systems.[22,27]

λ, Å	System	Fraction of atoms slowed down	Fraction of atoms reacting with hot atoms	k_0/k_0	k_{11}/k_0	Average reaction probability per collision		Average loss of energy per collision		Reference
						P_s	P_0	f_{tot}	$f_{elastic}$	
2537	DI–H_2	0.58	0.42	5.64	1.40					
	DI–C_2H_6	0 81	0.19	6.40	4.33					27
	DI–CH_4	0.94	0.057	24.3	16 7					
	DI–C_5H_{12}	—	—	4.65	4.80					
1849	HBr–D_2	0.39	0.61	2.04	0.65	0.26	0.17	0.32	0.32	22
	HBr–CD_4	0.94	0.062	81	15		0.0031	0.07	0.091	
	HBr–C_2D_6	0.86	0.14	11.8	6.1		0.018	0.19	0.052	
	DBr–H_2	0.38	0.62	1.54	0.60	0.41	0.35	0.50	0.50	
	DBr–CH_4	0.83	0.17	6.40	5.0		0.002	0.42	0.20	22
	DBr–C_2H_6	0.69	0.31	2.25	2.2		0.14	0.51	0.12	

As the kinetic energy of the H* atom increases, the role of "hot" reactions becomes more important. Thus, in the case of CH_4 and C_2H_6, the fraction of "hot" reactions by hydrogen atoms increases from 6 to 17 and from 19 to 31% respectively as the energy of the H* atoms is raised from 0.9–1.8 eV (λ = 2437 Å) to 2.5–2.9 eV (λ = 1849 Å). The ratio k_1/k_2 for hot T* atoms of energy ~ 3 eV is 3.5–4, as shown[9] by a study of the photolysis of TBr (λ = 1849 Å) mixed with CH_4 and C_2H_6. With tritium recoil atoms having an initial energy of 0.2 MeV, the "hot" reactions (1) and (2) account for 50–70% of the total amount of tritium atoms consumed[1–10].

Hot H* atoms obtained by the photolytic decomposition of HI have an enhanced reactivity, since they can bring about replacement reactions not only at room temperature (in the gas[19,23,28] and in the liquid phase[29,31]) but also, in the solid phase, at temperatures of -78°[22,31] and -196°,[30] as shown for the low-temperature photolysis of HI (0.01–0.1 mole %) in a matrix of 3-methylpentane. The quantum yield Φ_{H^*} is 0.2 in the liquid phase at 298°K and in the solid phase at 123°K; $\Phi_{H_{thermal}}$ = 0.8 at 298°K, falling to 0.2 at 77°K.

With thermal H atoms, low-temperature replacement reactions are effectively excluded by the large activation energy.

III. FORMATION AND REACTIONS OF EXCITED RADICALS OBTAINED BY PHOTOLYSIS OF ALKYL HALIDES AND OTHER COMPOUNDS

Radiolytic and photolytic processes can give rise not only to hot hydrogen atoms having an excess of kinetic energy, but also to "hot" vibrationally excited radicals whose reactivity increases markedly with the energy of the source of excitation.

The reactions of "hot" radicals obtained in the photolysis of alkyl iodides have been most fully investigated. Alkyl iodides have a continuous absorption spectrum in the region 2500–2600 Å. When an excited molecule of alkyl iodide decomposes, the energy excess $E_{h\nu} - D_{R-I}$ apportions itself among the residues in inverse proportion to their masses. For example, in the photolysis of CH_3I at λ = 2537 Å ($E_{h\nu}$ = 112 kcal mole^{-1}), $E_{h\nu} - D_{CH_3-I}$ equals 57 kcal mole^{-1} if I is in the $I^2P_{3/2}$ state and 35 kcal mole^{-1} if I is in the $I^2P_{1/2}$ state. Since the masses of CH_3 and I are very different, ~ 7/8 of this energy will be imparted to the CH_3 radical, and as a result the latter will become vibrationally excited.

Many papers[32–40] give experimental proof of the higher reactivity of vibrationally excited CH_3^* radicals as compared with thermal CH_3 radicals.

One usually considers the following scheme during photolysis of CH_3I:

$$CH_3I \xrightarrow{h\nu} CH_3^* + I \quad (16)$$

$$CH_3^* + CH_3I \longrightarrow CH_4 + CH_2I \quad (17)$$

$$CH_3^* + RH \longrightarrow CH_4 + R^\cdot \quad (18)$$

$$CH_3^* + CH_3I \longrightarrow C_2H_6 + I \quad (19)$$

$$CH_3^* + CH_3I \longrightarrow CH_3 + CH_3I \quad (20)$$

$$CH_3^* + M \longrightarrow CH_3 + M \quad (21)$$

and also the recombination reactions of thermal CH_3 and CH_2I radicals and I_2 addition reactions. It has been shown that the main reactions of the CH_3^* radical are the abstraction reactions (17) and (18), the rate of formation of CH_4 being unaffected by temperature over the range from -78° to 300°, whereas additions of inhibitors (I_2, O_2, NO) and of inert moderators (noble gases, N_2, CO_2) lower the rate of formation of CH_4.[36,38]

Reactions (17) and (18) are observed not only in the gaseous and in the liquid phase, but also in the solid phase at low temperatures. Formation of CH_4 has been reported at a temperature of 4°K in pure CH_3I,[39] at 77°K in hydrocarbon matrices[40,41], and at 20°K in solid inert matrices of Kr, Xe, and N_2 containing C_2H_6 and $(CH_3)_3CH$.[42] On changing from the liquid to the solid phase Φ_{CH_4} decreases by approximately a factor of 5–7, the decrease taking the form of a discontinuity at the phase transition point[40].

The decrease in Φ_{CH_4} on going over to the solid phase may be due to greater efficiency of the deactivation processes experienced by the CH_3^* radicals in the solid phase.

It is important to note that during solid-phase photolysis (77°K) of CH_3I and of solutions of CH_3I and CD_3I in methylcyclohexane, stabilisation of the CH_3^* radicals cannot occur to any significant extent[40,42]: only R· radicals formed by reactions (17) and (18) were detected by the ESR method.

On the other hand, partial stabilisation of the methyl radicals occurs in the photolysis of azomethane, since in this case the proportion of hot CH_3^* radicals (produced by the decomposition of the excited $CH_3-N=N-CH_3^*$ molecule) is not large.

The reactivity of CH_3^* increases with the excitation energy. Thus, Φ_{CH_4} values of 0.15×10^{-3}, 3.2×10^{-3}, and 30×10^{-3} have been reported[38] for the photolysis of CH_3I with light of λ = 3130, 2537, and 1849 Å respectively.

It is also found that the probability of the "hot" reaction (19) increases with the excitation energy, as shown by experiments on the influence of added inhibitors and inert moderators on the yield of C_2H_6.

The formation of "hot" $C_2H_5^*$ radicals during photolysis of C_2H_5I (λ = 2537 Å) in the liquid and in the solid phase was demonstrated by Luebbe and Willard[43] in spite of the much lower excitation energy of $C_2H_5^*$ as compared with CH_3^* (a consequence of the greater mass of the C_2H_5 radical).

"Hot" radicals appear also in various other photochemical processes. Thus, the flash photolysis of azo-

methane (λ = 3000–4000 Å) can give CH_3^* radicals in the primary act:

$$CH_3{-}N{=}N{-}CH_3^* \rightarrow N_2 + 2CH_3^* \quad (22)$$

followed by extraction of hydrogen from the neopentane present in the system as a second component:

$$CH_3^* + RH \rightarrow CH_4 + R^* \quad (23)$$
$$CH_3 + CH_3 \rightarrow C_2H_6. \quad (24)$$

The proportion of CH_3^* in this case is not large (~ 1% of the total number of CH_3 radicals formed), as shown by the low (~ 0.03) ratio of CH_4/C_2H_6.[40,43] When λ is increased from 3000 to 4000 Å this ratio decreases[43] by a further factor of 3–4. The lower yield of CH_3^* radicals in azomethane as compared with CH_3I is due to the fact that two bonds are broken when $CH_3{-}N{=}N{-}CH_3^*$ decomposes, and the energy excess is divided among at least three particles.

Several hot particles can form when the quantum energy of the incident light is increased. Thus, the photolysis of acetone in the vacuum ultraviolet region (λ = 1236 and 1470 Å) can result in the simultaneous production of CH_3^* radicals and hot hydrogen atoms[44]. The formation of hot acetyl radicals during the photolysis of ketones at λ = 2537 Å has been reported[45].

Several workers have shown[46,47] that the photolysis of diethyl ketone (λ = 2200–3100 Å) produces "hot" propionyl radicals $CH_3CH_2CO^*$ which subsequently decompose into C_2H_4, CO, and H. Hot halomethyl radicals produced in the photolysis of halomethanes also show enhanced reactivity towards displacement reactions[48].

The possibility of forming vibrationally excited radicals has been demonstrated, in the case of the photolysis of azoethane $(C_2H_5)_2N_2$, by changing from 3600 to 2300 Å.[49]

IV. FORMATION OF VIBRATIONALLY EXCITED ALKYL RADICALS BY THE ADDITION OF ATOMIC HYDROGEN TO ALKENES

"Hot" radicals can be obtained not only in photochemical processes and in radiolysis, but also in ordinary chemical reactions. The heat attending the addition of H atoms to C=C bonds is known to be ~ 40 kcal mole^{-1}. This reaction gives rise to vib.ationally excited alkyl radicals, which can decompose in the absence of stabilising collisions or extract hydrogen from RH, as was reported[50–52] for "hot" $C_3H_7^*$ radicals:

$$C_3H_7^* \rightarrow C_2H_4 + CH_3 \quad (25)$$
$$C_3H_7^* + H_2 \rightarrow C_3H_8 + H \quad (26)$$
$$C_3H_7^* + C_3H_6 \rightarrow C_3H_8 + C_3H_5^*. \quad (27)$$

The rate of decomposition of $C_3H_7^*$ depends on the structure of the radical: for n-$C_3H_7^*$ the rate of decomposition is 100–1000 times higher than for iso-$C_3H_7^*$. When H atoms add on to alkenes of higher molecular weight, the number of possible decomposition routes for the "hot" radicals increases. Thus, for $C_4H_9^*$ radicals two decomposition paths are possible[53]:

$$C_4H_9^* \rightarrow CH_3^* + C_3H_6 \quad (28)$$
$$C_4H_9^* \rightarrow C_2H_5^* + C_2H_4. \quad (29)$$

The decomposition constant of the $C_4H_9^*$ radical at 305°K is independent of pressure[54] over the range 0.036–115 atm.

A great deal of work has been done on the reactivity of vibrationally excited $C_2H_5^*$ radicals obtained by the reaction

$$H + C_2H_4 \rightarrow C_2H_{5vibr}. \quad (30)$$

We know from chemical kinetics that the basic reactions of thermal ethyl radicals obtained by the photolysis of diethylketone[55–57], acetaldehyde[58,59], azoethane[49,60], etc. are recombination and disproportionation reactions:

$$C_2H_5^* + C_2H_5^* \rightarrow C_4H_{10} \quad (31)$$
$$C_2H_5^* + C_2H_5^* \rightarrow C_2H_6 + C_2H_4 \quad (32)$$

with k_{32}/k_{31} = 0.1–0.2, and $E_{32} - E_{31}$ = 0.8 ± 0.2 kcal × × mole^{-1}.[61] If, however, the ethyl radicals are obtained in a vibrationally excited state by the addition of H atoms to C_2H_4 — mercury photosensitised Hg6($^3P_1$) decomposition of C_2H_4, etc. — the ratio k_{32}/k_{31} increases, but the scatter of experimental results is quite large (from 0.1 to 0.8) and the ratio depends on various factors such as the pressure in the system, the intensity of irradiation, the amount of mercury, the presence of inert additives, etc.[62–66]

The increased yield of C_2H_6 has been explained in various ways. It is suggested that vibrationally excited $C_2H_5^*$ radicals undergo disproportionation reactions more readily than thermal C_2H_5 radicals[65], and that they are able to extract hydrogen[64], but a unified point of view on this problem is still lacking. $C_2H_5^*$ radicals are relatively long-lived, and can experience up to 10^4–10^6 collisions before becoming thermalised, the efficiency of slowing down of $C_2H_5^*$ on C_2H_4, H_2, He, Ne, etc. showing large differences.

Current, Cvetanovich, Rabinovitch, and others[67–70] have made detailed studies of the stabilisation and decomposition of vibrationally excited ethyl radicals obtained by adding H and D atoms to C_2D_4 and C_2H_4. They postulated the reactions

$$C_2H_4 + D \rightleftarrows C_2H_4D^* \quad (33)$$
$$C_2H_4D^* \rightarrow C_2H_3D + H \quad (34)$$
$$C_2H_4D^* + M \rightarrow C_2H_4D + M. \quad (35)$$

The influence of pressure (0.05–3 mmHg) and temperature in the range from -78° to 160° on the ratio k_{35}/k_{34} was investigated, and the experimental results were analysed by Kassel's theory. It was shown that k_{34} is relatively insensitive to temperature, varying from 2.5 × 10^7 to 6.5 × × 10^7 s^{-1} between 195° and 300°K in the case of the $C_2H_2D_3$ radical. The ratio k_{35}/k_{34} is likewise insensitive to temperature, having the values 3.0 and 2.0 at 195° and 300°K respectively for $C_2H_2D_3$. However, a large isotope effect was noted in reactions (34) and (35): thus, for the $C_2H_3D_2^*$ radical under the same conditions k_{35}/k_{34} was 18 and 6.3 at 195° and 300°K respectively, i.e. significantly higher than for the $C_2H_2D_3^*$ radical[67].

It should be noted that vibrationally excited radicals can also be produced in reactions other than the addition of H atoms to alkenes (for example, in polymerisation[71] or in the addition of oxygen or halogen atoms to the C=C bond[72]). Studies of the reactivity of such radicals are very valuable in understanding a number of important processes (hydrocarbon oxidation, halogenation, etc.).

V. REACTIONS BETWEEN HOT H* ATOMS OBTAINED BY PHOTOLYSIS OF HI AND ETHYLENE

A great deal of work has been devoted to the study of the reactivity towards alkanes of hot H* atoms obtained in the photolytic decomposition of HI, but very little information

exists on the interaction between hot hydrogen atoms and alkenes. Yet, this problem is clearly very relevant from the point of view of explaining the influence of the kinetic energy of the H* atoms on the degree of excitation and on the reactivity of the resulting alkyl radical. Studies of the reactions of tritium recoil atoms have shown that alkenes can undergo not only extraction and substitution reactions, as in the case of alkanes, but also addition of a hot hydrogen atom to the double bond with formation of excited radicals [73] which subsequently decompose:

$$T + CH_3(CH_2)_2CH=CHCH_3 \rightarrow CH_3(CH_2)_3\dot{C}HTCHCH_3 \rightarrow CHT=CHCH_3 + CH_3(CH_2)_2. \quad (36)$$

The decomposition of excited radicals is a unimolecular process, analogous to the decomposition of the vibrationally excited radicals obtained by the addition of thermal hydrogen atoms to alkenes [53]. Lee and Rowland [6] have shown that the probability of stabilisation of excited radicals in a condensed phase at low temperatures is higher than in the gas phase

$$T^* + CH_3-CH=CH-CH_3 \rightarrow (CH_3-\dot{C}H-CHT-CH_3)^* \quad (37)$$

$$(CH_3-\dot{C}H-CHT-CH_3)^* \xrightarrow{RH} CH_3CH_2CHT-CH_3 \quad (38)$$

$$(CH_3-\dot{C}H-CHT-CH_3)^* \rightarrow CH_3CH=CHT+CH_3 \quad (39)$$

There is an almost complete lack of data on the reactions of hot H* atoms obtained by the photolysis of HI with alkenes. A systematic study of the reactions between hot H* atoms with 0.9–1.8 eV energy and ethylene was carried out in the Nuclear and Radiation Chemistry laboratory of the Institute of Chemical Physics of the Academy of Sciences of the USSR. The results have been partially reported in a number of papers [74-76]. Photolysis (λ = 2537 Å) of HI–C_2H_4 mixtures was found to give C_2H_6 and H_2 as the main products: butane and other hydrocarbons were not detected. The rate of formation of ethane ($W_{C_2H_6}$) is independent of temperature over a wide range (0–250°). Additions of inert moderators (helium and argon) affect $W_{C_2H_6}$ in different ways: argon has no effect, but helium causes a decrease in $W_{C_2H_6}$. The results are difficult to explain in terms of conventional kinetics. Let us consider the probable reaction scheme in the C_2H_4–HI system. Since C_2H_4 does not absorb in the 2500 Å region, the decomposition of HI with formation of a hot H* atom and an I atom is the only possible primary process resulting from photon absorption:

$$HI \xrightarrow{h\nu} HI^* \rightarrow H^* + I(^2P_{1/2} \text{ or } ^2P_{3/2}). \quad (40)$$

Hot H* atoms with 0.9–1.8 eV energy can undergo an abstraction reaction

$$H^* + HI \rightarrow H_2 + I \quad (41)$$

$$H^* + C_2H_4 \rightarrow H_2 + C_2H_3^\cdot \quad (42)$$

or they can become thermalised

$$H^* + HI \rightarrow H + I \quad (43)$$

$$H^* + C_2H_4 \rightarrow H + C_2H_4. \quad (44)$$

Thermal H atoms will, on the whole, add to the C=C bond, because abstraction from RH involves a large activation energy (~ 7–12 kcal mole^{-1}):

$$H + C_2H_4 \rightarrow H + C_2H_5\,{}_{vibr}. \quad (45)$$

Vibrationally excited C_2H_5 radicals dissociate into H and C_2H_4, or become thermalised. Thermal C_2H_5 radicals can recombine, disproportionate, be captured by I_2, or combine at the C=C bond (thus creating a polymerisation chain):

$$C_2H^\cdot + C_2H_5^\cdot \rightarrow C_4H_{10} \quad (46)$$

$$\rightarrow C_2H_6 + C_2H_4 \quad (47)$$

$$C_2H_5^\cdot + I_2 \rightarrow C_2H_5I + I \quad (48)$$

$$C_2H_5^\cdot + C_2H_4 \rightarrow C_4H_9^\cdot \xrightarrow{C_2H_4} C_6H_{13}, \text{ etc.} \quad (49)$$

The absence of butane and higher molecular weight hydrocarbons among the photolysis products, whilst H_2 and C_2H_6 are present, means that the experimental results are incompatible with the above scheme. We cannot ascribe the formation of C_2H_6 to disproportionation of C_2H_5 radicals, because for thermal C_2H_5 radicals k_{47}/k_{46} = 0.1–0.2.

The absence of C_4H_{10} may be due to inhibition of the C_2H_5 radical by iodine. Also, according to Benson and others [77], the activation energy for the removal of hydrogen from HI by thermal alkyl radicals is 1–2 kcal mole^{-1}. Therefore, the formation of ethane (but not of butane) in the system may be explained by postulating the reaction

$$C_2H_5^\cdot + HI \rightarrow C_2H_6 + I. \quad (50)$$

However, if the C_2H_5 radicals are thermal, the difference between the effects of He and Ar inert moderators on the rate of formation of ethane is difficult to understand.

A kinetic analysis in which only thermal particles were considered also failed to agree with the experimental results.

The present writer has stated a hypothesis according to which hot $C_2H_5^*$ radicals are formed, during photolysis, by the combination of H* and C_2H_4, the reactivity of $C_2H_5^*$ being determined by the kinetic energy of the hot hydrogen atom:

$$H^* + C_2H_4 \rightarrow C_2H_5^*. \quad (51)$$

Hot $C_2H_5^*$ radicals with $E_{C_2H_5^*} = Q + E_{H^*}$ (where Q is the heat of addition of H to a C=C bond, 40 kcal mole^{-1}) can extract hydrogen from RH:

$$C_2H_5^* + RH \rightarrow C_2H_6 + R^\cdot \quad (52)$$

where RH = HI or C_2H_4, and reaction (52) proceeds either without activation energy (in the case of HI) or possibly with a small activation energy for extraction from hydrocarbons.

This hypothesis allows us to explain the experimental results. Thus, if the $C_2H_5^*$ radical is hot it will not be captured by iodine and will mainly give rise to C_2H_6 by reaction (52). If the radical is unable to react by (52) and becomes thermalised the resulting $C_2H_5^*$ is captured by iodine with formation of C_2H_5I. Additions of He lower $W_{C_2H_6}$ because H* rapidly loses energy by collisions with He (as a result of the comparable masses of H and He), and consequently the probability of reaction (51), and therefore also (52), decreases. Additions of Ar (Fig. 1) have no effect on $W_{C_2H_6}$ because the thermalisation of H* atoms is much slower on argon than on helium. This is confirmed by the negligible effect of Ar additions on W_{H_2}, showing once again that reactions (41) and (42) are "hot" reactions.

In order to explain the effect of composition on W_{H_2} and $W_{C_2H_6}$, the photolysis of HI–C_2H_4 mixtures was investigated over a wide range of concentrations of the two components. The experiments were made under steady state conditions at a constant pressure of HI (30 mmHg), so that the initial rate of formation of H atoms was constant. When photolysis is carried out in mixtures containing an excess of HI the main reaction of the H* atoms is (41), and only a small

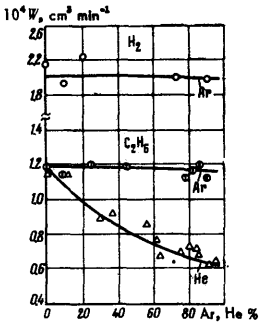

Fig. 1. Effect of He and Ar additions on W_{H_2} and $W_{C_2H_6}$ in the (C_2H_4 : HI = = 6 : 4)–Ar(He) system.

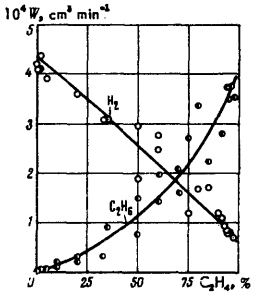

Fig. 2. Effect of composition on W_{H_2} and $W_{C_2H_6}$ in the HI–C_2H_4 system at 25° (P_{HI} = 30 mmHg).

fraction of the H* atoms will escape reaction (41) and take part in reactions (42) and (51). As the concentration of C_2H_4 in the mixture is increased, the contribution of reactions (42) [and particularly of reaction (51)] increases. The resulting $C_2H_5^*$ radicals can decompose, become thermalised, or take part in abstraction and addition reactions:

$$C_2H_5^* + HI \rightarrow C_2H_6 + I \quad (52a)$$

$$C_2H_5^* + C_2H_4 \rightarrow C_2H_6 + C_2H_3^* \quad (53)$$

$$C_2H_5^* + C_2H_4 \rightarrow C_4H_9^* \quad (54)$$

$$C_2H_5^* + M \rightarrow C_2H_5^* + M \quad (55)$$

$$C_2H_5^* \rightarrow H + C_2H_4 \quad (56)$$

Curves for the variation of W_{H_2} and $W_{C_2H_6}$ with composition are shown in Fig. 2. It can be seen that the decrease of W_{H_2} with increase of $[C_2H_4]$ is almost linear, whereas the increase of $W_{C_2H_6}$ shows a large departure from linearity.

It is important to note that the sum $W_{H_2} + W_{C_2H_6}$ is equal to the initial rate of formation of hydrogen in pure HI, to an accuracy of ±20%, over the whole concentration range. It follows that most of the H* atoms are consumed in reactions (41), (42), and (51), and that $C_2H_5^*$ radicals, unlike thermal $C_2H_5^*$ radicals, contribute mainly to the abstraction reactions (52) and (53) rather than to the addition reaction (54).

Introducing the condition

$$(W_{H_2})_0 \simeq (W_{H_2})_t + (W_{C_2H_6})_t \quad (VII)$$

and considering reactions (41)–(55), we can derive a kinetic equation of the form

$$\frac{W_{H_2}}{W_{C_2H_6}} = \frac{k_{42}}{k_{51}} + \frac{k_{41}}{k_{51}} \frac{[HI]}{[C_2H_4]}. \quad (VIII)$$

The plot of $W_{H_2}/W_{C_2H_6}$ against $[HI]/[C_2H_4]$ shown in Fig. 3 is evidently linear: from the intercept and slope of this straight line we can find k_{42}/k_{51} and k_{41}/k_{51}, and therefore also k_{42}/k_{41}. It turns out that $k_{42}/k_{41} \simeq 0.1$, in fair agreement with earlier results[22,28] for reactions of hydrogen abstraction from alkanes. Thus, the main reactions in the photolysis of HI–C_2H_4 mixtures are (41) or (51), according to whether HI or C_2H_4 is present in excess in the system. The ratio k_{53}/k_{52}, estimated by successive approximations, is also close to 0.1.

Hence, the principal reactions of hot H* atoms with E = 0.9–1.8 eV are those of extraction and addition at a π-bond, with formation of an excited radical. The excited $C_2H_5^*$ radical appears to be fairly long-lived, and is able to take part in chemical reaction (hydrogen abstraction) with RH until it decomposes.

The above estimates of k_{53}/k_{52} and k_{42}/k_{41} show that the cross-sections of these reactions depend to some extent on the strength of the bond, though the dependence is very much weaker (by several orders of magnitude) than in the case of thermal H atoms or $C_2H_5^*$ radicals.

It is important to note that the reactions of excited radicals are relatively insensitive to small additions of oxygen (Fig. 4), an efficient acceptor for thermal ethyl radicals.

Since the activation energy of reaction (50) is small (~ 1.5–2 kcal mole^{-1}), this reaction will compete with the "hot" reaction (52) only at elevated temperatures. Thus, it is interesting to examine the effect of temperature on $W_{C_2H_6}$ over a wide range of concentrations of HI–C_2H_4 mixtures. Fig. 5 shows temperature plots of $W_{C_2H_6}$ for 69, 90, 95, and 98% C_2H_4 respectively in the mixture. It is evident from the figure that even at 98% C_2H_4, when the hot reaction (41) can be effectively ignored, $W_{C_2H_6}$ is independent of temperature: this is evidence for the high efficiency of reaction (53). Helium additions cause the appearance of an activation energy (Figs. 5 and 6), the maximum value of E_{act} under full thermalisation of the hot H* atoms being ~ 1.5–2 kcal mole^{-1} (in agreement with the activation energy for the extraction of hydrogen from HI by thermal alkyl radicals). It must be noted that $W_{C_2H_6}$ decreases only by a factor of 2–3 at room temperature when H* atoms are fully slowed down. At lower temperatures (< 0°) the contribution of reaction (50) becomes less important, and $W_{C_2H_6}$ decreases more sharply.

It is interesting to consider the behaviour of excited radicals at low temperatures, when the thermal radicals are usually in a stabilised state. It has been reported[40,42] that CH_3^* could not be detected by ESR in the photolysis of CH_3I, although CH_4 was observed even at very low temperatures. When HI was photolysed in a matrix of 3-methylpentane[30] containing added alkenes (C_2H_4, etc.), ethyl, butyl, and other radicals were detected by ESR, though the authors consider that these were produced by the addition of thermalised hydrogen atoms to the alkenes. There are also data[32] on the photolysis of HI at 77°K in alkene matrices (C_2H_4, C_3H_6, see Table 2).

It is interesting to note that, as in our experiments on the gas-phase photolysis of HI–C_2H_4 mixtures, the main hydrocarbon product is C_2H_6 and the concentration of C_4H_{10} is low. Significant amounts of C_2H_5I are present: this

TABLE 2. Photolysis of HI–C_2H_4 and HI–C_3H_6 mixtures at 77°K (after Hughes and Purnell[32]).

Matrix	Irradiation time, min	Photolysis products	Amount, mol. %
HI 150 μmole C_2H_4 15 μ mole	65	C_2H_6	29
		n-C_4H_{10}	1
		C_2H_5I	70
		C_2H_2, C_4H_9I, C_4H_6, C_6H_{14}, C_3H_3I, C_1- and C_3-iodides	<1
HI 125 μmole C_3H_6 25 μ mole	40	C_3H_8	28
		2,3-dimethylbutane	2
		n-C_3H_7I	3
		i-C_3H_7I	67
		allene, diallyl, cyclopropane, C_3H_5I, methylacetylene	traces

may be ascribed to capture of ethyl radicals by I_2. The authors have put forward a hypothesis involving the formation of a reactive complex in the matrix when a photon is absorbed, followed by reactions within a cell. However, their results can be interpreted in terms of the formation of "hot" C_2H_5 radicals, produced by reaction (51), which are highly reactive even at liquid nitrogen temperature and can therefore abstract hydrogen from RH.

The results discussed above demonstrate that hot H* atoms with 1–3 eV energies have some special features as compared with thermal hydrogen atoms and very fast atoms (such as tritium recoil atoms): in particular, a weak temperature dependence of the rate of the abstraction reaction is possible near the chemical reaction threshold. When the energy is increased in the range 1–3 eV and above, the reactivity of the H* atoms increases. Studies of the reactivity of hot H* atoms in the energy range of a few electron-volts are particularly important, because these atoms can be formed in many photolytic reactions and during radiolysis. In particular, by reacting with alkenes these atoms can produce excited radicals as reactive intermediates which influence the final product distribution.

The formation of hot $C_2H_5^*$ radicals in the radiolysis of C_2H_4 and NH_3 was demonstrated by the present writer[17].

Hot H* atoms are formed by the radiolytic decomposition of excited RH molecules:

$$RH^* \rightarrow R^{\cdot} + H^* \qquad (57)$$

where RH = C_2H_4, NH_3, etc.

The ratio $C_2H_6 : C_4H_{10}$ serves as a measure of the energy of the $C_2H_5^*$ radicals. This ratio is appreciably higher than 0.1–0.2 (the value of k_{disp}/k_{rec} for thermal C_2H_5 radicals), and can approach unity [17,75,78-81] in the radiolysis of C_2H_4 and exceed unity in the radiolysis of C_2H_4–NH_3 mixtures [17,75]. The ratio is not a function of the pressure in the system or of temperature (in the range from +50° to -78°), and decreases when He is added to C_2H_4 or to a C_2H_4–NH_3 mixture [17,75]. Thus, as in the photolysis of HI–C_2H_4 mixtures, the enhanced yield of C_2H_6 in the radiolysis of pure ethylene and of ethylene mixed with RH can be explained starting from the hypothesis that a reactive intermediate (the excited ethyl radical) is formed. It is significant that in the radiolysis of NH_3–C_2H_4 mixtures small additions of O_2 affect the yield of C_4H_{10} (Fig. 7) more strongly than that of C_2H_6: this is difficult to understand on the assumption that these products are formed exclusively by reactions (46) and (47). An interesting observation made on the radiolysis of C_2H_4 at -196° is that not only did the $C_2H_6 : C_4H_{10}$ ratio not fall off, but it was even greater than unity, showing that the reactive $C_2H_5^*$ radical can be formed even at low temperatures [80].

The formation of reactive $C_2H_5^*$ radicals is obviously not specific to ethylene. The features obtained should be observable, to a greater or lesser extent, in the addition to alkenes of hot hydrogen atoms obtained both by the decomposition of excited molecules in radiolytic and photolytic processes and in chemical reactions accompanying nuclear transformations.

In contrast to the excited radicals obtained by the decomposition of a molecule, we have the new concept of an excited $C_2H_5^*$ radical formed by the collision of an ethylene molecule with a fast hydrogen atom. Whether under these conditions a vibrationally excited radical is formed, or whether electronic excitation can occur, is still not fully clear, because the electronic levels of $C_2H_5^*$ are not known.

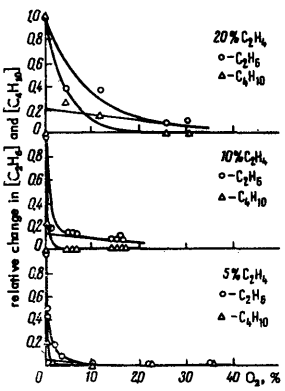

Fig. 7. Effect of added O_2 on the relative change in the yield of C_2H_6 and C_4H_{10} during radiolysis of (NH_3–C_2H_4)–O_2 mixtures. (Dose rate 1.2×10^{14} eV cm^{-3} s^{-1}, irradiation time 40 h.)

We know that the C_2H_4 molecule has low-lying electronic levels: 1.7, 4.4, 7.7, and 9.2 eV. [82] Since the levels of the $C_2H_5^*$ radical must lie below those of the $C_2H_4^*$ molecule, we cannot exclude the possibility of excitation of the electronic levels of $C_2H_5^*$ ($E_{C_2H_5^*} \simeq Q + E_{(H^*)} \simeq 3.8$ eV). When discussing kinetic mechanisms it is essential to make allowance for the possible formation of excited particles having enhanced reactivity. This is specially important in the case of photochemical processes occurring in the vacuum ultraviolet region (λ = 1236, 1440 Å) and during radiolysis, when hot atoms and radicals having several electron-volts of excess energy can be formed. "Hot" intermediate products (molecules, atoms, radicals) can be expected to form also in the reactions of recoil atoms, particularly tritium, with alkanes [2,9] as well as with alkenes [10].

Studies of the reactions of hot atoms and radicals having energies of the order of a few electron-volts should help to fill a gap in one of the most interesting regions of chemical kinetics: the region of intermediate energies, comparable with the energy of the chemical bond, which (unlike the high energy and the thermal energy regions) is as yet inadequately investigated.

I. INTRODUCTION

Quartz ceramics are a recently developed class of materials offering a range of valuable properties of particular interest in a number of new technological areas.

Modern technology often requires materials combining high dimensional stability over a range of temperatures with good thermal stability and low thermal conductivity.

Fused quartz has a very low coefficient of thermal expansion: it is used as a standard for assessing the relative temperature stability of materials and has been successfully incorporated in equipment for use at high temperatures [1-9]. However, because of the very high viscosity of molten quartz glass (exceeding that of ordinary glass compositions [10] by more than a factor of 100 at 2000°), and of its appreciable volatility, the fabrication of articles of quartz glass presents serious difficulties.

Furthermore, only a very limited range of sizes and configurations can be obtained by applying conventional glass technology to the production of quartz glass articles. Hence, we must look for alternative routes to the production of articles made from fused quartz.

The limitations in shape and size are being overcome by the success achieved in recent years in applying ceramic technology to the problem.

It should be noted that an established terminology for ceramic materials based on amorphous or crystalline silica is still lacking, and some clarification is essential. In the American literature we find the term "slip cast fused silica", in the German Democratic Republic "Quarzglaskeramik" (quartz glass ceramic) and "schlickergegossenes Quarzgut" (translucent quartz glass made by slip-casting). In the USSR, the terms "kvartsevaya steklokeramika" [3] (quartz glass ceramic) and "kremnezemnaya steklokeramika" [11] (silica glass ceramic) have been proposed for materials based on quartz glass (fused quartz), and "kersil" for a ceramic based on synthetic amorphous silicon dioxide [12].

We consider the term "steklokeramika" (glass ceramic) an unfortunate choice, because it implies a crystallised glass of the "Pyroceram" type. Our suggested term "kvartsevaya keramika" [13] (quartz ceramic) can be applied to all ceramic materials prepared by ceramic techniques from one of the following: fused quartz, synthetic amorphous silica, or crystalline silica. It is important also to distinguish between the various forms of raw material used for the ceramic (crystalline silica, quartz glass, silicic acid gel), because the type of raw material plays an important role in the technology and in determining the properties of the product.

Several methods of preparation of quartz ceramics are known. The first, proposed by Skaupy and Weissenberg [14,15], consists in fusing (at 1650–1680°) cold-formed articles of quartz sand.

The second method, proposed by Solomin [11], consists in preparing articles of finely powdered quartz glass by the slip-casting method, with a subsequent heat treatment.

The difference between these methods lies in the choice of starting material. In the former, the starting material is quartz sand or rock crystal, which is converted to the desired state in the finished article. This requires a much higher temperature than is used in the second method. In the latter method the starting material is finely divided fused quartz. However, the basic technological operations needed to prepare the ceramic from fused quartz and from crystalline silica are identical. The fields of application of the second method and the quality of the articles made from fused quartz are such that this method is emphatically the better.

Botvinkin and Zaporozhskii [3] have described a method of preparation of quartz ceramics devised in an attempt to develop a material with a higher thermal stability than ordinary quartz glass. Aqueous silica gel was used as a binder for the fine grains of a thermally stable glassy composition, thus duplicating the natural conditions for the formation of cementoquartzites, whose thermal stability is equal to that of optical quartz glass.

It was shown [3] that the high thermal stability is due to the specific properties of the solid silica gel which binds the crystalline grains of natural quartz, itself of indifferent thermal stability. A series of materials with a binder of the silica gel type was synthesised, in which finely divided, transparent or translucent quartz glass was the filler.

Heany [16] suggested a method for preparing articles from finely disperse silica obtained by the decomposition of various silicone compounds. The castings were fired at 1200–1500° for various times.

The many papers published in the last few years [17-53] have considerably extended the scope and the applications of this new material, have suggested a number of valuable improvements in the technology of its production, and have discussed some of its properties.

II. MATERIAL PREPARATION

The starting material for the preparation of ceramics from quartz glass consists of waste, transparent or translucent, quartz glass [23,30], or fused quartz with SiO_2 content of the order of 99.5% (as reported by Schulle [23]). The quartz glass should be carefully melted and free from coarse heterogeneous inclusions such as graphite, slag, etc. In the preparation of the ceramic from silica, the starting material is pure silica sand or rock crystal. Schulle and Ulbricht [24] find that quartz sand with SiO_2 content of not less than 99.6% is essential for high-quality articles. By studying separate fractions they showed that the impurities in the sand are concentrated in the fractions of less than 0.1 mm and more than 0.3 mm grain size: the 0.1–0.3 mm fraction, which accounts for over 90% of the quartz sand, was therefore used for preparing articles.

In order to increase the SiO_2 content, the sand was treated with 12% hydrochloric acid in a ball mill for one hour. The chemical composition of the milled and washed quartz sand and glass, and the size distribution of quartz glass [23,24], are given in Table 1.

TABLE 1. Chemical composition of quartz sand and quartz glass, and granulometric composition of quartz glass.

	Quartz sand, wt. %	Quartz glass, wt. %	Size of fractions, μm	Fractions, %
SiO_2	99.83	99.51	40	0
Al_2O_3	0.07	0.31	22—40	15.1
Fe_2O_3	0.01	0.03	10—20	8.6
CaO	0.03	0.06	5—10	12.3
MgO	0.01	0.04	2—5	24.6
$K_2O + Na_2O$	0.01	0.05	2	39.4

Impurities of alkali metal oxides are the most detrimental, because they induce and catalyse the cristobalite transformation.

Amorphous synthetic silica also may be used as a raw material for the preparation of quartz ceramics. The first technological operation in this case is to bake the raw silica in order to drive off the large amounts of adsorbed water. It has been reported[3] that as much as 70–100 g of water per 1 kg of charge can be removed from synthetic silica in 24–72 h by baking at 1000–1200°.

Certain impurities are frequently added to the charge in order to improve sintering and inhibit crystallisation. In this case the SiO_2 content becomes correspondingly lower.

For example, Palatskii[51] mentions the addition of kaolin and low-melting glass frit, which lowers the sintering temperature to 1050–1100°. A slight lowering (by 20–30°) of the sintering temperature of a ceramic made from fused quartz can be achieved by adding synthetic SiO_2, whose sintering and crystallisation temperatures are both lower. Other workers[37] have added B_2O_3 to inhibit crystallisation.

Quartz ceramics based on quartz glass have undergone by far the most intensive development in recent years: all the results quoted in this review will therefore apply to this type of ceramic unless accompanied by a statement to the contrary.

Quartz glass is comminuted in a jawbreaker or other type of crusher; still finer particles are obtained in a ball mill. Size analysis of the fine powder is carried out in a centrifugal air separator[49].

Fine milling is done in ball mills with quartz liners and quartz balls; vibratory mills also can be used[35]. In cases of iron pick-up magnetic separation must be resorted to[49,50]. The fineness of the powder can be controlled on a PSKh-2 apparatus[35]: fine powders with a specific surface area as large as 8000–10 000 $cm^2 g^{-1}$ have been prepared both for semi-dry pressing and for slip casting[35].

III. FORMING

Quartz ceramics are manufactured in various forms: with medium porosity (up to 20–30%), high porosity (up to 80%), foamed quartz ceramic[34,39-42,44], and ceramic from cast[20,32] or granular material[35]. The following methods of forming quartz ceramic are known: wet slip casting, semi-dry pressing, hot pressing in graphite moulds, hot casting from wax, extrusion, etc.

The slip casting method is the most widely used, probably because of the requirement for hollow articles, which are most conveniently formed by this method.

The slip consists of a concentrated suspension of very fine particles of SiO_2 in a dispersion medium (water).

The particles must be fine enough to prevent fast settling under the influence of gravity during the time needed for the casting process. From the difference in density between the solid and the liquid phase and a number of other factors it can be calculated[54] that the particle size should be in the range 0–10 μm. The size of the bulk of the particles should be such that the interactions between particles are determined essentially by surface forces rather than by gravity.

The dispersity of the material is characterised by the particle size distribution, which is measured by sedimentation analysis, but as an overall characteristic of the dispersity we can use the computed mean surface diameter given by the formula

$$d_{mean} = \frac{100}{\sum \frac{a_i}{d_i}},$$

where a_i is the proportion of each fraction in % and d_i is the nominal mean diameter of the respective fraction in μm.

A very important process takes place during milling of quartz materials: formation of silica gel, as a result of which the non-plastic material acquires some measure of plasticity. Gel formation results from the disruption of the crystal lattice at the surface of the quartz particles during milling, accompanied by chemical reaction between water and the SiO_2.[55,56] When the grain size is less than 0.5 μm the disturbance of the crystal lattice can extend throughout the bulk of the particle, as shown by differential thermal analysis curves[24].

All types of silica (quartz, cristobalite, vitreous silica) can be considered as SiO_2 aggregates[57]. If the exact stoichiometry SiO_2 is retained, a truncated tetrahedron must be present at the point of contact of tangential surfaces. A surface of silicon atoms tends to complete its tetrahedral coordination: at a water interface the coordination can be completed by the formation of OH groups at the surface of SiO_2. Hydration of the silica proceeds at the surface and is limited by the size of the particle.

It is possible to obtain a silica slip (by wet milling) without any binder or plasticiser additives. The slip is prepared (by "wet" milling) in ball mills with silicon or quartz balls and a quartz liner. Rubber-lined mills with silica balls can also be used. The use of other types of mill is not recommended if pick-up of harmful impurities is to be avoided. The slip is made up of distilled water and quartz powder ground in the mill until the required consistency and the prescribed particle size distribution are obtained. The milling time can vary over wide limits (20–100 h), depending on the size distribution of the starting quartz, on the amount of water present, and on many other factors. Nishanova and coworkers[35] prepared a slip of satisfactory quality by milling for 30 h a powder of 10 000 $cm^2 g^{-1}$ specific surface area. The water content of the slip is between 25 and 30%: at higher moisture levels shrinkage increases and the quality of the castings deteriorates.

When the impurity content of the starting material increases, the minimum permissible water content rises to 33–35% or higher. Since a decrease in the water content of the slip can have an effect on the subsequent production stages, attempts have been made[35] to minimise the wetness of the slip by using vibration during casting (vibro-casting). The slip used in this work had a water content of 20%. The optimum time of vibration of the moulds (50 Hz frequency, 1 mm amplitude) was 3 min.

The degree of milling of the slip must be such that 40–50% of the solid particles have a diameter less than 5 μm. If the solid phase in the slip has a coarser size, fast settling results, giving poor casting properties and castings of low mechanical strength. The correct size distribution of particles is also essential. Preponderance of one fraction leads to increased shrinkage, lower strength, and lower density, which hampers the subsequent sintering.

The viscosity of the slip is very important in slip casting. The most satisfactory method of measuring viscosity under these conditions is to time the delivery of 100 cm^3 of the slip from a pipette (Engler's apparatus). It has been shown that the optimum pH value for a slip containing crystalline SiO_2 is 1; this value was obtained by adding hydrochloric acid, which does not introduce undesirable impurities into the slip[24].

The present writers have found[45] that the minimum viscosity of a slip based on fused quartz is reached at pH 3–3.5. Addition of hydrochloric acid lowers, however, the strength of the castings. For example, when the pH was lowered from 5.9 to 1.6 the strength of the castings under bending decreased from 4.0 to 1.4 kg cm^{-2}. This can obviously be ascribed to decomposition of the silica gel formed during the wet milling process, which acts as a binder in this case.

However, the pH changes continuously during wet milling due to the formation of silicic acid, reaching pH 3.5–5 at the completion of milling from an initial value of 7. Thus, the optimum pH value is obtained without adding acid.

The slip casting method is used for manufacturing hollow articles; the mould material is plaster of Paris, and the passive part of the mould is made of aluminium, plastics, etc. Ceramic or paper moulds can also be used[18,38].

The high thixotropy of SiO_2 slips is noteworthy. The limiting to apparent viscosity of thixotropy varies between 2 and 3, and increases steeply with particle size.

Using a thixotropic slip, articles cast in wooden moulds have shown adequate strength. The moulds were then dismantled and the articles dried[32].

The most important criterion of the quality of slip casting is the density of the casting obtained. This is because a high density is very beneficial to the relatively low mechanical strength of the dried castings, and it minimises shrinkage during drying and firing (particularly important in the manufacture of items of large dimensions and complex shape). Sintering also is easier and faster with high-density castings. The density depends on the particle size of the solid phase present in the slip, and on the size distribution over the various fractions, because separate loose aggregates of particles lower the density of the casting. Equally important is complete removal of air bubbles from the slip, which can be achieved by vacuum treatment. Under otherwise identical conditions, the density and the mechanical strength of the dried slip vary almost linearly with grain size (Fig. 1).

One of the features of ceramics manufactured from fused quartz is the possibility of obtaining castings of low porosity and high mechanical strength as compared with other types of ceramic.

The present writers have shown[45] that the casting properties of the slip are improved by lengthy storage after milling. Depending on the characteristics of the slip, the optimum properties were developed after 3–7 days: the

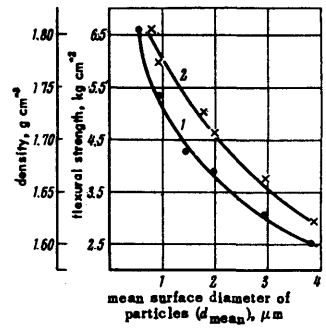

Fig. 1. Variation of density (1) and of flexural strength (2) of dry specimens with mean surface diameter of the particles (d_{mean}).

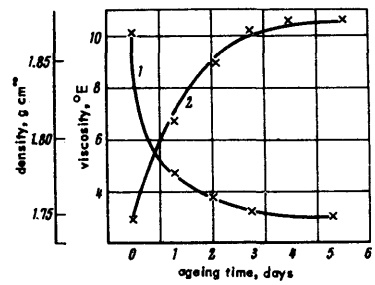

Fig. 2. Effect of ageing time on the properties of the slip and of the castings:
1) viscosity of the slip; 2) density of the castings.

viscosity decreased 2–8-fold, and the viscosity ratio changed from 2–3 to 1.2–1.3. Castings made from this slip can have a porosity of less than 12% and a strength of 25 kg cm^{-2} in transverse bending (Fig. 2).

We interpret the favourable effect of storage as follows. The silica gels formed during the wet milling process age with time; this is accompanied by evolution of the dispersion medium (water) from the diffusely bound to the free state, and therefore also by a decrease in viscosity. During the setting process closer packing can take place, because the diffusion layer around the particles is thinner.

Both the overflow and the pouring methods of casting can be used for the manufacture of quartz ceramics. Radome castings 750 mm in height and 450 mm in diameter have been made by the former method, which lends itself to the production of large articles without difficulty[18]. A radome 1220 mm in height also has been made by slip casting[36].

A mould release agent is used to prevent adhesion of the articles to the mould: for example, sodium alginate, which allows the passage of water[18]. However, the sodium alginate must be removed from the surface of the articles before baking, because it can cause undesirable crystallisation if it is allowed to penetrate into the material. In most cases, even a small shrinkage of the casting in the mould is sufficient to free the object without using release agents.

It is worth stressing that the shrinkage during drying is very small (0.1–0.5%, depending on the particle size and on the water content): hence, the size of articles which can be made by slip casting[18] can reach several metres, corresponding to a weight of 500 kg.

Quartz ceramics are also formed by using the slip casting method with 3–10% additions of a water-soluble gum. The article is dried, and the gum is hardened at 150–200°, which raises the strength of the unbaked articles in bending to 500 kg cm^{-2}. The gum burns off during sintering, but there is a loss of mechanical strength proportional to the amount of resin binder. Impregnation is used to achieve greater strength. The main advantage of this method of forming is that it allows the article to be machined on a lathe before baking. In this way one can make components with machine-cut screw-threads, electrical insulators of any shape, and nose cones for guided missiles[23].

A modification of slip casting is casting from compositions with a granular filler (casting compositions); another modification is casting from foaming slip. Casting from casting compositions consists essentially in adding to the normal slip a filler of granular fused quartz[31,35] of particle size between 0.25 and 1 mm.

To make larger castings, the maximum fraction size is increased. Under these conditions the ratio of slip to granular filler is of the order of 1 : 1. It is recommended that 100 parts by weight of the filler should be triturated with 2 parts by weight of water immediately before mixing with the slip. By using vibration during casting it is possible to lower the water content of the slip to 14.5–17.5%.[35]

Drying quartz ceramic presents no difficulty because the shrinkage is very small (less than 1%), and there are no distortion or crack formation problems. Both spontaneous drying at room temperature and forced drying in drying chambers can be used. A combination of the two methods is most common: 24 h at room temperature followed by treatment at 120° in a special drier[18]. The drying time is determined by the wall thickness of the article. For 10–15 mm wall thicknesses, drying is practically complete in 3–4 days at room temperature.

We may expect, however, complications to arise in the drying process as a result of the strong tendency of the slip towards gel formation when the particle size is made very small or the milling time is increased. This is because silicic acid gel does not readily give up OH groups on drying. In this case the drying procedure must be milder, and must be chosen to suit the fineness of milling, the degree of gel formation, and the size of the casting.

Foamed quartz ceramics are becoming very common: they are produced by slip casting with a suitable foaming agent in the slip.

Budnikov and Duderov have developed a new method for preparing highly porous articles on the basis of fused quartz[34]. The fused quartz, finely divided to an average particle size of 1–3 μm, is mixed with acid aluminium phosphate and with glyceryl adipate, and the foaming agent "Product 102-T" (methylphenylene di-isocyanate) is added to the resulting suspension. The starting mass has the following composition (in wt.%):

fused quartz	45.0
ester	20.9
foaming agent	13.2
aluminium phosphate	20.9

A mass of the above composition is foamed in closed steel moulds, allowing accurate control over the profile of the article. Foaming occurs as a result of the evolution of carbon dioxide by the reaction

$$n\mathrm{O{=}C{=}NRN{=}CO} + n\mathrm{HOOCR'COOH} \rightarrow n\mathrm{CO_2} + n\mathrm{O{=}C{=}NRNH{-}C(=O){-}R'{-}C(=O){-}OH}.$$

di-isocyanate (foaming agent); ester

The volume expansion obtained is greater than a factor of 10. The polymerisation of the polyester, which occurs at the same time as the evolution of carbon dioxide, strengthens the porous structure and gives it increased rigidity. Firing temperature 950–1000°, density of the finished article 0.33–0.40 g cm^{-3}, proportion of open pores 80–88%.

According to Walton, aluminium phosphate (which was examined as a possible impregnating material) induced cristobalite transition of the siliceous masses[33]. However, X-ray diffraction analysis of the specimens fired at 1000° for 28 h, and also at 1100°, did not reveal a more intense peak than the one formed during normal heat treatment and ascribed to cristobalite (Fig. 3). Hence it was suggested that the observed peaks are associated not with cristobalite (as assumed by Walton) but with cristalorphite, the cristobalite form of $AlPO_4$. The absence of cristobalite was later confirmed by differential thermal analysis, petrographic analysis, and dilatometric analysis.

According to an American patent[45], insulators are made from silicic acid and glycerol (1–5%): after mixing, the mass is dried at 120–300°, ground to 100 μm particle size, and furnaced at 1260–1650°, when the silica expands forming hollow microspheres. The density of the final product is 0.7–1.2 g cm^{-3}.

Hot casting from wax can be used as a casting method. The density of the articles in this case is lower than when slip casting is used. Articles of simple shape can be made by semi-dry pressing, using a specific pressure of between 800 and 1200 kg cm^{-2}. The water content of the powder lies between 8 and 10%. The granular composition is approximately the same as in slip casting. According to Nishanova and coworkers[35] the specific gravity of the pressings and their apparent porosity vary with the pressure used as shown in Fig. 4. The relatively high porosity of the semifinished product is worth noting, as it causes difficulties in the subsequent sintering. Owing to the low mechanical strength, reaching 4–6 kg cm^{-2} in bending after forming and 2–3 kg cm^{-2} after drying[24], additives are commonly used.

Ethyl silicate-40, an ester of silicic acid, has been found[23,24] to be a very effective additive. Under the influence of water this compound hydrolyses to give SiO_2 gel, and binds the quartz particles together. The binding effect persists at elevated temperatures, which makes this binder superior to dextrin, starch, etc.

Ethyl silicate-40 decomposes to amorphous silica which is transformed to cristobalite only after prolonged heating at temperatures in excess of 1000°. Furthermore, ethyl silicate-40 does not increase the tendency to crystallisation of a quartz ceramic, and does not introduce contamination.

Alternatively, 0.2% additions of urea–formaldehyde resin have been used[35].

Vasilos and Wagner[27] have described a method of preparation of quartz ceramics from ground quartz glass by hot pressing in graphite moulds, which involves the simultaneous application of heat and pressure. Hot pressing

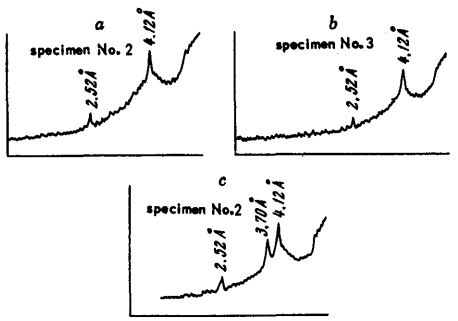

Fig. 3. X-Ray diffraction patterns of specimens: (*a*) fired at 1000°; (*b*) fired at 1100°; (*c*) fired at 1000° for 28 h.

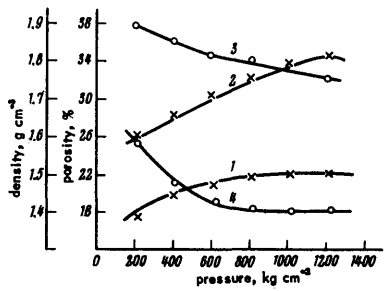

Fig. 4. Variation of the apparent porosity and of the density of a quartz ceramic with the porosity and the density of the raw material and with the applied pressure:
1) density before firing; 2) density after firing;
3) porosity before firing; 4) porosity after firing.

was achieved by applying pressure for 3 h at 1050–1450°. Graphite, which burns at ~800°, is added to the powdered quartz glass. Sintering under pressure results in relatively large shrinkage, which can amount to 5–15% or more according to the compressive strain. The porosity of the resulting material is less than 3%. If necessary, quartz glass articles with regions of different porosity can be manufactured by this method.

Vasilos[26] used three arbitrarily chosen fractions of fused quartz in the range 5–300 μm, prepared by grinding followed by acid leaching and separation on sieves.

Studies carried out on the hot pressing apparatus have shown that at 1100°, 1150°, and 1200°, and pressures in the range 70–170 kg cm^{-2}, for pressing times up to 90 min, the dispersity of the fused quartz has a negligible effect except for fractions up to 300 μm in size.

IV. THE ONE-COMPONENT SYSTEM AND ALLOTROPIC TRANSFORMATIONS OF SiO_2

The existence of the following modifications of silica is now recognised: quartz, tridymite, cristobalite, coesite, kitite, fibrous silica, stishovite, and quartz glass.

Fenner's well known phase diagram for SiO_2 clearly shows all the most important states of silicic acid (quartz, tridymite, cristobalite). It does not, of course, include all the recently discovered modifications listed above: for a detailed discussion of these allotropes and of contemporary ideas on silicon dioxide the reader is referred to the original papers[58–64].

Fenner's diagram shows the variation with temperature of the vapour pressure of the various modifications of SiO_2: polymorphic transformations are presented graphically.

Second-order transitions (within a given modification) are fast, but first-order transitions of the quartz–cristobalite type are slow. Hence, the temperature limits of stability of the individual modifications are meaningful only for prolonged heating in the presence of strong mineralisers. The smaller the difference in structure of the crystal lattices of two polymorphic forms of SiO_2, the faster is the transformation (under otherwise identical conditions).

In Fenner's diagram quartz is shown as thermodynamically stable from low temperatures up to 870°, tridymite from 870° to 1470°, and cristobalite from 1470° to the melting point.

The following problems are important in a study of the technology, structure, and properties of quartz ceramics: (1) the transformation of pure (upwards of 99% SiO_2) silica, quartz glass, and amorphous synthetic SiO_2 at the heat treatment temperatures into cristobalite, and the kinetics of this transformation; (2) the transition from high-temperature to low-temperature cristobalite; (3) the influence of impurities, of the gas medium, and of various other factors on these transformations.

Fenner's phase diagram for silica was not re-examined for many years. More recently it has been repeatedly pointed out that quartz is not converted into tridymite in the absence of mineralisers, and that Fenner obtained tridymite by using Na_2WO_4 as a mineraliser[65–69]: revision of the diagram therefore seemed desirable[70]. It was subsequently shown that pure silicon dioxide under atmospheric pressure can be converted into quartz or cristobalite by heating[71,72].

Flörke electrolysed crystalline samples of tridymite[73] in the temperature range 870–1470°. Under these conditions, the tridymite in the anodic region was converted into cristobalite (for electrolysis temperatures above 1000°) or into quartz (at temperatures below 1000°), suggesting the breakdown of the tridymite structure by the removal of a stabiliser.

Thus, the stability of tridymite is due to impurity atoms of alkali metals introduced into the lattice during the synthesis of tridymite.

The structure of tridymite, like that of other modifications of silica, consists of a particular sequence of layers of SiO_4 tetrahedra. When free from defects, tridymite should have a twofold periodicity of layers of SiO_4 tetrahedra, i.e. an AB|AB|AB|AB structure.

Like cristobalite, real crystals of tridymite contain regions showing twofold periodicity and others showing threefold periodicity. However, in contrast to cristobalite which is made up mostly of three-layer regions, two-layer regions are predominant in tridymite.

According to Flörke, tridymite should be treated as a highly defective form of cristobalite, and should not appear in the phase diagram. Flörke's revised phase diagram, shown in Fig. 5, includes only quartz and cristobalite, with a transition temperature in the region of 1050°: pure cristobalite does not change into any other crystalline form[74,75].

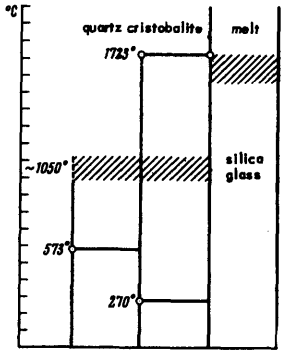

Fig. 5. Tentative revision of the phase diagram of pure SiO_2 (after Flörke).

Thus, whether we start from pure quartz, pure cristobalite, or from an amorphous form of silica (such as quartz glass or dehydrated silica gel), tridymite is not formed even after lengthy treatment in the temperature region 870–1470° (the stability region of tridymite according to Fenner). However, in the presence of small quantities of alkali metal oxides, tridymite forms quite readily in the stated temperature region. It follows that two phase diagrams for silica are needed, depending on the experimental conditions. When very pure silica is used (by far the commonest case in the preparation of quartz ceramics) the transformations are dictated by Flörke's diagram, but if the silica is in contact with other substances (in particular with alkali metal salts) Fenner's diagram should be used[58].

During the last few years many papers have been published on the allotropic transitions of SiO_2 and on the kinetics of crystallisation, and on the influence of various factors on these processes[82-110].

V. CONVERSION TO CRISTOBALITE AND ITS KINETICS

It has often been observed that the transformation of quartz to cristobalite, a solid-state reaction[95], begins at the free surfaces of grains, both internal and external. under the influence of high temperatures the cristobalite transformation of quartz spreads from these surfaces. The transformation of quartz follows this course because the free surface is the site of broken bonds between $[SiO_4]$ tetrahedra, which facilitate the rearrangement of the lattice through the enhanced mobility of the tetrahedra. The accurate and constant correlation between the crystallographic directions of quartz and of the resulting cristobalite is evidence that this transformation occurs in the solid phase.

By treating quartz glass as a non-stoichiometric material with a definite proportion of oxygen defects, Boganov and coworkers[104] explain the formation of a crystalline layer on the glass surface as follows.

When the surface of the glass is exposed, at high temperatures, to an oxygen-containing atmosphere, oxygen atoms penetrate the glass network by thermal diffusion. During some induction period, a fraction of the oxygen atoms dissolved in the boundary layer of glass fills, at random, vacant anion sites to an increasing depth below the original surface. However, formation of a local crystalline block in the region which has been made stoichiometric is possible only when this region reaches a definite critical size. This size is determined by the conditions of equilibrium between the deformation forces associated with the excess energy of a stoichiometric but disordered region and the bond-breaking forces at the surface of the resulting crystalline block. If the supply of the required amount of oxygen to the subsequently formed blocks is fast as compared to the characteristic formation time of the block the crystallisation process should proceed at a constant rate.

The temperature at which the cristobalite transition occurs during firing of a quartz ceramic is of the utmost importance, because the forms of quartz most resistant to the transformation (quartz glass) offer the best prospects of dense sintering and therefore also of improvements in a number of properties. The high-temperature α-cristobalite formed during heat treatment goes over to the low-temperature β-cristobalite during cooling: the attendant decrease in volume loosens the structure of the ceramic and degrades its thermal stability.

A more detailed study of the cristobalite transition temperature and of its dependence on a number of factors is therefore essential. The cristobalite transition temperature (1050°) given in Flörke's diagram is not associated with any particular heating time or with various other factors often found to be critical. According to Walton[31-33] and others, a fused quartz ceramic converts to cristobalite at temperatures above 1093° (2000°F). According to Schulle[23], conversion to cristobalite at 1100° occurs only after upwards of 20 h heating.

Verduch[82] studied the effect of time and temperature on the rate of formation of cristobalite, and showed that three stages are involved in cristobalite formation: the formation of crystal nuclei, fast crystallisation, and the subsequent (slow) crystallisation. The amorphous SiO_2 used for the investigation (silicic acid) began to crystallise at a temperature as low as 945° after 41 h, and at 985° crystallisation set in after 10 h.

The temperature variation of the nucleation process is described by the equation

$$\log t = \frac{22462}{T} - 13.32,$$

where t is the time needed for the formation of nuclei in seconds and T is the absolute temperature in degrees.

When the temperature is raised from 945° to 1085° the nucleation time decreases from 41 h to 0.5 h.

The next stage is the growth of a cristobalite structure. The amount of cristobalite formed is given by the equation

$$\log K = 5.98 - \frac{11122}{T},$$

where K is the amount of cristobalite formed per second (%), and T is the absolute temperature in degrees.

On raising the temperature from 945° to 1085° the quantity K increases from 7.87×10^{-4} to 7.00×10^{-3}.

The temperature at which cristobalite is crystallised from silicic acid determines the interplanar spacing of the cristobalite lattice, which decreases from 4.0825 Å to 4.062 Å when the temperature is raised from 1080° to 1425° (corresponding to a perfect cristobalite structure at 1425°).

The ordering of the structure proceeds from the centre of the crystal towards the periphery. The kinetics of the conversion of pure quartz into cristobalite depend on the

crystallite size. When the grains are small (~50 μm) the transformation in the temperature region 1270–1450° follows the equation

$$\log\alpha = -\frac{3ut}{r},$$

where u is a constant, t is the heating time, r is the initial radius of the quartz particle, and α is the fraction of quartz converted.

With coarser grains (~138 μm) the transformation proceeds in 2 stages: in the first stage cristobalite nuclei are formed on the surface of the grains and in the second stage cristobalite formation proceeds into the bulk of the grains. The rate of reaction for the first stage is lower than for the second, but the duration of the first stage decreases steeply on raising the temperature (from 1270° to 1450°). The rate constant for the first stage includes the surface factor $1/r^2$; the rate constant for the second stage includes the quantity $3u/r$, and is therefore proportional to $1/r$.

When the quartz particles are fine, the rate constants of the two processes are comparable, and the reaction proceeds, as it were, at a constant rate from beginning to end. The kinetics of the transformation of quartz are altered by the presence of a mineraliser (which can be either in the solid or in the liquid state at the transformation temperature).

If the mineraliser acts in the solid phase, the transformation of the quartz is fast only in the immediate vicinity of the grains of the mineraliser: hence, the mineralising activity is of short duration, and the remainder of the reaction proceeds slowly by the mechanism which operates in pure quartz. Increasing the amount of mineraliser increases the amount of quartz converted in the initial period, but the rate of reaction in the final period is significantly lower.

If the mineraliser forms a liquid phase at the conversion temperature its influence becomes much more marked, because the area of contact with the quartz grains is increased by capillary action[100].

It should be noted that there is a significant difference between the temperatures of fast cristobalite formation of amorphous and of crystalline SiO_2. Thus, whereas Brazilian quartz is converted into cristobalite at temperatures of the order of 1500°, quartz glass and silicic acid gel convert even at 1200° (after 4–5 h).

This disparity between the crystallisation temperatures of crystalline and amorphous SiO_2 arises because bonds have to be broken in crystalline SiO_2 before cristobalite formation can occur, and the process is therefore more hindered and slower than crystallisation from the gel[83].

The transformation of quartz, quartz glass, or silicic acid gel proceeds with formation of an intermediate phase called metacristobalite[106–109]. Metacristobalite is rapidly converted into the stable cristobalite, but in the presence of the required concentration of alkali metal cations it is converted into tridymite. The reaction scheme is the following:

crystalline silica, quartz glass, silicic acid gel
↓
metacristobalite
↓
cristobalite

The density of metacristobalite is close to that of cristobalite, 2.30 g cm^{-3}, and is therefore identical to the density of the disordered phase formed by bombarding quartz with neutrons[97].

Chaklader and Roberts[110] have put forward a hypothetical scheme for the conversion of quartz into cristobalite, which was subsequently developed by Chaklader[76].

The high-temperature α-form of cristobalite changes to the low-temperature β-form on cooling, with an appreciable volume change.

It has been shown that the temperature of the $\alpha \rightleftharpoons \beta$ cristobalite transformation is a function of the thermal history of the sample, and usually lies[85,89] in the range 200–280°.

Cristobalite formed at relatively high temperatures also shows a higher transition temperature to the β-form. According to Flörke[70], the ideal cristobalite structure shows a threefold periodicity of layers of SiO_4 tetrahedra, which can be expressed as a structure of the type ABC | ABC | ABC. Cristobalite is often obtained in a different structure, including regions of twofold periodicity. This type of cristobalite has a lower $\alpha \rightleftharpoons \beta$ transition temperature.

The transition temperature can also show hysteresis, the transition from the high-temperature to the low-temperature form occurring 35° lower than the transition in the opposite direction[83].

VI. EFFECT OF IMPURITIES ON CRYSTALLISATION

The cristobalite formation process can be accelerated by a wide variety of foreign ions. The specific effect of alkali cations does not depend on the formation of a liquid phase, nor does it depend on their concentration, although it is now well established that the presence of a liquid phase can greatly activate the cristobalite formation process[63,64].

The transformation of quartz to cristobalite is induced by introducing cations into the quartz crystal lattice because the lattice is thereby deformed and the activation energy of the transformation is accordingly lowered. The deforming effect of the added ion is expected to increase with the ionic radius of the cation within any one group of the Periodic Table. Thus, the efficiency of K^+ towards cristobalite formation should be greater than that of Na^+ and that of Ba^{2+} should be greater than that of Sr^{2+}, Ca^{2+}, and Mg^{2+}, as has been experimentally confirmed.

Impurity ions also show different catalytic effects towards cristobalite formation in quartz glass, as was established by the systematic researches of Kainarskii, Degtyareva, and others. Kind and Makhlina studied the influence of various additives on the crystallisability of translucent fused quartz[105]. The impurities investigated were mainly oxides present in the sand as natural impurities, as well as some other oxides (B_2O_3, ZrO_2, P_2O_5). In every case it was found that alkali and alkaline-earth oxides had a negative influence, increasing in the sequence $Na_2O \rightarrow K_2O \rightarrow$ $\rightarrow CaO \rightarrow MgO$, and aluminium oxide had a positive influence. The crystallisability of the quartz samples was measured in a high-temperature gradient furnace in the region 1420–800°, for 24 h.

These measurements showed that practically all oxides, and the alkalis and alkaline earths in particular, increases the crystallisability of translucent fused quartz. The crystallisation of samples containing added Al_2O_3 was

unique: an addition of 0.05% inhibits the crystallisation, the effect increasing with concentration. The negative influence of the basic oxides and the positive influence of Al_2O_3 on the properties of translucent quartz glass are explained as follows. The ions of alkaline and alkaline-earth oxides are not glass-formers: they fill the voids in the three--dimensional network, thus altering and loosening the structure of the quartz glass and breaking Si–O bonds. Since very many defect sites are present, the viscosity of the glass in the softening temperature region decreases, and other properties also are affected.

The aluminium ion (Al^{3+}), having sixfold coordination, can behave as a glass-former under the right conditions and be incorporated in the three-dimensional glass network at a tetravalent SiO_2 site.

In this case one positive charge is lacking in order to satisfy the valence requirements: this can be provided, for example, by an Na ion. As a result, the points of attack created by the presence of Na ions in the quartz glass are neutralised. The Na ion is fixed in the vicinity of the aluminium ion without giving rise to a point of attack. The glass structure is stabilised, and the crystallisability is lowered. Beyond the optimum concentration the Al ion apparently remains in the six-fold coordination but behaves as a glass modifier rather than as a glass former. When Al_2O_3 is added to translucent fused quartz the coordination of the Al ion can change under certain conditions: this leads to neutralisation of the negative influence of alkali oxides.

According to Kainarskii and Degtyareva, the crystallisation of quartz glass is inhibited by the presence of 1.5% by weight of Al_2O_3,[64] whereas small additions of Al_2O_3 enhance the crystallisation.

VII. EFFECT OF ATMOSPHERE ON CRYSTALLISATION

The atmosphere used for heat treatment also plays an important part in the crystallisation process. Lipinski and Schwiete demonstrated the effect of different gaseous atmospheres during firing on the formation of cristobalite. Specially pure synthetic amorphous silica, containing no more than $2-3\times10^{-3}$% Na_2O, was investigated. The extent of crystallisation was measured at temperatures of 1200°, 1300°, 1400° in the following ambients: vacuum, air, N_2, O_2, Ar, CO_2, CO. The crystallisation was shown to be significantly retarded in a medium of Ar, N_2, or CO_2. For example, at 1200° in air crystallisation began after 2.5 h, but in an atmosphere of CO_2 the time needed was 32 h. At the same temperature, crystallisation is extremely slow in CO, CO_2, and Ar during the first 20–25 h, whereas it reaches 80% after 8 h in air[101].

The crystallisation of industrial quartz glass produced in the Soviet Union has been investigated. The samples were prepared from transparent vitreous mouldings which contained a large number of fine tapered channels due to the particular production technique. Crystallisation was induced at 1300° in an air atmosphere over a period of 10–15 h. A crystalline layer several tenths of a millimeter thick was obtained, and crystallisation occurred on the inner surfaces of the open channels as well as on the external surface of the sample, but not on the surfaces of the closed channels[104].

This observation is a clear illustration of the undeniable influence of atmosphere on the crystallisation of the glass.

In a vacuum of the order of 1×10^{-5} mmHg, however, crystallisation was not merely delayed but completely absent after 30–50 h treatment at 1300°. These experiments also provided ample indirect evidence that silica undergoes intensive dissociation in the region of its melting point, giving off free oxygen, so that the melt becomes oxygen-deficient and is partly reduced.

It was also established that glasses prepared by melting in high vacuum under identical conditions behave quite differently when subsequently heated in oxygen, nitrogen, hydrogen, and air. The role of oxygen and water vapour as the main activators of the crystallisation process was also confirmed.

The increase in weight during crystallisation, which can amount to 0.1%, can be taken as proof that the crystallisation process is indeed closely associated with chemical oxidation of the glass during conversion to cristobalite.

As a result of their experimental work, the authors came to the following conclusions.

The crystallisation of quartz glass is primarily a chemical process rather than a thermodynamic relaxation process. Crystallisation occurs when the glass gains enough oxygen to form the stoichiometrically much more perfect cristobalite. No crystallisation takes place unless the stoichiometric formula SiO_2 can be achieved by some method or other.

Fused quartz is a chemical compound of formula SiO_{2-x}, showing no tendency to crystallise under conditions which allow the retention of this non-stoichiometric composition.

The discrepancy between Lipinski and Schwiete's results for vacuum heat treatment and those of Boganov and coworkers must be stressed.

Whereas Boganov et al.[104] reported that cristobalite formation was completely suppressed, the other investigators found that crystallisation in a vacuum was even more marked than in air, but the quality of their vacuum was not stated.

The crystallisation process is affected also by a number of technological factors. Botvinkin and Zaporozhskii have described an investigation of pure quartz glass (containing $1-2\times10^{-2}$% of impurities) prepared by different methods (high-frequency, vacuum compression, and oxy--hydrogen)[3].

The first crystals visible under the microscope appeared on the surface of the gas-melted glass after 72 h heating at 1350°, whereas with glass samples prepared in contact with graphite (high-frequency and vacuum compression method) crystals first appeared after 2–2.5 h at the same temperature. Thus, the rate of generation of crystallisation centres is approximately 30–35 times smaller for the electrically melted glass than for the gas-melted glass.

It should be noted that the crystallisation conditions of pure amorphous or crystalline SiO_2 cannot be the same as those of quartz ceramics, because crystallisation can be speeded up by the porosity and the high degree of dispersity of the starting materials.

VIII. SINTERING AND ANNEALING

Sintering of quartz ceramics prepared from pure silica materials proceeds without the appearance of a liquid phase. In the presence of impurities, however, whether deliber-

ately added or already present in the material, a liquid phase can be formed. The sintering mechanism of quartz ceramics can be visualised as viscous flow and volume diffusion.

According to Frenkel'[111], solid-phase sintering occurs by "viscous flow", and can be resolved in time into two phases: (1) the coalescence of particles, leading to the disappearance of open pores (cavities) and to the formation of disconnected closed pores of various shapes (spherical in the simplest model); (2) the shrinkage of closed pores under the influence of surface tension forces.

The first stage of the process proceeds at a constant rate, depending only on the surface tension and on the viscosity of the medium surrounding the pore:

$$\frac{da}{d\tau} = \frac{3}{4} \times \frac{\sigma}{\mu},$$

where a is the radius of the pore, σ is the surface tension, τ is time, and μ is the viscosity coefficient at the given temperature.

During the second stage the rate of the process decreases continuously because of the retarding effect of the gas trapped in the pores. The theory of Frenkel' does not take account, however, of a number of special features of the sintering process in real powdery bodies, such as the wide variety of particle size, the presence of pores of different sizes, etc.

Pines has shown[112,113] that these factors are of major importance in the sintering process. In particular, powdery bodies of different particle size sinter in different ways.

Following Pines and other workers we may assume that the sintering of a real powdery body results primarily from bulk diffusion, but also partly from surface diffusion. The mechanism of sintering in the absence of a liquid phase thus amounts to redistribution of the material in the body by directed self-diffusion. Interesting discussions of the sintering process can be found also in the papers by Kuczyński, Kingery, Coble, and Johnson and Cutler[114-117].

When considering the sintering of amorphous or crystalline SiO_2 one should first of all take into account the allotropic transformations of the compound, which are ignored by all the existing theories of sintering. Data showing the appreciable effect of these factors are available.

Nishanova and coworkers[35] have studied the sintering of a quartz glass ceramic containing a fairly high concentration of impurities (99.44% SiO_2). Their samples were prepared by pressing at 800 kg cm^{-2} powder from a vibro-mill having a specific surface area of 3100–9800 cm^2 g^{-1}. The bulk density of the samples before firing was 1.41–1.44 g cm^{-3}, their porosity was 34.5–36%. Annealing was carried out in a Silit furnace and in a gas-fired furnace. The results are summarised in Table 2.

The samples annealed in the gas-fired furnace gave somewhat different results, which confirms the influence of the gaseous medium.

Thus, the maximum strength was observed at 1250°, and further increase led to crystallisation. Somewhat greater densities and linear shrinkage factors were obtained in the gas-fired furnace.

The same workers also heat treated samples prepared by slip casting from a mass containing a granular filler. The filler, of fused quartz, included 0.25–0.5 and 0.5–

TABLE 2. Influence of degree of comminution of the powder and of firing temperature in a Silit furnace on the sintering and crystallisation of specimens.

Specific surface area, cm^2 g^{-1}	Firing temperature, °C	Linear shrinkage, %	Density, g cm^{-3}	Apparent porosity, %	Strength under compression, kg cm^{-2}	Flexural strength, kg cm^{-2}	Cristobalite content, %

	1350	9.2	1.88	16.8	—	117	63

1 mm fractions, and accounted for 30–50% of the total. Under these conditions the strength under compression reached 460 kg cm^{-2}. Summarising the findings of this paper, we note the rather low mechanical strength both under bending (up to 270 kg cm^{-2}) and under compression (up to 1490 kg cm^{-2}), due no doubt to low initial density and to the rather coarse size distribution.

Popil'skii and Nishanova[42] also investigated the sintering of pressed specimens (5 × 5 × 50 mm) under a specific pressure of 800 kg cm^{-2}. The starting material was translucent quartz glass (99.9% SiO_2). Grinding was done in a vibro-mill (dry method) or in ball mill (wet method) to a specific surface area of 10 000 cm^2 g^{-1}.

Sintering was continued for 2 h at temperatures of 1100°, 1150°, 1200°, 1250°, and 1300°. All the fired specimens showed high porosity, relatively low strength, and in most cases a linear thermal expansion coefficient higher than that of silica glass.

The authors concluded that samples prepared from wet-milled quartz glass (whether transparent or translucent) exhibit slow sintering and crystallisation, but they were unable to explain this effect. They also reported that 0.15% iron contamination has no particular influence on sintering and crystallisation.

From the results set out in Table 3, summarising the measurements of sintering, crystallisation, and strength on specimens made from all the starting material examined, we may conclude as follows.

TABLE 3.

Paste No.	Treatment of starting material	Porosity, % at cristobalite temperatures, °C					Coefficient of thermal expansion $10^6\ \alpha_{mean}$ in the range 20–400 (% in brackets) at cristobalite temperatures, °C					Flexural strength, kg cm^{-2} at cristobalite temperatures, °C

6	Wet mill, washed	35.8	35.8	34.2	29.5	16.0	0.54	0.54	0.54	0.54	6.29	—	—	30	140	260

If we scrutinise the results from the standpoint of a minimum coefficient of thermal expansion, we note that specimens with a low expansion coefficient (0.54×10^{-6}) show a porosity of 31.5–45.9% (for transparent quartz glass as the starting material) or 32.4–34.2% (for translucent quartz glass); the strength under bending varies from 30 to 165 kg cm^{-2} and from 30 to 180 kg cm^{-2} for the two cases respectively.

If maximum mechanical strength is the criterion, specimens made from sintered transparent quartz glass and having a strength of 305–310 kg cm^{-2} exhibit a thermal expansion coefficient between 1.01×10^{-6} and 1.42×10^{-6}, i.e. higher than the expansion of fused quartz glass by a factor of 2–3; the porosity under these conditions is 16–33%. The corresponding values for specimens from translucent quartz glass of strength 260–340 kg cm^{-2} are $6.29 \times \times 10^{-6}$–$0.72 \times 10^{-6}$; the porosity is 16–22%.

Therefore, the results are unsatisfactory as regards optimising this set of properties in specimens made by any particular regime. Thus, the thermal stability (an essential property of this material) falls off as the thermal expansion increases. However, the low mechanical strength and the high porosity of samples having a low thermal expansion can impair the thermal stability and also various other properties.

Walton showed that the mechanical strength of quartz ceramics is raised by a small amount of cristobalite formed during firing (Fig. 6). He suggests that very small particles begin to crystallise during firing, and are converted into cristobalite. Since these fine particles are distributed throughout the bulk, a very intimate binder of cristobalite is formed and causes incipient sintering during the firing operation: in other words, cristobalite appears between the coarser grains of the remaining fused quartz and acts as a binder for these grains.

However, in view of the higher sintering temperature of cristobalite, the suggestion that sintering of this material can occur at 1250° is unconvincing.

It may be thought that a small amount of cristobalite surrounded by a mass of amorphous quartz will not raise the thermal expansion coefficient to the value calculated by assuming additive behaviour, because the expansion of the microscopic cristobalite centres can be checked by the substrate.

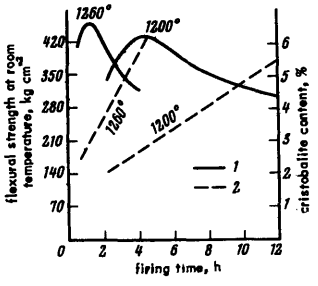

Fig. 6. Variation of the strength of a quartz ceramic with firing time and with cristobalite content:
1) limiting flexural strength; 2) cristobalite content.

A method of producing quartz ceramics from fused quartz has been patented[37], which prevents the formation of cristobalite by the addition of finely divided B_2O_3 to the starting composition, in conjunction with a protective gas atmosphere during sintering.

The amount of B_2O_3 added as a fine powder (up to 2–4 μm particle size) should be at least 1.2% of the weight of SiO_2; the mass to be formed is then prepared by a standard method. Firing must be done in a tightly sealed capsule or in a medium of quartz sand to prevent direct access of furnace gases. The firing temperature can be higher than the normal firing temperatures for quartz ceramics (up to 1350°). The firing time is 30 min. Sintering in a hydrogen atmosphere or in an atmosphere containing vapours of boron compounds produces good results.

Water vapour has been shown[47] to have a distinctly beneficial effect on the sintering of quartz ceramics. However, since water vapour also catalyses the crystallisation of amorphous SiO_2, the onset of cristobalite formation is lowered to 865° by water vapour[101].

The sintering of quartz ceramics to high relative densities without degrading the properties of the articles obtained is complicated by the devitrification phenomena leading to cristobalite formation discussed above. This accounts for the rather high porosity of quartz ceramics, which has an unfavourable effect on the properties. According to published data, the porosity of quartz ceramics varies between 10 and 30%.

To achieve high levels of sintering it is essential to take account of factors such as the density and particle size distribution of the preparation. Under otherwise similar conditions, a denser raw material and a finer granular composition lead to faster sintering at a given temperature. The variation of porosity and density after firing with the density and the porosity of the raw material is illustrated in Fig. 4.

The present writers[45] have demonstrated the profound effect of the state of comminution of the starting material on the sintering of fused-quartz ceramics. Fig. 7 shows the variation of the apparent porosity of specimens made by slip casting at firing temperatures of 1200° and 1250° with firing time, for different mean surface diameters d_{mean} of the particles (calculated by the formula given in Section III of this paper).

We have also shown[45] that a quartz-glass ceramic with zero apparent porosity can, in principle, be prepared, and that the strength and thermal expansion coefficient of this

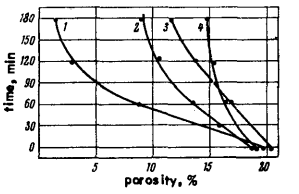

Fig. 7. Variation of apparent porosity with firing temperature and time and mean particle size:
1) firing temperature 1250°, d_{mean} 1 μm;
2) firing temperature 1250°, d_{mean} 2.5 μm;
3) firing temperature 1200°, d_{mean} 1 μm;
4) firing temperature 1200°, d_{mean} 2.5 μm.

material are close to those of quartz glass. The necessary conditions are: small particle size (60–70% of the particles below 5 μm), a very dense starting material (12–15% porosity), and firing at 1300–1450° for times varying from 1.5–2 h to 10–15 min according to the temperature.

The sintering of crystalline silica also is of interest. Dietz and Schulle[17] have investigated the sintering of quartz and cristobalite powders as a function of purity, particle size, temperature, and time. Pure cristobalite was obtained by firing powdered rock crystal at 1530° for 5 h. Specimens of the moistened powders were pressed at 1300 kg cm^{-2}. Quartz began to sinter at 1250°, as shown by an increase in strength and density.

Above 1450° a loss of strength was observed, and this was ascribed to the conversion of quartz into cristobalite. Cristobalite begins to sinter at temperatures beyond 1450°, but the effect of sintering on cristobalite is less marked than on quartz.

The sintering of siliceous materials proceeds in the solid phase, and the formation of a liquid phase as a result of the presence of impurities is of secondary importance. Dietz and Schulle[17] explain the densification and the increase in strength of the quartz by invoking an intermediate amorphous phase, formed during the transition of quartz to cristobalite induced by the mineralising effect of impurities. But this cannot account for the sintering of cristobalite, because no intermediate phase is formed in this modification of silica. The possibility of diffusion processes influencing the sintering of quartz and cristobalite is not excluded.

According to other workers[118], the decrease in porosity and the binding of quartz particles begins at 1580°, and sintering begins at 1605°. At 1620–1660° sintering is fast, and the pores between particles disappear. At 1660° the quartz crystals are converted into optically active cristobalite.

Chaklader and Roberts[110] examined specimens of pure (99.96% SiO_2) quartz, and observed intensive sintering during the first few hours' heating at 1500–1570°, followed by a loosening of the structure. Fig. 8 shows the strength under compression as a function of the time of heat treatment at 1570°. The loss of strength is due to the cristobalite transition undergone by the specimens. The authors suggest the following sintering mechanisms: surface or bulk diffusion, plastic flow, evaporation, or condensation. Sintering apparently occurs through a disordered surface layer on grains formed at high temperatures. Appreciable sintering is observed as soon as the transition phase is formed.

The sharp decrease in strength of the sintered specimens is explained by the formation of significant amounts of cristobalite, which does not sinter at these temperatures. The sintering process is explained by a mechanism involving the transformation of quartz into cristobalite. The expansion observed in the early stages of firing is the result of the conversion of quartz (density 2.65 g cm^{-3}) into a transition phase (2.30 g cm^{-3}) which is amorphous and has vitreous properties.

As soon as a thin layer of the transition phase is formed on the surface of the quartz particles, these particles tend to coalesce, and the strength accordingly increases. The shrinkage is due to the transfer of material to the pore volume. Necks are formed at the points of contact between particles under the influence of capillarity forces.

B: 1) quartz; 2) cristobalite; 3) intermediate phase.

A critical survey of available data on the sintering of crystalline silica, fused quartz, and amorphous synthetic silica leads to the following general propositions.

The occurrence of sintering and the sintering temperature are invariably associated with incipient crystallisation. The lower the temperature at which crystallisation of any particular form of silica begins, the lower will be the temperature of incipient sintering. There is also evidence that intense sintering occurs during the period immediately prior to crystallisation, i.e. during the stage of formation of metacristobalite. We have shown[45] that the specific gravity of a densely sintered ceramic made from fused quartz is often slightly higher than that of fused quartz (2.21 g cm^{-3}), suggesting partial conversion into metacristobalite not involving appreciable degradation of the properties. The method of formation and the pretreatment of the material also have an undeniable effect on the onset and on the kinetics of the sintering process.

In order to achieve higher densities in a ceramic based on fused quartz without at the same time causing the formation of cristobalite it is desirable to use finely milled powders. In this way the rate of sintering is increased more than the rate of onset of crystallisation. Conversely, coarser granular compositions retard the onset of crystallisation, but since sintering is very slow and much longer firing times are needed the amount of crystallisation is relatively large.

The initial density of the raw material plays an important part in quartz ceramics, high initial densities allowing extremely dense materials to be produced.

When specifying the firing schedule of an article it is important first of all to consider the possibility of cristobalite formation. The initial particle size distribution and the presence of impurities are also extremely important.

Fig. 9 summarises our results[45] on the effect of time and temperature on the onset of cristobalite formation for specimens prepared by slip casting from fused quartz containing 99.9% of SiO_2.

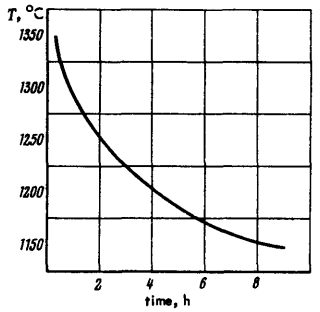

Fig. 9. Variation of the onset of crystallisation with temperature and time.

The maximum firing temperature is 1650–1680° for articles made from quartz sand, and 1250–1300° for articles made from fused quartz, The time of treatment at the maximum temperature is usually 1 h, but equally good results can be obtained for shorter times at higher temperatures.

Schulle and Ulbricht[24] have described the following firing schedule for articles made by slip casting from quartz sand. The specimens were heated at 1000° for 3 h in a Silit furnace before being subjected to the required firing temperature (1680°). After the prescribed firing time the specimens were removed from the furnace and placed in a cooling oven set at 900°, in which they were allowed to cool to room temperature.

Fleming[20] considers that 4 h at 1200° is sufficient for relatively small articles made of fused quartz, whereas larger articles need 1 h at 1260°.

The shrinkage during firing depends on the porosity of the starting preparation and on the maximum temperature and time of heat treatment, and is usually in the range 0.5–5%. With large articles there is a possibility of distortion of the lower parts.

IX. SURFACE IMPREGNATION AND SEALING

Quartz ceramics offer good electrical properties, similar to those of quartz glass. However, the unavoidable porosity associated with the conventional ceramic production techniques has an appreciable effect on the electrical properties. Furthermore, quartz ceramics have inadequate moisture resistance. In a number of applications both high density (absence of porosity) and moisture resistance are essential. However, the achievement of adequate density by sintering is made difficult by the cristobalite transformation discussed above.

In this connection, the following methods for achieving the required properties have been proposed: impregnation, glazing, surface melting, and hydrophobic coatings[31-33]. Impregnation consists, essentially, of soaking the fired porous article in a solution which can fill the pore volume and subsequent deposition of a solid phase from the solution. The rate, uniformity, and completeness of the soaking treatment depend on a number of factors: the magnitude of the surface tension at the interface between the impregnating solution and the body, the size and shape of the pores in the sintered article, and the viscosity of the penetrating solution.

The impregnation method has already been used in practice for powder-metallurgy articles. For example, porous sintered iron or steel is usually impregnated with various metals and alloys, mostly based on copper. In this application the sintered articles must be impregnated with much more fusible metals.

In the preparation of ceramic materials impregnation problems have attracted little attention so far, and the work discussed below is based exclusively on laboratory data[24,31-33].

The theoretical foundations of impregnation have been developed by Deryagin[119]. The basic postulates of his theory are essentially the following.

Let an element of the impregnation front move to a new position in a given time, filling a pore volume ΔV with a wall surface of ΔS:

$$p\,\Delta V = A\,\Delta S,$$

where p is the pressure drop across the layer l of impregnated volume due to the internal friction of the liquid and A is the specific work of wetting. Then,

$$l = k\frac{\Sigma}{\delta^2}\sigma\cos\theta,$$

where l is the thickness of the impregnated layer, k is the filtration coefficient, δ is the fractional pore volume, Σ is the specific surface area of the impregnated body, σ is the surface tension of the liquid, θ is the limiting contact angle.

Impregnation is carried out after a preliminary heat treatment, and is followed by drying and firing. The best results are obtained in practice by impregnating with true solutions of inorganic materials. Colloidally disperse silica does not give good results because of the very small pore diameter of quartz ceramics, which acts as a filter and removes the most finely dispersed colloids after a thin layer has been impregnated. Impregnation is achieved by using hydrolysed ethyl silicate: the concentration is adjusted so that the silica is held in solution low enough to ensure complete impregnation of the ceramic, whereupon the ethyl silicate forms a gel which deposits SiO_2 in the pores.

However, since these gels are aqueous, some residual porosity is unavoidable to allow the passage of the dehydration products during firing, and the method allows the porosity to be decreased but not completely eliminated.

When the porosity of the original ceramic is high, impregnation affords a significant improvement in strength and decrease in porosity[24].

As the porosity of the ceramic decreases, impregnation becomes slower. An aqueous solution of aluminium chloride has been examined as a possible impregnating agent[33]. Aluminium hydroxide was precipitated in the pores of the quartz ceramic by altering the pH. This material reacts with silica during sintering, forming mullite. However, since mullite is formed at temperatures above the crystallisation temperature of quartz ceramics, we are faced with the problem of avoiding the conversion of fused quartz into cristobalite and yet producing mullite, which can be sintered sufficiently to eliminate the porosity.

Glazing of quartz ceramics is difficult because of the very low thermal expansion coefficient of the material, which necessitates a glaze having either zero or a small negative thermal expansion coefficient.

Glazes of materials such as spodumene and petalite, which satisfy these requirements, have a flow temperature higher than the crystallisation temperature of quartz ceramics, and cannot be applied by ordinary methods. However, the glazes can be deposited by flame-spraying whilst retaining their low or negative thermal expansion coefficient. Surface sealing can be achieved also by fusing the surface layer of the glass ceramic with a plasma torch.

Both glazing and surface melting must be carried out whilst heating the ceramic to 1000–1100° to avoid large thermal stresses, and the article must then be annealed.

Hydrophobic coatings which are fired in flight by the temperature rise can be used for sealing antenna fairings [31].

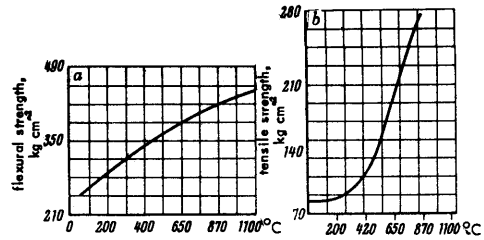

Fig. 11. Effect of temperature on the mechanical strength of quartz ceramics:
(*a*) flexural strength; (*b*) tensile strength.

X. PROPERTIES AND APPLICATIONS OF QUARTZ CERAMICS

Quartz ceramics made from fused quartz possess many of the valuable properties of the starting material: a low coefficient of thermal expansion, good high-temperature stability, good electrical parameters, high chemical stability. However, quartz ceramics also exhibit some properties which are not present in fused quartz (quartz glass). Unlike quartz glass, whose thermal conductivity rises quite significantly with temperature, quartz ceramics and quartz ceramic foams have a constant and fairly low thermal conductivity over the temperature range up to 1100°. As Fig. 10 shows, the thermal conductivity of quartz glass at 500° is approximately 5 times higher than that of quartz ceramics and 20 times higher than that of quartz foam.

A steep rise in the thermal conductivity of quartz ceramics is observed in the temperature region above 1100°, due to the formation of cristobalite. Furthermore, devitrified quartz glass breaks down on cooling, whereas the ceramic can retain its shape. A special feature of quartz ceramics in comparison with other types of ceramic is the increase of tensile and flexural strength with temperature, evidently associated with an increased plasticity and a lower brittleness [18,52]. The increase in strength is quite significant: as Fig. 11 shows, the strength under bending is much higher at 1100°. [18]

Another distinguishing feature of quartz ceramics as compared with other ceramic materials is their much smaller shrinkage both on drying (0.1–0.5%) and on firing.

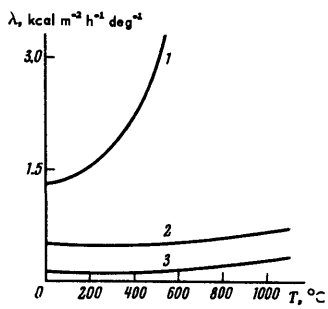

Fig. 10. Temperature dependence of thermal conductivity:
(1) transparent quartz glass, (2) quartz ceramic, and (3) quartz foam.

The main structural difference between quartz ceramics and quartz glass lies in their porosity, from which stem all the other differences in mechanical as well as electrical properties.

The influence of porosity on the mechanical, thermal, and dielectric properties of quartz ceramics has been investigated [46]. Specimens prepared by slip casting, hot pressing, and spray coating were divided into four groups: low (25–40%), intermediate (30–70%), high (85–90%), and very high (90–100%) density as compared with the theoretical density. It was shown that the properties of the ceramic depend on the type of raw material and on the method of preparation as well as on the pore volume, with the exception of the dielectric properties, which are determined exclusively by the porosity. The strength is as much a function of the method of forming as of the porosity.

The porosity of quartz ceramics is responsible for the low thermal conductivity of these materials, for their low mechanical strength (relative to that of quartz glass), and for the slight difference in electrical resistance. The ceramic, unlike quartz glass, is not transparent (having a white colour), and has a lower specific gravity. However, when the porosity is minimised (to the 1–2% level) the basic properties of the ceramic become almost identical to those of the glass.

Quartz ceramics have some advantages over other materials which have been considered for use in missile cones. Their dielectric constant at 10^{10} Hz should not vary by more than ±5% between room temperature and the maximum, and the tangent of the dielectric loss angle under these conditions should be less than 0.01. [31]

Of the three materials: quartz ceramic, corundum ceramic, and Pyroceram 9606, a ceramic made from fused quartz satisfies these requirements most fully [31,52].

Furthermore, rocket cones made by slip casting from fused quartz are much cheaper to produce [52] than those made from Pyroceram or Al_2O_3. Their flexural strength increases with temperature (by 33% at 1100°), as compared with a 67% decrease for Al_2O_3 and a 25% decrease for Pyroceram [52]. It has even been suggested [33] that articles can be made more cheaply in quartz ceramics than in fused quartz. Porous quartz insulators are used also in radar installations.

Many fields of application require high thermal stability, constancy of dimensions, low thermal conductivity, and other important properties: quartz ceramics satisfy these requirements fully. Quartz ceramics can be used in the newer technological areas, such as missile and nuclear technology, and also as general purpose refractories.

The devitrification of quartz ceramics at temperatures above 1100° does not exclude the use of these materials at the higher temperatures: the permissible concentration of cristobalite is determined by the specific conditions of use of the article. An important consideration is the duration of the exposure to the maximum temperature. Studies of the suitability of quartz ceramics for thermal shielding systems and for the manufacture of aircraft components have shown that quartz ceramics are the most promising material for these purposes. Among the articles which could be manufactured from quartz ceramics the following are listed: front flanges and nose cones for rockets, antenna fairings, nozzles for rocket engines, etc. In addition to their excellent dielectric properties, quartz ceramics offer a high thermal stability and low thermal conductivity, which make them suitable for these applications [31-33].

A rocket cone 61 cm in diameter and 1.22 m high has been made by slip casting. Its wall thickness was so uniform that no further mechanical operations were needed [36].

When a missile re-enters the denser layers of the atmosphere the temperature rises well above the melting point of quartz, and can reach 2500°. However, since the passage through the dense layers is of short duration, and the material has a high viscosity, the rate of wear of the nose cone is only ~0.025 mm s^{-1}.

The nose cone of the U. S. Titan intercontinental ballistic missile is an example of the use of quartz ceramics in space technology [49].

Quartz foam, which is used as a heat shield, is a very promising material for applications in aerospace technology [43,44]. In order to increase its mechanical strength, quartz foam is impregnated with organic resins [44].

Heat shields are also used for the nose cones of rockets in order to give reliable protection to the electronic systems against heat and radiation during passage through the dense layers of the atmosphere [29]. Rare-earth elements or their oxides are added to the fused quartz. The most favoured is gadolinium, or the other rare-earth elements with similar properties (La, Ce, Pr, Nd, Eu, Tb, Er, etc.). The concentration of the additive is kept between 0.1 and 10%. and this determines many of the properties of the shield. When nuclear radiation is present gadolinium is to be preferred, because it has the property of absorbing radiation. Without the addition of rare-earth elements, infrared radiation and heat are readily transmitted from the outer surface of the quartz layer to the inner regions when the nose cone is subjected to heating. However, the rare-earth elements cause absorption and back radiation from the outer layers of the nose cone.

In order to assess the properties of quartz ceramics, their ablation properties have been evaluated with an electric arc whose temperature was stabilised with air or water [32]. The specimen used for the test was cylindrical, with one hemispherical end. The rate of ablation was assessed by monitoring the rate of decrease in the length of the specimen whilst the arc discharge was applied. The experimental results and the working parameters of the test are summarised in Table 4.

Foamed quartz ceramics make high-grade reflectors of infrared radiation. This is because the outer layer of the quartz foam reaches a high temperature almost as soon as the lamps are energised and generates energy which is absorbed as infrared radiation. Furthermore, the underlying layers of the quartz foam greatly obstruct the transmission of infrared rays.

TABLE 4. Ablation data for quartz ceramics, obtained by plasma torch spraying.

Type of arc	Air stabilised	Water stabilised
Power, kW	100	60
Specimen diameter, mm	12.7	19
Gas velocity	Mach 2.5	100–1000 m s^{-1}
Duration of test, s	25	20
Ablation, cm	1.2	0.78
Rate of ablation, cm s^{-1}	0.048	0.039

Quartz ceramics are used in the manufacture of electrical insulators and of fairings for radar aerials. Ceramic insulators of any shape can be made by slip casting. After firing, these are impregnated with a synthetic resin or lacquer to eliminate the porosity.

Fig. 12 shows the temperature variation of electrical resistance of ceramic specimens, both with and without silicone varnish impregnation, as well as tan α and ϵ.

To test the possibility of using quartz ceramics as insulators in high-temperature nuclear reactors, a series of quartz rods was cast and fired at 1380° for 48 h in order to form cristobalite [19,33]. Another batch of rods, earmarked for studying the influence of neutron irradiation on the strength of quartz ceramics, was fired at 1260° for 1 h.

The quartz ceramic specimens were irradiated in an experimental reactor with a neutron flux of energy 816 mV r. Complete collapse of the cristobalite structure to the amorphous state was observed at a dose of about 4×10^{20} neutrons cm^{-2} s^{-1}. No permanent changes in flexural strength were noted in any of the irradiated specimens.

Fused quartz does not undergo changes under the influence of nuclear radiation, and has a small capture cross-section for thermal neutrons: this is why the material is used for containers in experiments involving radiation.

Irradiation with a dose of $\sim 2 \times 10^{20}$ neutrons cm^{-2} s^{-1} has little effect on the strength of quartz ceramics, which varies within the range ±10%.

The possibility of using a ceramic made from fused quartz in the atomic energy industry as a medium for fuel elements in the SiO_2–UO_2 system has been investigated. It

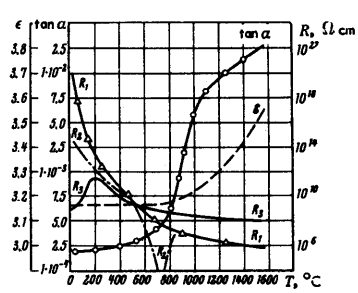

Fig. 12. Temperature dependence of the electrical resistance of quartz glass (R_1), impregnated (R_2), and non-impregnated (R_3) quartz ceramics, of the tangent of the dielectric loss angle (tan α), and of the dielectric constant (ϵ) of quartz ceramics.

was shown that these materials satisfactorily retain the gaseous fission products and are highly stable towards the breakdown caused by the recoil of fission products[19]. Quartz bodies prepared by casting and quartz foam should find widespread use as materials for thermal insulation in nuclear reactors.

The following applications may be quoted as examples of the use of quartz ceramics as refractories: dies for hot pressing, fixtures for rigidly welding cellular constructions of stainless steel, pipes for conveying molten aluminium, etc.

One of the applications of quartz ceramics is the monolithic lining of boilers: high-grade refractories were previously used for this purpose, but their life was limited to three months by temperature drops and by mechanical vibrations[33], whereas linings of quartz ceramic give service for upwards of two years. Another example of the use of quartz ceramics is in the lining of roasting kilns. Panels 122 × 152 × 15 cm in size were cast from a mass made from fused quartz, and used in the kiln assembly after being dried but in the unfired condition. The performance after one year's use of the kiln was satisfactory, although the temperature drop from the hot to the cold side of the blocks was of the order of 1000°.

Ceramic foam has been used for lining crucible furnaces for melting aluminium, with a resulting fuel saving of 50–60% as compared with the conventional refractory lining[33].

Quartz ceramics can be successfully applied to the production of casting moulds for repeated use[20,21]. To investigate the effect of devitrification, an iron melt was cast into a mould made of quartz ceramic (from fused quartz) and allowed to solidify completely. After 12 such cycles, no sign of crystallisation was observed in the material. It was also found that if the first cycle did not induce the onset of devitrification, the subsequent cycles also failed to bring it about.

TABLE 5. Properties of quartz glass, quartz ceramic, and foamed quartz ceramic.

Parameters	Quartz glass	Quartz ceramic	Foamed quartz ceramic
Density at 20°, g cm^{-3}	2.21	1.82–2.15	0.4–0.7
Overall porosity, %	0	1–20	50–60
Limiting strength at 20°, kg cm^{-2}			
crushing	5000–10 000	2500–5000	500–700
flexural	700–800	200–600	14–35
tensile	230–400	140–210	—
Limiting strength under impact bending, kg cm^{-2}	0.85–1.0	0.8–1.8	—
Thermal expansion coefficient, deg^{-1}, × 10^6	0.54	0.54	0.54
Thermal conductivity, kcal h^{-1} deg^{-1}			
at 0°	1.0–1.2	0.5	0.1
at 1200°	—	0.8	0.5
Specific heat, cal g^{-1} deg^{-1}, × 10^3 at 0°	200	200	—
Softening temperature under a load of 2 kg cm^{-2}, °C	1250	1250	1250
Dielectric constant			
at 20°	3.7	3.2–3.6	—
at 1000°	—	3.3–3.7	—
Tangent of the dielectric loss angle in the frequency range 30 kHz–10 MHz			
at 20°	6×10^{-4}	2×10^{-4}	
at 800°	6.7×10^{-4}	6×10^{-4}	
at 1200°	8×10^{-2}	8×10^{-2}	
Total linear shrinkage after drying and firing, %		1–6	1–6
Microscopic absorption cross-section for thermal neutrons at 2200 m s^{-1}	—	0.26	—
Macroscopic absorption cross-section for thermal neutrons at 2200 m s^{-1}	—	0.057	—
Relative slowing down	—	1.29	—

In another experiment one size of a quartz ceramic block was exposed to a high furnace temperature whilst the other side remained cold: the hot side crystallised at 1090°, but the crystallised regions were firmly bound by the uncrystallised substrate, as shown by a vibration test[31].

The main properties of quartz glass, quartz ceramics, and quartz ceramic foam are listed in Table 5.

---o0o---

Quartz ceramics can be manufactured by slip casting, slip foaming, hot pressing, semi-dry pressing, and various other methods from fused quartz, synthetic amorphous silica, and quartz sand.

Devitrification of the articles, which occurs at the maximum firing temperatures, can impair the thermal stability if it reaches appreciable proportions; however, by choosing the most appropriate firing schedules, the formation of cristobalite can be avoided or limited to low amounts.

The property of quartz ceramics which distinguishes them from other types of ceramic is their low coefficient of thermal expansion and their unusually high thermal stability. Compared with quartz glass, quartz ceramics have a significantly lower thermal conductivity (especially at high temperatures), and they do not break up as a result of cristobalite formation.

Quartz ceramics may find wide applications in the heat-resisting members of missiles, in nuclear technology, in the chemical and metallurgical industry, and as general purpose refractories.

Some specific features of the production of quartz ceramics must be pointed out. Devitrification during sintering is a complicating factor in the production of a densely sintered ceramic. It is therefore desirable to start from specially prepared fused quartz, which has a lesser tendency to form cristobalite (gas melting, avoidance of impurities conducive to crystallisation, etc.). It is important to maximise the density of the stock in order to assist sintering. Increasing the density of the ceramic can improve the physical and electrical properties of these materials very considerably.

Doping the quartz with rare-earth elements offers interesting possibilities because these elements can improve many of the properties of quartz.

STUDIES OF POLYMER SOLUTIONS CARRIED OUT IN POLAND

E. Turska

The field of studies on polymer solutions is very extensive and covers a wide range of varied problems. Such studies may be carried out with various aims in view — to define the properties of the solutions, or to characterise the macromolecules themselves from the properties of the solutions. Because of the variety of problems raised it is not possible to cover completely all work on the study of polymer solutions.

In order that the material presented shall be treated as fully as possible we shall consider only two questions, namely the determination of molecular weight and the study of polydispersity. We shall also examine some interesting papers on the hydrodynamics of solutions, and certain others.

In Polish literature on molecular weight determination, problems of practical importance arouse greatest interest. These papers generally describe experimental studies. The number of theoretical papers on this problem is much smaller.

Most attention has been paid to viscometric studies, and second place, as far as number of papers is concerned, is taken by work on procedures using the ultracentrifuge.

Papers on the determination and calculation of average molecular weight by osmometric and cryoscopic methods and from terminal groups are fairly numerous. There are fewer papers on light scattering by polymer solutions, and they have begun to appear only recently. There are also some papers which discuss the possible use of procedures which have not yet found such extensive application as those noted earlier.

The viscometric method, which requires simple apparatus, is the most convenient method for determining the molecular weight of polymers. It is becoming the most commonly used method of control in industry. The interest of Polish authors in this method is determined to a considerable extent by the practical approach.

Among the large number of papers in this field, mention may be made of the comparatively early determinations, the first to appear in the scientific literature, of the viscometric relationships for polyethylene terephthalate[1]. Tursa and Skwarski determined the molecular weights of a number of low-polymer polyterephthalate fractions by a cryoscopic method and, with the aid of viscometric data, they calculated the constants of the Mark–Houwink equation for the system studied.

Among recent work, mention may be made of a paper by Nadziakiewicz and Jedlińska[2] of the Lodz Synthetic Fibres Institute, devoted to methods of determining the degree of polymerisation of cellulose in solvents in which it does not undergo degradation under the influence of atmospheric oxygen. On the basis of published data and their own studies, they concluded that ethylenediaminecadmium hydroxide has a number of advantages as a solvent for cellulose. Overcoming difficulties in the procedure, associated with the low solubility of some forms of cellulose, the authors confirmed that the viscosity of the solution is linearly dependent on the degree of polymerisation in the range studied, and derived the viscometric equation.

Several other papers[3,4] have been devoted to studies of the dependence of the viscosity of solutions of cellulose in other solvents on the degree of polymerisation.

The viscosity of solutions of other polymers was studied by Kryszewski[5], Skwarski[6], Orszagh[7], Łaszkiewicz[8], and others.

Problems new to the scientific literature in this field were raised by Połowiński[9,10] of the Physical Chemistry of Polymers Faculty in Lodz Polytechnical Institute. Poło-

winski studied the dependence of the viscosity of solutions of graft copolymers on their molecular weight, carrying out the experiments using graft copolymers with accurately determined molecular structure. He suggested that when the solvents used are "good" solvents for the polymers present in the copolymers, the viscometric data can be explained on the basis of the theory of the viscosity of solutions of branched polymers, developed by Berry and Orofino. The premise adopted was confirmed experimentally.

Among these papers mentioned briefly, particular attention may be drawn to several devoted to the development of apparatus. These include papers on viscometers with replaceable capillaries[11], air-tight seals[12], and electronic control of the duration of flow of liquid, giving very high accuracy in the measurements[13], and modifications of a viscometer[14] in which dilution of the solution is carried out.

In addition to these papers, dealing directly or indirectly with the viscometric determination of the molecular weights of polymers, there is a fairly large number of papers describing studies of the viscosity of polymer solutions from another viewpoint. Because of space limitations, we merely cite these papers without giving details[15-31].

Studies using the ultracentrifuge to determine the molecular weight of polymers and the determination of polydispersity by sedimentation analysis have been carried out in Poland in only one research institute, namely the Scientific Research Institute of the "Oświęcim" Chemical Plant. Some papers have been devoted to a discussion of the applicability of the equations derived by various authors, particularly the Flory–Mandelkern equation, for the determination of molecular weights by the centrifuge method[32-34]. In some papers the results of the discussions were compared with the author's own experimental results. The materials studied were polycarbonates and copolymers of butadiene.

Most authors have dealt with methods for determining the average molecular weight.

In the field of osmometry, the following may be mentioned: a methodological paper by Marciniak and Szota[35] on measurements at elevated temperatures; a paper by Robalewski[36] on the "membrane balloon" effect in osmometry; the previously mentioned paper by Brzeziński[20] on the determination of the second virial coefficient and the molecular weight of an isotactic fraction of polypentene; a paper by Skwarski[37] on the osmometric determination of the molecular weights of *N*-substituted polyamides; and papers by Kalfus[38] on the errors in osmometric measurements, and modifications to apparatus preventing the membrane balloon effect.

Cryoscopy is now generally accepted as a convenient method for determining very low molecular weights[39-42] and those of polymers which have not been thoroughly studied.

Other methods for the quantitative determination of the molecular weight of polymers are for the most part modifications of chemical methods of determination from terminal groups[43,44], for example using tracer atoms or electrochemistry.

There are other noteworthy papers describing new techniques. These include a paper by Kryszewski[45], demonstrating the possibility of calculating the constants of the viscometric equation from the results of X-ray diffraction studies, and a paper by Łabudzińska[46] describing the construction of a simple apparatus of her own design, which makes it possible to determine the molecular weight and the second virial coefficient with sufficient accuracy from light scattering measurements. The method was tested using polystyrene solutions.

In general terms, we can say that none of the Polish research centres have carried out systematic studies on the determination of molecular weights as the main aim of their research work. Most of the papers cited deal with developments following from earlier work, for example on the kinetics of polymerisation processes or the study of the dependence of the properties of polymers on their molecular weight.

This approach is revealed in the nature of papers in this field. Polish authors have first of all developed measurement procedures, or introduced simplifying modifications, or have found systems and corresponding constants for studying a large number of interesting materials for which insufficient published data were available.

The situation is quite different when we come to the characterisation of polydispersity. Although in this field also studies involving the investigation of reaction mechanisms and other work on kinetics are being carried out, there is a large number of papers devoted exclusively to methods of fractionation and methods of determining molecular weight distribution functions.

Of the analytical methods characterising polydispersity, only two have aroused great interest: sedimentation analysis and turbidimetric titration. As already noted, only one research centre — The Scientific Research Institute of the "Oświęcim" Chemical Plant — has examined the use of the ultracentrifuge for the fractionation of polymers.

Of the papers which have been published there, two deal with the determination of the molecular weight distribution function for butadiene-styrene rubber (Kalfus and coworkers[47]) and stereoregular polybutadiene (Mitoraj[48,49]). The authors discuss the influence of the polymerisation parameters on the distribution function, and also the influence of the distribution function on the physicomechanical properties.

Analogous papers deal with the relationship between polymerisation parameters and the results of sedimentation analysis for polystyrene[50] and with extensive studies of the relationship between the polydispersity and properties of rubber[51].

All these papers are clearly experimental in character; a more theoretical approach is adopted in two papers by Kalfus[52,53], in which, contrary to the views of Schulz and Horbach, he puts forward a simplified method for evaluating the results of sedimentation analysis, involving standardisation and calibration.

Finally, one paper[54] has been devoted to purely methodological problems. The authors suggest the use of a preparative centrifuge for the fractionation of polymers. After centrifuging, the specimens are frozen and separated into fractions mechanically.

Again only one research centre in Poland — The Synthetic Materials Institute — has examined the use of turbidimetric titration to characterise polydispersity. This subject is discussed in several papers by Krozer and coworkers[55-57]. The authors, who used these methods to characterise polycarbonates, state that the degree of dispersion of the precipitate obtained is independent of mole-

cular weight, so that the turbidimetric curves obtained can be used to characterise the polydispersity. These methods are also being applied to other materials to permit comparison with results obtained by other methods.

Polish authors have shown much greater interest in methods for the preparative determination of polydispersity; there are a fairly large number of papers dealing with fractionation, and this work is being carried out in various research institutes. Considerable attention is being paid to fractionation by the separation of two liquid phases.

Here, mention must be made of work by Basiński and coworkers[58-60] on the fractionation of various vegetable tanning agents by the separation of two liquid phases in systems with mixed solvents.

In the Physical Chemistry of Polymers Faculty of Lodz Polytechnical Institute, the method involving the separation of two liquid phases is used for the fractionation of synthetic polymers which crystallise particularly readily.

Two systems suitable for the fractionation of polyamides have been found[61-67]. The first is the phenol–ethylene glycol–water system, and the second, which is more suitable from the experimental viewpoint since the rate of separation of the layers is high, is the phenol–tetrachloroethane–n-heptane system. The latter system has also been used with good results for polyethylene terephthalate[68,69].

A similar method involving a slightly different procedure was used to study the fractionation of polycarbonates[70]. Although polycarbonates crystallise slowly and with difficulty from melts, they crystallise readily from solution. For this reason, separation into liquid fractions is important. The authors chose the dioxan–n-heptane system, in which equilibrium is first established between the liquid phases, after which a precipitate forms. The fractionation of polycarbonates with the formation of solid precipitates was studied by Brzeziński and Wajnryb[71] using the chloroform–petroleum ether system.

A combined extraction–precipitation method is now being used in the Physical Chemistry of Polymers Faculty to characterise low-molecular-weight epoxy-resins[72].

The fractionation of poly(vinyl chloride) in the cyclohexanone–glycol system was studied by Ulińska and coworkers[73].

A group of papers has been devoted to the fractional dissolution procedure.

Fractionation involving the extraction of fine fibres of viscose rayon was studied by Skwarski[74]. The use of extraction in a fractionating column has been developed for several materials. Polyethylene has been fractionated in a Francis column at elevated temperature in the xylene–Cellosolve system using graphite as carrier[75].

The column method has also been used for the fractionation of polycarbonates[76], the results obtained being similar to those obtained by precipitation.

Pentone has been fractionated by extraction in a column at elevated temperature (117°) in the cyclohexanone–diethylene glycol system using sand as carrier[77].

A number of papers have been devoted to total fractionation. This method was developed for poly(vinyl alcohol) using the acetone–water system[78].

One joint experimental–theoretical paper[79] and one purely theoretical paper[80] have been devoted to studies of the selectivity of the method.

In addition, there are a large number of papers which deal with the problems of fractionation only indirectly. Some of these papers deserve special mention.

Sibiński and Gralewicz[81] studied the change in polydispersity taking place during the pre-ripening of alkali cellulose. The work is of technical importance, the material studied being cord cellulose.

Turska and Skwarski[82-84] studied chiefly the changes in the polydispersity of polyethylene terephthalate during polycondensation and thermal degradation. They confirmed that during polycondensation, with change in the degree of completion of the reaction, the distribution function changes in accordance with Flory's theory, whereas during thermal degradation it leads to products with greater molecular uniformity; the function obtained corresponds more closely to the theory of Korshak and Slonimskii. The changes in the polydispersity of polyethylene terephthalate under the influence of irradiation have also been studied[85]; the distribution found corresponds most closely to Flory's ideas. An analogous result was obtained in the heat treatment of stabilised polyamides[86].

A joint paper[87] was devoted to the dependence of the mechanical properties of butadiene–styrene rubber on the molecular weight distribution function. It was found that a relationship exists between the polydispersity of the specimens studied and the maximal elasticity, tensile strength, and other mechanical parameters. The influence of the conditions of the polymerisation of styrene on the molecular weight distribution was studied by Kalfus and coworkers[88]. Kamińska[89] carried out analogous studies for polyvinyl chloride.

In many papers on kinetics, which in view of their specialised subject matter will not be discussed here, the distribution functions were determined in order to characterise the product completely.

Summarising these problems related to the fractionation of polymer solutions, it may be concluded that the work carried out in Poland in this field is predominantly experimental in character. An undoubted achievement is the large number of new systems which have been developed and verified. It is worth emphasising that the new fractionation systems have considerable advantages from the practical viewpoint, since they generally reduce considerably the duration of the fractionation with an appreciable saving of time.

In addition to papers dealing with methods for characterising polydispersity, there are also in this field a fairly large number of studies of another type, devoted to an analysis of the changes taking place during the formation of polymers, and also on the determination of the dependence of the physicomechanical properties of polymers on the distribution function. Since it has been established many times that there is a close relationship between the polydispersity of a polymer and the possibility of its practical application, and also since the polydispersity undergoes marked changes under the influence of various parameters of the polymerisation processes, the studies devoted to these problems are extremely interesting.

While taking account of the pure research aspect, which in this field makes it possible to obtain information on phenomena and relationships which have not been clear

until now, it is necessary to emphasise the practical importance of this field of study. A knowledge of the changes associated with polydispersity, which can take place during an industrial process, may give important information for the correction and control of this process. Control of the change in distribution functions of the product obtained or a re-treated product, even with rapid methods of study (with which difficulties are still associated) can hardly provide extensive possibilities in industry. On the other hand, it would undoubtedly be very useful from the industrial viewpoint to be able to control a process for the production or processing of polymers by altering the molecular weight distribution as desired. To achieve this, thorough development of the theoretical principles is obviously necessary. This is one of the reasons why I consider that the study of the relationship between polymerisation processes and the polydispersity and properties of macromolecular products is a very important field of research.

The very important relationship between work which at first sight concerns purely theoretical problems and work concerning industrial problems is also clearly shown in another field, which is represented fairly extensively in Poland; this work is described in theoretical papers and in a small number of experimental papers devoted to work carried out in the Technical Physics Laboratory of the General Chemistry Institute, on the hydrodynamics of polymer solutions. The authors, Ziabicki and Takserman-Krozer, have for a number of years been making a thorough study of a single problem, which has still not been solved. This problem concerns the behaviour of macromolecules in fields with other than transverse velocity gradients. As far as polymer solutions are concerned, the theory of their behaviour in the field of a transverse velocity gradient, like that for capillary viscometers, has for long been extensively treated in the scientific literature.

It should be noted, however, that there exist a number of important phenomena to which this theory cannot be applied, such as the formation of jets from the spinning solution in the production of synthetic fibres. The authors cited are therefore gradually beginning to develop a more general theory. The first papers in this field are purely theoretical[90-93] and begin with the simplest systems, that is a field with longitudinal velocity gradient and an immobile rigid ellipsoidal molecule. The first papers examine problems of the viscosity of a dilute solution and the orientation of this type of rigid molecule. The subsequent papers deal with the more complicated case of flexible macromolecules in solution and the viscosity of dilute solutions of these macromolecules in a field with longitudinal gradient.

The next stage, published jointly by both authors[94-99], expands previous discussions, but from a slightly different viewpoint. This series of papers is devoted to the problem of the restoration and breakdown of liquid fibres. Of these papers, only the last is confirmed experimentally by fast cinematography.

The earlier papers examine theoretically possible mechanisms for the restoration and breakdown of the jet under the influence of various parameters.

Subsequent papers by Takserman-Krozer[100-107] examine and summarise earlier studies of the properties of solutions of flexible chain macromolecules in the field of a general velocity gradient. On the basis of theoretical discussions, the author reaches general solutions characterising the distribution function, the orientation and deformation of the macromolecules, the time dependences, and other quantities.

Despite the fact that other work by these authors has not yet solved the problem raised, it can be confidently stated that an important step forward has been taken in this field.

These papers also provide an interesting example of work which is clearly theoretical in character but which should undoubtedly have a considerable influence on methods for organising the industrial process of fibre formation.

Another field which although not represented by a large number of papers has nevertheless aroused the interest of a number of authors is the study of polyelectrolyte solutions. Here mention may be made of the work of Ulińska, Wojtczak, Huppental, and others in the General Chemistry Faculty of the Copernicus University in Torun[108-116], devoted primarily to the study of various properties of polymethacrylic acid solutions, namely its adsorption, analytical methods for its determination, etc.

Bolewski[117] is studying polyelectrolyte solutions from another viewpoint; he is investigating the influence of the ionic strength of the solution on its properties.

Kryszewski[118,119], who is concerned chiefly with other problems, has also devoted two interesting papers to polyelectrolyte solutions. It can be seen that this field is attracting fairly serious attention from Polish authors working on polymers.

As already noted, the general character of research work in Poland, devoted to the study of polymer solutions, can be described as involving attempts to apply science in the national economy. Even papers which appear purely theoretical are generally of value as providing a theoretical basis for future industrial processes. This is as it should be.

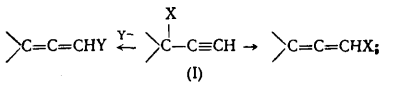
2. Addition reactions 241
3. Isomerisation of allenic compounds 243

IV. Naturally occurring compounds of allenic structure 244

I. INTRODUCTION

Research workers studying the chemistry of polyunsaturated compounds have recently been paying increasing attention to substances containing an allenic group in their molecule. This is not only because, from its chemical nature, the allenic double bond system is of great interest in the study of the reactivity of different types of polyunsaturated compounds. The interest is due in considerable measure to the fact that various types of functional derivatives containing this bond system, together with polyyne and diene groups, have been found among plant (including fungal) metabolites. Although the number of these natural compounds is still small, the very presence of such extremely unstable compounds among the products of the vital activity of cells is of great interest to biochemists. Furthermore, these types of compounds have been found to possess high antibacterial and fungicidal activity, which is to a considerable extent associated with the presence of an allene grouping.

Allenic systems are extremely unstable chemically, tending to undergo not only polymerisation and addition reactions but also ready acetylene–allene–diene conversions and various rearrangements. All this greatly hampers the synthesis and the chemical study of functional derivatives of the allene series, and makes it urgently necessary to work out convenient methods for the preparation of such polyunsaturated systems. Since great interest is being shown at the present time in various types of allenic compounds, and previous reviews[1-3] have discussed mainly allenic hydrocarbons, we consider that a literature survey of methods of synthesis and the reactivity of functional derivatives of allenic compounds will be of undoubted interest.



II. METHODS OF PREPARATION

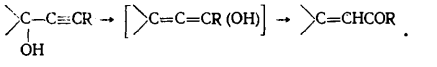
The published information shows that functional derivatives of the allene series are obtained mainly by two methods. One of these is based on various types of acetylene–allene rearrangement of acetylenic systems, whereas 1,4-addition at a butenyne bond system underlies the second method.

1. Isomerisation of Acetylene Derivatives

This general method of obtaining allene structures is based on two types of rearrangements characteristic of acetylene derivatives — (*a*) anionotropic rearrangement of

prop-2-ynyl systems of type (I) in the presence of catalysts or in the course of substitution reactions

(I)

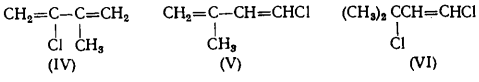


(*b*) prototropic isomerisation of prop-2-ynyl systems of types (II) and (III)

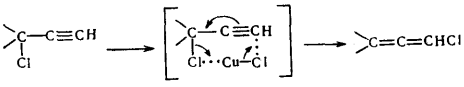
(II) (III)

Methods of synthesising functional derivatives of allene from the corresponding substituted derivatives of acetylene will be examined in this sequence.

(*a*) Anionotropic rearrangement of acetylenic alcohols and their derivatives. Rearrangement of an acetylenic to an allenic system is assumed to be an intermediate stage in the isomerisation, under the influence of acids, of acetylenic tertiary carbinols into unsaturated ketones (the Meyer–Schuster rearrangement)[4] and into $\alpha\beta$-unsaturated aldehydes (the Rupe rearrangement)[5]:

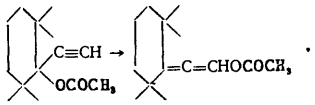


It has subsequently been shown that other acetylenic tertiary alcohols, including butenyne[6] and butadiyne[7] derivatives, are capable of analogous rearrangement. Among prop-2-ynyl derivatives, rearrangements of the chlorides of acetylenic tertiary alcohols have been studied the most thoroughly. Favorskaya and Favorskii[8] were the first to show that 3-chloro-3-methylbut-1-yne isomerises smoothly, under the influence of copper(I) chloride in ammonium chloride and concentrated hydrochloric acid, into 1-chloro-3-methylbuta-1,2-diene:

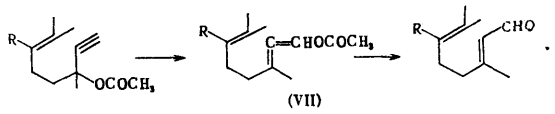


This method has been used to prepare several 1-chloroallene homologues[9–12], including the simplest 1-chloropropadiene[13], from various acetylenic alcohols.

It has subsequently been shown that such isomerisations do not yield unequivocal results: in the isomerisation of 3-chloro-3-methylbut-1-yne[9,14], for example, a mixture of products is formed, containing, together with the halogenoallene, such further isomerisation products as the chlorobutadienes (IV) and (V) and the dichloro-derivative (VI):

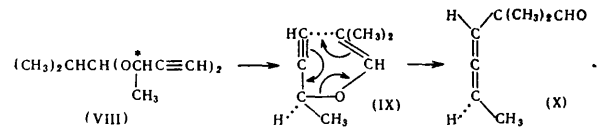


(IV) (V) (VI)



Considerably less work has been done on the rearrangement of acetylenic bromides[13,15–17]. The rearrangement of halogenoprop-2-ynyl systems to halogenoallenes represents a peculiar example of a 1,3-migration occurring by a mechanism of cyclic electron transfer[14]:

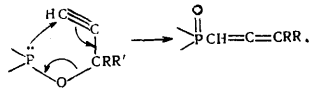
The isomerisation of acetates of acetylenic tertiary alcohols has also been described. The Landors[18], for example, observed the formation of an allenic acetate in up to 90% yield in the pyrolysis of 1-ethynyl-2,2,6,6-tetramethylcyclohexyl acetate:



Recently Isler and his coworkers[19] have established that such acetates readily undergo rearrangement when heated in glacial acetic acid in the presence of copper powder or salts of copper or silver:

(VII)

Almost quantitative yields of unsaturated acetates of the type (VII) were obtained in this way. By means of this reaction it has been possible to work out an elegant method for the synthesis of various $\alpha\beta$-unsaturated aldehydes, including citral, farnesal, and phytal [3,7,11,15-tetramethylhexadec-2-enol].



The synthesis has been described[20] of optically active 2,2-dimethylhexa-3,4-dienal (X) by the pyrolysis of dextrorotatory 2-methyl-3,3-bis-(1-methylprop-2-ynyloxy)propane (VIII). Formation of this product probably results from Claisen rearrangement of an intermediate 2-methylprop-1-enyl ether (IX) by a mechanism of cyclic transfer of electrons:

(VIII) (IX) (X)

It has recently been shown that, in the case of vinyl and chloroalkyl prop-2-ynyl ethers, the Claisen rearrangement is a general method for the synthesis of allenic aldehydes[21–23]. Allenic ketones are obtained in a similar manner, but they are very readily isomerised into conjugated dienones[24,25].

Detailed studies have recently been made of other interesting methods of synthesis, in which prop-2-ynyl esters are used for the preparation of allenes containing phosphorus. The prop-2-ynyl esters formed from acetylenic alcohols and halogen derivatives of tervalent phosphorus readily (in ether–pyridine at 20°) undergo intramolecular acetylene–allene rearrangement to give 75–100% yields of the allene derivatives. In view of the structure of the products, the rearrangement is explained by intramolecular migration in the five-centre intermediate system[26–28]:

Primary, secondary, and tertiary acetylenic alcohols can be successfully used in the above reactions[26–31]. Increasing the number of methyl substituents in the prop-2-ynyl portion not only increases the yield but also stabilises the allene derivatives, obviously owing to the inductive effect of the methyl groups, which prevent further prototropic isomerisation.

The rearrangement of prop-2-ynylammonium halides[32] under the influence of sodamide also results in allene derivatives. An interesting sequence of isomerisations into

allene and cumulene systems has been observed in amines containing a butenynyl group[33]:

$$(CH_3)_2CC{\equiv}CCH{=}CH_2 \rightarrow (CH_3)_2C{=}C{=}C{-}CH{=}CH_2 \rightarrow (CH_3)_2C{=}C{=}C{=}CHCH_2NR_2$$
(NR$_2$ at the first and second carbons)

It has repeatedly been observed that acetylene–allene isomerisation takes place during the occurrence of substitution reactions. Reaction of 3-chloro-3-methylalk-1-ynes with silver acetate in glacial acetic acid gives a mixture[34] of the allenic acetate (XI) and the normal acetylenic acetate (XII), the latter being the sole product when the reaction is conducted under the influence of potassium acetate:

$$R(H_3C)C{=}C{=}CHOCOCH_3 \xleftarrow{CH_3COOAg} R(H_3C)CCl{-}C{\equiv}CH \xrightarrow{CH_3COOK} R(H_3C)C(OCOCH_3){-}C{\equiv}CH.$$
(XI) (XII)

Silver propionate under similar conditions gave 3-methylbuta-1,2-dienyl propionate[35].

Prop-2-ynyl halides react with metal cyanides in the presence of copper(I) bromide at 60–120° to form allenic nitriles[36,37]. In the case of sterically hindered acetylenic tertiary bromides the yields reach 80%:

$$BrCRR'C{\equiv}CH \xrightarrow{Cu_2CN_2} RR'C{=}C{=}CHCN.$$

Interaction of 3-chloro-3-methylbut-1-yne with trialkyl phosphites at 130–150° results in moderate yields of dialkyl 3-methylbuta-1,2-dienylphosphonites[38]. Primary and secondary amines readily add on to prop-2-ynyl halides, merely forming acetylenic amines[39]. However, Hennion has recently reported[40,41] that, in the alkylation of certain sterically hindered prop-2-ynyl chlorides with tertiary amines, it has proved possible to obtain quaternary salts of allenylamines in 60–80% yields:

$$(CH_3)_2CC{\equiv}CH \xrightarrow{(CH_3)_3N} (CH_3)_2C{=}C{=}CH\overset{+}{N}(CH_3)_3\,\overline{Cl}.$$
(Cl at the propargylic carbon)

Not all tertiary amines react in this way, the type of reaction which occurs depending also on the basic strength and the nucleophilic character of the amine[41].

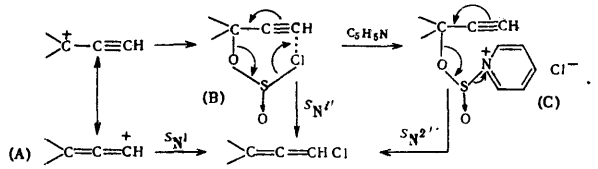
A general method for obtaining allenic acids (XIII) is based on the action of nickel carbonyl and hydrogen chloride on acetylenic alcohols[42–45], but the yields are usually low (10–20%):

$$RR'CC{\equiv}CH \xrightarrow[Ni(CO)_4]{HCl} RR'CC{\equiv}CH \xrightarrow[(R''OH)]{} RR'C{=}C{=}CHCO_2R''$$
(OH at the propargylic carbon; Cl at the propargylic carbon; (XIII))

where R = R′ = H, CH_3, C_2H_5; R = H, R′ = CH_3, C_3H_7, C_6H_5.

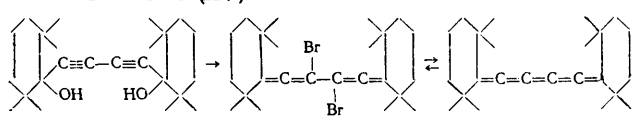
The reaction of prop-2-ynyl halides with acetylenic components (in particular with acetylenic alcohols) under the influence of copper salts in an amine medium provides an interesting route for the synthesis of acetylenic–allenic products (the yields reaching 80%)[46]:

$$R_2CC{\equiv}CH + HC{\equiv}CCH_2X \xrightarrow[NH_4OH]{Cu_2Cl_2} R_2CC{\equiv}CCH{=}C{=}CH_2$$
(OH at the propargylic carbon)



where X = Cl, Br, p-$CH_3C_6H_4SO_2$; R = H, CH_3, C_2H_5.

The isomerisation of acetylenic tertiary alcohols under the influence of concentrated hydrobromic acid in the presence of copper(I) bromide has recently been suggested as a method for the preparation of various 1-bromoallenes[47,48]:



$$RR'CC{\equiv}CH \xrightarrow{HBr/Cu_2Br_2} RR'C{=}C{=}CHBr.$$
(OH at the propargylic carbon)

This method gives a high yield (60–80%) of quite pure bromoallenes (the content of acetylenic derivatives does not exceed 2–5%). An extremely important feature is that in this case the reaction proceeds stereospecifically, and optically active 3,4,4-trimethylpent-1-yn-3-ol yields the optically active allenic bromide.

Jacobs[49,50] and Landor[51,52] used the reaction of acetylenic alcohols with thionyl chloride for the synthesis of chloroallenes. This reaction is conveniently conducted in dioxan medium, is accelerated by the addition of bases (pyridine), and from sterically hindered alcohols gives good yields (up to 75%) of chloroallenes. Acetylenic secondary alcohols give considerably lower yields, and the reaction is complicated by the formation of byproducts[50,53]. Both the above reactions are characterised by the absence of prop-2-ynyl halides as intermediate products, so that the formation of halogenoallenes is not a result of their anionotropic rearrangement. Furthemore, these reactions proceed stereospecifically, in spite of the disappearance of the centre of asymmetry present in the original acetylenic alcohol. It is hardly possible to explain these results on the assumption that the reaction involves intermediate formation of a carbonium ion (A). Formation of an optically active chloroallene could conceivably occur through a cyclic transition state (B) (by an S_Ni' mechanism). In that case, however, the reaction velocity should be independent of the catalytic action of bases. Nevertheless, in the absence of bases the reaction of acetylenic alcohols with thionyl chloride gives very low yields, even when sterically hindered alcohols are employed. This suggests an S_N2' mechanism, the role of pyridine probably consisting in formation of a pyridinium salt (C), in which the substitution takes place under the influence of chloride ions. Preservation of configuration can then be explained either by a double inversion or by formation of a rigid (undissociated) ion-pair[50]. In either case (S_N2' or S_Ni' mechanism) the chlorine should approach on the hydroxyl side of the alcohol. Thus the available data are not yet sufficient to settle unequivocally the problem of the reaction mechanism between acetylenic alcohols and thionyl chloride:

A few examples have been described of the formation of halogenated allenes by the reaction of acetylenic tertiary alcohols with phosphorus trichloride in pyridine[54] or with phosphorus tribromide[55,56]. By means of the latter reaction Bohlmann[55] obtained from the butadiynylene glycol (XIV), obviously as a result of a double prop-2-ynyl rearrangement, a 70% yield of a diallenic dibromide (XV), whose structure was established by conversion into the corresponding pentaene (XVI) and reconversion of the latter into the dibromide (XV):

(XIV) (XV) (XVI)

The corresponding allenic iodides are formed (mixed with acetylenic and 1,3-diene isomers) by the action of potassium or sodium iodide on the prop-2-ynyl halides[13,16,57,58] or

of hydriodic acid on acetylenic carbinols[59], but it is extremely difficult to isolate these iodides in the pure form owing to their great tendency to undergo polymerisation and rearrangement even on simple distillation. A practical method of synthesis consists in treating acetylenic alcohols with triphenylmethyl phosphite–iodine[60], the yields varying from 20% to 70%:

$$\underset{\underset{OH}{|}}{RCHC{\equiv}CH} \rightarrow RCH{=}C{=}CHI$$

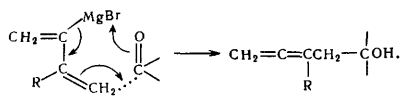
where R = H, CH_3, C_2H_5, C_3H_7, C_4H_9, C_5H_{11}, C_6H_5.

Another group of substitutions which yield allenic structures involve organometallic compounds (of magnesium, aluminium, and zinc) derived from prop-2-ynyl halides, which have been studied mainly by Prévost and his co-workers[61–63]. On the hypothesis that a free carbanion is formed[61], these workers consider that the MgBr derivatives result from attack by the electrophilic MgBr, so that the structure of the final product should depend on electronic and steric factors. In the case of prop-2-ynyl bromide (XVII, R = H) the carbanion will have the structure (XVIII), and since δ^- far exceeds δ'^- in this instance, the $^+$MgBr should attack the acetylenic carbon atom, which will yield the allenic system (XIX):

$$\underset{\underset{Br}{|}}{RCHC{\equiv}CH} \rightarrow \left[\overset{\delta'-}{R\overset{3}{C}H} \cdots \overset{2}{C} \overset{\delta-}{=} \overset{1}{CH}\right] \xrightarrow{\overset{+}{M}gBr} RCH{=}C{=}CHMgBr$$

(XVII) (XVIII) (XIX)

Similar relationships are observed with the bromides (XVII, R = CH_3); here steric hindrance at $C_{(3)}$ is also operative, which should result in the structure (XIX) exclusively. With the isomeric carbanion (XX), on the other hand, the steric factor will act in the opposite direction, and a mixture of acetylenic and allenic MgBr derivatives will be obtained:



$$\underset{\underset{MgBr}{|}}{H_3CC{=}C{=}CH_2} \leftarrow \left[\overset{\delta-}{H_3CC} \cdots C \cdots \overset{\delta'-}{CH_2}\right] \rightarrow H_3CC{\equiv}CCH_2MgBr.$$

(XX)

In conformity with these views, it is only in the last case that formation of a mixture of acetylenic and allenic alcohols has been observed[61] on reaction with carbonyl compounds. In all other cases 2-acetylenic alcohols are formed exclusively. The formation of allenic together with acetylenic alcohols has been established in the reaction of prop-2-ynylzinc bromides with ketones[62–65] and in the Reformatskii condensation of prop-2-ynyl bromides with aliphatic and aromatic aldehydes[66–70]. Using condensation with acetone as example, however, it was demonstrated that allenic alcohols are formed, not as a result of reaction of the allenic ZnBr derivative with acetone, but from isomerisation of the acetylenic alcohol under the influence of the zinc salt[63,71]:

$$\underset{H_3C}{\overset{H_3C}{\diagdown}}\overset{OH}{\underset{|}{C}}CH_2C{\equiv}CH \rightarrow \underset{H_3C}{\overset{H_3C}{\diagdown}}\overset{OH}{\underset{|}{C}}{-}CH{=}C{=}CH_2 \xleftarrow{\overset{CH_3COCH_3}{X}} CH_2{=}C{=}CHZnBr.$$

An interesting case of the formation of allenic alcohols has been observed in the reaction of magnesium halide derivatives of diene bromides with carbonyl compounds, which probably occurs by a mechanism of cyclic transfer of electrons[72]:

Formation of an allene derivative has recently been noted in the addition of prop-2-ynyl-lithium to aliphatic aldimines[73] and also in the reaction of orthoformic ester with prop-2-ynyl-magnesium (or -zinc) halides[74,75].

The carboxylation of prop-2-ynylmagnesium halides with carbon dioxide or chloroformic ester has been known for a long time. Marvel[76] described the preparation of allenic acids from acetylenic tertiary chlorides. It was later established that this is a general type of reaction, Grignard reagents derived from prop-2-ynyl primary bromides being most readily carboxylated (in yields of 50–70%)[77–81]:

$$RC{\equiv}CCH_2Br \xrightarrow[2.\ CO_2]{1.\ Mg} RC{\equiv}CCH_2CO_2H + \underset{\underset{CO_2H}{|}}{RC{=}C{=}CH_2} \quad (XXI).$$

Although the reaction is complicated by formation of a dimeric allenic acid (see Section III, 2), in most cases the allenic acids (XXI) can be easily isolated in the pure form. Secondary and tertiary prop-2-ynylmagnesium halides show greater difficulty in reacting with carbon dioxide, but yield pure allenic acids of the type (XXII)[82]:

$$\underset{\underset{Br}{|}}{C_6H_5C{\equiv}CC(R)CH_3} \longrightarrow \underset{\underset{CO_2H}{|}}{C_6H_5C{=}C{=}C}\overset{R}{\underset{CH_3}{\diagup}}$$

(XXII)

where R = H, CH_3.

The condensation of dimethylbenzamide with certain substituted prop-2-ynylmagnesium bromides yields mixtures of acetylenic and allenic ketones[83]:

$$RC{\equiv}CCH(R')Br \xrightarrow[2.\ C_6H_5CON(CH_3)_2]{1.\ Mg} \underset{\underset{R}{|}}{C_6H_5COC{=}C{=}CHR'} + \underset{\underset{R'}{|}}{RC{\equiv}CCHCOC_6H_5}$$

(b) **Prototropic rearrangement of acetylenic systems.** Allene derivatives containing COOR, CN, CO, etc. groups have been obtained by the prototropic rearrangement of acetylenic compounds in the presence of bases under comparatively mild conditions. The isomerisation of acetylenic into allenic hydrocarbons is usually reversible[84], although the relative proportions of the acetylene–allene–diene products are greatly dependent on the structure of the initial acetylene, and perhaps on the conditions under which the rearrangement takes place. It might have been expected that the presence of electron-acceptor groups (CN, COOR, CHO, CO) in the allyl position relative to the acetylenic bond would not only facilitate prototropic rearrangement of acetylene to allene but also stabilise the cumulated system. In fact, the acetylenic epoxide (XXIII) readily isomerises under the influence of zinc oxide into the allenic aldehyde (XXIV)[85,86]:

$$RC{\equiv}C{-}\underset{\underset{CH_3}{|}}{C}\overset{O}{\diagup\diagdown}CH_2 \rightarrow RCH{=}C{=}\overset{CH_3}{\underset{|}{C}}CHO.$$

(XXIII) (XXIV)

The oxidation of 2-acetylenic secondary alcohols[67,72,87–90] with chromium trioxide in acetone and sulphuric acid is also accompanied by prototropic rearrangement, giving up to 70% yields of various allenic ketones. Allenic aldehydes and ketones can be obtained by the acid hydrolysis of butenynyl ethers of the type (XXV)[91–94]:

$$\underset{(XXV)}{R'C{\equiv}CCH{=}CR(OC_2H_5)} \rightarrow R'CH{=}C{=}CHCOR$$

where R = H, Alk.

Rearrangement has been observed also in the reaction of prop-2-ynyl halides with copper and potassium cyanides[95-97], by means of which several allenic nitriles have been synthesised in up to 50% yields:

$$RCH{=}C{=}CHCN \xleftarrow{KCN} RC{\equiv}CCH_2Br \xrightarrow{KCN} RC{\equiv}CCH_2CN.$$

The isomerisation of prop-2-ynyl sulphides in the presence of sodium ethoxide yields allenic sulphides[98-100]:

$$HC{\equiv}CCHR(SC_6H_5) \rightarrow H_2C{=}C{=}CR(SC_6H_5).$$

Arens has shown also that substituted 1-ethylthioalkynes (XXVI) on rapid treatment with an equivalent amount of sodamide are capable of giving a carbanion (XXVII), which on hydrolysis or alkylation gives up to 85% yields of the corresponding allenic sulphides[100-103]:

$$RCH_2C{\equiv}CSC_2H_5 \xrightarrow{(NaNH_2)} \underset{\text{(XXVII)}}{R\bar{C}HC{\equiv}CSC_2H_5 \leftrightarrow RCH{=}C{=}\bar{C}SC_2H_5} \begin{cases} \xrightarrow{H_2O} RCH{=}C{=}CHSC_2H_5 \\ \xrightarrow{R'Br} RCH{=}C{=}CR'SC_2H_5 \end{cases}$$

(XXVI)

Under the same conditions only the branched 2-acetylenic ethers (XXVIII) are converted into allenic ethers[99,104], the 1-acetylenic ethers merely forming 1,3-alkenynes:

$$\underset{\text{(XXVIII)}}{RR'CHC{\equiv}CCH_2OC_2H_5} \rightarrow RR'CHCH{=}C{=}CHOC_2H_5.$$

Prototropic rearrangement takes place very readily with $\beta\gamma$-acetylenic acids. Thus but-2(and 3)-ynoic acids are completely isomerised into the allenic acid when heated with 18% potassium carbonate solution to 40° [105] or by the action of sodamide in liquid ammonia[106]. However, 4-phenylbut-3-ynoic acid under the same conditions forms an equilibrium mixture with 4-phenylbut-2,3-dienoic acid in the proportions 2 : 3.[107] An equilibrium mixture (1 : 2) is obtained also by the isomerisation of 4-phenylbut-2--ynoic acid[108]:

$$C_6H_5C{\equiv}CCH_2CO_2H \rightleftarrows C_6H_5CH{=}C{=}CHCO_2H \rightleftarrows C_6H_5CH_2C{\equiv}CCO_2H.$$

The esters of these acids undergo rearrangement far more readily. The reaction is almost quantitative in the presence of potassium carbonate solution at 20°.[105] 4-Bromobuta-2,3-dienoic[109] and 2-chlorobuta-2,3-dienoic[110] esters also have easily been obtained in this way:

$$XC{\equiv}CCH_2CO_2R \rightarrow XCH{=}C{=}CHCO_2R$$

where X = H, Br.

The simplest pentynedioic acid (XXXI) does not exist, since, on preparation by oxidising the alcohol (XXX)† with chromium trioxide, it immediately undergoes prototropic isomerisation into penta-2,3-dienedioic acid[111]:

$$\underset{\text{(XXX)}}{HOCH_2CH_2C{\equiv}CCO_2H} \rightarrow [HO_2CCH_2C{\equiv}CCO_2H] \rightarrow \underset{\text{(XXXI)}}{HO_2CCH{=}C{=}CHCO_2H}.$$

It has been shown that an allenic system can be obtained only when its further isomerisation is difficult or altogether impossible. In this connection it is of interest to note the prototropic rearrangement of octa-3,5-diyne-1,8-dioic acid (XXXII), not into the diallenic acid (XXXIII), but into octa--2,4-dien-6-yne-1,8-dioic acid (XXXIV)[112]:

$$\underset{\text{(XXXIII)}}{HO_2CCH{=}C{=}CHCH{=}C{=}CHCO_2H} \xleftarrow{\chi} \underset{\text{(XXXII)}}{HO_2CCH_2(C{\equiv}C)_2CH_2CO_2H} \rightarrow \underset{\text{(XXXIV)}}{HO_2C[CH{=}CH]_2C{\equiv}CCO_2H}.$$

† A formula corresponding to (XXIX) does not appear in the Russian text (Ed. of Translation).

Prototropic rearrangement accompanied by migration of the double bond has been observed[66] in the alkaline saponification of the esters (XXXV), but the allenic acids (XXXVI) could not be isolated in the pure form:

$$\underset{\text{(XXXV)}}{RC{\equiv}CCH{=}CHCH_2CO_2CH_3} \rightarrow \underset{\text{(XXXVI)}}{RCH{=}C{=}CHCH{=}CHCO_2CH_3}.$$

Certain hydroxy-compounds, containing a double bond and a triple bond separated by a methylene group, also rearrange into allenic alcohols when boiled with solutions of bases[72,113-115] or with aluminium oxide[115-117]:

$$\gtrless C(OH)-C{\equiv}CCH_2CH{=}CH-R \rightarrow \gtrless C(OH)-CH{=}C{=}CHCH{=}CH-R.$$

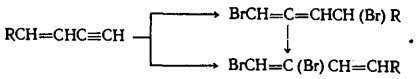
2. Addition to Butenyne Systems

The addition of various reactants to a butenyne bond system constitutes a general method for the preparation of allenes. However, in several cases involving the addition of alcohols, halogens, and hydrogen halides, this method is greatly restricted by the difficulty of separating the mixture of acetylenic, allene, and conjugated diene derivatives which is usually formed. Separation may be achieved by careful fractional distillation, in which high temperatures must be avoided as they might cause interconversion of the isomers. On the other hand, such reactions as the reduction of butenyne derivatives and the addition of amines and halide esters usually proceed quite unambiguously, representing convenient and frequently the only possible methods for the synthesis of allene compounds containing these groups in the middle of the chain.

Addition of alcohols. This takes place in the presence of alkoxides: hexa-1,5-dien-3-yne reacts with methanol to give 3-methoxyhexa-1,3,4-triene[118]:

$$H_2C{=}CHC{\equiv}CCH{=}CH_2 \rightarrow H_3CCH{=}C{=}\underset{|}{\overset{OCH_3}{C}}CH{=}CH_2.$$

In the case of butenyne the allenic product formed initially is converted at ordinary pressure by allene–diene isomerisation into a 1-alkoxybuta-1,3-diene, and under pressure by allene–acetylene rearrangement into an acetylenic ether[119]:

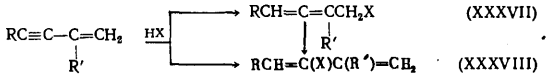


$$HC{\equiv}CCH{=}CH_2 \xrightarrow{CH_3OH} CH_2{=}C{=}CHCH_2OCH_3 \begin{cases} \rightarrow CH_2{=}CHCH{=}CHOCH_3 \\ \rightarrow CH_3C{\equiv}CCH_2OCH_3 \end{cases}.$$

Addition of thiols. In the presence of bases, thiols add to butenyne hydrocarbons mainly at the triple bond[120-122]: allenic sulphides are formed in insignificant quantity, and only in the case of butenyne itself has it been possible to isolate 4-alkylthiobuta-1,2-dienes[120,122]. The addition of thiols under radical conditions also results in partial formation of allenic sulphides[123]:

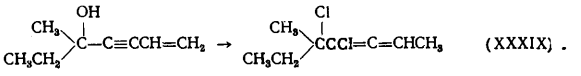
$$HC{\equiv}CCH{=}CH_2 \xrightarrow{RSH} \begin{cases} \rightarrow H_2C{=}CHCH{=}CHSR \\ \rightarrow H_2C{=}C{=}CHCH_2SR \end{cases}.$$

Addition of halogens. Only the bromination of butenyne and of alkenylacetylenes is of great practical interest[124,125]. In chloroform and at low temperatures butenyne is readily brominated to give a good yield of a



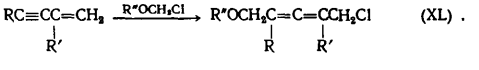
mixture of dibromides in which the allene and diene isomers predominate; with decrease in temperature the relative yield of the allenic dibromide increases:

It is possible that the diene dibromide is formed by allyl isomerisation of the allenic dibromide, which usually takes place very readily.



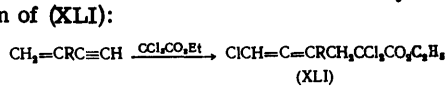
1,4-Addition predominates in the case of silicon-containing alkenynes [126]. The formation of halogenated allenes in small amounts has been noted also in the chlorination, chloroiodination, and halogenoarylation of butenyne and its homologues [119].

Addition of hydrogen halides. In the absence of catalysts, hydrogen chloride and hydrogen bromide add to butenyne [127-129] and its homologues [16,130-135] predominantly in the 1,4-positions to form the corresponding allene derivatives (XXXVII):



Some formation of halogenated dienes (XXXVIII) also occurs, either as a result of addition at the triple bond or by isomerisation of the halogenated allenes (XXXVII), the latter reaction taking place especially readily in the presence of copper salts (Cu_2Cl_2, Cu_2Br_2). Addition of hydrogen halides in the presence of these catalysts yields only the compounds (XXXVIII) [119]. When butenyne is hydrochlorinated in the presence of aluminium or zinc chloride instead of copper(I) chloride, the chief product is 4-chlorobuta-1,2-diene [129].

Nazarov and his coworkers [6] have established that but-3-en-1-ynylmethanols also add hydrogen halides, the 1,4-addition being preceded by replacement of the hydroxyl by halogen. The resulting allenic dihalide undergoes spontaneous isomerisation to the final conjugated diene products. Vartanyan [136] has recently succeeded in isolating (in 32% yield) the allenic dichloride (XXXIX) by the low-temperature hydrochlorination of 3-methylhept-6-en-4-yn-3-ol (at 18–20°):

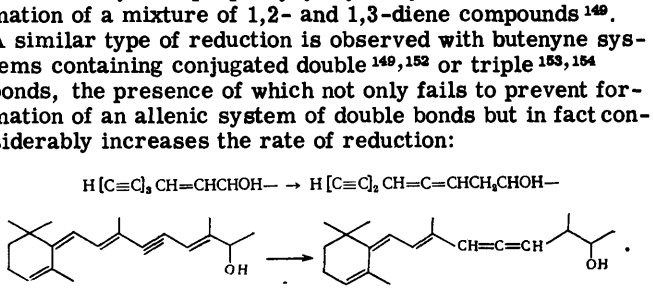


Addition of chloromethyl ethers. In the presence of bismuth trichloride as catalyst, addition to butenyne [137,138], hept-1-en-3-yne [139], 2-methylbutenyne [140], and hepta-1,6-dien-3-yne [141] takes place predominantly in the 1,4-positions to form chlorinated allenic ethers (XL):

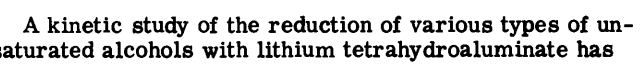
2,3-Dichlorotetrahydrofuran reacts in similar fashion with butenyne [142].

Ethers of secondary and primary alcohols derived from butenyne have recently been studied in this reaction [143]. It is interesting that allenic products are formed also in the reaction of t-alkyl halides with alk-1-en-3-ynes [144] in the presence of zinc chloride, the radical adding on to the double bond to give $C_2H_5CCl{:}C{:}CHCH_2C(CH_3)_3$. The reaction goes in the same direction (alkyl at the double bond) in the addition of trichloroacetic ester to alkenynes [145] with formation of (XLI):

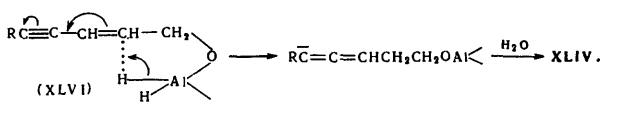
where R = H, CH_3. In contrast to this, addition of t-butyl chloride to butenyne takes place only at the triple bond, with formation of a halogenated diene (XLII) [119]:



Addition of hydrogen. 1,4-Addition of hydrogen to but-3-en-1-ynylmethanols, with formation of the corresponding allenic alcohols as side-products, has been observed during cathodic reduction [146] and during hydrogenation with coppered zinc dust [147]. However, these reactions have not yet been used successfully for the preparation of allenes.

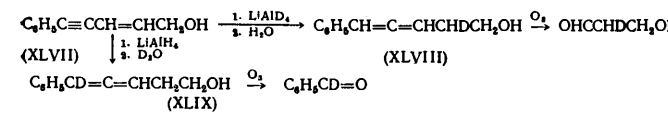


In 1954 Jones and his coworkers [148] studied the reduction of butenyne systems with lithium tetrahydroaluminate. Under these conditions alcohols of the type (XLIII) are selectively reduced (as a result of 1,4-addition) to give good yields of penta-3,4-dien-1-ol derivatives (XLIV) [149-152]:

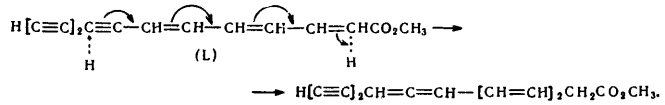


Further investigation of this reaction established that the presence of an allyl hydroxyl is a necessary condition for reduction to an allenic system. The simultaneous presence of allyl and prop-2-ynyl hydroxyls leads to the formation of a mixture of 1,2- and 1,3-diene compounds [149]. A similar type of reduction is observed with butenyne systems containing conjugated double [149,152] or triple [153,154] bonds, the presence of which not only fails to prevent formation of an allenic system of double bonds but in fact considerably increases the rate of reduction:

However, the compound (XLV) could not be reduced in this way [154]:

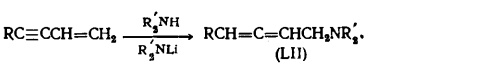


A kinetic study of the reduction of various types of unsaturated alcohols with lithium tetrahydroaluminate has shown [155] that nucleophilic addition of a hydride ion is the rate-determining stage in this reaction. In conformity with this, the mechanism of the reduction of pentenynol derivatives (XLVI) to allenes (XLIV) can be represented by the scheme

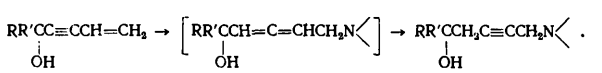


Results confirming the correctness of this mechanism have been obtained in a study of the reduction of 5-phenylpent-2-en-4-yn-1-ol (XLVII) with lithium tetrahydroaluminate and its deuterium analogue followed by decomposition with heavy and ordinary water respectively. The scheme below shows that only with the above reaction mechanism

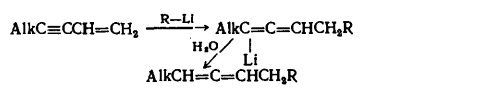
can deuterated allenes (XLVIII) and (XLIX) be formed, the position of the deuterium in these compounds being proved by ozonisation to the corresponding monodeuterated aldehydes [155]:



An unusual and extremely simple method of synthesising allenes, suggested by Bohlmann [154], is based on the reduction of alkenyne systems with aluminium amalgam in moist ether by Kuhn's method. Addition of hydrogen to the compound (L) takes place in positions 2 and 9, to give a very good yield of *trans-trans*-mycomycin (LI):

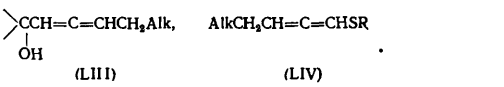


This new method of synthesising allenic structures evidently shows great promise for the preparation of complex natural allenes, and will undoubtedly find wide application.



Addition of primary and secondary amines. Addition of these compounds to butenyne usually takes place on heating in an autoclave at 100°, and is a promising method for the preparation of allenic amines (LII, R = H) [156]:

The same reaction has found application in the synthesis of allenic diamines (LII, R = $CH_2N<$) [157]. Alcohols containing the butenyne system and hexa-1,5-dien-3-yne hydrocarbons [157] readily add amines in the 1,4-positions, but, under the reaction conditions with excess of amine present, the resulting allenic amino-alcohols are readily isomerised to acetylenic derivatives:



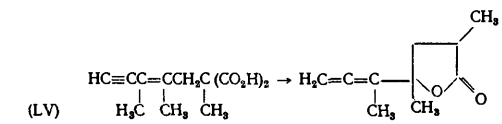
Addition of organolithium compounds. Petrov and Kormer [158] suggested a simple and general route for the preparation of allenes, based on the interaction of alk-1-en-3-ynes with organolithium compounds. This reaction involves an intermediate stage in which an allenyl--lithium is formed (with lengthening of the chain), hydrolysis of which gives good yields of allenic derivatives [159-162]:

where R = Alk, Ar, pyrid-2-yl, R'_2P, R'_2N, etc.

Addition of lithium alkyls to butenyne alcohols [163] and to alkylthiobutenynes [164] yields allenic alcohols (LIII) and sulphides (LIV) respectively.

In the case of chlorides and ethers containing a butenyne system the course of the reaction with lithium alkyls is more complicated, a mixture of allenes and cumulenes being obtained [165]. In the above reactions lithium derivatives of allenes are obtained as intermediate products, which opens up wide possibilities for the synthesis of various allenic compounds. Several reactions of 1-ethylhexa-1,2-dienyl-lithium have so far been studied. Its condensation with formaldehyde, oxiran, and many carbonyl compounds, both saturated and unsaturated, has led to the synthesis of a large number of allenic alcohols [166-168]:

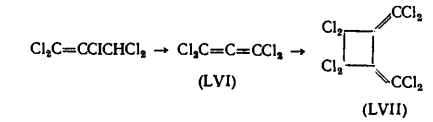
It is very significant that addition of allenyl-lithium at the multiple bonds in the starting materials was not observed.



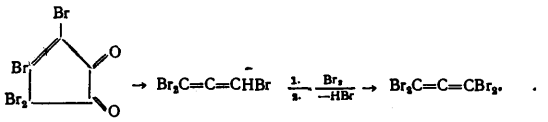
The allenic structure of the initial allenyl-lithium is preserved also during carboxylation [169], addition of pyridine and benzonitrile, and reaction with sodium benzoate [170]:

where R = CH_3, C_2H_5.

Alkenynyl-silicon and -germanium compounds on addition of lithium alkyls [171-174] and dialkyl-lithamides [175] yield mixtures of difficultly separable allenic and acetylenic products.



Other instances are known in which allenic derivatives are formed as a result of addition to butenynes. Among them are the reactions of butenyne amines with carbon disulphide [176], and also the formation of allenic lactones by the decarboxylation of malonic acids of the type (LV) [177,178]:



3. Other Methods

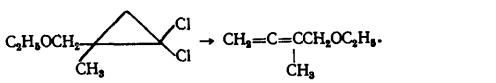
Dehydrohalogenation and pyrolysis are widely used for the preparation of polyhalogenated allenes. Blomquist [179] obtained 1,1-difluoroallene from ethylene and dibromodifluoromethane by a series of successive dehydrobrominations and brominations. This product has also been obtained by the pyrolysis of 1,1,2,2-tetrafluoro-3-methylenecyclobutane and of 2,2,3,3-tetrafluorocyclobutylidenemethyl acetate [180].

Dehydrohalogenation of the corresponding halogenated hydrocarbons by means of powdered or alcoholic potassium hydroxide or of sodamide has been used to obtain perfluoroallene [181], halogenoarylallenes [182,183], 4,4,4-trifluorobuta--1,2-diene [184], and alkoxyarylallenes [185-189]. The extremely reactive perchloroallene (LVI), which usually exists in dimeric form (LVII) [190,191], was obtained by Roedig [192] by the dehydrochlorination of pentachloropropene with sodamide in liquid ammonia:

This worker has recently succeeded in obtaining tri- and tetra-bromoallenes [193] by the reactions

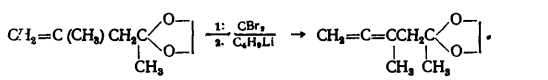
Arens [194,195] noted the formation of considerable quantities of allenyl ethers when the *cis*-forms of β-halogenoalkenyl ethers were subjected to prolonged heating with caustic potash. A more unequivocal result is obtained with allenic systems in which the structure is fixed [196-198]:

$$CH_3{=}CBrCH_2CN \rightarrow CH_2{=}C{=}CHCN\ (CO_2CH_3).$$



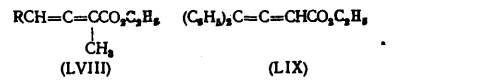
Isolated examples have been reported of the preparation of functional derivatives of allenes by the dehydration of alcohols [199] and the cleavage of acetals [200], nitro-derivatives [201], triglycerides [202], and derivatives of cyclobutane [203] and cyclopropane [204].

The reaction of but-2-ene-1,4-disulphonyl dichloride with ammonia and primary amines is accompanied by the evolution of hydrogen chloride and sulphur dioxide with the formation of allenic monosulphonamides [205]:



$$ClSO_2CH_2CX{=}CHCH_2SO_2Cl \xrightarrow{RNH_2} CH_2{=}C{=}CXCH_2SO_2NHR$$

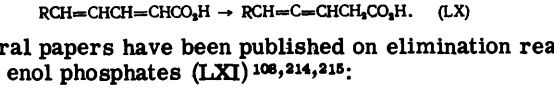
where X = H, Cl, CH_3.



The cleavage of *gem*-dihalogenocyclopropane derivatives with lithium alkyls in ethereal solution provides a simple and convenient method of obtaining certain allenic ethers [206,207]:

The successive action of dibromocarbene and butyl-lithium on unsaturated alcohols [208] or 2-substituted dioxolan derivatives [209] yields the corresponding allenic alcohols and acetals in 15-85% yield:

The Wittig reaction has recently found application for the synthesis of 1,2-dienes. It has been used to obtain, from acid chlorides [210] (or ketens) [211] and the appropriate phosphoranes, allenic esters of types (LVIII) and (LIX) respectively.



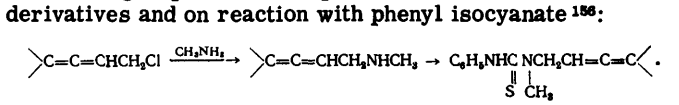
(LVIII) (LIX)

Optically active allene-1-carboxylic acids have recently been prepared in this way [212]. Alka-3,4-dienoic acids (LX, R = H, CH_3) are formed on ultraviolet irradiation of the alka-2,4-dienoic acids [213], but the yields are low:

$$RCH{=}CHCH{=}CHCO_2H \rightarrow RCH{=}C{=}CHCH_2CO_2H. \quad (LX)$$

Several papers have been published on elimination reactions of enol phosphates (LXI) [108,214,215]:

(LXI) (LXII) (LXIII)



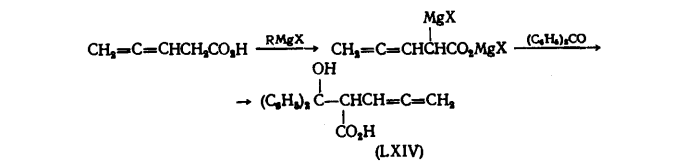
These reactions take place under comparatively mild alkaline conditions (at 25°), and simulate the biogenetic path for the synthesis of acetylenes in Nature [108,215]. Cymerman-Craig and Moyle [108] have shown that, in the presence of activating groups (C_6H_5, COOH), enol phosphates (LXI) are extremely readily converted into allenic compounds. The normal acetylenic products (LXII) formed at the same time may isomerise with (LXIII) under less basic conditions than are required for formation of the acetylenic group. The elimination of enol phosphates may, perhaps, be regarded as a chemical model of the biogenetic route for the formation of allenes in Nature.

III. CHEMICAL PROPERTIES AND REACTIONS OF FUNCTIONAL DERIVATIVES OF ALLENES

In conformity with the structure of allene [216,217], its functional derivatives are characterised by three types of chemical reactions — (1) reactions of the functional groups, not involving the allenic system, (2) additions at the allenic bonds, and (3) reactions involving isomerisation of the allenic system.

1. Reactions Not Involving the Allene Bond System

In halogenated allenic derivatives the halogen is extremely mobile, and can undergo various substitutions under the influence of neutral or weakly basic reagents (sodium carbonate, sodium acetate, potassium bromide, potassium iodide) [129,139,143,218]. Thus the action of amines on 4-chlorobuta-1,2-dienes has given various allenic amines [138,139-143,156], the allene group in which is preserved on formation of the derivatives and on reaction with phenyl isocyanate [156]:



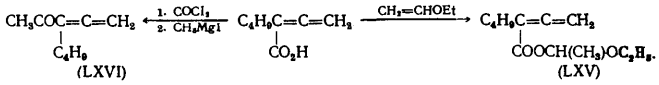
4-Chlorobuta-1,2-diene undergoes substitution with benzylmagnesium and especially phenylmagnesium bromide, to give allenic hydrocarbons [219]:

With other organomagnesium compounds [219-221] and with magnesium [222], however, only conjugated dienes are formed.

Penta-3,4-dienoic acid reacts with organomagnesium compounds to form a dimagnesium derivative, which with benzophenone yields an allenic product (LXIV) [223]:

(LXIV)

The reduction of 1-halogenoallenes with a zinc-copper couple in alcohol proceeds without affecting the double bonds [224], and provides a general method for the synthesis of allenic hydrocarbons [1]. Roedig [182] succeeded in reducing 1,1-dichloro-3,3-bischlorophenylallene by means of zinc dust in pyridine and glacial acetic acid:

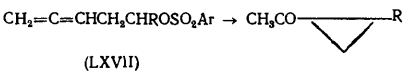


$$(ClC_6H_4)_2C{=}C{=}CCl_2 \rightarrow (ClC_6H_4)_2C{=}C{=}CH_2.$$

The allene group remains unaffected in the reduction of allenic ketones with lithium tetrahydroaluminate [89,90,93,225]. The oxidation of β-allenyl alcohols with chromium trioxide gives moderate yields of the corresponding acids [153,226,227]:

$$RC{\equiv}CCH{=}C{=}CHCH_2CH_2OH \rightarrow RC{\equiv}CCH{=}C{=}CHCH_2CO_2H.$$

2-Butylbuta-2,3-dienoic acid is stable to heating, and with excess of ethyl vinyl ether at 100° gives a quantitative



yield of the esterification product (LXV)[228]; the ketone (LXVI)[67] has been obtained by the action of methylmagnesium iodide on the chloride of this acid:

(LXVI) (LXV)

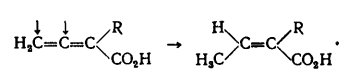
Allenic amides have also been obtained via the acid chlorides[43,78]. Kohler[229] prepared from 4-naphthyl-2,4-diphenylbuta-2,3-dienoyl chloride the corresponding carboxymethyl ester, which he separated into two optical enantiomers. In order to preserve the allene group in the original molecule, reactions must be conducted under mild and rigorously controlled conditions. However, side-reactions involving addition at the allenic bond system frequently occur[69,105,107].

An interesting rearrangement into acetylcyclopropanes[225,230] has recently been observed in the hydrolysis of sulphonates of the type (LXVII):

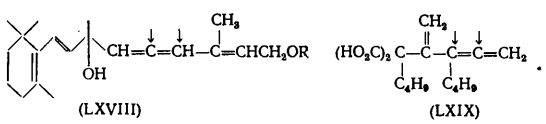
(LXVII)

where R = H, CH_3.

The allenic system is preserved in the unsymmetrical condensation of 1-halogenoallenes[231] by the Chodkiewicz method:



This is probably the most promising method for synthesising allenyne systems related to those occurring in Nature.

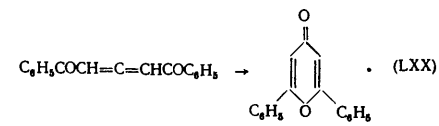


2. Addition Reactions

Reduction. The double bonds in allene readily undergo catalytic hydrogenation over platinum, palladium, or Raney nickel, with high yields of the resulting saturated products, and this method is widely used for the establishment of structure.

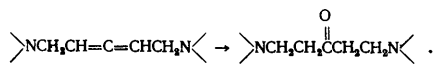
Incomplete hydrogenation of buta-2,3-dienoic acid in the presence of 1.5% of palladium on calcium carbonate gave *cis*-crotonic acid exclusively[105], i.e. the product resulting from addition of hydrogen at the $\beta\gamma$-double bond on the side opposite to the carboxyl:

The hydrogenation of 2-butylbuta-2,3-dienoic acid proceeds similarly[232], addition of hydrogen taking place at the less substituted double bond. Addition of hydrogen at one of the double bonds has been observed in the hydrogenation of the polyenol (LXVIII) in the presence of nickel[115], and also in the hydrogenation of the acid (LXIX) over platinum[233]:



(LXVIII) (LXIX)

The reduction of 1-halogenoallenes with lithium tetrahydroaluminate shows very unusual features. Allenic chlorides[49] give mainly alkenes, alkanes, and small amounts of alkynes. In contrast to this, 1-bromo-3-methylbuta-1,2-diene[16] gives a 75% yield of a mixture of hydrocarbons comprising 61% of 3-methylbutyne, 36% of isopentane, and small quantities of alkenes. A more detailed study has been made of the reduction of 1-chloro-3-methylbuta-1,2-diene[234] with lithium tetrahydroaluminate, when two competitive reactions are involved — (*a*) replacement of chlorine by hydrogen (or deuterium), accompanied by complete allene–acetylene rearrangement, and (*b*) addition of the reagent at the allene double bonds, leading on subsequent hydrolysis to a mixture of the above hydrocarbons.

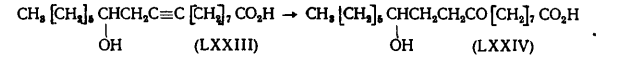


Addition of water, alcohols, thiols, and amines. Addition of these compounds, which is characteristic mainly of the acetylenic bond, takes place readily also with allenes. However, few examples of these reactions are known. 4-Chlorobuta-1,2-diene adds water in the presence of concentrated sulphuric acid[127], and allenic ketones are readily and quantitatively hydrated by dilute acids[72,90].

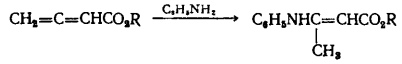
The action of 30% sulphuric acid on 1,5-diphenylpenta-2,3-diene-1,5-dione gave a 40% yield of the corresponding 4-pyrone (LXX), whose formation probably involves the initial addition of water[87,90]:

(LXX)

1,5-Bisdialkylaminopenta-2,3-dienes are hydrated when heated with mercury salts[157]:

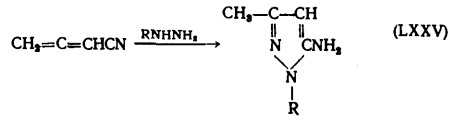


Allenic acids have been found to add water also in alkaline media[105,107]. Extraordinarily ready formation of the hydroxy-ketone (LXXII) was observed[69] on reduction of the sodium salt of the keto-acid (LXXI) with an alcoholic solution of potassium tetrahydroborate:



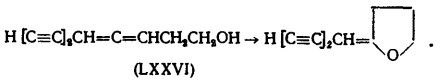
(LXXI) (LXXII)

It is interesting that hydration of the acetylenic acid (LXXIII) by mercury salts in sulphuric acid gives an isomeric hydroxy-keto-acid (LXXIV):



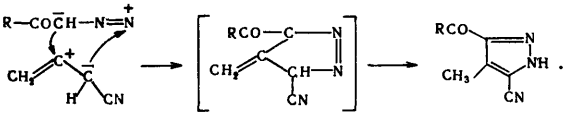
(LXXIII) (LXXIV)

Addition of alcohols and amines to allenes containing electronegative groups (CN, COOR, CO) takes place under considerably milder conditions than with acetylenic derivatives, the addition occurring at the unsubstituted double bond[105,235]. Brief treatment of buta-2,3-dienoic ester with aqueous–alcoholic caustic potash solution gives mainly β-ethoxycrotonic ester[105]. Piperidine and even aromatic amines add vigorously to an allenic ester even at room temperature, with formation of the corresponding β-substituted derivatives of crotonic ester[105]:



Alcohols, amines, and thiols add at the unsubstituted double bond also in buta-2,3-dienenitrile[97,236]. Addition of

substituted hydrazines is accompanied by ready cyclisation with the formation of an alkylated aminopyrazole (LXXV)[97]:

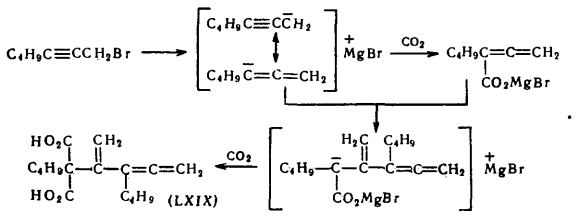


(LXXV)

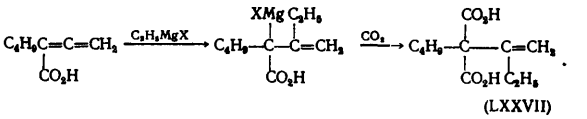
Allenic ketones give quantitative yields of the corresponding pyrazoles and oxazoles on reaction with hydrazine hydrate[90,94,237] and hydroxylamine[72]. An interesting case of intramolecular addition has been observed with the butadiynylallenic alcohol (LXXVI)[153]:

(LXXVI)

Such intramolecular additions may be of interest for the synthesis of various heterocyclic systems[90,97]. 1,3-Dipolar cycloadditions can also be used for this purpose. Success has recently been achieved in condensing buta-2,3--dienenitrile with various diazo-ketones[236] and obtaining the corresponding triazole and pyrazole derivatives:

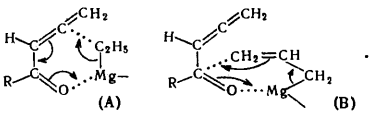


Addition of halogens and hydrogen halides. Addition to allenic compounds usually occurs very easily. Thus perchloroallene[192] and perfluoroallene[181] add two moles of chlorine even at -75°, and with 1,1-dichloro--3,3-di-*p*-chlorophenylallene[182] the reaction goes quantitatively at 20°. In the dark, however, perfluoroallene adds only one mole of chlorine and hydrogen halides[238]. On brominating 1,1-difluoroallene Blomquist[179] obtained a tetrabromide, but 1-chloro-5-ethoxy-4-methoxymethylenepenta-2,3-diene[143] and 1,1-dichloro-3,3-bischlorophenylallene[182] at 20° add bromine at only one double bond. Both the nitrile[97] and the ester[105] of buta-2,3-dienoic acid add only one molecule of bromine, at the unsubstituted double bond:



The addition of hydrochloric acid, however, takes place with the formation of $\beta\gamma$-unsaturated derivatives[97,105]. A similar type of addition has been observed also in the acid hydrolysis of the nitrile of octa-1,2-dienedicarboxylic acid[95].

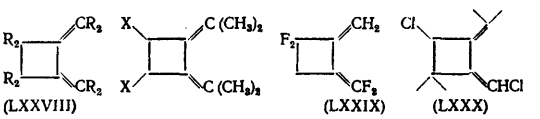
The literature describes several examples of the addition of Grignard reagents at allenic double bonds. Mention has been made above[78] of the preparation of the allenic dicarboxylic acid (LXIX) by carboxylation of the organomagnesium derivative obtained from 1-bromohept-2-yne, the reaction probably being represented by the scheme[233]



(LXIX)

It has also been shown[232,239] that the addition of organomagnesium compounds to 2-butylbuta-2,3-dienoic acid followed by carboxylation yields the unsaturated acid (LXXVII):

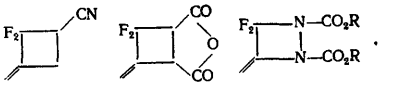
(LXXVII)



The structure of this acid (LXXVII) shows that the reaction results from addition at the $\alpha\beta$-double bond, not from 1,4-addition. Allenic ketones[72,89,90] with ethylmagnesium bromide also give products in which the ethyl group has been added at the allenic bond system, their formation probably involving a mechanism of cyclic transfer of electrons[72,240] (A):

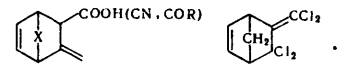
(A) (B)

This mechanism may be supported by the formation of normal Grignard reaction products of allenic ketones with allyl and prop-2-ynyl halides, which is also interpreted by an electron-transfer scheme. Formation of a six--membered ring is preferable to an eight-membered ring for normal addition at the carbonyl group (B), which might have occurred in addition of allyl (prop-2-ynyl) at the allenic system. Such an explanation, however, is not the only possible one, and the direction of the reaction may also be subject to steric factors[241].



Thermal dimerisation. This is more characteristic of halogenated allenes than of allenic hydrocarbons[3]. The reaction usually occurs even at low temperatures, and results in four-membered dimethylenecycloalkanes[16,110,180-182,190-193,242], whose structure as 1,2:1,2-addition products (LXXVIII) has been established by means of their infrared and nuclear magnetic resonance spectra and their chemical reactions:

(LXXVIII) (LXXIX) (LXXX)



where R = Cl, Br, F and X = Cl, Br. It has recently been shown[56,243] that the dimerisation of 1-halogenoallenes may result in 1,2:2,3-addition products, (LXXIX) and (LXXX). Dimeric products are formed also under the influence of acidic reagents, such as acetic acid, thionyl chloride, and phosphorus tribromide[244,245].

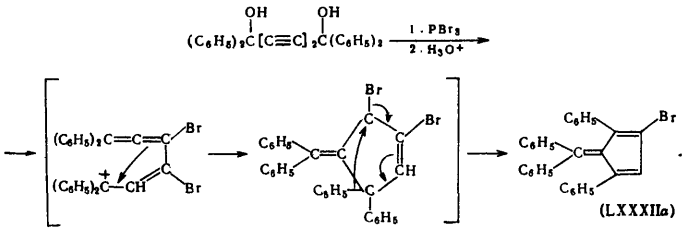
Halogenated allenes can undergo cycloaddition as well as dimerisation. Reaction of 1,1-difluoroallene with acrylonitrile, maleic anhydride, and azoformic ester yields the corresponding four-membered adducts[180]

Wotiz[228] noted that 2-butylbuta-2,3-dienoic acid does not undergo the Diels–Alder reaction, either as a diene or as a dienophile. It was subsequently shown, however, that allenic derivatives can be used as dienophiles of an unusual kind. Buta-2,3-dienoic acid was found[246] to give with cyclopentadiene an adduct of the type (LXXXI). Analogous

products are formed by the condensation of the corresponding nitrile[97] and of allenic ketones[247] with cyclopentadiene, furan, and certain other dienes.

(LXXXI) X = O, CH_2 (LXXXII)

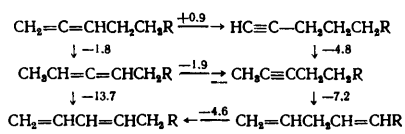
Roedig[192] has been able to effect the diene condensation of perchloroallene with cyclopentadiene (LXXXII) at -10°. The diene condensation of cyclopentadiene with optically active penta-2,3-dienedioic acid has recently been successfully employed[248] to establish the absolute configuration of the acid.



3. Isomerisation of Allenic Compounds

Isomerisation is a most characteristic feature of allenic derivatives. Under the influence of a solution of copper(I) chloride in concentrated hydrochloric acid, 1-halogenoallenes readily isomerise into conjugated 1-halogenobutadienes[8,9,14,64]. Jacobs and Petty[16] obtained a mixture of equal quantities of *cis*- and *trans*-1-bromo-3-methylbuta--1,3-dienes by the thermal isomerisation of 1-bromo-3--methylbuta-1,2-diene:

$$RCH_2CR'=C=CHX \rightarrow RCH=CR'CH=CHX.$$



However, certain 1-halogenoallenes could not be isomerised under these conditions[10,136,157].

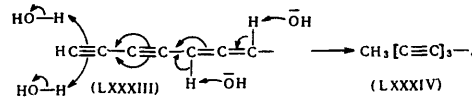
The interesting isomerisation has recently been described of tetraphenylhexa-2,4-diyne-1,6-diol in the presence of phosphorus tribromide in acetic acid[245], resulting in the fulvene (LXXXII*a*), this reaction undoubtedly involving intermediate allenic structures:

(LXXXII*a*)

Acetylene–allene isomerisations have already been mentioned above. Approximate heats of isomerisation (in kcal mole^{-1}) have been determined[249] for certain types of unsaturated compounds, which permitted these systems to be arranged as follows according to their tendency to interconversion

When discussing isomerisation in a series of functional derivatives of allene, however, we must bear in mind that the direction of isomerisation depends to a certain extent also on the nature of the functional groups. For example, allenic ethers[250] are in equilibrium with alkoxyacetylenic structures:

$$CH_2=C=CHOR \rightleftarrows CH_3C\equiv COR$$



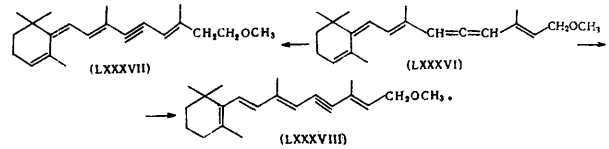
On the other hand, the isomerisation of derivatives of penta-2,3-diene-1,5-diol[139] and of allenic acids[105,227] yields only acetylenic compounds:

$$CH_3CH=C=CHCO_2H \rightarrow CH_3C\equiv CCH_2CO_2H.$$

The isomeric penta-3,4-dienoic acid[138] and other β-functional allenes[20,251] are converted under the same conditions into 2,4-diene derivatives:

$$CH_2=C=CHCH_2CO_2H \rightarrow CH_2=CHCH=CHCO_2H.$$

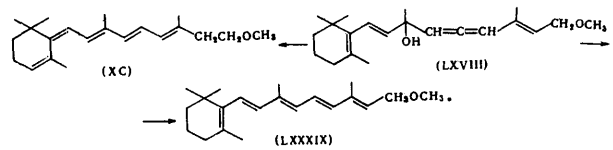
Allene–acetylene isomerisation plays an important part in establishing the structure of naturally occurring allene-polyynes. The mechanism of this rearrangement includes initial detachment of a proton by a strong base followed by its addition to another carbon atom of the molecule[84]. In the case of mycomycin[252,253] the rearrangement consists in migration of two protons and conversion of the allenediyne grouping (LXXXIII) into the corresponding alkatriyne derivative (LXXXIV):



(LXXXIII) (LXXXIV)

However, the methyl ester of *trans*-mycomycin (LI) very readily underwent alkaline isomerisation with the formation of the tridecatetraenediynoic ester (LXXXV), whose structure was proved by an alternative synthesis[154]:

$$H[C\equiv C]_2{-}CH{=}C{=}CH[CH{=}CH]_2CH_2CO_2CH_3 \rightarrow H[C\equiv C]_2[CH{=}CH]_4CO_2CH_3.$$



(LI) (LXXXV)

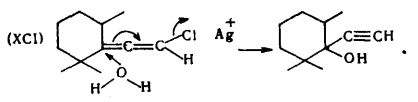
Interesting isomeric rearrangements have been observed with the allenic compound (LXXXVI)[115]. During chromatography on aluminium oxide it could already change into the acetylenic product (LXXXVII), and when boiled with alcoholic caustic soda it gave a mixture of (LXXXVII) and (LXXXVIII):

(LXXXVII) (LXXXVI) (LXXXVIII)

The polyenediol monomethyl ether (LXVIII) when boiled with lithium tetrahydroaluminate in ether isomerises into the methyl ether of vitamin A (LXXXIX), and on treatment with chromium acetate in strongly alkaline medium is converted into the *retro*-compound (XC)[115]:

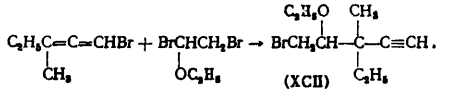
(XC) (LXVIII) (LXXXIX)

Isomerisation of an allenic system is observed also in the abstraction of hydrogen halide from allenic chlorides[132,254] and dibromides[125,126], and also during the dehydration of allenic alcohols formed by the Reformatskii reaction[68-70]:



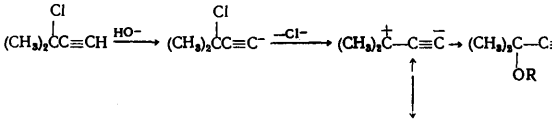
$$RCH_2CH=C=CHCH_2Cl \rightarrow RCH=CH{-}C\equiv CH \leftarrow \underset{\displaystyle OH}{RCHCH}=C=CH_2$$

CHEMICAL SOCIETY REFERENCE LIBRARY BURLINGTON HOUSE, W.1



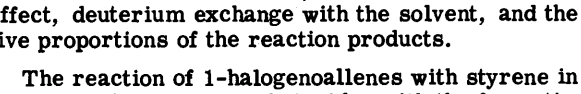
The cleavage of allenyl sulphides with sodamide[255], which gives 80–90% yields of a mixture of *cis*- and *trans*--isomers, may be of value for the preparation of substituted butenynes:

$$CH_3CH{=}C{=}C(R)SR' \xrightarrow{2\ equiv.\ NaNH_2} RCH{=}CH{-}C{\equiv}CH.$$

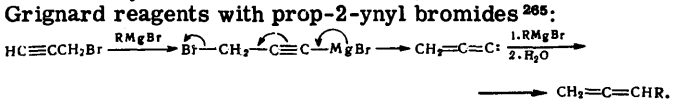


Substitutions in the halogenated allene series are often accompanied by isomerisation of the allenic system of double bonds. Although 1-chloro-3-methylbuta-1,2-diene does not react with silver acetate[34] and undergoes practically no solvolysis in 80% alcohol at 25°,[256] the allenyl chloride (XCI) is 90% converted into an acetylenic alcohol when heated with an alcoholic solution of silver nitrate[52]:

1-Bromo-3-methylbuta-1,2-diene reacts similarly with sodium iodide and with sodium phenyl sulphide, giving the corresponding acetylenic derivatives[16]. The action of ethoxy-1,2-dibromoethane on 1-bromo-3-methylpenta-1,2--diene also yields mainly acetylenic derivatives (XCII)[257]:



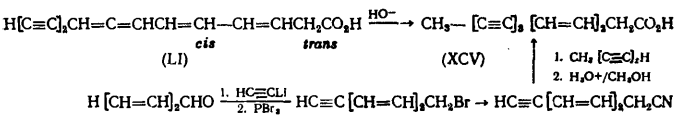
Interesting results have been obtained in a study of the solvolysis of 1-halogenoallenes. It has already been remarked above that 1-chloro-3-methylbuta-1,2-diene undergoes practically no solvolysis in 80% alcohol. In the presence of bases, however, the reaction is greatly accelerated, with the formation of 2-methylbut-3-yn-2-ol and its ethyl ether. A similar result is obtained with 3-chloro--3-methylbut-1-yne[256]. To explain these results, it was suggested that the rate-determining stage of the reaction was abstraction of a proton with formation of an intermediate carbene (XCIII):



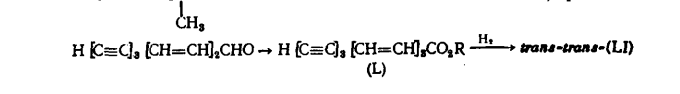
where R = H, C_2H_5. This mechanism of allene–acetylene rearrangement has found further support in the detailed work of Shiner and Wilson[17], who studied the kinetics, salt effect, deuterium exchange with the solvent, and the relative proportions of the reaction products.

The reaction of 1-halogenoallenes with styrene in the presence of potassium t-butoxide, with the formation of (XCIV)

where X = Cl, Br, also takes place by a carbene mechanism[258,259]. Alkynes of various structures[258,260–262] and dicarbene (:C=C=C:)[263,264] have also been used as starting materials in the above reaction with cyclohexene, isomeric butenes, and other alkenes.



Formation of allenecarbene as an intermediate product has recently been observed in a study of the reaction of Grignard reagents with prop-2-ynyl bromides[265]:

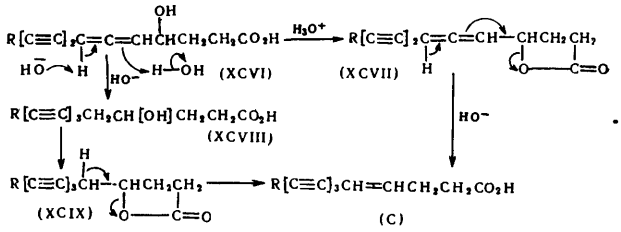


The accompanying formation of allenic hydrocarbons can best be explained by means of an intermediate allenecarbene.

IV. NATURALLY OCCURRING COMPOUNDS OF ALLENIC STRUCTURE

The number of compounds of this type is not yet large, but they constitute a very interesting group of optically active compounds exhibiting a broad spectrum of antimicrobial and fungicidal action. In chemical structure these compounds are polyunsaturated functional derivatives containing acetylenic, polyene, and allenic groups. The first representative of these substances was *mycomycin* (LI), which was isolated from the mould *Nocardia acidophylus* by Johnson and Burdon[266] in 1947. This antibiotic is very unstable in the crystalline state, and can be stored only in solution at -40°; it decomposes explosively at 75°. The structure of mycomycin was elucidated by Celmer and Solomons[252,267], who established that it contains an unbranched chain of carbon atoms with the empirical formula $C_{13}H_{10}O_2$. Absorption bands in the ultraviolet and infrared spectra[66,267] indicate the presence of diene and diyne groupings, unconjugated carboxyl, an allenic group, and ethynyl hydrogen. This together with other data has enabled mycomycin to be assigned the structure trideca--*trans*-3,*cis*-5,7,8-tetraene-10,12-diynoic acid (LI). In the presence of small amounts of alkalis, mycomycin undergoes isomerisation into the optically inactive isomycomycin (XCV), whose structure as trideca-*trans*--3,*trans*-5-diene-7,9,11-triynoic acid was confirmed by spectroscopic data and its complete synthesis by Bohlmann and Viehe[268] in 1954:

Bohlmann and Sugrow[154] synthesised *trans*-*trans*-mycomycin by reducing with aluminium amalgam the trideca--2,4,6-triene-8,10,12-triynoic esters (L) obtained by the reactions

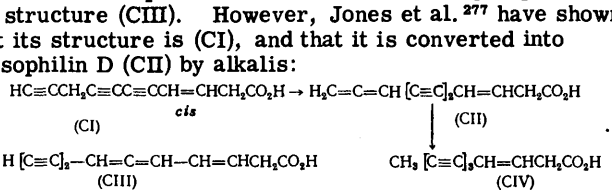


Synthetic *trans*-mycomycin is more stable towards alkalis, and its isomerisation half-life at pH 7.5 is 115 h, compared with the 3 h for natural *cis*-mycomycin[154].

Two other antibiotics having an allenic structure — *nemotin* (XCVII) and *nemotinic acid* (XCVI) — have been isolated from cultures of *Poria tenuis*, *P. corticola*, and the fungus B-841 (an unidentified Basidiomycete from white cedar)[269–271]. These two biologically active substances are very similar in their bactericidal spectrum, but differ considerably in fungicidal activity; they are very toxic, and cause contact dermatitis[269].

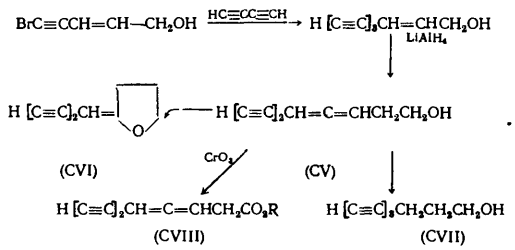
Both substances are extremely unstable, and can be prepared only in solution. When an attempt is made to isolate them from solution by lyophilic drying, they are converted into a dark polymeric mass[270]. Their ultraviolet and infrared spectra, catalytic hydrogenation, and chemical behaviour in alkaline and acid media[253,272] indicate that

nemotinic acid is a 4-hydroxyundeca-5,6-diene-8,10-diynoic acid (XCVI, R = H), while nemotin is its lactone.



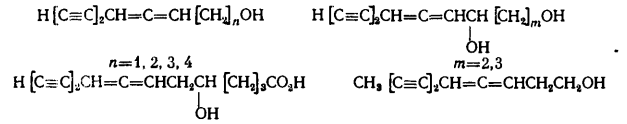
Study of the chemical transformations of these antibiotics showed[253] that at pH 10 nemotin undergoes rearrangement with cleavage of the lactone ring and formation of nemotin A (C, R = H). In contrast to this, nemotinic acid, which contains the same chromophoric group as does nemotin, is converted in alkaline medium into isonemotinic acid (XCVIII, R = H), from which the alkatriynoic lactone (XCIX) is readily formed; this compound can be further converted into nemotin A (C, R = H):

Odyssin (XCVII, R = CH_3) and *odyssic acid* (XCVI, R = = CH_3) are homologues of nemotin and nemotinic acid respectively, and are present with them in the culture liquid of the Basidiomycete B-841.[272,273] They are similar in chemical and physicochemical properties to the latter compounds, while their transformation products (R = CH_3) are more stable; the final structure of the compounds (XCVIII)–(C) has been proved by synthesis[177]:

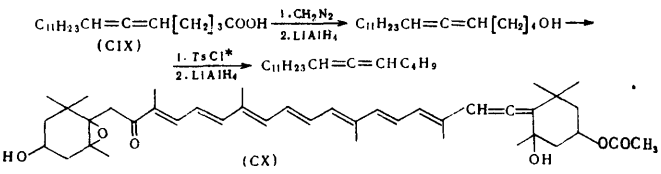


In addition to the above, two related polyunsaturated antibiotics — *drosophilins C* and *D* — have been isolated from the culture medium of the fungus *Drosophilia subatrata*[274,275] and *D. semivestita*[276]. It was formerly supposed that drosophilin C contained an allenic group and had the structure (CIII). However, Jones et al.[277] have shown that its structure is (CI), and that it is converted into drosophilin D (CII) by alkalis:

Thus drosophilin D (CII) contains a terminal allene group. It can be converted by further isomerisation into the alkenetriynoic acid (CIV).



Marasin (CV) is the only allenic antibiotic at present known in both optically active forms. In 1959 (-)-marasin was isolated from a culture of *Marasmius ramealis*[278], and quite recently (+)-marasin has been obtained from the culture medium of *Aleurodiscus roseus*[226]. The formula (CV) was assigned to marasin on the basis of a study of the chemical transformations and the infrared and ultraviolet spectra; this has subsequently been confirmed by a complete synthesis of the racemate[153].



In alkaline media all three forms of marasin are readily converted into the corresponding cyclic enolic ether, isomarasin (CVI), which on hydrogenation absorbs five moles of hydrogen with the formation of n-butyltetrahydrofuran, identified by gas–liquid chromatography. It is interesting that the alkaline isomerisation of (+)-marasin yields also a small amount of the alkatriynol (CVII).

Two new allenic antibiotics — nona-3,4-diene-6,8--diynoic acid (CVIII) and its methyl ester — have been isolated, together with (+)-marasin, from the culture medium of *Aleurodiscus roseus*[226], and have been synthesised from natural marasin.

It has recently been noted that *Odontia bicolor*[279] manufactures mycomycin and certain other allenic antibiotics, to which can be assigned the structures

Among natural allenic compounds the simplest is labal-lenic (octadeca-5,6-dienoic) acid (CIX), which has been isolated from the oil of *Leonotis nepetaefolia*[280]. This acid is extremely stable to alkalis and, in conformity with its structure, can be readily converted into octadeca-5,6-diene.

* Ts = *p*-$CH_3C_6H_4SO_2$ (Ed. of Translation).

The first allenic carotenoid to be isolated was fucoxanthin (CX), from seaweed[281]. Its proposed structural formula (CX) is extremely reliable[282,283], and agrees well with experimental results hitherto obtained.

Further investigation will undoubtedly lead to the isolation of other natural allenic compounds, which will enable us to elucidate the routes of their biogenesis and their role in the vital activities of micro-organisms.

I. INTRODUCTION

The interest taken by research workers in the chemistry of unsaturated organophosphorus compounds, which has increased extraordinarily during recent years, is explained by the potentialities of these compounds for use as monomers in the manufacture of plastics[1], intermediates in the synthesis of plasticisers[2], solvents for the extraction of compounds of the rare metals[3], finishing agents for textiles[4], additives to lubricating oils[5], and also as starting materials for the synthesis of various biologically active compounds[6-10]. Besides this, the great reactivity and the accessibility of unsaturated organophosphorus compounds of various classes makes them valuable materials for the study of the interaction of atoms in organic compounds of elements in the Third Period, in particular for elucidating the role of the vacant *d*-orbitals in the transmission of electronic influences in the molecule[11-14].

The first attempts to prepare acetylenic derivatives of phosphorus were made in 1921.[15] More recent work on the synthesis of tertiary acetylenic phosphines and of phosphonic esters containing 1,3-diene substituents attached to the phosphorus atom has been summarised in Gefter's monograph[1] (up to 1958) and in several reviews[16,17]. This section of the chemistry of organophosphorus compounds has developed so rapidly since 1958 that the number of compounds synthesised has more than doubled. During the past seven years original new routes have been worked out for the synthesis of highly unsaturated compounds containing acetylenic, allenic, and 1,3-diene substituents attached to the phosphorus atom. Data obtained from the study of unsaturated organic compounds of phosphorus by modern physical methods (ultraviolet, infrared, and nuclear magnetic resonance spectroscopy, dipole moments) have enabled certain conclusions to be drawn concerning the way in which phosphorus-containing groups are conjugated with multiple bonds. The present review summarises all these fresh results.

II. PREPARATION AND CHEMICAL PROPERTIES

1. Phosphines

Primary phosphines are usually obtained by the reduction of halogenophosphines and by the reaction of phosphine and its metal derivatives with alkyl halides and carbonyl compounds[18]. None of these methods has been used to obtain acetylenic or diene phosphines. Attempts to use the reduction of phenylethynylphosphonic ester with lithium tetrahydroaluminate to obtain a primary phosphine containing the phosphino-group directly linked to a triple bond were unsuccessful. Besides cleavage of the phosphorus–carbon bond, the triple bond was hydrogenated to a double bond with formation of α-styrylphosphine[19,20]:

$$C_6H_5C{\equiv}CPO(OC_2H_5)_2 \rightarrow C_6H_5CH{=}CHPH_2.$$

Two of the primary acetylenic phosphines which have been described were obtained by the reaction of sodium phosphide with acetylenic α-epoxides in liquid ammonia[21]:

$$RC{\equiv}C{-}\underset{CH_2}{\overset{}{C}}{-}\underset{O}{\overset{}{CH_2}} \xrightarrow[NH_3]{NaPH_2} RC{\equiv}CC(OH)(CH_3)CH_2PH_2$$

where R = CH_3 or C_4H_9.

No secondary phosphines have been described containing acetylenic or diene substituents. Tertiary phosphines,

however, represent the most thoroughly studied group of phosphines both with saturated and with unsaturated substituents.

The most widely applicable method of preparing tertiary phosphines is the reaction of organometallic compounds with three-coordinated phosphorus halides. Most of the tertiary acetylenic phosphines have been obtained by this method. A long series of papers in this field was initiated by de Mahler [15], who tried to obtain phosphorus carbide by the reaction of ethynylenedimagnesium di-iodide with phosphorus trichloride. Although the desired result was not achieved in this case [22-24], the synthesis became the most fruitful method of obtaining various tertiary acetylenic phosphines. Successful use was subsequently made of Iotsich complexes derived from acetylenic hydrocarbons, acetylenic alcohols [25,26] and sulphides [27], ethynylmagnesium [27,28] and butadiynylmagnesium bromides in tetrahydrofuran, and also ethynylenedimagnesium dibromide [24,27,29]. From the appropriate organomagnesium compounds and diaryl- or dialkyl-phosphinous chlorides compounds could be obtained containing alkenynyl [30,31], butadiynyl, and hexatriynyl [30] substituents attached to the phosphorus atom, as well as acetylenic diphosphines [24,27,29]:

$$R\,[C{\equiv}C]_nMgX + R_2PCl \rightarrow R\,[C{\equiv}C]_nPR_2.$$

The application of this reaction to phenylphosphonous dichloride and to phosphorus trichloride enabled tertiary phosphines to be obtained containing two [25] and three [32] acetylenic substituents. The yields in reactions of this type are usually high. A diminished yield is often due to instability of the final products.

Sodium acetylides in liquid ammonia can be used instead of organomagnesium compounds. The chlorophosphines are then replaced as starting materials by the corresponding alkoxy- or alkylthio-derivatives [27]:

$$HC{\equiv}CNa + ROPR'_2 \rightarrow HC{\equiv}CPR'_2 + RONa.$$

It must be supposed that sodium alkyl or aryl acetylides may be used equally successfully in this interesting reaction.

Another original route has also been proposed for the preparation of tertiary phosphines containing a terminal acetylenic group. Cleavage of 4-diphenylphosphino-2-methylbut-3-yn-2-ol in the presence of alkali leads to the formation of ethynyldiphenylphosphine in 68% yield:

$$(C_6H_5)_2PC{\equiv}CC(CH_3)_2OH \xrightarrow{KOH} (C_6H_5)_2PC{\equiv}CH + (CH_3)_2CO.$$

Unfortunately, no experimental details are given [25]. Finally, bisdibutylphosphinoacetylene is cleaved by phenyl-lithium with the formation of dibutylphosphine and ethynyldibutylphosphine [27]:

$$(C_4H_9)_2PC{\equiv}CP(C_4H_9)_2 + C_6H_5Li \rightarrow (C_4H_9)_2PC{\equiv}CLi + C_6H_5P(C_4H_9)_2$$
$$\downarrow H_2O$$
$$(C_4H_9)_2PC{\equiv}CH$$

The above phosphines containing a terminal acetylenic group readily undergo substitution of the acetylenic hydrogen. This method has been used to synthesise tertiary alkylacetylenic phosphines and acetylenic carbinols containing a dialkylphosphino-group attached to the triple bond [25,27].

Tertiary acetylenic phosphines can also be obtained from the lithium dialkyl phosphide and chloroacetylenes [33]:

$$R_2PLi + ClC{\equiv}CC_6H_5 \rightarrow R_2PC{\equiv}CC_6H_5 + LiCl.$$

This reaction is less convenient for obtaining acetylenic phosphines than, say, the organomagnesium synthesis. However, it is of theoretical interest, since it indicates the quite high reactivity of a halogen adjacent to a triple bond. A reaction of similar type has proved extremely fruitful in the synthesis of esters of phosphonic acids containing acetylenic substituents.

Petrov and Kormer proposed a method for preparing tertiary phosphines having an allenic group in the hydrocarbon substituent, which was based on the addition of lithium phosphides to alka-1-en-3-ynes [34]:

$$RC{\equiv}CCH{=}CH_2 \xrightarrow{LiPR'_2} RLiC{=}C{=}CHCH_2PR'_2 \xrightarrow{H_2O} RCH{=}C{=}CHCH_2PR'_2,$$

where R = CH_3, C_2H_5 and R' = C_2H_5, C_4H_9. Pent-1-en-3-yne yields as side-product an acetylenic phosphine: i.e. allene–acetylene rearrangement is observed [35].

Among phosphines containing conjugated diene substituents, only cyclic phospholes are known. These are obtained by the reaction of tetraphenylbuta-1,3-dienylenedilithium with dihalogenophosphines, or alternatively by the interaction of the 1,4-di-iodobutadiene derivative with disodium phenyl phosphide [36-39]:

$$\left.\begin{array}{l} LiC(C_6H_5){=}C(C_6H_5)C(C_6H_5){=}C(C_6H_5)Li + C_6H_5PCl_2 \\ IC(C_6H_5){=}C(C_6H_5)C(C_6H_5){=}C(C_6H_5)I + C_6H_5PNa_2 \end{array}\right\} \rightarrow \begin{array}{l} C_6H_5{-}C{-}C{-}C_6H_5 \\ C_6H_5{-}C\;\;\;C{-}C_6H_5. \\ \quad\quad\;\; P{-}C_6H_5 \end{array}$$

Heterocycles containing two conjugated double bonds and containing several heteroatoms besides phosphorus have been synthesised by this method.

It can thus be seen that methods for the synthesis of tertiary phosphines containing acetylenic or diene substituents are more varied than those for obtaining phosphines containing ethylenic substituents [40-45].

Acetylenic and diene phosphines are liquids or crystalline solids having the characteristic properties of phosphines. Those containing alkyl groups possess an unpleasant odour. The constants of the acetylenic and diene phosphines which have been described are given in Table 1. The only omissions from this are the phosphines mentioned in Ref. 30 without indication of their constants or yields (1-diethylphosphinopropyne, 1-diethylphosphino-2-phenylacetylene, and 1-diphenylphosphino-propyne, -butadiyne, -penta-1,3-diyne, and -hepta-1,3,5-triyne).

Little work has been done on the chemical properties of acetylenic phosphines. The strength of the phosphorus–carbon bond is strongly dependent on the structure of the phosphine. Thus bisdiphenylphosphinoacetylene is not cleaved by dilute alkali, silver nitrate, or cuprammonium solution; cleavage takes place only on alkaline fusion or prolonged boiling with a saturated alcoholic solution of potassium hydroxide [24]. Dibutylphosphinoacetylene disproportionates in the presence of alkaline catalysts in liquid ammonia, with the formation of bisdibutylphosphinoacetylene, which, as already noted, may be cleaved by butyl-lithium [27]. Heating 4-diphenylphosphino-2-methylbut-3-yn-2-ol with alkali leads to the elimination of acetone, as already mentioned, but does not affect the P–C≡ bond [25]. The enhanced stability of the phosphorus–acetylenic bond in comparison with acetylenic derivatives of other elements is explained by the small difference in electronegativities between carbon and phosphorus according to Pauling (2.8 and 2.1 respectively) [24], which can hardly be accepted as correct.

* Table 1 does not include compounds cited in Geffer's monograph.[1]

** X = anthrafuchsone.

Primary acetylenic phosphines — derivatives of acetylenic alcohols — do not give derivatives with 2,4-dinitrobenzoyl chloride, toluene-*p*-sulphonyl chloride, phenyl isocyanate, or picric acid, nor are they hydrogenated over platinum black or Raney nickel[21]. Tertiary acetylenic phosphines, however, can react both at the phosphino--group and at the acetylenic group. They add oxygen, sulphur, selenium, and halogenated hydrocarbons at the phosphorus, and compounds having alkyl substituents attached to the phosphorus are more reactive than aromatic or alkatriynyl phosphines[24,30,32,33]. As stated previously, tertiary phosphines containing a terminal acetylenic group undergo reactions involving substitution of the acetylenic hydrogen. Thiols in the presence of peroxides add at the triple bond[27]:

$$(C_4H_9)_2PC{\equiv}CH + C_2H_5SH \rightarrow (C_4H_9)_2PCH{=}CHSC_2H_5.$$

The chemical properties of phospholes give no grounds for assuming that these compounds are appreciably aromatic in character. They undergo both reactions characteristic of conjugated dienes (Diels–Alder reaction, formation of complexes with iron carbonyls) and reactions involving the lone pair of electrons on the phosphorus (addition of oxygen, sulphur, and selenium and complex formation)[36-39].

It follows from the above survey of the chemical properties of acetylenic phosphines that study of the influence of the triple bond on the well-known chemical properties of phosphines has been far from adequate, while the literature contains no discussion at all of the problem of the steric structure of acetylenic phosphines. An X-ray examination of bisdiphenylphosphinoacetylene[46] has shown that this compound crystallises in monoclinic form with four formula units in the unit cell.

2. Phosphine Oxides, Sulphides, Selenides, and Quaternary Salts

These compounds are usually obtained by the addition of oxygen, sulphur, selenium, and halogenated hydrocarbons to phosphines.

Oxidation of bisdiethylphosphinoacetylene with hydrogen peroxide gives the dioxide of this compound, while reaction with elementary sulphur yields the disulphide. On interaction of this diphosphine with alkyl iodides, however, only mono-derivatives of the type $(C_6H_5)_2PC{:}CP(CH_3)(C_6H_5)_2I$ are formed[24].

The addition of oxygen, sulphur, and selenium to *para*--substituted trisphenylethynylphosphines[32] or to cyclic phospholes[36-39] also results in formation of the corresponding oxides, sulphides, and selenides.

Oxides and sulphides of phospholes have been obtained also directly from phosphonic and phosphonothioic chlorides respectively and the dilithium derivative of tetraphenylbutadiene. A similar path, without phosphines as intermediate products, has recently been used to obtain oxides and sulphides of tertiary acetylenic phosphines. When Iotsich complexes interact respectively with thiophosphoryl trichloride and the corresponding *P*-alkyl and *P*-aryl dichlorides and *PP*-dialkyl monochlorides, phosphine sulphides are obtained containing 1–3 acetylenic substituents and also conjugated alkenynyl radicals attached to the phosphorus atom[47-49]:

$$RC{\equiv}CMgX + R'_nP(S)X_{3-n} \rightarrow R'_nP(S)(C{\equiv}CR)_{3-n}.$$

It is interesting that tetrasubstituted diphosphine disulphides cannot be obtained when Iotsich complexes are used, in contrast to what occurs with alkylmagnesium halides. In this respect phenyl and styryl substituents occupy an intermediate position: when they are initial reactants, a phosphorus–phosphorus bond is formed only when one of them contains an alkyl substituent[49].

Reaction of phenylethynylmagnesium bromide with styrylphosphonothioic chloride yields a tertiary phosphine sulphide containing two triple bonds and one double bond in the α-position to the phosphorus atom[49].

1-Halogenoalkynes react with triphenylphosphine to form quaternary phosphonium salts containing an acetylenic substituent. Fluoroacetylene reacts considerably more rapidly than does chloroacetylene[50]:

$$(C_6H_5)_3P + HC{\equiv}CX \rightarrow [(C_6H_5)_3PC{\equiv}CH]^+X^-.$$

A novel case of the Arbuzov rearrangement of esters formed by acids containing three-coordinated phosphorus with alcohols of prop-2-ynyl type, accompanied by acetylene–allene isomerisation, was described in 1962. Use of dialkyl- and diaryl-chlorophosphines and various acetylenic carbinols yielded in this way phosphine oxides containing an allenic group attached to the phosphorus atom[51,52]. The mechanism of this reaction will be discussed below (in Subsection 3).

The physical constants of phosphine oxides, sulphides, and selenides and quaternary phosphonium salts containing acetylenic substituents adjacent to the phosphorus atom are given in Table 1.

The chemical properties of compounds of this type have been little studied. The strength of the P–C≡ bond is appreciably lower in phosphine oxides and sulphides than in the corresponding phosphines. Bisdiphenylphosphinoacetylene dioxide and disulphide are cleaved with the evolution of acetylene by boiling with alcoholic caustic potash and even when chromatographed on alkaline aluminium oxide[24]. The oxides, sulphides, and selenides of tri--*p*-tolylethynylphosphine and tri-*p*-chlorophenylethynylphosphine are cleaved at the P–C≡ bond by alkali, silver nitrate, and Ilosvay reagent[32].

3. Phosphonous and Phosphonic Acids and Their Derivatives

During recent years an intensive study has been made of phosphonous and especially phosphonic acids containing unsaturated substituents, as well as of their derivatives.

The starting materials for the synthesis of saturated phosphonous acids and their derivatives are usually phosphines or halogenophosphines, which are subjected to oxidation, hydrolysis, alcoholysis, etc. They are also obtained by the reaction of phosphorohalidites with organomagnesium or organolithium compounds.

A general method for preparing saturated phosphonic acids is the reaction of alkyl halides with trialkyl phosphites, sodium dialkyl phosphites, or phosphorus trichloride in the presence of aluminium chloride, and also the addition of simple phosphorus derivatives to unsaturated compounds at multiple bonds.

Unsaturated compounds of the above types can be synthesised by these methods and also by such procedures as the addition of phosphorus pentachloride at multiple bonds with subsequent elimination of hydrogen chloride, the rearrangement of prop-2-ynyl phosphites, etc.

Interaction of ethynylmagnesium bromide in tetrahydrofuran with halogenated phosphorus derivatives has been used for the synthesis of phosphonous and phosphonic esters containing a terminal acetylenic group attached to the phosphorus atom. Dibutyl phosphorochloridite gives dibutyl ethynylphosphonite, which is hydrolysed to the corresponding acid ester[40-43]. By the use of dialkyl phosphorochloridates and phosphorofluoridates a few ethynylphosphonic esters have been obtained in low yields and in not entirely pure form[56,57]:

$$(C_4H_9O)_2PCl + BrMgC{\equiv}CH \rightarrow (C_4H_9O)_2PC{\equiv}CH \xrightarrow{H_2O} C_4H_9OP(O)C{\equiv}CH \quad (H)$$

$$(RO)_2P(O)X + BrMgC{\equiv}CH \rightarrow (RO)_2P(O)C{\equiv}CH$$

Examples have been given of the application of organomagnesium compounds to the synthesis of unsaturated phosphonites and phosphonates. This route proved inconvenient for the preparation of phosphonous and phosphonic acids, owing to experimental difficulties in the isolation of the final products and to the poor mobility of halogen in phosphorohalidates.

Reaction of phosphorus pentachloride with 1,3-diene hydrocarbons yields addition products, which can be converted into chlorides of the corresponding phosphonic, phosphonothionic, and phosphonoselenonic acids[68,77-80]:

$$CH_2{=}CHCH{=}CH_2 + 2\,PCl_5 \rightarrow ClCH_2CH{=}CHCH_2PCl_4{\cdot}PCl_5 \xrightarrow{H_2X} ClCH_2CH{=}CHCH_2P(X)Cl_2 \xrightarrow[NR_3]{} CH_2{=}CHCH{=}CHP(X)Cl_2.$$

These acid chlorides can be obtained from alkenyne hydrocarbons and phosphorus pentachloride directly in one stage[69-76,81-85]. These hydrocarbons add the pentachloride at the triple bond[71,81,82]:

$$CH_2{=}CHC{\equiv}CR + 2\,PCl_5 \rightarrow CH_2{=}\underset{Cl}{CH}C{=}\underset{R}{C}PCl_4{\cdot}PCl_5 \xrightarrow{SO_2} CH_2{=}\underset{Cl}{CH}C{=}\underset{R}{C}POCl_2 + POCl_3.$$

In the case of hydrocarbons containing a monosubstituted acetylenic group, however, the products of this reaction either add further a molecule of hydrogen chloride (with butenyne) or replace by chlorine a hydrogen atom in the saturated radical[71,72,81-83].

Shostakovskii, Guseinov, and their coworkers have published a series of papers on the addition of phosphorus pentachloride to alkoxy- and alkylthio-alkenynes[69,70,73-76,84,85]. The latest paper of this series[70] gives a more precise structure for the products, and shows that the reaction is represented by the equation

$$ROCH{=}CHC{\equiv}CH \xrightarrow[2.\ SO_2]{1.\ PCl_5} ROCH{=}CHCCl{=}CHPOCl_2.$$

The chlorides of phosphonic acids obtained by addition of phosphorus pentachloride to alkenynes have been converted by the usual methods into the corresponding esters, thio-esters, and amides.

Chlorides of phosphonic acids containing 1,3-diene substituents have been obtained also by the oxidative phosphorylation of butenyne, but the yields are low[86]:

$$CH_2{=}CHC{\equiv}CH + 2PCl_3 + O_2 \rightarrow CH_2{=}CHCCl{=}CH{-}POCl_2 + POCl_3.$$

Acetylenic hydrocarbons and phosphorus pentachloride have been used to obtain phosphonic acids and esters containing arylacetylenic substituents attached to the phosphorus atom. The chlorostyrylphosphonic chlorides formed initially were converted into the free acids[54] or the esters[66], and then dehydrochlorinated. Arylethynylphosphonic acids[55] and also 4-phenylbutadienylphosphonic acid[87] have been prepared for the first time by this method:

$$RC{\equiv}CH + PCl_3 \rightarrow RCCl{=}CHPOCl_2 \rightarrow RCCl{=}CHP(O)(OR')_2 \rightarrow RC{\equiv}CP(O)(OR')_2.$$

However, this is not a general path for the preparation of acetylenic phosphonates. When β-chloro-p-methoxystyrylphosphonic acid is used, for example, dehydrochlorination cannot be effected: the phosphorus–carbon bond undergoes fission[54].

The most fruitful reaction for the preparation of acetylenic phosphonates is the Arbuzov rearrangement. Early attempts to apply this process to halides of the prop-2-ynyl type containing a monosubstituted acetylenic bond resulted in the formation merely of isomeric compounds containing an acetylenic group attached to the phosphorus atom (in the case of prop-2-ynyl bromide[59]) or an allenic group[93]. This occurred also when a sodium dialkyl phosphite was used instead of the tertiary phosphite[59]. With prop-2-ynyl bromides having a disubstituted acetylenic group the "normal" Arbuzov rearrangement products were formed[61,64].

Halogenoacetylenes containing the halogen atom adjacent to the triple bond can also undergo the Arbuzov rearrangement with trialkyl phosphites, with formation of the normal products[65]. The most reactive compounds are those in which the triple bond is linked with another multiple bond, a benzene ring, or an electron-acceptor substituent such as a chlorine atom[58,64,67]. With respect to their reactivity the halogenoacetylenes are arranged in the series R–F > > R–Cl > R–Br > R–I, which is due to the diminution in polarisation of the ≡C–X bond in this sequence. Rearrangement involving halogenated acetylenes most probably takes place by the usual mechanism with the formation of a quasi-phosphonium compound as intermediate:

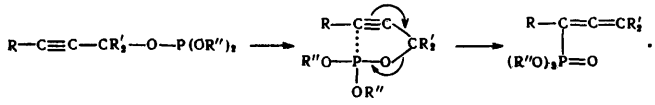
$$RC{\equiv}CX + P(OR')_3 \rightarrow RC{\equiv}CP(OR')_3X \rightarrow RC{\equiv}CP(O)(OR')_2 + R'X.$$

Phosphonic esters containing phenylethynyl, butenynyl, and butadiynyl substituents attached to the phosphorus atom have been obtained by this method, and several of them have been converted into the corresponding acid chlorides by the action of phosphorus pentachloride[68]. Dichloroacetylene gives with a phosphite under the same conditions diethyl chloroethynylphosphonate and bisdiethoxyphosphinylacetylene[58]. Use of monofluoroacetylene yields an ethynylphosphonic ester containing a terminal acetylenic group[58].

Phosphonic esters containing alkylethynyl substituents could not be obtained by the Arbuzov rearrangement[58,67]. Roundabout methods have been suggested for the synthesis of compounds of this type. Prop-1-ynylphosphonic ester is formed in low yield in the interaction of prop-2-ynyl bromide with triethyl phosphite[59] or sodium diethyl phosphite[64]. A more convenient method for the preparation of prop-1-ynylphosphonates is the reaction of dichloroacetone with two moles of triethyl phosphite, followed by treatment with sodium ethoxide[59]:

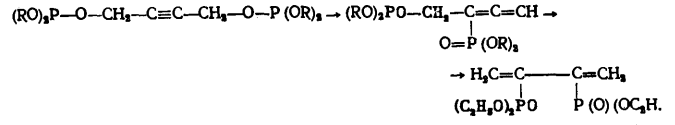
$$ClCH_2{-}CO{-}CH_2Cl \xrightarrow{P(OC_2H_5)_3} CH_2{=}\underset{O{-}PO(OC_2H_5)_2}{C}{-}CH_2Cl \xrightarrow{P(OC_2H_5)_3} CH_2{=}\underset{O{-}P(O)(OC_2H_5)_2}{C}{-}CH_2{-}P(O)(OC_2H_5)_2 \xrightarrow{C_2H_5ONa} CH_3{-}C{\equiv}C{-}P(O)(OC_2H_5)_2$$

and also prototropic isomerisation of esters containing allenic substituents attached to the phosphorus atom[61], which can be conducted with or without isolation of the intermediate allenic compound[62,63,88]:



$$(RO)_2POCH_2{-}C{\equiv}CH \rightarrow CH_2{=}C{=}CHP(O)(OR)_2 \rightarrow CH_3C{\equiv}CP(O)(OR)_2.$$

The latter is not a general method, since, when homologues are used, the prototropic isomerisation either goes in a different direction or does not occur at all[61,63].



A process which is probably suitable for the preparation of various homologues of alkynylphosphonic acids has been employed for the synthesis of a but-1-ynylphosphonate[58]:

$$C_2H_5MgBr + ClC{\equiv}CP(O)(OC_2H_5)_2 \rightarrow C_2H_5C{\equiv}CP(O)(OC_2H_5)_2.$$

As stated above, esters formed by acids containing tervalent phosphorus with alcohols of the prop-2-ynyl type readily isomerise to give compounds containing an allenic group adjacent to the phosphorus[51,52,61-63]. Pudovik and his coworkers[88,89] have been able to show, by special investigations using mixtures of prop-2-ynyl phosphites, that this reaction involves intramolecular isomerisation with formation of an intermediate five-membered ring:

This reaction, which is in essence a variety of the Arbuzov rearrangement accompanied by acetylene–allene isomerisation, has made available various compounds containing an allenic group attached to phosphorus. Acetylenic glycols yield, together with allenic compounds, 1,3-diene-phosphonates containing two phosphinyl groups[51,90,91]:

In the case of prop-2-ynyl alcohol, as already stated, the reaction may not halt at the stage of the allenic compound. Available data on the synthesis of an allenic phosphonate by bromination and dehydrobromination of an allyl compound[92] require verification.

Physical constants of phosphonous and phosphonic acids containing acetylenic and diene substituents, and also of their functional derivatives involving the phosphorus, are given in Table 1.

Unsaturated phosphonous and phosphonic acids undergo reactions involving the phosphorus atom which are characteristic of their saturated analogues. Phosphonic esters containing acetylenic substituents react with phosphorus pentachloride to form chlorides of the corresponding acetylenic acids[68], which possess properties characteristic of the chlorides of saturated phosphonic acids. Their alcoholysis in the presence of triethylamine and their amidation at the phosphinyl group have been described[68,70,73-76,85].

Nucleophilic reagents add readily at multiple bonds in phosphonic esters of the present type, either one or two molecules being taken up with formation of a vinyl or a saturated derivative respectively[94,95].

Allenic phosphonates add at the double bond adjacent to the phosphorus atom[96]. Such nucleophilic reagents as dialkyl phosphites, thiols, secondary amines and alcohols add readily at multiple bonds in diene phosphinic esters in the presence of basic catalysts. Esters of acids containing 1,3-diene substituents add predominantly in the 1,4-positions[97].

Diels–Alder reactions have been reported in which butadiene-phosphonic and butadiene-phosphonothioic esters act as diene components[98]. References have been made in patents to the possibility of polymerising butadiene-phosphonic esters in the presence of benzoyl peroxide[78]. Finally, mention must be made of an interesting case of fission of the P–C≡ bond in an attempt to add alcohol to a prop-1-ynylphosphonic ester, a phosphoric ester being formed[95].

We conclude this review of methods of synthesis and chemical properties by noting that a few esters have been described formed by acetylenic alcohols with phosphoric and phosphonic acids[99-103]. Methods of synthesising these compounds do not differ fundamentally from those used for the saturated analogues. Work on the preparation of esters formed by prop-2-ynyl alcohols with acids containing tervalent phosphorus[104-106] require verification, since in fact the compounds obtained obviously have a different structure[51,52,62,107].

III. ELECTRONIC INTERACTIONS IN ORGANOPHOSPHORUS COMPOUNDS CONTAINING ACETYLENIC AND DIENE SUBSTITUENTS

The possibility of the conjugation of phosphorus with aromatic substituents and with a double bond has been discussed repeatedly in the literature. Most authors conclude that the four-coordinated phosphorus atom is only slightly involved in conjugation[11-13,108-110]. Little work has yet been done on the conjugation of phosphorus with a triple bond or on the effect of phosphorus on extended highly unsaturated systems.

A paper on the synthesis of phosphacyclopentadienyl compounds[39] has discussed the aromatic character of these structures. Pentaphenylphosphole[36-39] displays chemical properties characteristic of non-aromatic diene systems, which suggests that the phosphorus electrons are not involved in an aromatic sextet, in contrast to the position with pyrrole, which possesses appreciable aromatic character.

The situation is similar in open-chain highly unsaturated systems in which a phosphorus atom is attached to acetylenic or alkenyne substituents. Here, too, conjugation is far more evident in the substituent itself than between this substituent and the phosphorus atom. This is indicated in particular by the surprising constancy of the infrared frequencies of a triple bond attached to a phosphorus atom, these being practically independent either of the valency state of the phosphorus atom or of the nature of other substituents attached to this atom and being determined mainly by the structure of the acetylenic substituent. The C≡C and ≡C–H stretching frequencies in organophosphorus compounds containing a terminal acetylenic group lie within the ranges 2040–2090 and 3165–3300 cm^{-1} respectively[27,28,30,51,52,58-59,60]. It is interesting that these frequencies are appreciably higher (2120 and 3318 cm^{-1}) in the phosphine $(n\text{-}C_4H_9)_2PCH_2CH_2C{\equiv}CH$.[35] The C≡C stretching frequencies are determined in the case of a disubstituted triple bond by the structure of the acetylenic substituent: they are usually lower, within the range 2080–2180 cm^{-1}, for triple bonds conjugated with a benzene ring through a multiple bond or with a substituent containing lone pairs of electrons[27,28,30-35,47,48,53,58,61,64,65,67,68,111].

Unconjugated triple bonds linked to phosphorus, as also both conjugated and unconjugated triple bonds remote from the phosphorus, usually have frequencies lying in the range 2200 cm^{-1} and above[30,47,48,59-62,67] (but see Ref. 27). Phosphonates containing alkadiyne substituents exhibit two bands

due to the triple bonds, the frequency of the triple bond linked to the phosphorus atom being depressed[67].

The infrared spectra of derivatives of phosphonic acids containing 1,3-diene substituents attached to the phosphorus atom also contain two bands. The stretching frequencies of the double bonds lie in the usual range (1540–1640 cm^{-1}). The frequencies of allenic groups adjacent to the phosphorus atom lie within the usual limits (1925–1965 and 862–867 cm^{-1})[34,35,51,52,61]. The phosphoryl group in unsaturated compounds shows frequencies differing little from those in saturated compounds[112], which also indicates the insignificance of conjugation between this group and the multiple bonds.

Although the usual $\pi-\pi$ conjugation in highly unsaturated organic systems is greater in magnitude than conjugation of the phosphorus with the $\pi-\pi$ systems, the presence of the latter is suggested by the dipole moments (Table 2). This follows in particular from the considerable dipole moments of acetylenic and especially conjugated acetylenic phosphonates[65,113].

Published proton nuclear magnetic resonance data for organic phosphorus compounds containing one unsaturated substituent attached to the phosphorus atom do not permit us to assess the presence of conjugation with the phosphorus atom. It is true that the signal due to the acetylenic proton occurs at a lower field in ethynyldiphenylphosphine than in ethynyldialkylphosphines, and this has been taken to suggest the presence of conjugation[30], but it can equally be explained by the inductive effect of aromatic substituents, especially as the same paper mentioned a similar shift in the signal on passing from phosphines to phosphine oxides, under the influence of the strongly electronegative P=O group[30].

The chemical shifts and spin–spin coupling constants $J_{P,H}$ for protons separated from the phosphorus atom by more than one carbon–carbon bond (some of which may be unsaturated) vary in conformity with general views emerging from the study of other classes of compounds. Thus, for example, the accumulation of triple bonds in a substituent attached to the phosphorus atom displaces the terminal proton signal towards strong fields. This effect is explained by the diamagnetic anisotropy of triple bonds[30].

Oxidation and the addition of sulphur to acetylenic phosphines produce a sharp increase in the coupling constant $J_{P,H}$, owing to the increased electronegativity of the phosphorus atom[30].

With increase in the number of triple bonds the value of $J_{P,H}$ for the protons in the terminal methyl group decreases as a result of the increasing distance between the interacting nuclei. The decrease in $J_{P,H}$ is in general inversely proportional to the cube of the distance between the phosphorus nucleus and the proton, and a direct dipole–dipole mechanism has been suggested for this interaction[67].

In the case of phosphines an acetylenic proton is more strongly cleaved from the phosphorus through two triple bonds than through one triple bond (1.45 and 0.5 c/s respectively). This interesting fact has not yet been explained[30].

In the phosphorus nuclear magnetic resonance spectra[31] the chemical shift of the phosphorus nucleus in a diethoxyphosphinyl group adjacent to a triple bond has a constant magnitude of about +9 ppm (relative to 85% H_3PO_4). The small difference in the chemical shifts of acetylenic phosphonates having the triple bond in the $\alpha\beta$- and $\beta\gamma$-positions with respect to the phosphorus atom (29 ppm) has been interpreted as evidence of weak conjugation between the phosphinyl group and the triple bond[64].

TABLE 2. Dipole moments of diethyl esters of unsaturated phosphonic acids.

Compound	μ, D
$CH_2{=}CHCH_2PO(OC_2H_5)_2$	2.86
$CH_2CH{=}CHPO(OC_2H_5)_2$	2.92
$C_6H_5CH{=}CHPO(OC_2H_5)_2$	3.68
$CH_3C{\equiv}CPO(OC_2H_5)_2$	3.94
$CH_2{=}C(CH_3)C{\equiv}CPO(OC_2H_5)_2$	3.84
$CH_2{=}CHC{\equiv}CPO(OC_2H_5)_2$	3.88
$CH_3CH{=}CHC{\equiv}CPO(OC_2H_5)_2$	4.06
$C_6H_5C{\equiv}CPO(OC_2H_5)_2$	4.17
$C_6H_5C{\equiv}CC{\equiv}CPO(OC_2H_5)_2$	4.39

Thus to the extent that it is possible at all to assess the electronic interaction between phosphorus and unsaturated systems by the methods used to judge $\pi-\pi$ conjugation[11–13], it must be concluded that phosphorus is less well conjugated with a $\pi-\pi$-conjugated substituent than is the substituent itself conjugated. Nevertheless, conjugation of a triple bond with phosphorus-containing groups is rather better than is that of a double bond[111].

A second interesting group within the class of compounds under discussion comprises those containing three unsaturated substituents attached to the phosphorus atom, their structure being close to tetrahedral. Cruickshank has shown[114] that strong $\pi-d$ bonding can be assumed in tetrahedral ions of the type XO_4^{n-} (where X = P, S, Cl), owing to the effective overlapping of two of the five vacant d-orbitals of the central atom ($d_{x^2-y^2}$ and d_{z^2}) with eight non-bonding $2p\pi$-orbitals of the oxygen atoms (two orthogonal orbitals on each atom). Apart from the appropriate symmetry of these orbitals, interaction is ensured by the decrease in their energy and increase in the magnitude of the overlap integrals[115,116] due to the presence of the positive charge on the central atom.

A definite analogy can be traced between tetrahedral ions and tertiary phosphine sulphides having three acetylenic substituents attached to the phosphorus atom. In fact each of the triple bonds has two orthogonal π-orbitals, and the datively bound sulphur atom has two orthogonal p-orbitals. It is true that, in view of the presence of the datively bound sulphur, tertiary phosphine sulphides should have had dipole moments of the order of 10 D (transfer of one electron along the bond), whereas actually their moments do not reach half this value. But this fact is immediately explained by $p-d$ interaction between the sulphur and the phosphorus[117].

The present Reviewers have studied the dipole moments and the ultraviolet, infrared, and ^1H-nuclear magnetic resonance spectra of a series of sulphides of unsaturated tertiary phosphines[47–49]. The long-wavelength band in the ultraviolet spectra undergoes a bathochromic shift as unsaturated substituents accumulate at the phosphorus atom, the absorption intensity changing disproportionately to the number of unsaturated substituents (Table 3). This fact has been interpreted as confirming conjugation of the unsaturated substituents with the central phosphorus atom.

It has been mentioned above that the frequency of the triple bond in the infrared spectra of sulphides of tertiary acetylenic phosphines is practically independent of the

$P(S)(CH{=}CHC_6H_5)_3$	277	46.12

number of acetylenic substituents attached to the phosphorus atom. Study of the ^1H-nuclear magnetic resonance spectra of these compounds shows that this does not imply the absence of transmission of electron interactions through the phosphorus atom[48]. Table 4 gives the chemical shifts and spin–spin interaction constants for the protons in methyl groups combined with the phosphorus atom [40 Mc/s, 10 mole % in CCl_4 and $(CH_3)_4Si$, internal standard].

As acetylenic substituents accumulate at the phosphorus atom, and also with increase in their electron-acceptor properties, the spin–spin interaction constant with the phosphorus nucleus increases, while the chemical shift of the protons decreases. With the protons of methyl groups adjacent to the triple bond, however, the usual dependence of the chemical shift on the electron-acceptor properties of the substituents breaks down[53] (Table 4). Firstly it must be noted that the chemical shift of the protons of methyl groups in prop-1-ynyl substituents is of the same order of magnitude as the chemical shifts of protons in methyl groups directly attached to the phosphorus atom, although the signal due to the former should have been located in the region of smaller fields (in view of the greater electron--attracting power of the triple bond). Furthermore, as triple bonds accumulate at the phosphorus atom the shift due to protons of methyl groups adjacent to a triple bond should still have been displaced to smaller fields, whereas actually it is raised (Table 4).

The results obtained can be explained by the superposition of three effects: on the one hand, there is actually a diminution in electron density under the influence of electronegative substituents, while on the other hand the protons are magnetically screened by the diamagnetic anisotropy of the triple bond, which to some extent balances the electronegativity effect. Finally, perhaps, the accumulation of identical acetylenic substituents at the phosphorus atom is accompanied by a decrease in the paramagnetic contribution of the phosphorus to the anisotropy owing to the enhanced symmetry of the molecule, which results in an additional increase in screening. As a result, maximum sphericity of the electron cloud of the molecule is achieved on passing to a trialkynyl derivative as a consequence of the maximum utilisation of the *d*-orbitals, and the proton chemical shift increases sharply. The spin–spin coupling constant increases in the same sequence as in the previous case, while its magnitude is appreciably less owing to the increase in distance between the protons and the phosphorus nucleus, which corresponds to general views on the way in which it varies.

A similar conclusion concerning the possibility of conjugation with the phosphorus atom in tetrahedral molecules of the sulphides of unsaturated tertiary phosphines is reached from a study of the dipole moments of these compounds[49]. Comparison of the dipole moments of tertiary phosphines and phosphine sulphides containing phenyl- and *p*-tolyl-ethynyl groups indicates that the vector of the resultant moment is directed from the acetylenic substituents towards the phosphorus atom. With the moment in this direction, it would be expected to decrease with increase in the electron-attracting power of the substituents. This is in fact observed in the halides of three-coordinated phosphorus, tertiary acetylenic phosphines, and also thiophosphoryl halides. In the case of the sulphides of tertiary acetylenic phosphines, however, an appreciable increase is observed in the dipole moments with increase in the sum of the inductive constants [σ^*-values] of the substituents attached to the phosphorus atom [Table 5]. This increase can be explained by the presence of some positive electronic effect acting in the same direction as the vector representing the overall moment of the molecule. The effect may be caused by the presence of moments due to the substituents themselves, the contribution of which to the total moment of the molecule will increase with increase in the number of these substituents. On the other hand, it can be explained by π–d interaction between the acetylenic substituents or the halogens and the phosphorus atom, this increasing with increase in the number of these substituents from 1 to 3, when maximum effective utilisation of the *d*-orbitals becomes possible: i.e. it increases in parallel with the dipole moment. In the sulphides of acetylenic phosphines, accumulation of acetylenic substituents is accompanied by a more rapid increase in π–π interaction than in the negative inductive effect of the substituents, and a general increase in dipole moment is observed. In the thiophosphoryl halides, in contrast, the negative effect increases more rapidly (as halogen atoms accumulate), and a general decrease in dipole moments is observed[53].

Published data indicate that the conjugation of phosphorus with highly unsaturated π–π systems is less marked than conjugation within the π–π systems themselves.

Furthermore, the phosphorus may be involved in conjugation with unsaturated substituents arranged tetrahedrally about the phosphorus atom, and, although this conjugation is small, it can be detected by physical methods. However, the possibility of fundamentally different explanations of the behaviour of organophosphorus compounds must be borne in mind.

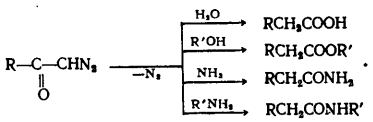
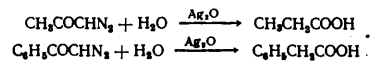
I. INTRODUCTION



The great reactivity and comparatively ready accessibility of α-diazo-ketones have contributed to the rapid development of the chemistry of this peculiar class of organic compounds — see the most important reviews[1-11].

Many methods are now available for the preparation of α-diazo-ketones, the most important of these being the Arndt–Eistert method[12-38], consisting in the interaction of acid chlorides or anhydrides with excess of diazomethane, and the Curtius method, which is in effect the oxidation of monohydrazones of α-diketones with yellow mercury(II) oxide[39-47] or with some other oxidant[48-51]. Other derivatives of α-diketones — e.g. the toluene-*p*-sulphonylhydrazones[52-60] and the mono-oximes[61-63] — can also be used to obtain α-diazo-ketones. A new method had recently been worked out for the synthesis of α-diazocarbonyl compounds from alkane- or arene-sulphonylazides and carbonyl compounds[64-70].



Among the various transformations undergone by α-diazo-ketones, the Wolff rearrangement is of most interest. The great amount of information which has accumulated in the more than 50 years since its discovery, the large quantity of experimental results obtained during recent years, and also the absence of reviews dealing specially with this question have led us to write the present paper. The literature is surveyed up to 1964 inclusive, and partly for 1965.

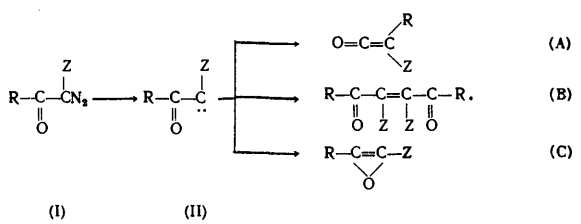
II. DEFINITION AND MECHANISM OF THE WOLFF REARRANGEMENT

The Wolff rearrangement — the conversion of α-diazo-ketones into acids and their derivatives — takes place on heating, in the presence of catalysts, or on ultraviolet irradiation in the presence of water, alcohols, ammonia, amines, etc:

In 1902 Wolff, while studying the properties of diazo-ketones[71,72], found that diazoacetone and diazoacetophenone, on interaction with water in the presence of silver oxide, did not undergo the usual replacement of the diazo-group by hydroxyl with formation of a hydroxy-ketone, but instead suffered rearrangement, with formation of propionic and phenylacetic acids respectively.

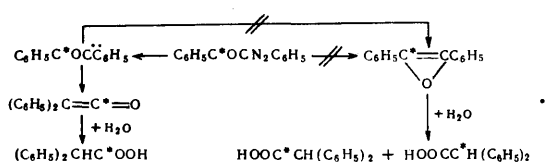
He showed in the same paper that, with aqueous ammonia to which a small quantity of silver oxide or silver nitrate had been added, diazo-ketones yielded amides even in the cold:

Independently of Wolff, in 1909 Schroeter.[73,74] observed an analogous rearrangement with "azibenzil" (benzoylphenyldiazomethane), and some authors therefore employ the term "the Wolff–Schroeter rearrangement".



Catalytic rearrangement was employed mainly in the early work, the catalyst being most often silver oxide or a silver salt[72,75]. Finely divided platinum[72] and copper[76] are used considerably less frequently. With copper, however, the Wolff rearrangement takes place under severe conditions, the yield of acid being sharply diminished owing to the formation of other reaction products, mainly diacylethylenes[77-86]. An exception is provided by copper(I) iodide, with which rearrangement can occur under milder conditions[87].

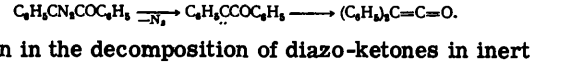
The thermal rearrangement of α-diazo-ketones is employed less often than the catalytic method, for with the more severe conditions there is risk of decomposition of the starting materials. Nevertheless, this method of rearrangement gives very good results in the preparation of acid derivatives — anilides and certain esters[75,88,89].



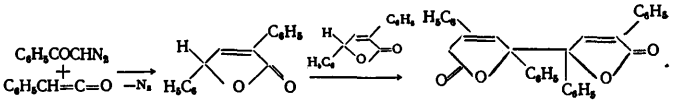
The considerable advantages of photolysis[90] as a method of effecting the Wolff rearrangement — the mild conditions for the reaction, the practical simplicity, and the possibility of considerably shortening the subsequent operations of separation and purification of the products — have rapidly brought it to the fore during recent years.

The mechanism of the Wolff rearrangement has now been studied quite fully. Wolff himself regarded the detachment of nitrogen as the cause of the reaction which he had discovered[71,72]: the residue remaining after detachment of nitrogen from the diazo-ketone molecule contains free valencies on the carbon atom, and undergoes rearrangement into a keten, which interacts with a hydroxy- or an amino-compound present in the reaction mixture to given an aicd or a derivative thereof.

The many subsequent investigations have convincingly shown that the first stage in the Wolff rearrangement is detachment of nitrogen from the diazo-ketone (I), accompanied by intermediate formation of a carbenone (II):

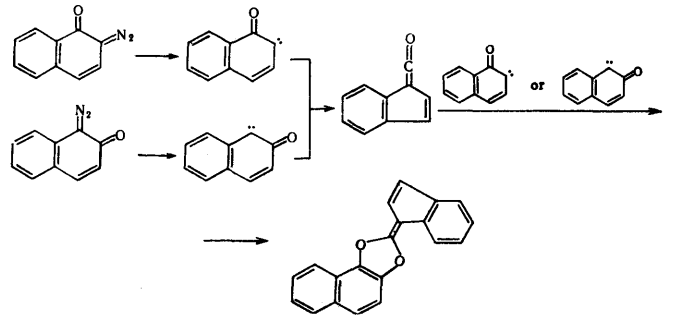


The defective octet in the intermediate compound (II) can be completed in three different ways — (A), (B), and (C) — the transition (II) → (A) resulting in formation of a keten, and from the latter the acid or its derivative, so that it represents the normal Wolff rearrangement. The bimolecular reaction (II) → (B) occurs comparatively rarely with diazo-ketones (for furthere details see Section V, 2). It usually takes place when R is a donor group, e.g. ethoxyl: thus, under the conditions of the Wolff rearrangement, diazoacetic ester is readily converted into diethyl fumarate[91]. Franzen has proved that formation of an oxiren (II) → (C) is not an intermediate stage in the Wolff rearrangement[92]. He effected the photochemical and thermal decomposition of azibenzil containing a labelled carbon atom in the carbonyl group, and showed that stabilisation of the carbenone occurs by migration of a phenyl group with formation of diphenylketen; the latter interacts with water to form diphenylacetic acid in which the whole of the activity is concentrated in the carboxy-group:

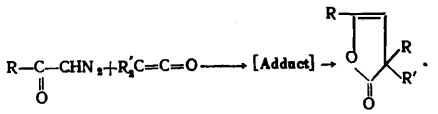


Thus the transformation (II) → (A), i.e. the Wolff rearrangement, is to be expected when R represents a hydrocarbon radical.

The intermediate formation of ketens in the rearrangement of diazo-ketones has in several cases been demonstrated experimentally [73,93-95]. Thus Schroeter isolated diphenylketen in the thermolysis of azibenzil in an aprotic solvent [73]:

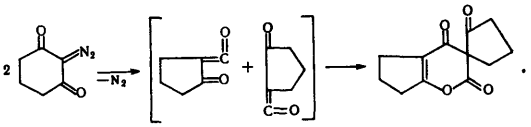


More often in the decomposition of diazo-ketones in inert solvents, however, ketens themselves are not obtained, but products of their further transformation, which is explained by the tendency to polymerise [96], and also to interact with the initial diazo-ketones or with the carbenones resulting from detachment of nitrogen from them. Thus the thermolysis of α-diazoacetophenone in dodecane led to the formation of a dilactone, to which has now been assigned the following structure [97]:



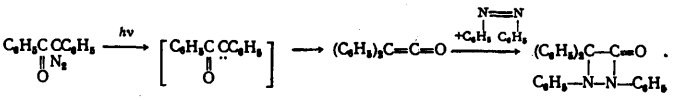
The formation of this compound is explained by interaction between the keten resulting from the rearrangement and the intermediate carbenone [98-100].

An analogous process obviously takes place in the thermal decomposition of diazonaphthaquinones [101]:

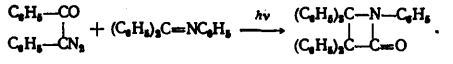


and in several other cases [102-105].

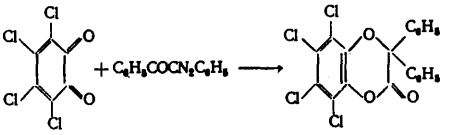
The interaction of ketens with diazo-ketones leading to the formation of βγ-unsaturated lactones is reported by Ried and Mengler [106-108], who assume that a short-lived addition product is produced, and stabilises itself by splitting off a molecule of nitrogen to give the unsaturated lactone:



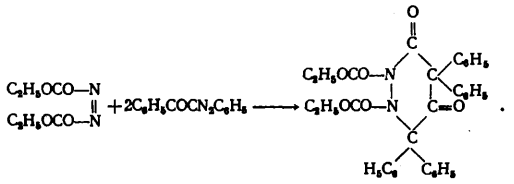
An interesting result has recently been obtained by Stetter and his coworkers [109] in the thermolysis of 2-diazocyclohexane-1,3-dione in xylene:



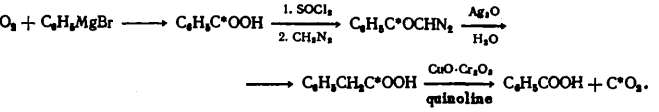
Formation of the final reaction product can be explained only by Wolff rearrangement of the initial diazo-ketone followed by dimerisation of the resulting keten.



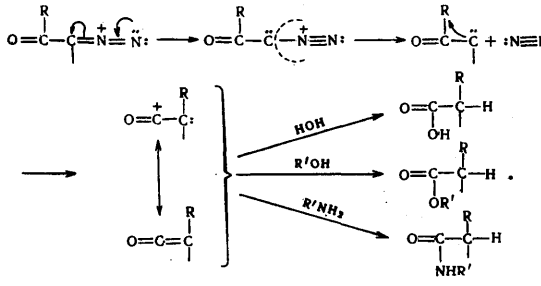
The formation of ketens during the Wolff rearrangement has been demonstrated in many cases by their reactions with specially added reagents. When azibenzil is illuminated in the presence of azobenzene, for example, a crystalline adduct is obtained which is a derivative of 3-oxodiazetidine [93]:



Cook and Jones [110] obtained the same compound from diphenylketen and *cis*-azobenzene. Ketens can add on also to azomethines (Schiff bases) to give β-lactams [111]:



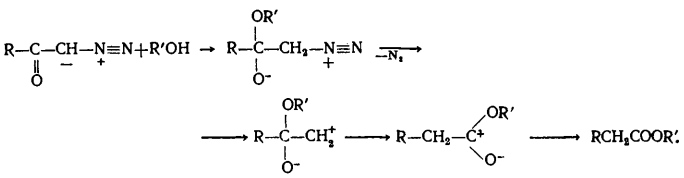
The keten arising in the photolysis of azibenzil could be recovered also by reaction with tetrachlorobenzo-*o*-quinone [93]:



and by illuminating azibenzil together with azoformic ester [112]:

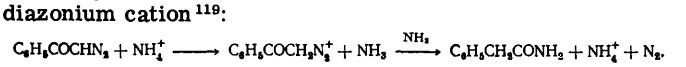
Conversion of the carbonyl group in a diazo-ketone into a carboxyl is established beyond doubt by the following cycle of reactions, in which radioactive carbon has been used [113]:

Thus the mechanism of the Wolff rearrangement can be represented by the scheme



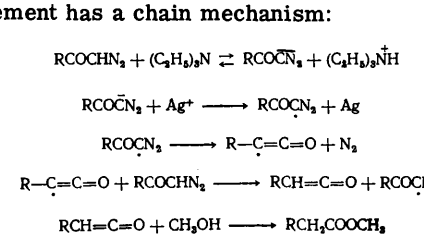
In the first stage, decomposition of the diazo-ketone with elimination of nitrogen results in the appearance of a carbenone characterised by an electron deficit. The carbenone is stabilised by the attack on a pair of electrons forming the β-bond. Depending on the reaction conditions, the resulting keten is converted into an acid, an ester, or an amide. Consequently the Wolff rearrangement represents a particular case of a large number of nucleophilic rearrangements occurring in saturated systems.

In the opinion of some authors[1], however, the carbenone structure is incompletely realised in the Wolff rearrangement, since transfer of the carbanion is assumed in several cases to occur synchronously with elimination of the nitrogen molecule:



During the rearrangement of benzoylphenyldiazomethane in the presence of alcohol, an ether of benzoin is formed as a side-product[114] (i.e. the nitrogen molecule is eliminated before the rearrangement occurs). In some cases formation of oxidation products of the intermediate carbene is observed[115-117]. Both facts contradict the synchronous mechanism.

Müller formulated the following mechanisms for the rearrangement of diazo-ketones in the presence of an alcohol or water[118]:



However, evidence is lacking for the intermediate formation of a betaine.

Other mechanisms have been suggested for the Wolff rearrangement. Thus Baddeley et al. consider that the rearrangement involves the intermediate formation of a diazonium cation[119]:

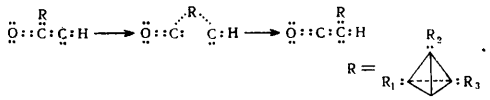
Such a mechanism is open to question, since the rearrangement of diazo-ketones is usually accomplished in neutral or even in weakly alkaline medium, where the appearance of a diazonium cation is improbable. Nevertheless, in isolated cases, when rearrangement occurs in acid medium[120,121], the possibility that a diazonium cation may be formed cannot be completely denied.

Newman and Beal[122], who were successful in effecting the Wolff rearrangement in homogeneous medium (in methanol in the presence of silver benzoate and triethylamine)[123-125], consider that under these conditions the rearrangement has a chain mechanism:

In their opinion this is supported by the following results: (1) reaction does not occur with diazo-ketones of the type $RCOCN_2CH_3$, which indicates that hydrogen must be present on the α-carbon atom; (2) reaction ceases on the addition of quinol, this obviously being due to reduction of the silver ion or of one of the intermediate products (reaction starts afresh on addition of excess of a silver salt); and (3) the reaction does not go in the absence of triethylamine, which confirms the first stage in the above mechanism.

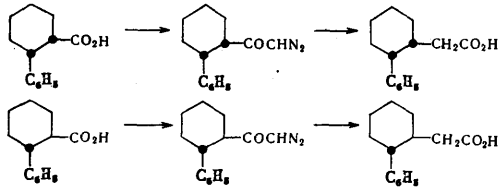
The possibility of a radical mechanism for the rearrangement of diazo-ketones is consistent with the fact that other examples of homolytic,1,2-rearrangements have recently been discovered[126-131]. It must be stressed, however, that this mechanism is possible only under the above conditions and only with diazo-ketones in which hydrogen is attached to the carbon atom adjacent to the diazo-group.

The generally accepted mechanism for the Wolff rearrangement, implying intermediate formation of a carbenone which rearranges into a keten, is evidently the most probable.



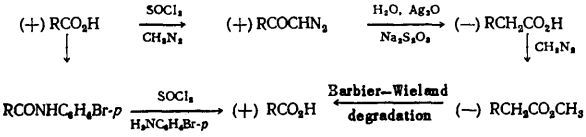
It is interesting that Dewar[132] suggested that the intermediate compound has the classical form of a π-complex:

This is consistent, in his view, with the fact that the Wolff rearrangement is an intramolecular rearrangement.



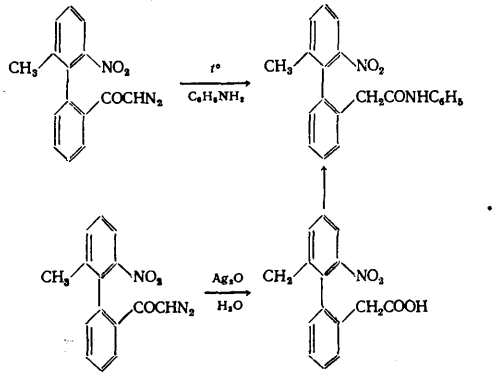
III. STEREOCHEMISTRY OF THE WOLFF REARRANGEMENT

A fundamental part of the mechanism of the rearrangement is the migration of the group R to an adjacent carbon atom. It might be supposed that during this process the group R would exist for a very short time as a kinetically independent particle. In order to assess the hypothesis critically, certain optically active compounds, in which R contained an asymmetric carbon atom, were subjected to the rearrangement. There could be three possibilities in such reactions: (1) racemisation might occur during the rearrangement, so that an optically inactive product would be obtained: (2) the compound might maintain its activity and configuration; or (3) while optical activity was preserved, there might be a change in configuration: i.e. Walden inversion might occur. Numerous investigations have established that, when optically active compounds undergo the Wolff rearrangement, the products are also optically active[133-139]. The retention of optical activity most probably means that the migrating group cannot exist in a free state even for a short period, but always remains within the force field of the molecule; while its bond with the adjacent carbon atom is still not completely ruptured, the group comes under the influence of another carbon atom, which prevents a change in configuration. This effect can be represented by the scheme[140]

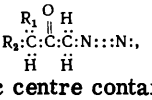


The above scheme gives a real idea of the migration of a pair of electrons from one carbon atom to another

(internal redox process). Such formulation of the process assumes the displacement to be strictly intramolecular (at no time does the system dissociate into either neutral or charged fragments). Under these conditions an optically active group should not be racemised in the course of the rearrangement. Moreover, inversion of configuration cannot occur with this formulation[141,142]. Thus Gutsche showed that configuration is maintained in the rearrangement of diazo-ketones obtained from *cis*- and *trans*-2-phenylcyclohexanecarboxylic acids[143]:

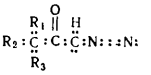


Lane[140] demonstrated the retention of configuration in the rearrangement of the diazo-ketone from (+)-2-methyl--2-phenylhexanoic acid, which was converted by the Arndt–Eistert method into optically active 3-methyl-3-phenylheptanoic acid. This was converted back, by Barbier–Wieland degradation, into the original acid. In this cyclic process initial and final products had the same optical rotation:



where R = n-$C_4H_9C(CH_3)(C_6H_5)$–.

The same worker showed[144] that, on thermolysis in boiling aniline, optically active diazomethyl 2′-methyl--6′-nitrobiphenyl-2-yl ketone gives without racemisation optically active 2′-methyl-6′-nitrobiphenyl-2-ylacetanilide. Rearrangement of the same diazo-ketone in aqueous–alkaline solution in the presence of silver oxide gave the optically active acid, which was then converted into the corresponding optically active anilide, found to be identical with the first anilide:



If the migrating group were able to detach itself even for an instant during the rearrangement, the blocking effect would have been removed, so that free rotation would have become possible, and racemisation would have occurred. Thus the possibility is eliminated of explaining the retention of optical activity by the presence of a free pair of electrons, which could act as a fourth substituent and prevent racemisation.

It is true that Bell[145] put forward the hypothesis that the radical may exist for a relatively short period in comparison with the time required for rotation of the two aromatic rings. It must be remarked that, if dextrorotatory 1-diazo-3-methyl-4-phenylbutan-2-one is subjected to the Wolff rearrangement, partial or complete racemisation (depending on the experimental conditions) takes place[146]. This phenomenon can be explained by the peculiar properties of the diazo-ketones

in which the asymmetric centre contains a mobile enolising hydrogen, since study of the behaviour of optically active diazo-ketones of the type

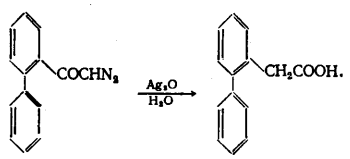
(where R_1, R_2, and R_3 are alkyl or aryl groups) under conditions of the Wolff rearrangement showed no trace of racemisation.

It must be emphasised that, when a secondary asymmetric atom is present, racemisation is observed usually in cases in which the Wolff rearrangement is conducted at temperatures exceeding 180° or in the presence of a catalyst, this obviously being due to tautomerisation of the diazo-ketone before rearrangement. The photolysis of diazo-ketones enables the Wolff rearrangement to be accomplished in the absence of a metal catalyst, and thus racemisation to be avoided during the reaction. Thus Wiberg and Hutton[147] established that, on ultraviolet irradiation, 1-diazo-3-methyl-4-phenylbutan-2-one gives mainly a rearrangement product in which the configuration is maintained.

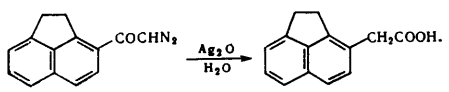
IV. CHIEF SYNTHETIC APPLICATIONS OF THE WOLFF REARRANGEMENT

The Wolff rearrangement is of quite general synthetic value, being widely applicable for the preparation of acids and their derivatives in the aliphatic, aliphatic–aromatic, aromatic, alicyclic, and heterocyclic fields. It is successfully employed also for ring contraction.

1. Wolff Rearrangement as a Method of Synthesising Homologous Acids

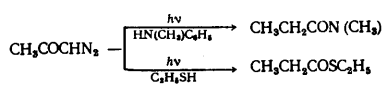


The Wolff rearrangement constitutes one stage in the Arndt–Eistert synthesis of homologous acids[19,75,148–152]:



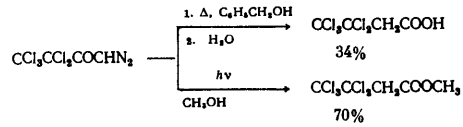
Thus, for example, an 81% yield of β-methyl-γ-phenylvaleric acid has been obtained by decomposing the corresponding diazo-ketone in the presence of silver oxide[153]:

Biphenyl-2-ylacetic acid has been obtained in 68% yield under the same conditions from biphenyl-2-yl diazomethyl ketone[154]:



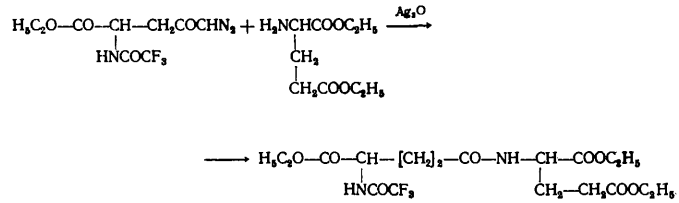
Acenaphthen-3-ylacetic acid is formed in approximately the same yield[155]:

The decomposition of diazo-ketones need not be conducted in aqueous medium: it is possible, and often even advisable, to effect the reaction in alcohol or aniline, since the rearrangement of diazo-ketones into acid derivatives usually occurs with rather better yields[65,156-161]. Ammonia and amines, especially aniline, add most smoothly, while the reaction goes less well with water and alcohols. Thus a 7% yield of *o*-nitrophenylacetanilide is obtained from diazomethyl *o*-nitrophenyl ketone, whereas ethyl *o*-nitrophenylacetate is obtained in 60% yield[162]. 1-Naphthylacetamide had been isolated in 84% yield from the corresponding diazo-ketone, whereas the yield of 1-naphthylacetic acid varies from 50% [162] to 70%.[27]



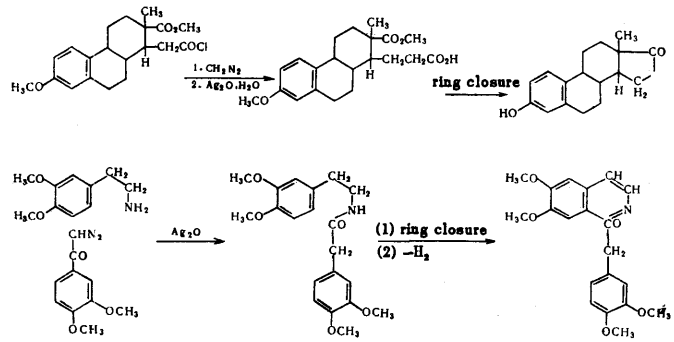
It is possible by using the classical method to effect the rearrangement of diazo-ketones under quite mild conditions, but the reaction products are then strongly contaminated by traces of colloidal silver or of silver salts. Moreover, the yields of the rearranged products are not always satisfactory[163,164], and in several cases, therefore, the thermal method of rearrangement is preferable. Thus an 85% yield of 2-1′-naphthylpropionanilide is obtained by thermolysis, whereas the yield of the acid itself on catalytic rearrangement of the same initial diazo-ketone is only 26%.[89] It is not at all possible under classical conditions to rearrange diazo-ketones obtained from *p*-anisoyl and *p*-toluoyl chlorides, whereas their thermolysis in benzyl alcohol permits the homologous acids to be isolated in yields of 76% and 79% respectively[89].

The photolytic method of effecting the rearrangement is the most widely applicable and the most convenient[93,94,115,165-172]. Whereas the yield of diphenylketen obtained by the thermal decomposition of azibenzil[73] is 77%, photolysis of the latter compound for 3 h enables a 92% yield of the keten to be isolated[93]. Irradiation of azibenzil in aqueous dioxan gives diphenylacetic acid[92,93,169] in excellent yield. If the illumination is conducted in ethanol, the ethyl ester is obtained. Weygand effected the photolysis of diazoacetone in the presence of *N*-methylaniline and ethanethiol respectively[173], and obtained a 77% yield of *N*-methylpropionanilide and a 67% yield of ethyl thiolopropionate:



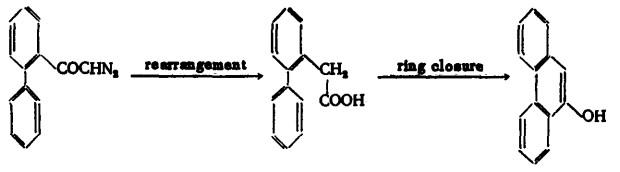
The photolytic method enables the Wolff rearrangement to be accomplished under the mildest conditions, and hence usually unaccompanied by any side-processes or resinification, which cannot be completely avoided in the catalytic or thermal decomposition of diazo-ketones.

It is especially important that the photolysis of diazo-ketones can often be successfully applied where the thermal and catalytic methods of rearrangement do not give positive results[4,174-180]. Thus 3,4,4-trichloro-1-diazobut-3-en-2-one $CCl_2{:}CClCOCHN_2$, because of its sensitivity to alkalis, does not rearrange under classical conditions, but can be converted into the corresponding acid by ultraviolet irradiation[175]. The great stability of 3,3,4,4,4-pentachloro-1-diazobutan-2-one makes rearrangement of this diazo-ketone impossible under classical conditions, but this can be achieved by thermolysis in benzyl alcohol in the presence of collidine at 150–190° [89] or by ultraviolet irradiation:



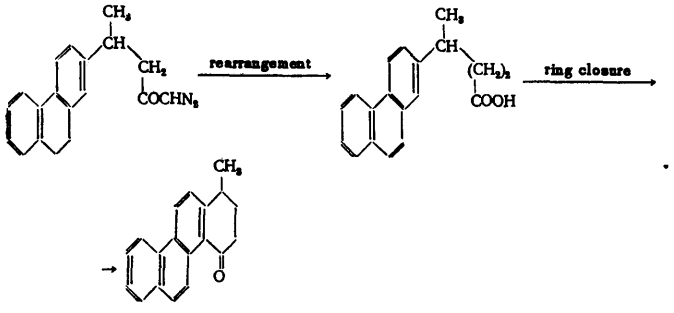
Mild reaction conditions (in photolysis or catalytic decomposition) make it possible to employ the Wolff rearrangement for the synthesis of complicated compounds containing functional groups, such as amino-acids and their derivatives[137-139,157,181], peptides, and polypeptides[5,135,136]. For example, the ethyl ester of δ-diazo-γ-oxo-*N*-trifluoroacetyl-L-norvaline in the presence of diethyl glutamate gives a good yield of triethyl *N*-trifluoroacetyl-γ-L-glutamyl-L-glutamate[134,182]:

An interesting example of the Wolff rearrangement is reported by Balenović[181], who succeeded in preparing α-methyl-β-alanine in 91% yield:



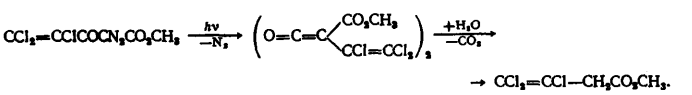
$$NH_2CH_2COCN_2CH_3 \rightarrow NH_2CH_2CH(CH_3)CONHC_6H_5 \rightarrow NH_2CH_2CH(CH_3)COOH.$$

In the work of this author the Wolff rearrangement is widely used for the conversion of α-amino-acids into β-amino-acids[5,157]. The rearrangement has been employed to obtain several intermediate products for the synthesis of natural substances, in isolated cases the natural substances themselves, e.g. oestrone, papaverine[183]:



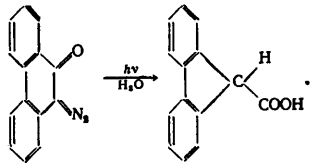
and several other related compounds[141,184]. It enables difficultly accesssible compounds to be prepared as well as compounds which cannot be obtained in other ways. Thus

the Wolff rearrangement constitutes one stage in the synthesis of 9-hydroxyphenanthrene[154]:



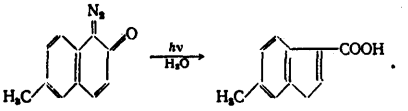
as also in the preparation of trimethoxyphenylacetic acid[185] and of 1,2,3,4-tetrahydro-1-methyl-4-oxochrysene[186]:

The Wolff rearrangement goes successfully also with diazo-ketones containing multiple bonds[122-125], the best results being obtained in a homogeneous medium, in the presence of silver benzoate and triethylamine. Wotiz[125], by using this method, isolated methyl non-7-ynoate in 80% yield, whereas under classical conditions the yield of this ester is 65%.[75]

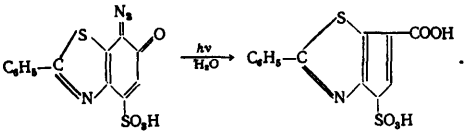


Comparatively few α-diazo-ketones cannot undergo the Wolff rearrangement. They include perfluorinated diazo--ketones: at least two methylene groups must be present between a perfluorinated radical and the carbonyl group for the rearrangement to give a satisfactory yield[157,179,187,188]. Diazo-ketones obtained from completely fluorinated propionic, butyric, and valeric acids, for example, do not undergo the Wolff rearrangement, and the diazo-ketone $C_3F_7CH_2COCHN_2$ gives only a small quantity of the homologous acid, whereas the diazo-ketone $C_3F_7[CH_2]_2COCHN_2$ rearranges normally and in good yield. Nevertheless, the diazo-ketones obtained from trifluoroacetic and trichloroacetic acids has been shown[159] to undergo the Wolff rearrangement, although only the esters of the homologous acids are obtained from them in satisfactory yield, whereas production of the acids themselves, their amides, and their anilides is poor.

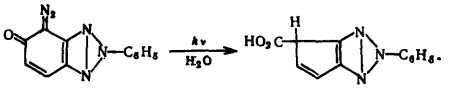
Ethyl trifluoro- and trichloro-acetylcarbenecarboxylates, which appear when trifluoro- and trichloro-α-diazoacetoacetic esters are illuminated, likewise do not undergo the Wolff rearrangement, probably owing to the strong electronegative effect of the trifluoromethyl and trichloromethyl groups[177]. However, recent work has shown[176] that the photolysis of the 4,5,5-trichloro-2-diazo-3-oxopent-4-enoic ester results in partial formation of the normal rearrangement products:



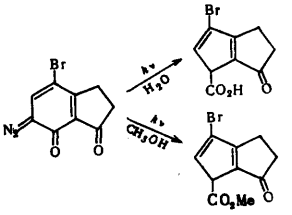
2. Wolff Rearrangement as a Method of Ring Contraction



The Wolff rearrangement is of great value in the cyclic α-diazo-ketones series, when it involves ring contraction. The photochemical rearrangement of "quinone diazides" or "diazo-oxides" is a method of synthesising acids in the cyclopentadiene series[189-193]. Thus when phenanthrene--9,10-diazoquinone is illuminated in aqueous dioxan containing added acetic acid, fluorene-9-carboxylic acid is obtained in 80–88% yield[189]:

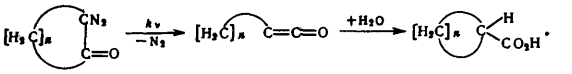


A 47% yield of 5-methylindene-1-carboxylic acid has been obtained by the photolysis of 6-methylnaphtha-1,2-diazoquinone[190]:



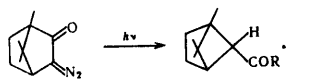
When 7-diazo-6,7-dihydro-6-oxo-2-phenylbenzothiazole-4-sulphonic acid is illuminated, the corresponding carboxylic acid is formed[190]:

4-Diazo-4,5-dihydro-5-oxo-2-phenylbenzotriazole gives 2-phenylcyclopentadienotriazole-4-carboxylic acid[191] in 43% yield:



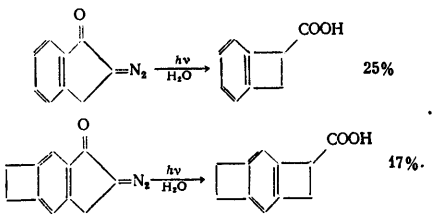
Horner and his coworkers have used the rearrangement of diazoquinones also to prepare pentalene derivatives[121]. They find that illumination of 4-bromo-6-diazo-6,7-dihydroindane-1,7-dione in dilute hydrochloric acid results in formation of the corresponding acid in 15% yield:

whereas exposure of the same compound in methanol to which concentrated hydrochloric acid has been added gives a 75% yield of the methyl ester of the acid.



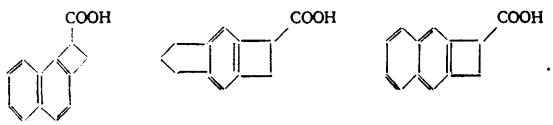
Alicyclic diazo-ketones on photolysis are converted into carboxylic acids with contraction of the ring[55,115,169]:

The tendency of diazo-ketones to undergo rearrangement is so great that rings are often formed which are

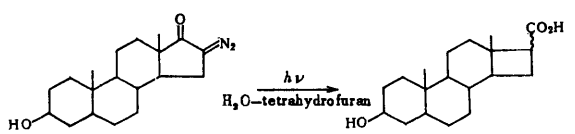


more strained than the original rings: five-membered from six-membered rings, and four-membered from five--membered rings[54,58,190,192-202]. Three cases have been reported in the pinane series in which the Wolff rearrangement did not take place[27]. Since, however, no indication was given of the reaction conditions, nothing can be said as to the reason for the absence of rearrangement in these cases.

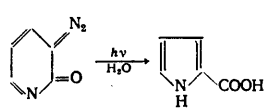
The photolysis of diazocamphor[169] in aqueous medium gives a 76% yield of 1,6,6-trimethylbicyclo[2,1,1]hexane--5-carboxylic acid (R = OH):



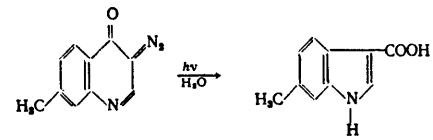
Irradiation of diazocamphor dissolved in ethanol, aniline, diethylamine, or dioxan containing hydrazine hydrate results in the formation of the ethyl ester, anilide, diethylamide, or hydrazide of this acid [R = OC_2H_5, NHC_6H_5, $N(C_2H_5)_2$, or $NHNH_2$ respectively].



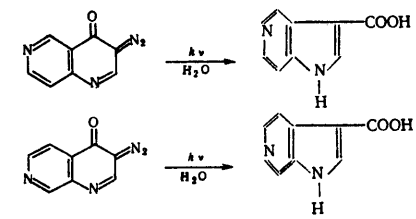
Horner and his coworkers applied the Wolff rearrangement to the preparation of cyclobutenobenzene derivatives, which for a long time had been regarded as unstable[115,194]:



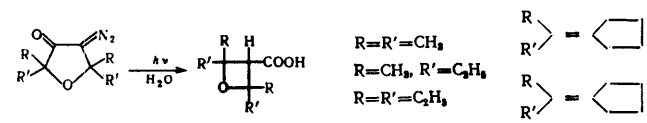
In spite of the low yields in individual cases, this reaction found wide application for the synthesis of complicated fused systems[55,194]:



There are several interesting examples of ring contraction also among steroids[203-208] and triterpenes[63]. Thus illumination of 16-diazo-3β-hydroxyandrostan-17-one yields 3β-hydroxy-D-norandrostane-16-carboxylic acid[208]:



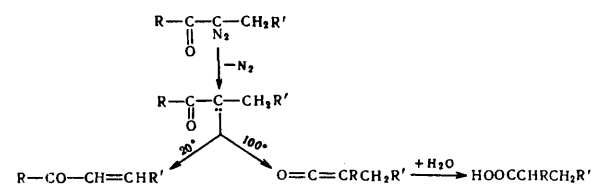
The Wolff rearrangement has been applied to heterocyclic α-diazo-ketones considerably less feequently. It was only in 1953 that Süs and his coworkers effected the Wolff rearrangement in certain nitrogen heterocycles of this type. Thus by the photolysis of 3-diazo-2,3-dihydro--2-oxopyridine they obtained pyrrole-2-carboxylic acid[190]:



Using the same method Süs was able to synthesise several indolecarboxylic and azolopyridinecarboxylic acids[209,210]. Thus he isolated 6-methylindole-3-carboxylic acid in 80% yield[209]:

The photolysis of 3-diazo-3,4-dihydro-4-oxo-1,6(and 7)--diazanaphthalenes gives the corresponding 1,5(and 6)-diazaindene-3-carboxylic acids in ~ 50% yields[210]:

We have accomplished the conversion of tetrahydrofuran derivatives into oxetancarboxylic acids[117,211,212].



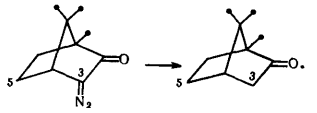
The reaction was conducted under classical conditions (in the presence of silver oxide), thermally, and photolytically. The best results were obtained by the photolysis of 2,2,5,5-tetra-alkyl-4-diazotetrahydro-3-oxofurans, the yields of the resulting 2,2,4,4-tetra-alkyloxetan-3-carboxylic acids being very high (60–97%), the reaction being simple to carry out, and no side-products being formed. This is the first example of the Wolff rearrangement among oxygen-containing heterocyclic α-diazo-ketones.

V. REACTIONS COMPETING WITH THE WOLFF REARRANGEMENT

Intramolecular rearrangement is not the only way in which the carbenone — the compound formed initially on detachment of nitrogen from a diazo-ketone — can be stabilised. The present Section discusses the chief transformations of α-diazo-ketones which compete with the Wolff rearrangement.

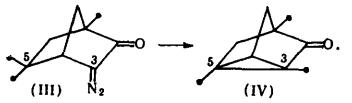
1. Hydrogen and Alkyl Migration

With diazo-ketones of the type $RCOCN_2CH_2R'$ rearrangement is accompanied by the migration of hydrogen, which results in the formation of an αβ-unsaturated ketone:



The relative proportions of the products depend on the reaction conditions. At room temperature the carbenone

is converted mainly into the $\alpha\beta$-unsaturated ketone. Thus on decomposing 3-diazo-4-phenylbutan-2-one in the presence of silver oxide, Franzen isolated 55% of 4-phenylbut--3-en-2-one[213]:

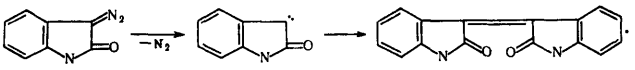


$$C_6H_5CH_2CN_2COCH_3 \longrightarrow C_6H_5CH{=}CHCOCH_3 + C_6H_5CH_2CH(CH_3){-}COOH.$$

At temperatures exceeding 100° the predominant reaction is rearrangement with formation of α-methyl-β-phenylpropionic acid. Franzen showed also that the reaction goes similarly under ultraviolet irradiation in the absence of a catalyst[213].

A new reaction of the same type — alkyl migration — has recently been discovered[77]. In contrast to photolysis, which gives the normal product of the Wolff rearrangement, heating diazocamphor in the presence of copper results in migration of a hydrogen atom† with formation of camphor[42]:

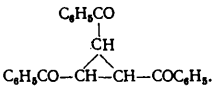
Compounds were therefore studied in which the $C_{(5)}$ position was occupied. Thus the diazo-ketone (III) was prepared from isofenchone, and its decomposition in the presence of copper bronze gave the ketone (IV) in 53% yield. In this case migration of a methyl group takes place, with formation of a $C_{(3)}-C_{(5)}$ bond:



Hence in this instance *C*-alkylation competes successfully with the Wolff rearrangement.

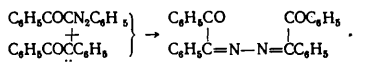
2. Dimerisation and Trimerisation

As already mentioned, copper, like silver, accelerates the elimination of nitrogen from diazo-ketones, and is therefore sometimes used as a catalyst in the Wolff rearrangement. However, in the presence of copper catalysts rearrangement of the diazo-ketone is usually suppressed by dimerisation of the intermediate carbenone to a diacylethylene[78-86]. It has been established that predominantly unrearranged products are formed in the presence of copper[76], cuprous oxide[87], cupric oxide[82,215-218], copper chloride[87,219], and copper acetate or benzoate[87]. The copper catalysts are assumed[220] to stabilise the carbenone, whose rate of rearrangement into a keten is so strongly diminished that intermolecular interaction begins to predominate over intramolecular conversion. Thus when diazoacetophenone is heated in an inert solvent in the presence of cupric oxide, 1,4-diphenylbut-2-ene-1,4-dione is formed, to which Paal[221] has assigned the *trans*-configuration:



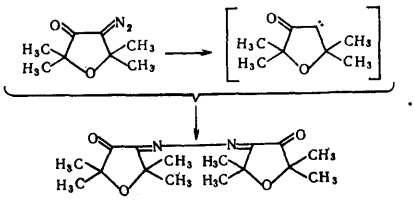
$$2C_6H_5COCHN_2 \xrightarrow{CuO} C_6H_5COCH{=}HCCOC_6H_5.$$

1,6-Diphenylhex-3-ene-2,5-dione $C_6H_5CH_2COCH{:}CHCOCH_2C_6H_5$, 1,2-distearoylethylene [octatriacont-19--ene-18,21-dione] $C_{17}H_{35}COCH{:}CHCOC_{17}H_{35}$, etc. have similarly been prepared from the corresponding diazo-ketones[78]. In some cases the dimerisation of carbenones occurs so readily in the presence of copper catalysts that this reaction is used as a method of synthesising symmetrical and even unsymmetrical unsaturated γ-diketones[79-85,241]. Isoindigo, for example, has been synthesised in this way[223]:

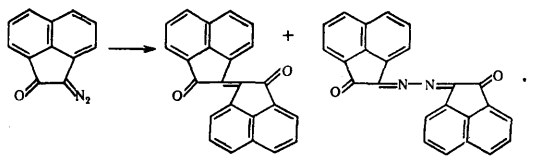


The course of the reaction is similar with 2-diazoindan--1-one[222].

In isolated cases[73,78] a more complicated intermolecular interaction of the intermediate carbenones — trimerisation — has been observed. Thus after boiling diazoacetophenone in isopentyl ether, Grundmann was able to isolate a very small quantity of *cis*-1,2,3-tribenzoylcyclopropane[78]



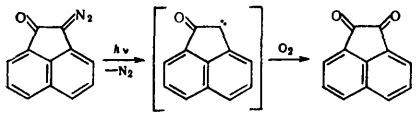
3. Formation of Ketazines



In the thermal decomposition of diazo-ketones — with or without a catalyst present — a further type of intermolecular reaction is possible, the intermediate carbenone interacting with the original diazo-compound[224-227]. Thus the decomposition of azibenzil in the presence of cupric oxide results in the formation of benzil monoazine[78]:

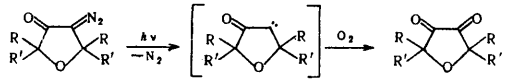
We have observed a similar course of reaction in the catalytic thermal decomposition of 4-diazotetrahydro--2,2,5,5-tetramethyl-3-oxofuran[212]:

The thermolysis of 2-diazoacenaphthen-1-one[228] results in a mixture of two products — biacenaphthenylidenedione and acenaphthenequinone monoazine:



The pyrolysis of 3-diazo-1-methyl-2-oxoindoline has also led to isolation of the corresponding ethylenic derivative and the azine — 1,1′-dimethylisoindigo and 1,1′-dimethylisatin azine[229].

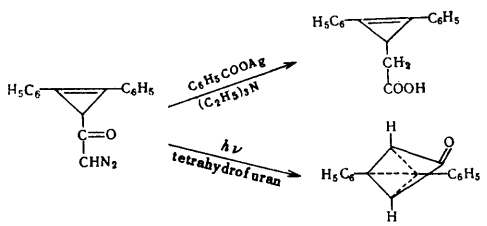
4. Oxidation of Intermediate Carbenones



Cases of the oxidation of carbenes have been described in the literature. Diphenyldiazomethane when exposed to light, for example, adds on oxygen and is converted into

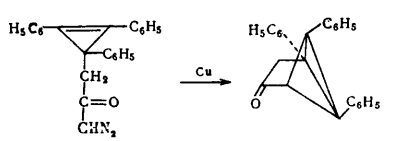
† There are other examples in which photolysis and thermolysis of diazo-ketones result in different reaction products[214] (see also Subsection 5, below).

benzophenone[224]. An analogous process, which completely suppresses the Wolff rearrangement, obviously occurs with diazoacenaphthenone[115], where only the corresponding α-diketone can be isolated after illumination:



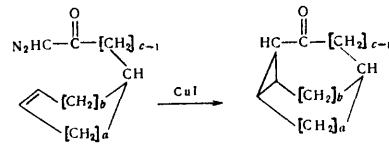
We have also observed the formation of small quantities of 2,2,5,5-tetra-alkyltetrahydrofuran-3,4-diones in the rearrangement of 2,2,5,5-tetra-alkyl-4-diazotetrahydrofuran--3-ones[212]:

where R = R′ = CH_3 and R = CH_3, R′ = C_2H_5.



5. Intramolecular Addition of Carbenones at a Double Bond

An unusual result has been recorded in recent papers by Masamune[230,231], who has studied the rearrangement of diazomethyl 2,3-diphenylcyclopropyl ketone. He found that heating this compound with silver benzoate in triethylamine goes normally with a good yield of the methyl ester of the homologous acid. However, photolysis of the same diazo-ketone in tetrahydrofuran results in formation of a ketone belonging to the tricyclo[1,1,1,$0^{4,5}$]pentane system:



Hence in this case the α-ketocarbene formed on ultraviolet irradiation of the diazo-ketone exhibits a greater tendency to intramolecular addition at the double bond[3,4,232-235] than to rearrangement.

A similar type of reaction has been observed also by Small[236] and by several other workers[237-240]. Thus boiling 1-diazo-3-triphenylcycloprop-2′-enylpropan-2-one in benzene in the presence of copper powder results in a 57% yield of 4,5,6-triphenyltricyclo[2,1,1,$0^{5,6}$]hexan-2-one:

In the above examples the intramolecular addition of the carbenone at the double bond is obviously governed by the structural peculiarities of the initial diazo-ketones — by the presence of a nucleophilic double bond in the diazo--ketone molecule, and also of a strained unsaturated three--membered ring, which disappears as a result of the reaction.

The catalytic decomposition of monocyclic diazo-ketones containing a double bond in the ring has been used by Doering for the synthesis of tricyclic systems[239]:

(where a = 0–4, b = 0–2, and c = 1 or 2), which he obtained in preparative yields. Other workers have carried out similar transformations[242,243].

CHEMISTRY OF NATURAL ALIPHATIC ACIDS CONTAINING A CONJUGATED SYSTEM OF DOUBLE BONDS

V.D. Solodovnik

CONTENTS

1. Introduction 272
2. General properties and methods of establishing structure 272
3. Dienoic acids 274
4. Trienoic and tetraenoic acids 276
5. Syntheses of naturally occurring polyenoic aliphatic acids. 280

1. INTRODUCTION

Until recently only a very small number of aliphatic acids containing a conjugated system of double bonds had been found in Nature. These acids had been isolated in individual cases from plant lipids, and were regarded in oil and fat chemistry as fairly rare exceptions. The view was even expressed that they might have been formed in the course of isolation, by the isomerisation of unconjugated polyenoic acids. However, several new representatives of this class of compounds have been discovered in recent years, and aliphatic acids containing conjugated double bonds have been shown to be present in the lipids from plants of a great variety of families and species. Sixteen natural conjugated polyenoic aliphatic acids are now known, and the number of natural sources for acids of this type is continually being extended.

Conjugated polyenoic acids form the basis of many long-established film-forming materials. The paint and varnish industry has hitherto made widespread using of drying oils, in which conjugated polyenoic acids either are present in the sodium form (tung oil) or have been formed, as a result of preliminary treatment, from unconjugated polyenoic acids present in linseed or other vegetable oil. In contrast to oils containing unconjugated polyenoic acids, the triglycerides of conjugated acids give valuable varnishes, which dry more rapidly and are more stable to the action of moisture and alkalis.

2. GENERAL PROPERTIES AND METHODS OF ESTABLISHING STRUCTURE

The C_{18} conjugated polyenoic acids most frequently encountered in Nature are colourless crystalline solids. Naturally occurring acids of this type containing a smaller number of carbon atoms in the chain melt below room temperature. They all dissolve well in polar organic solvents, and less well in non-polar solvents.

Polyenoic acids containing *cis*-ethylenic bonds readily isomerise into all-*trans*-isomers under the influence of light and especially in the presence of traces of iodine, sulphur, nitrogen dioxide, and other catalysts.

As a result of the presence of a chromophoric group, conjugated polyenoic acids are able to absorb ultraviolet radiation. Examination of the ultraviolet spectra of stereoisomeric dienoic acids has shown that *trans-trans*-isomers absorb at shorter wavelengths than do *cis-trans*- and *cis-cis*-isomers, the intensity of the absorption maxima diminishing in this sequence. Thus the ultraviolet spectra of the stereoisomeric octadeca-9,11- and -10,12-dienoic acids contain a single maximum at 230, 232, and 234 nm respectively for the *trans-trans*-, *trans-cis*-, and *cis-cis*-isomers[1]. The variation in the position of the absorption maximum and in its intensity is less marked in the spectra of the deca-2,4-dienoic acids, owing to conjugation of the diene group with the carboxyl, but is sufficient to distinguish them[2]. Variations in the ultraviolet spectra are still more marked among the stereoisomers of conjugated trienoic acids, since their spectra contain three absorption maxima (Table 1).

Infrared spectroscopy has an important place in establishing the structure of conjugated polyenoic aliphatic acids. Alkenes of the type RCH:CHR′ are characterised by an intense band at 950–1100 cm^{-1}, due to deformation vibrations

TABLE 1. Ultraviolet spectra of C_{18} conjugated trienoic acids (λ_{max}, nm).

Conjugation	Positions 8, 10, 12	Positions 9, 11, 13	Ref.
cis-trans-cis	265, 275, 287	264, 274, 285	3, 4, 5
		265, 275, 287	5
cis-cis-trans	not known	(264), 271, (279)*	4
cis-trans-trans	261, 271, 232	261, 271, 281	6, 3
trans-trans-cis	262, 272, 283	262, 272, 283	7, 8
trans-trans-trans	259, 269, 280	260, 269, 281	7, 6
	259, 269, 279	259, 268, 279	3, 5

* Values in parentheses relate to an unpurified specimen.

of the *trans*-ethylenic hydrogen atoms, or a band in the range 620–730 cm^{-1} with *cis*-alkenes[9,10], as well as a low-intensity peak in the range 1600–1660 cm^{-1}. These bands may occupy different positions within the above ranges depending on the nature of the substituents R and R′. In particular, the spectrum of elaidic acid contains a band at 968 cm^{-1}, whereas such absorption is absent with oleic acid[11]. The first systematic investigation of the infrared spectra of stereoisomeric conjugated dienoic acids was made on the methyl deca-2,4-dienoates and the corresponding deca-2,4-dienols[2]. Their spectra differed slightly in the position of weak bands in the region of C=C stretching vibrations (~1600 cm^{-1}) but differed very sharply in the region of deformation vibrations undergone by C–H bonds adjacent to ethylenic carbon atoms (940–1100 cm^{-1}) (Table 2).

Table 2 shows that the infrared spectra of the *trans-trans*-isomer contain only one intense band at 950–1010 cm^{-1}, whereas those of all the *trans-cis*-isomers contain also a somewhat less intense band at 950–970 cm^{-1}. The peaks at 1600–1660 cm^{-1} are considerably less intense and are less distinctive of the isomeric dienes.

The infrared spectra of nona-3,5-dienoic[11,12] and trideca-3,5-dienoic[13] acids also exhibit the presence of two bands (at 950 and 980 cm^{-1}) with the *trans-cis*-isomers and of one band in the same range with the *trans-trans*-isomers.

Analogous regularities are observed also in the infrared spectra of conjugated trienoic and tetraenoic acids. Without exception, all the all-*trans*-acids exhibit only one intense band, in the range 1000–940 cm^{-1}. Their isomers, containing both *cis*- and *trans*-ethylenic bonds, usually display two intense peaks in the same range of the infrared spectra (see examples in Table 3) and a band in the range 650–750 cm^{-1} which is characteristic of a *cis*-ethylenic bond. On the photochemical isomerisation of *cis-trans*-isomers into all-*trans*-forms, the peak at 960 cm^{-1} disappears, while the band at 1000 cm^{-1} shifts to 970 cm^{-1}. Thus a qualitative assessment of the character of the infrared spectra of conjugated polyenoic acids indicates whether they have an all-*cis*-, an all-*trans*-, or a *cis-trans*-configuration.

The relative proportions of *cis*- and *trans*-ethylenic bonds in conjugated polyenoic acids can be determined by measuring the intensity of the band in the range 970–1000 cm^{-1}, which is characteristic of non-planar deformation vibrations of *trans*-hydrogen atoms adjacent to double bonds. This parameter was found to be directly proportional to the number of *trans*-ethylenic bonds in a polyene chain, and is a multiple of the intensity of the corresponding band (968 cm^{-1}) in the spectrum of elaidic acid (provided that measurements are made on the same instrument)[11] (Table 3).

TABLE 2. Characteristic frequencies of infrared absorption bands due to ethylenic bonds in isomeric nona-2,4-dienols and methyl deca-2,4-dienoates.[2]

Configuration of 2,4-diene system	2,4-Dienols			Methyl deca-2,4-dienoates		
	stretching vibrations		deformation vibrations	stretching vibrations		deformation vibrations
	C=C (1)	C=C (2)	(CH=CH)$_2$	C=C (1)	C=C (2)	(CH=CH)$_2$
trans-trans	1660	1626	986, —	1647	1618	1001, —
trans-cis	1655	1616	983, 948	1639	1607	996, 969
cis-trans	1652	1609	984, 952	1640	1602	1002, 963
cis-cis	1651	1601	985*, 951*	1634	1592	1002*, 963*

* The presence of these bands is explained by contamination with *trans*-isomers owing to the ready isomerisation of the *cis-cis*-form.

TABLE 3. Extinction coefficients K of C_{18} aliphatic acids $CH_3[CH_2]_l[CH{:}CH]_m[CH_2]_kCOOH$ in the range 900–1000 cm^{-1} of the infrared spectra.[11]

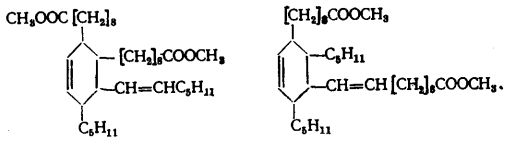
Besides physicochemical methods for investigating the structure of conjugated polyenoic acids, use is made also of such classical chemical methods as catalytic hydrogenation, halogenation, and oxidative cleavage. The last of these methods (ozonolysis and the permanganate–periodate method) enables the position of a polyene group in an aliphatic chain to be determined, since it involves formation of monocarboxylic and dicarboxylic acids each containing one extra carbon atom compared with the radicals attached to the double bonds:

$$RCH{=}CH{-}CH{=}CH[CH_2]_nCOOH \xrightarrow{[O]} RCOOH + HOOC[CH_2]_nCOOH.$$

The above methods make it possible to establish the structure of the acids and to determine the ratio of *cis*- and *trans*-ethylenic bonds. However, the sequence of the double bonds cannot be determined by these methods. In most cases this question can be answered by studying the products of the diene condensation of the polyenoic acids with maleic anhydride. Among conjugated dienes, it is usually only aliphatic *trans-trans*-dienes which undergo the Diels–Alder reaction. The *cis-trans*-dienes either do not react at all with maleic anhydride or else react under severe conditions in a manner differing from that of diene synthesis[14,15]. The formation of adducts with maleic anhydride may serve as evidence of the presence of a conjugated *trans-trans*-diene group in a polyene compound, and has been used in establishing the configuration of naturally occurring conjugated trienoic acids. In this case the configuration of the third ethylenic bond in the acid, which remains unchanged in the aliphatic chain of the adduct, can be confirmed by infrared spectroscopy: the methyl esters of adducts containing an exocyclic *trans*-ethylenic bond exhibit an intense band in the range 1000–950 cm^{-1}, whereas this band is absent with adducts containing a *cis*-bond[16,17].

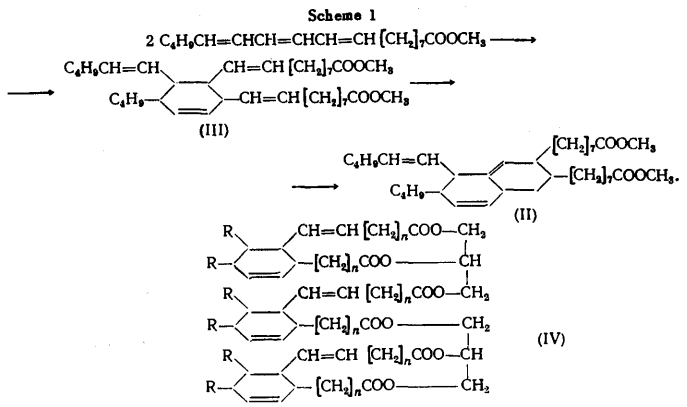


All natural polyenoic acids containing conjugated bonds are distinguished by considerable instability. They are extremely readily oxidised in the air, to form various hydroperoxides, which in turn initiate polymerisation processes[18]. Acids containing one or more *cis*-ethylenic bonds are oxidised considerably more readily than are all-*trans*-isomers[19] (see Table 4).

TABLE 4. Rate of oxidation of octadecatrienoic acids at 40°.[20]

Acid	Configuration of unsaturated system	Molar O_2/acid ratio after 100 min
α-Elaeostearic	*cis-trans-trans*, conjugated	2.68
β-Elaeostearic	*trans-trans-trans*, conjugated	1.02
Linolenic	*cis-cis-cis*, unconjugated	0.52

The presence of traces of water, irradiation, heating, and other factors considerably accelerate the polymerisation of these compounds[18,21]. These facts are of fundamental importance in the application of derivatives of polyenoic acids in the manufacture of varnishes.



The thermal polymerisation (in the absence of oxygen) of compounds containing different numbers of double bonds, of different degrees of conjugation, and differing in configuration also occurs at different rates. Thus the thermal polymerisation of conjugated *trans-trans*- and *trans-cis*- and of unconjugated *cis-cis*-dienoic C_{18} acids takes place at relative rates of 40 : 7 : 1.[21] Their polymerisation probably has a bimolecular mechanism of diene condensation[22], but intramolecular cyclic structures may be formed. It has been discovered that unconjugated and conjugated dienoic acids give identical dimerisation products, which indicates that the polymerisation of unconjugated polyenoic acids involves their conversion into conjugated acids[22]. The most detailed investigation that has now been made is of the structure of the products formed by the polymerisation of methyl octadeca-*trans*-10, *trans*-12-dienoate, which are obtained when it is heated at 250° for 5 h. The results of nuclear magnetic resonance, mass, and infrared spectroscopy and of ozonolysis have shown that the main products of this reaction are 3,4,5,6-tetrasubstituted cyclohexene dimers of type (I), having an αβ-ethylenic bond in a side-chain[23].

(Ia) (Ib)

Under these conditions trienoic esters probably form dicyclic dimers of type (II) or monocyclic dimers having the structure (III) (see Scheme 1)[22,24], whereas their triglycerides yield structures of type (IV). The dimeric molecules may undergo further condensation by interaction at isolated double bonds with the conjugated bonds of the monomers[25].

Scheme 1

3. DIENOIC ACIDS

Stillingic Acid

The only C_{10} dienoic acid which has been found in Nature is deca-2,4-dienoic (stillingic) acid, which has been isolated from the seed oil of *Sapium sebiferum* (the Chinese tallow tree) and *S. discolor*. The content of stillingic acid in the oils of these seeds does not exceed 4–5%. A 2,4-dienoic acid was first detected in these sources from the characteristic absorption maximum in the ultraviolet spectrum (260 nm);[26,27] soon after this it was isolated and characterised, and its structure was established[28-31].

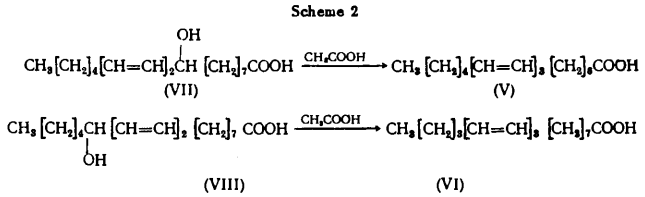
Stillingic acid oxidises in the air even at ordinary temperatures. Exhaustive hydrogenation yields n-decanoic acid. The products of destructive oxidation of its methyl ester are found to include n-hexanoic acid, the formation of which proves that the ethylenic bonds in the dienoic acid are located in the 2- and 4-positions[28]. Partial hydrogenation of methyl stillingate gave mainly the dec-3-enoic ester, together with small quantities of the dec-2-enoate and dec-4-enoate. Reduction of methyl stillingate with lithium tetrahydroaluminate gave deca-2,4-dienol, which had an ultraviolet absorption maximum at 231 nm (ε = 22 500), and on alkaline isomerisation a mixture of deca-4,6- and -5,7-dienoic acids was formed[31].

Since the configuration of the diene system of stillingic acid could not be established in the original investigation[28-31], nor could it be satisfactorily analysed or its crystalline derivatives characterised, a further detailed study was made of this acid[2]. In order to establish its configuration, all four possible geometric isomers of deca-2,4-dienoic acid were synthesised (see Section 5). The naturally occurring acid and the synthetic *trans*-2,*cis*-4-isomer had the same ultraviolet and infrared spectra and gave identical *p*-bromophenacyl esters and *S*-benzylthiouronium salts, so that the *trans*-2,*cis*-4-configuration was proposed for stillingic acid.

Dodeca-2,4-dienoic Acid

A dodeca-2,4-dienoic acid has been detected in the seed oil from *Sebastiana lingustrina* (Euphorbiaceae family), a plant growing in North America[32]. Two moles of hydrogen are absorbed on hydrogenation, with the formation of lauric acid. The position of the absorption maximum in the ultraviolet spectra of the methyl ester (268 nm) and of the acid (260 nm, ε = 33 400) is characteristic of 2,4-dienoic acids[2,33]. The configuration of the diene grouping in this acid has not yet been settled. From the position of the ultraviolet absorption maximum for methyl dodeca-2,4-dienoate, the acid may be supposed to be the *trans*-2,*cis*-4-isomer, but the position of the maximum in the ultraviolet spectrum of the acid itself and the extinction are characteristic of acids having a *trans-trans*-configuration.

Octadeca-*trans*-10,*trans*-12-dienoic Acid



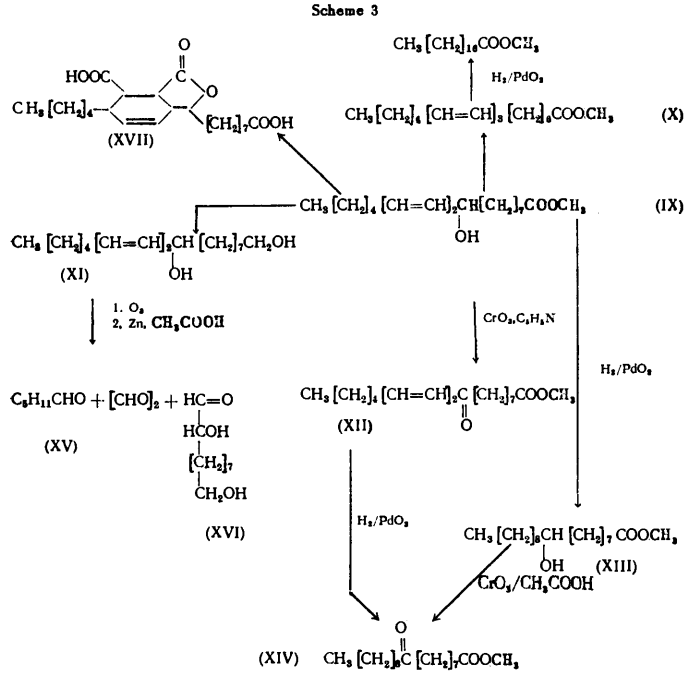
A positional isomer of this acid having an unconjugated system of double bonds — linoleic acid — is the most widespread "essential" fatty acid in Nature. In spite of this, no isomer of it having conjugated bonds was known until recently. There were only isolated references to the presence of such an isomer in lipids from the plant *Catalpa bignonioides* and *Chilopsis linearis*[5,8,34] and in some other

plants[35,36]. The seeds of *Chilopsis linearis*, a small ornamental tree from the Southern USA, contain a trienoic as well as the dienoic acid. Careful low-temperature recrystallisation of the mixture of these acids obtained by saponifying the seed oil resulted in the isolation of 9% of a dienoic acid having m.p. = 55–56° and λ_{max} = 232 nm (ϵ = 29 200), with infrared absorption bands at 985 and 930 cm^{-1}.[37] Catalytic hydrogenation of this acid yielded strearic acid. The location of the diene grouping at the 10,12-positions was proved by oxidative cleavage. Although only one intense absorption band is usually oserved in the range 900–1000 cm^{-1} in the infrared spectra of conjugated *trans*--*trans*-dienes, this configuration was assigned to the octadeca-10,12-dienoic acid which was isolated, since the latter formed an adduct with maleic anhydride (m.p. 102–103°) which gave no melting-point depression on fusion with a known specimen[38]. This acid had been obtained previously by the dehydration and isomerisation of ricinoleic acid isolated from castor oil[39], and by the alkaline isomerisation of linoleic acid[1].

cis-trans-9-Hydroxyoctadeca-10,12-dienoic and -13-Hydroxyoctadeca-9,11-dienoic Acids

The oil from the plants *Tragopogon porrifolius* (Compositae family) is known as a source of saturated epoxy--acids[40]. It has recently been found to contain a polyene fraction of unusual composition, in amount not exceeding 4–5% according to ultraviolet spectral data[7]. After separation of unsaponifiable products, conjugated dienoic acids having an ultraviolet absorption maximum at 233 nm and infrared absorption bands at 3580, 945, and 980 cm^{-1} were isolated. The first band indicated the presence of a hydroxyl, and the latter bands the presence of a *cis-trans*--diene grouping. The mixture of dienoic acids isolated was subjected to oxidative cleavage by the permanganate–periodate method, which showed the presence of diene groupings in the 9,11- and 10,12-positions. On boiling with glacial acetic acid the mixture of acids formed a mixture of octadeca-8,10,12- and -9,11,13-trienoic acids — (V) and (VI), see Scheme 2.

Scheme 2



Catalytic hydrogenation of this mixture of trienoic acids yielded stearic acid, whereas oxidative cleavage yielded valeric, suberic, and azelaic acids. The ease of dehydration indicated that the hydroxy-groups in the original acids occupied an allylic position with respect to the diene grouping. This suggestion was confirmed by study of the hydrogenation products obtained from the mixture of hydroxy-acids (VII) and (VIII), which comprised a mixture of monohydroxystearic acids of m.p. 65–66°. The location of the hydroxyls in the latter acids (at positions 9 and 13) was proved by oxidative cleavage to the corresponding dicarboxylic and monocarboxylic acids.

On the basis of the infrared spectra of the natural acids and their esters, a *cis-trans*-configuration was assigned to them. However, spectral data do not permit the possibility to be excluded that only one of the dienoic acids may possess a *cis-trans*-configuration, while the other may have a *cis*--*cis*- or *trans-trans*-configuration. The position of the *cis*- and *trans*-ethylenic bonds in the molecules of the natural acids remains undetermined.

Dimorphecolic Acid

In order to find new sources for valuable industrial oils, a study was made of the composition of lipids from a large group of plants of the Compositae family[41]. Several of them, in particular the oil from *Dimorphotheca aurantiaca* (or *D. sinuata*), were found to contain a considerable quantity (up to 50%) of a conjugated dienoic acid as well as epoxy--acids. Mild saponification of this oil gave a dienoic acid, sensitive to alkali under more severe conditions, which was purified by countercurrent distribution as the methyl ester in an acetonitrile–hexane system. The methyl ester (IX) exhibited optical activity, absorbed in the ultraviolet at 231 nm, and possessed infrared absorption bands corresponding to a conjugated *trans-trans*-diene (992 cm^{-1}) and a hydroxy-group. On boiling under conditions of acetolysis of the epoxy-compounds, the dimorphecolic ester was converted into a trienoic acid (X) containing no hydroxyl, which was reduced catalytically to stearic acid. Lithium tetrahydroaluminate reduction of the ester (IX) to the dienediol (XI) also confirmed the absence of an epoxy-group in the ester molecule (IX). Oxidation with chromium trioxide yielded the dienone (XII), which had a maximum in the ultraviolet spectrum at 275 nm, corresponding to $\alpha\beta$- and $\gamma\delta$-unsaturated ketones. The location of the hydroxyl in dimorphecolic acid was established by comparing the products obtained by reducing the keto-ester (XII) and oxidising the hydroxy-ester (XIII) with the identical synthetic keto-ester (XIV). Furthermore, ozonolysis of the dienediol (XI) yielded glyoxal and the aldehydes (XV) and (XVI), identified as their 2,4-dinitrophenylhydrazones. On the other hand, dimorphecolic ester (IX) reacts with maleic anhydride to form a lactone (XVII), which confirms the *trans-trans*--configuration of the 10,12-diene grouping in dimorphecolic acid[42] (see Scheme 3).

Scheme 3

Methods were later developed, to meet the requirements of the paint and varnish industry, for isolating dimorphecolic acid as its methyl ester from the triglycerides in *Dimorphotheca* oil, these involving transesterification of the oils in methanolic solution on a hydroxylated ion-exchange resin [43,44].

Dimorphecolic acid has subsequently been found in the oils from 29 species of plants, in which it constitutes 34–75% of the total acids [45]. There is indirect evidence of the presence in some of these specimens of another isomer of dimorphecolic acid, with the hydroxyl in position 13 and the diene grouping in positions 8 and 10. [46]

The ready dehydration of dimorphecolic acid makes it a very probable biological precursor of calendic acid (see below), which was found to accompany the former in most of the plants investigated [45].

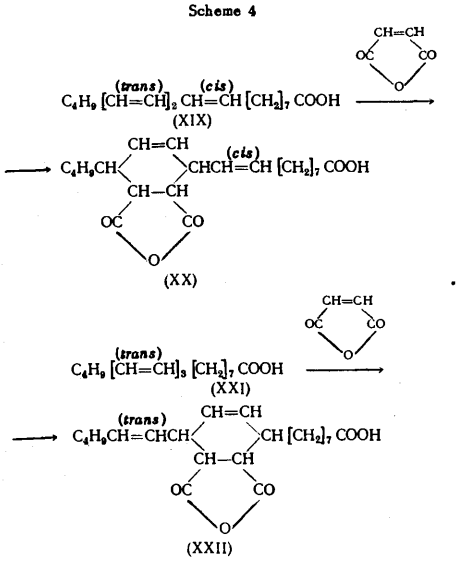
4. TRIENOIC AND TETRAENOIC ACIDS

Since trienoic acids may differ from one another both in the position of the triene system in the aliphatic chain and in the configuration of the double bonds, the number of possible isomers is very large. In spite of this, only eight naturally occurring acids of this type are known at the present time. They all oxidise and polymerise readily in air even at room temperature.

α-Elaeostearic Acid



α-Elaeostearic acid is the most widely occurring conjugated trienoic acid in Nature (Table 5). The best-known source of the acid is tung oil, from which it was isolated as long ago as 1875. [47,48] The formula $C_{18}H_{30}O_2$ was established for α-elaeostearic acid in 1902, and a higher-melting β-form was obtained for the first time [49]. Pure α-elaeostearic acid, isolated from tung oil and purified by low-temperature recrystallisation from alcohol, melts at 48°. [3,4] Under the influence of ultraviolet radiation in the presence of traces of iodine or sulphur, it is readily converted into β-elaeostearic acid melting at 72°. [4] Both acids form adducts with maleic anhydride on heating in benzene, these melting at 62.5° and 77° respectively [72], and bromination yields hexabromides melting at 139–141° and 157°. [73,74] α-Elaeostearic acid forms a crystalline *p*-phenylphenacyl ester melting at 63–64°. [70] On catalytic hydrogenation both acids give stearic acid, equimolecular mixtures of isomeric octadecenoic acids being formed as intermediate products [75–77]. The action of hydrazine on α- and β-elaeostearic acids involves reduction firstly of terminal units in the polyene chain, with the formation of the 11-enoic and the 9,11- or 11,13-dienoic acids, a *cis*-ethylenic bond in the polyene system being reduced rather more rapidly [78] [than the corresponding *trans*-bond (Ed. of Translation)].

The ultraviolet spectra of α- and β-elaeostearic acids show absorption maxima characteristic of trienes — at 261, 271, and 281 nm (ε = 36 000, 47 000, and 38 000 respectively); and at 259, 268, and 279 nm (47 000, 61 000, and 49 000). [3]

At 0° both forms add on two molecules of bromine to form tetrabromides, so for a long time they were regarded as dienoic acids, to which different cyclic structures were attributed. It was later suggested that the ethylenic bonds in the acids were conjugated [79], and valeraldehyde, valeric acid, and azelaic acid were detected in the hydrolysis products of their ozonides [80]. Together with the facts that on catalytic hydrogenation 1 mole of elaeostearic acid absorbed 3 moles of hydrogen and that its molecular refraction was too high to correspond to a diene, this enabled the true structure of the acid to be established [81,82]. The structure of elaeostearic acid was confirmed also by the 60% yield of glyoxal obtained on hydrolysis of its ozonide, while no succinic or malonic acid was detected [83]. Hexabromostearic acid was subsequently obtained [73,74] by bromination with ultraviolet irradiation and heating. Thus the structural formula of elaeostearic acid was finally established by 1930, but its configuration remained unelucidated.

The original investigations of the structure of the adducts formed by α- and β-elaeostearic acids with maleic anhydride did not provide the right answer to this question [72,81–87]. The location of the cyclohexene ring in the aliphatic chain of the adducts was merely established, and an adduct having the structure (XX) was shown to be formed from α-elaeostearic acid (XIX), since azelaic acid was detected among the products of the oxidative cleavage of this adduct (Scheme 4).

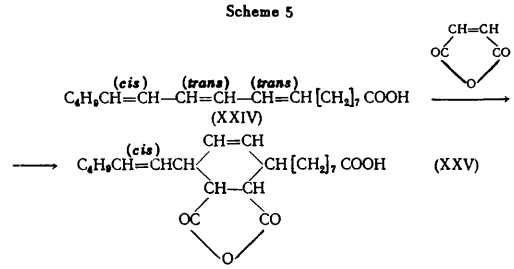
Scheme 4

The structure of the adduct formed by maleic anhydride with β-elaeostearic acid was established (XXII) in a similar manner[72].

After it had been ascertained that maleic anhydride undergoes diene condensation only with *trans-trans*-diene groups[14], several authors suggested that α-elaeostearic acid had the *cis*-9,*trans*-11,*trans*-13-configuration (XIX), while β-elaeostearic acid was the all-*trans*-isomer (XXI).[11,16,17,88] These configurations were subsequently confirmed by examination of the infrared spectra. Thus α-elaeostearic acid (XIX) exhibits intense absorption bands in the region of out-of-plane deformation vibrations of *trans*-ethylenic hydrogen atoms at 992 and 965 cm^{-1}, with intensity coefficients K of 1.43 and 0.416 respectively; the infrared spectrum of the β-isomer (XXI) has an absorption band at 994 cm^{-1} with K = 1.96, threefold the intensity of the corresponding band for elaidic acid at 968 cm^{-1}. From this it was concluded that the β-isomer had an all-*trans*-configuration. From the same considerations the α-acid (XIX) was assumed to contain one *cis*-ethylenic bond[11]. In this case one of three configurations — *trans-trans-cis*, *cis-trans-trans*, or *trans-cis-trans* — was possible, of which the second was the most probable, since α-elaeostearic acid formed only an adduct having the structure (XX). Furthermore, the infrared spectrum of the methyl ester of the adduct (XXII), in contrast to the adduct (XX), contained an absorption band in the range 1000–950 cm^{-1}, indicating that the ethylenic bond in the aliphatic chain of the adduct (XXII) had the *trans*-configuration[16,17].

The structure (XIX) for α-elaeostearic acid was finally proved by synthesis (see Section 5).[4,89]

Punicic Acid



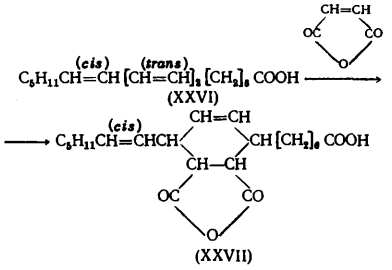
Punicic acid was first isolated from the seed oil of the pomegranate (*Punica granatum*)[90], where it forms 72% of the total aliphatic acids. It is met also in the plants *Momordica balsamina*[72], *Trichosanthes anguina* (43%)[70], *Ecballium elaterum* (Cucurbitaceae) (22%)[71], etc. The ultraviolet spectrum of punicic acid (m.p. = 42°) contains three maxima, at 265.5, 275 (ε = 47 800), and 287 nm. The infrared spectrum contains absorption bands at 988 and 937 cm^{-1} (K = 0.63 and 0.7 respectively)[91]. On the basis of these data it was suggested — erroneously, as appeared later — that punicic acid had a *cis-cis-trans*-configuration[91,92]. The acid does not form an adduct with maleic anhydride, and on ultraviolet irradiation is converted into β-elaeostearic acid (XXI).[16]

At roughly the same time an acid melting at 35–35.5°, which was termed "trichosanic acid", was isolated from the oil of the Japanese snake gourd (*Trichosanthes cucumeroides*)[90]. Its ultraviolet and infrared spectra were identical with those of punicic acid, and under the influence of ultraviolet radiation both acids isomerised into β-elaeostearic acid (XXI), so that trichosanic acid was assumed to be a third geometric isomer of α-elaeostearic acid (XIX). The presence of trichosanic acid in Japanese snake gourd[93,94], and also in the oil of the Indian snake gourd (*Trichosanthes anguina*)[94,95], was subsequently confirmed by other workers. In order finally to establish the structure of punicic and trichosanic acids, the synthesis was then undertaken of two isomeric octadecatrienoic acids by Scheme 10*b*. Comparison of natural and synthetic specimens showed that both punicic and trichosanic acids were octadeca-*cis*-9,*trans*-11,*cis*-13-trienoic acid (XXIII).

Catalpic Acid

Catalpic acid was isolated from the seed oil of the decorative plant *Catalpa ovata* (Bignoniaceae)[8], *C. speciosa*[71], and *Chilopsis linearis*[37,38]. α-Elaeostearic acid (XIX) had previously been found in the seed oil of various *Catalpa* species[68]. Pure catalpic acid was still less stable than punicic acid (XXIII) or α-elaeostearic acid. It melts at 31–32°, and oxidised rapidly in the air, being converted into a non-crystalline solid mass even at room temperature. Its ultraviolet spectrum contains absorption maxima at 262, 272 (ε = 49 300), and 283 nm, which are characteristic of conjugated trienes[8]. The character of these maxima, together with the results of elementary analysis and hydrogenation, showed that catalpic acid, like elaeostearic and punicic acids, is an octadecatrienoic acid containing a conjugated system of ethylenic bonds.

Scheme 5

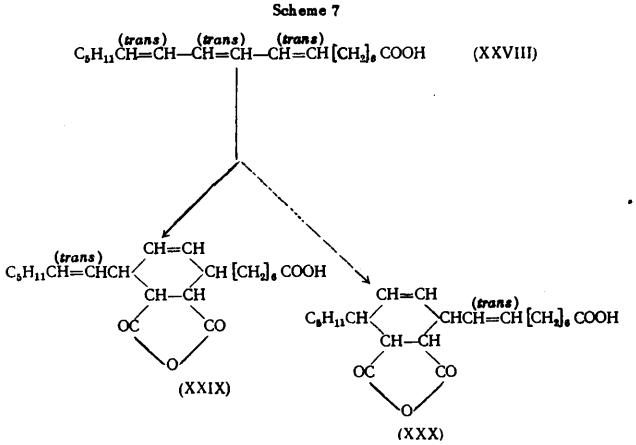


Gas–liquid chromatography of the products obtained by the oxidative cleavage of catalpic acid has shown that the triene grouping occupies the 9–13 positions. This is confirmed also by the isomerisation of catalpic acid (XXIV) into β-elaeostearic acid (XXI) on ultraviolet irradiation in the presence of iodine. The infrared spectrum of catalpic acid (XXIV) resembles that of α-elaeostearic acid, containing in particular bands at 987 and 957 cm^{-1} of the same relative intensities as with the latter acid. Catalpic acid (XXIV) readily forms an adduct (XXV) with maleic anhydride (Scheme 5), melting at 72.5–73.5° and possessing no infrared absorption band in the range 950–1000 cm^{-1}, so that the double bond in the aliphatic chain of the adduct has the *cis*-configuration. Of the eight possible isomers of octadeca-9,11,13-trienoic acid, only two — the *trans-trans-cis*- and *cis-trans-trans*-isomers — are able to form such an adduct. Since the latter isomer is α-elaeostearic acid (XIX), only the structure (XXIV) is available for catalpic acid. A complete synthesis of catalpic acid has recently been achieved by means of the Wittig reaction (Scheme 13).

Calendic Acid

Calendic acid has been isolated from the seed oil of *Calendula officinalis* (Compositae)[5]. Its isomer having the *trans-trans-trans*-configuration (β-calendic acid) is not present in this oil, but is obtained from it as a result of the isomerisation of calendic acid in the course of isolation[7]. Conjugated trienoic acids, in particular octadeca-8,10,12-trienoic acid, have been detected in other plants — *Calendula arvensis*, *Osteospermum*, *Chrysanthemoides* — which are closely related to *Calendula*[45,96]. Calendic acid (XXVI) (m.p. 40–40.5°) was purified by low-temperature recrystallisation from acetone, and elementary analysis showed it to be an octadecatrienoic acid. On catalytic hydrogenation, α-calendic acid absorbs three molecules of hydrogen to form stearic acid. Oxidative cleavage of calendic acid results in rupture of the bonds in the positions 8–13. The

infrared spectrum of calendic acid contains absorption bands at 990 and 955 cm^{-1}, which suggests the presence of conjugated *cis*- and *trans*-ethylenic bonds. A similar conclusion follows also from an examination of the positions of its ultraviolet absorption maxima (at 262, 272, and 283 nm). Calendic acid reacts readily with maleic anhydride (Scheme 6) to form an adduct of m.p. 73–74°, whose infrared spectrum does not contain the absorption bands in the range 1000–950 cm^{-1} which are characteristic of the spectra of adducts containing an exocyclic *trans*-ethylenic bond. Oxidative cleavage of the adduct by the permanganate–periodate method yields only one monocarboxylic acid — n-hexanoic acid — so that the adduct has the formula (XXVII). Thus the *trans*-8,*trans*-10,-*cis*-12-configuration has been established for calendic acid.



Scheme 6

(XXVII)

When calendic acid is treated with iodine in pentane and on ultraviolet irradiation, it passes into β-calendic acid (XXVIII), melting at 77–78° and exhibiting an intense infrared peak at 990 cm^{-1}.[11,17] A 950 cm^{-1} band is also present in the infrared spectrum of the photochemical isomerisation product, but its intensity is considerably less than in the infrared spectrum of the original *trans*-*trans*-*cis*-isomer (XXVI). The ultraviolet absorption maxima of β-calendic acid (XXVIII) are displaced to shorter wavelengths in comparison with natural calendic acid (XXVI) (258, 268, and 280 nm compared with 262, 272, and 283 nm)[7] (see Scheme 7). The infrared spectrum of the adduct formed by β-calendic acid with maleic anhydride (m.p. 70–71°) contains an absorption band at 963 cm^{-1}, which is characteristic of a *trans*-exocyclic double bond. Permanganate–periodate cleavage of this adduct gave both n-hexanoic and suberic acids, so that the adduct melting at 70–71° was a mixture of the isomers (XXIX) and (XXX). Further confirmation of the structure of calendic acid has been provided by its complete synthesis (Scheme 13).

Scheme 7

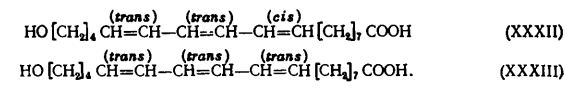
(XXIX) (XXX)

Jacarandic Acid

Another stereoisomer of calendic acid (XXVI) — jacarandic acid (XXXI), found in the seed oils of *Jacaranda mimosifolia* (Bignoniaceae) and *Dimorphotheca aurantiaca*[5,58] — is stereochemically analogous to punicic acid (XXIII). These two acids are very similar in spectral characteristics and in melting points (43.5–44°).

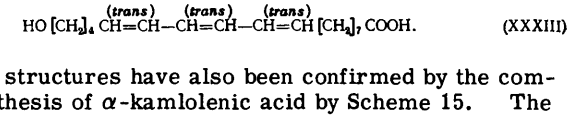
Jacarandic acid oxidises very readily in the air, and is extremely unstable at temperatures above -20°. Catalytic hydrogenation and oxidative cleavage have shown it to be a C_{18} acid having a triene grouping in the positions 8–12 of the aliphatic chain[5,31]. Furthermore, this acid does not form an adduct with maleic anhydride, and on ultraviolet irradiation passes into a higher-melting form which proves to be identical with β-calendic acid (XXVIII). All these results indicate the absence of a *trans*-*trans*-diene grouping and the presence of at least one *cis*-ethylenic bond in jacarandic acid. Structures containing *cis*-*trans*-*trans*-, *trans*-*trans*-*cis*-, or *trans*-*trans*-*trans*-triene systems are therefore excluded. The presence in the infrared spectrum of jacarandic acid of an intense band at 982 cm^{-1} (together with a band at 929 cm^{-1}), which is characteristic of a *trans*-ethylenic bond, also excludes a *cis*-*cis*-*cis*--configuration. The *cis*-*cis*-*trans*- and *trans*-*cis*-*cis*--structures were rejected on the grounds that the infrared and ultraviolet spectra of jacarandic acid (XXXI) and of synthetic octadeca-*cis*-9,*cis*-11,*trans*-13-trienoic acid[4] differ fundamentally. In particular, the ultraviolet spectrum of the synthetic acid contains only one absorption maximum, at 271 nm, with inflections at 263 and 279 nm, whereas the spectrum of jacarandic acid is characterised by a triplet at 265, 275, and 287 nm. Of the two possible remaining structures — *cis*-*trans*-*cis* and *trans*-*cis*--*trans* — the latter is inconsistent with the fact that the intensity of the absorption band at 982 cm^{-1} in the infrared spectrum of jacarandic acid is close to the intensity of the corresponding band of elaidic acid.

$$C_5H_{11}\overset{(cis)}{C}H{=}CH{-}CH{=}\overset{(trans)}{C}H{-}CH{=}\overset{(cis)}{C}H[CH_2]_6COOH \quad (XXXI).$$



On the basis of all the above results, the structure (XXXI) has been put forward for jacarandic acid.

Kamlolenic Acid

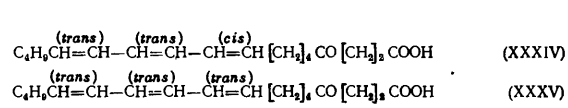


Kamlolenic acid is the main aliphatic acid in the oil from the kernels of *Mallotus philippinensis* (Euphorbiaceae), which has long been used as a purgative in popular medicine[97–100]. Like other trienoic acids, kamlolenic acid is known in the form of two geometric isomers[101]: the natural α-form melts at 77–78°; the β-isomer, formed from the α-form on ultraviolet irradiation, melts at 88–89°. Both forms yield crystalline methyl and *p*-bromophenacyl esters, acetyl derivatives, and 1-naphthylurethanes of the methyl esters[98,102]. On catalytic reduction both forms absorb three moles of hydrogen with the formation of 18-hydroxystearic acid[97–99,102]. The infrared spectra of the stereoisomeric kamlolenic acids and their methyl esters contain intense absorption bands at 3200 and 1060 cm^{-1}, due to a primary hydroxyl, while the spectrum of the α-isomer includes an intense doublet in the range 900–1000 cm^{-1}.[102]

Ozonolysis of methyl kamlolenate yielded the 9-oxononanoic ester, formed by cleavage of a 9,10-ethylenic bond[102]. Study of the infrared spectra of both isomeric forms, their acetyl derivatives, and the maleic anhydride

adducts led to the proposed structures (XXXII) for the α-form and (XXXIII) for the β-form [103-105].

(XXXII)



(XXXIII)

These structures have also been confirmed by the complete synthesis of α-kamlolenic acid by Scheme 15. The earlier suggestion that this compound was an unsaturated keto-acid [100] proved to be erroneous.

Licanic Acid

Licanic acid was first isolated in 1931, from the seed oil of the tropical tree *Licania rigida* [106]. In one of the early papers [107] the source of this acid was erroneously included in the family Couepia (*C. grandiflora*), on which basis it was given a different name, "couepic acid". Licanic acid was subsequently isolated also from other *Licania* species — *L. arbrorea* (*cacahunanche*) (Mexico) [108], *L. crassifolia* (East Indies) [109], *L. levenosa* (British Guiana) [110] — in the oils from which the content of this acid reaches 80% of the total acids. Furthermore, it accompanies eleaeostearic acid to form 35–70% of the seed oils from certain plants of the genus *Parinarium*, in particular *P. corymbosum* (*taritih*) [111], *P. glaberimum* (India) [19], *P. laurinum* (*makita*) (islands in the Pacific Ocean) [19], *P. macrophyllum* (*neou*) [62-64], and *P. sherbroense* (Africa) [65].

(XXXIV)

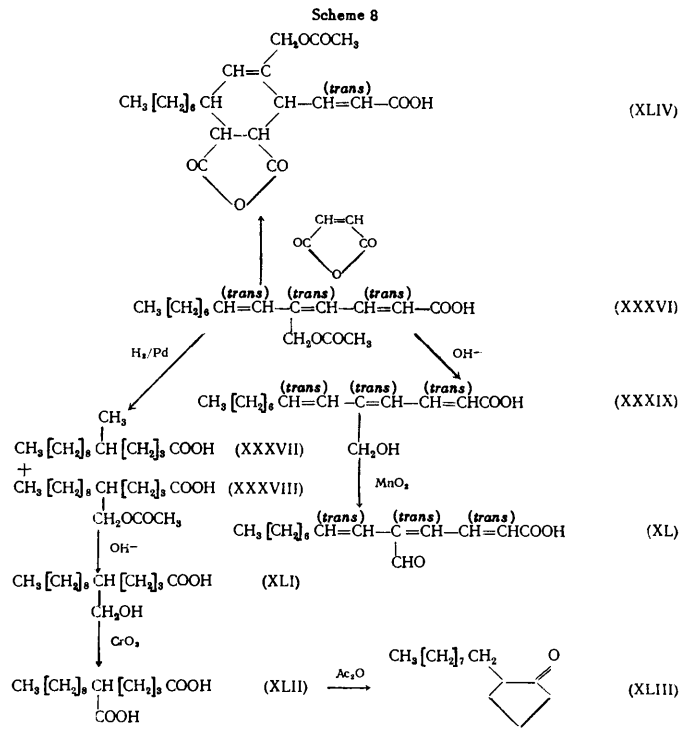
(XXXV)

Licanic acid melts at 63°. It forms a semicarbazone (m.p. 134–137° [112,113]) and an adduct with maleic anhydride (m.p. 79° [114]). Photochemical isomerisation of the natural α-licanic acid yields the higher-melting β-form (isolicanic acid, m.p. 99.5°). [16] Ultraviolet spectroscopy indicates that licanic acid contains a conjugated triene grouping. On catalytic reduction (after the absorption of three moles of hydrogen) 4-oxostearic acid is formed, and oxidation with dilute potassium permanganate solution at 0° yields n-valeric, 4-oxoazelaic, and oxalic acids. With maleic anhydride α-licanic acid forms an addition product in the 11,14-positions, since ozonolysis of the adduct yielded 4-oxoazelaic acid, while valeric acid was also detected in the case of β-licanic acid. On the basis of these results, and also the infrared spectra of α- and β-licanic acids and their adducts, the structures (XXXIV) and (XXXV) were suggested for these acids [16].

5-Acetoxymethyltetradeca-*trans*-2,*trans*-4,*trans*-6-trienoic Acid

Resinous substances in the leaves of the Australian tree *Eremophila oppositifolia* (Myoporaceae) contain, together with a large quantity of sesquiterpene alcohols, an unsaturated acetoxy-acid of m.p. 88–89° and empirical formula $C_{17}H_{26}O_4$. [115] The infrared spectrum of this acid contains bands corresponding to a conjugated triene grouping (980 and 965 cm^{-1}), an ester group (1743 cm^{-1}), and a carbonyl group (1686 cm^{-1}). Its ultraviolet spectrum contains a single maximum at 298 nm, characteristic of a triene system conjugated with a carboxyl.

On saponification of the acid (XXXVI) an intense band appears in the infrared spectrum at 3621 cm^{-1}, corresponding to an alcoholic hydroxyl. Catalytic reduction of the unsaturated acetoxy-acid (XXXVI) yields a mixture of 5-methyltetradecanoic acid (XXXVII) (hydrogenolysis product) and the saturated acetoxy-acid (XXXVIII) (see Scheme 8). The hydroxy-acid (XXXIX), obtained together with acetic acid on saponification of the natural acetoxy-acid (XXXVI), can be oxidised with manganese dioxide to the aldo-acid (XL), which indicates that its alcoholic hydroxyl occupies an allylic position [116]. The hydroxy-acid (XLI) is oxidised by chromic acid to a dicarboxylic acid (XLII), which on being heated with acetic anhydride yields 2-nonylcyclopentanone (XLIII), the formation of which proves that the side-chain in the natural acid (XXXVI) is attached to the $C_{(5)}$ atom.



The position of the triene grouping in the aliphatic chain of the natural acid (XXXVI) was established by ozonolysis (n-octanal was found among the reaction products). This acid interacts with maleic anhydride to form an adduct (XLIV), whose infrared spectrum contains an absorption band at 965 cm^{-1}, which indicates that the exocyclic ethylenic bond in the adduct has the *trans*-configuration [16,17].

On the basis of these results the structure 5-acetoxymethyltetradeca-*trans*-2,*trans*-4,*trans*-6-trienoic acid (XXXVI) has been proposed for the naturally occurring acid.

Tetraenoic (Parinaric) Acids

Parinaric acid (XLV), first isolated from the oil obtained from *Parinarium laurinum* nuts (Table 6), was originally regarded as a trienoic acid, isomeric with elaeostearic acid (XIX). [117,119] Subsequently catalytic hydrogenation and determination of the iodine number established that four ethylenic bonds were present, and they were proved by ultraviolet

spectroscopy [119,120] and oxidative cleavage [119] to be conjugated. Since propionic and azelaic acids were detected among the products of ozonolysis, the tetraene grouping in parinaric acid should occupy the positions 9–15 [118] (XLV).

Natural parinaric acid (the α-form), melting at 84–85°, can be converted by photochemical isomerisation into the β-form, having m.p. 95–96°, which was assigned the all-*trans*-configuration on the grounds that it formed an adduct with two molecules of maleic anhydride (XLVI). [124]

$$C_5H_9CH{=}CH{-}CH{=}CH{-}CH{=}CH{-}CH{=}CH\,[CH_2]_7\,COOH \qquad \text{(XLV)}$$

(XLVI)

The presence of four *trans*-ethylenic bonds in β-parinaric acid is further confirmed by the fact that the infrared band at 999 cm^{-1} due to such bonds is four times as intense as the 968 cm^{-1} band due to the *trans*-double bond in elaidic acid, and 40% more intense than the corresponding band in the infrared spectrum of α-elaeostearic acid (XXI). [11]

The infrared spectrum of α-parinaric acid also contains a band at 996 cm^{-1} due to a *trans*-ethylenic bond (together with a band at 952 cm^{-1}), the intensity of this band being half that of the corresponding band in the spectrum of the β-isomer, and double that of the band due to the *trans*-ethylenic bond in elaidic acid. It was therefore concluded that α-parinaric acid contains two *trans*-ethylenic bonds [11,124]. Since the α-isomer does not form an adduct with maleic anhydride, these bonds should be separated by one or two *cis*-ethylenic bonds. In such case α-parinaric acid may correspond to one of the three configurations — *cis-trans-cis-trans*, *trans-cis-trans-cis*, or *trans-cis-cis-trans* — but no data enabling a choice to be made among these configurations have yet been published†.

An investigation of the lipids from plants of the *Impatiens* genus revealed that the infrared spectrum of the seed oil was very similar to that of α-parinaric acid, but differed from the latter in the presence of an absorption band at 932 cm^{-1}. [124] An extremely unstable acid of m.p. 72–74°, termed impatienic acid and corresponding to parinaric acid in composition, was isolated by saponifying the oil in the cold and then rapidly recrystallising at low temperature. Its infrared spectrum was analogous to that of the original oil, but its ultraviolet spectrum was identical with that of α-parinaric acid (Table 7). When stored in a vacuum at 20° for a short while, impatienic acid changes into α-parinaric acid, the 932 cm^{-1} infrared band disappearing.

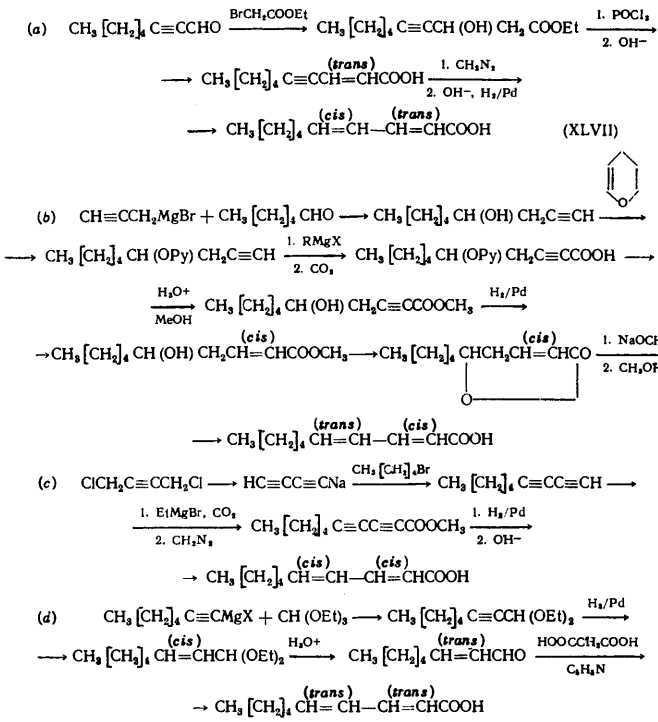
The problem of the configurations of parinaric and impatienic acids can probably be finally solved by means of the nuclear magnetic resonance spectra with appropriate synthetic models available.

5. SYNTHESES OF NATURALLY OCCURRING POLYENOIC ALIPHATIC ACIDS

In spite of the fact that conjugated polyenoic aliphatic acids are widely used in the paint and varnish industry, and that the first representatives of this class of compounds were discovered in Nature about a century ago, the synthesis of naturally occurring acids of this type has been accomplished only during recent years. And to this day triglycerides of vegetable origin serve as raw material for the manufacture of rapidly drying and durable varnishes.

This lag in synthetic work in this field is explained by the fact that the structures of most naturally occurring conjugated polyenoic acids have been established only comparatively recently. Furthermore, the presence in these compounds of a conjugated polyene system having various combinations of *cis*- and *trans*-ethylenic bonds makes them extremely unstable, with a marked tendency to undergo polymerisation, isomerisation, and oxidation. As a result, their synthesis necessitates the development of special procedures and methods, distinguished by their highly stereospecific character and the mildness of the conditions.

The methods first used to obtain these acids were based on the application of acetylenic syntheses and the Reformatskii reaction followed by dehydration and lengthening of the carbon chain. Thus stillingic acid (XLVII) and all its possible stereoisomers were synthesised in 1955 by Crombie [2] by means of the series of reactions shown in Scheme 9. Later Crombie and Jacklin used Schemes 10*a–c* to synthesise α-elaeostearic (XIX) and punicic (XXIII) acids and their stereoisomer — octadeca-*cis*-9,*cis*-11,*trans*-13-trienoic acid (XLVIII) — which is not found in natural sources [4,89].



The achievement of these syntheses enabled the structures of the above naturally occurring acids to be finally established. It must be noted, however, that the above methods are characterised by many stages and low yields of the final products, while the catalytic hydrogenation of intermediate compounds containing conjugated acetylenic bonds to form *cis*-alkenes often shows little selectivity.

† *Note added in proof*. Takagi has recently obtained partial reduction products — *cis-trans*- and *trans-trans*-octadecadienoic esters — by the action of hydrazine hydrate (50° for 3 h), which causes migration of double bonds during hydrogenation, on the ethyl ester of the parinaric acid isolated from the seed oil of cultivated balsam — m.p. = 85–86° and λ_{max} = 305 nm (ε = 72400) — on the basis of which he has ascribed the *cis*-9,*trans*-11,*trans*-13,*cis*-15 configuration to parinaric acid. [136]

320	58.8	320	66.3	313	87.0

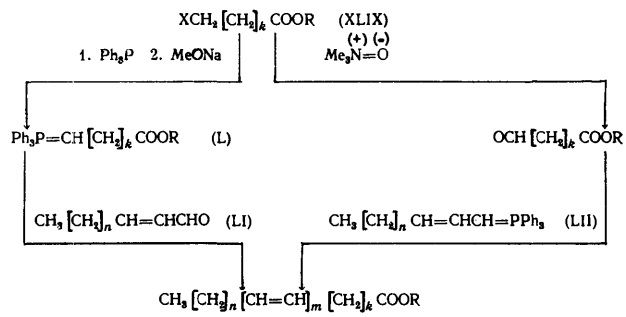
Scheme 9

Scheme 10

Furthermore, these methods are of limited application, and are apparently unsuitable for the synthesis of many types of natural conjugated polyenoic aliphatic acids which have become known in recent years.

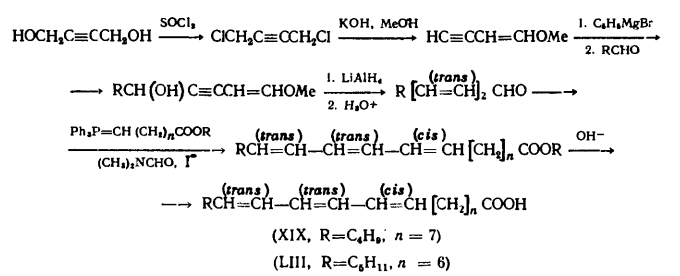
A few years ago Bergel'son et al. proposed a new method for synthesising these acids, based on the Wittig reaction, in which the general Scheme 11 was applied to the industrially available ω-chloroalkanoic acids (XLIX; R = H, X = Cl).[125-132] It was shown that the olefination of $\alpha\beta$-unsaturated aldehydes (LI) with phosphoranes (L) leads under certain conditions (in the presence of iodide ions in polar solvents) to the selective formation of a *cis*-ethylenic bond[130,131]. On the other hand, when saturated aldehydes are condensed with $\beta\gamma$-unsaturated phosphoranes (LII) in non-polar solvents, a *trans*-ethylenic bond is formed[6,132].

The application of these generalisations resulted in a new complete synthesis of α-elaeostearic acid (XIX) and of one of the isomers of calendic acid (LIII) by Scheme 12.[6,130,131] Since conjugated acids containing *cis*-ethylenic bonds are considerably more unstable than their all-*trans*-isomers, the *cis*-bond was introduced in the concluding stages. The yield of trienoic acids obtained by this method, calculated on the initial butynediol, was ~ 20%.



This same method was later proposed for the synthesis of octadeca-*cis*-8,*trans*-10,*trans*-12-trienoic acid (LIII) by other workers as well[133], who converted its ester, without isolating the latter, into the all-*trans*-isomer.

Two other naturally occurring conjugated trienoic acids — catalpic (XXIV) and calendic (XXVI) — were prepared for the first time by Bergel'son, Shemyakin, and their coworkers by the stereodirected *trans*-carbonyl-olefination of $\beta\gamma$-unsaturated phosphoranes according to Scheme 13.[132]



Jacarandic acid (XXXI) has been synthesised by the same investigators, using *cis*-olefination of a *cis-trans*-alkadienal in conformity with Scheme 14.[6]

* Ts = p-$CH_3C_6H_4SO_2$ (Ed. of Translation).

Scheme 15

(XXXII)

Bergel'son, Shemyakin, and their coworkers have synthesised the naturally occurring trienoic hydroxy-acid — kamlolenic acid (XXXII) — by successive *trans*- and *cis*--stereodirected carbonyl-olefination (Scheme 15).[134]

Dienoic and other known trienoic acids (e.g. licanic acid) can obviously be synthesised by means of stereoselective carbonyl-olefination.

REACTIONS OF OZONE WITH ALKENES

A. T. Menyailo and M. V. Pospelov

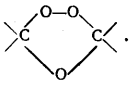
CONTENTS

1. Introduction 284

2. Interaction of ozone with alkenes 284

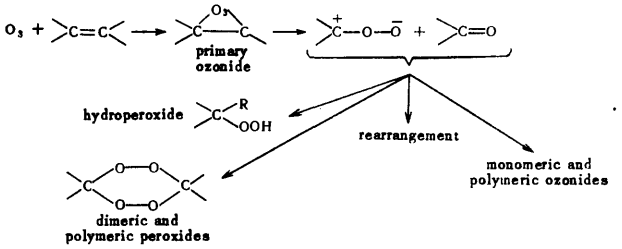
3. Properties of ozonisation products 289

4. Methods of analysis of peroxy-products of ozonisation 292



1. INTRODUCTION

Although the reaction of ozone with a carbon–carbon double bond has been known since 1855, when Schönbein was the first to accomplish the ozonisation of ethylene, a more or less clear idea of the nature of this reaction has been formulated only during the past 10–15 years. The products of ozonisation, which include, besides ozonides, α-substituted hydroperoxides, dimeric keto-peroxides, etc., occupy a prominent position in the chemistry of peroxy-compounds, owing to their ease of preparation and the possibility of converting them into aldehydes, alcohols, and other organic products. For many chemists, however, ozonisation has remained merely a means of determining the position of a double bond, and its value as a powerful synthetic tool is often underrated. The industrial application of ozonisation has recently been steadily increasing. Plant has already been operating during the past few years in which azelaic and nonanoic acids are manufactured by the ozonisation of oleic acid, and several other industrial methods have been developed[1-11]. Recent advances in the development of new applications of ozonisation and in improving the manufacture of ozone indicate that this reaction will become increasingly important in industry.

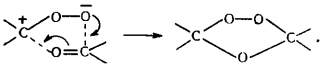


No review on ozonisation or the properties of the reaction products has been published in the Soviet literature. The foreign literature contains fundamental papers on this question[12-18], which discuss the preparation and chemical transformations undergone by ozonides of various structures. The present Reviewers have set themselves a more modest aim: this survey is concerned mainly with the synthesis of ozonides of aliphatic alkenes, a field in which research is being undertaken for the purpose of the practical exploitation of the ozonisation of alkenes for the production chiefly of higher aliphatic aldehydes, acids, and alcohols.

2. INTERACTION OF OZONE WITH ALKENES

In the early work on ozonisation, among which that of Harries[19-21] occupies an important place, many unsaturated compounds were subjected to this reaction, but no definite conclusions were reached concerning the structure of the products or the mechanism of the reaction. In 1925 Staudinger[22] suggested for an ozonide a formula comprising a five-membered peroxy–ether ring

This structure was subsequently confirmed by Rieche et al.[23,24] by an alternative synthesis of the ozonide of but-2-ene. However, ozonides do not constitute the sole products of ozonisation. A more or less general mechanism of ozonisation, covering interaction with various unsaturated compounds under various reaction conditions, was suggested by Criegee and his coworkers[25-39]. This mechanism provides an explanation of most of the experimental facts known at the present time. Criegee's scheme can be represented in general as follows

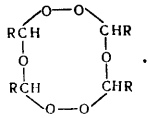


A key position in this scheme is occupied by the zwitterion, the life of which is taken to be sufficient for it to be regarded as a true intermediate product.

In most cases the primary ozonide, formed as a result of bipolar 1,3-addition of ozone to the alkene, immediately breaks down with fission of the O–O and C–C bonds by a concerted mechanism. The zwitterion is formed at one end or the other of the former double bond depending on which carbon atom receives the electron pair of the remaining C–C bond. The resulting zwitterion is stabilised by conjugation:

Stabilisation of the zwitterion can be effected in four main ways, by — (1) interaction with the simultaneously formed carbonyl compound, with formation of monomeric or polymeric ozonides, (2) dimerisation or polymerisation with formation of dimeric or polymeric peroxides respectively, (3) interaction with a proton-donating solvent with formation of hydroperoxides, or (4) rearrangement — the way in which it occurs being determined by the structure of the initial alkene, by the solvent, and to a less extent by the reaction conditions. In most cases the zwitterion reacts in more than one way simultaneously.

The first mode of stabilisation — bipolar addition of the 1,3-zwitterion to a carbonyl group[38] — usually takes place when the simultaneously formed carbonyl compound is an aldehyde:

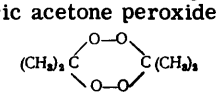


Ketones do not usually react with the zwitterion by the above 1,3-bipolar scheme leading to formation of an ozonide.

It has been noticed that most alkenes on ozonisation in an inert solvent give their "own" ozonides: i.e. a definite "cage effect" is operative. Thus the ozonisation of a mixture of oct-4-ene and hex-3-ene yields only the ozonides of

these alkenes, and the ozonisation of hept-3-ene gives only the ozonide of hept-3-ene [12]. However, this is not an absolute effect. Riezebos et al. [39] have reported the isolation of three pairs of stereoisomeric ozonides from the products of the ozonisation of methyl oleate. Loan et al. [40], while confirming the presence of a cage effect, showed, with the ozonisation of pent-2-ene as example, that some of the zwitterions jump out of the cage and enter into "extracellular" reactions even in highly dilute solution in an inert solvent. On the other hand, part of the ozonide reacts inside the cell even in the presence of excess of aldehydes, which are known to destroy the cage effect [28]. With increase in the concentration of alkene in the solvent, the relative proportions of "own" and "cross" ozonides approach the statistical values [40].

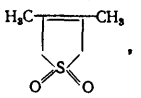
Criegee and his coworkers prepared several monomeric ozonides, purified them by distillation or recrystallisation, and determined their physicochemical constants [31]. These workers showed that only ozonides of low-molecular-weight alkenes are explosive: the ozonides of butene and higher homologues are quite stable liquids or solids, which can be subjected to distillation, crystallisation, and other operations. In all twenty-two monomeric ozonides were obtained in this work, including those of hex-1-ene, hex-2--ene, hex-3-ene, oct-3-ene, styrene, stilbene, etc. The preparation of ozonides of cyclopentene and cyclohexene had previously been reported [27]. The present Reviewers have isolated ozonides of hex-1-ene, hept-1-ene, and oct--1-ene, purified them by treatment with sodium bisulphite and fractional distillation on a column, and shown by infrared spectroscopy that the products were not contaminated with carbonyl compounds [41].



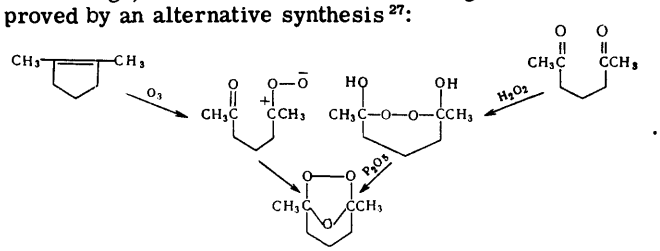
In the ozonisation of alkenes which yield monomeric ozonides as the main products, quite considerable quantities of compounds of high molecular weight are formed. Both Harries [19] and later investigators [14] have regarded these products as dimeric ozonides

Rieche et al. [24] obtained a product having this structure on synthesising the ozonide of but-2-ene from acetaldehyde and hydrogen peroxide.

The present Reviewers [42], on ozonising hex-1-ene, obtained, together with the monomeric ozonide, products of the addition to the zwitterion of two and three molecules of formaldehyde. The same work showed that a dimeric ozonide is not the main component of the residue remaining after the monomeric ozonide has been distilled off. The residue in the flask probably consists mainly of linear polymers containing a terminal hydroperoxy-group, the presence of which was confirmed by infrared spectra.



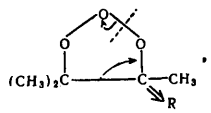
Another mode of stabilisation of the zwitterion is by its dimerisation or polymerisation. These reactions occur mainly when the carbonyl compound, formed together with the zwitterion on breakdown of the primary ozonide, is a ketone. Thus Criegee [27], on ozonising 2,3-dimethylbut-2--ene, obtained dimeric acetone peroxide



together with an extremely explosive substance, which he described as a polymer of the zwitterion $(CH_3)_2C^+-O-O^-$. Examples of other compounds which give a ketone and dimeric or polymeric peroxides on ozonisation are tetraphenylethylene [43], 1-8-octahydronaphthalene [25], bi(cyclohexylidene) [27], and bi(cyclopentylidene) [27]. Dimeric keto--peroxides can be obtained also by treating the corresponding ketones with persulphuric acid or hydrogen peroxide [16]. Polymeric peroxides have not yet been isolated as products of definite structure. They are usually described as explosive, viscous oils or amorphous solids [14,27]. Those of high molecular weight are probably linear polymers of the zwitterion $\rangle C^+-O-O^-$.

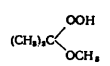
Before the publication of Criegee's work, many authors spoke of "perozonides" and "oxozonides" [12,14,20]. Most of these compounds containing more oxygen than the ozonide are probably dimeric or polymeric peroxides.

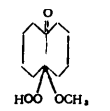
There are at least two exceptions to the rule that ozonides are not formed from compounds which give a ketone together with the zwitterion on ozonisation. The first exception is provided by cycloalkenes in which the double bond forms part of a five-membered (sometimes four--membered) ring, and the second by ketones containing an activated keto-group. Compounds of the first type include 1,2-dimethylcyclopentene [26,27,31], the cyclic sulphone [27]

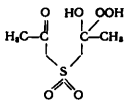


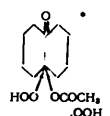
maleimide [31], certain derivatives of indene, and steroids. The ozonides of unsaturated five-membered rings are usually very stable. Thus the ozonide of the above sulphone melts at 154°, and is stable to heating (at 100° for 5 h). The driving force causing intramolecular cyclisation of zwitterions formed in the ozonisation of unsaturated rings is probably the formation of classical five- to seven-membered rings (together with five-membered trioxolan rings). Cyclohexene and cycloheptene derivatives, which would have given seven- to nine-membered rings on intramolecular cyclisation, yield mainly polymeric ozonides and peroxides on ozonisation [26,27,31]. In the case of five-membered rings, the structure of the resulting ozonides was proved by an alternative synthesis [27]:

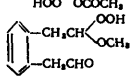
In the ozonisation of systems containing unsaturated five-membered rings, the yield of monomeric ozonides is higher if the hydrogen atoms attached to both carbon atoms linked by the double bond have been substituted. The absence of substituents in the zwitterion and (or) the carbonyl group at the ends of the decomposition product obviously permits intermolecular reaction to compete successfully with intramolecular cyclisation. An exception is the sulphone of 5,5-dimethylhexa-1,3-diene, which gives an 85% yield of the ozonide [27]. Ozonides of this type can be obtained also by the photoactivated autoxidation of certain furans (2-methyl- and 2,5-dimethyl-furan) [44] and also dimethylisobenzofuran [45].

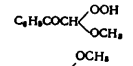


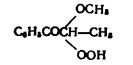












The second exception to the rule that ozonides are formed only from a zwitterion and an aldehyde is provided by the ozonisation of alkenes containing substituents possessing a considerable negative inductive effect. Criegee

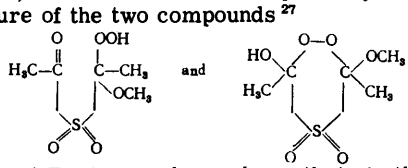
et al.[34] obtained monomeric ozonides from *cis*- and *trans*-$BrCH_2C(CH_3):C(CH_3)CH_2Br$ (I), $(CH_3)_2C:C(CH_3)COOCH_3$, and $(CH_3)_2C:C(CH_3)CHO$ (II). This shows that activated ketones — bromoacetone, methyl pyruvate, and methylglyoxal — react like aldehydes with the zwitterion. Both *cis*- and *trans*-isomers of (I) give mixtures of the corresponding liquid *cis*-ozonide and solid *trans*-ozonide (dipole moments 2.45 and 2.25 D respectively). These results were obtained when (I) was ozonised in pentane, whereas when dichloromethane is used as solvent, *cis*-(I) gives bromoacetone in 90% yield together with a peroxide (presumably a dimeric peroxide of bromoacetone). The ozonide obtained by the ozonisation of (II) is the ozonide not of (II) but of 4-methylpent-3-en-2-one. The formation of the same ozonide by these two compounds is explained by the fact that the methylglyoxal obtained in the first stage reacts in both cases not at the ketonic but at the aldehyde group. The results clearly show the influence of inductive effects on the breakdown of the primary ozonide: in all cases the electron pair of the C–C bond goes to the atom having the more electronegative substituent (the alternative in which an ozonide is formed from acetone, of course, is not included):

where R = CH_2Br, $COCH_3$, CHO. However, the formation of small quantities of a mixed anhydride of formic and acetic acids, which can result only from rearrangement of the zwitterion $CH_3COCH^+OO^-$, shows that migration of the electron pair to the other carbon atom does also take place.

TABLE 1. Products of ozonisation in solvents containing an active hydrogen atom.

No.	Alkene	Solvent	Product	Yield, %	Ref.
1	$(CH_3)_2C=C(CH_3)_2$	CH_3OH		77	27
2		$CCl_4 + C_2H_5OH$		68	27
3		CH_3OH		88	25
4		acetone + water		57	27
5		acetone + CH_3COOH		—	25
6		CH_3OH		42	46
7	$C_6H_5COCH=CHCOC_6H_5$	acetone + CH_3OH		60	47
8	$C_6H_5COCH=CCOC_6H_5$ CH_3	acetone + CH_3OH		74	47

* Unstable — isolated as benzoylperoxy-derivative.



All workers regard the products obtained by the ozonisation of alkenes in solvents containing an active hydrogen atom as α-substituted hydroperoxides

where R′ is the residue of an alcohol, acid, etc. Table 1 lists several alkoxy-, hydroxy-, and acyloxy-alkyl hydroperoxides obtained by ozonolysis in "active" solvents. Many of these substances are perfectly stable, and possess high melting points (the hydroperoxide No. 4 melts at 94–95°). Hydroperoxides obtained by the ozonolysis of cyclic molecules do not preserve a simple hydroperoxide form if an aldo-group is present at the other end of the chain[48]. This is explained by interaction between the hydroperoxy- and aldo-groups with formation of peroxyhemiacetals and peroxyacetals[11].

The examples in Table 1 relate to alkenes having substituents adjacent to the double bond. Murai et al.[49] have recently subjected an unbranched-chain α-alkene, oct-1-ene, to ozonisation in ethanol. They obtained a product which, from its molecular weight and content of available oxygen, they regarded as 1-ethoxy-n-heptyl hydroperoxide.

Intramolecular reactions occur during the ozonolysis of phenanthrene[50], naphthalene[51], and indene[52] in methanol or ethanol. A tendency to cyclisation is present even when a keto-group is located at the other end of the chain. The product of the ozonolysis of the cyclic sulphone of 2,3-dimethylbuta-1,3-diene in methanol is probably an equilibrium mixture of the two compounds[27]

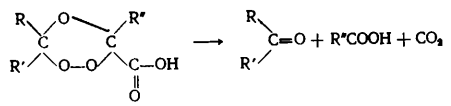
The present Reviewers have shown that, in the ozonisation of alk-1-enes in alcohols, the mode of stabilisation of the zwitterion depends on the relative proportions of alcohol and alkene. When hex-1-ene undergoes ozonisation with a hexene–ethanol molar ratio exceeding 1 : 10, formation of the hydroperoxide is accompanied by that of hex-1-ene ozonide[53].

Rearrangements, which together with epoxidation constitute a group of so-called "anomalous cases of ozonisation", are encountered far less frequently than the three types of reaction discussed above.

The ozonisation of alkenes in which groups which can cause steric hindrance are present on one of the carbon atoms joined by the double bond often results in epoxides or products of their rearrangement containing the same number of carbon atoms as the original alkene. Examples of such compounds are 1-mesityl-1-phenylethylene and 3,3,5-trimethyl-2-t-butylhex-1-ene, which on ozonisation give 2-mesityl-2-phenylvinyl alcohol[54] and an epoxide[55] respectively. Criegee[32] repeated the ozonisation of the first of these unsaturated compounds in the presence of triethylamine (to prevent rearrangement of the epoxide under the influence of the acids formed during the reaction), and obtained an epoxide which in the presence of acids readily rearranged into the enol obtained by Fuson[54]. Other cases are known of the formation of oxides of alkenes on ozonisation[56,57].

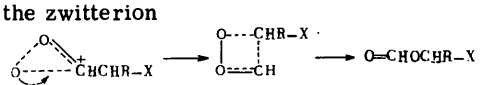
In many cases products have been isolated which contained fewer carbon atoms than would have been expected on the usual ozonolysis of the double bond. Formation of

such products has been observed most frequently in the ozonisation of compounds of the type

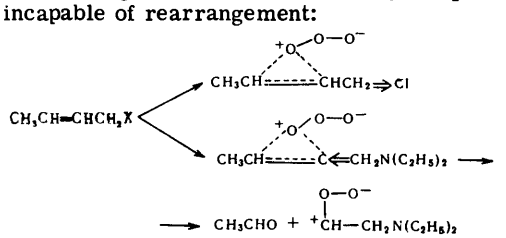


where R represents various substituents usually containing O, N, or S.

Young[58] and Leffler[62] ozonised compounds of the type RCH:CHCHR'–X (where X = Hal, OH, NR''_2, OR''', or OCOR'''') in inert solvents, and showed, from the results of a quantitative determination of the acids, that the usual products of ozonolysis are formed when X = Cl, Br, or $OCOCH_3$. They arranged the substituents X, according to their influence on the isolation of anomalous products, in the sequence Cl, Br, or $OCOCH_3 < p\text{-}OC_6H_4NO_2 < OC_6H_5 <$ $< OH < OCH_2CH_3 < N(C_2H_5)_2$. Examples of the compounds investigated by these workers are but-3-en-2-ol, which on ozonisation gives, together with formic acid (yield 75%), acetic acid (25%) (instead of lactic acid); and also CH_3CH: $:CHCH_2N(C_2H_5)_2$, giving on ozonisation, together with acetic acid (46%), formic acid (54%) (instead of diethylaminoacetic acid). The anomalous products were shown[58] to be formed neither as a result of allylic rearrangement of the initial alkene nor as a result of an oxidation process. All cases of the formation of anomalous products in large quantities involved spontaneous decomposition of peroxy-products of ozonisation with the evolution of carbon monoxide. The results were explained by rearrangement of Staudinger's "molozonide"



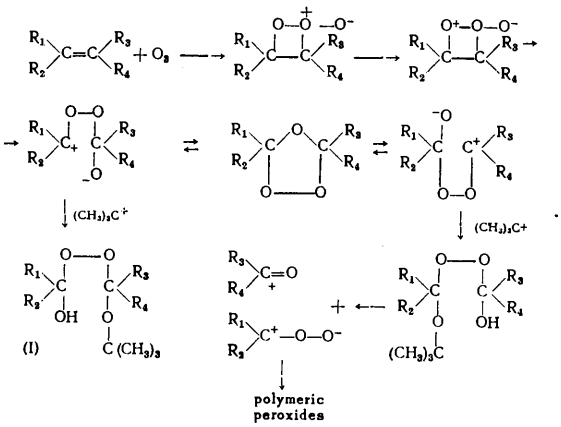
Similar results have been obtained in the ozonisation of CH_3CH:CHCOOH, CH_3CH:CHCHO, CH_3CH:$CHCOCH_2CH_3$, and several cyclic systems[59]. Barton and Seoane suggested[59] the mechanism



to explain the anomalous ozonolysis observed with $\alpha\beta$-unsaturated acids. This mechanism does not explain the formation of carbon monoxide.

Bailey[14] puts forward a mechanism involving rearrangement of the zwitterion

to explain anomalous ozonolysis. He interprets the increase in ability of the group X to promote rearrangement as its electronegativity diminishes in terms of the influence of inductive effects on the breakdown of the π-complex, the positive I-effect of the diethylamino-group favouring formation of a zwitterion containing X, i.e. of a zwitterion capable of rearrangement, whereas the high $-I$-effect of a halogen or $OCOCH_3$ contributes to formation of a carbonyl compound containing X and a zwitterion of type $R_2^+COO^-$, which is incapable of rearrangement:

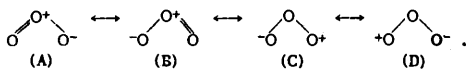


However, an anomalous course of the reaction was observed in the ozonisation of several 2-substituted naphthaquinones, which could not be explained in terms of differences between the inductive effects of the substituents[60]. Furthermore, if it is assumed that anomalous ozonolysis is caused by rearrangement at the zwitterion stage, *cis*-2--methyl-1,4-diphenylbut-2-ene-1,4-dione and 2-methylnaphthaquinone should give similar products, whereas actually the ozonolysis of these two compounds goes in opposite directions. Hence Bernatek et al.[60] have assumed that the course of anomalous ozonolysis is determined, not at the zwitterion stage, but at the stage of the primary ozonide, to which they attribute a structure in which the π-electrons are preserved (see below).

Small quantities of anomalous products are formed also in the ozonisation of "normal" alkenes. Thus the ozonolysis of dodec-6-ene yields 2–8% of valeric acid and 0.8–1.2% of butyric acid, that of cyclohexene gives 4.7% of glutaric acid and 1.8% of succinic acid[61], etc. These products are most probably formed not only as a result of rearrangement but also by the oxidation of "normal" products of ozonolysis. It is known[61,62] that the oxidation of aldehydes may yield products containing a smaller number of carbon atoms than the original aldehyde.

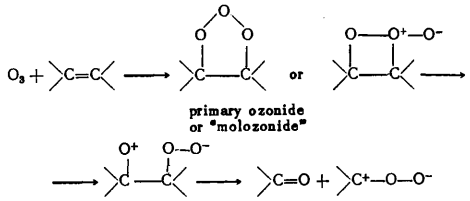
It is difficult to explain the formation of carbon dioxide, methane, and hydrogen in the ozonolysis of oleic acid[24], of methane from but-2-ene, of hydrogen from but-1-ene[63], and several other results.

Most anomalous products of ozonolysis are formed in inert solvents. In many cases the anomalous ozonolysis can be prevented by conducting it in methanol and then reducing the products[64]. However, the alkoxylated hydroperoxides which are formed sometimes also undergo rearrangement[30]. Anomalous ozonolysis has been observed also with the compounds C_6H_5COCR:$CHCOC_6H_5$, which give benzoic acid and methyl formate on ozonisation in methanol followed by slight heating or decomposition with alkali in the cold[47].



A mechanism differing somewhat from that of Criegee was suggested by Milas for the formation of peroxy-products of ozonolysis. According to this, the ozonide (the 1,2,4-trioxolan) is an intermediate in the formation of all ozonisation products. Milas postulates the existence of a zwitterion of the type $\diagdown C^+-O-O^-$, but assigns to it a subordinate role as intermediate in the formation of polymeric impurities. The main evidence of Milas' mechanism is the formation of the compound (I) on the ozonisation of alkenes in the presence of the trimethylcarbonium ion (i.e. in t-butyl alcohol and concentrated sulphuric acid)[65]:

In a later paper Milas uses the same mechanism to explain the formation of polymeric peroxides in the ozonisation of 2,3-dimethylbut-2-ene in pentane[66]. This mechanism, even if it is valid for the above cases, undoubtedly has a narrower range of application than Criegee's mechanism.

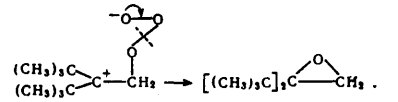


The most complex problem in the mechanism of ozonisation is the nature of the initial attack by ozone on the double bond and the structure of the primary products. This is due to the high speed of the initial reactions, which make a kinetic study extraordinarily difficult, and also the extreme instability of the initial products.

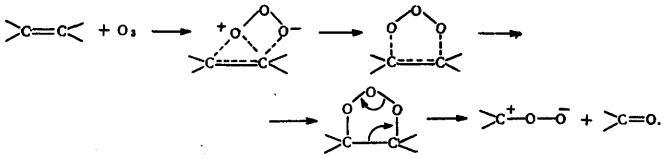
The structure of the ozone molecule is of fundamental importance to an explanation of the nature of the initial attack. Both bonds in ozone are 1.278 ± 0.002 Å long, with an angle of 116° ± 3° between them. The molecule is not paramagnetic; perhaps it is diamagnetic in the gaseous state. On the basis of these data it is represented by the following set of structures[67]

The electronic structure of the ozone molecule is such[67] that the central oxygen atom has three hybrid sp^2-orbitals lying in the same plane and one p-orbital perpendicular to this plane. Two of the three hybrid orbitals form σ-bonds with the terminal atoms, and the p-orbital forms a π-bond with one of the terminal atoms. The electrons forming this bond are delocalised. The third hybrid orbital is directed along the axis of symmetry of the molecule, and has an unshared pair of electrons. The surprisingly low dipole moment of the ozone molecule (0.56 ± 0.05 D) is explained by the fact that the high dipole moment of the third hybrid orbital operates in the opposite direction to the dipole moment of the canonical structures (A) and (B).

The addition of ozone to a double bond is usually supposed to proceed in the sequence



Criegee and Schröder[33] first isolated the primary ozonide of *trans*-2,2,5,5-tetramethylhex-3-ene, measured its heat of rearrangement into the usual ozonide (38.9 kcal × × mole^{-1}), and examined the reactions of this product with several substances. Reduction with sodium in liquid ammonia gave an αβ-diol. Ozonisation of the *cis*-tetramethylhexene under the same conditions did not yield a primary ozonide.

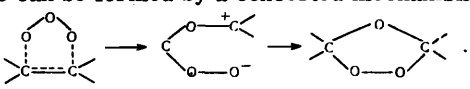


Later Schröder[68] and Greenwood[69] showed the formation of primary ozonides from *trans*-alkenes, and its absence with the *cis*-isomers, to be a general phenomenon. It was also established that the ozonisation of *cis*-2,2,5,5-tetramethylhex-3-ene yields *cis*- and *trans*-ozonides, whereas that of its *trans*-isomer gives predominantly the *trans*--ozonide[68].

Bailey et al.[70] examined the products of the ozonisation of monosubstituted derivatives of 1,4-diphenylbut-2-ene--1,4-dione with the aim of studying the mechanism of the initial attack by ozone on the double bond. The results obtained (i.e. the way in which the primary product decomposed, as a function of the substituent) pointed to none of the three schemes suggested previously — two-stage addition in conformity with the Markovnikov rule with formation of a four-membered ring (mode of decomposition determined by mesomeric effect of substituent), four-centre attack with formation of a five-membered ring (direction of decomposition determined by inductive effect of substituent), or a π-complex mechanism (the more stable of the two possible zwitterions being formed) — so that Bailey concluded that the type of attack varies with the nature of the alkene, and he listed five possible types of attack.

1. Electrophilic attack on a nucleophilic atom at the double bond, with formation of a σ-complex. This type of attack occurs, in Bailey's opinion, when marked steric hindrance is present at one end of the double bond, and it results in the formation of oxides of the alkenes:

2. Electrophilic attack on the double bond with formation of a π-complex. This type of attack takes place in the ozonisation of most unsaturated compounds†:



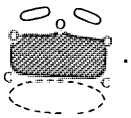
This mechanism enables most of the observed cases of ozonolysis to be explained in terms of the inductive effects of the substituents in relation to the five-membered ring of the primary ozonide. An exception is provided by *cis*- and *trans*-1,2,4-triphenylbut-2-ene-1,4-dione, whose ozonides break down in the opposite direction to that determined by the -*I*-effect of the phenyl group. In this case Bailey assumes partial maintenance of sp^2-hybridisation in the intermediate complex, and subsequent breakdown of the latter into a zwitterion by a concerted mechanism, the direction of which is determined by the mesomeric effect (+*M*) of the phenyl group.

3. Four-centre attack on the double bond with formation of a five-membered ring, which then breaks down as in mechanism 2.

4. Nucleophilic attack on an electrophilic atom.

5. Radical attack on certain saturated groupings (observed in the oxidising action of ozone).

In inert solvents and with not very stable zwitterions, an ozonide can be formed by a concerted mechanism:



Bailey explains the formation of a primary ozonide from *trans*-2,2,5,5-tetramethylhex-3-ene, and its absence (together with a high yield of the usual ozonide) on ozonisation of the *cis*-isomer, by competition between this mechanism and the usual Criegee mechanism, such competition being governed by steric hindrance.

† In earlier papers Bailey[71] had put forward the hypothesis that the π-complex was converted into a zwitterion and a carbonyl compound without a stage involving formation of a primary ozonide.

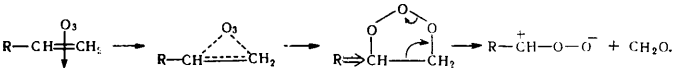
However, the paper by Bernatek et al.[60] already mentioned gives data on the effect of the substituent in the anomalous ozonolysis of a substituted naphthaquinone which do not fit into Bailey's scheme: i.e. no correlation is observed with either the inductive or the mesomeric effects of the substituents (Table 2). From this it was concluded that the direction of ozonolysis is determined by polarisability effects at the primary ozonide stage, i.e. that the primary ozonide preserves the sp^2-hybridisation throughout its existence.

By analogy with the structure proposed by Walsh[72] for oxiran, these workers[60] assign to the primary ozonide a structure in which the p_y- and p_z-orbitals of the oxygen atoms (each containing one electron) are located in the plane of the ring, while the p_x-orbitals are perpendicular to the ring and contain two electrons. The two trigonally hybridised carbon atoms each contain one sp^2- and one p_z-orbital in the plane of the ring, together with two sp^2--orbitals above and below this plane. Overlapping between the sp^2-clouds of the carbon atoms and the p_y-clouds of the oxygen atom creates a delocalised electron cloud, which is responsible for the polarisability of the molecule. In the molecular-orbital treatment the structure of the primary ozonide has the appearance

The presence of six electrons in the delocalised orbital supports the hypothesis that the primary ozonide possesses considerable capacity for conjugation. On this hypothesis the authors derived the parameter Δ (the "absolute substituent constant"), which relates to the carbon atom of the double bond which has the largest total substituent constant:

$$\Delta_1 = |\Sigma\sigma C_1| - |\Sigma\sigma C_2| \text{ when } |\Sigma\sigma C_1| > |\Sigma\sigma C_2|$$
$$\Delta_2 = |\Sigma\sigma C_2| - |\Sigma\sigma C_1| \text{ when } |\Sigma\sigma C_2| > |\Sigma\sigma C_1|,$$

where $\Sigma\sigma C_1$ and $\Sigma\sigma C_2$ represent the sums of the substituent constants σ in the Hammett equation at one of the carbon atoms. In the case of 2-substituted naphthaquinones a satisfactory correlation was obtained between the Δi and the yield of *o*-glyoxyloylbenzoic acid.



All ozonides contain a planar five-membered ring, and can therefore exist as *cis*- and *trans*-isomers. The existence of *cis*- and *trans*-ozonides was first detected by Schröder[68]. Privett and Nickell[73,74] isolated by thin-layer chromatography *cis*- and *trans*-ozonides of methyl oleate, and identified them from their infrared spectra. Riezebos et al.[39] isolated all six possible ozonides — *cis*- and *trans*-$CH_3[CH_2]_7CHO_3CH[CH_2]_7COOCH_3$, *cis*- and *trans*--$(CH_3[CH_2]_7CH)_2O_3$, and *cis*- and *trans*-$(CH_3OCO[CH_2]_7.$ $.CH)_2O_3$ — from the products of ozonisation. The products were characterised by their infrared and nuclear magnetic resonance spectra and by paper chromatography of their decomposition products (aldehydes and aldo-esters). The relative proportions of the ozonides depend on the temperature of ozonisation and the concentration of alkene in the solvent (petroleum ether). With a 10% concentration at 10° the distribution of all three above types of ozonides approximates to the statistical proportions of 2 : 1 : 1, but with a 0.5% concentration mainly the "proper" ozonide of methyl oleate is formed, the quantity of "cross" ozonides being small.

TABLE 2. Effect of substituent on yield of *o*-glyoxyloylbenzoic acid in the anomalous ozonolysis of 2-substituted 1,4-naphthaquinones.

Substituent	Yield, %	Substituent	Yield, %
—OH	90.4	—NHCOCH$_3$	13.8
—Cl	78.4	—O$^-$(OH + pyridine)	9.7
—C$_6$H$_5$	71.8	—NH$_2$	4.6
—OCOCH$_3$	71.3	—OCH$_3$	3.9
—N(CH$_3$)$_2$	21.0		

The formation of "cross" ozonides in the ozonolysis of methyl oleate brings us back to the question of the role of the "cage" of solvent molecules in the interaction of the zwitterion with the aldehyde. Escape of the zwitterion from the "cage" is fairly widespread in ozonisation. Loan et al.[40] ozonised pent-2-ene in the absence of solvent at -70°, and obtained a mixture of the ozonides of pent-2-ene, but-2-ene, and hex-3-ene in proportions close to random (2 : 1 : 1). When the initial ozonide was diluted with pentane, the yields of "cross" ozonides diminished. These workers observed that reaction takes place in the "cage" even in the presence of excess of a "foreign" aldehyde. From the relative proportions of the ozonides formed in this case it was assumed that 9.5% of the product recombines in the "cage", 51% yields the free zwitterion $CH_3CH^+OO^-$, and 39.5% gives the free zwitterion $CH_3CH_2CH^+OO^-$.

The experimental facts reported above and their interpretation permits us to make the following hypotheses concerning the course of the ozonisation of alk-1-enes of normal structure. On the basis of a scheme involving a π-complex passing into a molozonide five-membered ring, which is applicable to most alkenes, the direction of breakdown of the primary ozonide should be determined by the inductive effects of the substituents adjacent to the double bond. Since the distribution of inductive effects in this case is obvious — zero effect of hydrogen atoms and a positive inductive effect of an alkyl substituent — ozonisation of an alk-1-ene should involve formation mainly of an alkyl-substituted zwitterion and formaldehyde:

When the reaction is conducted in an inert solvent, the zwitterion reacts with the formaldehyde — the most reactive of the unsubstituted aldehydes — to form a monomeric ozonide. Some of the zwitterions may escape from the cage, but in view of the preferential occurrence of breakdown by the above mechanism, opportunities for the formation of "cross" ozonides are very limited. Ozonisation in active solvents — alcohols, carboxylic acids, etc. — should yield mainly the corresponding derivatives of the zwitterion $\diagdown CH^+OO^-$ and formaldehyde.

3. PROPERTIES OF OZONISATION PRODUCTS

It follows from the discussion in Section 2 that the main products of ozonisation are monomeric and polymeric ozonides, dimeric and polymeric peroxides, and also products of ozonisation — α-substituted hydroperoxides — in active solvents. Very little is known about the chemical properties of the ozonisation products. Ozonides have been somewhat more fully studied, but of dimeric and polymeric peroxides it is known only that in most cases they are explosive, viscous oils. Almost nothing is known also of the structure of the polymeric ozonides.

Since the first application of ozonisation was to determine the position of the double bond in unsaturated compounds, investigation of the products of ozonisation began with a study of methods for their conversion into stable products — acids, aldehydes, alcohols, etc. — which could be identified. For the most part these methods consisted merely in oxidation, reduction, thermal decomposition, and hydrolysis. Many of them were at one time patented, but only a few of them found industrial application.

Ozonolysis followed by oxidation is most often employed as a method for determining the position of a double bond. Asinger's method[75] — ozonisation in a hot suspension of silver oxide in the solvent — is generally used. It converts alkenes quantitatively into acids. Asinger has recently supplemented this method with gas-chromatographic analysis of the acids as their methyl esters[76]. Very often the decomposition products are oxidised with oxygen, while ozone or a metal salt is used as initiator. The firm Emery Industries Inc. uses this method to produce azelaic and nonanoic acids on an industrial scale from oleic acid of vegetable origin[1]. The very promising method of Otsuki and Funahashi[77] consists in ozonising oleonitrile and then subjecting the product to oxidising decomposition with formation of the 8-cyano-octanoic acid, which was then reduced to 9-aminononanoic acid. Examples of the oxidative ozonolysis of other compounds are given in Table 3. Several patents have been taken out on oxidative ozonisation[7-9]. Besides the oxidising agents which have been listed, use is made also of hydrogen peroxide as an aqueous solution or mixed with acetic, sulphuric, or formic acid. These methods have been described in the reviews by Long[12] and by Bailey[14]. Oxidative decomposition is sometimes accompanied by rearrangements[61].

Reduction of the ozonisation products is, perhaps, the method showing the greatest industrial promise. Existing methods of reduction can be divided into two groups — reduction to aldehydes and ketones, and reduction to alcohols.

For preparative purposes use is made most often of reduction with sodium or potassium iodide, reduction with zinc or magnesium in the presence of water or acetic acid[12,14], and also catalytic reduction on palladium or other catalyst[28,78,79]. Other reducing agents are sodium bisulphite, sulphur dioxide, tin(II) chloride, and formaldehyde. Examples of these reactions are given in Table 4.

Reduction of the ozonides with hydrogen on a Lindlar catalyst[79] at 0°, followed by gas-chromatographic analysis of the resulting aldehydes, is sometimes used for determining the position of a double bond.

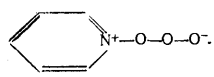


TABLE 3. Oxidative decomposition of products of ozonolysis.

Compound ozonised	Solvent	Product (acid)	Method of decomposition	Yield, %	Ref.
Cyclohexene	CH_3OH	adipic	$O_2 - O_3$, HCOOH	73	80
»	»	»	ditto	85	48

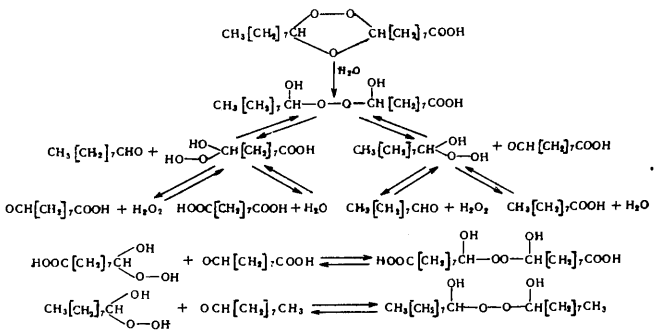
Camphene	camphenilone	CH_3OH	NaI	75	30

The reduction of ozonisation products to aldehydes and ketones is used in the preparation of piperonal from isosafrole and of vanillin from isoeugenol[83]. The reducing agents tried in this work were $NaHSO_3$, $FeSO_4$, $K_4[Fe(CN)_6]$, $SnCl_2$ + HCl, Sn + HCl, Zn + CH_3COOH, $(NH_4)_2Fe(SO_4)_2$, KI + CH_3COOH, H_2O + Zn, $AgNO_3$, quinol, pyridine, and piperidine. An aldehyde (3-oxobisnorchol-4-en-22-al) is formed also in the ozonolysis of ergosta-4,22-dien-3-one[84]. The role of added pyridine in these reactions is very interesting. Pyridine considerably increases the yield of piperonal and of the above hormone. The direction of the reaction on ozonisation in pyridine medium is probably a result of complex formation between pyridine or pyridine oxide (formed on ozonisation) and ozone[85]. This diminishes the electrophilic character of the ozone molecule, which can then react only with the most electron-donor double bond:

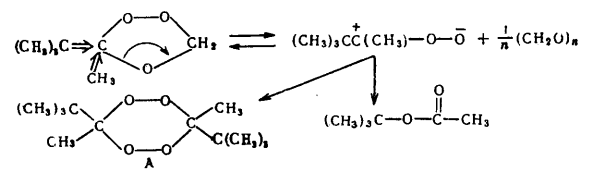
In the presence of pyridine the above steroid, as well as isosafrole, yields two moles of aldehyde, whereas in the absence of pyridine only one mole of aldehyde is formed. This is probably explained by the pyridine attacking the zwitterion with formation of pyridine oxide and the aldehyde:



Catalytic reduction has been used for the production of 9-aminononanoic acid. In one case the products of the ozonolysis of oleic acid were reduced in two stages, the second stage of reduction being conducted in the presence of ammonia or hydroxylamine[10,86]. Recently Pollart and Miller[87] have proposed a single-stage method of reduction without preliminary isolation of the carbonyl compounds. Hexamethylenediamine has been obtained similarly by the ozonolysis of cyclohexene. 9-Aminononanoic acid and hexamethylenediamine are starting materials for the manufacture of 9-nylon and 6,6-nylon respectively.

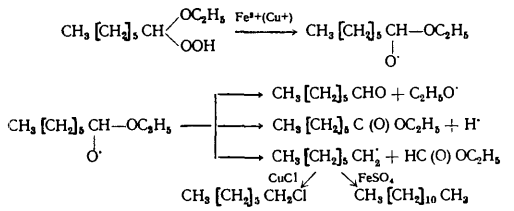
Treatment of the products of ozonisation with an acid solution of 2,4-dinitrophenylhydrazine yields hydrazones of the aldehydes[88].

Lithium tetrahydroaluminate, sodium tetrahydroborate, Grignard reagents, and methyl-lithium have been used to reduce the peroxy-products of ozonolysis to alcohols. Greenwood[89] reduced the ozonisation products of oct-1-ene, oct-3-ene, and hept-2-ene in hexane with lithium tetrahydroaluminate, and obtained respectively heptan-1-ol (95%), propan-1-ol + pentan-1-ol (87%), and pentan-1-ol (89%).



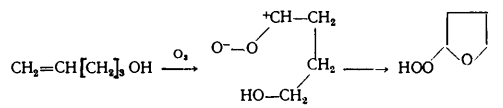
Criegee and Schröder[33] reduced the product of the ozonisation of *trans*-2,2,5,5-tetramethylhex-3-ene at -80° to -100°, which they termed the primary ozonide, with lithium tetrahydroborate, sodium tetrahydroborate, hydrogen iodide in ether, sodium in liquid ammonia, hydrogen on Raney nickel, methylmagnesium bromide, and isopropylmagnesium bromide. Besides the carbinol (neopentanol) found in all cases (other than hydrogen iodide and hydrogen), reduction with sodium in liquid ammonia gave a considerable quantity of a diol (2,2,5,5-tetramethylhexane-3,4-diol). Greenwood[90] obtained α-diols by reducing the ozonides of several other *trans*-alkenes (hex-3-ene, etc.). Sparks and Knobloch[91] reduced the products of the ozonisation of alk-1-enes with a Grignard reagent, and obtained in all cases the corresponding carbinols (products of the addition of the Grignard reagent). In later work Greenwood and Haske[69,92] have shown that, when the ozonide of hex-3-ene is reduced with isopropylmagnesium bromide, the main product is that resulting from addition of the Grignard reagent to propionaldehyde — 2-methylpentan-3-ol — accompanied by propane and propene.

Very little work has been done on the hydrolysis of ozonisation products. In most cases simultaneous formation of aldehydes and acids has been noted. The only mechanism of hydrolysis which has been suggested, in connection with an investigation by Rieche et al.[24] on the ozonide of oleic acid, involves as the first stage cleavage of the ether bridge in the ozonide molecule with formation of a peroxy-diol:

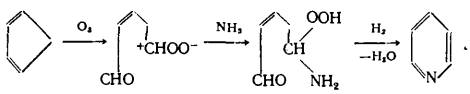


Evidence for this mechanism is the isolation, from the mixture resulting from hydrolysis of the ozonide, of products which the authors identified as 1,1′-peroxydinonanol and 9,9′-dihydroxy-9,9′-peroxydinonanoic acid. In a later paper[15] Rieche put forward the hypothesis that hydrolysis of an ozonide, like its formation, involves an intermediate stage in which a zwitterion is formed.

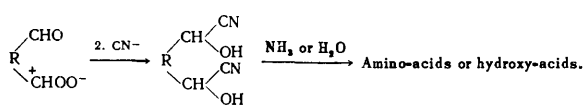
Very little work has been done also on the thermal decomposition of peroxy-products of ozonisation. Heating the ozonisation products of most alkenes usually gives complicated mixtures of unidentifiable products. Exceptions are the decomposition of naphthalene ozonide, which gives an 87% yield of phthalaldehydic acid when heated in methanol[51], and also the formation of a 69% yield of 2′-formylbiphenyl-2-carboxylic acid when the ozonide of phenanthrene is heated in methanol[50]. Sometimes rearrangements are observed on thermal decomposition. Criegee et al.[31] decomposed the ozonide of 2,3,3-trimethylbut-1-ene and obtained polymers of formaldehyde, a dimeric peroxide (A), and t-butyl acetate. They assumed that the latter two products were formed from a zwitterion containing a t-butyl radical:



Murai and Sonoda[49] have investigated the reaction of the ozonisation products of alkenes in alcohols. They reduced the product of the ozonisation of oct-1-ene in ethanol (which they termed 1-ethoxy-n-heptyl hydroperoxide) with aqueous solutions of iron(II) sulphate and of copper chlorides, and obtained ethyl formate, heptanol, ethyl heptenoate, hexyl chloride (in the case of cuprous chloride), and dodecane (with ferrous sulphate). Homolytic breakdown of the hydroperoxide was suggested as the reaction mechanism:



Diaper and Mitchell[93] ozonised ethyl undec-10-enoate in ethanol, subjected the product to alcoholysis at 28–170°, and obtained diethyl sebacate as the main product. They showed that the ester was formed mainly as a result of rearrangement of an alkoxy-hydroperoxide.



Several interesting reactions occur in the ozonisation of alkenes containing other functional groups, and also when ozonisation takes place in the presence of other compounds. Thus the ozonisation of unsaturated alcohols has been observed to involve cyclisation by the mechanism[94]

A very interesting type of ozonisation has been described by Fremery and Fields[95]. When cyclopentadiene is ozonised in the presence of ammonia or an amine, a hydroperoxide is formed which on reduction and dehydration yields pyridine:

The ozonisation of cycloalkenes in the presence of hydrogen cyanide results in the formation of biscyanohydrins, which can then be converted into amino-acids and hydroxy-acids[96]:

The number of technical processes based on ozonisation is at present limited, and production by these methods is on a small scale. However, the situation in this field should change in the immediate future. This is because of the great amount of research being undertaken and by

the rapid development of the technique of ozonisation. With respect to cost as an oxidant, ozone now occupies the second place after oxygen, which enters the final oxidation product‡.

Work undertaken at the Institute for Organic Chemistry of the German Academy of Sciences in Berlin is of great interest. Bertsch and his coworkers[97] have investigated the ozonisation of alk-1-enes with dodec-1-ene as example at temperatures between -20° and +20°. From the results obtained these workers carried out the ozonisation of the Kogasin fractions of the products of the Fischer–Tropsch synthesis (the 200–210°, 210–220°, and 220–235° fractions containing respectively 41%, 36%, and 32% of alkenes, mainly alk-1-enes), followed by decomposition of the ozonides with water vapour and hydrogenation over Raney nickel at 1–2 atma and 20°. Under these conditions aldehydes were reduced to alcohols, while acids remained unchanged. The yields of products obtained from the fractions were 16–19% of acids, 14–18% of alcohols, and 1.5–2.0% of aldehydes.

Thus the alkenes present in the Kogasins have been completely converted into oxygen-containing products. In later work Greiner and Wagner have studied the kinetics of the addition of ozone to alkenes in the liquid phase[98], the way in which formaldehyde is produced in the ozonisation of alkenes containing terminal and non-terminal double bonds[99], the rates of ozonisation of various alkenes[100], the design of ozonisers[101], and methods for the conversion of ozonisation products into acids[102,103].

Among other methods which have found technical application, mention must be made of the synthesis of strychnine[104] and certain hormones[84], and also the syntheses of piperonal from isosafrole and of vanillin from isoeugenol. Indo[83] made a detailed study of the latter two syntheses, established the structure of the intermediate peroxy-compounds, and worked out several reduction methods aimed at obtaining the maximum yields of vanillin and piperonal.

4. METHODS OF ANALYSIS OF PEROXY-PRODUCTS OF OZONISATION

Although the decomposition products of ozonides and peroxides can be determined by widely used and well studied methods, considerable difficulties are involved in analysing the peroxy-products themselves. In isolated cases use can be made of elementary analysis, determination of available oxygen, measurement of molecular weight, etc., the possibility of using a particular method being governed by the properties of the product to be analysed. In the elementary analysis, ozonides of alk-1-enes (from C_4 upwards) burn quite quietly (if the sample does not exceed 5 mg), but do not liberate iodine quantitatively on reaction with potassium iodide; polymeric products of ozonisation deflagrate when an attempt is made at elementary analysis. Molecular weights are best determined cryoscopically in benzene or bromoform, dichloroethane, etc.[105] Rast's method is unreliable, since the substances under investigation often decompose at the temperatures at which determinations are made by this method.

Peroxy-products of ozonolysis can be arranged in the sequence — hydroperoxides > ozonides > dimeric peroxides — according to ease of interaction with iodides. The reaction is quantitative only with hydroperoxides or ozonides which yield ketones on reduction. Ozonides and peroxides which give aldehydes on reduction often undergo rearrangement into carboxylic acids, which results in a diminution in the quantity of iodide oxidised. Dimeric peroxides often react very slowly.

The infrared spectra of ozonides have been investigated in some detail. Briner and his coworkers at first wrongly assigned to ozonides absorption bands in the region of the carbonyl group[106]. It was subsequently shown that these bands were due to contamination with carbonyl compounds formed by decomposition of the peroxy-products[28,41]. Criegee et al.[31] reported that thirteen out of eighteen ozonides contained an absorption band in the range 9.4–9.6 μm in the infrared spectrum, while the remaining ozonides absorbed at 8.8–9.4 or 9.6–10.0 μm. The present Reviewers have detected[41] two absorption bands — at 1110 and 1062 cm^{-1} — with all products of the ozonisation of n-alk-1-enes, and have regarded them as characteristic of the C–O bonds in an ozonide. Riezebos et al.[39] have observed absorption bands at 1110 cm^{-1} with the six isomeric ozonides of methyl oleate, together with bands at 830 and 1320 cm^{-1} with the *cis*- and *trans*-isomers respectively. Privett and Nickell[74] have also reported the same bands in the spectra of the *cis*- and *trans*-ozonides of methyl oleate. Similar differences have been found by Schröder[68] in the spectra of the stereoisomeric 2,2,5,5-tetramethylhex-3--enes. Greenwood and Haske[69,92] have compared the infrared spectra of hex-3-ene ozonide and di-n-propyl peroxide and have found several coincident bands — at 950, 1380, and 1460 cm^{-1} compared with 955, 1375, and 1453 cm^{-1} — for the two compounds. Loan et al.[40] have observed strong absorption at 1080–1110 cm^{-1} in the infrared spectrum of the ozonide of but-2-ene, which they have attributed to the ozonide group.

Calculations based on the tetra-atomic model molecule C–O–O–H have shown[107,108] that the infrared spectrum of a hydroperoxide should contain the bands listed in Table 5. From a study of the infrared spectra of several hydroperoxides and peroxyalkanols in the region of the hydroxyl--stretching vibrations[108] Terent'ev and his coworkers have assigned to vibrations of a free (or an intramolecularly hydrogen-bonded) hydroxyl the values 3580–3560 cm^{-1} for hydroxyl attached to a carbon atom combined with a peroxy-group, and ~3530 cm^{-1} for a hydroperoxy-hydroxyl.

The nuclear magnetic resonance (n.m.r.) spectra have also been studied with many ozonides. The signals obtained in the n.m.r. spectrum at 30 Mc/s with methyl oleate[39] are listed in Table 6.

TABLE 5. Absorption bands (cm^{-1}) in the infrared spectra of hydroperoxides.

Structure	Calc. for COOH	Cumene hydroperoxide	
		calc.	found
C—O—O	586	597	585
CO—OH	834	838	840
O—O	886	888	886
C—O	1156	1285	1270
O—O—H	1321	1324	1325
O—H	3450	3450	3556

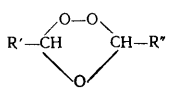
‡ The price of ozone per kilogramme is 17 cents in the USA and from 25 pfennigs in Western Germany.

TABLE 6. Signals due to products of the ozonisation of methyl oleate in the n.m.r. spectrum.

Ozonide	1.1 ppm	1.4 ppm	2.3 ppm	3.7 ppm	5.1 ppm
$(CH_3[CH_2]_7CH)_2O_3$	+	+	–	–	+
$CH_3[CH_2]_7CHO_3CH[CH_2]_7COOCH_3$	+	+	+	+	+
$(CH_3OCO[CH_2]_7CH)_2O_3$	–	+	+	+	+

Note. 1.1 – CH_3; 1.4 – CH_2; 2.3 – CH_2COOCH_3; 3.7 – O–CH_3; 5.1 – $CH\langle^{O-O}_{O}\rangle CH$–.

The n.m.r. spectrum of the ozonide of hex-3-ene contained[69] two overlapping triplets with centres at 4.90 and 4.94 ppm, a multiplet at 1.55 ppm, and two very close and overlapping triplets at 0.8 ppm. These signals were attributed respectively to methine, methylene, and methyl protons of the ozonide.



Loan et al.[40] observed in the n.m.r. spectrum of the ozonide of but-2-ene a doublet at 8.65 ppm (CH_3) and two overlapping quartets at 4.72 and 4.78 ppm (*cis*- and *trans*--CH). The n.m.r. spectrum of the ozonide of pent-2-ene showed a multiplet at 5.13 ppm (CH), a multiplet at 8.37 ppm (CH_2), a doublet at 8.65 ppm ($CH–CH_3$), and a triplet at 9.04 ppm ($CH_2–CH_3$). Finally, two overlapping triplets at 4.95 ppm (CH), a multiplet at 8.34 ppm (CH_2), and a triplet at 8.61 ppm (CH_3) were found in the n.m.r. spectrum of the ozonide of hex-3-ene.

Gas–liquid chromatography has also been used for the analysis of ozonides. Schröder[68] has employed a GESF--96 column to separate the *cis*- and *trans*-ozonides of hex--3-ene. Greenwood and Haske[69,92] used a cyanosilicone and diethylene glycol succinate for the same separation.

Thin-layer chromatography is often used for the analysis of ozonides and other peroxy-products of ozonisation, and for their isolation during preparation. A large number of solvents and reagents have been described which can be used for the separation and identification of various peroxides[109,110]. The analysis and identification of the peroxy-products of ozonolysis still remains in general a very difficult task, requiring the combined application of several methods of analysis.

---o0o---

As long ago as the first decade of this century chemists who had studied the reaction of ozonisation were concerned with the possibility of its wide practical application. The hydrolysis of unsymmetrical ozonides

yields as final products mainly the aldehydes R'CHO and R"CHO and the acids R'COOH and R"COOH. The mixtures of valuable oxygen-containing products obtained by the ozonisation of individual alkenes can be separated comparatively easily.

The ozonisation of alkenes is a rapid process, and the alkenes react completely. However, the explosive properties of many ozonides, and especially of the highly polymeric products obtained on the ozonolysis of alkenes, for many years halted work aimed at the wide practical application of this interesting reaction. Most researches were directed at the use of ozonolysis for studying the structure of organic compounds containing unsaturated bonds.

During this time vast experience has been ascumulated, and a detailed study has been made of the mechanism of the reaction and the chemistry of processes involved in the ozonisation of alkenes and the decomposition of ozonides. The technique of ozonisation has been brought to such a degree of perfection that this reaction can be accomplished to a large extent without danger, so that ozonisation of the higher alkenes can be applied on an industrial scale. An especially important future awaits the processing of higher alk-1-enes into oxygen-containing products – higher aliphatic acids, aldehydes, and alcohols.

The higher C_{7-18} alk-1-enes can be obtained relatively easily by the cracking or the high-speed cracking of alkanes. The resulting products can be separated without special difficulty into individual alk-1-enes from C_7 to C_{16}, which permits the production on their basis, by the application of ozonisation, of several individual oxygen-containing products of immense value to the national economy of the Soviet Union.

STABILISATION OF CONCENTRATED OZONE

S. A. Tokareva and I. I. Vol'nov

The chemical properties of ozone are characterised by two essential features: its chemical instability and its powerful oxidising action. At low concentrations (and in the absence of impurities) ozone decomposes quite slowly under normal conditions. At high concentrations ozone decomposes explosively. Ozone also behaves as a priming explosive in the liquid state (b.p. -111.9°) and in the solid state (m.p. -192.7°).

The applications of ozone in many areas of science and technology are becoming progressively wider: many workers have sought to prepare pure concentrated ozone and have investigated inert solvents which enable the gas to be separated from oxygen and stabilised.

Ozone is prepared, in the form of ozone–oxygen mixtures containing about 8–9 wt.% of ozone, by subjecting oxygen to the action of a silent discharge in ozonisers. The ozone may be concentrated by liquefaction, for example, in the apparatus shown in Fig. 1. Since the explosive propensities of ozone are largely determined by impurities, particularly those of organic origin, the oxygen fed to the ozoniser must be thoroughly purified. Methods of purification have been described in detail in papers [1,2] and also in a patent specification [3]. According to Platz and Hersh [1], if the concentration of organic compounds (expressed as CO_2) in the oxygen is less than 20 parts per million, it is possible to prepare stable 100% liquid ozone by liquefaction. Liquid ozone–oxygen mixtures also can be prepared by liquefaction — for example, by using the apparatus shown in Fig. 2 — because above -180° liquid ozone is miscible in all proportions with liquid oxygen. This is clear from the ozone–oxygen phase diagram [4] given in Fig. 3.

However, the explosion hazards of concentrated ozone depend not only on the presence of impurities, but also on local shock; hence the current interest in the use of inert sorbents or solvents to allow safe storage, transfer, and manipulation of concentrated ozone.

Studies of the adsorption isotherms of ozone on silica gel over a range of temperatures [5,6] have shown that the sensitivity of adsorbed ozone as an explosive is low. This allows ozone to be desorbed almost quantitatively by slightly raising the temperature (say, from -150° to -120°), thus providing a ready means for evolving concentrated ozone from the gas phase by an adsorption–desorption cycle.

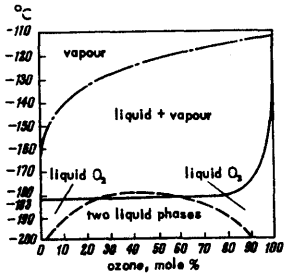

Fig. 3. Phase diagram for the ozone–oxygen system.

Up to 1960, carbon tetrachloride was the only solvent known to be inert towards ozone. However, this solvent has a very low solubility coefficient [7] (4.6 at -12°), and a relatively high melting point (-22.96°). Furthermore, there is a possibility of traces of phosgene being formed after prolonged contact between carbon tetrachloride and ozone. Nevertheless, it has been suggested [8] that liquid ozone can be stabilised by the addition of 0.5–25% of carbon tetrachloride.

A search for a new solvent, made by a group of French workers [9-16], led to the Freons, whose solubility coefficient for ozone at -110° is of the order of 1500–3500. The Freons are inert towards ozone because of the stability of the C–F bond (the bond energy for this class of compounds varies between 90 and 112 kcal mole^{-1}). The presence of traces of free fluorine in Freons has a stabilising effect on ozone. Ozone dissolved in Freons retains its chemical identity, and does not form complexes or solvates. Freons have a low solidification temperature, which assists the dissolution of ozone. Because of the chemical inertness of Freons, apparatus for working with these compounds can be constructed from a wide range of materials.

Ozone can be separated from oxygen at the ozoniser outlet by dissolution in a Freon, whereas oxygen does not dissolve. The solubility of ozone in Freons depends on the nature of the Freon, and is limited by the solidification temperature of the latter. The melting points and boiling points of the Freons used for dissolving ozone are set out in the first two lines of Table 1.

TABLE 1. Solubility coefficients for 100% ozone in various fluorochloromethanes and fluorochloroethanes.

Freon	CF-11	CF-12	CF-13	CF-22	CF-113	CF-114	CF-14
Formula	CCl_3F	CCl_2F_2	$CClF_3$	$CHClF_2$	$C_2Cl_3F_3$	$C_2Cl_2F_4$	CF_4
M.p., °C	−111	−158	−181	−160	−35	−94	−183.8
B.p., °C	+23.8	−29.8	−81.4	−40.8	+47.6	+3.5	−128.8
Temperature, °C	Solubility coefficient S_B^T (pressure dependent)						
−110±1	8.3—9	12—14	13—15	21—22			
−94±1	4.1—4.4	4.4—4.5					
−63±1	1.2—1.3					1.2—1.4	
−23±1	0.3—0.35				0.485—0.495		
	Solubility coefficient S_B^T (100%)						
−110±1	1610±80	2090±80	2180±80	3490±80			
−94±1	132±5	136±5				35±1	
−63±1	25.4±0.2				9.4±0.2		
−23±1	6.6±0.3						

The best solvent and stabiliser for liquid ozone is Freon-14. The phase diagram[17] for the liquid ozone–liquid Freon-14 system is reproduced in Fig. 4.

Two types of apparatus are used to dissolve ozone in Freons, depending on whether the melting point of the Freon is higher or lower than the boiling point of ozone (-111.9°). In the former case dissolution is obtained by bubbling the gas through liquified Freon to saturation. In the latter case the ozone and Freon are liquified simultaneously in a small distillation column to which the two gases are admitted in countercurrent. Fig. 5 shows the general layout of the apparatus; Fig. 6 is a more detailed sketch of the cell used for dissolution. The Freons are previously purified (to the 99.99% level) by distillation followed by drying with activated gels, 5 A zeolite, and phosphorus pentoxide. They are then condensed in a graduated vessel which has been carefully dried. A predetermined volume of Freon is distilled into the ozone saturator cell, also carefully dried. The saturation time depends on the temperature, pressure, and nature of the Freon. The saturation limit for a number of Freons was reached at -110°. The longest duration of the experiments was 6 h. When calculating the solubility, allowance was made for the "dead volume" of the cell (the space above the liquid phase) and for the mass of solvent lost by evaporation whilst bubbling the ozone–oxygen mixture. The solubility data, expressed as the Bunsen coefficient

$$S_B^T = \frac{V_{O_3}}{V_F}\frac{760}{P},$$

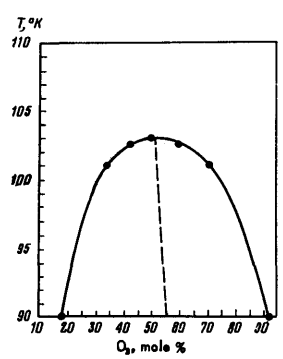

Fig. 4. Phase diagram for the liquid ozone–liquid Freon-14 system.

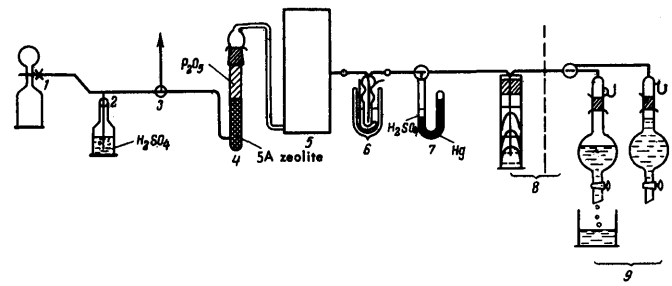

Fig. 5. Apparatus for dissolving ozone in Freons: 1) oxygen cylinder; 2) manostat; 3) oxygen discharge; 4) drying tube; 5) ozoniser; 6) dissolution cell; 7) manometer; 8) absorption towers; 9) volume meters.

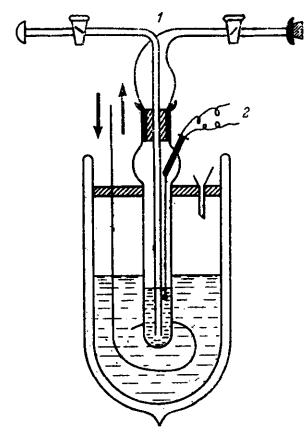

Fig. 6. Cell for ozone dissolution: 1) ozone inlet tube; 2) thermocouple.

where V_{O_3} is the volume of dissolved ozone under normal conditions, V_F is the volume of Freon at temperature T, and P is the effective total pressure in mmHg, are tabulated in lines 3–6 of Table 1. The remaining lines of the table list the solubility data expressed as the Bunsen coefficient, $S_B^T(100\%)$, for one atmosphere.

The best solvent for gaseous ozone is Freon-22, monochlorodifluoromethane $CHClF_2$, because it has a low molar volume.

Some mixtures of the Freons, for example a 50% mixture of CF-114 and CF-11, offer a higher solubility than the pure components. An increase in solubility with decrease in molar volume is observed on going from Freon-11 to Freon-12 and -13, in which ozone exhibits virtually ideal solubility.

For very low ozone concentrations at -63° and -23° the solubility of ozone calculated by the formula $S_B^T(100\%) = S_B^T\frac{P_0 - P}{P(P_0 - 1)}$ is very close to the value calculated by the direct proportionality law $S_B^T(100\%) = SP\frac{1}{P}$, as Table 2 shows.

This is evidence that dilute solutions of ozone in Freons obey Henry's law. The solubility coefficients for ozone

TABLE 2. Calculated solubility values for ozone.

	$S_B^T(100\%) = S_B^T \frac{P_0 - P}{P(P_0 - 1)}$			$S_B^T(100\%) = S_P \frac{1}{P}$

— 94	0.93	0.95		
— 63	1.01			
— 23	1.00			

($X^{100\%}$), expressed in mole fractions, are given in Table 3, together with the ratio of the real solubility to the ideal solubility Xi. It is clear that this ratio is close to unity, a rare occurrence in gas solubility.

From the data of Table 3, Chrétien and coworkers[9] have calculated the molar latent heat of dissolution of ozone in CCl_3F and CCl_2F_2, which turned out to be 3290 ± ± 50 and 3590 cal mole^{-1} respectively. The latent heat of evaporation of ozone is 3410 ± 100 cal mole^{-1} at the boiling point. These values are of the same magnitude, which suggests that no chemical reactions occur when ozone is dissolved in Freons, and that neither complexes nor solvates are formed.

Mahieux[10] also examined the possibility of obtaining mixtures of liquid and solid ozone with Freons, and measured the stability of these mixtures. The ozone was condensed in vessels of two types. One of the vessels (Fig. 7) is an ordinary spiral tube, fitted with a reservoir. The ozone–oxygen mixture obtained from the ozoniser is passed through the spiral cooled to about -140°. Only the ozone is liquified, and collects in drops in the reservoir, which already contains a known volume of condensed Freon. The alternative vessel (Fig. 8) includes a capillary through which the ozone–oxygen mixture is led into the condensed Freon, where the ozone condenses. It is best to use Freons CF-12 and CF-22 to condense the ozone. Freons having a boiling point lower than that of ozone are not recommended (for example, Freon-14). Freon-13 evaporates very rapidly under reduced pressure, entraining the ozone. The advantage of Freons CF-12 and CF-22 is that, because of their relatively high boiling point, the ozone evaporates first from the mixture. Also, the low melting point of these Freons (-158° and -181°) enables mixtures with solid ozone to be obtained at temperatures above the freezing point of ozone (-192.7°).

When ozone is condensed in Freon it forms a blue liquid which solidifies as the temperature is reduced to -192°, acquiring a transparent black colour if the molar concentration of ozone is ~60%. At lower ozone concentrations, liquid ozone and liquid Freon are miscible in all proportions without separating into layers. Layering occurs in

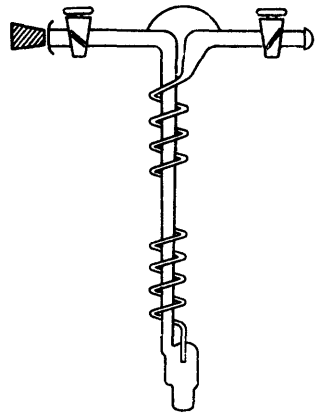

Fig. 7. Tube for liquefaction of ozone (with spiral).

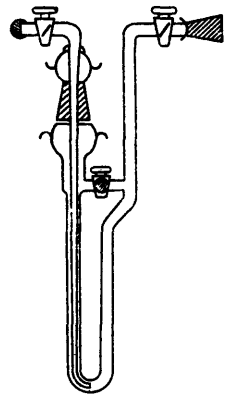

Fig. 8. Tube for liquefaction of ozone (with capillary).

the region from -230° to -270° for Freons CF-13, CF-12, and CF-22, but in practice the limiting temperature is that of liquid nitrogen (-196°), and therefore layering is not observed.

Streng and Grosse[18] have reported that ozone is unstable in the neighbourhood of its freezing point. Mahieux[10] showed that solutions of ozone in Freons are thermally stable, and that no explosive decomposition takes place when ozone is solidified in a Freon medium.

The condensation of ozone is more efficient than the dissolution process, since from 70 to 90% of the ozone passing through the Freon is retained by liquefaction as compared with 10–15% during dissolution. The concentration of ozone in ozone–Freon mixtures can reach 50%.

The preparation of solutions of ozone in Freons has practical importance[11]. The solubility of ozone in Freons enables ozone to be separated from oxygen and to be stored safely and for long times in a concentrated form: it offers a portable source of ozone which can always be handled and conveyed over any distance.

By evaporating ozone from these solutions we can obtain pure ozone or ozone mixed with oxygen or with inert gases

at a known concentration[12]. Various substances can be made to react directly with the ozone in an inert solvent medium[13].

Solutions of ozone may be stored in stainless steel bottles[11] of 5, 10, and 15 l capacity (calculated as 100% ozone). Below -50° these solutions may be stored indefinitely. At room temperature the decomposition time of the ozone (time for 50% decomposition of the stored ozone) is of the order of weeks. As a rule, vessels containing dissolved ozone are stored at -30° and transported at -15°. At the latter temperature the solutions can be kept for one month. The rate of decomposition of the ozone depends on the nature of the Freon and on the shape of the vessel. Solutions of ozone in Freon-12 have been examined for sensitivity towards mechanical, electrical, and explosive shocks, and for temperature resistance[19]. The sensitivity of both the vapour phase and the liquid phase of a 10% solution of ozone in Freon-12 towards a high-voltage electrical discharge and towards detonation at high pressures was tested. No detonation took place when explosion was initiated in the gas or the liquid phase of a 12% solution of ozone in Freon-12 at -78° and 105 atm (of helium). The gas and the liquid phase were tested for shock resistance by dropping a 5.6 kg weight from 35 cm, but it was found that solutions containing 10 wt.% of ozone in Freon-12 are completely safe at -78°. Experiments on the effect of temperature showed that increase in temperature does not produce an explosion, or even appreciable decomposition of the ozone.

We have recently confirmed[20] that solutions of pure ozone in Freon-12 and -113 can be prepared, and handled with safety during liquid-phase reactions with alkalis and peroxidic compounds.

Electron spin resonance (ESR) is the name given to the resonance absorption of the energy of an oscillating magnetic field by a paramagnetic substance in which the field induces transitions of unpaired electrons between split Zeeman levels. The ESR phenomenon was discovered by Zavoiskii[1] and interpreted theoretically for the first time by Frenkel'[2]. The ESR method is of particular value for the study of free radicals, because of its high sensitivity, the possibility of investigating free radicals directly in the course of reactions, and also the completeness and uniqueness of the information about their structure thus obtained. The number of ESR studies on free radicals is extremely large. In this review we shall confine ourselves to certain results relevant to the physics and chemistry of polymers.

I. THEORETICAL FOUNDATIONS OF THE ESR METHOD

1. The Basic Features of the Phenomenon

Consider a specimen containing unpaired electrons, for example a reaction mixture with free radicals. In the absence of an external magnetic field, all orientations of the spins and magnetic moments of the electrons have the same energies. An external magnetic field removes the degeneracy: only two orientations of the spins and magnetic moments of the electrons are now possible, along and against the field, since the electron spin is $S = 1/2$ and according to quantisation rules only $2S + 1 = 2$ states are possible. This means that the zero energy level splits into

at a known concentration[12]. Various substances can be made to react directly with the ozone in an inert solvent medium[13].

Solutions of ozone may be stored in stainless steel bottles[11] of 5, 10, and 15 l capacity (calculated as 100% ozone). Below -50° these solutions may be stored indefinitely. At room temperature the decomposition time of the ozone (time for 50% decomposition of the stored ozone) is of the order of weeks. As a rule, vessels containing dissolved ozone are stored at -30° and transported at -15°. At the latter temperature the solutions can be kept for one month. The rate of decomposition of the ozone depends on the nature of the Freon and on the shape of the vessel. Solutions of ozone in Freon-12 have been examined for sensitivity towards mechanical, electrical, and explosive shocks, and for temperature resistance[19]. The sensitivity of both the vapour phase and the liquid phase of a 10% solution of ozone in Freon-12 towards a high-voltage electrical discharge and towards detonation at high pressures was tested. No detonation took place when explosion was initiated in the gas or the liquid phase of a 12% solution of ozone in Freon-12 at -78° and 105 atm (of helium). The gas and the liquid phase were tested for shock resistance by dropping a 5.6 kg weight from 35 cm, but it was found that solutions containing 10 wt.% of ozone in Freon-12 are completely safe at -78°. Experiments on the effect of temperature showed that increase in temperature does not produce an explosion, or even appreciable decomposition of the ozone.

We have recently confirmed[20] that solutions of pure ozone in Freon-12 and -113 can be prepared, and handled with safety during liquid-phase reactions with alkalis and peroxidic compounds.

Electron spin resonance (ESR) is the name given to the resonance absorption of the energy of an oscillating magnetic field by a paramagnetic substance in which the field induces transitions of unpaired electrons between split Zeeman levels. The ESR phenomenon was discovered by Zavoiskii[1] and interpreted theoretically for the first time by Frenkel'[2]. The ESR method is of particular value for the study of free radicals, because of its high sensitivity, the possibility of investigating free radicals directly in the course of reactions, and also the completeness and uniqueness of the information about their structure thus obtained. The number of ESR studies on free radicals is extremely large. In this review we shall confine ourselves to certain results relevant to the physics and chemistry of polymers.

I. THEORETICAL FOUNDATIONS OF THE ESR METHOD

1. The Basic Features of the Phenomenon

Consider a specimen containing unpaired electrons, for example a reaction mixture with free radicals. In the absence of an external magnetic field, all orientations of the spins and magnetic moments of the electrons have the same energies. An external magnetic field removes the degeneracy: only two orientations of the spins and magnetic moments of the electrons are now possible, along and against the field, since the electron spin is $S = 1/2$ and according to quantisation rules only $2S + 1 = 2$ states are possible. This means that the zero energy level splits into

two sublevels (Zeeman effect) and the electrons are distributed between these sublevels (Fig. 1) in accordance with the Boltzmann law:

$$\frac{n_1}{n_2} = e^{-\frac{\Delta E}{kT}}, \quad (1)$$

where n_1 and n_2 are the numbers of electrons in the upper and lower levels, ΔE is the energy difference between the levels, T is the absolute temperature, and k the Boltzmann constant. The magnitude of the Zeeman splitting is

$$\Delta E = g\beta H. \quad (2)$$

In this expression β is a Bohr magneton and g the spectroscopic splitting factor, which is 2.0023 for a "free" electron. For most of the radicals investigated, the g-factor differs only slightly from this value. If in addition to the permanent magnetic field H an oscillating magnetic field with frequency ν acts on the specimen such that

$$h\nu = g\beta H \quad (3)$$

and directed perpendicular to the permanent magnetic field, the electrons pass from the lower to the upper level with absorption of energy from the field. At the same time electron transitions from the upper to the lower level with emission of energy are induced. But, since according to Eqn. (1) the number of electrons n_2 in the lower level is higher than the number of electrons in the upper level, it follows that on average there will be more transitions per unit time from the lower to the upper level than in the reverse direction, i.e. the oscillating magnetic field will tend to equalise the populations of the levels and its energy will be absorbed.

At the same time there exist the so-called relaxation processes which tend to restore the initial "Boltzmann" distribution of electrons, whereby their excess energy is converted into thermal lattice vibrations (spin–lattice relaxation) or the energy is redistributed among the electrons themselves (spin–spin relaxation). The rates of these relaxation processes, which can be characterised by the corresponding relaxation times T_1 and T_2 (the times during which the excess energy decreases by a factor of e), determine the maximum intensity of the oscillating magnetic field for which the Boltzmann distribution is still maintained. If, as happens fairly frequently (for example in macroradicals in polymers), the relaxation times are relatively high, thermal equilibrium breaks down at relatively low intensities (of the order of 1 mV) and the energy absorbed by the specimen from the oscillating magnetic field ceases to be proportional to the incident energy (saturation effect). In the absence of saturation, the energy absorbed per unit mass of the paramagnetic substance is defined by the expression

$$P_\nu = \frac{\pi^2}{2} \frac{N_0 g^2 \beta^2}{3kT} S(S+1) H_\sim^2 \nu^2 I(\nu). \quad (4)$$

Here N_0 is the number of unpaired electrons per gramme of the substance, $H_\sim$ the amplitude of the oscillating magnetic field, and $I(\nu)$ a "function of the line form". This function takes into account the finite width of the paramagnetic absorption line and is normalised in such a way that $\int_{-\infty}^{+\infty} I(\nu)d\nu = 1$. Bearing in mind that for lines which are not too broad one can put with sufficient accuracy $\nu = \nu_{res}$, we obtain the following expression for the total integral energy absorbed by unit mass of the specimen with $S = 1/2$

$$P = \pi^2 \frac{N_0 g^2 \beta^2}{3kT} H_\sim^2 \nu_{res}^2 = \frac{\pi^2 g^4 \beta^2}{3kTh^2} H_{res}^2 H_\sim^2 N_0. \quad (5)$$

The condition of the absence of saturation can be written in the form

$$\frac{1}{4}\gamma^2 H_\sim^2 T_1 T_2 \ll 1 \quad (6)$$

where γ is the gyromagnetic ratio for the electron.

2. Parameters of the Spectral Line

Fig. 2 shows the variation of the energy of the oscillating magnetic field P absorbed by the paramagnetic specimen with the strength of the steady magnetic field H for a constant frequency of the variable magnetic field. This is the relation one has in mind when one speaks of the ESR "spectrum". Fig. 2 shows the singlet spectrum corresponding to the structure of the energy levels in Fig. 1. The ESR spectrum can be characterised by the following fundamental parameters: intensity, g-factor (or the resonance strength of the magnetic field H_{res}), and the width and form of the lines.

Intensity of the spectrum. The intensity of the ESR spectrum is understood as the area S under the curve describing the variation of the energy of the oscillating magnetic field absorbed by the specimen with the strength H of the steady magnetic field (Fig. 2). It follows from Eqn. (4) that, other conditions being equal, the intensity of the spectrum is proportional to the number of unpaired electrons per gramme of the test substance:

$$N_0 = \alpha S, \quad (7)$$

where α is a proportionality coefficient which depends on the units in which S is measured and on the parameters of

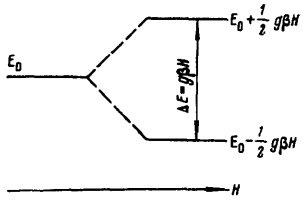

Fig. 1. Schematic representation of the Zeeman splitting of electronic levels.

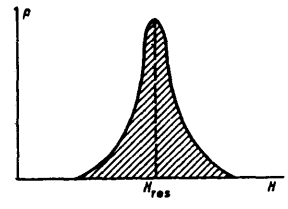

Fig. 2. A singlet ESR spectrum.

the measuring system. Thus if the coefficient α is known, the determination of the concentration of unpaired electrons in the specimen requires the experimental measurement of S. On the other hand, if α is unknown it is necessary to determine under identical conditions the values of S and S_{st} for the test specimen and a standard specimen with a known concentration N_{st} of unpaired electrons. Then the concentration of unpaired electrons in the test specimen is given by the expression

$$N_0 = N_{st}\frac{S}{S_{st}}. \quad (8)$$

The second method is in fact normally used in practice.

The g-factor. The g-factor is a measure of the contribution of the orbital magnetism to the total magnetic moment of the unpaired electron. The weaker is the interaction between the spin and the orbital momenta, the smaller is the difference between the g-factors of the paramagnetic substance under test and that of the free electron. As already stated, this is in fact what happens in free radicals. Since in most cases free radicals are complex asymmetric species, their orbital degeneracy is removed by the internal electric field, which arises from the surrounding atoms, and the orbital magnetism is greatly suppressed. For this reason, the spin–orbital coupling of the unpaired electron in free radicals is usually very weak. Only in rare cases does the g-factor of free radicals differ from that of the free electron by more than several thousandths (for example, $g > 2.01$ for radicals with an unpaired electron at a sulphur atom). On the other hand, in paramagnetic ions whose unpaired electrons belong to a deeply embedded d-shell, appreciable spin–orbital coupling is often observed. Since the g-factor can be determined with very high accuracy, its measurement can provide definite information about the magnitude of the spin–orbital coupling and can be used for the identification of free radicals.

It should be noted that, generally speaking, the g-factor is a tensor quantity. Therefore in single-crystal (or strongly oriented) specimens anisotropy of the g-factor can be sometimes observed. In other cases the anisotropy of the g-factor can cause some broadening of the resonance lines.

The form and width of the lines. The lifetime of unpaired electrons in the excited state, i.e. in the upper Zeeman level, determines the width of the ESR spectral line, in accordance with the uncertainty principle. The following fundamental processes determine the lifetime of excited unpaired electrons: (a) spin–lattice interaction; (b) spin–spin dipole interaction; (c) exchange interaction.

The transfer of energy from unpaired electrons to the molecules of the substance or to the lattice constitutes the basis of the mechanism of the *spin–lattice* relaxation. The coupling between the spin system and the lattice is magnetic (spin–orbital interaction). However, as already stated, the spin–orbital coupling in free radicals is weak. Therefore the spin–lattice relaxation time T_1 is relatively large (it can reach several seconds) and cannot make an appreciable contribution to the broadening of the resonance line. At the same time the large value of T_1 can in fact be responsible for the saturation effect.

Spin–spin interaction. Each unpaired electron in the constant external magnetic field H is acted upon, apart from the external field, by the local fields H_{loc} due to the magnetic moments of other electrons. The result is that the resonance condition (3) can be satisfied for individual unpaired electrons at various values of H, i.e. the resonance line is broadened. The strength of the local fields is inversely proportional to the cube of the distance between the unpaired electrons. Therefore spin–spin interaction increases with the concentration of unpaired electrons in the specimen and their interaction often in fact determines the width and form of the spectral lines. Two limiting cases of spin–spin interaction are possible.

a. The paramagnetic species are at large distances from one another and interact only during collisions, the duration of which is short compared with the periods between the collisions (this case obtains in gaseous and liquid phases at low concentrations of the paramagnetic species). The line form is then described by a Lorentzian curve:

$$I_L(H) = \frac{I_L(H_0)}{1+\left(\frac{H-H_0}{\Delta H_L}\right)^2}. \quad (9)$$

b. The paramagnetic species are in different quasi-steady-state local magnetic fields (solid phase, high concentration of paramagnetic species). In the absence of exchange interaction, the line form is in this case gaussian

$$I_G(H) = I_G(H_0)e^{-\frac{(H-H_0)^2}{\Delta H_G}}. \quad (10)$$

The characteristic line parameters ΔH_L and ΔH_G are related in the following way to the experimental line width $\Delta H_{1/2}$ at half the peak height:

$$\Delta H_L = 0.5\ \Delta H_{1/2};\quad \Delta H_G = \frac{1}{2\ln 2}\Delta H_{1/2}. \quad (11)$$

Exchange narrowing. If the local magnetic fields in which the paramagnetic species are situated change fairly rapidly, they become averaged out and line narrowing results. Such averaging out can be due to an exchange effect. The exchange effect arises when, as a result of their high concentration the electron clouds of the paramagnetic species begin to overlap. Extensive delocalisation of the unpaired electrons and rapid motion of the paramagnetic species can also lead to the averaging out of the local magnetic field. In all these cases the paramagnetic resonance lines become narrower in the central region, approaching Lorentzian line shape.

3. Hyperfine Structure (HFS) of the ESR Spectra

The hyperfine structure of the ESR spectra is due to the interaction of the unpaired electrons with the paramagnetic nuclei. According to the quantisation rules, the magnetic moment of a nucleus with a spin I has $2I + 1$ possible orientations relative to the external magnetic field. An additional magnetic field, set up by the nucleus at the location of the electron, has values corresponding to each of these orientations. Therefore each level is split into $2I + 1$ sublevels. The oscillating magnetic field does not give rise to reorientation of the nucleus, since its frequency does not correspond to resonance with respect to the nuclear transitions. Consequently the following selection rules operate for the electronic transitions: $\Delta M_I = 0$ and $\Delta S_Z = \pm 1$ (M_I is the nuclear magnetic quantum number and S_Z the projection of the electron spin in the direction of the field). As a result $2I + 1$ lines at equal distances appear in the spectrum. Fig. 3 shows as an example (in a schematic form) the splitting of the electronic levels in the interaction of an unpaired electron with a single proton ($I = 1/2$). It is seen

that a doublet is obtained instead of a singlet spectrum. In most modern ESR spectrometers the derivative of the absorption line with respect to the magnetic field (dI/dH) is recorded, rather than the line itself. For this reason, the spectral lines are of the form shown in the lower part of Fig. 3.

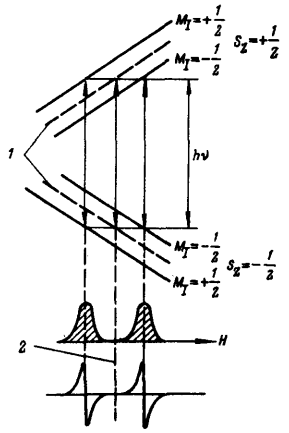
If the unpaired electron interacts with several magnetic nuclei, $\prod_r (2I_r + 1)$ lines of equal intensity appear in the spectrum (I_r is the spin of nucleus r). If the splitting due to different nuclei is such that the corresponding numbers of lines are integral multiples of one another, some lines overlap. The intensities of the components of such a spectrum bear simple multiple relations to one another. In practice, one frequently encounters the case where the interaction of an unpaired electron with several protons is the same. The number of lines in this spectrum is then $n + 1$ (where n is the number of protons) and the relative intensity of the kth line from the beginning of the spectrum is given by the coefficients of Newton's binomial:

$$C_n^{k-1} = \frac{n!}{(k-1)!\,(n-k+1)!}. \qquad (12)$$

Thus interaction with two protons gives rise to three lines with intensity ratios of 1 : 2 : 1 and interaction with three protons gives rise to four lines with intensity ratios of 1 : 3 : 3 : 1.

The interaction of electron spin with the magnetic moment of the nucleus consists of two parts[3]. The first part is analogous to the usual dipole–dipole interaction between two magnetic moments. This interaction depends on the direction of the external magnetic field relative to the radius vector joining the electron to the nucleus, and is therefore referred to as anisotropic. The second part is due to the isotropic contact interaction, which is independent of the direction and is proportional to the square of the modulus of the electronic wave function at the point where the nucleus is located.

Since the majority of free radicals have been investigated in the non-crystalline (or polycrystalline) state, the anisotropic interaction in them as a rule does not give rise to hyperfine structure, resulting only in the broadening of the spectral line. For this reason, the hyperfine structure of the spectrum of free radicals is usually caused by the isotropic interaction. This interaction is non-zero only when the density of the unpaired electron cloud is non-zero at the point where the nucleus is located. Only atomic s-orbitals or molecular σ-orbitals have a finite electron density at the nucleus and consequently can participate in the isotropic hyperfine interaction.



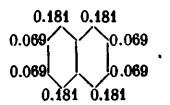


Fig. 3. Formation of the hyperfine structure of the ESR spectrum:
1) initial electronic levels; 2) position of the line in the absence of hyperfine splitting.

From this point of view, there should be no contact hyperfine interaction in aromatic free radicals, since the unpaired electrons in these radicals are located in π-orbitals with zero electron density in the plane of the ring where the hydrogen atoms are located. Nevertheless, the spectra of the majority of aromatic free radicals have a complex and highly resolved hyperfine structure. This can be understood within the framework of configurational interaction[4]. The result of such interaction is that a certain proportion of the excited σ-orbital state becomes combined with the purely π-orbital state of the electron. This leads to non-zero electron density in the plane of the ring and the appearance of hyperfine structure.

The hyperfine splitting ΔH can be calculated from the formula

$$\Delta H = Q\rho \qquad (13)$$

where Q is a constant (28 Oe for the aromatic CH bond) and ρ the unpaired electron density at the carbon atom to which the given hydrogen atom is joined. The distribution of electrons in conjugated systems between various carbon atoms is calculated by the usual methods of quantum chemistry — the valence bond or molecular orbital methods. We shall quote the distribution of electron density in the naphthalene radical-ion $C_{10}H_8^-$, which is a well-known initiator of anionic polymerisation. Calculation by the molecular orbital method yields the following distribution:

Consequently, theory predicts that, as regards their interaction with an unpaired electron, protons can be divided into two groups. Each group includes four protons and therefore a spectrum consisting of (4 + 1)(4 + 1) = = 25 lines may be expected, and is in fact observed experimentally.

In non-conjugated systems the principal mechanism of the interaction of the unpaired electron with hydrogen atoms is the so-called hyperconjugation. The phenomenon consists essentially in the overlapping of the orbitals of the radical π-electron with the electron clouds of other atoms. As a result, non-zero unpaired electron density can appear at the location of the nuclei of these atoms. For example, in ethyl radicals $CH_3-CH_2^{\cdot}$ the unpaired electron interacts not only with the two protons of the methylene group but also with the three protons of the methyl group. The spectrum of ethyl radicals produced on irradiation of ethane[5] shows that the unpaired electron interacts somewhat more strongly with the protons of the methyl group. This gives rise to a hyperfine structure of twelve lines (Fig. 4). The theory of hyperconjugation was developed by Mulliken and coworkers[6-9] and applied for the first time by McLachlan[10] to the calculation of ESR spectra. Vol'kenshtein and Milevskaya[11,12] used this theory to calculate the spectra of polymeric radicals. They obtained expressions

Fig. 4. ESR spectrum of the ethyl radical.

for the hyperfine splitting by the protons of the methyl and methylene groups joined to the carbon atom with the unpaired electron. When the possible conformations of the macroradicals and the statistical weights of these conformations are known, these expressions make it possible to estimate the hyperfine structure of the spectrum. Conversely, when a highly resolved structure of the ESR spectrum is available, it can be used to estimate the conformations of the radicals.

II. ELECTRON SPIN RESONANCE TECHNIQUE

The vast majority of the ESR spectrometers used nowadays operate in the ultrahigh frequency range, namely in the vicinity of 10^{10} c/s (wavelength 3 cm). The strength of the constant magnetic fields is then about 3000 Oe. Fig. 5 shows the block-circuit of an ESR spectrometer. The principal elements of this circuit are present in the majority of spectrometers, despite the wide variety of designs employed. A reflex klystron is normally used as a source of electromagnetic waves. The electromagnetic waves are conducted via a wave guide to a cavity resonator in which the test specimen is located. The frequency of the klystron oscillations is maintained to a high accuracy, with the aid of a special electronic circuit, at the value equal to the resonant frequency of the cavity. The resonator is positioned between the poles of a magnet (usually an electromagnet) in such a way that the ultrahigh frequency magnetic field in the specimen is perpendicular to the steady magnetic field.

The resonator is connected by a second wave guide to a crystal ultrahigh frequency detector. If the strength of the magnetic field is now altered, then under resonance conditions the ultrahigh frequency power dissipated in the resonator increases and a smaller power is applied to the detector. Various ways of recording the paramagnetic resonance signal are possible. In one of them the strength of the steady magnetic field is adjusted close to the resonance value and then an additional low-frequency magnetic field, whose amplitude greatly exceeds the width of the absorption line, is established in the gap of the magnet with the aid of special coils. This gives rise to a signal at the output from the detector corresponding to the form of the absorption line, at a frequency equal to twice the modulation frequency. After amplification with a broad-band amplifier, the signal can be detected on the oscilloscope screen. However, the need to use a broad-band amplifier in this method of signal detection greatly reduces the sensitivity of the spectrometer, because, in addition to the useful signal, the interfering noise signals which may originate from the klystron oscillator and the detector, are also amplified. Therefore this method can be used only when the test specimen contains a large number of free radicals.

If high sensitivity is required, another method of detecting the ESR signal is used. In this method the field of the electromagnet is varied linearly with time (Fig. 6) and passes through the resonance value. At the same time a radio-frequency magnetic field is set up with the aid of modulation coils. However, now its amplitude must be smaller than the width of the resonance line. It is readily seen that in this case we shall have at the output from the detector a variable potential with a frequency equal to the modulation frequency. This potential is amplified by a narrow-band resonance amplifier and is rectified with a phase-sensitive detector fitted with a very narrow-band filter. The form of the rectified signal corresponds to the first derivative of the absorption line. The signal is recorded with a pen recorder. The possibility of using very narrow-band filters (about 0.1 c/s) in this method of recording greatly increases the useful signal : noise ratio, since the noise is proportional to the square root of the transmission band width. The reduction of noise is also facilitated by the fact that a fairly high (up to 1 Mc/s) modulation frequency of the magnetic field is usually chosen.

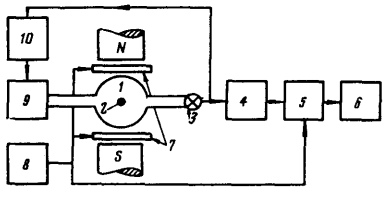

Fig. 5. Block-circuit of an ESR spectrometer:
1) cavity resonator; 2) specimen; 3) crystal detector; 4) amplifier; 5) phase-sensitive detector; 6) pen recorder; 7) modulating coils; 8) modulation generator; 9) Klystron; 10) AFC (automatic frequency control).

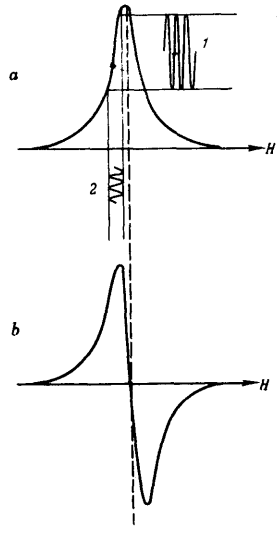

Fig. 6. Method using low amplitude modulation of the magnetic field:
1) resultant modulation of the ultrahigh frequency signal; 2) modulation of the magnetic field.

This makes it possible to avoid to a large extent the low-frequency noise from the crystal detector which occurs at the spectral density maximum. This spectrometer is one of the most widely used.

The type of resonator used in the spectrometer is determined by the specific features of the investigation. It is possible to use not only the transmission cavity shown in Fig. 5 but also a reflection cavity with an ultrahigh frequency compensating network. The superheterodyne method of signal detection is also employed, abeit much more rarely.

However, we shall not consider these problems in detail, the readers being referred to the appropriate literature [13,14]. In conclusion of this section we shall only mention that the maximum sensitivity of the existing spectrometers corresponds to 10^{-12}–10^{-13} mole of crystalline diphenylpicrylhydrazyl (DPPH) free radicals. But, since in most cases one deals not with crystalline materials but with solutions (or, for example, with polymerisation mixtures), greater interest attaches to concentration sensitivity, i.e. the minimum concentration of radicals which can be measured. Under most favourable conditions (specimen with small dielectric losses, correctly chosen relative dimensions of the resonator and specimen), the sensitivity corresponds approximately to 10^{-7} M for a spectral width of about 3 Oe.

III. INVESTIGATION OF FREE RADICALS BY THE ELECTRON SPIN RESONANCE METHOD

All studies on the electron spin resonance of free radicals can be divided into two large groups – the study of stable free radicals and the study of active intermediate radicals and reactions in which they participate.

1. Stable Free Radicals. Inhibition of Polymerisation

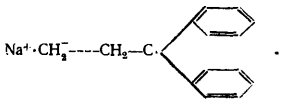
Apart from the naphthalene radical-ion discussed above, numerous stable and semistable radicals with a more or less complex system of conjugated bonds have been investigated: triphenylmethyl, semiquinones, $\alpha\alpha$-diphenyl-β-picrylhydrazyl, and many others. In recent years much attention has been given to the synthesis of polymers with a system of conjugated π-bonds. These polymers are organic semiconductors and frequently give a narrow singlet ESR signal.

Semistable and stable radicals are formed from radical reaction (oxidation and polymerisation) inhibitors. These are radicals derived from quinones and semiquinones, aromatic amines, aromatic nitro-compounds, and polycyclic hydrocarbons. The ESR method permits a quantitative approach to inhibition processes.

The study of the inhibition of polymerisation by this method [15] led to the discovery of a new important fact, namely that up to four inhibitor molecules are consumed and an equal number of stable radicals are formed for each active radical destroyed. This very large "stoichiometric coefficient", given by the expression

$$\frac{\text{number of inhibitor molecules consumed,}}{\text{number of deactivated radicals}}$$

implies that in the reaction of an active radical with an inhibitor molecule there forms initially a "hot" radical with an excess of vibrational energy, which is capable of further reactions with the monomer or other inhibitor molecules. Only after several such steps is the energy of the radicals reduced so much that they no longer initiate polymerisation. When an inert solvent is introduced into the system, the hot radicals are "cooled" as a result of collisions with solvent molecules and the stoichiometric coefficient tends to unity. The presence of hot radicals in polymerisation is evidence that energy chains can occur even in liquid-phase reactions.



2. Active Free Radicals. Polymerisation

As already stated, the sensitivity of modern ESR spectrometers is in most cases insufficient to investigate free-radical reactions in the liquid phase. However, it proved possible with their aid to solve certain important problems of polymerisation theory. An example of this kind is the mechanism of the initiation of polymerisation by alkali metals.

The hypothetical polymerisation mechanism was as follows. A complex consisting of the monomer molecule and a metal atom (charge-transfer complex) attacks a new monomer molecule and gives rise to a radical-ion which subsequently either recombines at the radical centre or grows in two directions at once:

To confirm this mechanism, it was necessary to detect the free radicals in the polymerising system. This was done in the polymerisation of diphenylethylene under the action of metallic sodium [16]:

In this case the radical proved to be so stable that it did not recombine and chain growth took place at the anionic centre.

The classical examples of radical polymerisation could be investigated only under special conditions. In 1953 Bamford and Jenkins showed [17] that in the polymerisation of certain monomers, in which the polymers formed are insoluble, part of the macroradicals are captured by the precipitated gel and stabilised. The ESR spectra of such radicals in polyacrylonitrile were investigated by Bamford and coworkers [18].

In 1958 Ingram and coworkers [19] succeeded in investigating the spectra of many free macroradicals by adding a precipitant to the polymerisation system. Another method of producing a large number of macroradicals was used by Fraenkel et al. [20] and Atherton et al. [21] It consists in the addition to the system of a certain amount of a cross-linking agent. During polymerisation part of the radicals remain trapped in the three-dimensional network formed. Finally, the spectra of radicals trapped in poly(methyl methacrylate) and poly(vinyl acetate) after the onset of the so-called gel-effect in photopolymerisation have been investigated [20,22]. However, it has been shown [22] that the trapped radicals are a side-product of the reaction and their concentration is not directly related to the process kinetics.

O'Donnell et al. [23] investigated the solid-phase polymerisation of barium methacrylate dihydrate. Irradiation at -196° of a single crystal of barium methacrylate dihydrate

gives rise to a fully isotropic spectrum which is attributed to $(CH_3)_2\dot{C}COO^-$ radicals formed when hydrogen adds to the double bond of the methacrylate ion. When the specimen is heated to 20°, a new, anisotropic spectrum appears, with nine lines if the magnetic field is parallel to the *a* or *b* axes of the pseudo-orthorhombic crystal and with 13 lines if the field is parallel to the *c* axis. This spectrum is attributed to the radical of the growing chain:

$$RCH_2\dot{C}(CH_3)COO^-.$$

The anisotropic properties of the spectrum showed that the growing radicals have a definite crystallographic orientation, or, in other words, the distribution of the monomer molecules in the crystal lattice determines the position of the growing macroradical.

3. Macroradicals in Solid Polymers. Structure and Spectra

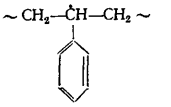
In 1951 Schneider and coworkers[24] observed the ESR spectrum of X-irradiated poly(methyl methacrylate). Their results and also subsequent studies showed that polymers are excellent media for the trapping of free radicals. The great advantage of polymeric matrices is the possibility of investigation of the radicals formed therein at relatively high temperatures (up to the softening temperature of the polymers), because of the powerful inhibition of the motion of the polymeric chains. This greatly extends the range of free-radical processes which can be studied by the ESR method, the polymer constituting an irreplaceable model system for the investigation of fundamental free radical reactions. A wide variety of methods for the preparation of radicals are used: radiolysis under the action of radiation of all types, trapping of free radicals in polymerisation processes, mechanical destruction of polymers.

The greatest number of studies on the electron spin resonance of irradiated polymers were undertaken to interpret the ESR spectra and to determine the structure of macroradicals. It can now be regarded as established[25-27] that, on irradiation of polyethylene at a low temperature, alkyl radicals are formed as a result of the scission of hydrogen atoms:

$$\sim CH_2-CH_2-\dot{C}H-CH_2-CH_2\sim.$$

Their spectrum consists of six lines corresponding to the interaction of the unpaired electron with one α-proton and with four β-protons. On raising the temperature (and also when the irradiation is carried out at room temperature), the spectrum disappears and the spectrum of another radical with an odd number of lines is observed. The latter is most likely due to radicals of an allyl type:

$$\sim CH_2-\dot{C}H-CH=CH_2\sim.$$



Such radicals are also produced as a result of the migration of the unpaired electron along the polymeric chain (via a consecutive relay-type transfer of hydrogen atoms) and its trapping by the double bond formed in consequence of radiolysis.

The ESR spectrum of the macroradicals in irradiated Teflon has also been investigated[28-20]. The spectrum is due to fluoroalkyl radicals:

$$\sim CF_2-CF_2-\dot{C}F-CF_2-CF_2\sim.$$

At room temperature the spectrum consists of ten lines due to the interaction of the unpaired electron with the fluorine atoms in the α- and β-positions. At a high temperature (250°) it is possible to observe an additional splitting caused by the interaction of the unpaired electron with the fluorine atoms in the γ-position.

The spectrum of free polystyrene radicals has been investigated in the course of the mechanical destruction of polystyrene in a vacuum[31,32] (Fig. 7). It consists of a poorly resolved triplet with a separation of 19 Oe between the components. Most probably this spectrum is due to radicals of the type

which can form as a result of the removal of hydrogen atoms from the polymeric chain by the more active primary radicals generated in the mechanical destruction of polystyrene. The hyperfine structure is formed as a result of the interaction of the unpaired electron with the protons of the neighbouring methylene groups. The non-equivalence of the protons (equivalent interaction of the unpaired electron with four protons would have given rise to a five-line spectrum) can be explained by the impossibility of free rotation of these groups about the C–C bonds. The relatively low extent of hyperfine splitting of the spectrum is due to the considerable delocalisation of the unpaired electron in the phenyl ring and the decrease of its density at the carbon atoms of the chain. Such delocalisation is possible if the plane of the ring coincides with the plane of the corresponding section of the chain. At the same time the electron density at the individual atoms within the ring is insufficient to give rise to additional lines and is responsible only for a certain broadening of the main lines. It is interesting that the hyperfine splitting in the spectrum of radicals generated in the mechanical destruction of isotactic polystyrene[31] is 34 Oe. This difference can be explained by the fact that the phenyl rings in isotactic polystyrene lie in planes almost perpendicular to the main chain and therefore they cannot withdraw the unpaired electron by conjugation. The ratio of the extents of splitting in the spectra of atactic and isotactic polystyrene is in good agreement with the ratio of the unpaired electron densities at the α-atom of the polystyrene radical calculated by the molecular orbital method for parallel and perpendicular orientations of the phenyl ring[12].

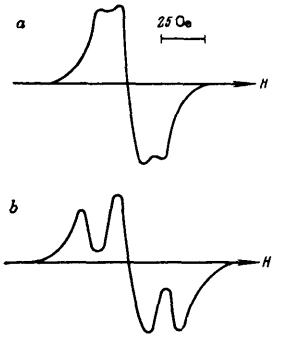


Fig. 7. ESR spectra of polystyrene macroradicals:
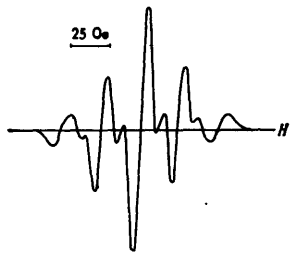
a) atactic polystyrene; *b*) isotactic polystyrene.



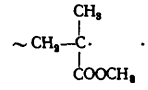


Fig. 8. ESR spectrum of poly(methyl methacrylate) macroradicals.

Fig. 8 shows the spectrum of the macroradicals in poly(methyl methacrylate). It is of the same form regardless of the methods of obtaining the radicals and is a result of the superposition of two series of hyperfine structure lines, a quintuplet and a quadruplet, with binomial intensity distributions in each series. The distances between the neighbouring lines in both series are the same and equal to 26 Oe. The centres of these spectra coincide, so that the quadruplet lines are located in the gaps between the quintuplet lines.

In 1958 Ingram et al.[19] and Abraham et al.[33] put forward the hypothesis that the ESR spectrum of poly(methyl methacrylate) is due to growing polymeric chain radicals:

The presence of two series of lines in the spectrum is then explained by the existence of definite conformations of these radicals, arising because of the impossibility of free rotation of the methylene group. In one of the conformations both protons of the methylene group are close to the nodal plane of the π-electron cloud of the unpaired electrons, interacting only weakly with the latter. This conformation corresponds to the quadruplet spectrum, which reflects the equivalent interaction of the unpaired electron with the three protons of the methyl group. In the other conformation one of the protons of the methylene group is located close to the meridian plane of the unpaired electron cloud and interacts with the latter in the same way as the protons of the methyl group. The four protons give rise to the quintuplet. On the other hand, the second proton of the methylene group interacts only very weakly with the unpaired electron. This hypothesis was subsequently confirmed in experiments on deuteriated derivatives of poly(methyl methacrylate)[34,35]. When both hydrogen atoms of the methylene group are replaced by deuterium atoms, only the quadruplet series remains in the ESR spectrum. This is explained by the fact that the hyperfine structure associated with deuterium atoms is usually unresolved. For this reason, the replacement of a hydrogen atom by deuterium is equivalent to the elimination of this atom from participation in the generation of the hyperfine structure. The quadruplet spectrum remaining after the substitution of the hydrogen atoms of the methylene group by deuterium corresponds to the interaction of the unpaired electron with the protons of the methyl group. When the protons of the methyl group are replaced by deuterium, there remains only a doublet spectrum corresponding to the interaction of the unpaired electron with one of the protons of the methylene group. Recently Fischer[36] investigated the polymerisation of methyl methacrylate in aqueous emulsion and established that the spectra produced in this process consist of the familiar groups of four and five lines, but each of these lines is in turn split into several further lines. This is probably due to the fact that, when the spectra of radicals in the liquid phase are observed, it is possible to achieve the resolution of the additional splitting by the protons of the methylene group, which in the solid phase is masked as a result of the line broadening caused by the anisotropic interaction.

IV. REACTIONS OF MACRORADICALS IN POLYMERS

1. Destruction of Macroradicals

The processes involved in the destruction of macroradicals in polyethylene after radiolysis were studied by several groups of investigators. In all these experiments it was established that the alkyl radicals are rapidly destroyed on raising the temperature of the specimen, while the destruction of the allyl radicals is very much slower. The kinetics of the destruction of radicals proved to be different in the experiments of various workers. Thus Lawton et al.[27] found that the kinetics of the destruction of alkyl radicals is consistent with a first-order equation. Charlesby et al.[37] observed the destruction of alkyl radicals according to a bimolecular law. Cracco et al.[38] established that alkyl radicals recombine according to a first-order law but with two different rate constants. On the other hand, allyl radicals are destroyed by a process which is neither of first nor of second order according to Charlesby et al.[37] and which is of first order according to Lawton et al.[27] Lawton[27] explains the kinetics of radical destruction (which he observed) as a result of the non-uniform distribution of the radicals in space. Charlesby et al.[37] suggest a uniform distribution of radicals and believe that a mechanism involving the migration of the radical state along the chain is responsible for their destruction.

The reason for the differences between the rates of destruction of radicals in the studies quoted above should probably be sought in the differences between the polyethylene specimens investigated (for example, it has been established[37] that the rate of destruction of alkyl radicals in specimens of low-pressure polyethylene is much higher than in high-pressure polyethylene). Possibly this is the explanation of the different kinetics of the destruction processes.

The recombination of radicals in Teflon has been investigated in detail by Tsvetkov et al.[39], who studied the recombination of both the initial fluoroalkyl radicals and the peroxy-radicals produced in the interaction between the initial radicals and oxygen. They established that the recombination in Teflon can be described by the usual bimolecular law, assuming that the recombination rate constant in the amorphous phase is higher than in the crystalline phase (specimens of different degrees of crystallinity were investigated). The recombination rate constants were determined from the rates of recombination of the peroxy- and fluoroalkyl radicals.

Ohnishi and Nitta[40] studied the destruction of radicals in irradiated poly(methyl methacrylate). They established that several hours after the beginning of the reaction the bimolecular law comes to hold exactly for the destruction of

radicals. On the other hand, in the first few hours deviations from the second-order law are observed. Shida et al.[41] investigated the destruction of radicals in irradiated poly(methyl methacrylate) during the initial period (up to 20 min) and found that the destruction of radicals is governed by a monomolecular law. Ohnishi and Nitta[40] determined the activation energy for radical recombination, which proved to be 28 kcal mole^{-1}. They believe that the radicals recombine as a result of the rotation of molecular segments, the activation energy for which has the same value[42]. Ohnishi and Nitta[40] found that the destruction of radicals is accelerated by oxygen, but failed to explain this phenomenon.

The recombination of macroradicals in γ-irradiated poly(vinyl chloride) has been investigated by Kuri et al.[43] and also by Egorova et al.[44] In both studies it was established that the destruction of radicals proceeds according to a second-order law with an activation energy of 38 kcal$\times$ $\times$ mole^{-1} [43] or 44 kcal mole^{-1}.[44] Like Ohnishi and Nitta[40], Kuri et al.[43] noted that oxygen accelerates the destruction of radicals.

It is noteworthy that in all the studies examined (with the exception perhaps of the work of Charlesby et al.[37]) it was assumed that the destruction of radicals in polymers occurs in the course of the collision during the rotation or displacement of smaller or larger sections of the polymeric chains. However, analysis of the available data[45,46] on the diffusional mobility of polymeric molecules shows that the idea of the interaction of macroradicals via collisions is inapplicable to the solid phase. Furthermore, the mechanism of the destruction of free radicals in polymers involving simply their collision as a result of mechanical displacement cannot account for the accelerating effect of oxygen on the destruction of macroradicals and the different rates of destruction of peroxy- and hydrocarbon radicals. Therefore it must be assumed that a different mechanism of the interaction between radicals obtains in polymers. Such mechanism is migration of radical states, whose existence has been established by Bresler et al.[32] This mechanism consists in the removal by the macroradicals of hydrogen atoms from the neighbouring chains, which results in the migration of the radical centre within the polymer. Such migration continues until two radical centres collide and annihilate one another by recombination or disproportionation. These workers investigated the destruction of macroradicals produced in the mechanical breakdown of polystyrene, poly(methyl methacrylate), and poly(vinyl acetate). The experiments showed that the destruction of radicals in the initial stages of the process is fully consistent with bimolecular kinetics and the reaction rate constants determined from the kinetic curves are consistent with the Arrhenius equation. The rate constants for the destruction of macroradicals are listed in Table 1.

It is noteworthy that the constants listed in Table 1 were determined with an accuracy limited by a factor having the dimensions of volume. The explanation is that, as shown by experiments on the reactions of macroradicals produced in the mechanical degradation of polymers by various gaseous agents, these radicals are not distributed uniformly throughout the bulk of the polymer, but are concentrated in a thin surface layer whose thickness is unknown. When oxygen is admitted into the tube containing the particles of the polymer with the macroradicals, the radicals are oxidised at a very high rate and are converted into peroxy-radicals with a characteristic asymmetric spectrum (Fig. 9). At temperatures below -50° the number of peroxy-radicals does

TABLE 1.

Polystyrene	$10^{20} \exp [(-24000 \pm 2000)/RT]$

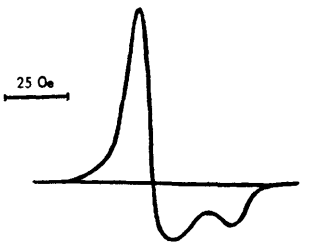

Fig. 9. ESR spectrum of peroxy-macroradicals.

not change at an appreciable rate. On raising the temperature, they begin to interact and disappear many times faster than the radicals with an unpaired electron at a carbon atom. In this case the equation for bimolecular kinetics is fully satisfied. The rate constants for the destruction of the peroxy-radicals are listed in Table 2.

It is seen that in polystyrene, for example at 20°, the peroxy-macroradicals disappear one thousand times faster than the intrinsic macroradicals of polystyrene. This is irreconcilable with the explanation of the radical destruction by collisions, because it is clear that the mechanical mobility of the initial and peroxy-radicals is identical. From the standpoint of the hydrogen removal process, the entire picture is clear: the primary radicals are relatively inactive and remove hydrogen from the neighbouring chains with difficulty. On the other hand, the peroxy-radicals are very reactive in the hydrogen removal step. There is yet another observation confirming the mechanism involving the migration of radical states. If after complete oxidation of the initial radicals the pressure of oxygen is reduced, the rate of destruction of radicals falls. At first sight this finding appears to be extremely surprising, because it would appear that molecular oxygen can have no influence on the behaviour of peroxy-radicals. However, from the standpoint of the radical state migration mechanism this phenomenon is quite natural. If there were no excess of dissolved oxygen in the polymer, the migration process would come to a stop when the peroxy-radicals became converted into secondary hydrocarbon radicals. No further reaction would then occur. On the other hand, when the system contains oxygen, the latter again adds to the new radical, removes hydrogen once more, etc. until two radicals annihilate one another as a result of a random

TABLE 2.

Polymer	$K = k/V$, mole^{-1} s^{-1}	Oxygen pressure, mmHg
Poly(methyl methacrylate)	$10^{21} \exp [(-23000 \pm 500)/RT]$	760

Polystyrene	$10^{15} \exp [(-12000 \pm 500)/RT]$	760
Polystyrene	$10^{14} \exp [(-12000 \pm 500)/RT]$	0.1

encounter. Thus the relay-type hydrogen transfer process is accompanied by chain oxidation of the polymer:

$$R\cdot + O_2 \rightarrow RO_2^{\cdot};\ RO_2^{\cdot} + R'H \rightarrow ROOH + R'\cdot;\ R'\cdot + O_2 \rightarrow R'O_2\cdot$$

and so on. The accumulation of peroxides in the polymer was confirmed by a special experiment.

2. Oxidation

The possibility of studying the reactions of macroradicals in polymers with various gaseous agents was demonstrated in several investigations. Thus Kuri and Ueda [47] studied the effect of sulphur dioxide on the radicals of various irradiated polymers. Kuri et al. [43] established that gases such as H_2S, NO, NO_2, and I_2 very rapidly destroy the radicals in irradiated poly(vinyl chloride), while hydrogen and sulphur dioxide do not react with the radicals. In another study Kuri et al. [48] observed the reactions of various gases with radicals in irradiated acrylamide and methacrylamide. The reactions of polymeric radicals with various gaseous agents were studied by Tsvetkov et al. [49]; they investigated the oxidation of fluoroalkyl radicals and their interaction with hydrogen and nitric oxide.

Several typical reactions, such as oxidation, removal of hydrogen, and the addition of monomers, were studied by Bresler et al. [50] In this investigation macroradicals were produced by mechanical destruction of polystyrene, poly(methyl methacrylate), and poly(vinyl acetate). The oxidation of radicals was studied at an oxygen pressure of 760 mmHg and at low temperatures. The kinetics of the process were followed by observing the increase of the intensity of the spectrum due to peroxy-radicals. In order to separate the overlapping spectra of the peroxy-radicals and the initial hydrocarbon radicals, the experiments were performed at a relatively high level of microwave power in the cavity (about 25 mV). Under these conditions strong saturation of the spectra of the primary radicals takes place, so that they are virtually undetectable and the spectra of the peroxy-radicals, which are saturated to a much smaller extent, are observed against what is virtually a zero background. The kinetics of the oxidation reaction are satisfactorily consistent with a monomolecular law, showing that the radicals are located in the immediate vicinity of the surface formed on breakdown of the polymers. Table 3 presents the oxidation rate constants calculated from the experimental data. It should be borne in mind that such determination does not yield the true oxidation rate constant but the product of the constant and the concentration of oxygen. Since on changing the temperature the concentrations of adsorbed and desorbed oxygen also change, the dissolution and adsorption of oxygen in polymers were studied and the temperature variation of the concentration of sorbed oxygen was determined [51] in order to find the true oxidation rate constant. The true constants k for the oxidation of polymeric radicals were determined by dividing the experimental constants K by the concentration of oxygen $[O_2]$.

3. Removal of Hydrogen

The next type of reaction which has been investigated is the abstraction of hydrogen by macroradicals. Cumene was used as the hydrogen donor. When cumene vapour is admitted into the tube with the specimen containing free radicals, the intensity of the spectrum due to the initial radicals decreases. A new spectrum does not appear because the low-molecular cumenyl radicals formed in this reaction rapidly recombine. Since the diffusion coefficients of cumene in polymers are very low, it was to be expected that the reaction of radicals with cumene would occur only on the surface of the polymer. Indeed experiment shows that the destruction of radicals is entirely consistent with monomolecular kinetics. The rate constants K calculated from the experimental data are presented in Table 4.

If the cumene adsorption constants are taken into account, the true constants k for the removal of hydrogen are obtained (last column of Table 4). In the temperature range investigated polystyrene radicals do not react with cumene at an appreciable rate. This finding may appear surprising, since, judging from the activation energies for the recombination and oxidation of radicals, polystyrene radicals should be no less active than the other radicals investigated. Thus we see that there is no direct correlation between the activity of the radical in a given reaction and the corresponding activation energy. This is because the preexponential factor, which can vary markedly from radical to radical, is no less rate-determining than the activation energy. Indeed, if, for example, we calculate the exponential terms in the rate constant expressions for the reactions of poly(methyl methacrylate) and poly(vinyl acetate) radicals with cumene at 250°K, we find that they differ only by a factor of 50. At the same time, the preexponential factors for these constants differ by a factor of 10^5.

4. Monomer Addition Reaction

The addition of the methyl methacrylate monomer to the macroradicals in polystyrene and poly(vinyl acetate) has been investigated. When the monomer vapour at a pressure of 10 mmHg is admitted into the tube containing a specimen of the ruptured polymer, the spectrum of the initial methyl methacrylate radicals changes at a very high rate (close to room temperature). The kinetics of the process were followed in this case by observing the increase in the intensity of the new spectrum, since it is much broader than the spectrum of the initial radicals and the extreme lines of its hyperfine structure do not overlap with the initial spectral lines, which makes it possible to separate the spectra of methyl methacrylate and other radicals. Here too the shape of the kinetic curves is entirely consistent with monomolecular kinetics and the temperature variation of the reaction rate constants agrees with the Arrhenius law. The rate constants K are listed in Table 5, which also includes the constants determined taking into account the monomer adsorption constants.

5. Some Problems of the Reactivity of Macroradicals

In the examination of the experimental data obtained[32,50] attention is drawn to the high activation energies for the reactions investigated compared with those for reactions in gas or liquid phases. Indeed the recombination of radicals in gas and liquid phases involves very low (virtually zero) activation energies. On the other hand, the activation energies found for macroradical destruction processes in solid polymers exceeds 20 kcal $mole^{-1}$. The reaction involving the removal of hydrogen by macroradicals may be compared with the chain transfer reaction in polymerisation. However, the activation energy for chain transfer in liquid-phase radical polymerisation of vinyl monomers is on average 10–15 kcal $mole^{-1}$, i.e. lower by a factor of more than two than the experimental activation energies for the reactions of macroradicals with cumene. The same may be said of the monomer addition reaction: the analogous chain growth reaction in polymerisation involves much smaller activation energies.

We shall now examine the problem of the absolute rate of destruction of macroradicals which should obtain on the basis of the radical state migration mechanism. For a free radical to be capable of removing a hydrogen atom from a neighbouring unit of the polymeric chain, it must first of all migrate over a distance δ separating it from this unit, i.e. on average over a distance of 3–5 Å (cross-sectional diameter of the polymeric chain). The time required for this is given by the formula

$$\tau = \tau_0 \exp(E_m/RT) \tag{14}$$

where E_m is the activation energy for the migration of the radical centre and the preexponential factor $\tau_0 = h/kT$ (h is the Planck constant, k the Boltzmann constant, and T the absolute temperature). Consequently, the frequency of the collisions of the given radical with hydrogen atoms is

$$\nu = \frac{1}{\tau} = = \frac{kT}{h} \exp(-E_m/RT). \tag{15}$$

However, each collision does not of course lead to the removal of hydrogen. The frequency of effective collisions, i.e. those which can lead to the removal of hydrogen atoms by the radical, is evidently

$$\nu_{eff} = \nu e^{\frac{-E_1 + S_1 T}{RT}} \tag{16}$$

where E_1 is the activation energy and S_1 the entropy of activation in the hydrogen removal reaction.

The average rate of movement of the radical centre is in this case

$$V = \delta \nu_{eff} = \delta \frac{kT}{h} e^{S_1/R} e^{-\frac{E_m + E_1}{RT}}. \tag{17}$$

Hence we find that the number of collisions of radical centres with each other per unit time is

$$N = V \sigma n^2 = \frac{\delta kT}{h} e^{S/R} e^{-\frac{E_m + E_1}{RT}} \sigma n^2 \tag{18}$$

where σ is the effective cross-section for the collision of two radical centres, and n the number of radical centres per unit volume. Knowing the number of collisions, we can express the rate of the bimolecular recombination or disproportionation reaction in the form

$$-\frac{dn}{dt} = N e^{S_2/R} e^{-E_2/RT} \tag{19}$$

where S_2 is the entropy of activation in the reaction of radicals with one another and E_2 the activation energy for this reaction. On combining Eqns. (18) and (19), we obtain finally

$$-\frac{dn}{dt} = A e^{\frac{S_1 + S_2}{R}} e^{-\frac{E_m + E_1 + E_2}{RT}} n^2. \tag{20}$$

Thus we see that the measured activation energy is the sum of the activation energies for three processes. In order to determine the activation energy for the intrinsic macroradical recombination process, it is necessary to subtract from the experimental value the activation energies for the migration of the radical centre and for the removal of hydrogen. The first of these energies probably does not differ markedly from the activation energy for the diffusion of low-molecular substances in polymers, say the monomer, i.e. is 13–15 kcal $mole^{-1}$. The activation energies for the removal of hydrogen should probably be the same as those for chain transfer in polymerisation, i.e. about 10–15 kcal $mole^{-1}$. Thus the sum of these two activation energies is 23–30 kcal $mole^{-1}$. We see that these values are very close to the experimental activation energies for the destruction of the initial hydrocarbon radicals. Hence follows the conclusion that the activation energy for the intrinsic macroradical recombination process is virtually zero, in complete agreement with all data on the recombination of radicals in gas and liquid phases.

It is readily seen that, for reactions of macroradicals with various reagents, the diffusion coefficients of the low-molecular reagents in the solid polymers should be included as multipliers in the rate constants for the reactions†. This is clear from the following considerations. Diffusion in solids is known[52] to be effected by successive jumps of the molecules (or atoms) between certain equilibrium positions. Suppose that the residence time of the molecules of the low-molecular reagent in an equilibrium position is τ and the distance between two neighbouring equilibrium positions is δ. Then the average rate of migration of these molecules is

$$\bar{u} = \delta/\tau \tag{21}$$

and the number of binary collisions of the reagent molecules with free radicals per second is

$$N = \bar{u} \sigma [R][C] \tag{22}$$

where σ is the effective collision cross-section and [R] and [C] are the concentrations of the radicals and the reagent molecules. According to Frenkel'[52], the diffusion coefficient can be expressed as follows in terms of δ and τ:

$$D = \frac{\delta^2}{\tau}. \tag{23}$$

† It must be emphasised that what is meant here is not the diffusion of these molecules from outside into the polymer but their thermal motion within the surface layer, which is so thin that the time required for the attainment in it of a steady-state concentration of the reacting molecules is much smaller than the reaction time.

From the last three equations, we obtain for the number of binary collisions the expression

$$N = A_1 D [R] [C]. \quad (24)$$

Hence the reaction rate constant can be written thus:

$$k = A_1 D e^{-\frac{\epsilon}{RT}} \quad (25)$$

where ϵ is the activation energy for the reaction. However, the diffusion coefficient D also depends on temperature:

$$D = D_0 e^{-\frac{E}{RT}}. \quad (26)$$

Here E is the activation energy for the diffusion process. On substituting Eqn. (26) in Eqn. (25), we obtain the final expression for the reaction rate constant:

$$k = A_2 e^{-\frac{E+\epsilon}{RT}}. \quad (27)$$

Thus the experimental activation energy is essentially the sum of the activation energies for the intrinsic reaction of the radical with the reagent molecule and for the diffusion of the latter. Table 6 presents the values for monomer addition reactions obtained by subtracting from the experimental activation energies (Table 5) the activation energies for the diffusion of the monomer in polymers.

It is seen that the activation energies thus obtained are very close to the values known for liquid-phase reactions. This is evidence in favour of the validity of the hypothesis concerning the effect of diffusion on the rate of reaction.

On the basis of the data presented, one may arrive at certain conclusions concerning the relative reactivity of macroradicals in oxidation, hydrogen removal, and double bond opening reactions. Data on the interaction of macroradicals with cumene and methyl methacrylate show that the activation energy is not a fully comprehensive characteristic of the reactivity of free radicals. The preexponential factor is often decisive.

From the standpoint of the theory of absolute reaction rates, the difference in the reactivities of radicals is explained by the difference in the free energies of the active complexes. The free energy, which comprises the energies of the atoms combined in the molecule minus the molecular entropy multiplied by the absolute temperature, can in fact serve as a true measure of the activity of a particular radical. It is by no means surprising that, on transition to the active-complex state, the number of degrees of freedom of a system consisting of a radical and molecule which it is attacking can change significantly, if only because such attack presupposes a highly specific mutual disposition of the two species. This means that there is also a marked change in the entropy of the system, i.e. ultimately considerable deviations of the preexponential factor from the value predicted by the collision theory are obtained. It is remarkable that a phenomenon similar to that described above is also observed in the usual radical polymerisation. Table 7 presents data on chain propagation rates in the polymerisation of certain vinyl monomers. The data were taken from Bengough and Melville[53].

TABLE 6.

Polymer	E, cal mole^{-1}
Poly(vinyl acetate)	11000±2000
Polystyrene	6800±1000

TABLE 7.

Monomer (T = 30°)	Rate constant, litre × mole^{-1} s^{-1}	E, kcal mole^{-1}	Preexponential factor $10^7 A$, litre × mole^{-1} s^{-1}
Vinyl acetate	1240	7.3	24.0
Styrene	55	7.8	2.2
Methyl methacrylate	143	6.1	0.5
Methyl acrylate	720	7.1	10.0

It is seen that, within the vinyl series alone, the absolute rates of chain propagation can vary by a factor as large as 25 (vinyl acetate–styrene). At the same time, the activation energies are almost identical. This implies that all the differences are due to the steric factor, i.e. the steric conditions which obtain when the macroradical approaches the monomeric molecule.

The macroradicals which have been investigated by the present authors can be arranged in the same activity series as regards the monomer addition and oxidation reactions: vinyl acetate, styrene, methyl methacrylate. In the reaction involving the removal of hydrogen from cumene the activity series changes, since styrene proves to be virtually inert at the temperatures investigated.

V. MACRORADICALS IN THE MECHANICAL DEGRADATION OF POLYMERS

In 1959 Bresler et al.[31] observed for the first time by the ESR method the free radicals which are generated in polymers on their mechanical breakdown. Subsequently this method of producing radicals in polymers was used by other workers[54,55]. The ESR study of the free radicals produced in the mechanical breakdown of polymers will undoubtedly play a major role in the elucidation of the physics of mechanical action on polymers themselves. Thus Zhurkov et al.[56] investigated the radicals produced on unidirectional compression of ebonite and their accumulation as deformation increases. When the deformation is relaxed, the number of radicals falls. The study of radicals produced on stretching Kapron‡ fibres[57] revealed a considerable similarity between the radical accumulation curves and the creep curves for the material, which indicates a relation between the creep and the number of ruptured chemical bonds.

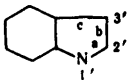
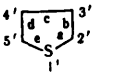
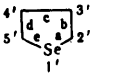
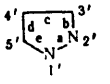
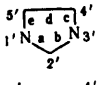
1. INTRODUCTION

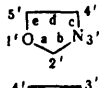


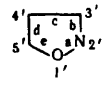


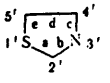


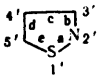


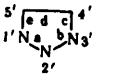


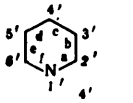


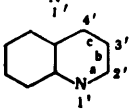


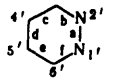


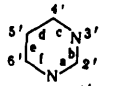


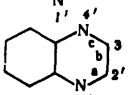


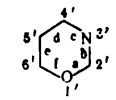


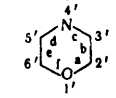


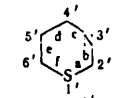


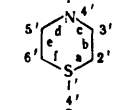


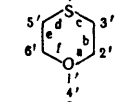


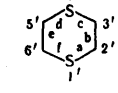


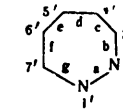


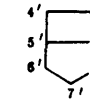


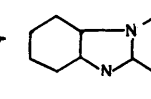


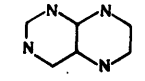








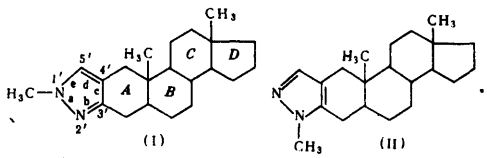




The study of structural modification of steroidal compounds, the scope of which is unequalled in any other branch of medical chemistry, has the aim of finding more active and more specific steroidal pharmaceutical preparations, free from harmful side action. Among the many known analogues of the steroids a special place is occupied by heterocyclic derivatives, the synthesis of which is linked with the hope of obtaining compounds which exhibit instead of the ordinary hormonal action completely different types of physiological activity — anabolic, anti-inflammatory, hypotensive, anti-tumour, etc.

The heterocyclic derivatives of steroids can be divided into two groups, the first of which includes compounds containing the heteroatom in the constitution of the cyclopentanoperhydrophenanthrene skeleton, and the second are the steroids with the normal carbon skeleton and heterocyclic substituents connected with it in some manner or other. The present review considers steroids of the second group which contain heterocyclic systems with N or S atoms condensed with the steroid skeleton and having not less than two C atoms in common with it. Only two brief reviews [1,2] have been published on this subject, and they do not adequately represent the experimental information that has been amassed.

At present there is no generally accepted nomenclature for heterocyclic derivatives of steroids. A simplified nomenclature is usually employed, with allowance for the steroidal nature of the compounds, since the rational nomenclature for condensed heterocyclic systems is much more complex. However, some authors take the steroid skeleton as the base component, others the heterocyclic ring. Thus, compound (I) is named [4,3-*b*]pyrazoloandrostane (as in the present review†), or pyrazolo[4,3-*b*]androstane, or, finally, androstano[3,2-*c*]pyrazole. In addition to the index of the bond, the mutual arrangement of the steroidal skeleton and the heterocycle can be denoted also by the numbers of the atoms; according to this system compound (I) can be named pyrazolo[3′,4′–3,2]androstane. There are also differences in the finer details of nomenclature. For example, in the Italian literature compound (I) is named as a derivative of 1′-methylandrostano[3,2-*c*]-pyrazole, but compound (II) as a derivative of 1′-methylandrostano[2,3-*d*]pyrazole [2]; at the same time most authors



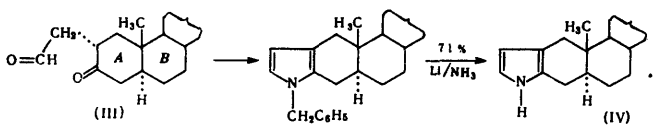
† There are, however, a number of errors and inconsistencies in the Russian text and therefore subsequently in this translation (i) the IUPAC method of denoting the manner of fusion by placing the numbers and letters *after* the designation of the attached component has been adopted and (ii) the compounds are referred to as steroido[...]heterocycles when the numbering in the Russian agrees with this system (Ed. of Translation).

TABLE 1. Types of heterocyclic derivatives of steroids.

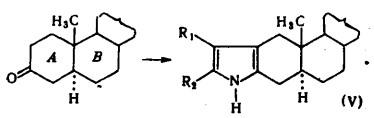
Name and formula of heterocycle	Atoms of the steroid skeleton in common with the condensed heterocycle
Five-membered heterocycles with one heteroatom	
1. Pyrrole 	1,10,9,11-, 2,3-, 3,4,5-*, 5,10,9-**, 6,5,10,19-*, 16,17-, 18,13, 17,20-*, 20,21-*
2. Indole 	2,3-, 3,4-
3. Thiophen 	4,5,6-, 5,10, 9-**
4. Selenophen 	6,5,10,19-*
Five-membered heterocycles with two heteroatoms	
5. Pyrazole 	1,2-**, 2,3-, 3,4-, 4,5-**, 15,16-, 16,17-, 16,17-**, 20,21-
6. Imidazole 	20,21-
7. Oxazole 	9,11-*, 20,21-**
8. Isoxazole 	2,3-, 2,3-**, 3,5,6-, 6,7-, 16,17,, 16, 17-**
9. Thiazole 	2,3-, 9,11-**, 11,12-, 16,17-, 20,21-, 22,23-
10. Isothiazole 	16,17-, 16, 17-**
Five-membered heterocycles with three heteroatoms	
11. Triazole 	2,3-
Six-membered heterocycles with one heteroatom	
Pyridine 	2,3-, 4,5,6-
13. Quinoline 	2,3-, 16,17-
Six-membered heterocycles with two heteroatoms	
14. Pyridazine 	2,3,4,5-**, 5,6,7,8-**
15. Pyrimidine 	2,3-, 2,3 **, 16,17-
16. Quinoxaline 	2,3-, 3,4-, 6,7-, 17,17a-, 20,21-
17. 1,3-Oxazine 	2,3-**, 3,4-**, 3,4,5-*
18. Morpholine 	3,4-**
19. 1,3-Thiazine 	1,9,10-**, 5,10,9-**
20. 1,4-Thiazine 	2,3-**
21. 1,4-Oxathiane 	2,3-**, 3,4-**
22. 1,4-Dithiane 	3,4-**
Seven-membered heterocycles*	
23. 1,2-Diazepine 	16,17-**
Condensed heterocyclic systems with several heteroatoms	
24. 1,2-Diazabicyclo-[3,2,0]heptane 	16,17-*
25. 1,9,11-Triaza-fluorene 	2,3-
26. Pteridine 	3,4-

* Fully hydrogenated heterocyclic system.
** Partly hydrogenated heterocyclic system.
*** Considered together with condensed heterocyclic systems in Section 7.

keep the same designation of the skeleton for (I) and (II), naming (II) as a derivative of 2′-methylandrostano[3,2-*c*]-pyrazole:

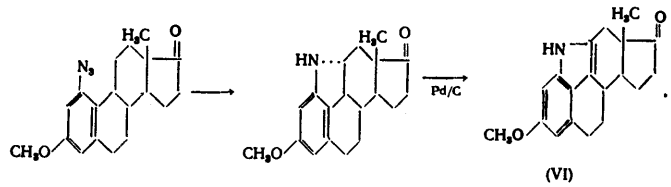


The numbering of the heterocycles adopted in the present review is shown in Table 1, in which are collected the types of heterocyclic derivatives of steroids known at present‡.

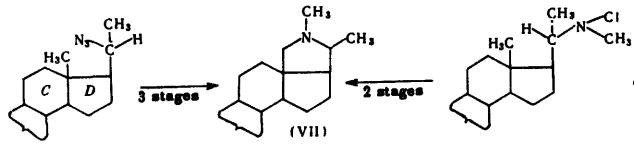


2. FIVE-MEMBERED HETEROCYCLES WITH ONE HETEROATOM

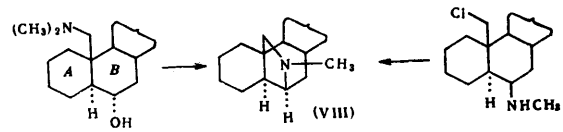
This section deals with the steroidal derivatives of pyrrole, indole, thiophen, and selenophen.



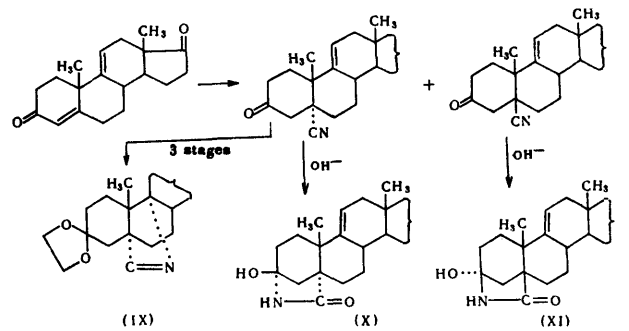
Steroids containing a pyrrole ring can be obtained by a great variety of methods. For example, three synthesis paths for steroido[3,2-*b*]pyrroles are known. The first of these consists of a Knorr cyclisation of γ-keto-aldehydes of the androstane series (III) with benzylamine; when the 1′-benzyl derivatives thus formed are reductively debenzylated, the unsubstituted androstano[3,2-*b*]pyrroles (IV) are obtained[6]:



Condensation of 3-ketosteroids of the cholestane series with ethoxyiminoacetoacetate in the presence of zinc and acetic acid gives steroido[3,2-*b*]pyrroles of the type (V; $R_1 = CH_3$, $R_2 = CO_2C_2H_5$)§. Finally, in the patent literature[8] there is a description of a third method of making such compounds, by the reaction of 3-ketosteroids of the androstane series with α-aminoaldehydes or α-amino-ketones of the general formula $R_2CH(NH_2)COR_1$, where R_1 and R_2 are hydrogen or a lower alkyl radical. The reaction takes place in ethanol under the action of metallic sodium and leads to the corresponding androstano[3,2-*b*]pyrroles of type (V):

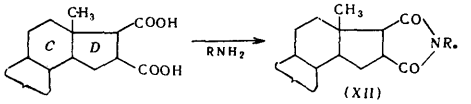


One of the methods of synthesis of partly or fully reduced pyrrolosteroids is thermal or photochemical cyclisation of azido-derivatives. Thus, the methyl ether of 1-azido-oestrone forms the 1,11α-imino-derivative on heating in n-hexadecane; the dehydrogenation of the latter leads to compound (VI), which can be considered as a derivative of pyrrole, having the atoms C_1, C_{10}, C_9, and C_{11} in common with the steroidal skeleton[9]:



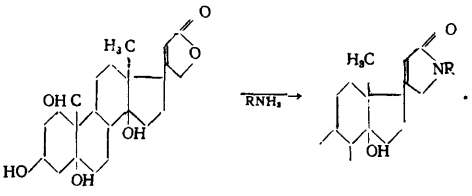
Derivatives of 1′-methylsteroidopyrrolidines (VII) can also be obtained by photolysis of 20β-azidosteroids followed by reduction with $LiAlH_4$ and *N*-methylation[10]. Another method of synthesising such compounds starts from 20α-(*N*-chloro-*N*-methylamino)steroids, which are converted into (VII) by photolysis in acid medium followed by cyclisation under the action of bases[11-14]:

Pyrrolidine derivatives of type (VIII) are also obtained by two paths — in the successive treatment of 19-dimethylamino-6α-hydroxysteroids with $CH_3C_6H_4COCl$, KI, and $LiAlH_4$ [15] and in the action of alkali on 19-chloro-6β-methylaminosteroids, which, in turn, are formed in the photolysis of 6β-*N*-chloro-*N*-methylamino-derivatives in H_2SO_4:[16]



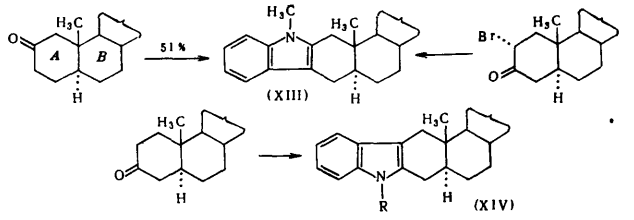
Derivatives of the steroido[3,4,5-*bc*]pyrrolidines (X) and (XI) are formed in the cyclisation by alkalis of 5α- and 5β-cyanosteroids, which are the products of the addition of HCN to Δ^4-3-ketosteroids[17,18]. When the initial steroid has $\Delta^{9(11)}$-bonds (as in the example quoted), the protection of the keto-group of the 5α-cyanosteroid by formation of the ethylene ketal, reduction of the cyano-group by $LiAlH_4$ to an imino-group, and cyclisation under the action of Al_2O_3 leads to a steroido[9,10,5-*bc*]pyrroline (IX):[17]

‡ This review does not deal with steroidal alkaloids of the conessine group, which contain a pyrrole ring, nor those of the solanidine group, which contain the quinolizine system, since their chemistry is considered in detail in corresponding monographs.[3-5]

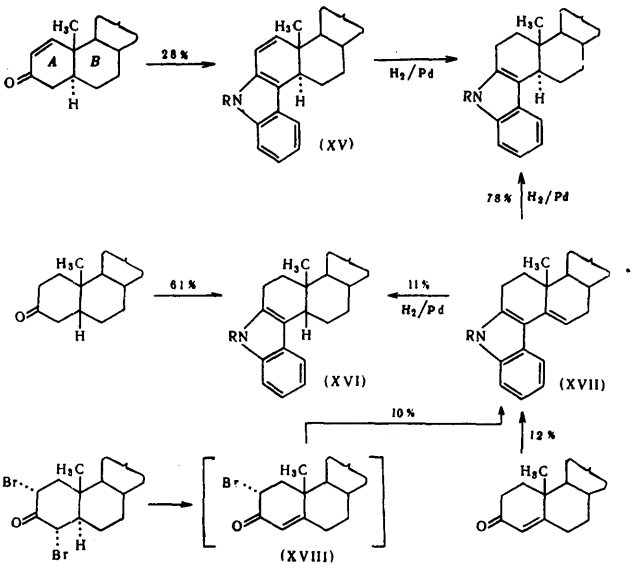


§ Derivatives of 5′-ethoxycarbonyl-4′-methylandrostano-[17,16-*b*]pyrrole were obtained in low yields from 17-ketosteroids by the same method.[7]

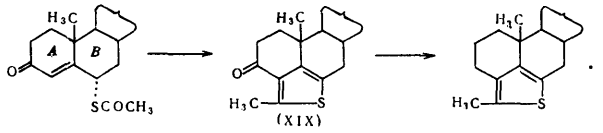
The cyclic imides of the 16β,17β-dicarboxysteroids (XII; R = H, alkyl, C_6H_5) are derivatives of androstano[16,17-*c*]-pyrrolidine. These compounds are active as antiepileptic agents and as depressants of the central nervous system [19]:



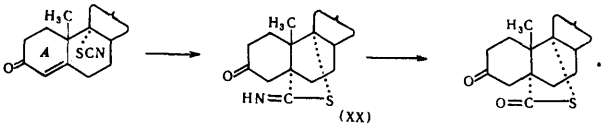
(XII)



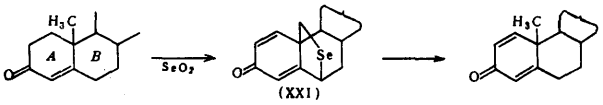
The products of the reaction of strophanthidin with primary and secondary amines can be classified among the pyrrolosteroids; these compounds not only retain the original cardiotonic activity of strophanthidin, but, unlike it, are active when introduced orally [20-22]:



Indole derivatives condensed with the steroidal skeleton in positions 2 and 3 are formed by two methods. The first of these — a Fischer reaction with *N*-methyl-*N*-phenylhydrazine — allows 1′-methylcholestano[2,3-*b*]-indole (XIII) to be obtained from 2-ketocholestane. The same product was also obtained by the second method — by the reaction of 2α-bromocholestan-3-one with *N*-methylaniline [23]. Since the Fischer reaction usually proceeds in the direction of enolisation of the original ketones, when the 3-keto-5α-steroids of the cholestane, cholane, and androstane series react with phenylhydrazine or its *N*-methyl derivative, indolo[3,2-*b*]steroids (XIV; R = H, CH_3) are formed, isomeric to compounds of the type (XIII): [7,8,23-28]



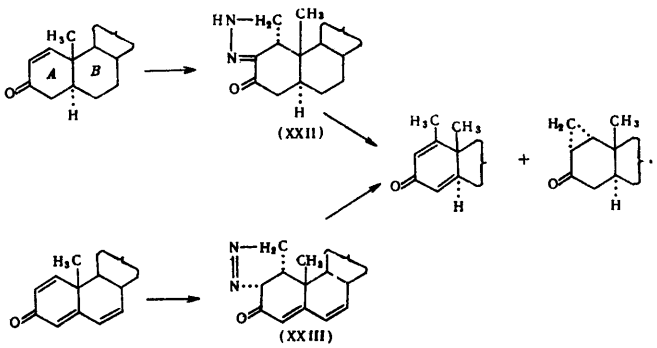
The steroido[3,4-*b*]indoles (XV)–(XVII) are formed from 3-keto-5β-cholestanes and also Δ[1]-3-keto- and Δ[4]-3-keto-cholestanes on reaction with phenylhydrazine and its α-methyl derivative (the yields shown on the scheme are for R = CH_3). [23-27] The catalytic hydrogenation of the Δ[5]-bond of the steroidoindole (XVII) leads to a mixture of the 5α- and 5β-derivatives in the ratio 7 : 1; [23] the same products are obtained by counter-synthesis from other 3-ketosteroids. Compound (XVII) is formed in low yield also on heating a mixture of 2α,4α-dibromocholestan-3-one and dimethylaniline to 200°. [28,29] The mechanism of the conversion apparently involves the reaction of the intermediate product 2α-bromo-Δ[4]-3-ketone (XVIII) with *N*-methylaniline, which is obtained *in situ* by partial demethylation of the dimethylaniline.



The [6,5,4-*bc*]steroid derivatives of thiophen (XIX) are formed in the chromatography of the 6α-thioacetates of Δ[4]-3-ketosteroids of the androstane, pregnane, and cholestane series on alkaline Al_2O_3. The Huang–Minlon reduction of compounds of type (XIX) give analogues without a keto-group. The thiophen derivatives of testosterone and progesterone are devoid of the usual hormonal activity [30,31]:

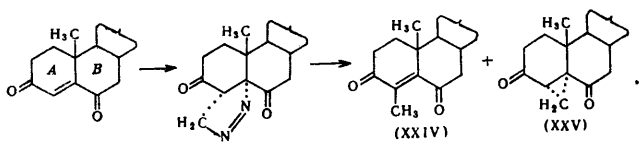
The imidothioethers (XX) formed in the electrolytic reduction of 9α-thiocyanatocortisol or its 17-keto-analogue, can also be considered as reduced analogues of thiophen. Hydrolysis of (XX) leads to the corresponding thiolactones [17,32]:

In the dehydrogenation of Δ[4]-3-ketosteroids by selenium dioxide, steroidal derivatives of selenophen (XXI) are formed as side-products. On treatment with Raney nickel they are converted into Δ[1,4]-3-ketosteroids [33]:



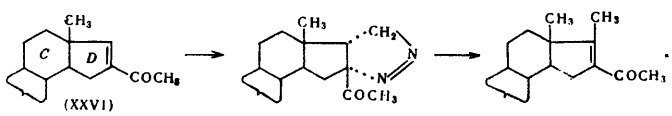
3. FIVE-MEMBERED HETEROCYCLES WITH TWO HETEROATOMS

This group of heterocyclic derivatives of steroids includes compounds which contain pyrazole, imidazole, oxazole, isoxazole, thiazole, or isothiazole rings, and also cyclic ketals of hydroxymercapto- and dimercapto-steroids.

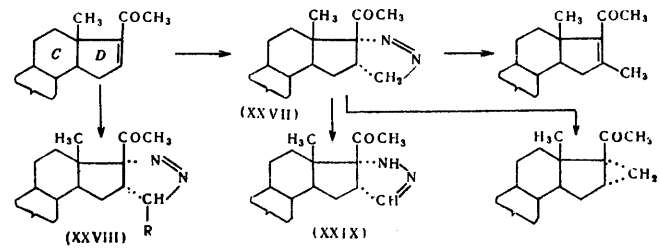


Of these compounds, the pyrazole derivatives are of the most importance practically, owing to their high physiological activity. There are two main methods used at present for the preparation of the steroidal derivatives of pyrazole. The first of these consists of the addition of a diazo-compound to the C=C double bond of unsaturated ketones and leads to steroidopyrazolines. The second method, which allows heteroaromatic steroidopyrazolines to be obtained, consists in the action of hydrazine derivatives on 1,3-dicarbonyl compounds of the steroid series.

The addition of diazoalkanes and diazoacetic ester to unsaturated steroidal ketones proceeds with a high yield (70–90%). The steroidopyrazolines obtained have no interest themselves as physiologically active compounds, but are used as intermediates in the preparation of alkylsteroids.

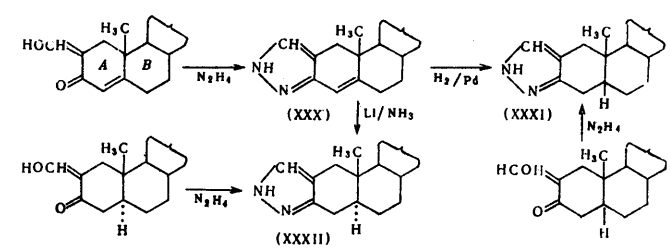


When Δ^1-3-ketosteroids of the androstane and pregnane series react with diazomethane, $\Delta^{2'}$-pyrazoline derivatives (XXII) are formed[34-39], and when $\Delta^{1,4,6}$-3-ketosteroids react, the isomeric or $\Delta^{1'}$-derivatives (XXIII).[35] Pyrolysis or acidolysis of the pyrazolines of both types leads to mixtures of the 1-methyl and 1α,2α-methylene derivatives, the ratio of which depend on the reaction conditions.

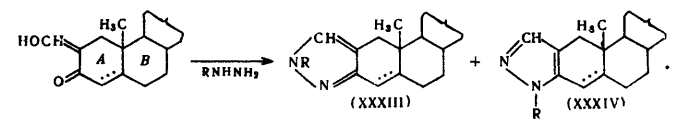


The action of diazomethane on cholest-4-en-3,6-dione leads to a pyrazoline, in the pyrolytic decomposition of which a 4-methyl derivative (XXIV) is formed, and in photolysis, a mixture of equal amounts of (XXIV) and the 4α,5α-methylene derivative (XXV):[40,41]

The 16-acetyl-Δ^{16}-steroids (XXVI) add on diazomethane at the Δ^{16}-bond, with the formation of the [17,16-*c*]pyrazoline, which forms a 17-methyl derivative on pyrolysis[42]:

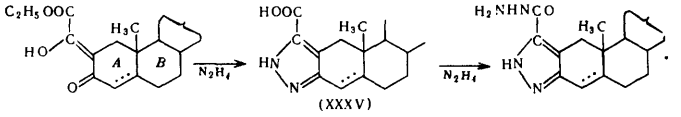


The Δ^{16}-20-ketopregnanes which are isomeric with (XXVI) react with diazomethane to form pyrazolines of the type of (XXVII), which on splitting under different conditions give mixtures of 16-methyl- and 16α,17α-methylene-steroids; the isomerisation of (XXVII) with BF_3 in dimethylformamide leads to the $\Delta^{5'}$-pyrazoline (XXIX).[35,43-51] The addition at the Δ^{16}-bond of diazoethane or diazoacetic ester with the formation of the corresponding 5'-substituted pyrazolines (XXVIII; R = CH_3, $CO_2C_2H_5$) has also been described[52,53]:

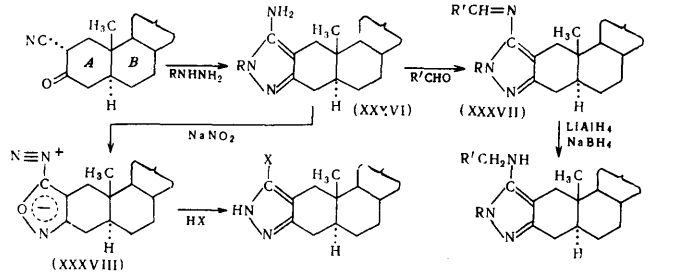


Pyrazole derivatives are usually obtained by the action of hydrazine and its analogues on hydroxymethylene or oxalyl derivatives of steroidal ketones; in individual instances cyano- and epoxy-ketones of the steroid series were also used as starting materials.

The reaction of 2-hydroxymethylene-3-ketosteroids, and also of their Δ^4- and $\Delta^{4,6}$-analogues, with hydrazine hydrate in ethanol or acetic acid leads to the formation of steroido-[3,2-*c*]pyrazoles (XXX)–(XXXII). The yields of the products usually exceed 60% and in isolated instances reach 90–95%. This method has been used to obtain pyrazole derivatives of oestrane and androstane[54-73], pregnane[61,74-81], and also cholestane and stigmastane[55,61]. Catalytic hydrogenation of the Δ^4-bond of compound (XXX) leads to 5β-dihydro-derivative (XXXI),[55,61] and Birch reduction to the 5α-isomer (XXXII);[82] in both instances the reduction does not affect the pyrazole ring.

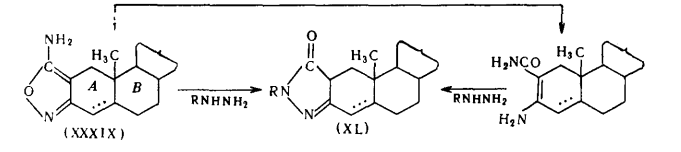


Both 1'-substituted (XXXIII) and 2'-substituted (XXXIV) steroidopyrazoles can evidently be formed when 2-hydroxymethylene-3-ketosteroids react with hydrazine homologues. Since in the alkylhydrazines the substituted nitrogen atom is more nucleophilic, when R = CH_3 the preferential formation of the isomer (XXXIII), which was also obtained in predominant amount from Δ^4-3-ketosteroids and exclusively from 3-keto-5α-steroids[2,54,57,74,83], is to be expected. With phenylhydrazine and its *p*-substituted derivatives a nitrogen atom in the β position to the phenyl group is more nucleophilic; therefore in the given instance formation of the isomer (XXXIV; R = C_6H_5) occurs preferentially or exclusively[54,74,79,84-87]:



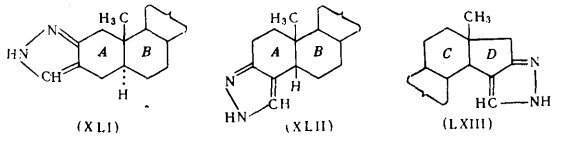
With hydrazine hydrate, 3-keto-2-oxalylsteroids form 5'-carboxypyrazoles (XXXV), the further reaction of which with hydrazine leads to the corresponding hydrazides[57,88]. In the patent literature[89] there is also a description of the

production from 3-keto-2-trifluoroacetylsteroids of the analogues (XXXV), which contain a trifluoromethyl group instead of a carboxyl group:

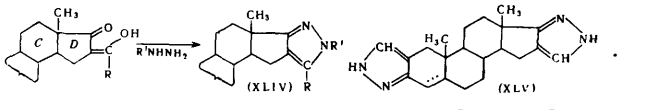


(XXXV)

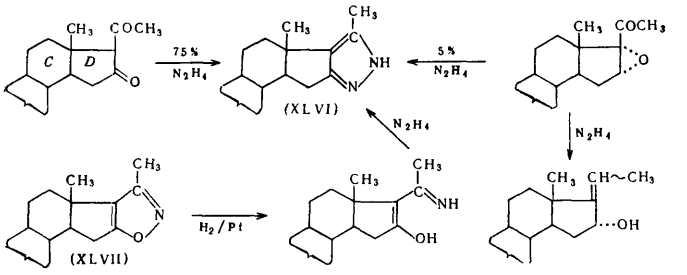
On heating 2α-cyano-3-ketosteroids with hydrazine and its derivatives, 5′-aminosteroido[3,2-*c*]pyrazoles (XXXVI; R = H, CH_3, C_6H_5) were obtained. With aldehydes they form the corresponding Schiff bases (XXXVII; R′ = H, CH_3, C_2H_5, C_6H_5), the reduction of which by complex metal hydrides leads to 5′-monoamino-substituted pyrazoles. Diazotisation of 5′-aminopyrazoles (XXXVI; R = H) in aqueous medium leads to the diazopyrazoles (XXXVIII), the diazo-group of which is capable of being replaced by halogen with the formation of 5′-bromo- and 5′-iodo-derivatives [2,57]



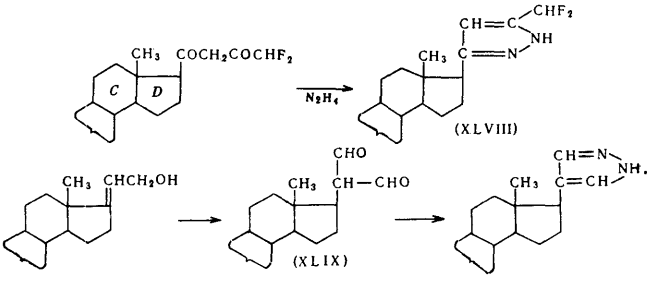
(XXXVIII)



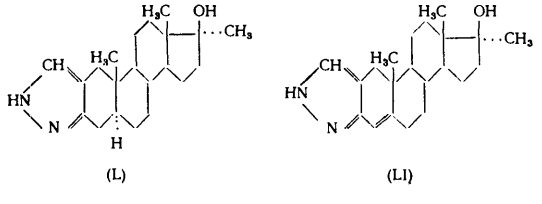
Steroidal pyrazolones of type (XL) can be obtained by two methods, by the reaction of hydrazine with 5′-aminosteroido[3,2-*c*]isoxazoles (XXXIX) or with the unsaturated β-aminocarboxamides obtained from (XXXIX) on catalytic hydrogenation [2]:



The reaction of hydrazine hydrate with 3-hydroxymethylene-2-keto- [90], 4-hydroxymethylene-3-keto- [55,61], and 15-hydroxymethylene-16-keto- [2] steroids leads respectively to steroido[2,3-*c*]- (XLI), [3,4-*c*]- (XLII), and [16,15-*c*]- (XLIII) pyrazoles:

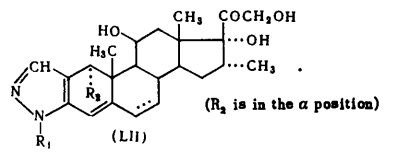


The condensation of hydrazine and its analogues with 16-hydroxymethyl- or 16-ethoxy-allyl derivatives of the 17-keto-steroids of the androstane or oestrane series leads to steroido[17,16-*c*]pyrazoles (XLIV; R = H, $CO_2C_2H_5$; R′ = H, CH_3) in 50–70% yields [91–94]. In the formation of 3,17-diketones with subsequent treatment with hydrazine, steroido[3,2-*c*:17′,16′-*c*]dipyrazoles (XLV) were obtained [2,83,95]:



The derivatives of the 5′-methylsteroido[16,17-*c*]pyrazole (XLVI), which are isomeric with (XLIV), are formed in the reaction of 16,20-diketopregnanes with hydrazine hydrate [96–98] and as a side-product in the Huang-Minlon reduction of 16α,17α-epoxy-20-ketosteroids [99–101]; in the latter instance, the main product of the reaction is a mixture of the *cis*- and *trans*-isomers of 16α-hydroxy-$\Delta^{17(20)}$--compounds. [16,17-*c*]Pyrazoles saturated in ring A were also obtained from steroido[17,16-*d*]isoxazoles (XLVII) by the catalytic hydrogenation of the latter and reaction of the ketimines thus formed with hydrazine hydrate [102]:

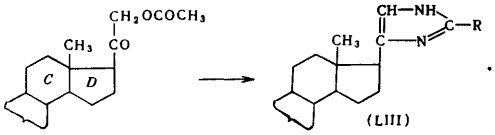
Pyrazole derivatives condensed with the steroids in positions 20 and 21 were obtained by two methods. The reaction of the 21-difluoroacetyl derivative of hydroxypregnenone with hydrazine led to the 5′-difluoromethyl-[20,21-*c*]pyrazole (XLVIII). [89] The isomeric pyrazolo-[20,21-*d*] derivative is formed by the action of hydrazine on the dialdehyde (XLIX), which is obtained in six stages from $\Delta^{17(20)}$-21-hydroxysteroid [103]:



Stercido[3,2-*c*]pyrazoles of the androstane and pregnane series exhibit extremely interesting physiological activity. In the androstane series the introduction of the pyrazole grouping allows the androgenic and anabolic activities to be separated. Thus the ratio of anabolic and androgenic activities of the pyrazolo[3,2-*c*] derivatives of 4,5α-dihydro--17-methyltestosterone (L) is 120 times greater than for 17α-methyltestosterone [54]. The high value of pyrazoloandrostanes as anabolic agents is also confirmed by the results of clinical tests [34,104–110] Compounds (L) (Stanozolole, Androstanazole) and (LI) (Oxystenazole) are now manufactured on an industrial scale for use as oral anabolitics:

The introduction of electron-withdrawing substituents (CO_2H, $CONHNH_2$) into the 5′ position of the pyrazole ring

lowers the anabolic activity in comparison with the unsubstituted compounds and with analogues with 5′ electron--donating substituents (CH_3, NH_2).[2] With the unsaturated Δ^4- and $\Delta^{4,6}$-derivatives, with a fall in the anabolic activity the appearance of significant oestrogenic activity was noted[54,60,111]. The introduction of 6α-CH_3, 7α-$SCOCH_3$, or 9α-F-11β-OH groupings into the steroidal nucleus of pyrazoloandrostanes sharply reduces the anabolic activity, which is the exact opposite to the unsubstituted androstanes, in which such substitution increases the activity[54,62].

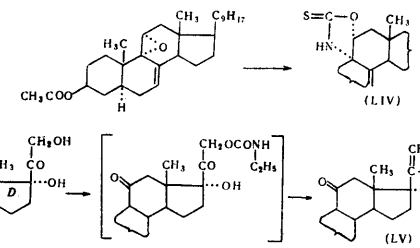


Derivatives of corticosteroids with [3,2-*c*]pyrazole rings with 2′-aryl substituents (LII) are the most active of the known anti-inflammatory agents, hundreds and even thousands of times more active than cortisol (Table 2). The activity is increased on the introduction of *p*-fluoro-substituent into the 2′-phenyl nucleus and reduced by the introduction of any other substituent. The isomeric 1′-phenylpyrazoles are of low activity. It is very important that the increase in anti-inflammatory activity on the introduction of the pyrazole ring is not accompanied by an increase in the mineralocorticoidal activity[74,84-86,112].

(LII)

Unlike the steroido[3,2-*c*]pyrazoles, the derivatives of oestrane and androstane (XLIV) and (XLVI) with pyrazole rings in positions 16 and 17 are almost completely devoid of oestrogenic and androgenic activity. At the same time these derivatives retain the hypocholesterolemic and, to some extent, the anabolic activity of the original compounds[91-93,97].

The [20,21-*d*] derivatives of imidazole (LIII) were obtained by the reaction of 21-acetoxy-20-ketopregnanes with $Cu(OCOCH_3)_2$, NH_3, and CH_2O in ethanol, with subsequent decomposition of the copper salt formed by hydrogen sulphide. Use of acetaldehyde or benzaldehyde instead of formaldehyde allows the corresponding 2′-substituted imidazoles (LIII; R = CH_3, C_6H_5) to be obtained[113]. It has been shown[114] that these compounds reduce the blood pressure. The hypotensive activity decreases on alkylation of the imidazole ring and the introduction of oxygen substituents in position 11:



(LIII)

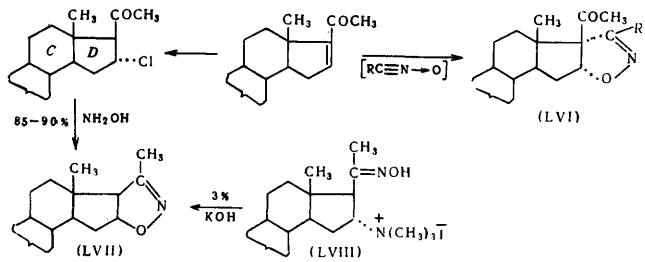


TABLE 2. Anti-inflammatory activity of steroido[3,2-*c*]pyrazoles of type (LII) in a test on the suppression of granuloma.[74,84-86,112]

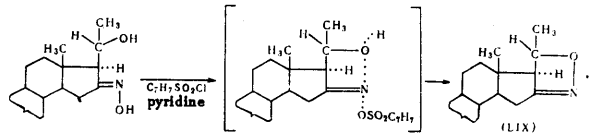
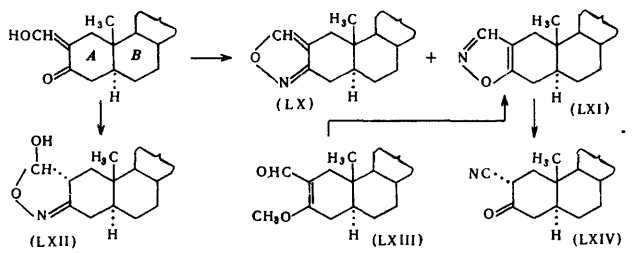
Substituent			Anti-inflammatory activity (control = 1)
R_1	R_2	presence (+) or absence (−) of Δ^1-bond	
H	F	−	10
p-ClC_6H_4	H	−	15
C_6H_5	H	−	60
p-FC_6H_4	H	−	100
2,4-$F_2C_6H_4$	H	+	115
p-FC_6H_4	F	−	500
p-FC_6H_4	H	+	600
C_6H_5	F	+	2000

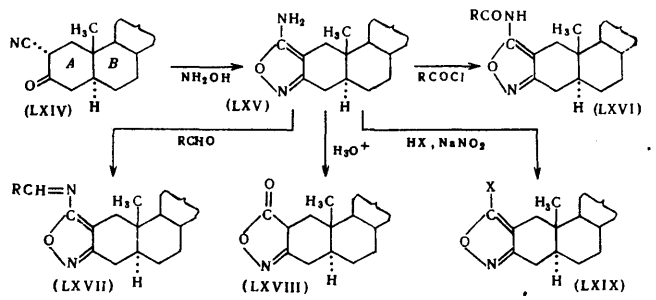


Steroidal derivatives containing a partly or completely hydrogenated oxazole ring have as yet been obtained in only two instances. The action of thiocyanic acid in ether on 9α,11α-epoxide of the ergostane series leads to a [9,11-*d*] derivative of oxazolidine (LIV); its formation apparently includes the anomalous *cis*-9α,11α-opening of the epoxide ring[115]. In the reaction of prednisone with ethyl isocyanate, instead of the expected 21-carbamate a product of its cyclisation was obtained, the [20,21-*d*]oxazolidone (LV):[116]

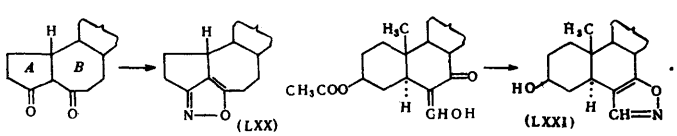
Derivatives of isoxazole have been studied much more. Three methods of synthesis are known for partly reduced derivatives. 3′-Methylandrostano[17,16-*d*]isoxazolines (LVII) are formed in high yield in the formation of oximes of 3β-acetoxy-16α-chloropregnenone and with low yield in the treatment of the trimethylammonium iodide derivative (LVIII) with alkali[117]. The reaction of Δ^{16}-20--ketopregnanes with nitryl oxides formed *in situ* by the treatment of the hydrochlorides of hydroxamic acids with triethylamine, gave, as a result of 1,3-dipolar addition, pregnano[17,16-*d*]isoxazolines (LVI; R = CH_3, C_6H_5) in 50–95% yields[118]:



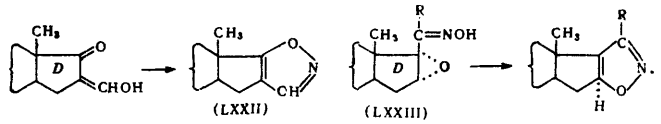
Under Beckmann rearrangement conditions, the oximes of 16-keto-20α-hydroxysteroids yield 5′-methylandrostano-[16,17-*c*]isoxazolines (LIX). The most probable mechanism is cyclisation from the anti-forms of the initial oxime with retention of the $C_{(20)}$ configuration[119]:



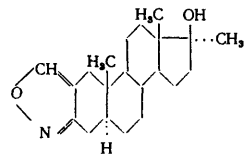
The principal starting materials for obtaining heteroaromatic isoxazolosteroids are the oxymethylene-, cyano-, and epoxy-ketones of the steroid series. Reaction of 2-hydroxymethylene-3-ketosteroids with hydroxylamine leads to a mixture of steroido[3,2-*c*] (LX) and [2,3-*d*] (LXI) isoxazoles[57-59,120-128]. When the reaction is carried out under mild conditions, in addition to these products up to 15% of 5′-hydroxy[3,2-*c*]-2′-isoxazolines (LXII) are formed, which are converted into (LX) on heating with acetic anhydride[124,129]. The ratio of (LX) to (LXI) depends on the pH, the solvent, and temperature. Thus when it is carried out in aqueous alcohol, 8% (LX) and 82% (LXI) are obtained, but in pyridine solution the composition of the



mixture is the reverse — 91% (LX) and 6% (LXI).[123,124] The reaction of Δ^4-, $\Delta^{4,6}$-, and 4,4-dimethylsteroids leads exclusively to [2,3-*d*]isoxazoles (LXI).[58,120,122,124] The same products are also formed from methoxy-derivatives of type (LXIII).[72] On treating the reaction products with sodium methoxide the [3,2-*c*] derivatives (LX) remain unchanged, but the [2,3-*d*] derivatives are converted into 2α-cyano-3-ketosteroids (LXIV).[57,122-125] This reaction allows mixtures of (LX) and (LXI) to be separated, and also serves as a convenient preparative method for the synthesis of 2α-cyanosteroids (LXIV):

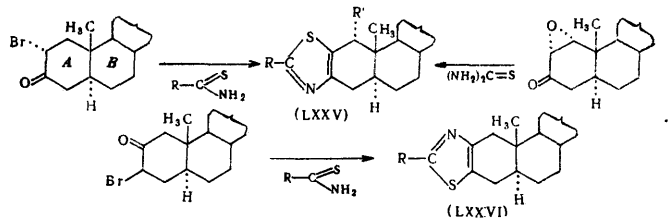


In an analogous manner to the above synthesis of 5'-aminopyrazoles, the reaction of (LXIV) with $NH_2OH.HCl$ in pyridine leads to 5'-amino[3,2-*c*]isoxazoles (LXV).[57] The 5'-amino-group of compound (LXV) is easily acylated by acyl chlorides and by ethyl chlorocarbonate with the formation of the corresponding acylates (LXVI; R = alkyl) and urethanes (LXIV; R = OC_2H_5).[2] Condensation with aldehydes gives Schiff bases (LXVII), which are reduced by sodium tetrahydroborate to the corresponding 5'-alkylamino-derivatives. On hydrolysis of (LXV) with mineral acids, deamination occurs with formation of the 5'-isoxazolones (LXVIII) but diazotisation in HCl or HBr allows the corresponding halo-derivatives to be obtained (LXIX).[2] The derivatives of 5'-aminoisoxazole are used as intermediates for the synthesis of other heterocycles — mainly analogues of pyrazole and pyrimidine.

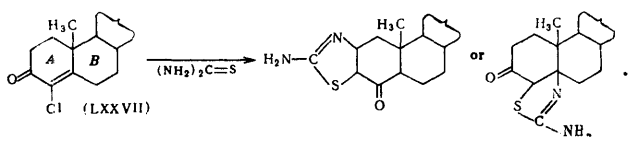


The 3,6-diketo-derivatives of A-nor-B-homo-oestrane react with hydroxylamine to form [3,5,6-*cd*]isoxazoles (LXX) which exhibit anabolic activity[130,131]. Under the same conditions 6-hydroxymethylene-7-ketocholestanol gave a [6,7-*d*]isoxazole derivative (LXXI):[120]

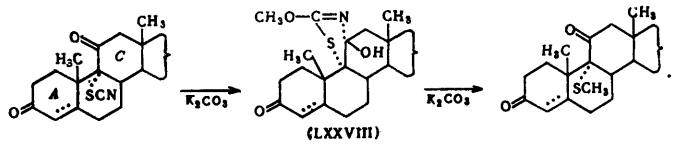
The action of hydroxylamine on 16-hydroxymethylene--17-ketosteroids of the androstane and oestrane allows [16,17-*d*]isoxazoles (LXXII) to be obtained[132]. Their isomers, the [17,16-*d*]isoxazoles, are formed in the dehydration of oximes of the (LXXIII; R = CH_3, C_6H_5) type with $POCl_3$ in pyridine[133]:



The introduction of the isoxazole grouping in the 2,3-position of androstane leads to an increase in the anabolic and a reduction in the androgenic activity. The [2,3-*d*] isomers are the more active in this. The introduction of Δ^4- and Δ^6-bonds, and also of 3'-alkyl, 4,4-dimethyl, and 6α-methyl substituents lowers both forms of activity[34,124]. Results have been obtained[58,120] on the presence of antitumour activity in the Δ^4-androstano[2,3-*d*]isoxazoles. Unlike the pyrazolosteroids, the isoxazolo[2,3-*d*] derivatives of the corticosteroids are devoid of hormonal activity[122]. Compound (LXXIV) has found practical application as an anabolic agent under the name of "Androisoxazole"[134-138]:

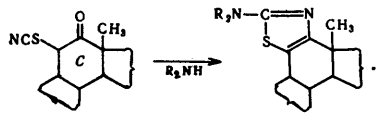


(LXXIV)

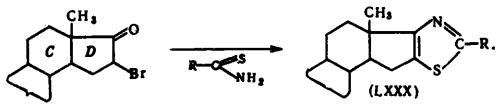


The [3,2-*d*] derivatives of thiazole are formed on boiling alcoholic solutions of 2α-bromo-3-ketosteroids of the androstane, pregnane, and cholestane series with thiourea and its *N*-alkyl derivatives[7,139-143], and also with thioamides[122,140,144-146]. In the first instance 2'-alkylaminothiazolosteroids (LXXV; R = NH_2, $NHCH_2CH{=}CH_2$, NHC_6H_5; R' = H) were obtained in 30–80% yields and in the second 2'-alkylthiazolosteroids (LXXV; R = H, CH_3; R' = = H) in 20–50% yields. 1α-Hydroxy-derivatives (LXXV; R = NR_2; R' = OH) are formed by the action of thiourea on 1α,2α-epoxy-3-ketopregnanes[147]. Reaction of 3β-bromo--2-ketosteroids with thioamides gave the isomeric (LXXV) [2,3-*d*]thiazole derivatives (LXXVI; R = H, CH_3, C_6H_5).[148] High anabolic and low androgenic activity has been noted for both types of derivative in the androstane series[145,148], and in the pregnane series there is anti-inflammatory activity[147].

Androstane derivatives of 2'-aminothiazole were also obtained in the treatment of 4-chloro-Δ^4-3-ketosteroids (LXXVII) with thiourea in alkaline medium; but it was not shown whether the compounds possessed [2,3-*d*] or [4,5-*d*] structures[139]:

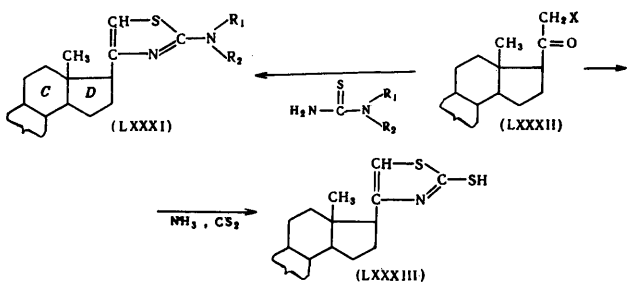


The 9α-thiocyano-derivatives of adrenosterone and cortisone are converted into 2′-methoxysteroido[11,9-*d*]thiazolines (LXXVIII) in 50–70% yields by the action of a solution of potassium carbonate in aqueous methanol at room temperature. Boiling with potassium carbonate solution allows (LXXVIII) to be converted into the 9α-methylthio-derivatives in 35–50% yields. When there are Δ^1- or Δ^4-bonds in the molecule, boiling a solution of (LXXVIII) in methanol leads to isomerisation into thiazine derivatives (see below)[149,150]:



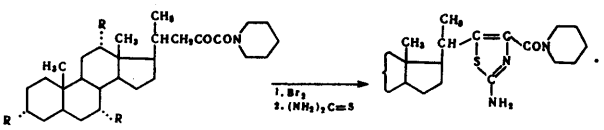
(LXXVIII)

The reaction of 12-keto-11β-thiocyanosteroids of the cholane and spirostane series with secondary amines in dioxan leads to 2′-piperidinosteroido[12,11-*d*]thiazoles (LXXIX) or the corresponding 2′-morpholino-, 2′-piperazino-, and 2′-diethylamino-derivatives. The compounds obtained exhibit antihormonal activity[151,152]:



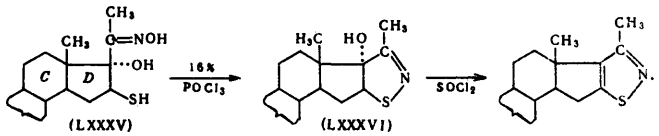
(LXXIX)

On heating 16β-bromo-17-ketosteroids with thioacetamide or thiourea in ethanol, 2′-substituted [17,16-*d*]thiazole derivatives (LXXX; R = CH_3, NH_2) are obtained[153,154]:



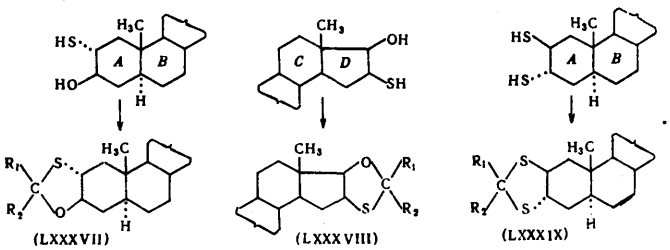
(LXXX)

2′-Aminosteroido[20,21-*d*]thiazoles (LXXXI) are formed in the condensation of thiourea and its *N*-alkyl derivatives with 21-substituted 20-ketopregnanes (LXXXII; X = Cl, I, OH, OSO_2CH_3, $OSO_2C_6H_4CH_3$). When X = I the yields reach 80–100%, but when X = $OSO_2C_6H_4CH_3$ they do not exceed 35–60%.[155-160] The reaction of (LXXXII; X = Cl) with ammonia and carbon disulphide in ethanol leads to a 2′-mercapto-derivative (LXXXIII).[161] The products obtained are cardiotonic media with a toxicity lower than for the heart aglycones[155,126].



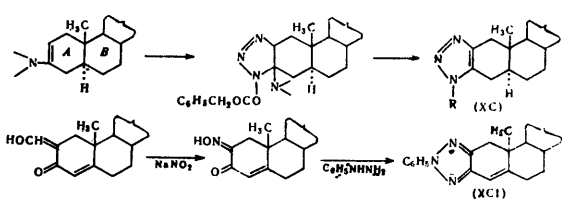
(LXXXI) (LXXXII) (LXXXIII)

The last group of thiazolosteroids — [23,22-*d*]thiazole derivatives — was obtained on successive bromination and treatment with thiourea of the piperidylamides of 23-ketocholanic acids (LXXXIV; R = H, $OCOCH_3$):[162]



The Beckmann rearrangement of the oxime (LXXXV) under the action of $POCl_3$ in pyridine gives compound (LXXXVI), dehydration of which leads to a derivative of androstano[17,16-*d*]isothiazole[153,163,164]. This reaction is still the sole example of the synthesis of steroid derivatives of isothiazole:

(LXXXV) (LXXXVI)

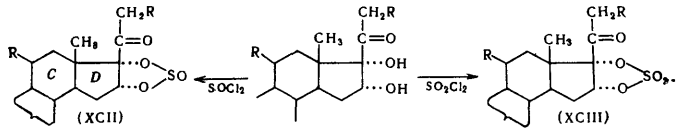


In this section mention must also be made of the preparation of heterocyclic derivatives of the androstane and cholestane series (LXXXVII)–(LXXXIX) by the reaction of vicinal hydroxymercapto- and dimercapto-steroids with aldehydes and ketones[165-169]:

(LXXXVII) (LXXXVIII) (LXXXIX)

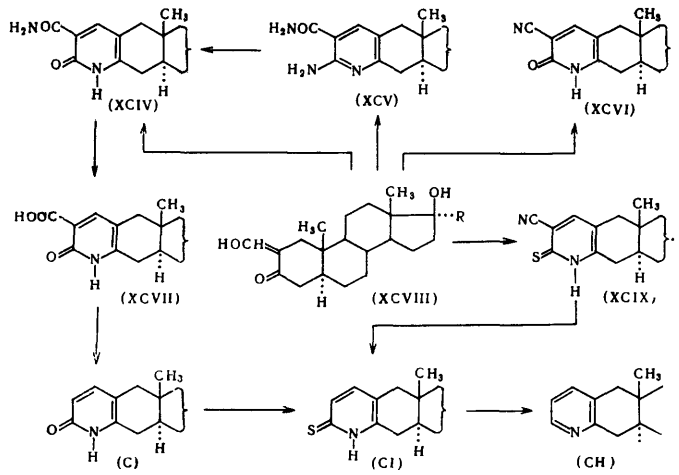
4. FIVE-MEMBERED HETEROCYCLES WITH THREE HETEROATOMS

Derivatives of triazole condensed with ring A of the steroidal system have been synthesised by two methods. According to the first of these, enamines of the 3-keto-5α-steroids of the androstane and pregnane series are reacted with benzyl azidoformate, to form 1′-benzyloxycarbonylsteroido[2,3-*d*]triazoles, the hydrogenolysis of which by lithium tetrahydroaluminate leads to unsubstituted [2,3-*d*]-triazoles (XC; R = H).[170,171] The compounds of the type (XC; R = C_6H_5) can also be obtained directly from the enamines by reaction with phenyl azide[170-172]. The second method of synthesis starts from hydroxymethylene derivatives of Δ^4-3-ketopregnanes, which on treatment with $NaNO_2$ and the subsequent reaction of the keto-oximes obtained with phenylhydrazine gives 2′-phenylsteroido[2,3-*d*]triazoles (XCI):[172]



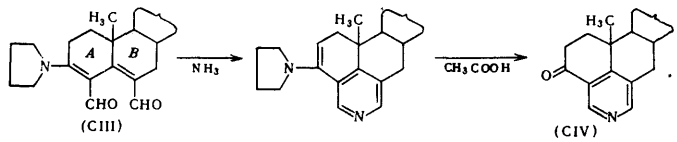
(XC) (XCI)

The introduction of the 1′-phenyl[2,3-*d*]triazole grouping in the molecule of corticosteroids raises by a factor of 5–7

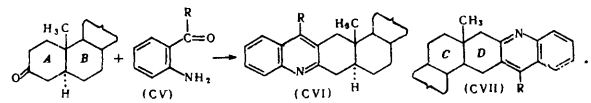


the anti-inflammatory activity of the latter. On the other hand, isomeric 2′-phenyltriazoles (XCI) are devoid of anti-inflammatory activity, which shows its high structural specificity [172].

The cyclic sulphites (XCII) and sulphates (XCIII) of 16α,17α-dihydroxysteroids can also be included among the five-membered heterocycles with three heteroatoms. Compounds of this type with R = H have a high gestagenic activity, and those with R = OH have anti-inflammatory activity [173-176]:

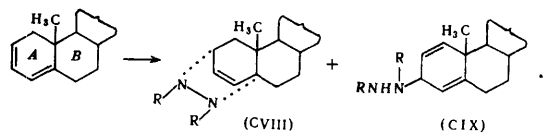


5. SIX-MEMBERED HETEROCYCLES WITH ONE HETEROATOM



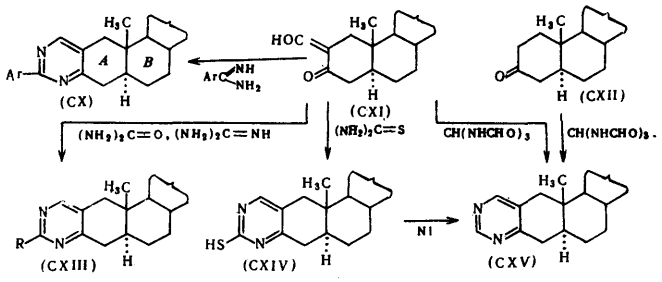
Derivatives of pyridine and quinoline belong to this group of heterocyclic steroids. Androstano[3,2-*b*]pyridines are formed by the reaction of 2-hydroxymethylene-3-keto-steroids (XCVIII; R = H, CH_3) with cyanoacetamide and its derivatives. On boiling a mixture of the reagents in ethanol with triethylamine leads to a cyanopyridone (XCVI) and when the reaction is carried out at 180° without a solvent the carboxamide (XCIV) is obtained. Compound (XCVI) is also formed in low yield on boiling (XCVIII) with malononitrile. The reaction of (XCVIII) with cyanothioacetamide gives the cyanothiopyridone (XCIX) in good yield, and that with malonamide amidine gives the 6′-amino-derivative (XCV), the diazotisation of which leads to (XCIV). Alkaline hydrolysis of (XCIV) gives a pyridone carboxylic acid (XCVII), which at 300° is decarboxylated into the pyridone (C). The thiopyridone (CI) was obtained in analogous fashion; it is also formed from (C) by the action of P_2S_5 in pyridine. The reductive desulphidation of (CI) by Raney nickel gives the androstano[3,2-*b*]pyridine (CII). This compound has a high ratio of anabolic to androgenic activity, but both types of activity are weak [177-179]:

The dialdehyde (CIII), obtained from the pyrrolidylenamine of testosterone by the Vilsmeyer reaction (dimethylformamide and $POCl_3$), under the action of gaseous ammonia in methanol solution gives enamines, the hydrolysis of which by acetic acid leads to a derivative of androstano[4,5,6-*cd*]-pyridine (CIV): [180]



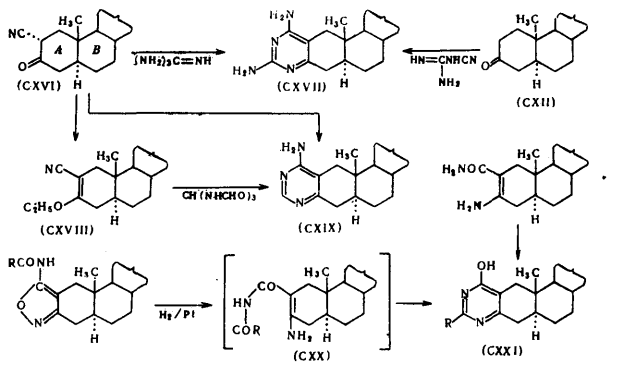
The condensation of 3-keto-derivatives of cholane and cholestane with *o*-aminobenzaldehyde (CV; R = H), anthranilic acid (CV; R = OH), and isatin (CV; R = CO_2H) gives the corresponding 4′-substituted steroido[3,2-*b*]quinolines (CVI). Decarboxylation of (CVI; R = CO_2H) by heating in a vacuum allows the 4′-unsubstituted analogues [7,181-183] to be obtained. Steroido[17,16-*b*]quinolines (CVII; R = H, CO_2H) were obtained in a completely analogous fashion from 17-keto-derivatives of androstane and oestrane in yields of up to 90%. [182,183] It is reported [182] that compounds of the type of (CVI) and (CVII) exhibit haemolytic activity:

6. SIX-MEMBERED HETEROCYCLES WITH TWO HETEROATOMS

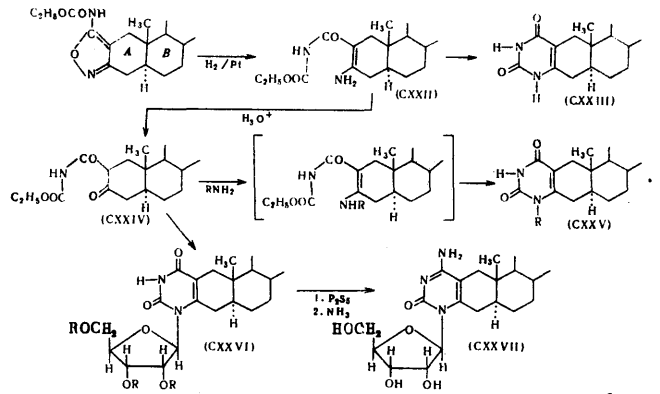


This section deals with the steroidal derivatives of pyridazine, pyrimidine, quinoxaline, 1,3-oxazine, morpholine, 1,3- and 1,4-thiazine, 1,4-oxathiane, and 1,4-dithiane.

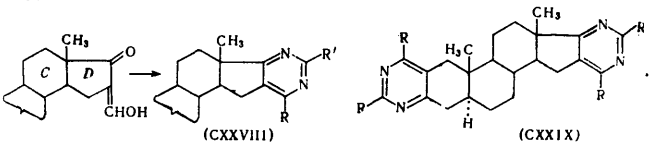
A diene condensation of cholesta-2,4-diene with diethyl azoformate on boiling in benzene leads to a mixture of 21% of a cholestano[2,3,4,5-*cde*]tetrahydropyridazine (CVIII; R = $CO_2C_2H_5$) derivative and 11% of a substitutional addition product (CIX; R = $CO_2C_2H_5$). For cholesta-5,7-diene the yield of pyridazino-derivative drops to 4%, and in the mixture the substituting addition product is greatly predominant (yield 36%): [184]



One of the methods of synthesising steroido[3,2-*d*] derivatives of pyrimidine is the reaction of 2-hydroxymethylene-3-ketosteroids (CXI) with various amino-compounds. With the hydrochlorides of arylamidines (acetamidine does not react) (CXI) forms 2′-aryl derivatives (CX; Ar = phenyl, *o*- and *p*-nitrophenyl, pyridyl) [122,145,185-187], with urea and thiourea, 2′-hydroxy- (CXIII; R = OH) and 2′-mercapto-derivatives (CXIV), [57] and with guanidine, the 2′-amino-derivative (CXIII; R = OH_2). [57,188] Treatment of (CXI) or the unsubstituted 3-ketosteroids (CXII) with

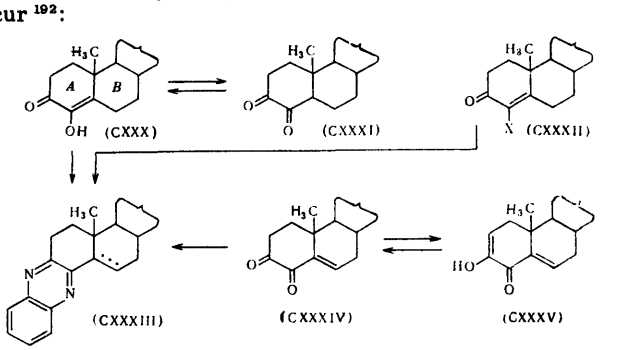


trisformylaminomethane gives 2′-unsubstituted [3,2-*d*]-pyrimidines (CXV), which are also formed in the reduction by Raney nickel of 2′-mercapto-derivatives (CXIV):[57]

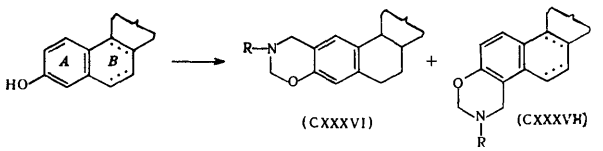


Another group of pyrimidine derivatives with substituents in the 6′-position was obtained from 2α-cyano-3-keto-steroids (CXVI) and their enol ethers (CXVIII). Reaction with trisformylaminomethane led to the 6′-amino-derivative (CXIX) and reaction with guanidine to the 2′,6′-diamino-derivative (CXVII). The last group of compounds is formed also on fusing (200–250°) 3-ketosteroids (CXII) with cyanoguanidine[2,189]. The β-aminocarboxamides obtained from 5′-aminoisoxazoles (see Section 3) react with amidines or trisformylaminomethane to form 6′-hydroxy[3,2-*d*]pyrimidines (CXXI) containing hydrogen, alkyl, or aryl in the 2′ position. The same compounds were obtained from 5′-acylaminoisoxazoles, the catalytic hydrogenation of which gives *N*-acyl derivatives (CXX), which are cyclised in the course of the reaction into (CXXI; R = alkyl, aryl)[2]:

2′,6′-Dihydroxypyrimidines tautomeric with the 2′,6′-diketotetrahydropyrimidines were obtained from 5′-ethylurethanoisoxazoles (see Section 3). Catalytic hydrogenation gave the 2-(*N*-ethoxycarbonyl)carboxamide (CXXII), which is readily cyclised into 2′,6′-diketo-derivative (CXXIII). On the other hand, acid hydrolysis of (CXXII) leads to the corresponding 3-ketone (CXXIV), which reacts with primary amines to form enamines which are cyclised into derivatives of 3′-alkyl-2′,6′-diketoandrostano[3,2-*d*]-pyrimidine (CXXV; R = alkyl, cycloalkyl, aryl). By using 2,3,5-tri-*O*-benzoyl-β-D-ribofuranosylamine as the primary amine, a steroidal nucleoside was obtained — a derivative of uridine (CXXVI; R = H). Treatment of the tribenzoyl derivative (CXXVI; R = $OCOC_6H_5$) with phosphorus pentasulphide in pyridine and subsequent amination led to a steroidal analogue of cytidine (CXXVII):[2]

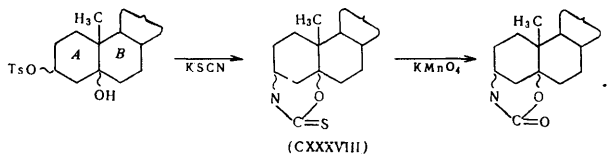


The reaction of 16-hydroxymethylene-17-ketosteroids with trisformylaminomethane, acetamidine, or cyanoguanidine gave the corresponding [17,16-*d*]pyrimidines (CXXVIII; R = H, NH_2; R′ = H, CH_3). [3,2-*d*:17,16-*d*]-Dipyrimidines (CXXIX; R = H, NH_2) were obtained from 2,16-bishydroxymethylene-3,17-diketosteroids by the same methods[2,95,189–191]:

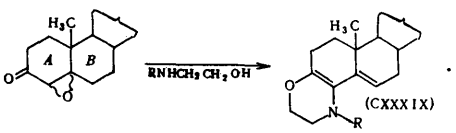


Both [3,2-*d*] and [17,16-*d*]pyrimidine derivatives of androgenic and oestrogenic hormones almost completely loss the hormonal activity and are completely devoid of anabolic and anticholesterolemic activity. Moreover they exhibit significant antibacterial activity against Gram-positive micro-organisms[2,189].

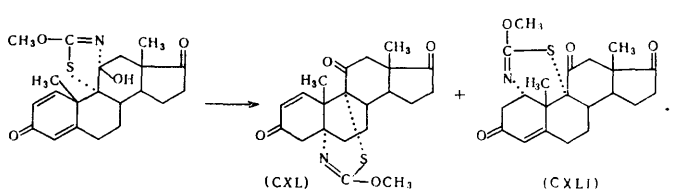
The formation of quinoxaline derivatives of steroids on reaction with *o*-phenylenediamine serves as a proof of the existence of α-diketo-groupings in the molecule. Examination of the conditions of formation of these derivatives is most convenient with the 3,4-diketones. Saturated diketones exist predominantly in the ketoenol form (CXXX), not in the diketo-form (CXXXI), and react with phenylenediamine only on fusion up to 120°.[192] The same product — the [3,4-*b*]quinoxaline (CXXXIII) — is formed also on boiling the 4-bromo- and 4-chloro-derivatives (CXXXII; X = = Br, Cl) with *o*-phenylenediamine in acetic acid[193,194]. The diketone (CXXXIV) and ketoenol (CXXXV), which contain the Δ^5 bond, give the same quinoxaline derivative but (CXXXIV) reacts when a solution of the components in ethanol is heated, whereas (CXXXV) requires fusion of a mixture of the dry components at 135° for reaction to occur[192]:



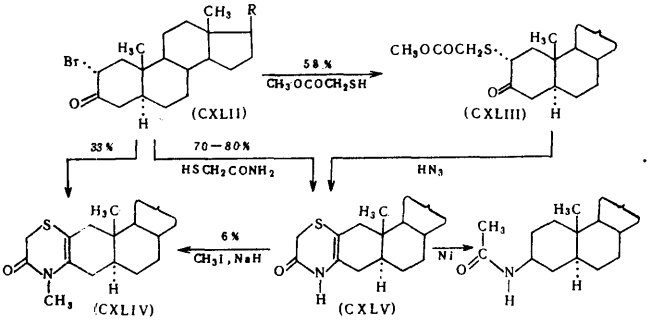
The preparation of quinoxaline derivatives from 2,3-diketo-[195], 6,7-diketo-[196], and 20,21-diketo-[197-199] steroids and also from 17,17a-diketones of the D-homo series[200] has been described.



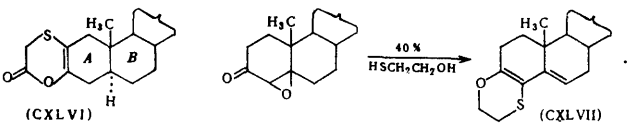
The reaction of phenolosteroids with formaldehyde and amines in the presence of alkali leads to the production of 1,3-oxazines. When only ring A is aromatic, then mixtures (in 30–50% yields) of steroido[2,3-*e*] (CXXXVI) and [3,4-*e*] (CXXXVII) oxazines in the ratios from 3 : 1 to 6 : 1 are formed (R = cyclohexyl, benzyl, phenethyl). Compounds with aromatic rings A and B are converted with yields of ~ 80% into homogeneous [3,4-*e*] analogues. The products obtained exhibit significant antitumour activity[201,202]:



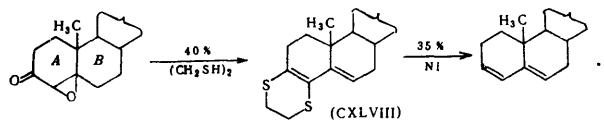
The tosylates of the epimeric 3β,5α- and 3α,5β-dihydroxycholestanes react with potassium thiocyanate to form [4,5,6-*de*] derivatives of 1,3-perhydro-oxazinethione (CXXXVIII) with the 3α,5α- and 3β,5β-configurations respectively. Permanganate oxidation converts (CXXXVIII) into the corresponding perhydro-oxazinones[203]:



The 4′-alkyl[3,4-*b*]morpholines (CXXXIX) were obtained by boiling in ethylene glycol a mixture of 4,5-epoxy-17α-methyltestosterone and *N*-alkylaminoethanols[204]:



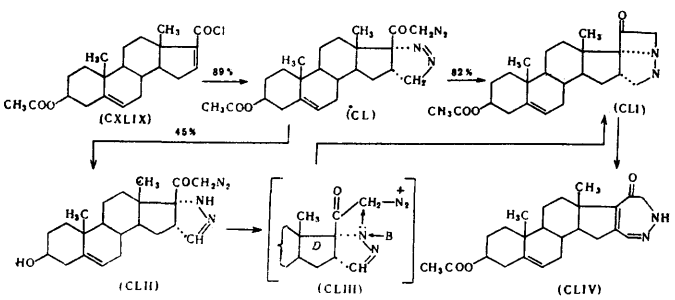
Derivatives of 1,3-thiazine are formed on boiling in methanol the androstano- and pregnano-[11,9-*d*]thiazolines and with a Δ^1 or Δ^4 bond, described in Section 3. The isomerisation involves breaking of the C–N bond at $C_{(11)}$ and the attachment of nitrogen to $C_{(1)}$ or $C_{(5)}$; as a result the Δ^4 compounds give the [5,10,9-*de*]-1,3-thiazine derivatives (CXL), and the Δ^1 compounds the [9,10,1-*de*]-1,3-thiazine derivatives (CXLI). When there is the $\Delta^{1,4}$-3-keto-structure the Δ^1 bond reacts preferentially; thus, in the example shown below the ratio of the products with cyclisation at the Δ^4 and Δ^1 bonds is (CXL) : (CXLI) = 1 : 7.[149,150]:



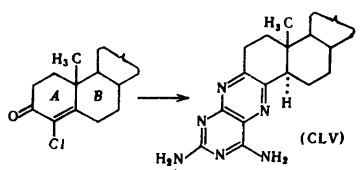
Condensation of 2α-bromo-3-ketosteroids (CXLII) of the androstane (R = $OCOCH_3$) or pregnane (R = $COCH_3$) series with mercaptoacetamide in collidine leads to high yields of [3,2-*e*] derivatives of 1,4-thiazenones (CXLV). The formation of 3-acetamido-derivatives in the desulphurisation of (CXLV) confirms that nitrogen is joined to the $C_{(3)}$ atom of the steroidal skeleton. *N*-Methylation of (CXLV) gives, in low yields, the 4′-methyl derivatives (CXLIV) which can be obtained more conveniently from (CXLII) by reaction with *N*-methylmercaptoacetamide. Another method of making (CXLV) consists in the condensation of (CXLII) with methylmercaptoacetate followed by treatment of the mercapto-derivative formed (CXLIII) with ammonia. Thiazenones of the androstane series have a ratio of anabolic to androgenic activity of 4–8 (methyltestosterone = 1):[205,206]

The cyclisation of the mercapto-derivative (CXLIII) under the action of *p*-toluenesulphonic acid in benzene gave the [2,3-*e*] derivative of 1,4-oxathiane (CXLVI) in 54% yield[205,206]. Steroido[3,4-*b*]-1,4-oxathianes (CXLVII) were obtained in the reaction of 4β,5β-epoxy-3-ketones of the androstane and cholestane series with mercaptoethanol under the action of polyphosphoric acid[207]:

In an analogous fashion to the formation of (CXLVII), 4β,5β-epoxycholestan-3-one with ethanedithione gives $\Delta^{3,5}$-cholestadieno[3,4-*b*]-1,4-dithiane (CXLVIII), the reductive desulphurisation of which by Raney nickel leads to $\Delta^{3,5}$-cholestadiene[207]:

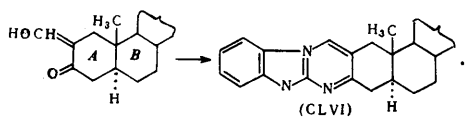


7. CONDENSED HETEROCYCLIC SYSTEMS WITH SEVERAL HETEROATOMS

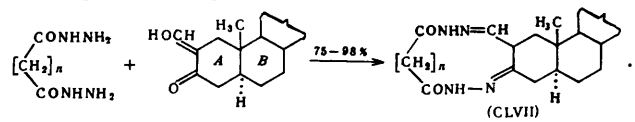


Steroidal derivatives of 1,2-diazabicyclo[3,2,0]-heptane are formed by the reaction of two molecules of diazomethane with 3β-acetoxy-5,16-etiadienyl chloride (CXLIX). The 21-diazo[17,16-*c*]pyrazoline (CL) obtained in the first stage loses nitrogen when heated with acetic acid and (CLI) 16α,17α,21-[3,1,1-(2-pyrazolino)]-5-pregnen-3β-ol-20-one acetate¶ is formed. Alkaline hydrolysis of the acetate (CL) is accompanied by migration of the

¶ Better named 3′-oxoazetidino[1′,2′ : 2,3]pyrazolidino[4,3-*k*]-androst-5-en-3-yl acetate (Ed. of Translation).



double bond in the pyrazoline ring from the $\Delta^{1'}$- to the $\Delta^{2'}$--position. Since the compound obtained (CLII) is cyclised into (CLI) more readily than the $\Delta^{1'}$-isomer (CL) the sequence of reactions (CL) → (CLII) → (CLI) was adopted. The most probable mechanism of the cyclisation is the attack of the nitrogen of the pyrazoline ring by the protonated diazoketone (CLIII). On heating (CLI) with a mixture of acetic acid and sodium acetate there is rupture of the bond between $C_{(17)}$ and nitrogen with the formation of a [17,16-*d*]diazepinone (CLIV), which are the sole representatives of steroidal derivatives with seven-membered heterocycles[208-210]:



The reaction of 4-chlorotestosterone acetate with an excess of 2,4,5,6-tetra-aminopyrimidinium hydrogen sulphate in a mixture of ethanol and acetic acid gives a derivative of 2',4'-diaminoandrostano[4,3-*g*]pteridine (CLV), which is a highly active antagonist for folic acid[211]:

A third representative of condensed heterocycles — cholestano[3,2-*b*]-1',9',11'-triazafluorene (CLVI) — was obtained in good yield by the reaction of 2-hydroxymethylenecholestan-3-one with 2-aminobenzimidazole[7]:

In conclusion, mention must be made also of the cyclic hydrazones (CLVII; n = 0–6) which are formed by the reaction of 2-hydroxymethylene-3-ketoandrostanes with the hydrazides of dicarboxylic acids. These compounds are representatives of steroidal 9–15-membered heterocycles containing four nitrogen atoms[212]:

HALOACETYLENES

K.M.Smirnov, A.P.Tomilov,
and A.I.Shchekotikhin

CONTENTS

I. Introduction 326

II. Synthesis of the haloacetylenes and some of their derivatives 326

1. Preparative methods for haloacetylenes 326
2. Synthesis of derivatives of the haloacetylenes 328
3. Analytical determination of the haloacetylenes 328

III. Physical properties of the haloacetylenes 329

1. General characteristics 329
2. Combustibility and explosibility 329
3. Physiological activity 330
4. Structure of the molecule. Spectra 330

IV. Chemical reactions of the haloacetylenes 332

1. Reactions at the triple bond 332
2. Hydrogen exchange 334
3. Halogen exchange 334
4. Decomposition of the haloacetylenes. Oxidations 336
5. Molecular compounds of the haloacetylenes 336

I. INTRODUCTION

This review deals with the halogenated acetylenes XC≡CH and XC≡CX, where X = I, Br, Cl, or F. The chemistry of the haloacetylenes is developing rapidly and opens wide prospects for the use of these compounds in organic synthesis. Information about this class of compounds has not been systematised and it seems desirable to make the material accumulated in this field more accessible. The review covers literature published up to November 1966.

The first acquaintance of investigators with halogenated acetylenes began in 1860, when Sawitsch[1] found that the action of alcoholic solutions of sodium ethoxide (or potassium hydroxide) on tribromoethane or heating it with solid potassium hydroxide to 100° gives, in addition to dibromoethylene, a gaseous substance which ignites spontaneously in air, attacks the eyes, and gives an explosive precipitate with an ammoniacal solution of copper(I) oxide. Somewhat later Reboul[2,3] found that it was bromoacetylene but he invariably obtained it mixed with acetylene. Pure bromoacetylene was obtained only in 1885 by Sabaneev[4]. In 1865 Berend[5] first obtained di-iodoacetylene by the reaction of silver acetylide with an ethereal solution of iodine. In 1880 Wallach[6] obtained chloroacetylene on boiling barium ββ-dichloroacrylate with barium hydroxide: he characterised the product, obtained some derivatives of C_2HCl, and found that the reaction proceeds through the intermediate formation of chloropropionic acid, which is readily decarboxylated:

$$CCl_2{=}CHCOOH \rightarrow ClC{\equiv}CCOOH \rightarrow C_2HCl + CO_2.$$

Lemoult[7] obtained dibromoacetylene in 70% yield by heating an alcoholic solution of tribromoethylene with an excess of alcoholic potassium hydroxide in a stream of nitrogen and described its properties. Dichloroacetylene was discovered in 1914: Böeseken and Carrière[8] obtained it on heating the barium trichloroacrylate. Grignard and his coworkers[9], in studying the reaction of equimolecular amounts of iodine and ethynylenedimagnesium dibromide, found a little iodoacetylene among the reaction products, in addition to the main product (up to 65%), monoiododiacetylene.

In the monohalo-substituted acetylene series fluoroacetylene was the last to be discovered. It was synthesised in two different ways: by pyrolysis of fluoromaleic anhydride and by reaction of magnesium with 2-bromo-1,1-difluoroethylene. Both methods were published by Middleton and Sharkey[10] in the USA and by Yakubovich and coworkers in the Soviet Union[11].

The first information about difluoroacetylene began to appear in the literature in 1947. In an American patent[12], which describes the preparation of perfluorinated alkynes of the type $R_FC{\equiv}CR_F$, difluoroacetylene is mentioned among the products. However, the method of making it is not described there and its physicochemical characteristics are not given. In another American patent[13], which describes the synthesis of fluoropropioloyl fluoride FC≡CCOF by the pyrolysis of difluoromaleic anhydride, difluoroacetylene is mentioned as one of the products of the pyrolysis. However, it was not isolated. The author observed only the formation of a compound of composition C_4F_4, which he took to be a dimer of difluoroacetylene. In the brief information about the preparation of difluoroacetylene[14] there is also nothing about the method of preparation, purification, and properties of the substance. Slight traces of difluoroacetylene were found among the products of the photolysis of tetrafluoroethylene[15] and of the radiolysis of hexafluoroethane[16]. According to an American patent[17], the dihaloacetylenes, including difluoroacetylene, are obtained by pyrolysis of liquid or gaseous halogenated hydrocarbons at 1200–1300°C in high vacuum. Chlorofluoroacetylene was recently obtained[18] by dehydrohalogenation of 1,1-dichloro-2-fluoroethylene at 120°C in a vacuum.

The study of the halogenated acetylenes for over a century has developed rather slowly. On the one hand, the investigations, which were not stimulated by practical requirements, were theoretical and carried out on a very limited scale. On the other hand, work with haloacetylenes is accompanied by considerable difficulty and danger since these substances ignite and explode violently on contact with air. Moreover, they exhibit comparatively high toxicity. Only with the development of appropriate experimental techniques and of contemporary physical methods of investigation were significant advances made in this field. However, bromochloroacetylene, chloroiodoacetylene, bromofluoroacetylene, bromoiodoacetylene, and iodofluoroacetylene are now known.

II. SYNTHESIS OF THE HALOACETYLENES AND SOME OF THEIR DERIVATIVES

1. Preparative Methods for Haloacetylenes

The methods at present known for the production of haloacetylenes can be classified as follows, according to the reactions on which they are based.

A. The hypohalite method is based on the fact that hypohalite in alkaline medium acts on acetylene or a substance with an acetylenic hydrogen [19]:

$$CH{\equiv}CH + 2\,OX^- \rightarrow XC{\equiv}CX + 2\,OH^-.$$

Biltz and Küppers [20], having obtained di-iodoacetylene by the reaction of alkaline hypoiodite, iodine, and acetylene, ascribe to the hypoiodite the role of oxidant in the iodination. However, iodic acid, which they used as an oxidant, seemed of low activity and such oxidants, like the free hypohalogenous acids, add to the triple bond [19]:

$$RC{\equiv}CH + 2\,HOX \rightarrow [RC(OH)_2CHX_2] \rightarrow RCOCHX_2.$$

Hypoiodites are the most active; they react almost instantaneously. Hypobromites and hypochlorites are less active, especially the latter. The rate of reaction continually decreases in this sequence and a correspondingly more alkaline medium is required to effect the reaction; hypochlorite, for example, requires concentrated alkali [21,22].

Isolated authors have modified this method to obtain dihaloacetylenes (especially C_2I_2). The production of monoiodoacetylene in this way has recently been described [23,24].

The method described above [20] is the most convenient process for the preparation of *di-iodoacetylene*:

$$C_2H_2 + KOI + I_2 \rightarrow C_2I_2 + KI + H_2O.$$

The reaction proceeds rapidly and the yield of the product is close to theoretical. Dehn's method [25] is often used for the same purpose; water, NaOCl, and KI act on calcium carbide:

$$CaC_2 + 2\,H_2O + 2\,KI + 2\,NaOCl \rightarrow C_2I_2 + Ca(OH)_2 + 2KCl + 2\,NaOH + 2KCl.$$

The yield of C_2I_2 is 80–90%. An interesting variation of the hypohalogenite method for obtaining di-iodoacetylene was proposed by Dussol [26]. He electrolysed, between platinum electrodes, an aqueous solution of potassium iodide saturated with acetylene. The iodine discharged at the anode reacts with acetylene in the alkaline medium, forming di-iodoacetylene with a current efficiency of 85%.

The same method is recommended for obtaining dichloroacetylene for demonstration experiments [27]. However, in view of the low yields this method has no preparative value [28].

B. Dehydrohalogenation of polyhaloethanes or polyhaloethylenes by alcoholic or solid alkali; this method allows both dihaloacetylenes and monohaloacetylenes to be obtained:

$$CH_2XCHX_2 + 2\,MOH \rightarrow 2\,MX + 2H_2O + HC{\equiv}CX;$$

$$CHX{=}CX_2 + MOH \rightarrow MX + H_2O + XC{\equiv}CX;$$

$$CHX{=}CHX + MOH \rightarrow MX + H_2O + HC{\equiv}CX$$

where X = Cl or Br.

Dehydrogenating agents other than alkali hydroxides can also be employed, for example, catechol potassium or sodium salts [29] and catechin [30]. Dehydrohalogenation under the action of the alkali metals [31,32] has been described; it proceeds by a radical mechanism. For example, the formation of chloroacetylene from 1,2-dichloroethylene under the action of potassium can be represented as follows [32]:

$$K + C_2H_2Cl_2 \rightarrow KCl + \cdot C_2H_2Cl$$

$$\cdot C_2H_2Cl + C_2H_2Cl_2 \rightarrow C_2HCl + HCl + \cdot C_2H_2Cl.$$

Method B seemed the most promising for the preparation of *dichloroacetylene* and *dibromoacetylene* [7,33]. The method of obtaining dichloroacetylene by the dehydrohalogenation of trichloroethylene was developed by Ott and coworkers [34]. These authors passed trichloroethylene vapour at 130° over fused and uniformly ground KOH and obtained C_2Cl_2 in 65% yield. However, explosions in the reaction tube frequently occurred. Subsequently Ott and coworkers showed [35] that the addition of 1% water glass (containing 50% silicate) to pure, solid KOH makes the procedure safe. It is noted that 10% silicate completely deactivates the KOH. According to other investigators [36], the addition of even 2% sodium silicate makes the alkali inactive.

Haloacetylenes were also obtained from certain polyfunctional halogenated compounds. Under the action of alkali such compounds liberate haloacetylene and simultaneously undergo destructive decomposition with the formation of other products. In several studies the author discusses the mechanism of such reactions. For example, according to Wagner and Pines [37] the formation of chloroacetylene in the decomposition of ββ-dichlorovinyltrichlorosilane under the influence of aqueous KOH takes place in stages, through the intermediate formation of a carbanion, which then reacts with the solvent and forms dichloroethylene or loses a chloride ion and gives chloroacetylene:

$$OH^- + Cl_3Si{-}CH{=}CCl_2 \rightarrow (CH{=}CCl_2)^- + Cl_3Si(OH);$$

$${-}CH{=}CCl_2^- + H_2O \rightarrow CH_2{=}CCl_2 + OH^-;$$

$${-}CH{=}CCl_2^- \rightarrow C_2HCl + Cl^-.$$

Under the action of alcoholic alkali dimethyldihalovinylmethanols [3,4-dihalo-2-methylbut-3-en-2-ols] decompose with the formation of acetone and monohaloacetylene [38]:

$$(CH_3)_2C(OH)CX{=}CHX \xrightarrow{HX} (CH_3)_2C(OH)C{\equiv}CX \rightarrow CH_3COCH_3 + C_2HX$$

$$(CH_3)_2C(OH)CX{=}CHX \rightarrow CH_3COCH_3 + CHX{=}CHX \xrightarrow{-HX} C_2HX.$$

According to Zincke [39], the decomposition of α-dichloromethyl-β-chlorovinyldiketone[1,1,5-trichloropent-4-en-2,3-dione] on heating with an excess of alkali in a current of hydrogen takes place as follows:

$$\begin{array}{l} CHCl_2{-}CO \quad H \qquad\quad CHCl_2{-}COH \\ ClHC{=}CH{-}CO \quad OH \rightarrow \quad CHCl{=}CHCOOH \end{array}$$

$$CHCl_2{-}COH \rightleftarrows CCl_2{=}CHOH;$$

$$CCl_2{=}CHOH + NaOH \rightarrow CCl{\equiv}CH + NaClO + H_2O.$$

C. Dehalogenation of polyhaloethanes or polyhaloethylenes by a metal was used to obtain monohaloacetylenes:

$$CX_2{=}CHX + M \rightarrow MX_2 + XC{\equiv}CH \text{ (for example, X = Br, M = Zn),}$$

$$CXY{=}CHY + M \rightarrow MY_2 + CX{\equiv}CH \text{ (for example, X = F, Y = Br, M = Mg).}$$

Viehe and Franchimont [40] proposed a preparative method for obtaining *fluoroacetylene* (yield 80%) from dibromofluoroethylene with magnesium in tetrahydrofuran.

D. Reaction of metal acetylides with halogens and some of their compounds which contain a negative group (for example, with cyanogen chloride). The halogen replaces both hydrogen atoms in acetylene, irrespective of whether one or both hydrogen atoms were substituted by metal [41]:

$$MC{\equiv}CM + 2X_2 \rightarrow 2MX + XC{\equiv}CX;\ HC{\equiv}CM + 2X_2 + MOH \rightarrow H_2O + 2\,MX + XC{\equiv}CX$$

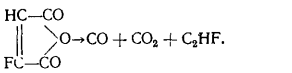
where X = Br or I. The principal use of this method is the preparation of di-iodoacetylene [5,42–44]. Evidently another example of this type of reaction must be that described [45] between sodium acetylide and epi-iodohydrin [1,2-epoxy-3-iodopropane], [45] but the yield of C_2I_2 from this is insignificant.

E. Reaction of the same reagents as in Method D with ethynylenedimagnesium dibromide, which also leads to dihaloacetylenes:

$$BrMgC{\equiv}CMgBr + 2X_2 \rightarrow MgBr_2 + MgX_2 + XC{\equiv}CX$$

where X = Br or I.

F. The decomposition of mercury monohaloacetylides is a preparative method for obtaining *bromoacetylene* and *chloroacetylene* [46]:



$$Hg(C{\equiv}CX)_2 + 4KCN + 2H_2O \rightarrow 2KOH + K_2Hg(CN)_4 + 2HC{\equiv}CX.$$

The initial mercury salts are readily obtained by shaking the corresponding dihaloethylenes CHX=CHX with mercury(II) cyanide in ~ 10% KOH solution:

$$2HXC{=}CXH + Hg(CN)_2 + 4KOH \rightarrow 2KCN + 2KX + 4H_2O + Hg(C{\equiv}CX)_2.$$

Fitzgibbon [47] showed that only *cis*-1,2-dichloroethylene forms a mercury bis(chloroacetylide) in this reaction. This salt liberates C_2HCl under the action of conc.HCl. *trans*-1,2-Dichloroethylene reacts with an alkaline solution of mercury(II) cyanide in another way. The author separated at least three products of the reaction, including $Hg(CCl{=}CHCl)_2$, which when boiled with conc. HCl gives dichloroethylene and $HgCl_2$.

G. The destructive decomposition of various halogen-containing compounds on heating, irradiation, etc. C_2I_2, C_2HCl, and C_2Cl_2 were obtained by heating the barium salts of iodopropiolic [48], $\beta\beta$-dichloroacrylic [6], and trichloroacrylic [8] acids respectively. The formation of C_2Cl_2 occurs in the pyrolysis of carbon tetrachloride [49]. The decomposition of dibromomuconic acid leads to the formation of C_2HBr. [50] Of the reactions of this type the most interesting from the preparative standpoint is a method of obtaining *fluoroacetylene* by the pyrolysis of fluoromaleic anhydride at 600–800°:

$$\rightarrow CO + CO_2 + C_2HF.$$

The yield of C_2HF is close to theoretical [10].

2. Synthesis of Derivatives of the Haloacetylenes

Some derivatives of haloacetylenes have been synthesised by the methods described above. Thus, Grignard and coworkers [51–53] obtained various haloacetylenes of the type RC≡CX (X = Br or I):

$$RC{\equiv}CMgX + BrCN \rightarrow MgXCN + RC{\equiv}CBr.$$

Bourguel and Truchet [54] obtained substituted chloroacetylenes by the reaction:

$$RC{\equiv}CNa + C_6H_5SO_2Cl \rightarrow C_6H_5SO_2Na + RC{\equiv}CCl.$$

Nazarov and Bergel'son [55] synthesised 4-bromo-2-methylbut-1-en-3-yne by the dehydrobromination of *cis*-1,2-dibromo-3-methylbuta-1,3-diene:

$$CH_2{=}C(CH_3){-}CBr{=}CHBr + CH_3ONa \rightarrow NaBr + CH_3OH + CH_2{=}C(CH_3)C{\equiv}CBr.$$

The reaction of 3,3,3-trifluoro-1,2-dihaloprop-1-enes with molten sodium hydroxide at elevated temperature [56] gave 1-chloro- and 1-bromo-3,3,3-trifluoroprop-1-ynes:

$$CF_3CX{=}CHX + NaOH \rightarrow H_2O + NaX + CF_3C{\equiv}CX.$$

For X = Cl the temperature of the reaction is 280–290°C and the yield 19%; for X = Br, they are 180–190°C and 27% respectively.

Eglinton and McCrae [57] obtained 1-bromoacetylenes in 80% yields by the action of bromine on organomercury compounds:

$$(RC{\equiv}C)_2Hg + 2Br_2\,(\text{in } CCl_4) \rightarrow HgBr_2 + 2RC{\equiv}CBr.$$

Various substituted haloacetylenes RC≡CX (R = Ar, $-CH_2OH$, $-CH_2OAr$, $-CH_2OCOAr$, alkenes, etc.; X = Br, I) were obtained in yields up to 50–80% by the reaction of the corresponding copper acetylides with halides (in solvents) [58–60]:

$$RC{\equiv}CCu + X_2 \rightarrow CuX + RC{\equiv}CX.$$

Chloro-, bromo-, and iodo-acetylenes were also obtained in analogous fashion [61]:

$$LiC{\equiv}C{-}C{\equiv}CH + X_2 \rightarrow XC{\equiv}C{-}C{\equiv}CH + LiX.$$

t-Butylfluoroacetylene is obtained by the dehydrohalogenation of the fluorohaloalkenes $(CH_3)_3CHC{=}CBrF$ and $(CH_3)_3CCCl{=}CHF$. [62] We note that the last is capable of spontaneous polymerisation to form interesting products. Among these are found 1,2,3-tri-(t-butyl)trifluorobenzene and other fluorinated derivatives of the valence isomers of benzene [62,63].

Tsmur and Ivanik [64] have described an interesting preparation of bromo(diethylamino)acetylene:

$$CH_2BrCON(C_2H_5)_2 \xrightarrow{PCl_5} CH_2BrCCl_2N(C_2H_5)_2 \xrightarrow{-2HCl} BrC{\equiv}C{-}N(C_2H_5)_2.$$

The lithium, sodium, and potassium salts of chloroacetylene are obtained, as Viehe [65] showed, by the reaction of a metal amide with *cis*- or *trans*-dichloroethylene in liquid ammonia:

$$ClCH{=}CHCl + 2LiNH_2 \rightarrow LiCl + LiC{\equiv}CCl + 2NH_3.$$

3. Analytical Determination of the Haloacetylenes

Little has been published on methods of analysis of the haloacetylenes. A procedure for the quantitative analysis of bromoacetylenes has been described, based on a specific method for the liberation of a halide, which is inert to ordinary hydrolysis. Chodkiewicz and coworkers [66] give two variants of this method.

According to the first variant 1-bromoacetylene is treated with a mixture of an acetylene compound with a trace quantity of copper(II) sulphate, a reductant (hydroxylammonium sulphate), and an organic base (for example, ethylamine) in a water–methanol medium.

According to the second variant the 1-bromoacetylene reacts with $CuSO_4$ and ethylamine in the same medium. In both variants the bromine is brought into an ionic state and determined argentometrically. The results of the analysis are reproducible with an accuracy of up to 1–2%. Both variants are also applicable to the determination of iodine in 1-iodoacetylenes, but only the second variant is applicable to the analysis of chloroacetylenes.

Widmann [67] determined the concentration of dichloroacetylene by the addition of an excess of 0.1 *N* solution of iodine in CCl_4 to an ethereal solution of the C_2Cl_2. The reaction mixture was kept for 2 h in daylight, after which the free iodine was titrated with thiosulphate. The author also found that there was a linear relation between the concentration of dichloroacetylene and the refractive index, and also the density, of ethereal solutions of C_2Cl_2. [36,38] Ott employed for analysis the ability of C_2Cl_2 to react with

certain substances with the formation of a dye. For example, an ethereal solution of C_2Cl_2 was added to a hot alcoholic solution of quinaldineiodoethylate [sic]† and the blue polymethine dye formed precipitated with perchlorate. Dyes were obtained similarly with 2-methylbenzthiazole and the corresponding selenium compound[68].

III. PHYSICAL PROPERTIES OF THE HALOACETYLENES

1. General Characteristics

With the exception of fluoroacetylenes, the halogenated acetylenes have a disgusting odour.

Under ordinary conditions C_2HBr, C_2HCl, and C_2HF are colourless gases; C_2HI, C_2Cl_2, and C_2Br_2 are liquids; and C_2I_2 is a solid.

C_2HBr condenses to a colourless liquid at room temperature and a pressure of 3 atm.[3] Aqueous and alcoholic solutions of C_2HBr and C_2HCl shine in the dark and give a strong ozone reaction[69,70]. The latent heat of vaporisation of C_2HBr is 58 cal deg^{-1} [cal g^{-1}? (Ed. of Translation)], and that for C_2HCl is 89 cal deg^{-1} [cal g^{-1}? (Ed. of Translation)].[70] The vapour pressure of C_2HBr has been measured from -58.7° (27.4 mmHg) to -1.2°C (610 mmHg) and that of C_2HCl from -68.0° (111.7 mmHg) to -35.9°C (636.9 mmHg) (see Briscoe and coworkers[71]).

The vapour pressure of C_2HF has been measured at various temperatures from -150° (26 mmHg) to -109.8°C (543 mmHg) (see Viehe and Franchimont[40]). The values of some thermodynamic quantities have been calculated for C_2HF and C_2F_2 in the temperature interval from 293.15° to 6000°K: standard free energy, entropy, change in enthalpy, and equilibrium constants for dissociation or ionisation[72]. The unusually low boiling point of fluoroacetylene shows the presence in it of only weak hydrogen bonds.

Di-iodoacetylene is readily volatile even at room-temperature[73]. The values of some thermodynamic functions have been calculated for it for temperatures from 373.16° to 1000°K: enthalpy, free energy, entropy, heat capacity[74]. The crystal lattice of solid di-iodoacetylene has been studied by X-ray diffraction[75,76].

Recently similar thermodynamic functions have been calculated for C_2HBr, C_2HCl, C_2HF, and their deuterated derivatives within the temperature limits 100–2000°K in terms of rigid rotator and harmonic oscillator models. The mean vibration amplitudes for molecules of the same compounds and the molecular polarisabilities have also been calculated[77] The calculated values of the latter for C_2HBr, C_2HCl, and C_2HF were 59.3203, 50.4078, and 31.8698 cm^3 × 10^{-25}. The values found for C_2HBr and C_2HCl were 68.1559 and 56.6645 cm^3 × 10^{-25} respectively.

Lemoult's calculated heat of combustion of dibromoacetylene is 260 kcal mole^{-1} and the heat of formation 71.4 kcal mole^{-1}. Pascal[79] gives values he found experimentally for the molecular magnetic susceptibility of dibromoacetylene and dichloroacetylene: 748 × 10^{-7} for C_2Br_2 and 526 × 10^{-7} for C_2Cl_2. The calculated values are 767.5 × 10^{-7} and 548 × 10^{-7} respectively.

Table 1 gives the most important physical constants and some physicochemical properties of halogenated acetylenes.

† The exact nature of this compound is not clear in Reference 68 (Ed. of Translation).

TABLE 1. Physical properties of haloacetylenes.

Haloacetylene	M.p., °C	B.p., °C	Dipole moment, D	Solubility	
				in water	in organic solvent
Bromoacetylene	—	−2[70] 4.7±0.1[71]	0[89]	soluble[2,6,70,93]	soluble in alcohol[4,93] very soluble in $C_2H_2Br_2$[3]
Chloroacetylene	—	from −32 to −30[69] −29.6±0.1[71]	0.44[89]	soluble[69]	soluble in alcohol[69]
Iodoacetylene	—	32[9]	—	—	—
Fluoroacetylene	from −165 to −160[11]	−104[11] −104.3[40] −105[87]	0.75±0.01[90] 0.73[91]	insoluble	soluble in diethyl ether
Di-iodoacetylene	74[80,81] 77–78[82,83] 78[45,73] 78.5–78.9[44] ~80[86] 81[35,43,82] 82[84–86]	98/4 mmHg (decomp. with explosion)[44]	0.33·10^{-18} e.s.u.[92]	insoluble[44]	soluble in ordinary organic solvents[43,73,80]
Dibromoacetylene	from −25 to −23[10]	76[33] 76–76.5[88] 80[7]	—	insoluble[7]	soluble in many organic solvents[7]
Dichloroacetylene	from −68 to −64[21] from −66 to −64.2[10]	32[21] 32–33/748 mmHg[5]	— —	insoluble insoluble	soluble in tetrachloroethane[24]; diethyl ether[21,24]

Note. The superscripts denote literature references.

2. Combustibility and Explosibility

Most of the halogenated acetylenes studied are capable of spontaneous ignition in air and also on heating. Often on contact with atmospheric oxygen they explode with great violence which makes it difficult and hazardous to work with them. *Bromoacetylene* burns in air with a purple smoky flame[1–3,50]. With pure oxygen it explodes with a flame and copious liberation of carbon[3]. Some authors[71] consider that C_2HBr cannot be mixed with oxygen at elevated pressure without explosion. *Chloroacetylene* also ignites and explodes on contact with air[6,46,69,94]. When insufficiently diluted with hydrogen it explodes with the formation of carbon; with insufficient air it inflames and burns with deposition of soot. The lower explosion limits with oxygen at 100°C are: for C_2HCl, 0.6–2.0 mmHg pressure, and for C_2HBr 2.5–4.5 mmHg. The presence of argon, nitrogen, and helium affect this limit for C_2HCl. The ignition of C_2HBr is inhibited by the addition of CS_2, C_2H_4, or SO_2.[71] In the gas phase fluoroacetylene is stable in air and only on setting fire to a stream of the gas does it burn, with a blue flame[10,11,40]. Viehe and Franchimont[40] reported that they did not observe explosions with C_2HF in any state of aggregation. Other investigators[10,87] showed that liquid fluoroacetylene exploded violently but the reasons are not clear. These reports are confirmed by experiments made by the authors of the present review. It has been stated[10] that solid C_2HF does not explode. *Di-iodoacetylene* decomposes to the elements with a powerful explosion on heating to 80–100°C.[87,95] According to other work, decomposition with explosion sets in between 121° and 128°C; the explosion of C_2I_2 has also been noted on vacuum distillation (4 mmHg, 98°C).[44] Jaeschke[96] reported the explosion of the dry product in work after Franzen. C_2I_2 bursts into flame sometimes even at low temperatures[44] and explodes on mechanical shock or friction. An example has been described of a violent explosion with a serious wound in an

attempt to spread crystals of C_2I_2 with a pestle[97]. *Dibromoacetylene* takes fire in air and burns with a red, smoky flame[88]; it explodes very violently on heating, decomposing with formation of carbon[7,19], and also on coming in contact with oxygen; it even explodes in an atmosphere of CO_2 or N_2 containing traces of oxygen[33]. *Dichloroacetylene* explodes violently on contact with air[19,34], and also on moderate heating[19]; diluted with nitrogen, it ignites in air[98]. Out of contact with air it decomposes with explosion at 130°C.[27]

3. Physiological Activity

Nothing has yet been published about the toxicity of iodoacetylene and fluoroacetylene. All the other mono- and di-haloacetylenes known at present are substances which exhibit comparatively high toxicity. Sabaneev[4] and Nef[93] compare bromoacetylene with phosphorus in toxicity. Ingold[69] states that inhalation of even traces of chloroacetylene produce very unpleasant sensations. Di-iodoacetylene vapour strongly attacks the eyes[43] and mucous membranes[1,73]; it is a strong poison for micro-organisms and an effective inhibitor of putrefraction, its activity to it being approached only by the extremely toxic cyanogen iodide[73], but it does not find use in the fight against putrefraction owing to its high toxicity and disgusting odour. Mebert[99] found that subcutaneous introduction of 0.2–0.3 g di-iodoacetylene into rabbits weighing 1.5–2.0 kg was lethal in two days bringing about emphysema. Loew[100] studied the toxic action of di-iodoacetylene in dilutions of 1 : 5000, 1 : 10 000, 1 : 20 000, 1 : 100 000, and 1 : 1 000 000 on bacteria (*Bac. subtillis, Bac. fluorescens liquefaciens*), fungi (spores of penicillin, *Aspergillus*), yeasts, lower algae (diatoms, *Oscillarien*, *Spirogyrafäden*), the infusoria *Flagellaten*, and also *Zimnaen*, *Copepoden*, *Nematoden*, and *Rotatorien*. The author found that in the presence of di-iodoacetylene, even in very great dilutions, all the micro-organisms did not develop, but either lost mobility, or usually perished. Of the vertebrate animals, they made tests on mice and porpoises. When introduced subcutaneously or *per os*, C_2I_2 acts slowly, owing to its poor solubility, but inhalation of its vapour leads to rapid destruction of the animals.

Inhalation of dibromoacetylene produces a severe, long-lasting headache[33,88], a sensation of weakness[88], difficulty in breathing, and pronounced loss of memory[33].

Dichloroacetylene shows its toxicity quite specifically[68]. On inhaling the ether addition compound of dichloroacetylene mice died from respiratory paralysis[35].

Ott and Bossaller[101] have shown, in a work devoted to the chemical reactions of dichloroacetylene, that "lower aliphatic alkylchloroacetylenes are evidently very toxic compounds, the action of which brings about prolonged disturbance of the nervous system. It appears in weakness of the legs, maintained for a week, and for some time walking is generally impossible. Temporary paralysis of the optic nerves also occurs".

4. Structure of the Molecule. Spectra

Nef[43,93] thought that the mono- and di-haloacetylenes have not a linear, but an acetylidene structure: XHC=C or X_2C=C, with a bivalent carbon atom, which also confers specific properties on these compounds. Such a view was held subsequently by Lawrie[33], and by Nekrasov[88]. Other investigators — Lemoult[102], Ward[103], Biltz[104], and Ott[34] — supported a linear structure for the haloacetylenes, chiefly on the basis of a study of their chemical properties. According to Ingold[69] the monohaloacetylenes are tautomeric compounds, since the acetylenic hydrogen atom is labile: $XC{\equiv}CH \rightleftharpoons XHC{=}C$. The properties of chloroacetylene which sharply distinguish it from acetylene, he explains by the fact that in chloroacetylene (and also in bromoacetylene) this equilibrium at ordinary temperatures is more displaced to the side of acetylenic structures than in acetylene. The dihaloacetylenes, according to Ingold, exhibit stable acetylene structures. Howell and Noyes[105] considered that the properties of di-iodoacetylene are readily explained if it is assumed that the iodine atoms in this compound are positive, and it is not necessary to resort to Nef's bivalent carbon atom.

In later work objections against the acetylidenic structures were based on the results of studies of the haloacetylenes by physical methods. Thus, Sidgwick[106] doubted the existence of acetylidenic structures on the basis that the terminal carbon in such molecules only has a valency sextet. He considers that the controversy about the structure of di-iodoacetylene was settled in favour of the linear structure of its molecule since the dipole moment of this compound was found to be 0.33 D, that is, closer to zero. Glockler and Morrel[107] initially favoured the linear structure on the basis of a study of the Raman spectrum of di-iodoacetylene in alcoholic solution, but in later work[108] supported a non-linear structure for this compound. However, Cleveland and Meister[109], on comparing their results from an investigation of the vibrational spectrum of di-iodoacetylene with data of other authors, again supported the linear, symmetrical structure for this compound. There have been other investigations of the spectra of di-iodoacetylene[110-112]. Table 2 gives some of the results obtained in these investigations.

de Laszlo[119] studied the structure of C_2I_2, C_2Br_2, and C_2Cl_2 by electron diffraction in the gas phase and concluded that the first two compounds had linear structures. However, he thought that the experimental results agreed with the acetylidene structure for dichloroacetylene. An investigation of the radial distribution curve led him to the conclusion that dichloroacetylene is a mixture with $\geq 20\%$ molecules with a linear structure. de Laszlo thought that a difference in the structure of C_2Cl_2 may also appear in some of its chemical properties. For example, C_2Cl_2, unlike di-iodo- and dibromo-acetylene, invariably explodes on contact with air, forms carbonyl chloride on oxidation, etc.

The results of other authors who investigated dichloroacetylene by the same method completely disagree with those of de Laszlo. Thus Hassel and Viervoll[123] found de Laszlo's conclusion about the C_2Cl_2 structure erroneous, and on the basis of an analysis of the experimental data they concluded that its molecule is linear, symmetrical, and corresponds to the formula Cl–C≡C–Cl. Hassel and Taarland[120] came to the same conclusion, and also Finbak and Hassel[121], who also studied the molecular structure of C_2Cl_2 by electron diffraction.

The linear structure of bromoacetylene and chloroacetylene was demonstrated by electron diffraction[23]. Microwave spectroscopy confirmed the linearity of the molecules of chloroacetylene[115] and showed an analogous structure of fluoroacetylene[23].

The structure of iodoacetylene has not yet been studied.

The infrared spectra of all the monohaloacetylenes are now known. The infrared spectra of gaseous C_2HF, C_2HBr, C_2HCl, and their deuterated derivatives have been studied and published in the detailed review of Hunt and Wilson[23] and more recently also by Nagarajan and Hariharan[77]. Brown and Tyler[24] investigated the infrared spectra of C_2HF, C_2DF, and C_2HI. Other authors[10,11,40] have also considered the infrared spectrum of fluoroacetylene.

Displacement of the bond frequencies to longer wavelengths is observed in the infrared spectra of deuterated monohaloacetylenes. The force constants of the C–halogen bonds in these molecules are considerably greater than in the corresponding haloethanes and are essentially the same as in the cyanogen halides, but the C–halogen bond length is much (~ 10%) shorter than in the corresponding haloethanes and a little greater than the same bonds in the cyanogen halides[23].

White observed the $J = 1 \rightarrow 2$ transition taking place in the microwave spectrum of DC≡CCl obtained with the aid of a spectrometer of high resolution, and found a hyperfine structure, due to the quadrupole moment of the deuterium. He measured the constants of quadrupole interaction of deuterium, 175 ± 20 kHz, calculated the field gradient at the deuterium nucleus, $q = (8.85 \pm 0.9) \times 10^{-14}$ e.s.u., and discussed the results obtained[124,125].

The bond lengths in the haloacetylene molecules were calculated from the results of microwave spectroscopy[91], but chiefly from the investigation of these substances by electron diffraction. Table 2 gives the vibration frequencies found in the infrared spectra of halogenated acetylenes and also the calculated values of the lengths and force constants of the bonds in these molecules according to the work of various authors. The Stark effect which can be observed in the microwave spectrum of C_2HCl was close to that calculated[115].

Bykov[126] proposed a scheme for calculating the electronic charges of the bonds, starting from the values of the electronegativities of the atoms and calculated the σ- and π-electron charges of the bonds in the chloroacetylene molecule; such a calculation gives:

$$\underset{0.91}{\overset{1.91}{H}} \quad \underset{2.00}{\overset{2.00}{C^{2\pi}}} \quad \underset{2.00}{\overset{2.09}{C^{2\pi}}} \quad \underset{1.09}{\overset{}{Cl}}$$

(the lower row is for π-electrons).

Anno and Sado[127] found that the relation between the length and order of the C–Cl bond in the chloroacetylene molecule is expressed by a relation similar to that given earlier by Coulson for C–C bonds[127].

Analysis of the infrared and microwave spectra for chloroacetylene led some investigators to conclude that the C–Cl bond has some degree of double-bond character, which explains the resonance of the

$$H-C\equiv C-C \quad \text{and} \quad H-\overset{-}{C}=C=\overset{+}{Cl}$$

structures[113,115]. Comparison of chloroacetylene with methyl chloride shows that on going to chloroacetylene the length of the C–Cl bond decreases from 1.786 Å (in CH_3Cl) to 1.632 Å (in C_2HCl). During this the force constant of this bond rises sharply, by approximately 45%. In analysing this fact, Duchesne[118] finds that the concept of resonance is here insufficient, since it can explain the increase in the force constant of the bond to the extent of only ~ 15%. The author assumes that this phenomenon is explained by the large value of the overlap integral of the chlorine and carbon orbitals.

An analogous tendency also appears in the C–F bond in fluoroacetylene[23,24,40]. See Moreau[128] for the electronic structure of C_2HF and C_2HCl.

TABLE 2.

Haloacetylene	Bond frequencies found in the infrared and Raman spectra, cm^{-1}			Lengths of the bonds in the molecule, Å			Force constants of the bonds in the molecule, 10^{-5} dyn cm^{-1}

IV. CHEMICAL REACTIONS OF THE HALOACETYLENES

All the haloacetylenes are very reactive substances. They vigorously add halogens and various nucleophilic reagents, and polymerise. Monohaloacetylenes enter into reactions which depend on the presence of a labile acetylenic hydrogen atom. Thanks to the displacement of electrons towards the electronegative halogen atoms, the hydrogen in such compounds is more protonic than in acetylene. For this reason it readily reacts with substances of basic character.

As already mentioned, Howell and Noyes [105], in objecting to the acetylidenic structure of Nef, expressed an opinion about the positive nature of the halogen in the haloacetylene molecules. Although the conclusions advanced by the authors on this basis are quite controversial and on the whole do not constitute a sufficiently weighty argument, such a standpoint is firmly based, bearing in mind the strong *I*-effect of the C≡C group. The latter can be shown as follows.

Petro [129] considered the problem of the influence of hybridisation of the carbon atom on bond polarity. On going from sp^3-hybridisation to sp^2- and sp- the electronegativity of the carbon atom rises appreciably. This leads to a corresponding rise in the dipole moment of the H–C bond:

$$\text{H—C}\,(sp^3) = 0.31$$
$$\text{H—C}\,(sp^2) = 0.63$$
$$\text{H—C}\,(sp) = 1.05.$$

The prediction of the direction of polarisation of the C–halogen bond in haloacetylene molecules (sp-hybridisation) is especially interesting. Let us consider, for example, chloroacetylene. The dipole moment of the chloroacetylene molecule is 0.44 D. The dipole moment of the H–C bond in C_2HCl is 1.05 D. Since the dipole moment of the molecule is significantly lower than the dipole moment of the H–C bond, then starting from the fact that the dipole moment of a molecule is the vector sum of the ≡C–H and ≡CCl moments, it can be concluded that in the chloroacetylene molecule, which has a linear structure, the direction of the Cl–C vector is opposite to the H–C vector, that is, the bond has the character $\equiv\bar{C}-\dot{C}l$. Analogous discussions are evidently also correct for C_2HBr and C_2HF.

It is known that compounds with positively charged halogen atoms exhibit certain specific physical and chemical properties [130,131], which are also encountered in the haloacetylenes. Thus, the haloacetylenes are of low stability and readily decompose with explosion. Di-iodoacetylene displaces iodine from a solution of potassium iodide, the iodine atom is replaced by hydrogen on hydrolysis, and oxidises phenylhydrazine with release of nitrogen. Some other reactions of haloacetylenes [132,133] can also be explained from the standpoint of the concept of the positive nature of the halogen atom.

We considered it desirable to classify the reactions of haloacetylenes as follows: (1) reactions at the triple bond; (2) reactions with replacement of hydrogen; (3) reactions with replacement of halogen; (4) decomposition of the haloacetylenes, and oxidations; (5) molecular compounds of haloacetylenes.

1. Reactions at the Triple Bond

a. Reactions with halogen and hydrogen halides. Bromoacetylene [2,3], chloroacetylene [6,19,39], and fluoroacetylene [10,11] react vigorously with bromine, adding two molecules of the latter:

$$CH \equiv CX + 2Br_2 \rightarrow CHBr_2 - CXBr_2.$$

Bromoacetylene adds HI and HBr, the latter forming *trans*-dibromoethylene [134]. An American patent [135] stated the possibility of obtaining fluoro-compounds by the reaction of chloroacetylene with HF in the presence of BF_3 at 70–250°C, but the composition of the products formed was not given.

Di-iodoacetylene, on adding on free chlorine and bromine at the triple bond, also exchanges both iodine atoms during this. For example, hexachloroethane is obtained in good yield in the reaction of chlorine with solid di-iodoacetylene [44,105] or on passing dry chlorine into a chloroform solution of this substance [73]. On standing for many days with bromine in a sealed glass vessel, C_2I_2 is converted into hexabromoethane [73]. In chloroform solution at ~ 0°C, bromine is added immediately. The product is a mixture of ICBr=ClBr (80%), CI_2=ClBr (10%), and CBr_2=CBrI (10%).[43] On treatment with an ethereal solution of iodine, di-iodoacetylene is smoothly converted into periodoethylene [43]. The solvent and temperature play an important part in this. For example, in benzene the reaction takes place on heating for 1 h; [44] in boiling toluene the addition of two atoms of iodine is instantaneous [20,73]. However, equivalent quantities of iodine and di-iodoacetylene in carbon disulphide combine (in the absence of light) only after several days [73,136]. The reagent is greatly inhibited by oxygen [137].

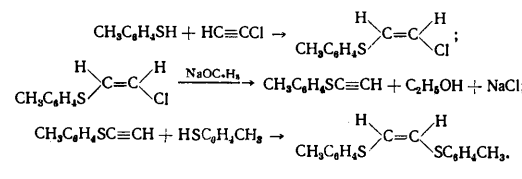
Under the action of bromine (without a solvent or in ether) dibromoacetylene is converted into tetrabromoethylene in 89% yield [19,88]. One molecule of iodine is also added, being converted into symmetrical dibromodi-iodoethylene in 82.5% yield [19]. Hydriodic acid gives both dibromoiodoethylene CBrI=CHBr and dibromodi-iodoethylene. If the HI is not purified from free iodine, then only the latter of these products is obtained in practice [33].

Dichloroacetylene adds elemental chlorine to form hexachloroethane. With bromine water, tetrabromodichloroethane is obtained [19]. With elemental bromine, without a solvent or in carbon tetrachloride medium, dichloroacetylene gives *sym*-dibromodichloroethylene [34]. It slowly reacts with a dilute ethereal solution of iodine, adding on one molecule of iodine and forming dichlorodi-iodoethylene [34,35]. The same reaction proceeds rapidly in carbon tetrachloride [35].

b. Reactions with ammonia and amines. Chloroacetylene does not react with ammonia. With diethylamine in diethyl ether it slowly forms diethylformamide and diethylammonium chloride. It reacts with aniline only at 150–160°C, forming anilinium chloride and indole [138]. Fluoroacetylene reacts with liquid ammonia forming ammonium fluoride and acetonitrile. According to Viehe and Franchimont [40] the mechanism of the reaction is the nucleophilic addition of amide ions at the triple bond with subsequent elimination of a fluoride anion: the intermediate formation of aminoacetylene is proposed:

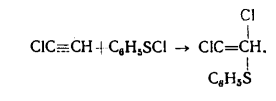
$$FC\equiv CH \xrightarrow{NH_3} \left[H_2N-C(F)=C^-\right] \longrightarrow NH_2C\equiv CH \longrightarrow CH_3CN.$$

Dichloroacetylene in ethereal solution reacts with gaseous ammonia, forming ammonium chloride and chloroacetonitrile in good yield. The intermediate formation of chloroaminoacetylene is proposed [139]:



$$ClC\equiv CCl + NH_3 \rightarrow ClCH=C(NH_2)Cl \xrightarrow{-HCl} ClC\equiv CNH_2 \rightarrow CH_2ClC\equiv N.$$

With primary amines dichloroacetylene forms, in addition to the hydrochloride of the base, aminoamidines in good yield[139], analogous to those obtained earlier by other authors from tetrabromoethane or trichloroethylene with aniline and other aromatic amines[140,141]. With diethylamine the asymmetric 2-chloro-1,1-bis(diethylamino)-ethylene is formed[138]:



$$(C_2H_5)_2NH + ClC{\equiv}CCl \rightarrow (C_2H_5)_2NCCl{=}CHCl;$$
$$(C_2H_5)_2NCCl{=}CHCl + (C_2H_5)_2NH \rightarrow HCl + [(C_2H_5)_2N]_2C{=}CHCl.$$

The passage of dichloroacetylene into an excess of triethylamine gave a quaternary ammonium salt which was converted into the perchlorate and the hexachloroplatinate(IV); a compound with gold(III) chloride was also characterised[139].

c. Reactions with sulphur-containing, mercury-containing, and other reagents. In the presence of the $C_2H_5O^-$ ion chloroacetylene adds *p*-tolylthiol to form *cis*-1,2-bis-(*p*-tolylthio)ethylene (77.4%) and *cis*-1-chloro-2-(*p*-tolylthio)ethylene (20.3%). Traces of *p*-tolylthioacetylene are also formed[142]. The initial addition product *cis*-1-chloro-2-(*p*-tolylthio)ethylene is converted, as a result of dehydrohalogenation, into *p*-tolylthioacetylene, which then also reacts with the *p*-tolylthiol. During this there is trans-nucleophilic addition of the latter at the triple bond with formation of *cis*-1,2-bis-(*p*-tolylthio)ethylene[143]:
