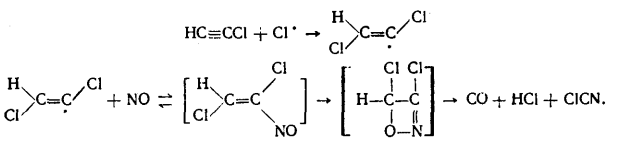
Such a reaction mechanism is confirmed by the fact that treatment of *cis*-1-chloro-2-(*p*-tolylthio)ethylene with sodium ethoxide in alcohol gives *cis*-1-ethoxy-2-(*p*-tolylthio)ethylene[144]. The reaction of chloroacetylene with benzenesulphenyl chloride[145] in ether gave *trans*-1,2-dichloro-2-phenylthioethylene in 38% yield:

The reaction of fluoroacetylene with thiophenol proceeds by nucleophilic addition of the latter with formation of 1-fluoro-1-phenylthioethylene[146]. The addition of thiophenol to dichloroacetylene in alcoholic–ethereal solution gave *cis*-1,2-dichloro-2-phenylthioethylene, in addition to *cis*-1,2-dichloro-2-ethoxyethylene as a side-product[145]. In the presence of alkoxides, dichloroacetylene adds alcohols without loss of halogen, forming $\alpha\beta$-dichlorovinyl esters[139]:

$$CCl{\equiv}CCl + ROH \rightarrow HCCl{=}CClOR.$$



Chloroacetylene, on reacting with an aqueous solution of mercury(II) chloride, gives tris(chloromercury)acetic acid $(ClHg)_3CCO_2H$.[46] The following mechanism for the reaction is proposed:

$$HC{\equiv}CCl + 2\,ClHg^+ + 2\,Cl^- = (ClHg)_2CHCCl_3 \xrightarrow{-HCl} \xrightarrow{+ClHg^+ + Cl^-}$$
$$\rightarrow (ClHg)_3CCl_3 \xrightarrow{H_2O} (ClHg)_3COOH.$$

Sherwood and Gunning[147] described an interesting reaction of chloroacetylene with nitrogen monoxide, induced by a chlorine radical, leading to the breaking of the triple carbon bond:

$$HC{\equiv}CCl + NO \xrightarrow{Cl^\cdot} ClCN + CO + HCl.$$

The authors irradiated a rarefied mixture of C_2HCl, NO, and $COCl_2$ (a source of chlorine radicals) with radiation from a quartz mercury lamp at room temperature through a filter which cuts off the short waves. They give a reaction mechanism with hypothetical formation of an intermediate product of cyclic structure:

When chloroacetylene served as the source of radicals diacetylene was also found in the products:

$$C_2HCl \xrightarrow{+h\nu} C_2H^\cdot + Cl^\cdot$$
$$C_2H^\cdot + C_2HCl \rightarrow C_4H_2 + Cl^\cdot.$$

On passing fluoroacetylene into a neutral solution of potassium tetraiodomercurate(II) HgI_2 adds at the triple bond and forms, in over 90% yield, bis-(2-fluoro-2-iodovinyl)-mercury — white, well-formed crystals, m.p. 97°C:[148]

$$FC{\equiv}CH + HgI_2 = (FIC{=}CH)_2Hg.$$

Dichloroacetylene reacts vigorously with sodium ethyl malonate. A solution of dichloroacetylene in diethyl ether is used for the reaction. The reaction mixture contains chloroethylenebismalonic ester [sic] plus a variable amount of its hydrogenation product. In an analogous reaction with the sodium derivative of diethyl ethylmalonate the main reaction product was diethyl (chloroethynyl)ethylmalonate $ClC{\equiv}C.C(C_2H_5)(CO_2C_2H_5)_2$ (~ 55%). About 33% tetraethyl chlorovinylenebis(ethylmalonate) $(C_2H_5OCO)_2C(C_2H_5).CH{=}CCl.C(C_2H_5)(CO_2C_2H_5)_2$ was also obtained; the residue (12%) was a mixture of the ester of α-methylbutyric acid (80%) and the ester of α-chlorovinylbutyric acid (20%).[139] Dichloroacetylene reacts sluggishly with diazoacetic ester; the product isolated corresponded to the empirical formula $C_{10}H_{12}N_4Cl$, but was not studied further[101]. 1,2-Dichloro--1-nitroethylene was obtained in good yield by the addition of NO_2 to dichloroacetylene[101]; the mechanism of this reaction has not been studied. The action of NO_2Cl (in ether) leads to 1,1,2-trichloro-2-nitroethylene[149]. The reaction of dichloroacetylene with thiocyanate in ether gave 1,4-bis-thiocyanatobut-2-ene in 80% yield; the mechanism of this reaction also has not been explained[150].

d. Polymerisation. Monohaloacetylenes are trimerised into symmetrical trihalobenzenes, but the yields are usually low. The main mass of the product consists of polymers whose structure has not been investigated.

Gaseous bromoacetylene does not polymerise but the liquid does. The polymerisation is catalysed by light and a molecular compound of composition $[(C_6H_5)_3P]_2NiBr_2.n\text{-}C_4H_9Br$.[151] In the liquid phase under the action of light it yellows and becomes turbid in a few hours, but after a month it has become almost completely converted into turmeric-coloured powder, only partly soluble in organic solvents. Tribromobenzene amounts to ~ 10% of the polymerisation products[4].

The copolymerisation of C_2HBr with vinyl acetate was effected in sealed glass ampoules, the reaction mixture

being kept in bright sunlight for 11 days [152]. The product was a brown amorphous substance soluble in chloroform and acetone. The copolymer decomposes at 101–102°C and by analysis it corresponds to the composition $[(CH_3COOCHCH_2)(CHCBr)]_n$. Copolymerisation with styrene was carried out similarly. The reaction products isolated were coloured solids, which by analysis and molecular weight corresponded to copolymers of composition $[(C_6H_5CHCH_2)(CHCBr)]_2$; $[(C_6H_5CHCH_2).(CHCBr)]_2$; $[(C_6H_5CHCH_2)_4(CHCBr)]_3$. [152] The reaction of C_2HBr with octacarbonylcobalt gave a solid infusible substance corresponding to the empirical formula $C_3H_3BrCoO_6$. [151]

On illumination and heating with a 100 W lamp, chloroacetylene polymerises even in the gaseous state. It gives, together with 1,3,5-trichlorobenzene, a polymer which decomposes at 290°C. [69,153]

Fluoroacetylene polymerises spontaneously at room temperature in the absence of polymerisation initiators, whether in the light or whether in the dark [11], forming a brown powder [10,11] soluble with difficulty in organic solvents. The solubility of the polymer shows its linearity, and the colour its polyene, conjugated structure [11]. A little *sym*-trifluorobenzene is also formed [10]. Dichloroacetylene is converted into resinous products and hexachlorobenzene at a temperature below 130°C. [27] Hexachlorobenzene is also formed, together with other products, in diethyl ether under the action of light or in heating the solution on the water-bath under pressure [139]. Other authors [19] maintain that dichloroacetylene is insensitive to light.

2. Hydrogen Exchange

Bromoacetylene and chloroacetylene form copper salts with solutions of copper(I) oxide in ammonia. Copper bromoacetylide is evidently unstable and is converted into copper acetylide [13,50]. Copper chloroacetylide is more stable although it changes rapidly in air: the concentration of copper in it is 9% in excess of theoretical. Under the action of HCl or KCN the substance liberates chloroacetylene, which shows the structure to be ClC≡CCu. [6,46] Silver chloroacetylide is obtained similarly [6,32,39,46,69], and also releases C_2HCl under the action of HCl and KCN. The copper and silver salts of chloroacetylene explode more violently than the corresponding salts of acetylenes, especially the silver salt, which explodes even under water [69]. The lithium salt of chloroacetylene is obtained by the reaction of *cis*- or *trans*-1,2-dichloroethylene with lithium amide, and also with organolithium compounds, for example, with n-butyl-lithium in absolute ether [154,155]:

$$CHCl{=}CHCl + LiC_4H_9 \rightarrow C_4H_{10} + CCl{\equiv}CH + LiCl;$$
$$CCl{\equiv}CH + LiC_4H_9 \rightarrow C_4H_{10} + CCl{\equiv}CLi.$$

The mercury salts of bromoacetylene and chloroacetylene $(BrC{\equiv}C)_2Hg$ and $(ClC{\equiv}C)_2Hg$, in distinction from the chlorovinyl compounds, do not exhibit the properties of quasicomplexes. They are indifferent to the action of triphenylphosphine; aqueous and alcoholic solutions of potassium cyanide or potassium iodide bring about only hydrolysis (alcoholysis) of these substances with release of the haloacetylene:

$$(BrC{\equiv}C)_2Hg + 2H_2O + 4I^- \rightarrow 2\,BrC{\equiv}CH + HgI_4^{2-} + 2\,OH^-$$

but do not lead to the liberation of elemental carbon [156]. With an aqueous solution of silver nitrate, fluoroacetylene forms only a yellow salt, also extremely explosive on heating or friction [10,11].

Deuterated derivatives of monohaloacetylenes BrC≡CD, ClC≡CD, and FC≡CD were obtained by repeatedly passing C_2HBr, C_2HCl, and C_2HF through weakly alkaline D_2O and were purified by distillation. The exchange of hydrogen by deuterium reached 70%. [23,90]

3. Halogen Exchange

The bromine atom in bromoacetylene is replaced by copper on reaction with an ammoniacal solution of copper(I) oxide. The formation of copper acetylide is proved by the production of pure acetylene when this precipitate is treated with HCl. [50] Reboul describes the decomposition of bromoacetylene in the initial stage of this reaction by the equation:

$$C_2HBr + 3\,Cu_2O \rightarrow C_2HCu_3 + CuBr + 3\,CuO.$$

Zavgorodnii and Petrov assume that in the reaction of bromoacetylene with sodium trialkyltin in liquid ammonia the lability of the hydrogen atom in the C_2HBr molecule exceeds the lability of the bromine atom. As a result of the reaction the authors obtained trialkyl(bromoethynyl)-tin(IV), together with μ-ethynylbis(trialkyltin): [157]

$$HC{\equiv}CBr \xrightarrow{R_3SnNa} R_3SnC{\equiv}CBr \xrightarrow{R_3SnNa} R_3SnC{\equiv}CSnR_3$$

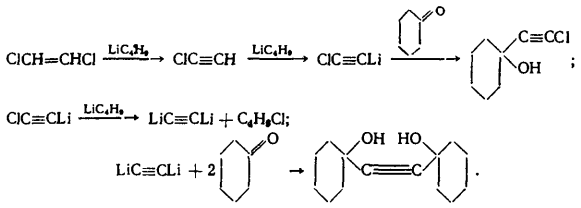
where R = CH_3, C_2H_5.

Study of the reactions of dichloroacetylene showed that the first chlorine atom undergoes various reactions very readily. Its activity in reactions with ammonia and amines is comparable with the activity of chlorine in acid chlorides [139], and Viehe [154] speaks of them as "positive, capable of being replaced by metal". Under the action of alcoholic potassium hydroxide dichloroacetylene is partly converted into chloroacetylene and potassium hypochlorite. Arens [132] presents this reaction as a nucleophilic substitution of a hydroxide ion for the chloroacetylide ion at the chlorine:

$$ClC{\equiv}CCl + OH^- \rightleftarrows ClC{\equiv}C^- + OHCl;$$
$$ClC{\equiv}C^- + H_2O \rightleftarrows ClC{\equiv}CH + OH^-.$$

With organolithium compounds dichloroacetylene almost quantitatively exchanges the chlorine atom for lithium with the formation of a lithium salt of chloroacetylene [65]:

$$RLi + ClC{\equiv}CCl \rightarrow RCl + LiC{\equiv}CCl.$$



With the aid of such salts a chloroethynyl group has been introduced into the molecules of various organic compounds [65], for example:

$$LiC{\equiv}CCl + CH_3CH_2CHO \rightarrow CH_3CH_2CH(OH){-}C{\equiv}CCl;$$
$$2\,NaC{\equiv}CCl + Br(CH_2)_6Br \rightarrow 2\,NaBr + ClC{\equiv}C(CH_2)_6{-}C{\equiv}CCl;$$
$$NaC{\equiv}CCl + (C_6H_5)_3SnCl \rightarrow NaCl + (C_6H_5)_3Sn{-}C{\equiv}CCl.$$

In the decomposition of LiC≡CCl by water chloroacetylene is formed in 85% yield [154]; by the carbonisation of this salt chloropropiolic acid is obtained; reaction with orthocarbonic ester gives the ethyl ester of this acid, and with aliphatic acid anhydrides chloroethynylketones [155] are formed:

$$ClC{\equiv}CLi + (C_2H_5CO)_2O \rightarrow ClC{\equiv}CCOC_2H_5 + C_2H_5COOLi.$$

Reactions between cyclohexane and LiC≡CCl show that both chlorine atoms in dichloroacetylene can be successively replaced by lithium[155]:

With silver nitrate in water or alcohol, dichloroacetylene forms a precipitate sensitive to light, apparently consisting of C_2Ag_2 and AgCl.[19] Dichloroacetylene and also di-iodoacetylene replace both halogen atoms on reaction with Ilosvay solution. The first gives Cu_2C_2,[19] the second a mixture of Cu_2I_2 and Cu_2C_2.[42]

Exchange of the halogen atoms in reactions with organometallic compounds is characteristic for all the haloacetylenes.

With ethylmagnesium iodide bromoacetylene forms ethynylenedimagnesium dibromide[132]:

$$HC{\equiv}CBr + 2\,C_2H_5MgBr \rightarrow BrMgC{\equiv}CMgBr + C_2H_5Br + C_2H_6.$$

Fluoroacetylene reacts to form alk-1-ynes[87]:

$$2\,FC{\equiv}CH + 2\,RMgBr \rightarrow MgBr_2 + MgF_2 + 2\,RC{\equiv}CH$$
$$FC{\equiv}CH + RLi \rightarrow LiF + RC{\equiv}CH.$$

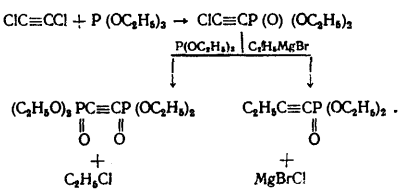
With butyl-lithium and phenyl-lithium, hex-1-yne and phenylacetylene are obtained respectively[40]; alkynes are also obtained with many other alkyl-lithiums or Grignard compounds (R = CH_3, n-C_5H_{11}, n-C_6H_{13}, n-C_7H_{15}, $CH_2C_6H_5$).

Dichloroacetylene reacts readily with organomagnesium compounds with the formation of 1-alkyl- or 1-aryl-2-chloroacetylenes of the general formula ClC≡CR. In this way 2-chloro-1-phenylacetylene was obtained in yields of 70% and other 2-choroacetylenes in yields of 40–52% (R = *p*-tolyl, *p*-anisyl, cyclohexyl, dodecyl)[101], and also various unsaturated compounds, including chloro(phenyl)diacetylene[154]:

$$C_6H_5C{\equiv}CMgCl + ClC{\equiv}CCl \rightarrow MgCl_2 + C_6H_5C{\equiv}C{-}C{\equiv}CCl.$$

The reaction of ClC≡CR, in which R is an unsaturated radical, with organolithium compounds, gives highly unsaturated compounds, for example, diphenyloctatetrayne and *cis,cis*-deca-2,8-diene-4,6-diyne.

The haloacetylenes RC≡CX (mainly with X= Br) readily undergo the Arbuzov rearrangement under ordinary conditions with the formation of the esters of alk-1-ynylphosphonic acids:



$$R'C{\equiv}CX + (RO)_3P \rightarrow R'C{\equiv}C{-}\underset{\underset{O}{\|}}{P}(OR)_2 + RX.$$

The yields are 67% for R′ = C_6H_5 and 48% for R′ = $-CH{=}CH_2$.[158] Analogous products were obtained also by the reaction of 1-bromoacetylenes with sodium dialkyl phosphites[133]:

$$(C_2H_5O)_2P(O)Na + BrC{\equiv}CR \rightarrow (C_2H_5O)_2P(O)C{\equiv}CR + NaBr$$

where R = CH_3, C_2H_5, C_3H_7, C_4H_9, C_5H_{11}, C_6H_{13}, C_6H_5; yields 37–72%.

Ionin and Petrov showed[159] that dichloroacetylene also reacts readily with trialkyl phosphite. The chlorine atom in the diethyl chloroethynylphosphonate is labile. For example, it is replaced in the action of a second molecule of triphenylphosphine, organomagnesium compounds, etc.:

Di-iodoacetylene reacts with phenylhydrazine, exchanging one iodine atom by a phenyl radical[25]:

$$C_2I_2 + 2\,C_6H_5NHNH_2 \rightarrow C_6H_5NHNH_2 \cdot HI + N_2 + H_2 + C_6H_5C{\equiv}CI.$$

In reactions with organomagnesium compounds, both iodine atoms are exchanged by the residue MgX:

$$2\,RMgX + IC{\equiv}CI \rightarrow XMgC{\equiv}CMgX + 2\,RI.$$

Hence di-iodoacetylene can be used as an iodinating agent. The reaction is effected by simple addition of an ethereal solution of di-iodoacetylene to an ethereal solution of a Grignard compound with stirring at 0°C. The conversion proceeds without difficulty and with almost quantitative yield[86,97]. Therefore di-iodoacetylene is becoming a useful auxiliary medium for preparative organic chemistry. By this method, for example, iodobenzene is obtained from phenylmagnesium bromide and di-iodoacetylene in 95–97% yield. In a similar reaction phenylethynylmagnesium bromide with 2-iodo-1-phenylacetylene in the presence of cobalt(II) chloride gave diphenyldiacetylene with a yield of 75%. However, phenylethynylmagnesium bromide and di-iodoacetylene in this way did not give diphenyltriacetylene[160]. The reaction proceeds just as with other organomagnesium compounds:

$$2C_6H_5C{\equiv}CMgBr + IC{\equiv}CI \rightarrow 2\,C_6H_5C{\equiv}CI + BrMgC{\equiv}CMgBr.$$

Both iodine atoms in di-iodoacetylene can be replaced by hydrogen. Such exchange proceeds during reaction with potassium iodide in neutral or weakly acid aqueous solution:

$$IC{\equiv}CI + 2H_2O + 2\,KI \rightleftarrows H{-}C{\equiv}C{-}H + 2\,KOH + 2\,I_2.$$

C_2I_2 in alcoholic solution is also converted into acetylene under the action of zinc dust in dilute H_2SO_4 or by sodium amalgam. Also both iodine atoms are replaced by hydrogen in the electrochemical reduction of C_2I_2 at a mercury cathode. The reaction is[161]:

$$I{-}C{\equiv}C{-}I + 4e + 2\,H^+ \rightarrow H{-}C{\equiv}C{-}H + 2I^-.$$

The synthesis of bis(trimethylsilyl)acetylene by the reaction of tetrabromoethylene with trimethylchlorosilane and metallic magnesium in tetrahydrofuran[162] should be expected to lead to the conversions being considered, since the reaction undoubtedly proceeds through the intermediate formation of dibromoacetylene with subsequent replacement of both bromine atoms by the trimethylsilyl radical:

$$CBr_2{=}CBr_2 + 3\,Mg + 2\,(CH_3)_3SiCl \rightarrow 2\,MgBr_2 + MgCl_2 + (CH_3)_3SiC{\equiv}CSi(CH_3)_3.$$

Exchange of halogen atoms can be effected by the action of halogens on haloacetylenes. Information has been given above about the formation of hexachloro- and hexabromo-ethane from di-iodoacetylene. Ingold[69] observed the formation of di-iodoacetylene on passing chloroacetylene into a benzene solution of iodine. However, that conversion is accompanied by other reactions; therefore it has no preparative value.

4. Decomposition of the Haloacetylenes. Oxidations

Various authors[73,163,164] have observed the decomposition of di-iodoacetylene in light or on heating in solvents, proceeding by the equation:

$$2\,C_2I_2 = C_2I_4 + 2\,C.$$

Study of the kinetics in various solvents (benzene, chloroform, alcohol, etc.) at 100°C and 138°C showed that this is a first-order reaction. The mean temperature coefficient of its rate has been determined and it has also been found that the influence of the solvent on the rate constant is not great. The reaction is brought about by the violet part of the solar spectrum[80] and is catalysed by HgI_2.

The explosive decomposition of the haloacetylenes on heating without solvent proceeds with the release of carbon. Bromoacetylene and chloroacetylene decompose according to the equation[6,39]:

$$C_2HX \rightarrow HX + 2\,C$$

the dihaloacetylenes decompose to the elements. Bromoacetylene burns in air to give CO, CO_2, and HBr.[93] Lawrie[33] found that on oxidation in absolute alcohol by dry oxygen dibromoacetylene is 78.4% converted into C_2Br_4 by the reaction:

$$2C_2Br_2 + O_2 = C_2Br_4 + 2CO;$$

~15.6% of it is oxidised to oxalyl bromide, and ~6.1% forms ethyl dibromoacetate. Biltz[104] also found the formation of oxalyl bromide in the oxidation of C_2Br_2 by atmospheric oxygen, quoting this fact in support of the acetylenic structure of the substance. However, later work did not confirm Lawrie's results. Hauptmann writes that the oxidation of dibromoacetylene by oxygen in absolute alcohol either does not occur at all, or proceeds extremely slowly and does not go far. Straus and coworkers[163] assume that the reasons for the violent explosions of C_2Cl_2 and C_2Br_2 with traces of oxygen must be sought in the nature of the products of the addition of oxygen and not in the decomposition or oxidation itself. Other authors[71] state that the oxidation of chloroacetylene and bromoacetylene proceeds by a chain mechanism and the difference in the oxidation of acetylene and haloacetylenes C_2HX may be ascribed to the different relative stabilities of the intermediate peroxide compounds formed in the oxidation. Dichloroacetylene burns with the formation of carbonyl chloride[98].

In its careful oxidation, greatly diluted with carbon dioxide, CO and CO_2 are obtained, as well as carbonyl chloride, and the reaction can be expressed by the equation[35]:

$$2\,C_2Cl_2 + 5O \rightarrow 2\,COCl_2 + CO + CO_2.$$

A substance of general formula $(COCl)_x$ is formed simultaneously, which gives an anilide with aniline. However, its structure has not been found precisely. On passing oxygen into a 5–10% ethereal solution of dichloroacetylene the same substance was obtained as the main reaction products; formation of oxalyl chloride was not observed[34]. Di-iodoacetylene in neutral solutions is slowly oxidised in the air[42,43,73]:

$$2\,C_2I_2 + O_2 \rightarrow C_2I_4 + 2\,CO.$$

Ingold[69] oxidised chloroacetylene with hypochlorous acid and isolated chloroacetic acid, chloral hydrate, and dichloroacetaldehyde hydrate. The oxidation of di-iodoacetylene with cold conc. HNO_3 (d = 1.4) or chromic acid (in acetic acid) gives CO_2 and C_2I_4, but cold fuming HNO_3 gives CO_2, iodine, and tri-iodovinyl nitrate $I_2C{=}C(I)ONO_2$.[43]

5. Molecular Compounds of the Haloacetylenes

Such compounds are described for dichloroacetylene and di-iodoacetylene. Ott and Packendorff[35] found that with diethyl ether dichloroacetylene forms even under ordinary conditions a compound with b.p. 32.5°C at 743 mmHg. Ether depresses the autoxidation of dichloroacetylene and the compound does not ignite in a stream of pure oxygen, and also shows great resistance to bromine and ozone. It contains 62% C_2Cl_2, which corresponds to a molar ratio of the components, and decomposes water — in this, owing to the partial solubility of ether in water the dichloroacetylene released ignites. Ott[68] showed the importance of this compound: the C_2Cl_2 content in it is readily determined by volumetric analysis, and it allows various experiments with dichloroacetylene to be carried out without danger even in lectures. Recent investigators in working with dichloroacetylene have usually employed a solution of it in ether. Under other conditions the reaction of C_2Cl_2 with ether is more complex. In a boiling solution under the action of sunlight or ultraviolet radiation in the presence of catalysts (t-butyl peroxide, azo-bisisobutyronitrile) the reaction leads to the formation of several products, chiefly[150]:

$$CHCl{=}CClCH(CH)_3{-}O{-}C_2H_5 \text{ and } [CHCl{=}CClCH(CH_3)]_2O.$$

Analogous products (each in the form of *cis*- and *trans*-isomers) were obtained with chlorofluoroacetylene[18].

Other authors state that C_2Cl_2 reacts with ether at room temperature to form 1,2-dichloro-1-ethoxybut-1-ene and other similar compounds which have not been studied[27].

With secondary and tertiary amines di-iodoacetylene forms the compounds $(C_3H_7)_2NH.(C_2I_2)_2$, $(C_2H_5)_3N.(C_2I_2)_2$, and $C_5H_{11}N.(C_2I_2)_2$.[25] Furthermore, a compound of it with 1,4-dioxan is known[165], of composition $C_4H_8O_2.C_2I_2$.

Prévost states[166] that iodoacetylene forms various vinyl iodobenzoates with the complex $[(C_6H_5CO_2)_2Ag]^-I^+$. The same author observed an interesting reaction — the formation of C_2I_2 by the action of acetylene on the above complex — taking place, he thought, according to the equation:

$$2\,[(C_6H_5CO_2)_2\,Ag]^-I^+ + HC{\equiv}CH \rightarrow 2\,[(C_6H_5CO_2)_2Ag]^-H^+ + IC{\equiv}CI.$$

A reaction described by Nieuwland and Vogt[44,167] is also of interest. The authors showed that iodine is capable of replacing both hydrogen atoms in acetylene in a medium of liquid ammonia, and in this way C_2I_2 can be obtained in good yield:

$$C_2H_2 + 2I_2 + 2NH_3 \rightarrow C_2I_2 + 2\,NH_4I.$$

I. INTRODUCTION

In the last ten years, the mechanism of the formation of hydrocarbons and their derivatives from CO and H_2 by the Fischer–Tropsch process has been discussed[1-4] in connection with the mechanism of the hydropolymerisation of alkenes under the influence of small quantities of CO in the presence of H_2.[5,6] This relates chiefly to processes on Co catalysts, since it is only on these catalysts that the hydropolymerisation of alkenes takes place[7-9]. This group of reactions based on CO is of general interest for the theory of heterogeneous catalysis, since in this field data have been obtained indicating the existence of planar chains and also the important part played by intermediate surface compounds of the radical type in various heterogeneous catalytic reactions. It is therefore convenient to combine the examination of the mechanism of the hydropolymerisation of alkenes with a discussion of new data on the mechanism of the Fischer–Tropsch reaction, particularly since they are associated with a number of common unresolved or partially resolved theoretical problems.

Among the fundamental more or less completely solved problems in the mechanism of the Fischer–Tropsch reaction we can include first of all the carbide hypothesis[10] and the Rideal–Craxford neocarbide theory[11-13], according to which bulk carbides or surface carbides respectively, formed from CO and the metal of the catalyst, are intermediate products. These views were subjected to well-founded criticism as early as the nineteen forties[14-18]. Of the later data refuting these hypotheses, we may mention the results of work by Roginskii and coworkers[19] on the exchange of carbides, labelled with ^{14}C, with carbon monoxide on a Co catalyst and of work by Indian authors[20], who showed that under the normal conditions of the preparation of hydrocarbons on a Co catalyst, the CO is present on the surface chiefly as the chemisorbed gas and is not fixed to any significant extent in the form of carbides; a single treatment in a vacuum at 200° removes the CO from three-quarters of the surface.

Another hypothesis which has been refuted is the theory[11-13] of a "giant" molecule, formed by the polymerisation of methylene radicals and undergoing hydro-cracking under the influence of atomic hydrogen to give the final products. The justified[21] rejection of this hypothesis, however, had to some extent an undesirable effect, since it led to an underestimation of the part played by degradation processes in the reaction and the part played by hydrocarbon radicals in the formation of the chains.

The most important, continuously discussed theoretical problems related to the mechanism of the two reactions being considered are: (1) the part played by oxygen compounds as intermediate products; (2) the part played by heterogeneous hydrocarbon and oxygen-containing radicals at the start of chain formation and in the process of chain growth; (3) the chemistry of the formation of C–C bonds between the units of the chains — the choice between polymerisation and condensation schemes, and (4) the part played by degradation processes in the formation of the final reaction products.

II. THE THEORY OF INTERMEDIATE FORMATION OF ALCOHOLS IN THE FISCHER–TROPSCH REACTION

The theories of intermediate alcohol formation in the Fischer–Tropsch reaction are held chiefly by American (Storch and Emmett) and English (Gibson) workers, who have made extensive studies of the reactions of alcohols under the conditions of the preparation of hydrocarbons from CO and H_2. Since it was initially assumed[22] that methanol is formed from CO and H_2 on the catalyst surface, the transformations of this alcohol were studied first. The starting point was provided by the results of our work[23], according to which the rate of formation of hydrocarbons from methanol in the presence of a catalyst consisting of $Co-ThO_2$ on kieselguhr at 200° is less than that for the reaction from CO and H_2, so that the formation of hydrocarbons from this alcohol is preceded by its decomposition to CO and $2H_2$. These results, in the opinion of Storch and coworkers[24], do not necessarily indicate that the methanol decomposes; the authors considered it possible that a primary complex is formed from the alcohol on the catalyst. Shortly afterwards, Kummer and Emmett[25] reached the same conclusion with reference to the transformation of methanol on an Fe catalyst, on the basis of their radiochemical studies. Our results were confirmed, however, by Gibson and coworkers[26], who pointed out that the primary reaction in the presence of a Co catalyst is the decomposition of methanol to CO and $2H_2$, from which the hydrocarbons are formed in a secondary reaction. These contradictions led Darby and Kemball[27] to make a detailed study of the transformation of methanol on a $100Co : 6ThO_2 : 3MgO : 200$ kieselguhr catalyst at various points along the catalyst layer. It was found that at 192° methanol reacted to the extent of 53%, of which only 1% was converted into reaction products. Analogous results were obtained over a wide range of temperatures (163–210°). The reaction was of first order with respect to alcohol, the reaction rate was decreased by carbon monoxide, and when allowance was made for the side reaction of methane formation from CO and H_2, it was found that the addition of H_2 has little influence on the kinetics, which is given by the equation:

$$-\frac{dp_{CH_3OH}}{dt} = k\frac{p_{CH_3OH}}{1+bp_{CO}}.$$

Hydrogen is adsorbed less strongly than methanol; its adsorption possibly takes place on different centres. The rate-limiting stage of the process might be the adsorption of the alcohol, which takes place less extensively than the adsorption of CO, or the decomposition of the adsorbed methanol. It was concluded that methanol is not converted directly into the reaction products but undergoes preliminary decomposition to CO and H_2, in agreement with published results[23,26].

On the basis of data on the transformations of methanol, ethanol, and formic acid on a Co–ThO_2–kieselguhr catalyst, Eidus[23] suggested that when the catalytic reduction of CO by hydrogen is incomplete, the formation of the methylene radical is preceded by the formation of an oxymethylene radical on the surface. It was later shown[28] that a CH_2O complex is formed during the successive adsorption of CO and H_2 on a catalyst of this type. The fact that methanol is not converted directly into hydrocarbons on a Co catalyst was attributed[27] to the fact that the methanol adsorption complex, inactive in the hydrocarbon synthesis, is isomeric with the active oxymethylene and is slowly converted into the latter; this explains the too low concentration of oxymethylene radicals formed from methanol:

Taking into account published data[29], it was concluded[27] that the reaction of methanol takes place in different ways on Co and Fe catalysts. Emmett and coworkers[30] found that when 1.4% methanol labelled with ^{14}C is added to the original $CO : H_2$ mixture in the presence of an Fe catalyst at 240° and 1–7.8 atm, the growth of the hydrocarbon chains can begin with the alcohol; the alcohol can take part to a slight extent in chain growth. Analogous results were obtained with formaldehyde, which, however, decomposes rapidly and completely on the catalyst surface with the formation of CO and CO_2, whose radioactivity is equal to that of the original formaldehyde. The molar radioactivity of the final reaction products increases linearly with increase in the number of carbon atoms in the molecule (the C number). The addition of 1.4% CO_2, labelled with ^{14}C, to the original mixture of CO and H_2 showed that at atmospheric pressure, other conditions being equal, CO_2 undergoes little conversion into CO or hydrocarbons, evidently due to the low rate of reaction of water gas. It was concluded[30] that neither methanol nor formaldehyde, on adsorption, form a complex identical to the primary complex from which growth of the carbon chain begins in the preparation of hydrocarbons from CO and H_2.

Evidence put forward in support of the intermediate formation of alcohols in the preparation of compounds from CO and H_2 includes the similarity in the structures of the alcohols and hydrocarbons in the Synthol process on an Fe catalyst (p. 474 of Ref. 24) and also the similarity in the curves giving the distribution of the branched alcohols and hydrocarbons formed on this catalyst with respect to C number[31]. Weitkamp[31] considers that the formation of alcohols and hydrocarbons on Fe catalysts takes place by a single mechanism with the primary formation of both alcohols and alkenes, and also that the alcohols do not undergo dehydration and are not precursors of the alkenes.

Studies on the correlation of the rates of decomposition of alcohols in mixtures with CO and H_2 with the rates of their formation from CO and H_2 on Co catalysts were carried out by Gibson and coworkers[26,32,33]. Under the usual conditions of preparation (190°, 10 atm) from a $CO : 2H_2$ mixture on a standard catalyst ($100Co : 5ThO_2 : 8MgO$: 200 kieselguhr), the final product contains only 1% of alcohols and aliphatic acids. If, however, the reaction temperature is lowered and the duration of contact decreased, the concentration of normal primary alcohols may increase to 60%. These results are also taken as evidence for the intermediate formation of alcohols. The alcohol-enriched reaction product obtained at 10 atm and 160–170° from a 37.5 g m^{-3} $CO : 2H_2$ mixture with a degree of conversion equal to 10–20% was studied[26] to determine the distribution of the alcohols with respect to C number. The distribution was compared with the relative stability of the normal primary alcohols under the conditions of preparation in a mixture with H_2 or $CO + H_2$. It was concluded that ethanol and higher primary alcohols are converted directly into hydrocarbon products without intermediate decomposition with the formation of CO. Slightly different results were obtained[23] for ethanol, which decomposes on a Co–ThO_2–kieselguhr catalyst at 200° with the formation of a gas with composition: 48.3% H_2, 27.7% CH_4, 9.6% CO, 9.0% C_2H_6, 2.9% unsaturated hydrocarbons, and 2.5% CO_2. It was assumed that the initial product is acetaldehyde, which subsequently decomposes to CH_4 and CO. Hydrocarbons are formed in 6% yield in a secondary reaction from CO and H_2. According to Gibson's data[32], ethanol was found to be the most stable of the alcohols studied under the reaction conditions; at 150° it is converted into saturated gaseous hydrocarbons and water; at 185° it forms gases, containing 9% CO, and liquid hydrocarbons, whose yield, however, was 21% greater (relative to the ethanol used up in the reaction) than could have been obtained in the normal preparation from CO and H_2. The alcohol is apparently dehydrated to form ethylene, which reacts with CO and H_2, undergoing hydropolymerisation[5,6]. Homologues of ethanol decomposed in the mixture with $CO + H_2$ at 150° at a rate comparable with the rate of preparation from CO and H_2. The chief reaction was dehydration. In accordance with its stability, ethanol was obtained in the preparation from CO and H_2 in relatively high yields: 8.6% of the total liquid products and more than 50% of the total alcohols in the aqueous layer. Decrease in the temperature of the reaction and increase in the pressure and volume rate of the original gas led to a decrease in the rate of decomposition of the alcohols and a simultaneous increase in their concentration in the product of the preparation from CO and H_2. The yield of alcohols also increased with decrease in the degree of conversion of the original mixture and increase in the $CO : H_2$ ratio in this mixture. Decrease in the temperature of the reaction and in the $CO : H_2$ ratio, and increase in the degree of conversion of CO and in the activity of the catalyst led to an increase in the average molecular weight of the final product. At a low degree of conversion of about 20–30%, increase in pressure from 1 atm to 11 atm led to a decrease in the average molecular weight, whereas at degrees of conversion greater than 50% an increase in the average molecular weight was observed[33]. The alcohols are not formed from alkenes by an oxo-synthesis scheme via the aldehydes, but are most probably formed directly from CO and H_2 by a mechanism involving the stepwise growth of the carbon chain on the catalyst[34–38]. The most probable process[32] is the stepwise attachment of methylene radicals to the end of the growing chain, which terminates in an oxymethylene group[23]. The chains are desorbed by hydrogen with the formation of saturated alcohols. If the desorption does not depend on the C number and a definite fraction (α) of chains with any C number are desorbed before further growth, the curve giving the distribution with respect to C number for the alcohols formed at the start of the reaction is given by the formula

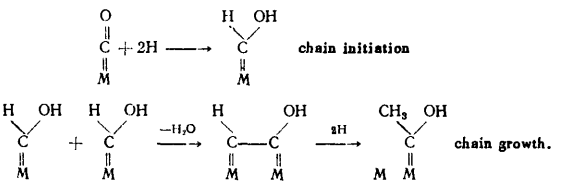
$$Y_n = K \cdot \alpha (1-\alpha)^{n-1},$$

where Y_n is the molar quantity of alcohol with C number equal to n, and K a constant. With a correction for stability, the calculated curve coincides with the experimental curve, the maximum corresponding to ethanol, in agreement with the experimental data.

Comparison of the curves giving the distribution of the alcohols with respect to C number with the distribution

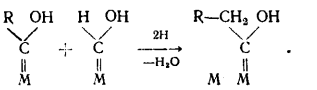
curve for the hydrocarbons obtained on a Co catalyst by Martin[39] under ordinary conditions shows some discrepancies. The curve giving the yield of hydrocarbons, unlike the curve giving the yield of alcohols, which shows a maximum at C_2 in the range C_2–C_5, showed a minimum. This difference might be contradictory to the theory of intermediate alcohol formation. It was suggested that in the preparation, ethanol undergoes dehydration to ethylene, which subsequently undergoes hydrocondensation with CO[40] and hydropolymerisation[5,6]. Since the rates of these reactions decrease on going from ethylene to propene and butene[41,42], the maximum on the curve should be displaced towards C_5. It is not excluded that ethanol reacts with CO and H_2 without decomposition, as is the case on an Fe catalyst[25,29].

The results of the correlation of the rates of formation and decomposition of the alcohols and the influence of the process conditions on these rates were taken[32,33] as confirming the theory of intermediate alcohol formation, although it is possible that alkenes are also primary products. The reaction mechanism changes to some extent with change in the conditions: if these are favourable for the preparation of hydrocarbons, the formation of the chains involves methylene radicals, into which the oxymethylene radicals, which are unstable under these conditions, are converted; if, however, the conditions are favourable for the preparation of alcohols, there is an increase in the stability and concentration of the oxymethylene radicals, and these play a predominant part in the growth of the chains. It is possible that a decrease in the length of the carbon chains takes place as a result of secondary hydro-cracking reactions.



In Gibson's opinion[32], the results of Eidus and coworkers[5] indicate that the growth of the hydrocarbon chains begins only in the presence of radicals containing oxygen, since ethylene and hydrogen are converted into into ethane, and the addition of less than 1% CO leads to the formation of higher hydrocarbons. The appreciable yields of hydrocarbons with odd C number indicates dissociation of the ethylene molecule into two methylene radicals.

III. START OF FORMATION AND GROWTH OF CARBON CHAINS



1. Radiochemical Studies of the Formation of Hydrocarbons from CO and H_2 Using Labelled Alcohols

Important radiochemical studies on the mechanism of the Fischer–Tropsch reaction were carried out by Emmett and coworkers, who studied the reactions of the original gaseous mixtures with added alcohols labelled with ^{14}C. The reaction was first carried out on an Fe catalyst promoted with Al, Zn, and Th oxides, at atmospheric pressure and 230° with a $1CO : 1H_2$ gas mixture containing 1.6 vol.% ethanol labelled with ^{14}C in the methyl or methylene group. It was found that the molar radioactivity of the methane was negligible, that of the C_5–C_{10} hydrocarbon fraction appreciable and independent of the C number, and that of the C_2–C_4 fractions slightly less than that of the liquid hydrocarbons. These results show that ethanol does not decompose before taking part in chain growth and that its adsorption complex plays the part of intermediate product in the preparation. The radioactivity of the C_2 fraction indicates successive dehydration and hydrogenation of the alcohol. Experiments on the stepwise splitting of the propane molecule showed that ~90% of the attached C atoms combine with the α-C atom of the adsorbed alcohol complex and only ~10% with the β-C atom.

Experiments under the same conditions with the addition of 1.5% labelled propanol or isobutyl alcohol to the original gas gave C_2–C_{10}, C_3–C_{10}, and C_4–C_{10} fractions which had an almost constant molar radioactivity, equal to between one-third and one-half the radioactivity of the original alcohol. Isopropyl alcohol underwent intensive conversion into isobutane and isobutene. Only one C_7 molecule out of 15 and one C_9 molecule out of 27 were formed with the participation of labelled isopropyl alcohol. t-Butyl alcohol apparently did not take part in the formation of hydrocarbons under these conditions. Experiments with labelled propanol gave n-butane containing ^{14}C, and isobutane containing no ^{14}C. In experiments with labelled isopropyl alcohol, on the other hand, the isobutane was radioactive and the butane was not. Adsorbed methanol also took part in the formation of carbon chains, but with an efficiency which was only one-quarter of that for the other alcohols used. These results led to the conclusion that in the Fischer–Tropsch synthesis on Fe catalysts the CO and H_2 form primary complexes similar to the adsorbed complexes of primary alcohols. Kummer and Emmett[29] put forward a scheme for the growth of the carbon chains, similar to the schemes advanced by others[31,35,38]. In this scheme the chief part in the formation of the carbon chains is played by the CHOH radical. This takes part in the formation of C–C bonds by condensation with the liberation of water from the hydroxyl of one oxymethylene group and the hydrogen of another:

In general:

Chain termination takes place by desorption of aldehydes, hydrogenation to alcohols, decomposition to alkenes, etc.

Subsequent experiments with the addition of labelled ethanol[43,44] showed that it is included in the reaction products more intensively in the preparation on a once-promoted Fe catalyst than on a twice-promoted catalyst, and more intensively on a catalyst which had not been treated with nitrogen than on a catalyst treated with nitrogen. The radioactivity of the reaction products decreased with increase in pressure in the range 1–21 atm. The radioactivity of the alcohols formed on a catalyst treated with nitrogen was approximately the same as that of the hydrocarbons in the range of C numbers C_3–C_6. With the addition of 0.04 vol.% strongly radioactive ethanol, it was shown that the increase in the extent to which the alcohol is included is slower than the increase in the partial pressure of alcohol in the original gas.

In experiments with an Fe catalyst at 224°, with the addition of 1.5% propanol or propanal to the original gas, almost half of the final products were formed with the participation of these compounds; the butane and butenes had the normal structure.

Soviet workers [45] published the results of experiments on the preparation on a 100Co : 18ThO_2 : 100 kieselguhr catalyst with a CO : 2H_2 mixture containing added labelled ethanol at 195°. The molar radioactivity of the C_6–C_{29} hydrocarbons was constant and independent of the C number. An average of one molecule out of 18 was formed with the participation of the alcohol. The molar radioactivity of the methane and C_2–C_4 hydrocarbons was slightly less than the molar radioactivity of the liquid hydrocarbons. In analogous experiments by American workers [43], one hydrocarbon molecule out of 60 was formed with the participation of labelled ethanol with the same concentration in the original gas, that is, the quantity was much less than that in the presence of any Fe catalyst. The methane had approximately the same radioactivity as the higher hydrocarbons, whereas on Fe catalysts it had a radioactivity which was 10–100 times less than that of the higher hydrocarbons. In the product of the reaction with a Co catalyst, the greatest molar radioactivity was shown by the C_2 fraction; this was attributed to the fact that the species included in the chain was not ethanol, but its dehydration product, ethylene, which undergoes partial hydrogenation to form ethane. When 1.5% ethanol is added, it is included in the chain to a greater extent than when 0.04% is added, but the increase is less than the increase in the concentration. Emmett and coworkers [43] concluded that on Fe catalysts, alcohols are intermediate products in the preparation of hydrocarbons from CO and H_2, but that the mechanism of the preparation on Co catalysts differs from that on Fe catalysts.

Soviet workers [45] consider that these and other data [25,29] indicate that transfer of the chain, which begins with the adsorption of alcohol molecules, produces material chains with a number of units up to n - 1, where n is the C number of the hydrocarbons. The observed coefficient 1 : 18 may express the ratio of the units in the reaction and material chains. Thus one unit in the reaction chain corresponds to one material chain. The fact that the molar radioactivity of the liquid hydrocarbons is constant with change in C number reflects the single mechanism of chain formation with the direct participation of the labelled alcohol or its adsorption complex. This participation, however, may be manifested not only in the initiation of chain growth, as assumed by Emmett and coworkers [25,29], but also in the termination of the material chains, which leads to the same results. The Soviet workers [45] point out that neither their results nor the results of Emmett and coworkers [25,29] provide a basis for rejecting the methylene-polymerisation scheme, since it has not been proved that CH_2 radicals cannot take part in chain growth initiated by alcohol. A parallel reaction without inclusion of alcohol also does not exclude the participation of CH_2 radicals. Moreover, a stage involving the polymerisation of CH_2 radicals on a Co catalyst is confirmed by the hydropolymerisation of alkenes [5,6]. The oxymethylene-condensation scheme for the formation of carbon chains is more probable for the mechanism of the iso-synthesis in the presence of oxide catalysts, in view of the semi-contact character of the hydrogenation of CO under these conditions [46].

The fact that the adsorption complexes of alcohols tend to bring about the growth of carbon chains in the presence of CO and H_2 on Co and Fe catalysts still does not prove that the true primary complex formed from CO and H_2 is an alcohol-like product. It was therefore of interest to add compounds of other classes to the original gas.

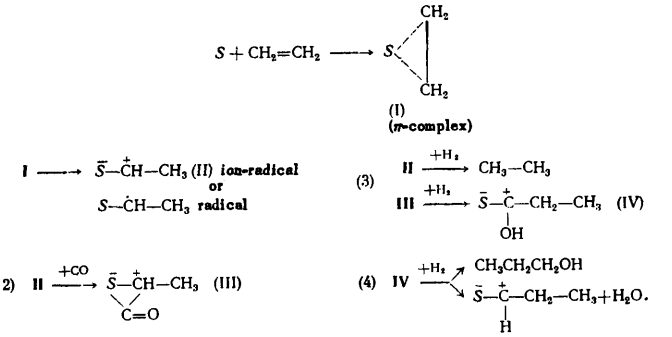
Experiments on a Co catalyst were carried out with gas containing added acetaldehyde or ethanol labelled with ^{14}C in both carbon atoms, and with methyl formate labelled in the methoxycarbonyl group [47]. The products of the reaction with ethanol and acetaldehyde showed a constant molar radioactivity with increase in C number, whereas the products of the reaction with methyl formate showed a linear increase in the molar radioactivity with increase in C number, the molar radioactivity in the first two reactions amounting to 5–6%, and that in the last reaction to 63% of the radioactivity of the original labelled compound. This shows that methyl formate, like formic acid [23], decomposes on the catalyst surface with the formation of CO, which, however, reacts at the moment of formation, since the radioactivity of carbon monoxide in the gas is low. The similarity in the results of the experiments with ethanol and acetaldehyde indicates that the aldehyde is reduced to the alcohol. Chain growth is due to an adsorption complex of alcohol, but it has not been proved that it contains oxygen.

2. Radiochemical Studies of the Formation of Hydrocarbons from CO and H_2 Using Labelled Alkenes

Experiments carried out at 195° on a Co catalyst with an original mixture of CO and H_2 containing ethylene labelled with ^{14}C are of particular interest in the investigation of the mechanism of the hydropolymerisation of alkenes [5,6]. Under these conditions, ethylene is converted into higher hydrocarbons to the extent of 25% and into ethane to the extent of 50%. The molar radioactivity of the liquid hydrocarbons remained constant with change in C number and at concentrations of ethylene in the original gas equal to 0.78% and 1.48% it amounted to 10% or 22% respectively of the radioactivity of the added ethylene. Thus under these conditions the extent to which the labelled compound took part in chain formation increased in proportion to its concentration. The results obtained show that ethylene is present in the primary complex bringing about the growth of the material chains on the catalyst. Chain termination by ethylene must be excluded, since increase in its concentration in the original gas does not lead to a decrease in the yields of the higher hydrocarbons. The hydropolymerisation of ethylene [5,6] also provides evidence against chain termination by ethylene.

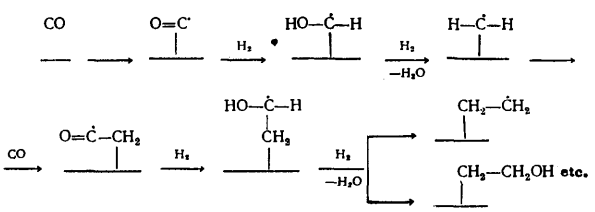
Comparison of published data [45,47,48] indicates that ethylene takes part to a greater extent than ethanol in the formation of hydrocarbons on a Co catalyst. One molecule out of 4–5 is formed with the participation of the labelled compound when using ethylene, compared with the figure of one molecule out of 18 for ethanol. It is possible that the alcohol is first dehydrated to form ethylene, which then enters the complex initiating chain growth. This casts doubt on the applicability of the condensation scheme. All these facts taken together leave no doubt that the growth of hydrocarbon molecules on the catalyst surface takes place by a chain mechanism.

Experiments [19] on a Co catalyst at 195° with an original mixture containing 1.5% labelled propene showed that the molar radioactivity of the liquid products remained constant with change in the C number, but that propene took part in the formation of products to a smaller extent than ethylene: only one out of 12 hydrocarbon molecules was produced with its participation. The lower reactivity of propene compared with ethylene was previously observed in hydropolymerisation under the influence of CO. [41,49] An interesting feature is that increase in the concentration of labelled alkene in the original mixture of CO and H_2 above a definite limit may lead not only to participation of the alkene in the



formation of the primary complex, but also to its participation in chain growth. This was observed[19] by the addition of 4.8% ethylene, when the molar radioactivity remained unchanged with change in the C number of the hydrocarbons in the range 5–9, but increased for hydrocarbons above C_9. This phenomenon can be regarded as an intermediate stage between the Fischer–Tropsch reaction and the hydropolymerisation of the alkene. Under these conditions one out of 1–2 molecules of C_5–C_9 hydrocarbons was formed with the participation of the labelled carbon of ethylene.

In the reaction on an Fe catalyst at 224° with a $CO:H_2$ mixture containing 1.25% labelled ethylene, the quantities of hydrocarbons formed with its participation amounted to 12% at 1 atm and 6% at 6.5 atm. These results show that ethylene may initiate chain growth, but not to the same extent as primary alcohols[44].

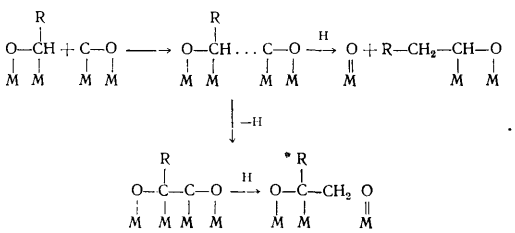


A very interesting series of studies has been carried out by Kryukov, Bashkirov, Kagan, and their coworkers on the mechanism of the preparation of alcohols and hydrocarbons on fused Fe catalysts at 160–300° and 20–150 atm at a volume rate of gas equal to 500–2000 h^{-1}, using the tracer method[50–55].

Under these conditions, butanol labelled with ^{14}C and added in quantities of 0.04–0.1% to an original $1CO:2H_2$ mixture remained 90–95% unchanged. Less than a hundredth of the resulting hydrocarbons above C_4 and of C_6–C_9 alcohols could have been formed with its participation[51]. Thus butanol is not an intermediate product of the preparation. The slight radioactivity of the pentanol and hexanol formed, however, indicated the formation of a radioactive complex containing oxygen. Labelled butene added to the original gas (90 atm and 220°) underwent hydrogenation, oxidation, and hydro-cracking, took part to some extent in the formation of C_5 products, but took no part in the formation of alcohols and hydrocarbons above C_9.[52] As expected, methanol was less stable than butanol under these conditions and underwent various transformations, particularly decomposition to CO and H_2.[51] It took part not only in chain formation, but also in chain growth, as indicated by the increase in the molar radioactivity of the product with increase in the C number. The fact that the radioactivities of alcohols and hydrocarbons with equal C numbers were the same was attributed to their formation from the same "precursor", that is, from the same primary complex, formed from CO and H_2 and containing oxygen in addition to carbon and hydrogen[50,51]. The primary complex bringing about growth of the carbon chain is formed by the reaction of CO, activated on an Fe atom dissolved in iron carbide, with hydrogen, physically adsorbed on neighbouring carbide atoms[54]. An interesting feature is that in the study of the part played by iron carbides using CO labelled with ^{14}C in experiments on fused catalysts (300° and 20 atm) it was found[53] that in this instance they cannot be regarded as intermediate products. The carbides were hydrogenated to form methane and exchanged carbon with CO. Both of these processes took place very slowly. Only one out of 3000 CO molecules underwent exchange and five out of 3000 CH_4 molecules were formed from the labelled carbide. Hydrocarbons could have been formed via the carbides to the extent of only 0.03%. Even from this low degree of conversion of carbides into reaction products it is possible to estimate the part played by methylene radicals in chain formation. On the basis of data obtained in a study of ethylene added to the original gas and iron carbides labelled with ^{14}C, it was concluded[55] that the chains may grow simultaneously in two main ways: by condensation of intermediate oxygen-containing compounds with the liberation of water, and by polymerisation of surface compounds which may or may not contain oxygen. In the polymerisation scheme, growth of the carbon chain takes place at the end of the molecule which does not contain the hydroxyl group. An analogous dual mechanism for the growth of carbon chains in the iso-synthesis[56–59] was proposed by Eidus[46]. A slight difference was that Eidus[46] assumed stepwise growth not only by groups containing one C atom but also groups containing several C atoms. Some of the stages in the two schemes, particularly in the initial stages, are similar or even identical.

To explain the participation of ethylene in chain initiation, Roginskii and coworkers[19] proposed a step scheme in which ethylene, after formation of a π-complex with the catalyst and conversion into an ion-radical or ethylidene radical, combines with an adsorbed CO molecule, forming successively, and with the participation of hydrogen, ion-radicals or α-hydroxypropylidene radicals and then α-propylidene, with regeneration of the unsaturated carbon atom in the α-position to the catalyst:

Voevodskii and coworkers[60] put forward a chain scheme for the preparation of organic compounds from CO and H_2, involving the gradual growth of a univalent surface radical:



3. Radiochemical Studies of the Formation of Hydrocarbons from CO and H_2 Using Labelled Keten

Blyholder and Emmett[61] used keten labelled with radioactive ^{14}C in the methylene group. The experiments were carried out on an Fe catalyst at atmospheric pressure and 247° with the addition of 2% keten to a $CO:H_2$ mixture. The hydrocarbon product had an almost constant molar radioactivity, which was independent of the C number and equal to the radioactivity of the original keten. Analogous experiments were made with the addition of 0.25% labelled keten to a $1CO:2H_2$ mixture (Co–ThO_2–MgO–kieselguhr catalyst) at 185°. The molar radioactivity of the hydrocarbons was approximately independent of the C number and amounted to one-third of the radioactivity of the keten. The methane formed was not radioactive. Since the adsorbed keten

underwent intensive introduction into the reaction products, it was concluded that its adsorption complex is similar to the primary complex of the Fischer–Tropsch reaction. It was assumed that the keten molecule is joined to the catalyst surface by metal–carbon and metal–oxygen bonds. The following three possible results from the introduction into the reaction of a keten labelled in the methylene group were examined: (1) for dissociation of the keten into methylene and CO, assuming the applicability of the methylene–polymerisation scheme, the reaction product should have a molar radioactivity directly proportional to the C number; (2) with dissociation of the keten into CH_2 and CO, if polymerisation of the methylene radicals or their inclusion in the preparation by another mechanism do not take place, the reaction product should not be radioactive, whereas the methane should be radioactive; and (3) if the keten does not dissociate, but initiates chain growth, the reaction product should have a radioactivity which is independent of the C number. The experimental data appear to confirm the third possibility.

The results obtained show that on Co and Fe catalysts the keten is converted almost completely into reaction products, indicating that it is strongly adsorbed and possibly that an oxygen–catalyst bond is formed. The possibility of formation of such a bond is indicated[62] by the exchange of O atoms between $^{12}C^{16}O$ and $^{13}C^{18}O$ on an Fe catalyst, which shows that the CO is joined to the surface through the C and O atoms. In accordance with this, Blyholder and Emmett[61] proposed a reaction scheme in which the keten and CO are adsorbed through the C and O atoms, and new C–C bonds are produced between the carbon of the carbon monoxide and the carbon of the carbonyl group of the keten without condensation with the liberation of water. Oxygen is liberated in the form of atoms adsorbed on the catalyst:

The keten is adsorbed more strongly than saturated alcohols, so that it is more effective at the start of chain growth. According to Blyholder and Emmett[61], alcohols should undergo preliminary dehydration before forming the initial complex. This is indicated by the ability of ethylene to form a complex which brings about chain growth. Ethane does not exhibit these properties.

Blyholder and Emmett[61] considered three possible results of the use of keten, but they did not consider the fourth, most probable possibility: dissociation of the keten with the subsequent participation of the methylene radical in chain initiation. New conclusions were reached in subsequent work[63]. The reaction was carried out on a once-promoted Fe catalyst at 256° with the addition of 0.7% keten, labelled in the carbonyl group, to the original gas, and on a Co catalyst at 189° with the addition of 0.5% of the same keten. Hydrocarbons with molar radioactivity directly proportional to the C number were formed on both catalysts. Thus the keten undergoes preliminary dissociation on the catalyst with the formation of a methylene radical, which initiates the chain, and carbon monoxide, which takes continuous part in the chain growth. The exchange of carbon between CO and the keten under these conditions is slight and is not reflected in the results. Convincing confirmation was thus obtained for the initiation by heterogeneous methylene radicals of the growth of chains in the Fischer–Tropsch synthesis on Co and Fe catalysts. This shows that not only oxygen-containing but also hydrocarbon radicals exhibit these properties. The results obtained, however, did not touch on the polymerisation of CH_2 radicals. It would be of interest to use higher concentrations of keten, labelled in the methylene group, to study this process. The CH_2 radicals would then take part in chain growth in a fashion analogous to that of ethylene at higher concentrations[19]. An interesting feature is that the addition of 0.5–0.7% keten to the original gas led to an increase in the yield of lighter products.

4. Radiochemical Studies of the Hydropolymerisation of Ethylene Using Labelled CO

Gibson and Fletcher[64] described a study of the mechanism of the hydropolymerisation of ethylene under the influence of CO. The chief aim of this work was to investigate the part played by two types of radical: hydrocarbon radicals and oxygen-containing radicals. It was assumed that an oxygen-containing radical initiates chain growth, since hydropolymerisation does not take place in the absence of CO but takes place to an appreciable extent at a concentration of 0.1% CO in the original gas[5]. The reaction was carried out on a $100Co : 5ThO_2 : 8MgO : 200$ kieselguhr catalyst at 185° with a $C_2H_4 : H_2$ mixture containing 5% CO labelled with ^{14}C. 50–60% of the CO and almost all the ethylene, 50% of which was hydrogenated to form ethane, took part in the reaction. The molar radioactivity of the C_4–C_{10} hydrocarbons increased regularly with increase in the C number. Approximately one out of 6–7 carbon atoms was produced from CO. The molar radioactivities of the methane and ethane were low. Side-products of the Fischer–Tropsch reaction were formed in small quantities. With the exception of appreciable yields of C_4 hydrocarbons, the formation of large quantities of other true polymeric forms was not observed. Gibson and Fletcher[64] consider that this confirms the earlier conclusion (see p. 341) that ethylene dissociates into two methylene radicals, forming hydrocarbons and methane. Comparison of the radioactivity of the hydrocarbons with the radioactivity of the original CO shows that some of the molecules formed do not contain C atoms originating from the CO. This means that after initiation of the reaction, chain growth can continue and be renewed to some extent without the participation of CO. Gibson and Fletcher[64] quote the results of Eidus and coworkers[65], according to which, after the reaction of a mixture of CO, H_2, and C_2H_4, it is possible to obtain liquid hydrocarbons for some time by passing a mixture of C_2H_4 and H_2 containing no CO over the Co catalyst. These experiments were repeated[66] using ^{14}CO; the same results were obtained, and both the volatile and high-boiling fractions of the reaction product contained ^{14}C. These data[64,65] show that the formation of hydrocarbon chains is also possible even when the original C_2H_4–H_2 mixture does not contain CO. Chain growth is initiated by radicals on the catalyst surface, for which CO is necessary at the start of the reaction. These heterogeneous radicals can apparently be subsequently regenerated from ethylene even in the absence of CO. This explains the absence of ^{14}C in a fraction of the reaction products, and their formation from a mixture of C_2H_4 and H_2.

Determination of the radioactivities of each of the three C atoms in the molecule of the propene liberated[64] gave the following radioactivity ratio:

$$\overset{1}{CH_2}=\overset{2}{CH}-\overset{3}{CH_3}$$
$$304 : 26.5 : 220 .$$

The low radioactivity of the central C atom shows that it comes chiefly from the ethylene. The radioactivity may provide a measure of the quantity of propene formed by the Fischer–Tropsch reaction from CO and H_2. If the propene were formed by the direct attachment of a C atom from CO to an ethylene molecule by hydrocondensation[40,67,68], one of the terminal C atoms should show a high radioactivity. The high radioactivity of both terminal C atoms is apparently due to migration of the double bond, which takes place readily on a Co catalyst; this has been shown many times[69-76]. The propene formed from CO and H_2 then exhibits radioactivity:

$$CH_2=CH-CH_3$$
$$26.5 : 26.5 : 26.5.$$

The initial distribution of the radioactivity in the propene formed by the hydropolymerisation of ethylene is as follows:

$$\overset{1}{CH_2}=\overset{2}{CH}-\overset{3}{CH_3}$$
$$471 : 0 : 0 .$$

A study was made[77] of the distribution of the radioactivity in propanol, whose yield amounted to 4% of the liquid products of the reaction. The propanol was converted into propene by a method which prevented movement of the double bond. The following radioactivity distribution was observed:

$$\underset{15}{\overset{3}{CH_3}-\overset{2}{CH_2}}-\overset{1}{CH_2OH}$$
$$85$$

The molar radioactivity of the propanol was 11 times the radioactivity of the propane and more than one-third of the radioactivity of the original carbon monoxide. All the propanol was formed according to the reaction

$$CH_2=CH_2 + {}^{14}CO \longrightarrow CH_3CH_2{}^{14}CH_2OH.$$

Less than 10% of the C_3 products was formed with the participation of ^{14}CO, and the greater part was formed from the carbon of the ethylene. It was therefore concluded that the ethylene dissociates into two methylene radicals. The distribution of the radioactivity is of the same type for propene and propanol, as a result of the fact that the ^{14}C is attached to the ethylene in the form of CH_2 or oxygen-containing radicals with one ^{14}C atom in each instance; it is possible that propene is formed from propanol. Since the original gas contains a large quantity of ethylene, the hydropolymerisation is not identical with the Fischer–Tropsch reaction, but the fact that the radioactivity distribution is the same for propanol and propene was taken[77] as confirming the previous suggestion that in the Fischer–Tropsch reaction on a Co catalyst the primary products are alcohols, from which alkenes and alkanes are produced by dehydration and hydrogenation.

The characteristics of the liquid product of the hydropolymerisation of ethylene, obtained from an equimolar mixture of ethylene and hydrogen containing ~5% CO are given in the Table. The slight discrepancies in the data must be attributed to slight differences in the composition of the Co catalysts used in the experiments.

The reaction products are forms with odd and even C numbers (see Table). Gibson and Clarke[78] confirmed the

TABLE. Characteristics of the liquid product of the hydropolymerisation of ethylene.

Fraction	Concentration, wt. %	Concentration of unsaturated compounds, %	Concentration, wt. %	Concentration of unsaturated compounds, %
	according to Ref. 78		according to Ref. 79	
C_5	20	73	11	100
C_6	28	62	18	68
C_7	8	54	17	65
C_8	13	53	13	60
C_9	10	52	9	51
$>C_9$	21	—	32	—

data of Eidus and coworkers[5], who showed that the yield of C_4 and higher hydrocarbons increases with increase in the CO concentration in the range 0.3–5%. The yield of methane does not increase, and the quantity of ethylene converted into ethane decreases from 90% to 35% with increase in the CO concentration from 0.3% to 6.1%.

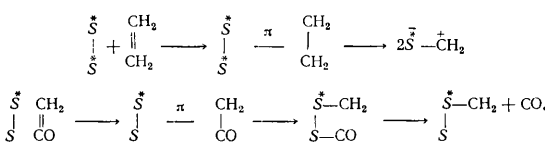
The distribution of the radioactivity over the individual atoms in the hexene and heptene molecules was determined[78] by a specially developed method for the stepwise degradation of these molecules. The following radioactivity ratios were obtained:

$$\overset{6}{C}-\overset{5}{C}-\overset{4}{C}-\overset{3}{C}-\overset{2}{C}-\overset{1}{C}$$
$$2.3 : 6.2 : 40.7 : 41.8 : 7.9 : 1.1$$

$$\overset{7}{C}-\overset{6}{C}-\overset{5}{C}-\overset{4}{C}-\overset{3}{C}-\overset{2}{C}-\overset{1}{C}$$
$$0.6 : 13.1 : 22.4 : 30.9 : 31.8 : 0.9 : 0.3.$$

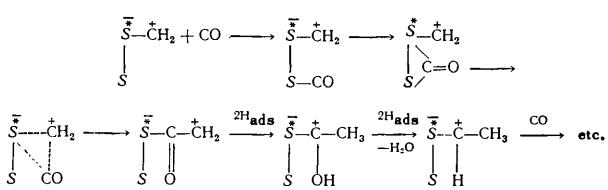
The accuracy of these figures increases with increase in the actual figures, from ±30–50% for the values 0.6–2.3 to ±1–5% for the values 30–42. Thus in hexene and heptene the central two or three C atoms respectively have a high radioactivity and the terminal atoms have a low radioactivity. The double bonds lie chiefly between atoms 2 and 3 in hexene and between atoms 2 and 3 or 3 and 4 in heptene.

Gibson and Clarke[78] consider that the mechanisms of chain growth in hydropolymerisation and the formation of hydrocarbons from CO and H_2 are similar. Stepwise attachment of species containing one C atom to the growing chain takes place. The distribution of the radioactivity in the final product is the same as that in the chain with the same C number on the surface. The radioactivities of each C atom 3 and 4 in hexene and heptene correspond to the increase in radioactivity for the attachment of one atom from ^{14}CO. The properties of the radicals produced from CO and from C_2H_4 are different, in agreement with the conclusions reached by Blyholder and Emmett[63].



In a study of the radioactivity distribution in propanol, hexene, and heptene, with the assumption that the reactive group (hydroxyl or multiple bond) is the growing end of the chain, Gibson and Clarke[78] reached the following conclusions: (1) chain growth is initiated by the reaction of CO, or an oxygen-containing radical formed from it, with an adsorbed radical produced from ethylene, to give a chain of three C atoms; (2) chain growth involves the attachment, to this radical of three C atoms (or its derivative), of radicals each containing one C atom, and also of oxygen and radicals produced from CO or ethylene. Chain growth does not take place in the absence of oxygen-containing radicals. These radicals, which are produced from ethylene, may be formed from hydrocarbon radicals, if their concentration on the

surface is high, by reaction with adsorbed oxygen, produced according to the scheme proposed by Blyholder and Emmett[63] (see p. 344). The formation, from hydrocarbon radicals, of oxygen-containing radicals active in chain growth apparently explains two observations: firstly, the presence of non-labelled C atoms in the centre of the chains, and secondly the formation of higher hydrocarbons from a mixture of ethylene and hydrogen on a catalyst which has taken part in the reaction of a ternary mixture of C_2H_4, H_2, and CO;[65,66] and (3) chain termination takes place by the reaction of the growing chain with radicals produced from ethylene and containing one or two C atoms.



A considerable difference is observed in the influence of the concentration of CO in the original gas in the Fischer–Tropsch reaction and in hydropolymerisation. The latter takes place more slowly with increase in the CO concentration above 5%, apparently due to the adsorptive displacement of the alkene from the catalyst surface, as a result of which the rate of the process is determined by the conversion of carbon monoxide into methylene radicals. The adsorptive displacement of the alkene by carbon monoxide also explains the lower rate of hydropolymerisation of propene[49] and butenes[80,81] at CO concentrations of 10–15%.

On the basis of new radiochemical data, Ronginskii[82] developed his scheme[19] of chain growth (see p. 343) to include methylene radicals or ion-radicals in the primary stage. It is assumed that there exist on the surface unique active centres S, on which the growing chains are fixed. The centres differ in their structure and in the concentration of modifying additives from the other active centres S on which other processes take place, for example, the adsorption of CO and H_2.

The primary active forms with the properties of chain growth initiators are assumed to be heterogeneous radicals or the simplest carbonium ions $S-CH_2$ or $S-CH_2$, which are formed in particular by the dissociation of ethylene or keten:

The growth of the carbon chains takes place with the participation of CO and H_2 by a number of successive processes of the same type: CO and the methylene ion radical combine on the surface to form a keten molecule which is adsorbed by two C atoms and which is converted into a different adsorbed state — a keten molecule adsorbed only by the C atom of the carbonyl group. Under the influence of hydrogen, the carbonyl group is converted successively into a hydroxymethine group and then into a methine group with the liberation of a molecule of water. Chain growth continues with the attachment of CO, adsorbed on the surface, to the ethylidene ion-radical (see p. 343).

Chain termination takes place by hydrogenation to saturated hydrocarbons:

On the basis of the fact that the isotopic effect α_i (H_2, D_2) for the Fischer–Tropsch reaction is 0.77,[83] it was concluded that any stage in which the transition state is formed with the participation of free hydrogen molecules cannot be the rate-determining stage; the same is true of the diffusion, adsorption, and desorption of hydrogen. According to Roginskii[82], the kinetics of the reaction[43] and the fact that the isotopic effect α_i is < 1 show that the limiting stage must be one of the stages in the formation of additional methylene radicals, involving the participation of carbon monoxide and hydrogen in the adsorbed state.

IV. DEGRADATION OF CARBON CHAINS

All the above schemes consider only growing chains. Degradation processes, apart from the dissociation of ethylene into two methylene radicals, which unlike the dissociation of keten into CH_2 and CO has not been experimentally proved, is not considered in these schemes. Experiment shows, however, that degradation processes play an extremely important part in hydropolymerisation[84–86]. It is assumed that the species undergoing decomposition are semi-hydrogenated forms of alkenes consisting of heterogeneous hydrocarbon radicals, and that this decomposition takes place intensively in the presence of CO; this can probably be attributed to the action of radicals containing one carbon atom[87,88]. The formation of radicals with a smaller C number from chains with a large C number is observed particularly clearly in the hydropolymerisation of isobutene[89–98] and higher alkenes such as hex-1-ene[99,100] and oct-1-ene[101]. These processes take place with the participation of hydrogen, the concentration of the latter in the original gas influencing the reaction rate and the composition of the final products[102,103].

It has been noted that the products of the hydropolymerisation of alkenes, in addition to polymeric forms, contain compounds with C numbers which are not multiples of that of the original alkene. Their concentration in the high-boiling fraction of the condensate, which contains hydrocarbons with a C number greater than that of the original alkene, increases with increase in the C number of the latter and has the values (wt.%): 34, 44, 73, 80, and 85 for ethylene, propene, but-1-ene, pent-1-ene, and oct-1-ene respectively[74,104]. This is attributed to the fact that the greater the C number of the original alkenes, the greater the number of "non-multiple" hydrocarbons which can exist; this number is equal to n - 1 when the C number of alkene is equal to n.

Examination of the methods by which higher hydrocarbons with a non-multiple C number can be formed leads to the conclusions that they cannot be formed in such large quantities entirely by hydrocondensation of the original alkene with CO according to the scheme:

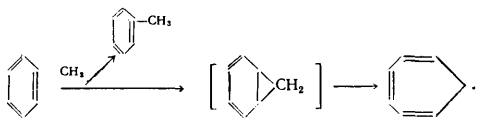
Non-multiple hydrocarbons are formed chiefly by rupture of the C–C bonds in the course of the process with the subsequent reaction of the resulting radicals with adsorbed alkene molecules.

The number of molecules of the original normal α-alkene taking part in the formation of higher hydrocarbons and corresponding to one CO molecule taking part in the same reaction (yield with respect to initiator) is usually greater than unity, indicating [105,106] a chain mechanism for the reaction, in good agreement with the radiochemical data examined above. The yield with respect to the initiator decreases with increase in the C number of the original alkene, other conditions being equal. At ratios in the original gas $H_2 : CO \simeq 8$ and $C_nH_{2n} : H_2 \simeq 1$, the yield with respect to initiator is equal to 6–8 for ethylene, ~ 4 for propene, ~ 3 for but-1-ene, and ~ 2 for hex-1-ene [104]. Thus 12 C atoms react for every CO molecule, irrespective of the molecules in which they are present. All these reacting atoms are apparently adsorbed on the catalyst surface; this may lead to some deformation of the carbon chains and bring about an increase in the ease of rupture of the C–C bonds in the reaction with the formation of heterogeneous radicals. Adsorption by all C atoms of the alkene takes place at low concentrations of CO under the conditions of the radical-chain reaction of growth and degradation of the carbon chains. At higher CO concentrations, the C atoms of the alkene which do not adjoin the multiple bond are displaced from the surface by the carbon monoxide being adsorbed. The alkene is then adsorbed only by the C atoms of the double bond without deformation of the other bonds, and chain growth takes place by a hydrocondensation scheme without rupture of the C–C bond (see p. 346). Thus depending on the concentration of CO and H_2 in the original gas and the adsorption properties of the alkene, one form of adsorption is replaced by the other, as a result of which the hydropolymerisation is replaced by hydrocondensation [107].

V. INITIATED HETEROGENEOUS-CATALYTIC REACTIONS

The heterogeneous-catalytic reaction examined above, namely the hydropolymerisation of alkenes in the presence of hydrogen, is initiated at 190–200° by small quantities of CO. A new heterogeneous-catalytic reaction, taking place only in the presence of initiator, was discovered recently. This is the hydropolymerisation of alkenes, initiated at 100–120° by small quantities of oxygen in the presence of hydrogen on Co catalysts [108-113]. Under the optimal conditions, this reaction takes place to the extent of 35–45%, and the hydrogenation of the alkene to the alkane with the same number of carbon atoms takes place to the extent of 17–30%, calculated on the original alkene (C_2–C_4). The optimal concentration of oxygen in the original alkene–hydrogen mixture amounts to ~ 2%. Hydropolymerisation under the influence of oxygen always takes place at the same time as hydrogenation of the alkene. A catalyst which is inactive with respect to hydrogenation is also inactive with respect to hydropolymerisation. As with the hydropolymerisation of alkenes initiated by carbon monoxide, the initiation of the hydropolymerisation by oxygen is followed by the formation of new intermediate active forms on the catalyst surface, indicating degradation processes. In addition to true polymeric forms, the reaction products contain hydrocarbons in whose molecules the numbers of carbon atoms are not multiples of the number in the original alkene. The results obtained have made it possible to develop the concept of "initiated heterogeneous-catalytic reactions" [114], an example of which is provided by the hydropolymerisation of alkenes under the influence of CO or O_2. A characteristic feature of initiated heterogeneous-catalytic reactions is that they take place entirely on the surface of the solid catalyst and that they require not only a specific catalyst but also the presence, in the reaction zone, of a compound which differs from the direct starting materials and which does not react in stoichiometric proportions. This compound starts the reaction and acts as initiator. The initiator may or may not take part in the development of the process and the formation of the final products, depending on the reaction conditions.

Conditions were found under which CO undergoes almost no reduction by hydrogen and is not included in the final products of the hydropolymerisation of ethylene at 190°. The quantities of CO taken for the reaction and obtained after the reaction were identical. The yields and compositions of the reaction products, however, differed little from those observed in the reaction involving the reduction of CO. The reaction does not take place in the absence of CO.

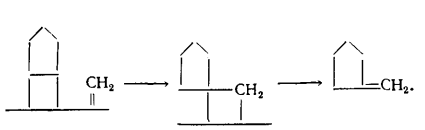


The $C_2H_4 : H_2$ ratio in the original gaseous mixture has a characteristic influence on the reduction of CO in the hydropolymerisation of ethylene. When this ratio is less than 1.0–1.2, CO reacts to the extent of 60%, but when the ratio is greater than 1.7, the CO is not used up. In the hydropolymerisation of propene, butene, and isobutene, the CO is reduced and used up in the reaction. In the joint hydropolymerisation of ethylene and its homologues, the quantity of CO used up is greater, the smaller the volume ratio of ethylene to hydrogen in the original gas [115].

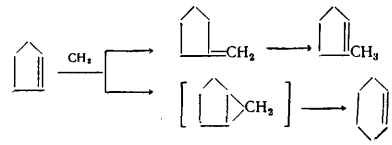
It is possible to picture several ways in which hydropolymerisation is initiated by carbon monoxide. One possibility is that the carbon monoxide is reduced to some extent to surface intermediate products of the methylene and oxymethylene radical type, which take part in the initiation, and also possibly in growth of the carbon chains, so that they appear in the final products. During the reaction, the CO is regenerated, and the molecules of the regenerated CO may contain carbon atoms which come not from the original CO but from the alkene. Another way in which the reaction may be initiated by carbon monoxide does not involve the participation of CO at the start of formation and growth of the hydrocarbon chains and hence does not involve introduction of its carbon atoms into the final products. This takes place when the adsorption is hindered by a high concentration of ethylene. It may be assumed that in order to take part in the reaction in the form of CH_2, CHOH, and similar radicals or in the form of CO, the carbon monoxide should be adsorbed by both the C and O atoms. When adsorption is hindered, this is unlikely, and the CO is adsorbed through only the C atom. In this adsorbed form reduction is probably impossible, but the formation of $CO.nH_2$ complexes on the catalyst surface is still possible, and in these complexes the active hydrogen is capable of reacting with an alkene molecule, converting it into a heterogeneous radical which initiates the hydropolymerisation.

The hydropolymerisation of ethylene without consumption of CO and hence without the liberation of water indicates that the formation of hydrocarbon chains is in principle possible not by a dehydration-condensation scheme [29] but by a polymerisation scheme with a correction for degradation processes [86,87]; this is extremely important for an understanding of the mechanism of the reaction.

VI. HYDROCONDENSATION OF CARBON MONOXIDE WITH CYCLIC HYDROCARBONS



The catalytic hydrocondensation of carbon monoxide with alkenes [40] is one of the first stages of the Fischer–Tropsch reaction and the hydropolymerisation of alkenes under the influence of CO. It is also of independent importance, however. It demonstrates the ability of CO, mixed with H_2, to act as an alkylating agent, particularly a methylating agent, leading to the formation of the homologues of alkenes. Hydrocondensation takes place selectively with cyclic hydrocarbons, although the yields are low, since these hydrocarbons do not undergo further hydropolymerisation. This reaction was first used to prove the formation of surface methylene radicals from CO and H_2 on a skeletal Co–Ni catalyst during the conversion of benzene into toluene [116]. The formation of toluene from benzene, CO, and H_2 was also observed [117] over an Fe–Cu catalyst. When the same reaction was carried out at 190° and 1–20 atm (Co–ThO_2–kieselguhr catalyst) the reaction products were found to contain small quantities of cycloheptatriene in addition to toluene [118]. Its formation was attributed to the reaction of methylene radicals with benzene with the intermediate production of the norcaradiene structure:



The formation of cycloheptatriene and toluene from benzene, CO, and H_2 takes place by parallel reactions [119].

A mixture of cyclohexene, CO, and H_2 gave up to 10% of the monomethyl and dimethyl derivatives [120,121]. Cyclopentadiene, CO, and H_2 gave 4–5% of the monomethyl, dimethyl, and trimethyl derivatives [122].

The hydrocondensation of CO with cyclopentene gave a mixture of hydrocarbons with C number greater than that of the original cycloalkene, in yields of 33% relative to the CO reacting or 5% with respect to the cyclopentene passed. After complete hydrogenation, the product was found to contain 45% methylcyclopentane, 20% ethylcyclopentane, 8% propylcyclopentane, and 27% cyclohexane hydrocarbons (10% cyclohexane, 10% methylcyclohexane, and 7% ethylcyclohexane) [74,123]. The process involving increase in the size of the ring is associated directly with the hydrocondensation [75]. It was shown [126] that the formation of a six-membered ring from a five-membered ring is not associated with isomerisation of the five-membered ring or with the formation of methylenecyclopentane according to Herington's scheme [34]:

It was suggested [124] that by analogy with the formation of cycloheptatriene from benzene via the norcaradiene structure, hydrocarbons with a six-membered ring are produced from cyclopentene with the intermediate formation of the bicyclo[1,0,3]hexane structure:

The ease of alkylation decreases in the order: cyclopentene > cyclohexene > benzene. Alkylation is favoured by a decrease in the concentration of CO in the original gas from 20% to 5%. [125]

---o0o---

From the present review it may be concluded that in the preparation of hydrocarbons from CO and H_2, the latter form a primary complex (the C_1 complex) on the catalyst surface, and that the growth of the carbon chain begins from this complex. Chain growth involves the successive attachment of structural units containing one carbon atom to the primary complex. Experiments with the addition of a small quantity of compounds labelled with ^{14}C to the CO–H_2 mixture show that these compounds can be divided into two groups. The reaction with compounds of the first group gives liquid products whose molar radioactivity increases regularly with increase in the C number of the fraction. These compounds include formaldehyde, methanol, methyl formate, and keten labelled in the CO group. The reaction with gas containing compounds of the second group gives liquid products whose molar radioactivity remains constant with change in the C number. These compounds include ethanol, propanol, acetaldehyde, propanal, ethylene, propene, and keten labelled in the CH_2 group. These apparently take part in the formation of a primary complex which is analogous to or identical with the C_1 complex, either as the complete molecule or as a part of the molecule containing the labelled ^{14}C atom. For example, keten enters the primary complex in the form of the CH_2 group, and ethylene enters completely (or, less probably, as a CH_2 radical formed by the dissociation of $CH_2{=}CH_2$); alcohols enter the complex completely on Fe catalysts but in the form of the dehydration product (the alkene) on Co catalysts. Substances of the first group undergo preliminary decomposition with the formation of CO, which reacts further, taking part in chain growth. When added in larger quantities, ethylene may be included in the chain during its growth. This shows that a structural unit with two or more C atoms may also take part in chain growth. In the same way, the primary complex may contain not merely one, but also two or more C atoms. The initiation of the chains by methylene radicals formed by dissociation of keten shows convincingly that the presence of an oxygen-containing radical is not essential for chain initiation. This process also takes place with the participation of a hydrocarbon radical. The primary complex apparently may or may not contain oxygen, depending on the conditions; there is then an increase in the probability of the condensation or polymerisation scheme for C–C bond formation.

The fact that chain growth under certain conditions takes place exclusively according to the polymerisation scheme and not by condensation with the liberation of water is shown by new data, according to which the hydropolymerisation of ethylene under the influence of CO takes place under certain conditions with almost no consumption of the latter, and hence without the liberation of water.

It has been shown that degradation processes play an important part in the formation of carbon chains. The hydrocondensation of unsaturated hydrocarbons with CO may take place not only with the formation of a straight chain, but also via three-membered complexes analogous to the products of the reaction of multiple bonds with carbenes.

The concept of initiated heterogeneous-catalytic reactions has developed; according to this concept, an important part is played not only by the solid catalyst but also by an initiator which is not involved in the stoichiometry of the reaction.

PHASE EQUILIBRIA BETWEEN IMMISCIBLE GASEOUS PHASES

D.S.Tsiklis and L.A.Rott

INTRODUCTION

Until very recently there were reckoned to be five types of equilibria: crystal–crystal, crystal–liquid, crystal–gas, liquid–liquid, and liquid–gas. The theory of these phase equilibria was developed by Konovalov[1], Stoletov[2], Gibbs[3], van der Waals[4], Kuenen[5], and others. There was also convincing experimental confirmation of the theoretical predictions.

It now seems astonishing to us why the possibility of the existence of yet another type of equilibrium — gas–gas equilibrium (the existence of which could have been postulated even by simple analogy) — was generally not discussed right up to the end of the XIXth century. Even at the time of Dalton, scientists were surprised[6] that gases did not behave as liquids and did not take up positions in relation to one another according to their specific gravities. The explanation for such behaviour of gases was found in the fact that at low pressures they are mechanically (energetically, in modern terminology) independent.

The concept of the energetic independence of gases, true only at moderate pressures, greatly suppressed interest in a search for equilibrium between gaseous phases. Even after van der Waals[7] and Kammerlingh-Onnes and Keesom[8] had made, in the 1890's, a theoretically based prediction of the possibility of the existence of such an equilibrium, about 50 years elapsed before the first experimental work appeared, carried out by Krichevskii[9]. The results completely confirmed the predictions of the Dutch scientists.

Such a prolonged break is explained not solely to the viability of the concept of the energetic independence of gases. van der Waals and his students correctly predicted that the phenomenon of restricted mutual solubility of gases is possible because there is a great similarity between liquids and strongly compressed gases. Hence it seemed natural to search for this phenomenon at high pressures. The absence of the technical means necessary for this was a second reason, which for long delayed the experimental confirmation of this interesting phenomenon. However, as we shall see subsequently, it can also be observed at comparatively low pressures.

But somehow or other, if the honour of the theoretical prediction of and basis for the new type of equilibrium belongs to the Dutch scientists, that of resurrecting their forgotten ideas, experimentally verifying these ideas, and developing further the theory of phase equilibria with allowance for this new equilibrium belongs wholly to Soviet scientists[10].

RESTRICTED MUTUAL SOLUBILITY OF GASES

The works of van der Waals and his coworkers contained not only an indication of the possibility of equilibrium between two gaseous phases at temperatures above the critical temperatures of the two components of a binary mixture but also predictions about the form of the critical curve.

According to these predictions two types of such equilibria are possible. *The first type* (to which belong systems containing helium) is characterised by the critical curve (in coordinates of pressure and temperature) in leaving the critical point of the less volatile component (Fig. 1) being directed towards the side of high temperatures. The curve is convex towards the temperature axis and at the point *M* turns towards lower temperatures. The reversal occurs at appreciable pressures and after it the curve is directed towards the side of the critical point of the more volatile component. Fig. 2 shows the phase diagram for this type of equilibrium.

Second type. On leaving the critical point of the less volatile component, the critical curve (Fig. 3) is at first directed towards the side of lower temperatures. The curve is convex towards the temperature axis and passes through a minimum — point *D*. Its name, according to van der Waals terminology, is the double homogeneous point. Then the curve turns towards the side of high temperatures and subsequently its form does not differ from that described for the first type†.

Fig. 4 shows a phase diagram for this type of equilibrium as we visualise it now. In the temperature region from the critical temperature of the less volatile component to the temperature of the double homogeneous point both liquid–gas and gas–gas equilibria exist. In the temperature region from the critical point of the less volatile component up to the temperature maximum *M* there is only gas–gas equilibrium.

METHOD OF INVESTIGATION

Phase equilibria between two gaseous phases have been investigated by analytical and synthetic methods. These methods (details of the apparatus and experimental technique) have been described in sufficient detail already[12]. Here it is possible only to mention that by analytical is meant those methods in which the compositions of the coexisting phases are determined by the analysis of specimens taken from each phase. In working by synthetic methods a mixture of the two components of known quantitative composition is made up and then the moment for the disappearance or appearance of one of the phases is observed, by measuring the temperature, pressure, or volume (or all three parameters) of the system.

Many of the studies carried out in our country employed analytical methods in equipment with a mercury piezometer (Fig. 5) (a Callietet tube[13]). The piezometer is a metal

† We will not deal with the form of the critical curve in the region close to the critical point of the more volatile component (see, for example, Vogel[11]).

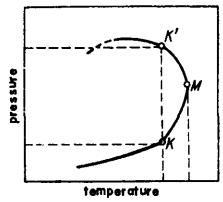

Fig. 1. Critical curve of systems giving the first type of separation. K critical point of the less volatile component; M maximal temperature of existence of gas–gas equilibrium; K' upper critical point of the gas–gas equilibrium.

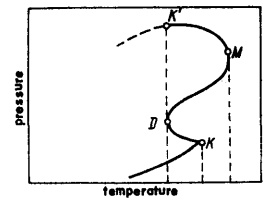

Fig. 3. Critical curve of systems giving the second type of separation. K critical point of the less volatile component; D double homogeneous point; M maximal temperature of existence of gas–gas equilibria; K' upper critical point for the gas–gas equilibrium.

separating funnel filled with mercury. A mixture of known composition which is being studied is prepared outside the apparatus, run into the piezometer [14], and the temperature and pressure for the experiment created in the apparatus. Layering takes place. The upper phase is forced out by the mercury through the upper valve and is analysed. After all the upper phase has left the lower phase is forced out. The operations of forcing out the phases are carried out at constant pressure produced by pumping mercury from beneath into the piezometer under the pressure of a working fluid, which is supplied by a multiplier (Fig. 6).

The use of mercury at temperatures above 200°C is undesirable, both from the standpoint of accident prevention and also because it is soluble in compressed gases. Therefore, mercury-free equipment is used [15–18]. In this, the mixture is created in a high pressure vessel fitted with an electromagnetic stirrer and the compositions of the phases are determined by withdrawing specimens of the phases from above and below the vessel (Fig. 7).

Arons and Dipen [19] used the synthetic method for investigating gas–gas equilibria in the helium–xenon system. They prepared a mixture of xenon and helium of known concentration and filled a glass piezometer with it. The piezometer was put in a high pressure vessel with a sight glass (Fig. 8). The mixture in the piezometer was compressed by mercury. The phase diagram of the system could be constructed from observations of the appearance and disappearance of a meniscus and by noting the pressures corresponding to the appearance and disappearance of a bubble of the upper or lower phase. The volumes of the coexisting phases could also be measured with this apparatus.

Gas–gas equilibrium of the first type starts at the critical point of the less volatile component, which is usually found at moderate temperature and pressure. Making use of this, Krichevskii proposed, and Khodeeva [20] put into practice, a method in which the less volatile component is introduced into a glass ampoule of known capacity in such a quantity that it is at its critical volume. The critical temperature of the substance is measured and then a small quantity of the second component is added and the critical temperature of the mixture again measured. If the critical temperature is higher — that is, the meniscus between the phases disappears at a higher temperature — than the critical temperature of the pure component (less volatile), then a region of gas–gas equilibrium of the first type must exist in the system.

REVIEW OF THE EXPERIMENTAL DATA

After Krichevskii and his coworkers[21-23] had observed the phenomenon of restricted mutual solubility of gases, another 25 systems with a region of phase equilibria between two gaseous phases were found. Table 1 lists all the systems‡.

Table 1 shows that all the systems with helium give layering of the first type. Layering of the second type is usually observed in systems containing a polar component. An exception is water: layering of the first and of the second type is observed in systems with water.

We will discuss two systems in greater detail: helium–carbon dioxide, as a representative of systems giving the first type of layering, and ammonia–nitrogen, a system with the second type of layering.

The $He-CO_2$ system[24] was studied at temperatures from 25° to 100°C and pressures up to 10 000 at. Figs. 9 and 10 give the phase diagram and critical curve and repeat the picture represented in Figs. 1 and 2, with the difference that the critical curve of the real system does not return towards lower temperatures as the pressure is raised.

‡ It is evident from the table that the great majority of investigations of this phenomenon have been made in the Soviet Union.

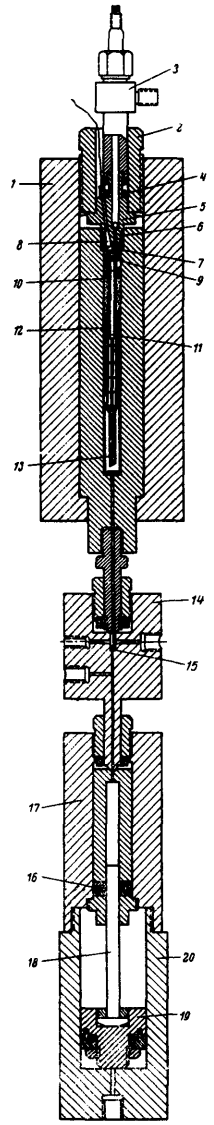

Fig. 6. Drawing of apparatus for investigating the equilibrium between two gas phases at pressures of up to 20 000 at:
1) double-walled high-pressure vessel; 2) female screw; 3) valve; 4) isolating ring; 5) head seal; 6) packing; 7) exhaust ring; 8) electrical entry; 9) head piezometer; 10) solenoid; 11) stirrer armature; 12) beaker with mercury; 13) spring; 14) valve box; 15) reversing valve; 16) packing for piston of multiplier; 17) cylinder of high-pressure multiplier; 18) high-pressure piston; 19) low-pressure piston; 20) low-pressure cylinder.

At temperatures less than the critical temperature of CO_2 liquid–gas equilibrium is observed. The curves of this equilibrium (the curve for the solubility of helium in liquid carbon dioxide and that of the latter in compressed helium) start at a point corresponding to the saturation vapour pressure of CO_2 at the given temperature. At temperatures

TABLE 1. Systems in which gas–gas equilibrium has been observed.

System	Intervals of investigation		Reference	Type of gas–gas equilibrium
	temperature, °C	pressure, at		
Ammonia–nitrogen	90—175	16 000	21—23,25	second
Ammonia–methane	45—100	10 000	23	second
Ammonia–nitrogen–hydrogen, three compositions with 22, 50, and 75 % hydrogen in the mixture without ammonia	90—120	5 500	23	second
Ammonia–nitrogen–methane with 20 and 80 % methane	55—110	5 500	26	second
Ammonia–argon	70—140	10 000	27	second
Nitrogen–sulphur dioxide	35—40	9 000	28	second
Helium–ammonia	125—175	10 000	24	first
Helium–carbon dioxide	25—100	10 000	24	first
Helium–ethylene	25—150	10 000	29	first
Helium–propane	100—150	7 000	30	first
Helium–benzene	300	1 000	31	first
Helium–methanol	245	3 000	31	first
Helium–hexane	245	3 000	31	first
Helium–sulphur dioxide	175—200	7 000	31	first
Helium–xenon	5—65	2 000	19	first
Helium–acetylene	36	64	20	first
Helium–ethane	32	51	20	first
Water–butane	200—430	6 000	15	first
Water–nitrogen	300—350	6 000	32	second
Water–carbon dioxide	250—350	3 500	16,17	second
Water–argon	350—400	4 000	33	second
Helium–dinitrogen monoxide	37	74	34	first
Helium–Freon-12	25—122	330	35	first
Helium–Freon-22	100	330	36	first
Helium–Freon-114B2	216—223	330	36	first
Helium–butane	—	—	37	—
Water–benzene	265—300	700	38	second
Water–n-heptane	295—355	700	38	second
Water–n-pentane	300—352	700	38	second
Water–2-methylpentane	300—355	700	38	second
Water–toluene	280—310	700	38	second

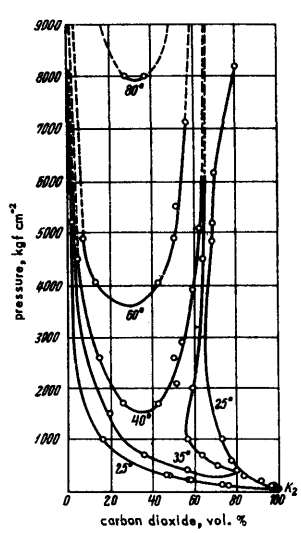

Fig. 9. Gas–gas and liquid–gas equilibria in the helium–carbon dioxide system.

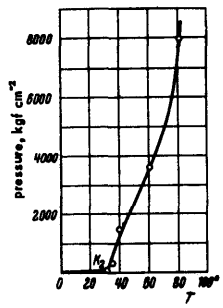

Fig. 10. Critical curve in the helium–carbon dioxide system.

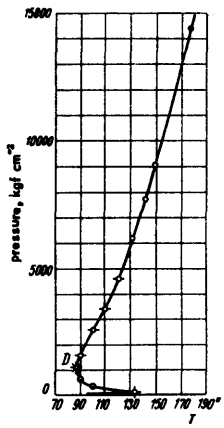

Fig. 12. Critical curve in the ammonia–nitrogen system. The symbols are the same as in Fig. 11.

greater than the critical temperature of CO_2 the curves leave the ordinate axis and form a characteristic horn. As the temperature is raised the horn is gradually obliterated.

The NH_3-N_2 system. This system was studied at temperatures from 90° to 175°C and pressures up to 16 000 at. Figs. 11 and 12 give the phase diagram and critical curve, which are similar to Figs. 3 and 4, except for the form of the curve at higher temperatures and pressures.

We will consider in greater detail the phase diagram of such a system represented three-dimensionally (Fig. 13) in the coordinates pressure–composition–temperature. Two regions of phase equilibria are clearly evident here: liquid–gas equilibrium and gas–gas equilibrium. The loops of the liquid–gas equilibrium start on the vapour pressure curve of the less volatile component (here, ammonia). The composition region occupied by these branches decreases with rise in temperature and shrinks to a point at the critical

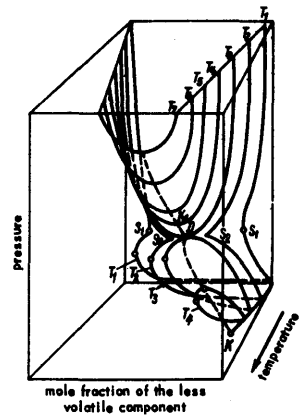

Fig. 13. Space diagram for systems which give the second type of layering.

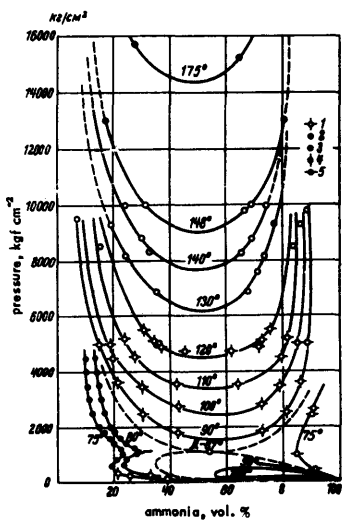

Fig. 11. Liquid–gas and gas–gas equilibria in the ammonia–nitrogen system. Data from: 1) Ref. 21; 2) Ref. 23; 3) Ref. 25; 4) Ref. 39; 5) Ref. 40.

point of the less volatile component. The gas–gas equilibrium curves are situated in the same composition interval but at other pressures. The region of this equilibrium also extends to the side of temperatures higher than the critical temperature of the less volatile component.

The point corresponding to the temperature minimum on the critical curve is clearly evident on the diagram. This is point D, at which the gas–gas and liquid–gas equilibrium curves touch. In van der Waals terminology it is called the binary homogeneous point§. The binary homogeneous point is a singular point. On raising the temperature above the temperature of this point the equilibrium loop breaks into two parts — the curves of the gas–gas and liquid–gas equilibria. On reducing the temperature below the temperature of the binary homogeneous point breaking of the loops also takes place, but now it is along the pressure axis. As a result fantastic forms of the solubility curves

§ This terminology is derived from the theory of folds[41] on the basis of which the existence of the types of gas–gas equilibria was also predicted.

for gas in liquid (right branches) and liquid in gas (left branches) are produced. It can be noted from this that at the moment of the break (longitudinal) points of return (S_2) appear on the curves; these points then degenerate into the points of the solubility maxima for gas in liquid and liquid in gas (S_1).

Fig. 13 shows that the solubility curves for gas in liquid and liquid in gas have a very complex form, especially close to the binary homogeneous point. The solubility of gas in liquid under pressure first increases with the pressure, passes through a maximum, decreases, and then (if the possibility of the existence of an upper critical point of gas–gas equilibrium is considered) should start to rise again.

The solubility of liquid in gas at first decreases with rise in pressure, passes through a minimum, starts to rise, reaches a maximum, falls again, subsequently hardly changes with the pressure, and finally (if the upper critical point is considered) can start to rise again.

This complex form for the curves has a theoretical explanation[10]. The fact is that both the minimum and the maxima on the solubility curves for liquid in gas and gas in liquid are points at which the partial molar volume of the substance and its molar volume become equal¶.

At low pressure the partial molar volume of a substance in its infinitely dilute solution ($\overline{v}_2'$) is much greater than the molar volume of the substance in the condensed phase v_2^0. But with increase in pressure the value $\overline{v}_2'$ rapidly approaches v_2^0 and becomes equal to it since the compressibility for $\overline{v}_2'$ is greater than the compressibility for v_2^0. In this a liquid in gas solubility minimum is observed. At still higher pressures $\overline{v}_2'$ becomes less than v_2^0 and the solubility starts to rise. However, this decrease cannot be continued indefinitely. With rise in pressure the intermolecular interaction starts to increase. Therefore the partial molar volume of the substance in the gas phase begins to increase. It again becomes equal to the molar volume and a solubility maximum appears on the curve.

Similar arguments show that the gas-in-liquid solubility maximum occurs at a pressure when the molar volume of the gas being dissolved equals the partial molar volume of this gas dissolved in the liquid.

Fig. 13 shows clearly that the presence of gas–gas equilibrium curves allows all the known facts about phase equilibria in binary systems to be explained. For example, it becomes quite clear that the gas–gas equilibrium curves do not start and do not end on the vapour pressure curves of the less volatile component and have nothing in common with the liquid–gas equilibrium curves. It is also understandable that the points of the maxima and minima on the curves are degenerate points of reversal formed from the double homogeneous point. Hence it can be concluded that if a solubility maximum is found in investigating the solubility of a gas in a liquid, a region of gas–gas equilibrium should occur in that system.

We will return briefly to the question of the reversal of the critical curve. On considering solutions of helium as intrusion solutions, Tsiklis and Zhukhovitskii[42] showed that here there is generally no reason to expect reversal. This, however, does not signify that it cannot happen in other instances. But if such a reversal is possible in principle, then it should occur at rather high pressures, when the solubility of the gas again starts to increase with pressure owing to a further change in the partial molar and molar volumes. But at such high pressures crystallisation of the gases can begin. In this instance the critical curve generally will not be continuous. The gas–gas equilibrium changes into a new form of equilibrium — crystal–gas equilibrium (Fig. 14).

On considering the experimental data on gas–gas equilibrium in the systems investigated it is noticeable that for each of the types (first and second) the experimental results repeat Figs. 2 and 4 well. They differ, of course, in the parameters of the curves and especially in the coordinates of the double homogeneous point and the temperature interval between it and the critical point of the less volatile component. In this respect the water–nitrogen system is especially characteristic. In it the binary homogeneous point is at 364°C, that is, 10 deg below the critical temperature of water. For the ammonia–nitrogen system it is at 87°C, that is, 46 deg below the critical temperature of ammonia; and in the CO_2–H_2O system it is at 260°C, that is, 108 deg below the critical temperature of water.

To conclude the discussion of the existing experimental data it is necessary to add the following. Visual observations have been made of the helium–ethylene system[29]; the layering process takes place instantaneously. Initially during the compression of a homogeneous mixture strong eddy currents, similar to convection currents, are observed. On reaching the pressure at which layering occurs a sharp visible meniscus appears (Fig. 15). Its appearance is rapid and is accompanied by a fall of "rain" from the drop of heavier phase. The presence of a meniscus contradicts the conclusion that gas–gas equilibrium is a phase transformation of the second order[43].

The surface tension at the boundary of separation in the helium–ethylene and helium–carbon dioxide systems was measured in an analogous apparatus with sight glasses by the capillary method[44]. It was found that, for example, in the helium–ethylene system at 600 at and 18°C the surface tension is ~ 0.5 erg cm^{-2}.

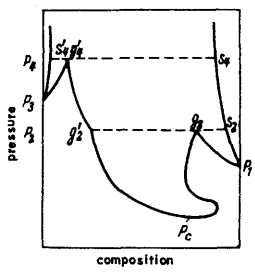

Fig. 14. Gas–gas and crystal–gas equilibria in systems of the first type. P_1 pressure of crystallisation of the pure less-volatile component; P_2 pressure at which the gas phases g_2' and g_2 and the solid phase s_2 are in equilibrium; P_4 pressure at which the two solid phases s_4' and s_4 and one gas phase g_4' are in equilibrium.

¶ Here it is necessary to consider the solvent to be a pure substance.

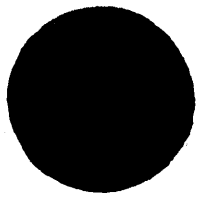

Fig. 15. Meniscus in the helium-ethylene system.

The surface tension in these systems increases with pressure and decreases with rise in temperature. The dependence of σ on P can be represented by the equation:

$$\sigma = \alpha(P - P_c)^2,$$

where α is a constant and P_c the critical pressure. Fig. 16 shows that this condition is obeyed over a wide range of pressures.

Finally, mention must be made of another interesting phenomenon, which is observed in systems with a restricted solubility of gases. We refer to the barotropic phenomenon. This is that with increase in pressure the upper phase becomes heavier and sinks in the lower. Close to the critical point (any equilibrium) the curve in coordinates v (specific volume of the phase on the curve of coexistence) and N_2 (composition) is to the first approximation a parabola with its axis perpendicular to the tangent through the critical point. The gas–gas equilibrium curve (for the second type) in coordinates of pressure against composition is symmetrical with respect to the axis passing through mole fraction 0.5. Therefore an analogous picture will be observed for curves plotted in coordinates of v and N_2.

Fig. 17 shows the liquid–gas and gas–gas equilibrium curves in coordinates v and N_2. A liquid phase of composition A_1 will be in equilibrium with gas phase A_2. At higher pressure the phase of composition B_1 is in equilibrium with a gas phase of composition and volume B_2. On approaching the binary homogeneous point tne difference in volumes decreases and close to the critical point of the gas–gas equilibrium the specific volumes of the coexisting phases become equal (D_1 and D_2). Then the phase in which there is more of the component with higher molecular weight also has the highest specific gravity. Subsequently the volumes of the phases again become unequal but now the volume of the phase containing the component with higher molecular weight diminishes more rapidly and the barotropic phenomenon intensifies.

Hence, the barotropic phenomenon can occur when the molecular weight of the liquid is less than the molecular

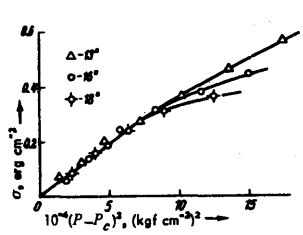

Fig. 16. Variation of σ with $(P - P_c)^2$.

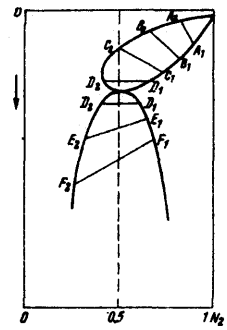

Fig. 17. The barotropic phenomenon.

weight of the gas and the form of the gas–gas equilibrium curve is such that the chords joining the coexisting phases can become parallel to the composition axis.

The barotropic phenomenon was first observed by Kammerlingh-Onnes [45] in investigating liquid–gas equilibrium in the hydrogen–helium system at 20.1°K. In investigations of gas–gas equilibria the barotropic phenomenon has been observed in the ammonia–nitrogen, ammonia–nitrogen–hydrogen (with 22% hydrogen), and ammonia–nitrogen–methane (with 17% methane) systems and also in the argon–ammonia [27,46], water–carbon dioxide [16,17], and water–argon [33] systems.

Despite the fact that the molecular weight of water is less than that of butane, the barotropic phenomenon is not observed in this system†. Evidently it is very important that the form of the phase curve should permit the condition of lines parallel to the composition axis to be fulfilled.

---o0o---

An isotropic substance at temperatures greater than critical is usually called a gas. Therefore the equilibrium state of the two gaseous phases in the above systems can unreservedly be considered to be gas–gas equilibrium. The credit for the theoretical basis for the equilibrium existence of two gaseous phases at supercritical temperatures is due to Dutch physicists, as mentioned above. However, the possibility of such a state in a system was discussed independently of them, but subsequently. Thus Randall and Sosnik [47] considered gaseous solutions of argon in ethylene at supercritical temperatures. On plotting the activity γ of a component against its mole fraction they concluded that an increase in the constant a in the Hildebrand equation could lead to the mathematical conditions necessary for the separation of the mixture into two phases. However, for this the value of $\log\gamma$ should rise to the same value, which they considered improbable. In the final analysis these authors were convinced of the impossibility of phase separation.

Shottky [49], starting from general ideas about the reasons for the breakdown of a homogeneous mixture into two phases, admitted the possibility of the existence of gas–gas equilibrium at high pressures. Evidently, neither Shottky

† This confirms the correctness of the experimental data according to which a gas–gas equilibrium of the first type is observed in the system (concerning which Schneider [48] has doubts, in relation to Connoly's work [38]).

nor Randall and Sosnik knew of van der Waals' work and expressed their views before the appearance of experimental works in this field.

Even after these works had been published, Dodge[50] wrote, in 1944, ".... systems consisting of gases and vapours are always homogeneous. No one has ever observed more than one gaseous phase". However, Lindros and Dodge[18] subsequently repeated the investigation of the ammonia–nitrogen system, and on finding layering, were convinced of Dodge's error.

Hildebrand[51] wrote, in the third edition of his book: "gases are infinitely miscible and hence raise no problems of miscibility...."‡.

Nobody can now dispute that at temperatures above the critical temperatures of both components a region where the system is heterogeneous can exist. But some authors consider that the phenomena observed should be called equilibrium between two liquid phases[52,53], since the density of the phases at high pressures hardly differs from the liquid density. Others[54,55] assume that this is equilibrium between gas and liquid. Schneider[48] says: "the so-called gas–gas equilibrium" and cannot imagine why the critical curve for liquid–gas equilibrium changes smoothly (for the first type) into the gas–gas equilibrium curve. Discussion on this has been published (see Krichevskii and Tsiklis[56]) but cannot be given in this article.

Here it is proper to state the following. It becomes clear from Fig. 13 that gas–gas equilibrium has no relation to liquid–gas equilibrium. The fact that in a single region of temperature but at different pressures there are two phase equilibrium curves does not signify at all that both phase equilibria are of the same type. It is known, for example, that in the temperature region through which passes a liquid–vapour equilibrium curve there may also pass the liquid–liquid equilibrium curve. But no one ascribes these equilibria to the same type on this basis. Incidentally, Schneider[48] admits that the critical curve for liquid–gas equilibrium can be curved and change continuously into the critical curve of liquid–liquid equilibrium. But if this is possible, then why should change to gas–gas equilibrium be impossible?

van der Waals and Kohnstamm[57] wrote: ".... Hence it follows that (as Kammerlingh-Onnes and Keesom noted) in this instance with strict observance of terminology it is necessary to speak of the equilibrium of two gaseous phases. Actually, there is no basis for calling one of the two phases liquid in a completely closed fold and therefore here one must speak of gas–gas equilibrium at all temperatures exceeding the critical temperature of the second component".

It must be stated once again that liquid–gas equilibrium is the most incorrect name: the equilibrium investigated does not begin and does not end on the liquid–gas equilibrium curve of a pure component. To this it can be added that this question has been discussed repeatedly[58]. Quite recently Rowlinson[59] produced weighty evidence in support of the name gas–gas.

‡ It is interesting in this connection to note that recently Mal'nev and Pekar[68], who considered theoretically a gas in which a high percentage of the molecules are excited to the same electronic energy level (for example, in a laser regime), showed that owing to the anomalously large intermolecular forces the layering of such a gas into two phases of different (in the number of excited molecules) composition is possible. This separation can occur even at atmospheric or even lower pressures.

SOME QUESTIONS OF THEORY

As experimental results accumulate it becomes more and more necessary to give a theoretical explanation for the observed experimental facts.

The problem of the prediction of the possibility of layering of gas mixtures and even pre-calculating the parameters of the critical points of the layering would be solved relatively simply if there was an equation of state giving the behaviour of the binary systems being considered. Then by using the known thermodynamic relations (1) and (2):

$$(\partial \ln f_2/\partial N_2)_{P,T,K} = 0, \quad (1)$$

$$(\partial^2 \ln f_2/\partial N_2^2)_{P,T,K} = 0, \quad (2)$$

where f_2 is the volatility of a component, N_2 its mole fraction, and K the critical phase, the pressure and composition of the critical point can be calculated. However, such an equation does not exist and, as Rakovskii noted[60], "the enormous power of the apparatus of thermodynamics stumbles about our ignorance of the actual equations of state"§.

Such a calculation could also be carried out if we had experimental data about the variation of the volume of the gaseous solution and of the components of the mixture with pressure and composition at different temperatures. Then, by calculating the volatility of a component of the solution a graph can be constructed in coordinates of $\ln f_2$ against N_2. The existence on such a graph of a point of inflection with a horizontal tangent (see, for example, Tsiklis and coworkers[61]) signifies that there is a region of layering in the system.

Usually such data are not available in the literature, and it is more difficult experimentally to obtain them than to make a direct investigation of the phase equilibria in the system.

The literature shows that attempts have been made to judge the possibility of the appearance in a given system of a region of gas–gas layering by comparing the properties of the components of the system. Mixtures should show layering when their components have not so much strong intermolecular interaction, as different.

Thus, Kreglewski[62] used the Hildebrand solubility parameter (Δ) and showed that the greater the difference between the value of Δ^2 of the components of the mixture the more probable the layering of the mixture. The solubility parameter is determined by the expression

$$\Delta = -(E/v)^{1/2} \quad (3)$$

where E is the energy of the component and v the molar volume. According to van Dranen's hypothesis[64], at the critical point the negative potential energy of a substance is $E = \frac{3}{2}RT_c$. Consequently, relation (4) holds for the critical point:

$$\Delta^2 = {}^3/_2 \frac{RT_c}{v_c}. \quad (4)$$

Table 2 gives values of Δ^2 for the components of the mixtures investigated and shows that in reality in all the mixtures which show layering the difference in the values

§ Schäfer[63] attempted to use for this purpose an equation of state with virial coefficients. By finding the values of these coefficients, Schäfer calculated by a very complex path the conditions of layering in the N_2–NH_3 system and obtained good agreement with experiment.

TABLE 2. Values of Δ^2 of the components of the mixtures investigated.

Component	T_c, °K	v_c, cm³ mole⁻¹	$(\Delta)^2$, at	Component	T_c, °K	v_c, cm³ mole⁻¹	$(\Delta)^2$, at
He	5.23	57.7	11.2	C_2H_6	526.1	260.0	266.4
H_2	33.25	65.7	63.2	C_2H_4	283.1	124.0	381.0
N_2	126.0	90.3	172.0	CO_2	304.1	93.3	399.0
C_4H_{10}	425.8	58.0	204.0	SO_2	430.4	123.7	228.0
C_5H_{12}	507.8	283.0	221.0	CH_3OH	513.0	129.0	490.0
C_3H_8	370.6	200.0	227.0	NH_3	406.1	72.9	685.0
CH_4	190.7	99.0	237.0	H_2O	647.0	54.7	1460.0
Ar	150.7	75.5	246.7				

of Δ^2 of the components is significant. Nevertheless, Kreglevskii's criterion is approximate. It does not allow a quantitative estimation of the parameters of layering to be given. Moreover, in a series of instances the calculation leads to erroneous results. For example, for the ammonia–hydrogen system the difference in the values of Δ^2 for ammonia and hydrogen is greater than in the ammonia–nitrogen system, but layering does not occur in the ammonia–hydrogen system.

Temkin[65] proposed a strict criterion of layering. By using the van der Waals equation of state for a binary mixture and the Helmholtz equation for free energy, he found the conditions for the development of the so-called longitudinal fold on the surface in the coordinates free energy–volume–composition, which, in accordance with the theory of folds[41], is also the condition for the layering of the mixture.

For calculation according to this criterion it is necessary to find the value of the coefficients a_1 and a_2 of the equation of state for the pure components and a_{12} for the binary system. Layering in the system is possible if Eqn. (5) is fulfilled for a mixture of non-polar components¶ and Eqn. (6) for mixtures containing polar components:

$$a_1 < 0.053\, a_2 \qquad (5)$$

$$^1/_2(a_1 + a_2) - a_{12} > {}^8/_{27}\, a_2. \qquad (6)$$

From Eqns. (5) and (6) it is evident that layering is possible when for mixtures of non-polar components the quantity a_1 is significantly less than a_2 and for a mixture with polar components a_{12} is less than the half-sum of the values of a_1 and a_2. Calculation shows that all systems with helium should show layering. Experiment confirms the calculation. It appears that even mixtures of helium and xenon — two noble gases — show layering. The results for layering in systems which contain water also agree with calculation.

However, this criterion is also approximate, since it is based on the van der Waals equation of state and this, as is known, is only qualitative, since it does not describe fully the behaviour of a substance at high pressures.

The layering of a homogeneous system, including also a phase transformation of the gas–gas type, indeed serves as a touchstone for any statistical theory of the condensed state of a substance.

In the theory based on the use of a method of correlating functions, phase transformations are connected with the singularities of the integral equations for these functions. Attempts to connect the crystal–liquid phase transformation with the presence of branching points in the integral equation for a single-index unary distribution function appeared quite fruitful.

In Rott's works[66] the phase transformation of interest to us here is considered from the standpoint of the statistical theory of the conditions for distribution. In it the phase transformation is connected with the singularity of the configuration integral. The latter is directly extended also to the distribution function itself (in the present instance the so-called two-index correlation functions). This can be traced also to the reverse dependence. If the state of the homogeneous system cannot be realised, then the distribution functions corresponding to it, say the most minor E_{11}, should transform to zero, which transforms the configuration integral into infinity. Therefore a knowledge of even the minor distribution functions (for the binary system there are two such functions) allows the approximate condition for the phase transformation to be found without resort to calculation of the configuration integral itself.

Thus for dilute binary solutions a final evaluation is obtained which allows us to find whether the occurrence of layering of the gas–gas type is possible or impossible; the parameters of the molecular interaction are calculated during this.

The criterion for layering in the given instance is the parameter β, given by

$$\beta = \frac{3.31\,\frac{\epsilon}{k}\,\sigma^4}{Tr_0^4}, \qquad (7)$$

where r_0 is the radius of the molecular volume ($v = \frac{4}{3}\pi r_0^3$), ϵ and σ are the parameters of the Lennard–Jones potential, k is Boltzmann's constant, and T the temperature.

It appears that the nature of the change in β is approximately the same for many substances. At the critical temperature $\beta \simeq 4$–5, at the triple point $\beta \simeq 28$ for the liquid phase and 34 for the solid.

In calculating the parameter β for a two-component system values of T and r_0 for the less volatile component (subsequently, for water, as an example) must be inserted in the denominator of Eqn. (7) and values of ϵ and σ for the more volatile (non-polar component) in the numerator. In this the value of β for the case when gas–gas layering of the first type is possible in the neighbourhood of the critical point of the less volatile component should be greater than its value at the critical point (that is, 4–5).

From the experimental results it is evident that features of the phase equilibrium known previously as features of helium solutions (the presence of a characteristic horn on the pressure–mole fraction curves near the critical point of the less volatile component) are present also in other binary systems the components of which do not differ greatly in energetic respects. Such are also all the systems with water considered below. Table 3 gives the values of β for a series of binary systems (aqueous solutions) in the vicinity of the critical point of water (for all the systems shown the critical density of water is greater than the density of the dissolved component at its critical point).

Experiment confirms the calculations. The layering in the water–butane systems is of the first type. In the water–nitrogen and water–carbon dioxide systems gas–gas equilibria of the first type are not observed. Gas–gas equilibria of the second type are observed.

¶ In essence Eqn. (5) is the particular case of Eqn. (6) when it is assumed that $a_{12} = \sqrt{a_1 a_2}$.

TABLE 3. Values of β for systems containing water.

System	β	Layering of the first type	System	β	Layering of the first type
Butane–water	~21	possible	Methane–water	2.4	impossible
Benzene–water	~28	»	Ethane–water	7.3	»
Propane–water	~42	»	Nitrogen–water	2.0	»
Octane–water	~82	»	Carbon dioxide–water	4.0	»

Attempts to use the methods of the statistical theory of "free volume" for the calculation of layering have been made recently [19].

New results obtained comparatively recently which relate to systems consisting of helium and fluorine compounds do not fit into the framework of any of the theories mentioned.

According to the criteria of Kreglewski, of Temkin, and of Rott, these systems (He–$CClF_3$, He–CHF_3, He–$CH_2{=}CF_2$, and He–SF_6) ought to have a region of gas–gas equilibrium of the first type. Experiment showed that they did not possess such a region [20,34].

In addition to that, mixtures of helium with other fluorine compounds, for example, He–$C_2Br_2F_4$ (Freon-114B2), He–$CHClF_2$ (Freon-22), and He–CCl_2F_2 (Freon-12) behave normally [35,36].

Evidently there is something new and interesting here in the unusual behaviour of the gaseous solutions of fluorine compounds. It is known [51,59,67] that liquid solutions which contain hydrocarbons and their fluoro-derivatives are also distinguished by unusual behaviour.

From the experiments described it is clear that the existence or absence of a region of gas–gas equilibrium of the first type in mixtures of helium and fluorine compounds is connected with features of the structure of these compounds. Evidently a negative part in the existence of layering is played by the polarity of the C–F bond and the small size of the fluorine atom. The latter assumes the approach of helium and fluorine, which can lead to polarisation of the helium and the production of additional interaction, which is unfavourable for layering†.

With a decrease in the number of fluorine atoms in the molecule, owing to the introduction of chlorine, bromine, or hydrogen, layering is produced.

---o0o---

The comparatively recently observed phenomenon of restricted mutual solubility of gases was for a long time regarded as exotic. It can be hoped that the material presented in this review will disperse these doubts.

Gas–gas equilibrium is a widespread phenomenon. It has its place in the series of phase equilibria. Not only investigators occupied with the study of phase equilibria, but also technologists should take this phenomenon into account. This must be done both now (since this equilibrium starts at pressures and temperatures which are usual for many technological processes of the chemical and petroleum industries) and especially in the future, when high pressures will come into chemistry on a full scale.

This phenomenon will undoubtedly be used to explain many facts by geochemists, who are concerned with the problems of the formation and migration of petroleum, and also by scientists dealing with hydrothermal syntheses within laboratories and with the observation of these processes in nature.

It cannot be doubted that the number of experimental studies concerned with gas–gas equilibrium will grow and accordingly will extend our knowledge of this new and interesting phenomenon.

NEWTONIAN VISCOSITY OF CONCENTRATED SOLUTIONS OF POLYMERS

A.A.Tager and V.E.Dreval'

The factors which influence the irreversible flow of high-molecular compounds and of their concentrated solutions have attracted increasing attention in recent years because of their relevance to current problems in the technology of polymer fabrication. However, the study of viscoelastic properties in polymers is important not only as a route to formulating the scientific foundations of technology: it can also provide valuable information on the nature and on the rates of conformational changes in macromolecules and also on their mutual arrangement (i.e. on the structure of the polymer and of its solution[1]).

Studies of the rheological properties of concentrated solutions of polymers began in the 1930's, when it was shown[2-4] that the anomalous flow of polymer solutions (and of the polymers themselves) arises from the interplay of elastic (reversible) deformations and viscous (irreversible) flow. It was subsequently shown[5] that relaxation phenomena are associated with the elastic deformations. Thus, concentrated polymer solutions give rise to a viscoelastic system: to investigate these solutions we must separate reversible from irreversible deformations, and also examine the rate of shear as a function of stress over a wide range of these parameters.

For polymer solutions of intermediate concentration this function gives, when plotted on logarithmic coordinates, a characteristic S-shaped curve with linear lower and upper sections at 45° to the horizontal axis[6] (Fig. 1).

Over these sections of the plot (i.e. in the regions of small or large shear rates or stresses) the viscosity coefficient is constant and the flow is Newtonian. The viscosities corresponding to the two linear sections are usually termed the maximum and the minimum Newtonian viscosity. It should be noted that with very concentrated solutions of high polymers, and with melts, the upper linear section (Fig. 1) is not observed: hence, most of the published values for the maximum Newtonian viscosity have been measured at insufficiently high stresses and shear rates. However, in many systems the viscosity depends on the applied shear stress even under these conditions, as can most clearly be seen by plotting the logarithm of the viscosity against the logarithm of the stress[7]. In this case the Newtonian viscosity is obtained by extrapolation to zero stress or to zero shear rate.

Low stresses cannot break down the structures present in melts or in solutions: hence, the Newtonian viscosity at low shear rates describes the flow of the solution without any disturbance of its structure. In this sense, studies of the Newtonian viscosity of polymer solutions are a very

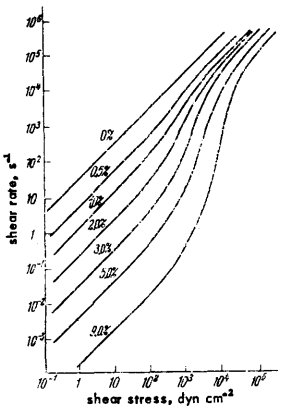

Fig. 1. Flow curves for solutions of polyisobutylene in decalin[6]. The numbers by the curves denote solution concentration.

important method of characterising their structure, particularly since direct structural examination of the solution (e.g. by electron microscopy) presents serious difficulty. At the same time, an extensive investigation by Vinogradov and coworkers[8,9] has shown that the maximum Newtonian viscosity has a fundamental significance, since it can be used as a normalising factor for a number of rheological characteristics.

Studies of the maximum Newtonian viscosity indicate that the flow mechanism of polymers and of their concentrated solutions is a general one. Hence it may be desirable to review briefly the main experimental and theoretical advances in the study of the viscosity of these polymers. Recent progress in this field is due mainly to the work of Kargin, Rebinder, Slominskii, Bartenev, Vinogradov, Trapeznikov, Ferry, Flory, Fox, Bueche, and others.

By generalising the large fund of experimental results obtained in recent years, two fundamental empirical relations have been derived, which relate the viscosity coefficient of a polymer (η) to the molecular weight (M)[10,11] and to temperature[12] respectively. Thus, for a large number of quite different polymers the plot of $\log\eta = f(\log M)$ consists of two intersecting straight lines whose point of intersection corresponds to a critical value of the molecular weight, M_c. Polymers for which $M > M_c$ obey the equation

$$\log\eta = 3.4\log Z + C, \qquad (1)$$

where Z is the degree of polymerisation and C is a constant. The second universal relation, known as the Williams, Landel, and Ferry (WLF) equation[12], states that the temperature dependence of the viscosity of polymeric substances can also be described by a universal empirical equation:

$$\log a_T = \log\frac{\eta_T \rho_S T_S}{\eta_S \rho_T T} = -\frac{C_1^0 (T - T_S)}{C_2^0 + T - T_S}, \qquad (2)$$

where η_T and ρ_T are the viscosity and the density of the polymer at the given temperature T, whilst η_S and ρ_S are the viscosity and the density of the polymer at the standard temperature T_S (reference temperature), chosen so as to make the plots of $\log a_T = f(T - T_S)$ for the different polymers coincide; C_1^0 and C_2^0 are coefficients dependent on the nature of the polymer and on the reference temperature. For polyisobutylene $T_S = 243°K$, $C_1^0 = 8.86$, and $C_2^0 = 101.6$. For other systems these coefficients are retained and the reference temperature is varied.

Eqn. (2) is applicable over the temperature range from the glass transition temperature T_g to $T_g + 100°$. Under these conditions the ratio $\rho_S T_S/\rho_T T$ is close to unity. Hence $\log a_T \simeq \log \eta_T/\eta_S$.

If the reference temperature is defined as the glass transition temperature of the experimental material, Eqn. (2) becomes universally applicable to polymers and low-molecular glass-forming liquids:

$$\log a_T = \log\frac{\eta}{\eta_g} = -\frac{17.44\,(T - T_g)}{51.6 + T - T_g}, \qquad (3)$$

where η_g is the viscosity at the glass transition temperature.

The glass point is the most convenient reference temperature because it can be determined for each polymer by an independent method, but measurements of viscosity and other mechanical properties are difficult to make in the neighbourhood of T_g. A temperature approximately 50° higher than the glass point is therefore commonly used: $T_S = T_g + 50°$.

Eqn. (2) is a particular case of the temperature dependence of any viscoelastic property, and demonstrates the principle of temperature–time superposition first formulated for polymers by Aleksandrov and Lazurkin[5]. Essentially, the principle states that temperature and the time of application (frequency) of a force play identical roles because the deformation shows a relaxation behaviour. Therefore, plots of the property against temperature can be mutually superimposed by shifting them along the temperature axis. This means that the ratio of the relaxation times (τ_r) at two temperatures is a constant:

$$\frac{(\tau_r)_T}{(\tau_r)_{T_S}} = a_T = \frac{\eta \rho_S T_S}{\eta_S \rho T}.$$

Thus, the Newtonian viscosity is directly related to the relaxation time of the system.

Eqns. (1) and (2) can also be derived theoretically, starting from the fundamental postulates of the theory of the viscous flow of liquids and polymers.

Since liquids occupy a position intermediate between gases and solids, the liquid state has been treated from the point of view of both these states. At the turn of the century liquids were discussed by analogy with gases. X-Ray diffraction studies of simple liquids revealed the existence of ordered regions and gave rise to the hypothesis of a quasi-crystalline liquid structure. In reality, the liquid state is qualitatively different from the others, and can be described by means of the radial density distribution function[13].

Contemporary statistical theories of the liquid state are of two kinds: (a) the more accurate and more complicated theories based on studies of molecular distribution functions, and (b) the less accurate but simpler "lattice" theories or "free volume" theories, based on the concept of a quasi-crystalline liquid structure.

The idea of "free volume" in a liquid is not entirely unequivocal. Thus, in the statistical theory of liquids this term denotes a complex integral which can be evaluated to give a "mean" volume within which the "average" molecule is able to move freely at a given temperature. This "free volume" does not actually exist in a liquid: it is a fictitious

quantity which appears in statistical calculations as a result of the particular method of approximation used[13]. Yet, a number of workers have attempted to ascribe a physical significance to this term. Most of them interpret liquid free volume as empty regions between molecules, i.e. as voids or "holes" of molecular (monomer) dimensions arising from irregularities in packing[1]. Frenkel'[14] showed by thermodynamic arguments that molecular voids (vacancies) can exist also in real crystals. However, the free volume in crystals is different in nature from the free volume in liquids. Crystal free volume is due to asymmetry in the vibrations of the particles, and its distribution among the particles is continuous (Fig. 2*a*). This is the so-called vibrational volume. Liquid free volume consists of two parts: 1) a continuous part, also associated with the vibrations of the particles in the liquid, and 2) a discrete part, due to voids (Fig. 2*b*). The latter enables the particles to undergo continuous place exchange, i.e. the "holes" in a liquid are fluctuating entities[14,15].

The free volume of a substance is difficult to measure. Most commonly, the free volume v_f of a liquid or a crystal is determined as the difference between the specific volume of the material at the given temperature (v_{sp}) and at the absolute zero (v_0), the latter being obtained by extrapolating to $T \to 0$ the linear plot of $v_{sp} = f(T)$ (Fig. 3):

$$v_f = v_{SP} - v_0. \tag{4}$$

As the free volume increases, the specific volume of the liquid also increases: the major contribution to the thermal expansion coefficient of a liquid is the increase of free volume with increase of temperature.

The internal friction of liquids depends on the free volume, since relative movement of the molecules is made possible by the presence of free space between the molecules. This relation was first pointed out by Bachinskii[16], who proposed the equation

$$\eta = \frac{C}{v - w}, \tag{5}$$

where v is the specific volume of the liquid and w is the arithmetic mean of the volumes of 1 g of the liquid at the given temperature and at the freezing point. The difference $v - w$ was termed the "free" volume. If we write Eqn. (5) in the form

$$v = w + \frac{C}{\eta} \tag{6}$$

it is obvious that the plot of $v = f(1/\eta)$ at any given temperature should be a straight line not passing through the origin: this was confirmed for 66 different liquids. Associated liquids do not obey Eqn. (6).

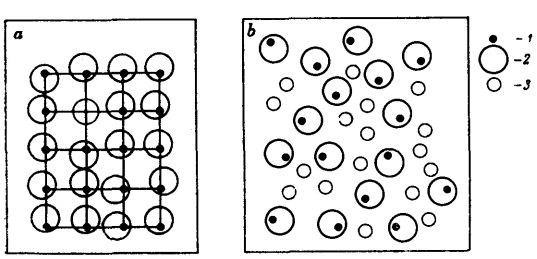

Fig. 2. Schematic representation of free volume[15]: (*a*) crystal; (*b*) liquid; 1) molecules, 2) vibrational volume of molecules, 3) "holes".

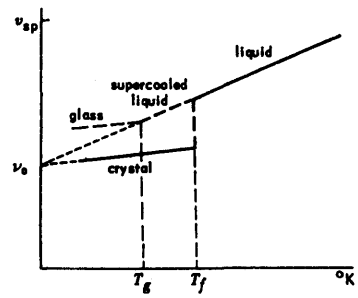

Fig. 3. $v-T$ diagram for a substance in the condensed phase.[15]

More recently, Doolittle[17] proposed another empirical equation for the viscosity of a liquid:

$$\ln \eta = \ln A + B\frac{v_0}{v_f}, \tag{7}$$

where v_0 and v_f are the occupied and the free volume respectively.

Eqn. (7) may be written in the form

$$\eta = A\, e^{Bv_0/v_f}. \tag{8}$$

It is interesting to note that the temperature does not appear explicitly in Eqns. (5) and (7). This is one of the most fundamental aspects of the modern theory of viscous flow, which is treated as a process made up of the activated jumps of individual elementary units of flow from one equilibrium position to another. The jumping frequency is controlled by the height of a potential barrier, and is denoted by the symbol I.

The activation theory of liquid flow, proposed by Frenkel'[14] and developed by Eyring and others[18], leads to the following expression for the temperature dependence of viscosity:

$$\eta = \frac{N_A h}{V} e^{\Delta G_{visc}/RT}, \tag{9}$$

where V is the molar volume of the liquid, ΔG_{visc} is the free energy of activation of the viscous flow of one mole of molecules passing from one equilibrium position to another. If we write $\Delta G_{visc} = \Delta H_{visc} - T\Delta S_{visc}$, Eqn. (9) takes the form

$$\eta = \frac{N_A h}{V} e^{\frac{-\Delta S_{visc}}{R}} e^{\frac{\Delta H_{visc}}{RT}} \tag{10}$$

The plot of $\log \eta = f(1/T)$ is thus a straight line whose slope is a measure of the quantity ΔH_{visc}, the heat of activation of the viscous flow. This quantity is determined by the temperature coefficient of viscosity. ΔS_{visc} is the entropy of activation of the viscous flow.

Experimental observations have shown that Eqns. (9) and (10) apply only over a narrow range of temperatures. Over a wider temperature interval the plot of $\log \eta = f(1/T)$ is curvilinear, and Kobeko suggests that the curvature of this plot is a characteristic of the liquid state[19]. From plots of this type one calculates the so-called apparent heat of activation of viscous flow:

$$\Delta H_{visc} = \frac{d \ln \eta}{R\, d\,(1/T)}, \tag{11}$$

which is itself a function of temperature. It can be shown theoretically that the heat of activation of viscous flow is

related to the temperature coefficient of the molecular jumping frequency I and also to the temperature coefficient of the free volume [20]:

$$\Delta H_{visc} = -R\left[\frac{\partial \ln I}{\partial (1/T)}\right]_{v_f} - R\left(\frac{\partial \ln I}{\partial v_f}\right)\left[\frac{\partial v_f}{\partial (1/T)}\right]. \quad (12)$$

Thus, the decrease of liquid viscosity with increase of temperature stems from two distinct causes: 1) the increase in jumping frequency and 2) the increase in free volume.

All these conclusions of the theory of the viscous flow of liquids are used in discussions of polymer flow. It is assumed that the elementary unit of flow is a portion (or segment) of the polymer chain rather than the entire chain. Chain segments are interconnected by valence bonds, and they interact with the segments of neighbouring chains, so that their motions are not mutually independent. The viscosity of the polymer is given as the product of two quantities: a function of the chain length $F(Z)$ and the reciprocal of the jumping frequency I:

$$\eta = \frac{F(Z)}{I}. \quad (13)$$

The form of the function $F(Z)$ is the same for all polymers: it allows for the interaction between units, and is independent of temperature. The jumping frequency depends both on temperature and on the local disposition of the units (i.e. on the free volume). The greater the free volume, the greater are the specific volume and the jumping frequency I, and the lower is the viscosity of the liquid or polymer [20].

Free volume considerations have proved very fruitful in bringing about an understanding of the viscous flow of polymers. Thus, it became clear that the quantity a_T in the WLF Eqn. (2) is related to the free volume of the polymer, and that the equation itself can be deduced theoretically from Doolittle's equation [1,12]. The expression obtained is indistinguishable from the WLF equation if the fractional free volume at the glass point is taken as $f = 0.025$, and the thermal expansion coefficient as $\alpha = 4.8 \times 10^{-4}$ deg^{-1}.

Bueche [21,22] also used free volume considerations, and proposed that the resistance to flow of a polymer arises from: (1) friction of the segments of the polymer chain as it moves relatively to its neighbours; (2) interaction between the segments joined by primary valence bonds into a long chain; (3) interlocking of the chains with formation of a network structure. If the chain consists of N monomer units and ζ_0 is the molecular (monomeric) friction factor, related to I (the number of jumps of the unit) and to δ (the average change in the position of its centre of gravity) by the expression

$$\zeta_0 = \frac{6kT}{I\delta^2}; \quad (14)$$

the viscosity coefficient is given by

$$\eta = FN\zeta_0, \quad (15)$$

where the proportionality coefficient F depends on the molecular weight of the polymer.

When $M > M_c$ (see p. 362)

$$\eta = k'M\rho\zeta_0; \quad (16)$$

when $M < M_c$

$$\eta = kM^{3.5}\rho^4\zeta_0 \quad (17)$$

where ρ is the density of the polymer, k' and k are constants.

I. CONCENTRATED SOLUTIONS OF POLYMERS

The term concentrated usually denotes solutions in which the solute molecules can interact with each other. In polymer solutions interactions of this type give rise to a steep increase in viscosity as compared with the viscosity of the pure solvent. Ferry [1] proposed that polymer solutions should be called concentrated if their relative viscosity is of the order of 100 or more. The lower concentration limit of the polymer can vary from 1% (for unusually long, rigid chains) to 10% (for flexible polymers of low molecular weight). The upper limit is the undiluted polymer.

Studies over a wide range of concentration, temperature, polymer chain length, and solvent type can lead to significant advances in establishing the relationships which govern the viscosity of concentrated polymer solutions.

1. Effect of Concentration

Up to the year 1960 our understanding of the isothermal concentration dependence of the viscosity of polymer solutions was limited, because most of the data then available related to a narrow concentration range. Thus, owing to experimental difficulties, most of the workers studied the viscosity of polymer solutions in the concentration range up to 0.2 [23-46] or 0.5 [47-52] weight fraction of the polymer.

Far fewer papers have dealt with the viscosity of solutions over the whole or most of the concentration range [53-58], but in recent years such papers have appeared in increasing numbers [60-69].

The viscosity of a solution varies with concentration as shown by the curves of Fig. 4. For solutions of polymers of fairly high molecular weight, and at low concentrations of the polymer, the curve is convex towards the ordinate axis. On further increasing the concentration the viscosity increases more slowly. A steeper rise sets in again when very concentrated polymer solutions are held near the glass point of the polymer. This effect is due to the rapid decrease of the relative free volume [70].

There have been repeated attempts to establish analytically the relation between the viscosity and the concentration of the solution. Thus, Flory [54] studied the viscosity

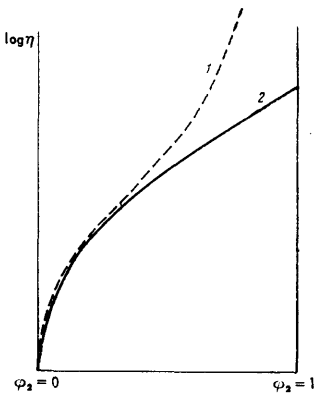

Fig. 4. Variation of solution viscosity with concentration:
1) solutions of glassy polymers; 2) solutions of elastic polymers.

of solutions of poly(decamethylene adipate) over the entire composition range from pure solvent to the pure polymer, and showed that above 0.1 weight fraction of the polymer the viscosity varies with concentration according to the equation

$$\log\eta = A + B\omega_2^{1/2} \quad (18)$$

where ω_2 is the weight fraction of dissolved polymer, and A and B are constants. Eqn. (18) can be obtained from the equation relating the viscosity of a polymer melt to its molecular weight[71] by treating the solvent molecules as short polymer chains. Hence it was concluded that the mechanism of flow of concentrated polymer solutions is analogous to that of the polymers themselves: in the flow of concentrated solutions also the polymeric chains move as a result of the motion of their individual segments. Eqn. (18) was confirmed experimentally by the work of Spencer and Williams[47] on the viscosity of polystyrene solutions in the concentration range between 0 and 0.5, and also by an investigation[25] of the viscosity of butadiene–styrene rubber solutions in the concentration range between 0.10 and 0.19 weight fraction of the polymer. It was not confirmed, however, over a wider range of concentrations[48-51] for solutions of poly(vinyl acetate), polyisobutylene, and polystyrene.

Attempts were made to apply to the flow of concentrated polymer solutions the equation derived by Martin for the flow of dilute solutions of polymers[26,47]:

$$\log\frac{\eta_{sp}}{C} = \log[\eta] + K[\eta]C \quad (19)$$

where C is the concentration, $[\eta]$ is the characteristic viscosity, and K is a constant.

It follows from the reported measurements that Eqn. (19) satisfactorily describes the experimental results of the authors only if the concentration does not exceed 0.12 weight fraction of the polymer.

All the equations given above are empirical. There are now a number of theoretical equations for the concentration dependence of the viscosity of polymer solutions, derived on the basis of the fundamental concepts discussed above and on the assumption that dilution decreases the relaxation times of the system and the monomer friction coefficients.

In a solution, each monomer unit of a polymer chain is surrounded both by the units of neighbouring chains and by solvent molecules, the latter being able to move much more readily than the former. Hence, introducing small molecules whose motion (unlike that of the segments of molecular chains) immediately produces irreversible structural changes is enough to raise the fluidity, i.e. to lower the viscosity of the system[72].

The theoretical interpretation of the dilution of a polymer system is usually that the decrease in viscosity stems from the increase in free volume brought about by the introduction of the solvent. The following arguments are generally used: (1) the free volume of the solvent is greater than that of the polymer; (2) the volume of the solution is an additive function of the volumes of the components; (3) the free volume of the solution is the sum of the free volumes of the components:

$$v = v_1 + v_2 \quad (20)$$

where v, v_1, and v_2 are the volumes of the solution, the solvent, and the polymer respectively, and

$$v_f = (v_f)_1 + (v_f)_2 \quad (21)$$

where v_f, $(v_f)_2$ are the mean free volumes of the solution and the polymer (at the same temperature), and $(v_f)_1$ is the newly formed free volume resulting from the addition of solvent. Two attempts to derive the concentration dependence of the viscosity of polymer solutions have been reported. The first is due to Fujita and Kishimoto[73], who assumed that $(v_f)_1$ increases when the volume of solvent is increased, but is also a function of concentration and of temperature. If $(v_f)_1$ is assumed to be a function of temperature only, Eqn. (21) takes the form

$$v_f = (v_f)_2 + \gamma(T)v_1, \quad (22)$$

where $\gamma(T)$ is a function which characterises the particular polymer–solvent system.

Dividing Eqn. (22) by Eqn. (20) we obtain an expression for the relative free volume of the solution:

$$f = \frac{v_f}{v} = \frac{(v_f)_2}{v_2} + \left[\gamma(T) - \frac{(v_f)_2}{v_2}\right]\varphi_1, \quad (23)$$

where φ_1 is the volume fraction of solvent in the solution.

The ratio $(v_f)_2/v_2$ is the relative free volume of the polymer at temperature T, and it can be expressed in the form $f(T, 0)$ at $\varphi_1 = 0$ if the free volume of the solution is described by the function $f(T, \varphi_1)$. Eqn. (23) can then be written

$$f(T, \varphi_1) = f(T, 0) + \beta'(T)\varphi_1, \quad (24)$$

where

$$\beta'(T) = \gamma(T) - f(T, 0). \quad (25)$$

Using Eqns. (7) and (8) for T = const, the authors arrive at an expression of the form

$$-\frac{1}{\ln a_C} = f(T, \varphi_1^*) + \frac{f(T, \varphi_1^*)}{\beta'(T)}\cdot\frac{1}{\varphi_1 - \varphi_1^*} \quad (26)$$

$$a_C = \frac{\eta(T, \varphi_1)(1 - \varphi_1^*)}{\eta(T, \varphi_1^*)(1 - \varphi_1)}, \quad (26a)$$

where $\eta(T, \varphi_1)$ and $\eta(T, \varphi_1^*)$ are the viscosity coefficients of solutions for which the volume fractions of the first component are φ_1 and φ_1^* (chosen as a standard solution), $f(T, \varphi_1^*)$ is the free volume of the solution of standard concentration, and $\beta'(T)$ is a function which can be calculated from Eqn. (25).

It follows from Eqn. (26) that the plot of $\frac{1}{\ln a_C} = f\left(\frac{1}{\varphi_1 - \varphi_1^*}\right)$ should be a straight line whose slope is a measure of $\beta'(T)$ and whose intercept on the ordinate axis gives the value of $f(T, \varphi_1^*)$. The standard state can be defined as a solution of any arbitrary concentration, or the pure polymer.

The authors tested their equation with the following systems: polystyrene–diethylbenzene[56], polystyrene–dibenzyl ether[20], polystyrene–decalin[51], poly(methyl methacrylate)–diethyl phthalate[58], and poly(methyl acrylate)–diethyl phthalate[66].

Eqn. (26) holds for very concentrated solutions, and departures from linearity are observed when $\varphi_1 > 0.5$. The slope of the straight line increases with temperature, i.e. the quantity $\beta'(T)$ varies, and therefore also $\gamma(T)$, which (as was to be expected) has different values for different systems. The function $f(T, 0)$, i.e. the relative free volume of the polymer itself, calculated from the intercept of the straight line on the ordinate axis, is constant for a given polymer. Its temperature dependence can be approximated by two straight lines intersecting at the glass point of the polymer. Quantities calculated from Eqn. (26) for the polystyrene–ethylbenzene[65] and polyisobutylene–toluene[64]

systems are plotted in Fig. 5. Minor departures from linearity can be observed for the first system at $\varphi_1 > 0.5$, whereas for the second system Eqn. (26) is obeyed over practically the whole of the concentration range.

The second attempt to derive a theoretical equation for the concentration dependence of the viscosity of a polymer solution is due to Kelley and Bueche[74], and is based on similar premises. The authors express the relative free volume of the polymer and of the solution at a given temperature T in the form

$$v_{f_2}/v_2 = 0.025 + 4.8 \times 10^{-4}(T - T_g). \quad (27)$$

and

$$v_{f_1}/v_1 = 0.025 + \alpha_S(T - T_g') \quad (27a)$$

where 0.025 is the relative free volume of the material at T_g; 4.8×10^{-4} deg^{-1} is the temperature coefficient of the relative free volume of the polymer (see p. 364); α_S is the temperature coefficient of the relative free volume of the solvent, which for liquids is of the order of 10^{-3} deg^{-1}, T_g and T_g' are the glass points of the polymer and the solvent respectively. Assuming additivity of the free volumes, the following expression is obtained for the relative free volume of the solution:

$$v_f/v = \varphi_2[0.025 + 4.8 \times 10^{-4}(T - T_g)] + (1 - \varphi_2)[0.025 + \alpha_S(T - T_g')]. \quad (28)$$

Using Eqns. (8) and (17) the authors arrive at an expression for the viscosity of the solution:

$$\log \eta/B = 4 \log \rho[\varphi_2[0.025 + 4.8 \times 10^{-4}(T - T_g)] + (1 - \varphi_2)[0.025 + \alpha_S(T - T_g')]]^{-4}, \quad (29)$$

where ρ is the density or concentration by weight of the polymer in solution, φ_1 and φ_2 are the volume fractions of the solvent and of the polymer, η is the viscosity of the solution, and B is a parameter which includes the molecular weight of the polymer.

The authors tested the validity of Eqn. (29) on the following systems: polystyrene–diethylbenzene[56], poly(methyl methacrylate)–diethyl phthalate[57], and polyisobutylene–xylene[50]. For the first of these systems, taking T_g' = = -110°, good agreement was found between theory and experiment. The agreement was good also for the third system at 25° (T_g' = -50°) and for the second system at 120° and 140° (T_g' = -65°). At 60° the second system showed significant discrepancies between theory and experiment.

Calculated and experimental data for the polystyrene–ethylbenzene, polystyrene–decalin[65], and polyisobutylene–toluene[64] systems are reproduced in Fig. 6. The experimental points for the latter system lie on the theoretical

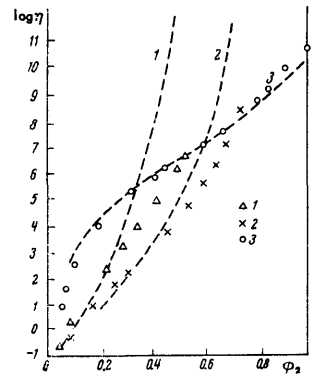

Fig. 6. Variation of viscosity with volume fraction of the polymer in solution at 20°: 1) polystyrene–decalin; 2) polystyrene–ethylbenzene; 3) polyisobutylene–toluene. The broken curves were calculated theoretically using Eqn. (29).

curve, whereas for the first two systems the theoretical and the experimental curves do not coincide.

The better agreement between theory and experiment at temperatures above the glass point of the polymer itself is striking, and cannot be fortuitous. It arises from the fact that the packing density of the macromolecules of polymers in the elastic state is very close to that of molecules of their low-molecular-weight analogues[75]. Hence there is practically no contraction when polymers such as polyisobutylene are mixed with iso-octane or other similar liquids of low molecular weight[76]. In systems of this type the principle of additivity of free volumes, which underlies the theoretical treatments, is valid to a first approximation. But it is very doubtful whether this principle can be applied to solutions of glassy polymers, particularly those which are loosely packed, and which undergo considerable contraction on dissolution[76]. Also, Eqns. (27) are evidently generally applicable only at temperatures above T_g for the polymer[1].

2. Variation of the Viscosity of Solutions with the Molecular Weight of the Dissolved Polymer

The early investigations of the viscosity of concentrated polymer solutions were made over a narrow range of molecular weights of the polymer: from 8.6×10^4 to 1.0×10^5,[47] or from 0.32×10^6 to 1.10×10^6.[50] Under these conditions Ferry showed that the viscosity of the solutions varied as the 3.4th power of the molecular weight of the polyisobutylene.

Bueche's papers describe a detailed study of the influence of the molecular weight of polymers on the viscosity of their concentrated solutions. This worker examined 15 polystyrene fractions (molecular weights between 5.0×10^4 and 10×10^6 [56]) and 14 fractions of poly(methyl methacrylate) covering molecular weights from 5.0×10^3 to 5.0×10^6,[57] at two concentration levels and one concentration level respectively. He showed that the variation of the logarithm of viscosity with the logarithm of chain length for a polystyrene solution of concentration 0.44 and a poly(methyl methacrylate) solution of concentration 0.25 weight fraction of the polymer is expressed, as in the case of the polymer itself,

by two intersecting straight lines. The lines corresponding to the longer chains are steeper and all have the same slope of 3.4, i.e. they are described by Eqn. (1). It was subsequently found that the viscosity data for solutions of polyacrylonitrile [44,46] and poly(vinyl alcohol) [29,33] are also described by this equation. The variation of viscosity with chain length of the dissolved polymer was established over wide concentration limits in the work of Porter and Johnson [59,77] and of Tager and coworkers [63]. Fig. 7 shows the results obtained for solutions of 7 samples of polyisobutylene of molecular weight between 0.9×10^3 and 1.2×10^6. It is obvious from the figure that in the concentration range which was investigated (from 0.05 volume fraction of the polymer upwards) the variation is described by two intersecting straight lines. The slope of the lines corresponding to the higher values of molecular weight is independent of the concentration of the solution, but the slope of the left-hand branches (corresponding to low molecular weights) increases with concentration. The slope of the right-hand branches is 3.4, i.e. these lines obey Eqn. (1). In agreement with Bueche's theoretical predictions [56] (p. 364) and with his data for polystyrene solutions, both the straight lines and their points of intersection are shifted towards larger Z values by decreasing the concentration of the polyisobutylene solution. However, the product of the critical chain length Z_C (given by the intersection of the straight lines) and of the concentration of the solution remains approximately constant (see Table).

The value of the product of critical chain length and concentration depends on the nature of the dissolved polymer: the more rigid the polymer chain, the lower is $Z_C\varphi_2$. Thus, values of 180 and 80 have been reported for solutions of polyisobutylene [63,69] and of poly(vinyl alcohol) [33] respectively. The same investigations reveal that Z_C varies with temperature and that increase of temperature causes a slight increase in the value of $Z_C\varphi_2$.

Ferry and coworkers [51,52] found that the viscosity of solutions of polyisobutylene, cellulose trinitrate, and cellulose tributyrate, when referred to the viscosity of the solvent, is a unique function of the product $Z^{3.4}\varphi_2^5$: the curves

TABLE. Product of the critical chain length Z_C and of the volume fraction of the polymer φ_2 for polyisobutylene solutions in iso-octane at 20°. [69]

φ_2	$Z_C\varphi_2$	φ_2	$Z_C\varphi_2$
0.05	140	0.30	210
0.10	160	0.40	200
0.15	150	0.50	180
0.20	140		

for solutions of all three polymers coincide. This relationship was shown to be valid also for solutions of poly(vinyl alcohol) [33]. However, the authors themselves point out that the expression does not apply at high concentrations [51]. Tests of the expression over a wide range of concentrations and molecular weights of dissolved polymer, using solutions of polyisobutylene [69] and poly(methyl methacrylate) [66], showed that the expression does not hold.

3. Effect of Temperature on the Viscosity of Polymer Solutions

Most investigations of the viscosity of concentrated polymer solutions have been confined to a fairly narrow temperature interval of 40–60° [25,27,28,36,37,47–51,62–65,78,79], and only a few studies [56,57,66–68] have dealt with temperature changes of 100–200°. The results indicate that over a 40–60° temperature interval the logarithm of the viscosity varies linearly with reciprocal temperature, but over a wider range of temperatures non-linearity sets in, and the curvature increases with the concentration of the solution (Fig. 8).

As we have already pointed out, curvature in the plot of $\log\eta = f(1/T)$ is associated with the nature of the liquid state [19]. A similar variation of the logarithm of the viscosity is found with low-molecular liquids, their solutions, and polymer melts and solutions. Measurements of specific heat, mechanical properties, volume changes, and viscosity indicate that the molecules of a multicomponent liquid form a single continuous system [19].

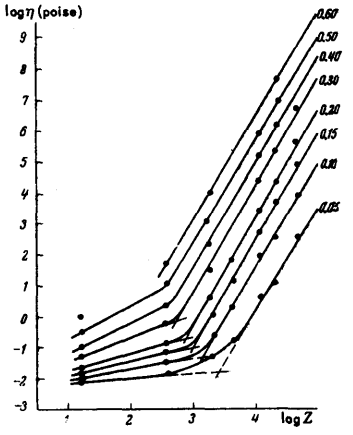

Fig. 7. Variation of the viscosity of polyisobutylene solutions in iso-octane with degree of polymerisation of the polymer [63]. The numbers by the straight lines denote the volume fraction of polyisobutylene in solution.

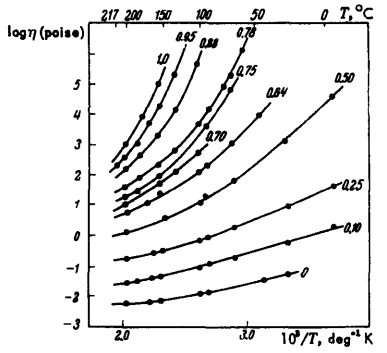

Fig. 8. Temperature dependence of the viscosity of polystyrene solutions in dibenzyl ether [20]. The numbers by the curves denote the weight fraction of the polymer in solution.

A concentrated solution of a polymer is also a single continuous system, differing from the polymer itself by having shorter relaxation times. Since the nearest neighbours of the polymer segments are solvent molecules, mutual friction takes place, and the jumps of segments and small molecules alike require a definite activation energy. Hence the term "energy" or "heat of activation" can be applied to concentrated solutions of polymers just as it can to the polymers themselves. (Very dilute solutions of polymers are an exception, and involve a radically different friction mechanism[80].) These terms are applied to concentrated solutions of polymers[48,52,56,57] and to plasticised systems[72].

The heat of activation for viscous flow depends on the concentration of the solution. It increases with increasing volume fraction of the polymer: linearly over a relatively narrow concentration range (from $\varphi_2 = 0.05$ to $\varphi_2 = 0.5$)[27,28,36,37,47,49] and non-linearly over a wider range of compositions[56,57,62-65]. It can be seen from Fig. 9 that the heat of activation for flow rises most steeply at high concentrations for solutions of polymers close to the glassy state: at $\varphi_2 = 1$ (polymer), ΔH_{visc} is of the order of hundreds of kilocalories per mole.

The slope of the function $\log\eta = f(1/T)$ increases when the material (or the solution concentration) is changed because the intermolecular interaction energy increases[19], as a result (in the present case) of a decrease in the free volume, or of approaching the glass point of very concentrated solutions[70].

The heat of activation for the flow of a solution depends also on the molecular weight of the dissolved polymer: this was demonstrated for solutions of cellulose tributyrate[52] and of poly(vinyl alcohol)[33,46], which were investigated over the composition range up to $\omega_2 = 0.40$ and $\omega_2 = 0.25$ respectively. Measurements were made over the whole composition range and a wide range of molecular weights for solutions of polyisobutylene[63,77]: the results are shown in Fig. 10. For not too high concentrations ($\varphi_2 < 0.35$) the heat of activation increases with the molecular weight of the polymer; at concentrations $\varphi_2 > 0.35$ we find a sharp increase in ΔH_{visc} on going from $M = 10^2$ (iso-octane) to 0.9×10^3 (from 1.9 to 14.5 kcal mole^{-1}).

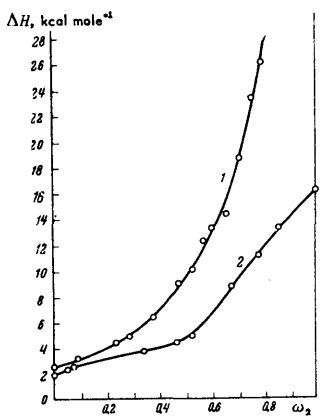

Fig. 9. Variation of the heat of activation for viscous flow with weight fraction of the polymer in solution:
1) polystyrene–diethylbenzene[56]; 2) polyisobutylene–toluene.[64]

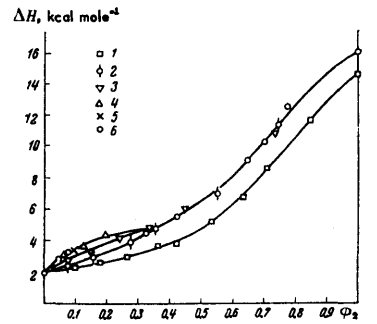

Fig. 10. Concentration dependence of the heats of activation for viscous flow of polyisobutylene solutions in iso-octane[63]:
1) $M = 0.9 \times 10^3$; 2) $M = 2.0 \times 10^4$; 3) $M = 1.1 \times 10^5$; 4) $M = 2.4 \times 10^5$; 5) $M = 6.5 \times 10^5$; 6) $M = 1.2 \times 10^6$.

Increasing the molecular weight of the polymer from 0.9×10^3 to 2×10^4 raises ΔH_{visc} by 1.6 kcal mole^{-1} (from 14.5 to 16.1). Further increase of molecular weight has no effect on the heat of activation for viscous flow.

The lack of dependence of the heat of activation for the flow of concentrated polymer solutions upon the molecular weight of the dissolved polymer, like the general validity of Eqn. (1), argues for a general mechanism of flow in polymers and their concentrated solutions. Hence we may suggest that other relationships, derived for the flow of polymers, should also be valid for solutions of polymers. Thus, Ferry[1] states that the temperature dependence of the viscosity of concentrated solutions of polystyrene, poly(vinyl chloride), poly(vinyl acetate), and cellulose tributyrate is satisfactorily described by the WLF equation.

A similar relationship was recently proposed[67] for polymer solutions: the equation obtained is

$$-\frac{T-T_0}{\log a_T} = \frac{[f(\varphi_1,T_0)]^2}{a_f(\varphi_1)} + (T-T_0)f(\varphi_1 T_0) \qquad (30)$$

where T and T_0 are the experimental and the reference temperature respectively; $f(\varphi_1, T_0)$ is the relative free volume of a solution of the given concentration φ_1 at the reference temperature T_0; $a_T = \eta(\varphi_1, T)/\eta(\varphi_1, T_0)$, and $af(\varphi_1)$ is a function of concentration. The plot of $-(T - T_0)/\log a_T = f(T)$ is a straight line whose slope measures $f(\varphi_1, T_0)$ and whose intercept on the ordinate axis measures $af(\varphi_1)$. The linearity of this function was confirmed in the poly(n-butyl methacrylate)–diethyl phthalate system.

4. Effect of the Nature of the Solvent on the Viscosity of Polymer Solutions

The effect of the nature of the solvent on the viscosity of concentrated solutions of polymers has been least thoroughly investigated, in spite of the essential relevance of intermolecular interaction and of its influence on all rheological properties. As already stated, the addition of small, readily mobile molecules to a polymer causes a dramatic increase in the fluidity and free volume of the system. Hence we can suggest that the addition of solvents and plasticisers to a polymer should affect the viscosity and all related properties in direct proportion to the volume fraction of the solvent and irrespectively of the nature of the solvent: the same conclusion follows also from a number of

theoretical equations. The earliest studies of the problem appeared to confirm this point of view. Thus, Ferry and coworkers[49-51] examined solutions of poly(vinyl acetate) in five solvents, of polyisobutylene in two solvents, and of polystyrene in two solvents up to weight fractions of the polymer of $\omega_2 = 0.5-0.6$, and showed that the viscosities are similar at a given volume fraction, but differ if the solutions are compared at a given weight fraction†.

The influence of the nature of the solvent on the viscosity of polymer solutions has been studied also by other workers[26,38,42,47,59], but either over a limited concentration range or over a limited range of solvents. A detailed study of the problem was made with solutions of polyisobutylene in six chemically different liquids, and of polystyrene in five liquids, over a wide range of compositions and at temperatures between 20° and 50°.[62,64,65,69] It was shown that even the viscosity of solutions of a polymer as elastic as polyisobutylene, whose chains contain only groups of a single type, depends on the nature of the solvent. The effect of solvent on the viscosity of polymer solutions is specially marked when the polymer is close to T_g under the conditions of the experiment. Thus, the viscosities of decalin and ethylbenzene solutions of atactic polystyrene at 20° and equal volume fractions differ by a factor of several hundreds.

With rise in temperature the concentration–viscosity curves of solutions in different solvents tend to coalesce, and at temperatures above T_g for polystyrene the viscosities of decalin and ethylbenzene solutions differ only by the viscosity difference between the solvents themselves.

The fall of viscosity with increase of temperature is not the same in solutions in different solvents: in other words, the heat of activation for viscous flow also depends on the nature of the solvent. It is important to note that the order of the plots of $\log\eta = f(C)$ and $\Delta H_{visc} = f(C)$ is the same, both for polyisobutylene and for polystyrene solutions. This suggests that the viscosity of concentrated solutions of polymers, like the viscosity of low-molecular liquids and their mixtures, is determined by the heat of activation for flow[19].

Several workers have suggested[26,42,49-51] that the viscosity of a polymer solution is controlled by the viscosity of the solvent. Thus, there is evidence[62,64,65,69] that the viscosity of the solution is highest in the most viscous solvent and lowest in the least viscous solvent. However, the viscosities of decalin and toluene (or ethylbenzene) at 20° differ by about a factor of 5, as compared with a factor of 12 for polyisobutylene solutions and a factor of several hundreds for polystyrene solutions in these solvents. Hence, viscosity differences between solutions of polymers depend on the viscosity of the solvent but are not wholly determined by it. The basic reason for differences in fluidity of solutions in different solvents is component interaction. Therefore it is very important to compare viscosities with parameters which characterise the interaction: as far as possible, the comparison should apply to the same concentration region.

† It may be useful to stress that when comparing any property of solutions in different solvents one should not use weight fractions, since their value depends on the density of the liquid. The concentration of the solution should be given in mole or volume fractions. Using the former units we compare the solutions at a constant concentration of solvent molecules, using the latter units we compare them at a constant degree of filling of space by different solvents. With a property such as viscosity it is more correct to compare solutions of equal volume fraction.

We must first of all consider the thermodynamic affinity between the polymer and the solvent, measured by the chemical potential difference $\Delta\mu_1$ or by the second virial coefficient A_2. Experimentally measured values of $\Delta\mu_1$ and A_2 show that iso-octane is a good solvent for polyisobutylene whereas butyl propionate is a poor solvent[81]. In the composition range between $\varphi_2 = 0.5$ and $\varphi_2 = 1$ the viscosity coefficients of polyisobutylene solutions in the two solvents are identical. Decalin is a poor solvent for polystyrene, whereas ethylbenzene is a good solvent. In the former the viscosity and the heat of activation are much higher than in the latter. But ethyl acetate also is a poor solvent for polystyrene, yet the viscosities of ethyl acetate and ethylbenzene solutions are very similar. Thus, there is no correlation between the viscosity coefficient of a solution and the thermodynamic affinity of the polymer for the solvent. Hence, it is not generally correct to assume, over a wide concentration range, that the viscosity or the heat of activation of a solution in a thermodynamically more active solvent must be higher (or lower) than in a poor solvent.

It must be noted that no correlation is observed between viscosity and the heat of dissolution (i.e. the enthalpy change). Knowing the differences in chemical potential of a component, $\Delta\bar{\mu}_i$, and its partial enthalpy, $\Delta\bar{H}_i$, we can calculate the partial entropy of mixing, $\Delta\bar{S}_i$:

$$\Delta\bar{\mu}_i = \Delta\bar{H}_i - T\Delta\bar{S}_i. \qquad (31)$$

The entropy of mixing is largely determined by the flexibility of the polymer chain[72,75]. When flexible polymers are dissolved the partial entropy of mixing of the solvent $\Delta\bar{S}_i$ is always greater than in the dissolution of polymers with rigid chains, since in the former case the number of configurations which the chains can adopt in solution (and therefore also the thermodynamic probability of the solution) is greater than in the latter.

For polyisobutylene solutions, the values of $\Delta\bar{S}_i$, which characterise the flexibility of the polymer chain, decrease along the following series of solvents: toluene > CCl_4 > > iso-octane ≃ cyclohexane[81].

Thus, in solutions of elastic polymers solvent interactions take the form of changes in the flexibility of the chain. The viscosity of the solution is lowest in the solvent which makes the polymer chain most flexible, as was to be expected from the general theoretical considerations outlined above. However, the viscosity of the solvent itself also plays a role, and on occasions these two factors can be mutually opposing. Thus, the viscosity of CCl_4 is greater than that of iso-octane by about a factor of two, but the polyisobutylene chain is less flexible in iso-octane solutions than in CCl_4. The two factors cancel each other out, and the two solutions have identical viscosities.

At elevated temperatures the rate [amplitude?] of the torsional vibrations of the units increases: the kinetic flexibility of the polymer chain increases, the whole set of conformations becomes available[82], and the influence of the nature of the solvent becomes less marked. At a certain temperature, solutions of equal φ_2 in solvents of equal viscosities have the same viscosity. This is very clearly seen for solutions of polyethylene at $T > T_f$: the viscosities of solutions in decalin, dodecane, xylene, and monochlorobenzene lie on a common curve[69].

Thus, we can make the following statement regarding the viscosity of polymer solutions at experimental temperatures higher than T_g: the lower the viscosity of the

solvent and the greater the flexibility of the polymer chain in that solvent, the lower will be the viscosity of the solution.

The situation is a great deal more complicated when T_g for the dissolved polymer is significantly higher than the experimental temperature: this is particularly true of polymers with polar side-chain substituents which interact strongly both with each other and with the solvent molecules. In this case it is impossible to explain the effect of solvent on the viscosity of concentrated polymer solutions without detailed consideration of the structure of solutions.

II. NEWTONIAN VISCOSITY AND STRUCTURE OF THE SOLUTIONS

Studies of the viscous, optical, and other properties of very dilute polymer solutions show that the individual macromolecules have a coiled, globular form, and can move independently of each other[80]. This model applies only to very dilute solutions; when the concentration is increased the molecules begin to interact. The problem, therefore, is to identify the concentration at which these interactions set in and the configuration of the interacting molecules.

As long ago as in 1931 Staudinger[83] proposed the idea of a "critical" concentration, i.e. a concentration at which rod-shaped polymer molecules begin to touch. Boyer and Spencer[84] prefer to redefine the "critical concentration" as the concentration at which a random distribution of globular molecules becomes close packed. Their calculations show that the critical concentration depends on the molecular weight of the polymer and on the nature of the solvent. Thus, for solutions of polystyrene in benzene C_{crit} (g/100 ml) = $= 30.6M^{-1/2}$, whilst for solutions of polystyrene in ethyl methyl ketone $C_{crit} = 69.1M^{-1/2}$. When the molecular weight is $\sim 10^6$, $C_{crit} = 0.03-0.06$ g/100 ml (i.e. is very small). Using modified Ostwald viscometers with very narrow capillaries (d = 0.2 mm and 1600–3900 s outflow time for the pure solvent), Streeter and Boyer[85] observed anomalies in the viscosity at high dilutions. Their results show that the corrected viscosity varies linearly with concentration only down to 0.1 g/100 ml: further dilution gives a sharp upward bend in the curve, and still further dilution (below C = 0.002 g/100 ml) makes the curve bend down again, forming a maximum. Critical concentration values of 0.03–0.07% were obtained from these experiments[85], but subsequent work failed to confirm the results. Thus, Frank[86] did not observe any anomalies in the concentration dependence of the light-scattering asymmetry of the same solutions. Öhrn suggested[87], as a result of his calculations, that the phenomena observed by Boyer and coworkers were due to adsorption of polymer molecules on the viscometer walls, resulting in a decrease in diameter as well as a decrease in concentration. By working with a viscometer provided with three capillaries of different diameters he found that the largest anomalies are observed with the narrowest capillaries. Batzer's studies[88] of the viscosity of poly(vinyl chloride) solutions with different degrees of chain branching support this explanation. Therefore we must conclude that the effects observed by Streeter and Boyer have no bearing on the existence of a critical concentration.

Interest in this problem has been renewed in recent years. Horth and Rinfret[89] studied the concentration dependence of the density of poly(vinyl acetate) solutions, and concluded that a "critical" concentration exists, varying from 0.75 to 0.09 g/100 ml as the molecular weight varies from 80 000 to 3 200 000. From their measurements of the concentration dependence of the heat of mixing of poly(vinyl acetate) with methanol and tetrachloroethane Parent and Rinfret[90] obtained appreciably lower values of the critical concentration (φ_2 = 0.02–0.005).

We feel that the term "critical" is an unfortunate one, because the properties of the solutions as a rule do not vary discontinuously with concentration. The so-called singular points on property–composition curves are due to the presence of specific interactions between the components[91]. Experimental observations of density discontinuities at a strictly defined concentration are also unconvincing: no discontinuities were observed in analogous measurements on polystyrene and polyisobutylene solutions[76]. What is undeniable, however, is that the macromolecules begin to interact at some definite level of concentration which must be a function of the molecular weight of the polymer and of the nature of the solvent: under these conditions the solutions contain aggregates or associations of molecules rather than individual molecules. Polymer association effects have been discussed even in dilute solutions[92–95]. The interaction forces will depend, of course, on the nature of the polymer and of the solvent: dipole–dipole interaction predominates in poly(vinyl chloride) solutions in polar solvents, whilst in solutions of polybutadienes in octane or chloroform dispersion interactions are predominant. The latter are quite substantial if allowance is made for the increase in polarisability with molecular length. But this interaction is invariably present, and associations are formed.

It remains to be established what these associations consist of, how the macromolecules are distributed within the associations, and what is the configuration of the macromolecules. Boyer and Spencer assumed, in their first paper, that the globular molecules remain unchanged in form when they come into contact, but they were subsequently forced to postulate unwinding or uncoiling during interaction. The view that uncoiling must take place when the macromolecules interact follows directly from our knowledge of the structure of the polymers themselves, which are often prepared by concentrating their solutions. With the exception of a few ("globular") polymers, the polymers themselves do not contain unchanged globular formations. According to the views current until very recently, an amorphous polymer consists of a conglomeration of entangled, more or less straight, molecular chains, whereas in a crystalline polymer ordered regions alternate with regions of entangled chains. The entangled chain model was adopted in the theory of the viscosity of concentrated solutions, whose basic postulate is that all the chains are mutually intertwined as in a ball of tangled threads. The number of interlocks increases with the molecular weight of the polymer.

However, as Kargin and coworkers were the first to point out[96], the concept of tangled chains does not apply to a real polymer. Very large numbers of so-called supermolecular structures have been reported in polymers, and it has been shown that even in the amorphous state polymers have an ordered bundle-like structure[97]. The formation of bundles of chains, observed in amorphous polymers, must be preceded by uncoiling and mutual orientation of the chains.

Since very dilute solutions contain globular molecules whereas in the polymers themselves the chains are rela-

tively straight, the first effect must be an unfolding or uncoiling of the globular molecule as the solution becomes more concentrated: this has been confirmed by an electron-microscopic study of poly-α-butylene solutions[98]. Colophony (a substance whose glass point is above room temperature) was used as the solvent, thus enabling the structure of the solution to be "frozen" during the investigation. It was found that in poly-α-butylene solutions of concentration 0.1–0.5%, the molecules have a linear configuration and interact with each other to give appreciably ordered formations. These experiments suggest that individual globular molecules are to be found only in the more dilute solutions.

Unfortunately, it is impossible at present to examine the structure of the more concentrated solutions in the electron microscope, and therefore the indirect methods of investigation such as light scattering and viscosity studies play an important role. The first indications of the uncoiling of chains in polyelectrolyte solutions with increase of concentration and of degree of ionisation came from viscosity studies[99]. Zubov and Lipatov explain the sharp increase in viscosity obtained by concentrating aqueous solutions of poly(methacrylic acid) by postulating uncoiling of molecular chains and the formation of supermolecular structures[100]. A similar unfolding of globular molecules occurs in solutions of polymeric non-electrolytes.

Recently, an attempt was made[101] to estimate the shape of interacting macromolecules by comparing the concentration dependence of the relative viscosity of polymer solutions with that of suspensions of rigid spherical particles. It was concluded that the ratio $\log\eta_{rel}/C$ (where η_{rel} is the relative viscosity) increases gradually with the former, but decreases with the latter, when the concentration increases. The author[101] ascribes this difference to different interaction mechanisms. The collision of two rigid spheres produces a "dumb-bell", which contributes to the viscosity more than each isolated sphere. On the other hand, when two polymeric molecules collide, molecular aggregates are formed, and these contribute less to the viscosity than the two separate macromolecules. The papers by Maron and coworkers[102,103] contain similar conclusions, from viscosity data, on the change in shape of interacting particles.

Thus, when the concentration of a polymer solution is increased the globular molecules unfold, and the chains, more or less straightened, begin to interact. This is accompanied by a sharp increase in light scattering by the solution, which decreases, however, when the concentration is increased still further[104].

In the concentration region where light scattering decreases, the viscosity rises steeply, evidently due to the formation of a continuous disordered network in the solution. However, this network is composed of aggregates of more or less linear chains rather than of interlocking and entangled long molecular chains. Interlocking of macromolecules in solutions is as unlikely as it is in polymers, because it would be inconsistent with the observed rapid establishment of equilibrium in solutions following temperature or concentration changes. The relaxation time of chains is very large, and unravelling processes should be exceedingly slow. In practice (in the neighbourhood of a phase separation temperature, say) a turbid solution becomes instantly transparent, corresponding to the appearance of a maximum on the viscosity polytherm[105,106]. This is evidence that the solution contains aggregates which can rapidly regroup in response to a temperature change.

When the concentration of the solution is increased the degree of aggregation also increases, the network becomes more ordered, and fluctuations in concentration decrease. This is accompanied by a continuous increase in viscosity and by a decrease in the intensity of excess light scattering.

The non-linearity of the changes in heat of activation for the viscous flow of polymer solutions and the sharp increase of ΔH_{visc} at $\varphi_2 > 0.5$ are evidence for the existence of a concentration region in which interactions between chains are very strong. In this region of compositions we are evidently dealing with the highly ordered supermolecular structures which are found in the polymers themselves.

Hirai has derived[107], on the basis of the concept of bundles or "beams" of chains in solutions, a theoretical equation for the dependence of the heat of activation for viscous flow upon concentration and molecular weight of the polymer: this equation corresponds exactly to the experimental curves shown in Fig. 10.

Thus, the whole of the available experimental data on the viscosity and light scattering properties of concentrated polymer solutions points to the existence, in polymer solutions, of a number of concentration regions with different degrees of order and chain conformations: (1) the region of dilute solutions, in which the globular molecules become uncoiled and form aggregates as φ_2 is increased; (2) the concentration region in which the aggregates combine into a continuous network whose degree of order increases with φ_2; (3) the region of very concentrated solutions, in which highly ordered supermolecular structures are formed. All the transitions are reversible both towards concentration and towards dilution.

Thus, when a polymer comes into contact with a low-molecular liquid the molecules of the latter penetrate only between the ordered supermolecular structures (interbundle swelling). This is true whether the liquid is a good solvent or a poor solvent. According to the size of the solvent molecules, and to their affinity for the polymer, disintegration of the bundles may occur in different ways; hence the size of the supermolecular structures at a given value of φ_2 depends on the nature of the solvent. In decalin solutions of polystyrene the bundles do not break down appreciably, whilst in ethylbenzene solutions substantial disintegration occurs: the viscosity of the former solutions at 25° is much greater than that of the latter. In the high concentration region the viscosity of polyisobutylene solutions is the same in a good solvent (iso-octane) as in a poor solvent (butyl propionate). This also suggests that the molecules of these liquids penetrate only between the bundles, whose existence has been proved for the case of rubber-like polymers[108]. Butyl propionate cannot penetrate into the bundles and the swelling is limited. Iso-octane can enter the bundles, so that the latter disintegrate and the degree of ordering decreases. At a definite concentration (which is lower the better the solvent) the molecules begin to break apart and only at very low concentrations can we expect isolated globular macromolecules to form.

All that has been said agrees satisfactorily with Kargin and Kozlov's recent views[109,110] on interbundle plasticising, and is in keeping with a general flow mechanism common to polymers and their solutions. According to generally accepted ideas, based on the fact that polymers and low-molecular liquids have very similar heats of activation for viscous flow, the elementary unit of flow of a polymer is a

chain segment. However, the heats of activation [fluidity?] of polymers and of their concentrated solutions are higher than those of liquids by one order of magnitude, and those of glassy polymers are higher by two orders of magnitude. This suggests that the jumps involve portions of a bundle rather than individual segments, i.e. that the viscous-flow properties are determined by the collective motion of chains[1].

ADVANCES IN THE SYNTHESIS OF UNSUBSTITUTED AMINO-ACIDS

E.N.Safonova and V.M.Belikov

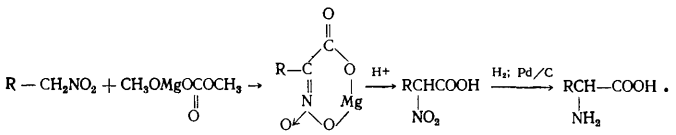
Recently there has been a considerable increase of interest in the synthesis of biologically important amino--acids, due to the fact that these amino-acids are ceasing to be objects of theoretical studies only and are becoming available as products of industrial manufacture and are widely used in the food industry and in agriculture. Since the number of studies published recently in this field is fairly large, their critical review is essential.

The present review is concerned with the synthesis of eight unsubstituted amino-acids: valine, leucine, isoleucine, phenylalanine, threonine, lysine, methionine, and tryptophan. A review on the synthesis, degradation, and racemisation of yet another important amino-acid, glutamic acid, was published in 1963.[1] Since the detailed review of the literature on the synthesis of amino-acids in the book of Greenstein and Winitz[2] covers the original literature up to 1958, we shall consider in detail only later studies which appeared up to the middle of 1965 and also some work published in the second half of 1965. Earlier work will be quoted for the purpose of exposition. Initially we shall describe general methods of synthesis and then specific methods for each individual amino-acid, starting with monoaminomonocarboxylic acids and then continuing with more complex acids. Since the usual chemical syntheses yield racemic amino-acids, the separation of the DL-forms into optical isomers is of primary importance. Among the reviews dealing with this problem, there is one which was published relatively recently[3]. However, all these reviews describe only individual aspects of the problem and are to a large extent obsolete.

GENERAL METHODS OF SYNTHESIS

The simplest general method of the synthesis of all amino--acids is the ammonolysis of the corresponding α-halogeno--substituted acids. The amination reaction itself presents no difficulties and the applicability of this reaction is restricted solely by the availability of the α-halogeno-acids. Until recently the halogeno-derivatives of aliphatic acids only were available. In 1956–1959 Nesmeyanov, Freidlina, and coworkers developed a new method for the synthesis of α- and ω-chlorocarboxylic acids and their derivatives with other functional groups based on the telomerisation of ethylene[4,5]. $\alpha\alpha\alpha\omega$-Tetrachloroalkanes, obtained in the radical--chain telomerisation of ethylene and carbon tetrachloride, are converted into amino-acids according to the following general mechanism:

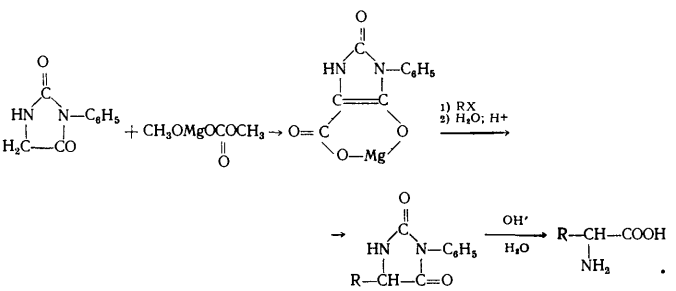
$$CCl_3CH_2(CH_2)_nCl \xrightarrow[SbCl_5]{FeCl_3,\ AlCl_3} CCl_2=CH(CH_2)_nCl \xrightarrow{HX} \rightarrow CCl_2=CH(CH_2)_nX \xrightarrow[CH_3COOH\ or\ (CH_3COO)_2Hg]{Cl_2/H_2SO_4} HOOCCHCl(CH_2)_nX \xrightarrow{NH_3} HOOCCH(NH_2)(CH_2)_nX,$$



where X is the substituent and n ranges from 0 to 15.

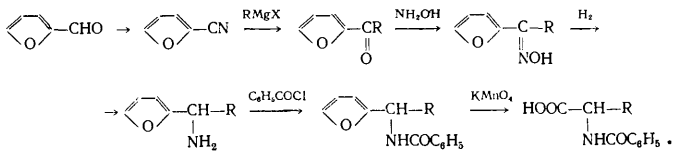
The following amino-acids were obtained in this way: phenylalanine (X = C_6H_5, n = 1), glutamic acid (X = COOH, n = 2), and lysine and ornithine [X = $C_6H_4(CO)_2N$, n = 4 and 3]; the phthalic acid group was removed by hydrolysis with concentrated hydrochloric acid. Ammonolysis of $\alpha\omega$-dichlorovaleric acid (X = Cl, n = 3) yields proline[7-9].

α-Nitro-acids and their derivatives constitute another convenient intermediate for the synthesis of α-amino-acids. In 1952 Weisblatt and Little outlined the principal ways of using nitroacetic ester for the synthesis of α-amino-acids: (1) alkylation of nitroacetic ester with alkyl halides, alkylarenesulphonates, and alkyl sulphates in the presence of alkaline catalysts, with carbinols in the presence of boron trifluoride, and with substituted dialkylamines and quaternary ammonium bases; (2) condensation of nitroacetic ester by reaction of the Knoevenagel type with aldehydes



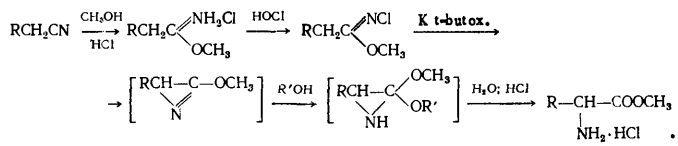
and ketones in the presence of the appropriate catalysts; (3) addition of nitroacetic ester to substances containing an activated double bond. After the introduction of the required substituents, the nitro-group is reduced and the ester is hydrolysed[10]. These workers and a number of other investigators developed, on the basis of nitroacetic ester, methods for the synthesis of tryptophan[11], threonine[12,13], leucine[14], glutamic acid[15], glycine[16,17], α-aminobutyric acid[13], and other amino-acids. Interest in nitroacetic ester has recently increased appreciably in connection with the development of a simple method for its preparation from nitromethane and alkali[18]. Nitromalonic ester has also been used for the preparation of tryptophan[19-21], proline[22], ornithine[23], and glutamic acid[24]. Valine[25,26], leucine[26], isoleucine[27], and the *O*-methyl ester of threonine[26] have been obtained by the reduction of the esters of substituted α-nitroacrylic acids. The α-nitro-ϵ-lactams of these acids[28] can apparently be used as intermediates in the synthesis of $\alpha\omega$-diamino-acids.

For the preparation of α-nitro-acids, Finkbeiner proposed a reaction involving the carboxylation of primary nitro-paraffins with methoxymagnesium methyl carbonate in dimethylformamide[29-32]:



The chelate structure of the magnesium salt of the α-nitro-acid formed stabilises the molecule. The free nitro-acid is isolated by acidification and then reduced to the amino-acid. DL-Alanine, DL-α-aminobutyric acid, and DL-norvaline were obtained in this way from nitroethane, 1-nitropropane, and 1-nitrobutane in yields of 46, 34, and 42% respectively, relative to the nitro-paraffin; the authors state that the conditions used were not optimum[29].

The general synthesis of amino-acids by the carboxylation and alkylation of phenylhydantoin was achieved with the aid of methoxymagnesium methyl carbonate:



The following amino-acids were obtained by this procedure (the amino-acid and the alkylating agent are listed, the percentage yield with respect to 3-phenylhydantoin being indicated in brackets): valine, isopropyl bromide (38); leucine, isobutyl bromide (46); phenylalanine, benzyl chloride (97); tryptophan, gramine (53); proline, 1,3-dibromopropane (45); lysine *N*-(4-bromobutyl)phthalimide (45); glutamic acid, the sodium salt of β-chloropropionic acid (30).[33,34]

In 1958 Terent'ev and Gracheva suggested that furfural be used as a cheap raw material for the preparation of amino-acids[35]. Furfural is converted into a ketone which is in turn converted into the corresponding oxime, the latter being reduced to the amine with zinc in acetic acid. The amino-group is then protected by acylation, the furan ring is oxidised with alkaline permanganate, and the acyl derivative of the amino-acid is obtained, the free acid being isolated after hydrolysis:

The *N*-benzoyl derivatives of the following aliphatic amino-acids were obtained in this way: leucine, alanine, norvaline, norleucine, α-aminobutyric acid, and α-amino-isoheptanoic acid [R = $CH_2CH_2CH(CH_3)_2$]. When *N*-benzoyl-isopropylfurylamine is oxidised, the valine derivative cannot be isolated[36]. In addition, *N*-benzoylaspartic acid and proline were obtained from the furan derivatives[37]. β-Amino-acids are obtained by the condensation of furfural and nitro-alkanes with subsequent reduction of the nitro-group with lithium aluminium hydride and the oxidation of the furan ring[38]. The aldol condensation of furfural with alkyl methyl ketones, accompanied by the hydrogenation of the unsaturated ketone, ammonolysis, and oxidation, yields γ-amino-acids[39].

Baumgarten proposed a very interesting method for the conversion of nitriles into α-amino-acids. The reaction proceeds as follows:

Partial hydrolysis of the nitrile yields the hydrochloride of the methyl imino-ester, which is converted into the *N*-chloro-imino-ester by chlorination. The latter undergoes rearrangement into the methyl ester of the amino-acid hydrochloride under the action of potassium t-butoxide. The rearrangement is a special case of the conversion of *N*-dichloro-s-alkylamines into α-amino-ketones. The following amino-acids were obtained from nitriles (the percentage yields with respect to the nitrile are indicated in brackets): phenylalanine (44), leucine (59), alanine (51), glycine (51), norvaline (21), and phenylglycine (51).[40]

We think it desirable to consider in the general section the following widely known synthetic methods for amino-acids.

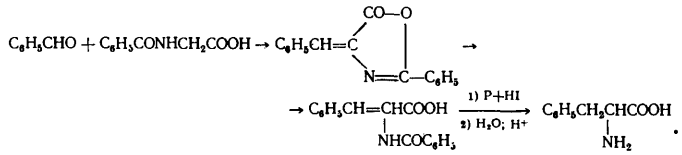
1. Syntheses based on malonic, acetamidomalonic, cyanoacetic, and acetoacetic esters.

2. The azlactone method for the synthesis of aromatic amino-acids and the related procedures which are based on the principle involving the utilisation of the mobility of the hydrogen atoms of the activated methylene group (condensation of aldehydes with dioxopiperazines, hydantoins, etc.).

3. The cyanohydrin method (the Strecker synthesis).

4. The applications of the Schmidt method in the synthesis of amino-acids.

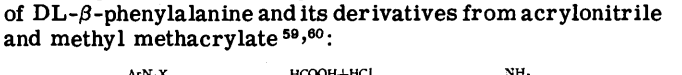
The new variants and the most important examples of the application of these methods will be examined in fair



detail in connection with the description of the procedures for the preparation of the individual amino-acids.

The problems associated with the synthesis of mixtures of amino-acids from the simplest carbon and nitrogen compounds under the action of various physical factors (temperature, irradiation, ultrasonic vibrations, electric discharge, etc.) are outside the scope of this review.

Phenylalanine

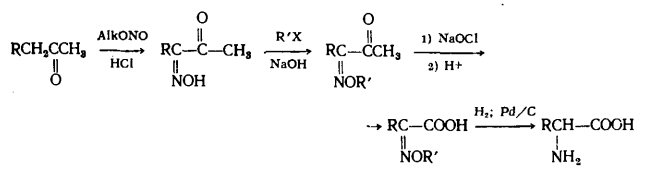


The principal methods for the synthesis of phenylalanine are at the same time the general methods for the preparation of other aromatic and aliphatic monoaminomonocarboxylic acids. Therefore in the subsequent consideration of the syntheses of valine, leucine, and isoleucine we shall refer to the reactions described in this section.

The method proposed by Erlenmeyer (known as the Erlenmeyer synthesis) for the synthesis of aromatic amino-acids by the condensation of benzaldehyde (or other aromatic aldehydes) with hippuric acid is widely known. The azlactone formed hydrolyses and after reduction and liberation of the amino-group phenylalanine is obtained[41]:

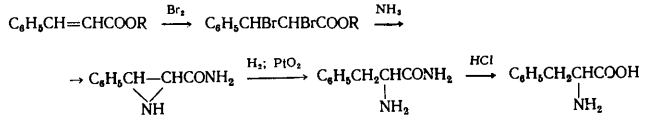
The yield of phenylalanine is 63–67% with respect to the azlactone[42] or 55% with respect to hippuric acid[43]. When acetylglycine is used instead of hippuric acid, the yields reach 72%.[44-46] Various modifications of this method are known, consisting in the condensation of benzaldehyde with heterocyclic compounds containing an active methylene group: hydantoin[47-50], dioxopiperazine[51], 1-benzoyl-2-mercaptohydantoin[52,53], 2-mercaptothiazolone[54,55], and rhodanine[56]. Reduction and hydrolysis of the resulting benzylidene derivatives yields amino-acids.

The application of the Meerwein reaction proved extremely fruitful in the synthesis of aromatic amino-acids, in particular phenylalanine and tyrosine[57-61]. A very convenient method for the preparation of α-halogeno-β-arylpropionic and β-arylisobutyric acids, based on the halogenoarylation of acrylic acid derivatives, was developed, which made it possible to find a general method for the synthesis of DL-β-phenylalanine and its derivatives from acrylonitrile and methyl methacrylate[59,60]:



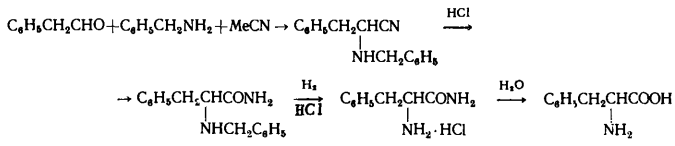
where X = Cl or Br.

α-Chloro-β-phenylpropionic acid was obtained in 40% yield; when it was aminated with aqueous ammonia, the yield of phenylalanine was 40–42%, the use of liquid ammonia increasing the yield of the amino-acid to 80%. The halogenoarylation of acrylic acid with subsequent amination gave phenylalanine with an overall yield of 10% with respect to aniline[61]. Another method for the preparation of α-chloro-β-phenylpropionic acid was proposed by Freidlina and coworkers:



The acid, isolated in 63% yield, was subjected to ammonolysis with an excess of aqueous ammonia under pressure, the product being phenylalanine in 77% yield[7].

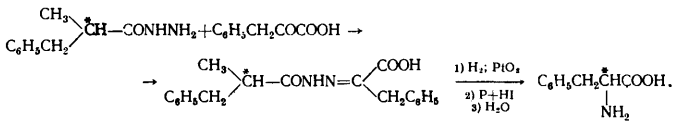
Monoaminomonocarboxylic acids can be obtained from alkyl ethyl ketones via α-hydroxyimino-ketones by the following mechanism:



The methyl ketone is nitrosated with alkyl nitrite or an alkali metal nitrite, the ketone oxime being alkylated with diethyl sulphate. Hoffmann degradation of the α-alkoxyimino-ketone gives the α-alkoxyimino-acid, which is reduced to the amino-acid. In this way it was possible to obtain phenylalanine from methyl β-phenylethyl ketone in 50–53% yield, alanine from ethyl methyl ketone in 14 and 32% yield, and valine from isobutyl methyl ketone in yields of 34 and 31%.[62-65] In addition, tyrosine, norleucine, 3,4-dihydroxyphenylalanine, and phenylglycine were also obtained[66].

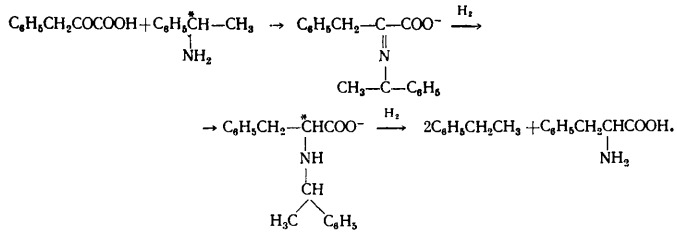
Interesting reactions occur in the preparation of phenylalanine from cinnamic esters. The cinnamic acid ester is converted into the ester of αβ-dibromo-β-phenylpropionic acid by treatment with bromine. The product obtained when this ester is treated with an excess of 25% solution of ammonia under pressure was initially incorrectly assumed to be the amide of α-amino-β-phenylacrylic acid [$C_6H_5CH{=}CC(NH_2)CONH_2$].[67] Later it was shown that the compound is in fact a derivative of aziridine[68]. Hydrogenation of the intermediate product with subsequent hydrolysis gives phenylalanine in 25% yield with respect to the ester of αβ-dibromo-β-phenylpropionic acid[69]:

The synthesis of phenylalanine by the Strecker method was achieved by Erlenmeyer[70] in 1882 but has not been used since. In 1963 a modification of the method was proposed for the preparation of alanine, valine, leucine, and phenylalanine, consisting in the initial reaction of the aldehyde, metal cyanide, and benzylamine (instead of ammonia); the resulting (*N*-benzyl)amino-nitrile is hydrolysed to the amine, the benzyl group is removed by hydrogenation, and the amino-acid is obtained after hydrolysis[71]:



The methods for the preparation of phenylalanine with the aid of malonic, cyanoacetic, and acetoacetic esters and their derivatives are distinguished by their great variety. New modifications of these methods are being proposed by investigators also at the present time. Since a complete description of these syntheses would be unduly cumbersome and their exclusion from the review would render the range

of syntheses of unsubstituted amino-acids incomplete, we have confined ourselves to a Table in which the key features of the syntheses are given and other amino-acids obtainable by the same method are indicated.



Reductive amination of phenylpyruvic acid with hydrogen and ammonia in the presence of the palladium catalyst is a reaction analogous to the reduction of oximes and phenylhydrazones of α-keto-acids[93]. Reductive amination is particularly convenient for the synthesis of phenylalanine labelled at the nitrogen[94]. A series of Japanese patents describe the reductive amination of phenylpyruvic, pyruvic, and oxoglutaric acids in the presence of various complex cobalt salts[95-97] and also with sodium borohydride[98]. The cobalt complexes were used in the preparation of phenylalanine by the hydrogenation of α-acetamidocinnamic acid[99].

The preparation of phenylalanine, leucine, and α-aminobutyric acid by the Grignard reaction has been noted. However, the yields of the amino-acids did not exceed 5–10%.[100]

Several methods have been proposed for the preparation of optically active phenylalanine (and also valine, alanine, and glutamic acid) by the reaction of substances containing an optically active group in the molecule, with formation of a new centre of asymmetry. However, the asymmetric yield is usually low. For example, the product of the condensation of the hydrazide of an optically active acid with an α-keto-acid is reduced and then decomposed, a compound with a new centre of asymmetry being obtained[101]:

The optical isomers of phenylalanine, alanine, and valine were obtained by the catalytic hydrogenation of the corresponding α-keto-acids in the presence of D(+)- and L(-)-α-methylbenzylamine:

The asymmetric centre of the amino-acid arises in the stage involving the hydrogenation of the Schiff base. The degree of asymmetry thus introduced depends on the structure of the initial substances and the properties of the catalyst[102]. The preparation of L-phenylalanine by the hydrogenation of α-acetamidocinnamic acid in the presence of Pd/C and small amounts of L-methionine[103] has been described. Akabori suggested that optically active amines and amino-acids be obtained with the aid of an asymmetric hydrogenation catalyst, consisting of a reduced protein–palladium complex prepared by the adsorption of $PdCl_2$ on fibres of silk fibroin. L-phenylalanine was obtained in this way from the ethyl ester of α-acetoxyiminophenylpropionic acid[104].

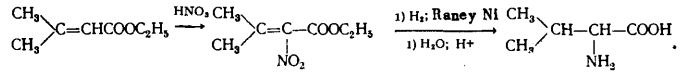


TABLE.

Starting material	No. of stages	Total yield, %	Other amino-acids obtained by the same method	Refs.
$C_6H_5CH_2CH(COOK)COOC_2H_5$	4	—		72
$CH_2(COOC_2H_5)_2$	4	31—36		73,74

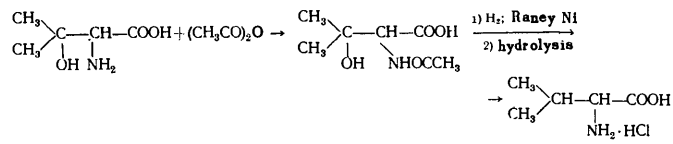
То же	2	68	alanine, leucine, isoleucine, methionine, valine, and tyrosine	88—92



Valine

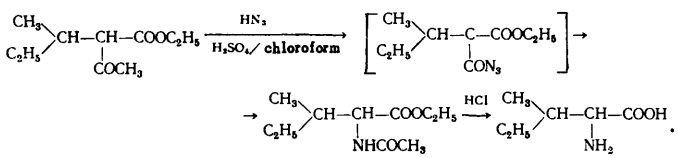
Valine is obtained most simply by the ammonolysis of α-halogenoisovaleric acid. When ammonia is allowed to act on α-bromoisovaleric acid, the yields of valine reach 78%;[105] treatment of the acid with hexamethylenetetramine results in almost quantitative yields of valine[74,106].

Various modifications of the Strecker synthesis have been examined by Gaudry[107]. Valine is obtained from isopropylmalonic ester in about 70% yield by the Schmidt reaction in a single stage[108]. The hydrogenation of the ethyl ester of ββ-dimethyl-α-nitroacrylic acid with subsequent hydrolysis results in the formation of valine in a yield of about 50%:[25,26]

The application of the Akabori method (see below) to the synthesis of valine merits attention. The *N*-acetyl derivative of hydroxyvaline obtained by the condensation of acetone with copper glycinate is reduced in the presence of Raney nickel, valine being obtained in 80% yield[109]:

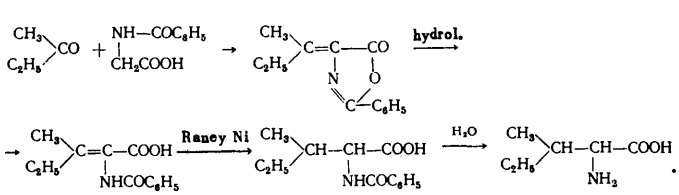
A number of studies described in the preceding sections are also relevant to the synthesis of valine[33,62-65,82-85,88]. The failure in the attempt to obtain valine (and isoleucine) from furan derivatives[36] and also by the alkylation of the amides of acylaminomalonic acids[81] is probably due to steric hindrance.

Leucine



All the classical methods for the synthesis of amino-acids have been used in the preparation of leucine: amination of α-halogeno-derivatives of isocaproic acid with ammonia or hexamethylenetetramine, the Strecker synthesis from isovaleric aldehyde, and the syntheses with the aid of acetoacetic and malonic ester derivatives. Recently a number of new modifications have been proposed for the preparation of leucine [10,14,26,33,36,71,78,81-83,85,88,100,108].

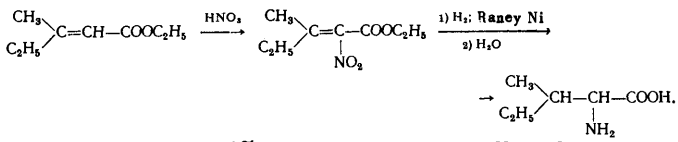
Isoleucine



The difficulties in the synthesis of isoleucine are caused in the first place by the presence in this compound of two asymmetric carbon atoms, and hence of diastereoisomeric forms, and in the second place by the steric hindrance due to the large size of the s-butyl group. So far no methods are available for directed synthesis whereby isoleucine free from alloisoleucine could be obtained. The most favourable isoleucine : alloisoleucine ratio obtainable during synthesis is 3 : 1.

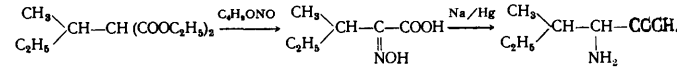
A 49% yield (after recrystallisation) of a mixture of racemic diastereoisomers containing 89% of DL-isoleucine was obtained by the bromination and amination of s-butylmalonic ester [110]. The use of acetamidocyanoacetic ester gives a 40% yield of the product with an isoleucine : alloisoleucine ratio of 3 : 1. [111] The mixture of diastereoisomers, obtained in a yield of about 60% in the reduction of the oxime of the ethyl ester of ethylmethylpyruvic acid [112] and also of its phenylhydrazone [88], contains up to 66% of isoleucine.

When isoleucine is synthesised by the Schmidt reaction, one obtains from s-butylacetoacetic ester a 40–50% yield of a mixture of racemic diastereoisomers, from which 72% of DL-isoleucine can be isolated [113,114]:



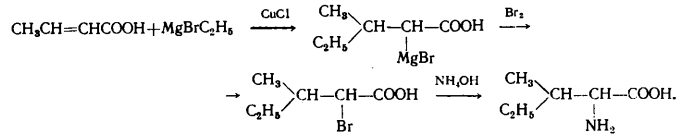
When s-butylmalonic acid is used in the same reaction as the starting material, the yield of the racemic mixture is 66%. [108] Certain modifications of the cyanohydrin synthesis make it possible to obtain a mixture of racemates containing more than 60% of isoleucine [115-117]. Attempts have been made to find stereospecific methods for the synthesis of isoleucine. 4-s-Butylidene-2-phenyloxazol-5-one, formed when ethyl methyl ketone was allowed to act on hippuric acid, was separated into two isomers by hydrolysis with alcoholic alkali. However, the subsequent reduction and hydrolysis of the *N*-benzoyl derivative of s-butylideneglycine involve partial inversion of configuration, and therefore the product contains only 78% of DL-isoleucine [113,118]:

In the preparation of isoleucine from the optically active D-isopentyl alcohol (by its oxidation to the aldehyde followed by synthesis using the cyanohydrin method) one obtains approximately equal amounts of L-isoleucine and D-alloisoleucine, which can be separated by crystallisation [119-121].

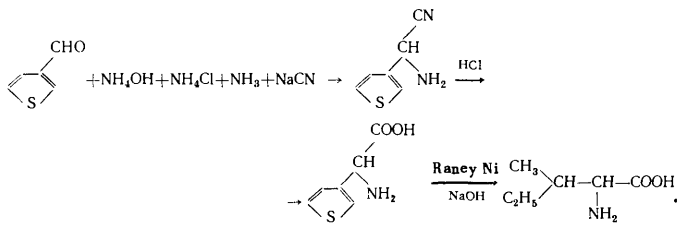


Two methods have been proposed for the conversion of s-butylcyanoacetic ester into isoleucine. The first is the Darapskii method (a modification of the Curtius rearrangement). In this case the ethoxycarbonyl group is converted into the amino-group ($COOC_2H_5 \rightarrow CONHNH_2 \rightarrow CON_3 \rightarrow \rightarrow NHCOOC_2H_5 \rightarrow NH_2$) and the carboxyl is obtained by the hydrolysis of the cyano-group. The second method is Hoffmann degradation ($CN \rightarrow CONH_2 \rightarrow NH_2$), which consists in the conversion of the cyano-group into the amino-group. The initial s-butylcyanoacetic ester has two asymmetric carbon atoms and is a mixture of racemic diastereoisomers, one of which predominates. Thus, the ratio of diastereoisomers in the resulting isoleucine depends on the method by which s-butylcyanoacetic ester is converted into isoleucine. (The investigators concerned suggest that there is no inversion of configuration in the amination and hydrolysis.) Indeed, when a non-purified ester obtained by the hydrogenation of the ethyl ester of α-cyano-β-ethyl-β-methylacrylic acid made from ethyl methyl ketone and cyanoacetic acid is used, the first method yields 60% of isoleucine in the mixture with an overall yield of the racemic diastereoisomers of 55%, while the second method gives 40% of isoleucine with an overall yield of 50%. [122,123] However, if the initial ester is made by the alkylation of cyanoacetic ester with s-butyl bromide, Darapskii's method gives 42% of isoleucine (overall yield 32%) [124] and the Hoffmann method gives about 60%. Consequently the ratio of the diastereoisomers in the initial s-butylcyanoacetic ester is not the same in the different methods of its preparation.

The amide of s-butylcyanoacetic acid is converted into isoleucine by the Hoffmann method in a single stage with a yield of 46%. [125] The yield of isoleucine obtained from the amide of s-butylmalonic acid is 74%. [126] s-Butylideneacetic acid prepared from ethyl methyl ketone and bromoacetic acid by the Reformatskii reaction can be converted into isoleucine in two ways. The first involves the usual operations: hydrogenation, bromination in the α-position, and ammonolysis. Isoleucine is then obtained in 32% yield, the isoleucine : alloisoleucine ratio being 71 : 29. The second procedure involves nitration with 81% nitric acid free from nitrogen oxides, followed by reduction:



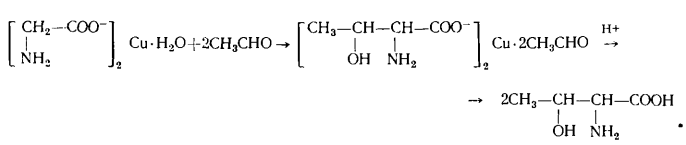
The yield is about 20% and the isoleucine : alloisoleucine ratio is 77 : 23.



Isoleucine is formed in the reduction of α-hydroxyimino-β-methylvaleric acid obtained by the nitrosation of s-butylmalonic ester with butyl nitrite [114]:

A synthesis of isoleucine from crotonic acid using a Grignard reagent has been proposed recently [127]. It involves the following mechanism:

An interesting study has been made of the preparation of isoleucine from thiophen. 3-Thienylglycine obtained from thiophen-3-aldehyde by the Strecker method is subjected to reductive desulphurisation with Raney nickel, an equimolar mixture of DL-isoleucine and DL-alloisoleucine being obtained with an overall yield of 23%:



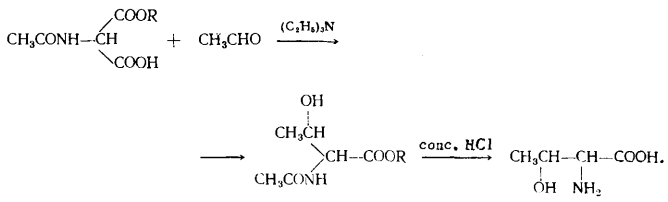
The 3-thienylglycine was separated into the optical isomers. Desulphurisation of the L-isomer gives a 21.5% yield of a product containing more than 50% of L-alloisoleucine. The investigators suggest that the conformation of the molecule adsorbed on the catalyst is stereochemically more favourable for the formation of the *allo*-form [128]. We shall see below, in the examination of the methods of synthesis of threonine, that those involving catalytic hydrogenation result in the preferential formation of the *allo*-isomer.

Threonine

The characteristic features of the chemical synthesis of threonine (α-amino-β-hydroxybutyric acid) are due to the necessity to introduce into the molecule both the amino- and the hydroxy-group. In the threonine molecule there are two centres of asymmetry (as in isoleucine) and therefore there exist two diastereoisomeric forms, of which only the L-*threo*-form is the natural amino-acid.

At the present time one may regard as the best the method of synthesis of threonine proposed by Akabori, which consists in the Knoevenagel condensation of the copper complex of glycine with acetaldehyde in the presence of alkaline reagents [129]:

In this reaction the complexed copper successfully combines the functions of activating the hydrogen atom in the methylene group and of protection of the amino-group. Since the copper complex of allothreonine is much more soluble than the threonine complex, the mixture of copper threoninates obtained in the reaction is convenient for the separation of the diastereoisomers [130-133]. The free amino-acids are isolated by the decomposition of the complex with hydrogen sulphide or on an ion-exchange resin. The amount of DL-threonine in the reaction product exceeds by a factor of two the amount of DL-allothreonine. This is virtually the principal value of the Akabori method, since other methods serve essentially for the preparation of allothreonine and the inversion of allothreonine into *threo*-threonine with thionyl chloride gives rise to additional difficulties and is not adequately effective [134,135].

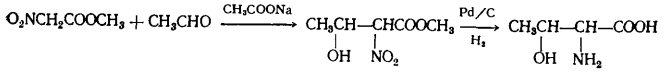


The undoubted advantages of the method described above include the small number of stages (two stages, including the isolation of the free amino-acid), good yields, speed, availability of the starting materials, and the possibility of regenerating the copper. A large number of papers and patents are devoted to the development of this method of preparing threonine. The principal results of these investigations are as follows. (1) The use of methanol as the solvent instead of water improves the yields and favours the formation of a purer crystalline product; (2) when the reaction is carried out under more severe conditions (elevated temperature, higher alkalinity of the medium), and the content of the *threo*-form in the product increases, but the overall yield falls (it has been shown that the copper complex of threonine is more stable under severe conditions than the complex of the *allo*-form); (3) the addition of pyridine increases the overall yield [129,136-143].

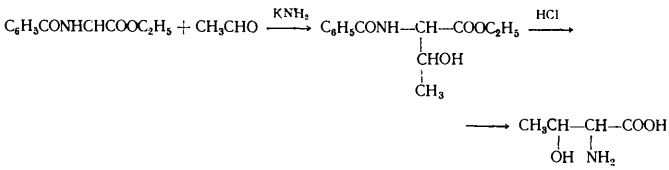
There is a patent describing the preparation of threonine (*threo* : *allo* = 3 : 1) by the reaction of copper glycinate with vinyl acetate in an aqueous medium in the presence of potassium carbonate [144].

Akabori investigated the reaction of acetaldehyde with cobalt triglycinate, which exists in two isomeric forms (α and β). The overall yield of the isomeric threonines, particularly with the β-form of the complex, is poorer than with copper glycinate, but the ratio of the *threo*- and *allo*--forms is more favourable (7.6 instead of 2.9). The poorer yield may be due to the much greater stability of cobalt glycinate compared with copper glycinate, and the change in the ratio of the *threo*- and *allo*-forms with temperature and duration of the reaction confirms that the stability of the cobalt threoninates is different [145]. An attempt has been made to obtain optically active threonine with the aid of the optically active cobalt complex of the type L-$[Co(EH)_2GLY]I_2$, where EH is ethylene- or propylene--diamine. The asymmetric yield of threonine was only about 8%. [146-148]

The possibilities of the Akabori methods are not restricted to the preparation of threonine. The use in this reaction of formaldehyde and other aldehydes and ketones and also of copper alaninate (instead of the glycinate) makes it possible to obtain a wide variety of α-amino-β-hydroxy--acids [109,149-154].



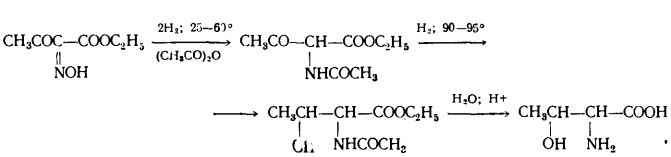
Recently a relatively simple general method has been proposed for the synthesis of α-amino-β-hydroxy-acids by the condensation of aldehydes with acetamidomalonic acid or its half-ester, which is a modification of King's method [155] (preparation of serine by the condensation of formaldehyde with ethyl acetamidomalonate):



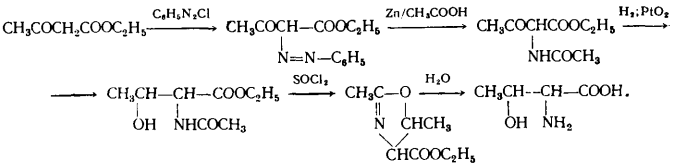
When R = H, serine is obtained in 50.4% yield and when R = CH_3, 53% of threonine consisting of 95% of the *allo*--form and 5% of the *threo*-form is obtained [156,157].

The synthesis of threonine based on nitroacetic ester is fairly simple and convenient. Methyl nitroacetate condenses smoothly with acetaldehyde, methyl α-nitro-β--hydroxybutyrate being obtained Its hydrogenation over

5% palladium on charcoal in a methanol–acetic acid mixture gives an equimolar mixture of the diastereoisomeric threonines with an overall yield of 66%:

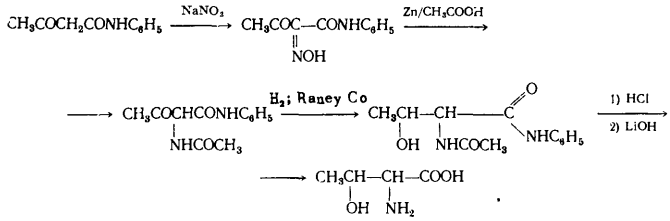


The reduction of α-nitrocrotonic acid in the presence of Raney nickel in methanol results, together with the normal reduction to α-aminobutyric acid, in the addition of methanol to the double bond and subsequent reduction to *O*-methylthreonine [13]. There are a number of patents describing syntheses of threonine. A 52% yield of threonine (the ratio of the *threo*- and *allo*-forms is not indicated) was obtained by the condensation of ethyl hippurate with acetaldehyde in the presence of alkali metal amides [158]:



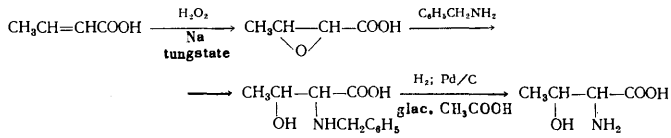
In another synthesis glycine and paraldehyde are condensed in dilute alcoholic solution of hydrochloric acid [159]. The treatment of the Schiff base obtained from aminoacetonitrile and formaldehyde with acetaldehyde followed by hydrolysis probably also yields threonine [160].

The syntheses of threonine from acetoacetic ester derivatives with a nitrogen-containing group in the α-position (=NOH or $=NOC_2H_5$; [161-163] $NHCOCH_3$; [170] $-N=NC_6H_5$ or $-NH-N(C_6H_5)(COCH_3)$ [164-169]) are based on the catalytic hydrogenation of the nitrogen-containing group to the amino-group and of the carbonyl group to the hydroxy-group. The reduction is performed in one or two stages (the nitrogen-containing group is reduced first and then the carbonyl group). The reaction involves 3–4 stages, but the amount of the *threo*-form in the mixture of epimers, which is obtained as a rule in a high yield, does not exceed 30–40% in the most favourable cases, the usual percentage being not more than 15–20. For example, threonine is obtained in an overall yield of about 70% from α-hydroxyiminoacetoacetic ester, the ratio of the *threo*- and *allo*-forms being 21 : 79: [162]



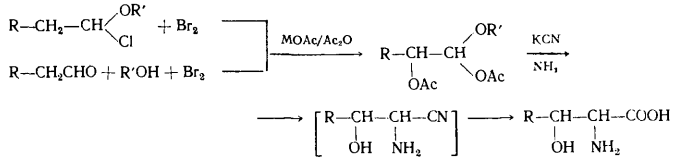
The preparation of threonine via the α-phenylazoacetoacetic ester has been investigated in detail:

After hydrogenation the product contains 80–85% of the *allo*-form of the ethyl ester of *N*-acetylthreonine. Under the action of thionyl chloride the configuration is inverted and a mixture containing 83% of DL-threonine is produced. The overall yield is 57%. [164]



The use of a stereospecific hydrogenation catalyst, Raney cobalt, to increase the content of the *threo*-form in the mixture of diastereoisomers obtained by the reaction

has been described. The reaction products contain 56% of *threo*-threonine [171].



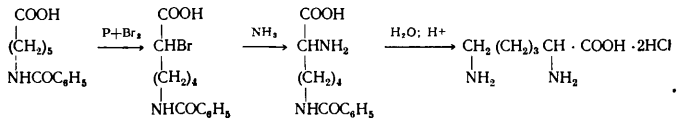
The first practical method of preparing threonine, which is also a general method for the preparation of α-amino-β-hydroxy-acids, was developed by Carter [172,173]. Its principle consists in the addition of hypobromous acid to unsaturated acids. It was established that this reaction takes place in only one way, with formation of α-bromo-β-hydroxybutyric acid (the second isomer, α-hydroxy-β-bromobutyric acid, does not form), which can be converted by amination into threonine, consisting mainly of the *allo*-form. Carter was the first to demonstrate the existence of threonine diastereoisomers, separated the epimeric racemates, isolated natural threonine, and investigated the interconversions of the *threo*- and *allo*-forms via the azlactone [174]. Modifications of this method are used for the synthesis of allothreonine [175-177].

The possibility of the selective synthesis of diastereoisomeric α-amino-β-hydroxy-acids has been demonstrated recently. Pure allothreonine was obtained in an overall yield of 50% by the following reaction [178]:

The epoxy-ring is opened in this process exclusively with the formation of the α-amino-β-hydroxy-acid, without admixtures of the α-hydroxy-β-amino-acid. Furthermore, ring opening takes place in such a way that the initial *trans*-form of the acid gives only *erythro*-isomers and the *cis*-form gives only *threo*-isomers. Unfortunately, the preparation of *threo*-threonine by this procedure has not been described; however, pure *threo*- and *erythro*-isomers of β-hydroxy-DL-aspartic acid have been obtained from maleic and fumaric acids [179].

Until recently Strecker's method for the synthesis of α-amino-β-hydroxy-acids has not been used, except for serine, since under the conditions of this reaction higher hydroxy-aldehydes isomerise to hydroxy-ketones. However, when acylal ethers of α-hydroxy-aldehydes are used, the reaction is successful:

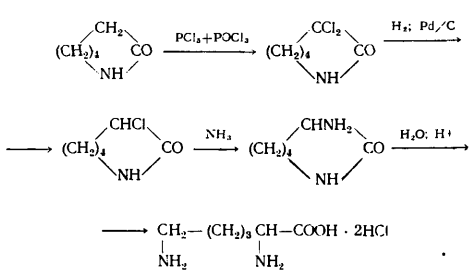
M = Na for R containing up to three carbon atoms and M = Ag for R containing more than three carbon atoms. The yields



are 60–80% for R ranging from CH_3 to C_4H_9 and 45–60% for R ranging from C_5H_{11} to $C_{10}H_{21}$, i.e. are in general higher than is usual in the Strecker synthesis [180,181]. α-Alkoxypropionaldehyde is converted into threonine in 44% yield with the ratio *threo* : *allo* = 3 : 2. [182]

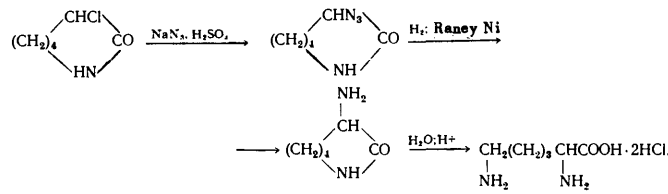
At the present time there are a number of fairly reliable methods for the quantitative and semi-quantitative estimation of the diastereoisomeric threonines in a mixture. These methods include paper chromatography [146], infrared spectroscopy [183], and gas–liquid chromatography [184,185].

Lysine

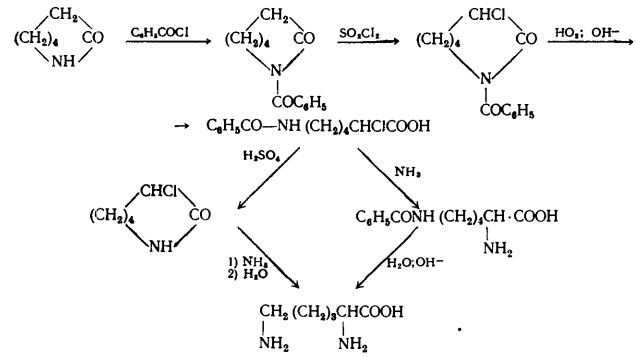


The problem of the chemical synthesis of lysine (αω-diaminocaproic acid) continues to attract the attention of many investigators. Among the methods available at present for the synthesis of lysine there are some which have been developed in detail and others which only provide a guideline for further research. To facilitate the exposition, the data have been grouped as follows: (1) syntheses of lysine from ε-aminocaproic acid derivatives, in particular from caprolactam; (2) syntheses based on telomerisation products; (3) syntheses by the cyanohydrin method; (4) other methods.

ε-Benzoylaminocaproic acid and caprolactam are the traditional starting materials for the synthesis of lysine. The at first sight simple problem, the introduction of only one amino-group into the α-position of an otherwise "finished" molecule, has been solved over a period of almost sixty years. In one of the first syntheses of lysine ε-benzoylaminocaproic acid was obtained in a three-stage synthesis from *N*-benzoylpiperidine and then converted into lysine as follows:

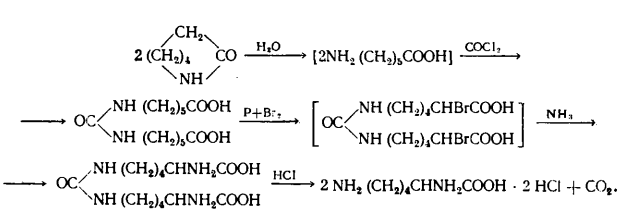


Although this synthesis is still extremely imperfect, it served as the basis for further studies [186]. Initially, caprolactam served as the starting material for the preparation of ε-benzoylaminocaproic acid. In many of the subsequent investigations improved methods of halogenation [187,188] and ammonolysis were employed (in particular bromination was replaced by chlorination with sulphuryl chloride) [189]. Rational utilisation of these advances made it possible to increase the yield of lysine from 23 to 68% with respect to caprolactam [190].

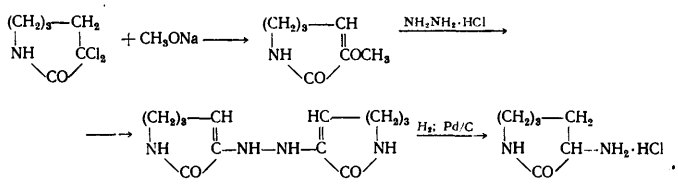


Later the attention of investigators was attracted to the possibility of direct halogenation and amination of caprolactam. It was found that in this case a complication arises in the halogenation, since two halogen atoms are introduced simultaneously into the caprolactam molecule, and in order to obtain α-chloro-ε-caprolactam it is necessary to reduce the dihalogeno-derivative formed initially:

A fundamental study has been made of the conditions of the chlorination and bromination of both caprolactam itself and its acetyl derivative, the conditions of the ammonolysis of α-halogeno-ε-caprolactam with aqueous and liquid ammonia in the presence of various salts, and the conditions of the hydrolysis of α-amino-ε-caprolactam. When optimum conditions are provided, the yield of lysine amounts to about 50% with respect to ε-caprolactam [191–193]. α-Amino-ε-caprolactam and then lysine can be obtained with the same yield by the reduction and subsequent hydrolysis of α-azido-ε-caprolactam [194,195]:

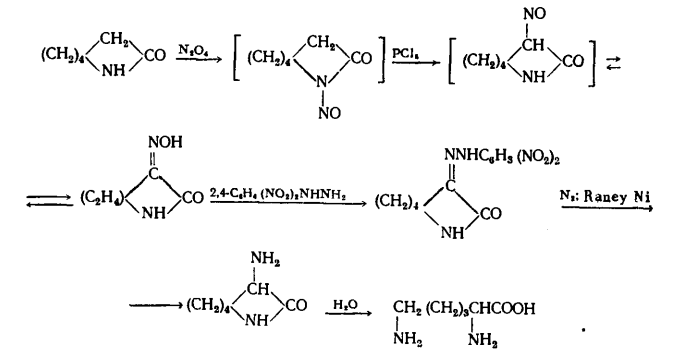


In contrast to ε-caprolactam, *N*-benzoyl-ε-caprolactam can be monochlorinated in the α-position. Then one obtains by alkaline hydrolysis ε-benzamido-α-chlorocaproic acid, whose subsequent conversion into lysine can be achieved in two ways:



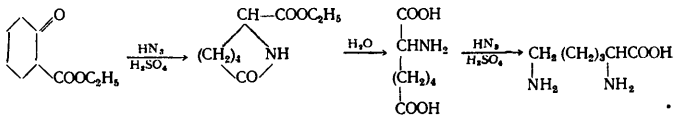
Amination with subsequent hydrolysis gives lysine in an overall yield of 73% and debenzoylation followed by hydrolysis and amination gives a 60% yield of lysine [196].

Apart from these procedures developed in detail, a number of modifications have been outlined, whereby it is possible to avoid certain difficulties in the existing syntheses, but these procedures require further development. For example, a new method has been proposed for the protection of the amino-group in aminocaproic acid with the aid of phosgene:

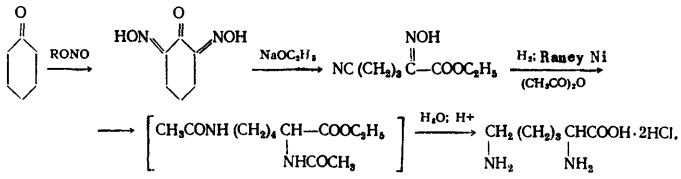


The overall yield of lysine is only 11%. [197,198]

A patent describes a method for the preparation of α-amino-ε-caprolactam from αα-dichloro-ε-caprolactam and hydrazine hydrochloride by the following mechanism[199]:

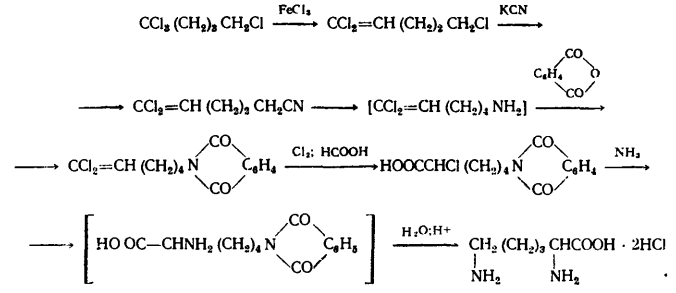


It has been shown that lysine can be synthesised via α-hydroxyiminocaprolactam. Treatment of caprolactam with nitrogen tetroxide gives an *N*-nitroso-compound, which rearranges into α-hydroxyimino-ε-caprolactam under the action of phosphorus pentachloride. The product is converted into the dinitrophenylhydrazone of α-oxo-ε-caprolactam from which α-amino-ε-caprolactam is obtained after hydrogenation:



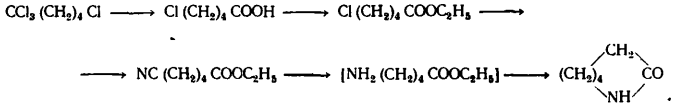
This fundamentally new reaction makes it possible to eliminate the halogenation stage[200,201].

The Schmidt reaction has been used in an interesting way for the preparation of lysine from 2-ethoxycarbonylcyclohexanone:

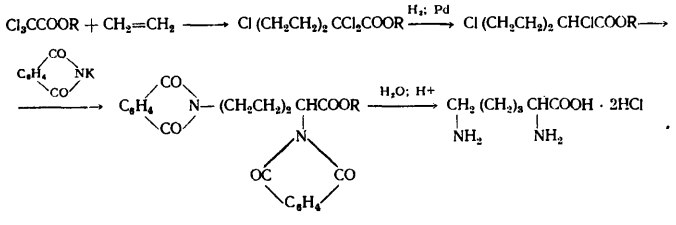


The overall yield is 60%. Only the ω-carboxy-group reacts[202].

It has recently been stated that α-nitro-ε-caprolactam can be used as the starting material for the synthesis of lysine[28]. An original procedure involving the use of cyclohexanone in the synthesis of lysine, which has been developed by Ferris, includes three stages: (1) preparation of 2,6-dihydroxyiminocyclohexanone by the nitrosation of cyclohexanone with alkyl nitrites in ether containing hydrochloric acid; (2) reaction of 2,6-dihydroxyiminocyclohexanone with sodium ethoxide in alcohol in the presence of acetic anhydride (Beckmann rearrangement of the "second kind")[203,204] with formation of the ethyl ester of 5-cyano-2-hydroxyiminovaleric acid; (3) hydrogenation of this ester in the presence of Raney nickel in acetic anhydride containing sodium acetate with subsequent hydrolysis using hydrochloric acid. The overall yield of lysine monohydrochloride is 63%:[205-208]

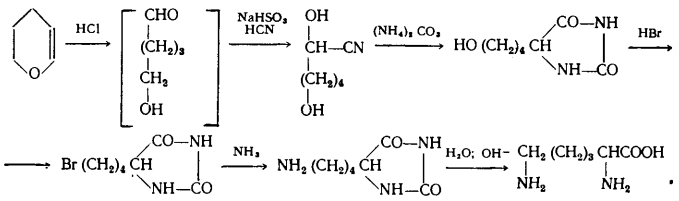


In a similar way ornithine was obtained from cyclopentanone and 4-methyl-lysine from 4-methylcyclohexanone[209,210].

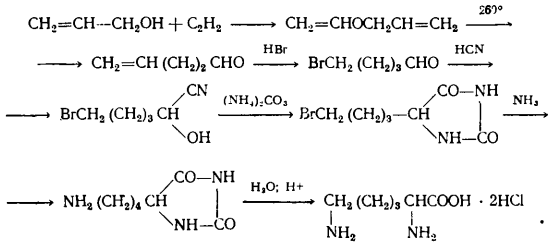


New possibilities arose in the field of synthesis of amino-acids and in particular lysine in connection with the telomerisation reaction. As already stated, ααaω-tetrachloroalkanes, which have now become available, serve as the starting material for the preparation of various amino-acids. The following procedure has been proposed for the synthesis of lysine from ααaω-tetrachloropentane[6,7,211,212]:

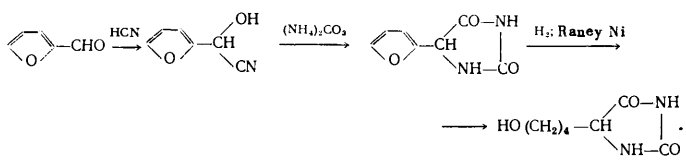
The overall yield of lysine is 44%. It has also been suggested that ε-caprolactam be obtained from tetrachloropentane[213]:



The ε-caprolactam is then converted into lysine, by the already known mechanism, via *N*-benzoylcaproic acid. One of the principal products of the telomerisation reaction of ethylene and trichloroacetic acid is ααω-trichlorocaproic acid — a new starting material for the synthesis of lysine. Hydrogen is substituted for one of the chlorine atoms in the α-position by hydrogenation and then the remaining α- and ω-chlorine atoms are replaced by amino-groups with the aid of potassium phthalimide:



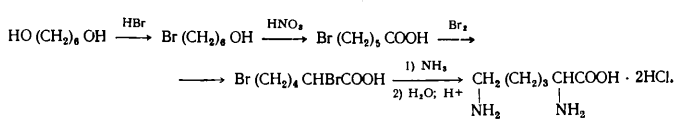
The yield of lysine is 53% with respect to the ester of ααω-trichlorocaproic acid. Simple ammonolysis is recommended for technical synthesis. This method undoubtedly merits attention in view of its exceptional simplicity and the availability of the starting materials[214].



The oldest methods include the synthesis of lysine by the cyanohydrin method. Here one must mention the Gaudry method, which has also been studied by other investigators:

The initial dihydropyran is converted by the action of hot dilute hydrochloric acid into δ-hydroxyvaleric aldehyde, from which 5-(4-hydroxybutyl)hydantoin is obtained by treatment with hydrogen cyanide and ammonium carbonate. The next stages are replacement of the hydroxy-group by a halogen and ammonolysis; acid or alkaline hydrolysis complete the synthesis. The yield of the product is 30–40%.[215,216] Modifications of this method make it possible to obtain up to 51% of lysine[217]. The search for a readily available raw material for the preparation of the aldehyde component is being continued. Thus a patent describes the preparation of lysine (and other amino-acids) via vinyl ethers[218]:

5-(4-Hydroxybutyl)hydantoin can be obtained from the readily available furfural:



The hydantoin is then converted into lysine by the method described above. The total yield is 32%.[219]

Lysine can be obtained from piperidine in the following way. *N*-Chloropiperidine, formed when piperidinium acetate is acted upon by calcium or sodium hypochlorite, is dehydrohalogenated by booling with alcoholic alkali. The reaction product, the α-trimer of 2,3,4,5-tetrahydropyridine, is treated with ammonium carbonate, hydrogen cyanide, and water, lysine being isolated after purification on an ion-exchange resin[220].

Malonic ester synthesis has been widely used for the preparation of lysine. The use of malonic[221,222] and acetamidomalonic[223-225] esters has been described. δ-Bromovaleric acid[222], γ-chlorobutyronitrile[221], 1-bromo-4-chlorobutane[223], and acrolein[224,225] have served as components in these syntheses. The yields of lysine reach in some cases 30–40%[222] and even 55%.[223]

When hexane-1,6-diol is used as the starting material, it is possible to obtain lysine by the following simple operations:

The overall yield is 38%. The greatest difficulties in the synthesis are associated with the selective replacement of a hydroxyl by a halogen and the oxidation of the primary alcohol group to the carboxyl[227].

α-Aminogluconic acid can be converted into 5-hydroxylysine, the reduction of which gives lysine itself[228]. In the synthesis of lysine by the Finkbeiner method the chelate complex of 3-phenylhydantoin and methylmagnesium bromide can be alkylated with *N*-(4-bromobutyl)phthalimide[33,34].

Attempts have recently been made to obtain L-lysine by the Kolbe electrochemical reaction. A mixture of the monomethyl ester of *N*-phthaloyl-L-glutamic acid and *N*-phthaloyl-β-alanine was electrolysed in dimethylformamide. After appropriate treatment L-lysine was obtained in amounts which so far are only of theoretical importance[226].

In conclusion it is appropriate to mention that L-lysine for food and fodder additives can be obtained by combining chemical synthesis with stereospecific microbiological synthesis. For example, diaminopimelic acid prepared from ethoxydihydropyran is converted with the aid of *Bacillus sphaericus* into L-lysine. This method is also suitable for the separation of synthetic DL-lysine into optical isomers[229]. A combination of chemical and biological syntheses has been proposed by Ferris and coworkers. 2-Hydroxyiminoadipic acid is obtained by the hydrolysis of 5-cyano-2-hydroxyiminovaleric acid [synthesised from 2,6-di(hydroxyimino)-cyclohexanone]. This substance is added to a nutrient medium containing baker's yeast, lysine being isolated after fermentation[230].

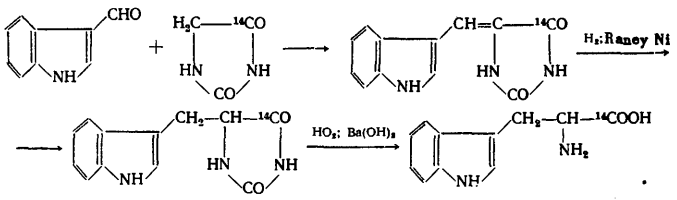
Tryptophan

The chemical synthesis of tryptophan can be conveniently examined using the following classification of methods proposed by Hellmann in his review published in 1949.[231]

I. Syntheses from compounds containing the indole ring.

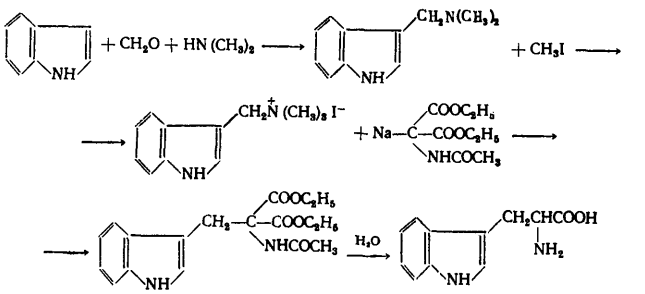
a. Condensation of indole-3-aldehyde with compounds containing an active methylene group.

b. Alkylation of esters of acylamino- and nitro-acids with gramine and diethylaminomethylindole.



c. Alkylation of indole with various reagents.

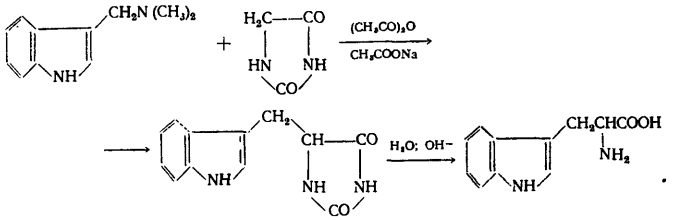
II. Syntheses involving the formation of the indole ring.



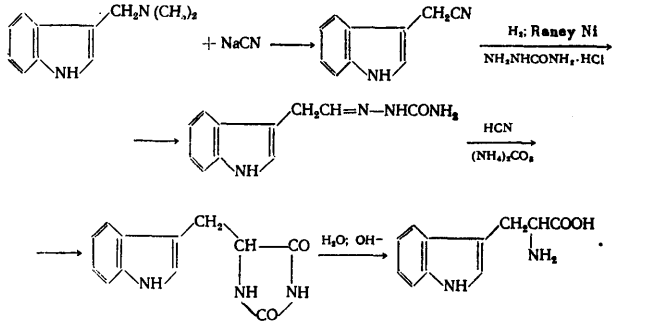
The syntheses of the first group, in particular the alkylation with gramine, have been studied extensively and are sufficiently simple for the preparation of tryptophan under laboratory conditions.

The preparation of tryptophan by the condensation of indole-3-aldehyde with benzoylglycine (the azlactone method) is

not used at the present time. The condensation of indole-3-aldehyde with hydantoin is used for the synthesis of tryptophan labelled at the carboxyl[232]:

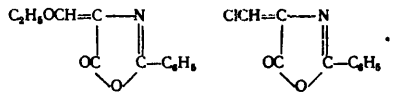


Gramine (dimethylaminomethylindole), obtained by the Mannich reaction from indole, formaldehyde, and dimethylamine, is widely used in tryptophan syntheses. For example, tryptophan can be obtained by the following reaction from acetamidomalonic ester and gramine[233,234]:

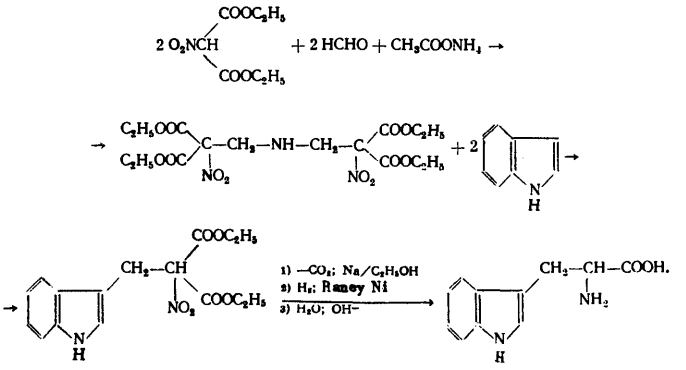


The yields of tryptophan reach 66% with respect to indole[235,236]. When formamidomalonic ester is used instead of acetamidomalonic ester and diethylaminomethylindole instead of gramine, the yield of tryptophan increases to 90%.[237] The following esters have also been alkylated with gramine in the same way (the percentage yields with respect to gramine are indicated in brackets): acetylcyanoacetic (71, with respect to indole)[83], acetamidoacetoacetic[238], acetoacetic (58)[239,240], cyanoacetic (22)[239], nitroacetic (45)[10,11], and nitromalonic (77)[19].

Gramine has been used in the synthesis of tryptophan hydantoin[241]:



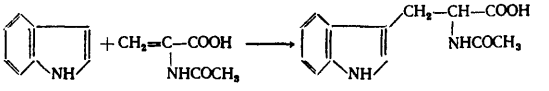
β-Indolylacetonitrile, obtained in quantitative yield by the alkylation of cyanide salts with gramine, serves as a new starting material in the synthesis of tryptophan:



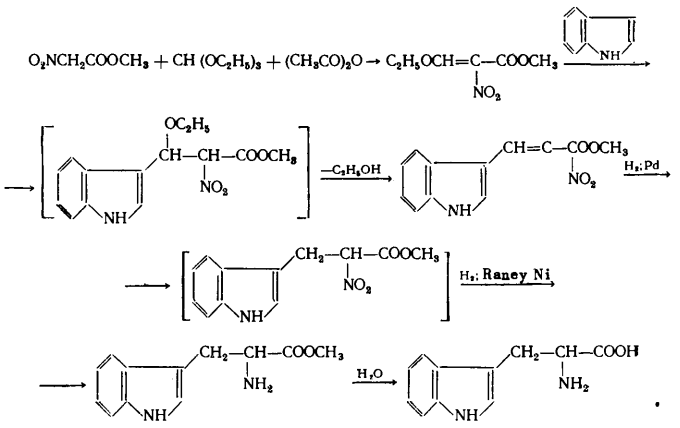
The semicarbazone of β-indolylacetaldehyde is prepared by the reduction of 3-indolylacetonitrile in the presence of semicarbazide. The semicarbazone is obtained as the *syn*-isomer, which on standing is converted into the more stable *anti*-isomer. The *syn*-isomer is more reactive and is converted into hydantoin in 66% yield, while the yield of hydantoin from the *anti*-isomer is 38%. The hydantoin is hydrolysed in the usual way and tryptophan is isolated in an overall yield of 33% with respect to gramine[242].

Gramine has been used as the alkylating agent in the preparation of tryptophan by the Finkbeiner method[33].

The procedures for the preparation of tryptophan in which indole is the starting material are simpler, since the necessity for the synthesis of gramine is eliminated. Alkylation of indole by a Mannich base derived from piperidine, formaldehyde, and formamidomalonic ester followed by hydrolysis and decarboxylation gives tryptophan in 71% yield[243]. A new method for the preparation of azlactones by the alkylation of indole with 4-ethoxymethylene-2-phenyl-5-oxazolone[244] and 4-chloromethylene-2-phenyl-5-oxazolone[245] makes it possible to obtain tryptophan in two stages with yields up to 75%:

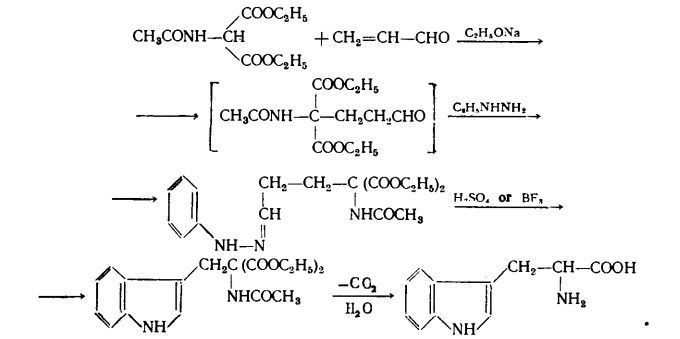


The key reaction in a new synthesis of tryptophan based on nitromalonic ester is the alkylation of indole with 1,1,5,5-tetraethoxycarbonyl-1,5-dinitro-3-azapentane — a Mannich base obtained from nitromalonic ester, formaldehyde, and ammonia:



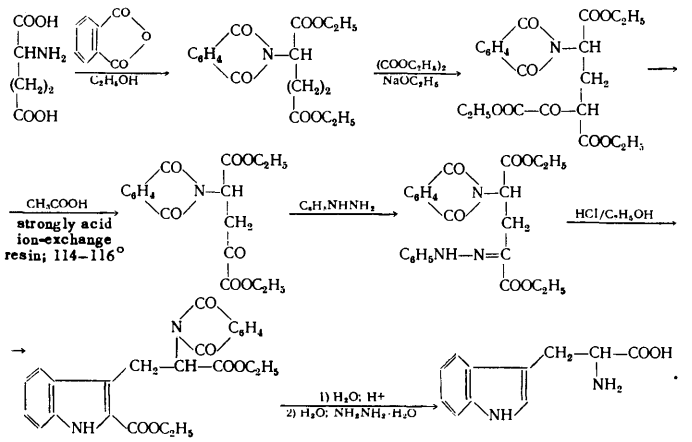
The decarboxylation, reduction of the nitro-group, and hydrolysis are carried out without isolating the intermediates. The overall yield with respect to indole is 50%.[20,21]

A simple method for the synthesis of *N*-acetyltryptophan in 57.7% yield consists in the addition of indole to α-acetamidoacrylic acid:

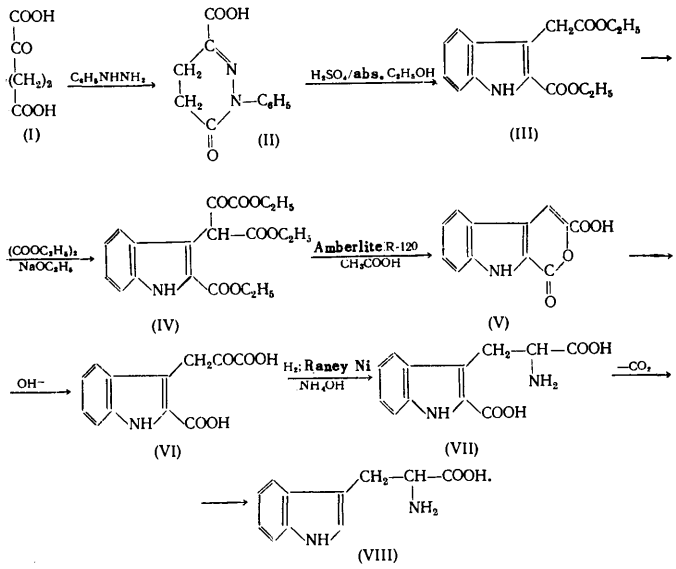


N-Acetyl-2-methyltryptophan and *N*-acetyl-7-methyltryptophan were obtained similarly[246].

Tryptophan has been obtained in 45% yield with respect to indole by an original method based on nitroacetic ester, using ethoxynitroacrylic acid as an intermediate[247]:

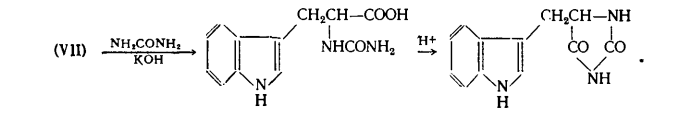


In all the cases examined the indole ring is introduced as such into the molecule, i.e. essentially each synthesis is only a partial synthesis of tryptophan. The Fischer reaction made it possible to perform the complete synthesis of tryptophan from starting materials not containing indole. The condensation of acetamidomalonic ester with acrolein must be regarded as the most successful procedure of this kind. The condensation product is treated with phenylhydrazine and the resulting phenylhydrazone is cyclised:



The overall yield with respect to acetamidomalonic ester is 43%.[248-250] Ion-exchange resins can be used as catalysts of the condensation of acrolein with acetamidomalonic ester and the cyclisation of phenylhydrazone[251].

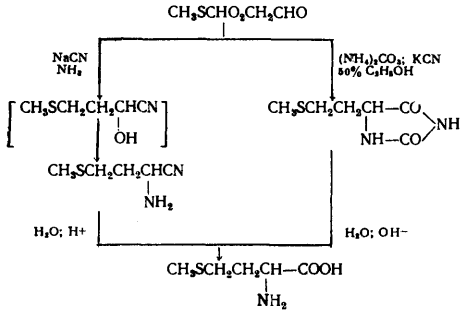
In 1961 an attempt was made to prepare optically active tryptophan from optically active L-glutamic acid by the reaction



However, the attempt was unsuccessful, since racemisation takes place in the condensation with diethyl oxalate in an alkaline medium[252].

Another similar method is the synthesis of tryptophan from oxoglutaric acid, which includes seven stages with an overall yield of 35% (with respect to the initial acid)[253]:

A modification, starting with the conversion of the intermediate pyrone derivative (V), has been described in a patent[254]. Compound (V) is converted into β-(2-carboxy-3-indolyl)pyruvic acid (VI), which is reductively aminated to β-(2-carboxy-3-indolyl)-α-aminopropionic acid (VII). Further conversion of compound (VII) takes place by the mechanism



The hydantoin is hydrolysed and tryptophan is obtained in 50% yield. There is also a patent concerning the decarboxylation of compound (VII).[255] Tryptophan hydantoin can be obtained by the condensation of the phenylhydrazone of β-(hydantoin-5-yl)propionaldehyde. The latter was prepared by the reduction of 5-(β-cyanoethyl)hydantoin in the presence of phenylhydrazine[256,257].

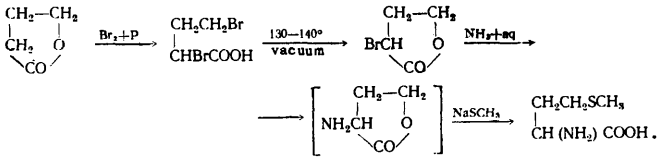
Methionine

Methionine (α-amino-γ-methylthiobutyric acid) is the most important source of sulphur and plays an exceptionally important role in metabolism. The methods for the synthesis of methionine have not changed significantly in recent years. At the present time there are three fairly thoroughly developed procedures for the synthesis of methionine: (1) the cyanohydrin method; (2) syntheses with the aid of esters; (3) syntheses based on butyrolactone. The cyanohydrin method must be regarded as the most convenient and the most suitable for industrial manufacture. The starting material is β-methylthiopropionaldehyde which is obtained in good yield by the catalytic addition of methanethiol to acrolein[258,259]:

$$CH_3SH + CH_2{=}CHCHO \rightarrow CH_3SCH_2CH_2CHO$$

β-Methylthiopropionaldehyde is converted into methionine via an aminonitrile[258-263] or via hydantoin[250,259,264]:

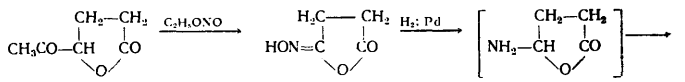
If the reaction is performed at atmospheric pressure, the process via hydantoin gives best results (the total yield with respect to acrolein is 60%).[264] The application of pressure makes it possible to obtain in high yield α-amino-γ-methylthiobutyronitrile, the hydrolysis of which gives methionine. The yield of methionine is 82%,[260] but according to other data it is almost quantitative[262].



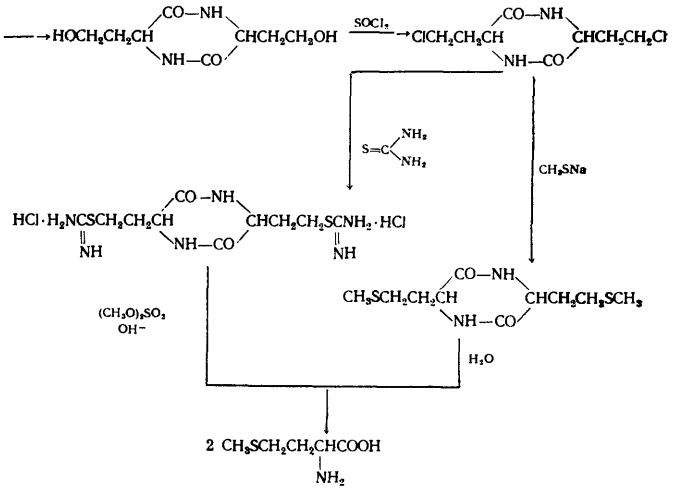
In the synthesis of methionine based on acetic and malonic ester derivatives α-chloro-β-methylthioethane, obtained from ethylene monothioglycol,

$$HSCH_2CH_2OH + (CH_3O)_2SO_2 \xrightarrow{OH^-} CH_3SCH_2CH_2OH \xrightarrow{SOCl_2} CH_3SCH_2CH_2Cl\ ,$$

is used as the alkylating agent. The yield varies from 70 to 90% depending on the purity of the starting material[265]. Acetamidocyanoacetic[68], phenylacetamidocyanoacetic[85], acetamidomalonic[266], formamidomalonic[267], and phthalimidomalonic[265,268] esters were alkylated with α-chloro-β-methylthioethane. The alkylated esters were then converted by simple operations (hydrolysis, decarboxylation) into the amino-acid, the yields varying from 24 to 60%.



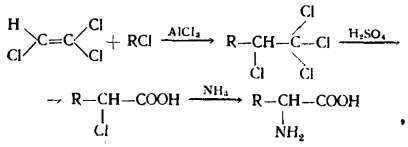
The phenylhydrazone of γ-methylthio-α-oxobutyric acid, obtained by the action of phenyldiazonium chloride on (β-methylthio)ethylcyanoacetic ester, gives a 49% yield of methionine on reduction with zinc in hydrochloric acid[89]. The ethyl ester of (β-methylthio)ethylcyanoacetic acid has been converted into methionine by the Darapskii method ($-COOC_2H_5 \rightarrow CONHNH_2 \rightarrow CON_3 \rightarrow NHCOOC_2H_5 \rightarrow NH_2$).[124]



Butyrolactone can be converted into methionine in several ways. The simplest method includes four stages:

The total yield is 37%.[269]

In the free state α-amino-γ-butyrolactone readily dimerises with the formation of dioxopiperazine, which can serve as an intermediate in the synthesis of methionine:



The total yield of the amino-acid when the methylthio-group is introduced with the aid of sodium methylsulphide amounts to 24% with respect to the butyrolactone[270]; 36% of methionine is obtained via the thiuronium salt[271]. α-Amino-γ-butyrolactone can be converted into α-amino-γ-hydroxybutyric acid and then into methionine by the halogenation of the hydroxy-group and the replacement of the halogen by CH_3S. The amino-group is protected by benzoylation[272] or the hydantoin is obtained[273].

---o0o---

During the preparation of this review for printing, several papers on the synthesis of essential amino-acids were published. Baumgarten and coworkers continued the study of the general method for the preparation of α-amino-acids from imino-esters[274] which they proposed earlier[40]. A general method for the synthesis of α-amino-acids by the carboxylation and alkylation of hydantoin was put forward by Finkbeiner[275]. A new synthesis of DL-isoleucine and DL-valine from trichloroethylene and alkyl chlorides takes place as follows:

where R = $CH_3-CH-CH_3$ or $CH_3-CH-C_2H_5$. DL-Isoleucine and DL-alloisoleucine are obtained in a ratio of 35 : 65.[276]

Perekalin et al. suggest that the dihydrochloride of lysine be obtained from butadiene and nitroacetic ester. Butadiene is nitrohalogenated, the resulting halogenonitrobutene is alkylated with ethyl nitroacetate, and then the ethyl ester of 2,5-dinitrohex-4-enoic acid is reduced with hydrogen in the presence of acid palladium and hydrolysed with hydrochloric acid[277].

A new modification of the Akabori method[278] for the preparation of threonine was put forward. An increase in the amount of alkali used in the reaction made it possible to reduce the reaction time to 30 min and to reduce the temperature. The threonine : allothreonine ratio in the reaction product is 41 : 9, the overall yield of the diastereoisomers being 86%.

CARBON SUBOXIDE IN ORGANIC SYNTHESIS

L.B. Dashkevich and V.G. Beilin

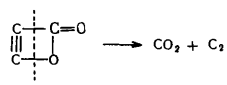
CONTENTS

I. Introduction 391
II. The structure and physicochemical properties of carbon suboxide 391
III. Methods of preparation 392
IV. Chemical properties of carbon suboxide 393

I. INTRODUCTION

Carbon suboxide C_3O_2 (dioxoallene, dioxopropadiene), discovered by Diels in 1906, is a very unusual compound with four cumulative double bonds. The first investigations of Diels and coworkers [1] showed that it should be regarded as an internal dianhydride of malonic acid. Like methylene, carbon suboxide should be included, in principle, among the few "key compounds", and the study of its chemical properties will undoubtedly lead to the discovery of new and specific methods of organic synthesis.

Although carbon suboxide was actually discovered before keten, it has been much less investigated. Nevertheless malonic addition reactions occupy a fairly important position in practical organic chemistry. The malonyl radical is known to be incorporated in many biologically active compounds: barbiturates, pyrazolidinediones, substituted esters and amides of malonic acid, etc.



Nowadays, in the practical application of malonic addition reactions malonic acid, diethyl malonate, and malonyl dichloride are used. Compared with these compounds, carbon suboxide has a number of advantages, which consist in high yields of the desired products, their relative purity, and in the specificity of the reactions which take place only when carbon suboxide is used.

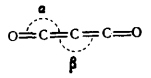
There exists no general review of the literature in which the reactivity of carbon suboxide with respect to various classes of chemical compounds is considered systematically. Grauer's review [2] published in 1960 covers the literature up to 1956 only and is far from complete. Of the earlier work, one may mention the paper of Vol'kenshtein [3], who more than thirty years ago drew attention to the promising possible applications of carbon suboxide. Recently carbon suboxide has been increasingly attracting the attention of investigators both in the Soviet Union and abroad.

The aim of the present article is to describe the present state of the chemistry of carbon suboxide, a knowledge of which may prove of interest to chemists working in the field of organic synthesis.

II. THE STRUCTURE AND PHYSICOCHEMICAL PROPERTIES OF CARBON SUBOXIDE

Until comparatively recently the structure of the C_3O_2 molecule remained controversial, which was to a large extent due to the difficulty of obtaining sufficiently pure carbon suboxide. Diels proposed the linear structure of 1,3-dioxopropadiene for carbon suboxide [1]. Most of the investigators working with carbon suboxide support this view, mainly on the basis of the methods of preparation of carbon suboxide — from malonic acid and its derivatives. Hypotheses have also been put forward that carbon suboxide can exist as the lactone of β-hydroxypropiolic acid [4]. Attempts were made to confirm this structure by the value of the dipole moment allegedly found for carbon suboxide [5], and also by its thermal decomposition to C_2 and CO_2: [6]

These views are in conflict with the molar refraction and molar dispersion of carbon suboxide [7,8].



Numerous electron diffraction [9-12] and spectroscopic studies in the last decades established that carbon suboxide has an acyclic structure [13]. Infrared and Raman spectra [13-22] and also its ultraviolet spectra [23] have been investigated. The interatomic distances and the valence angles in the suboxide molecules were calculated from these data:

C=C	C=O
1.28±0.15Å	1.16±0.015Å

Thus the C=C bond in carbon suboxide is shorter than in alkenes (1.34 Å) and in keten (1.32 Å). [24] The length of the C=O bond is close to the interatomic distance in the carbonyl group of keten (1.17 Å) and in chloro- and fluoro-carbonyl compounds (1.18 and 1.17 Å), [25,26] but differs significantly from the length in aliphatic ketones (1.22–1.24 Å). [26]

Vol'kenshtein [27], who explained this shortening of the interatomic distance by the pronounced displacement of the electron cloud towards the oxygen atoms, suggested that the C_3O_2 molecule be represented thus: O=C=C=C=O.

While the interatomic distance data can be regarded as adequately reliable, the problem of the steric disposition of the atoms in carbon suboxide remained controversial until very recently. The following values have been calculated for the valence angles:

180±10°	180±10°	[11]
180°	158°	[14]
180°	180°	[15]

Data suggesting the presence of a dipole moment in carbon suboxide [5] and also calculations of the force constants of the molecule [28,29] suggested a zigzag structure (symmetry group C_{2h}). However, the study of the infrared spectra of carbon suboxide in various states of aggregation [18] and also the study of their fine structure [18,20,22] indicate a linear structure for the C_3O_2 molecule (point symmetry group $D_{\infty h}$). Earlier data [5], indicating a dipole moment of 0.7 D in carbon suboxide, were probably obtained in consequence of the presence of an admixture of keten [12,30].

Some of the physicochemical characteristics of carbon suboxide are as follows. At the normal temperature carbon suboxide is a gas with a sharp specific smell.

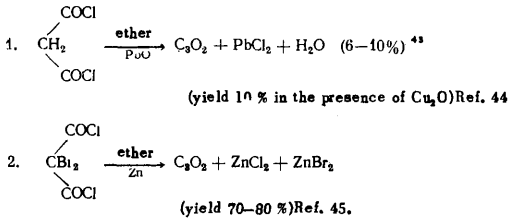
B.p. + 6.8°C (Refs. 31,32); m.p. −107°C (Ref. 33)
−108°C (Ref. 34)
−111.3°C (Ref. 35)
−112.5°C (Ref. 36)
Vapour pressure at 0° 567–568 mmHg (Ref. 31)

$n_D^0 = 1.45538$ (Ref. 7).

There are no reliable data in the literature on the heat of formation of carbon suboxide. The following values may be quoted

$\Delta H_f(C_3O_2)$ = 47.7 kcal mole^{-1} (Ref. 37)
55.0 kcal mole^{-1} (Refs. 38,39)
18.0 kcal mole^{-1} (Ref. 4)
8 ± 5 kcal mole^{-1} (Ref. 40)
Dissociation energy D_0 = 635.234 kcal mole^{-1} (Ref. 40)
Molar heat of combustion of C_3O_2 = 234.6 kcal mole^{-1} (Ref. 37), 300 kcal mole^{-1} (Ref. 6).

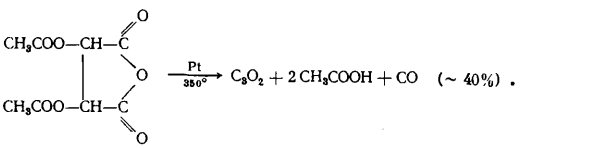
Tables of the thermodynamic functions of carbon suboxide at temperatures up to 2000°K [22] and 6000°K [40] have been set up.



Carbon suboxide is soluble in the majority of organic solvents. Ethyl ether, tetrahydrofuran, and dioxan are especially often used in practice. It is a very toxic compound. Even at low concentrations it acts as a powerful lachrymator and at high concentrations causes asphyxiation. It has been established that carbon suboxide is a powerful blood poison (its effect on haemoglobin is analogous to that of carbon monoxide). The maximum permissible concentration of carbon suboxide in a dry atmosphere is 0.2–0.4%. [41]

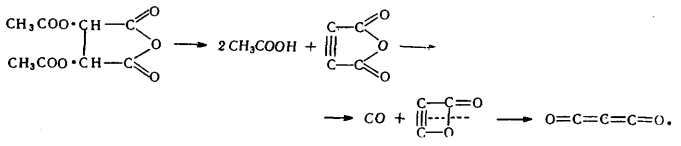
III. METHODS OF PREPARATION

A fairly large number of reactions are known in which the formation of carbon suboxides is observed. However, only some of them are of practical importance. All the known methods can be arbitrarily divided into two groups. (a) preparations based on malonic acid and its derivatives (the structure of the carbon skeleton is retained in the process); (b) pyrolysis of β-dicarbonyl compounds which involves degradation of the carbon skeleton.



a. Diels was the first to obtain carbon suboxide on heating diethyl malonate with phosphorus pentoxide [1]. Subsequently the ester was replaced by malonic acid itself. In the latter case the yield of carbon suboxide amounted to 18–20% after a number of improvements [7,33,42]. The maximum yield of carbon suboxide from diethyl malonate was obtained by Korshak and coworkers (30–37%). [34]

Staudinger proposed two methods for the synthesis of carbon suboxide:

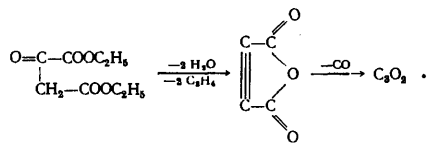


So far an 80% yield of carbon suboxide has been obtained only by the second method. However, an important disadvantage of this method is that carbon suboxide is not obtained in a free form but in ethereal solution. This restricts the scope of the method. Furthermore, the synthesis of the starting materials is relatively complex and very time-consuming. Another disadvantage of this entire group of methods for the synthesis of carbon suboxide is that malonic acid and its derivatives are used as the starting materials, and they themselves are capable of "malonylation". For this reason, the second group of reactions is of considerable interest.

b. The most practical method for the preparation of carbon suboxide proved to be the pyrolysis of the anhydride of diacetyltartaric acid, proposed by Ott and Schmidt [46]:

Subsequently Hurd and Pilgrim showed that the high-temperature non-catalytic pyrolysis of the anhydride leads to approximately the same results (quartz tube, 750°). [47]

The following mechanism has been proposed for the synthesis of carbon suboxide from the anhydride of diacetyltartaric acid:

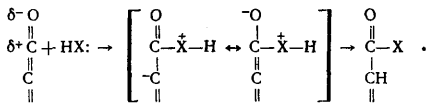


This mechanism of the pyrolysis is confirmed by the formation of carbon suboxide in the pyrolysis of acetylenedicarboxylic acid under analogous conditions [48] and also by the absence of radioactivity from the carbon suboxide obtained from the anhydride of acetyltartaric acid labelled with ^{14}C in the acetyl groups [48,49].

The technique of the pyrolysis has undergone various modifications. For example, it has been suggested that sand be used instead of mercury to force the acetyltartaric acid anhydride melt from the burette into the pyrolysis tube [50]. Later it was shown that it is more convenient to use the anhydride of diacetyltartaric acid in acetic anhydride [48].

Various data have been quoted for the temperature conditions of the pyrolysis and the yields: 625–650°C (40–49%);[47] 570–600°C (41%);[51] 700–725°C (40%);[48] 700–750°C (43–46%).[52]

A large number of dicarbonyl compounds have been pyrolysed in connection with research into new reactions involving the formation of carbon suboxide. Carbon suboxide forms in the pyrolysis of lactic acids, succinic acid derivatives, acetylenedicarboxylic acid and its esters, certain β-keto-esters, etc.[48,53,54] Among the reactions investigated, only the pyrolysis of diethyl oxaloacetate (yield 48%)[48] is of practical importance.



In the pyrolysis of diethyl [4-^{14}C]oxaloacetate it proved possible for the first time to obtain carbon suboxide labelled with ^{14}C. The molecular radioactivity (MR) of carbon suboxide was found to be smaller by a factor of two than that of the initial diethyl oxaloacetate. This shows that the 1-^{12}C and 4-^{14}C atoms of the carbon skeleton of oxaloacetic acid participate in the decarboxylation to an equal extent. This finding suggests that the process proceeds similarly to the pyrolysis of the anhydride of diacetyltartaric acid[48]:

The formation of carbon suboxide has also been observed on passing a weak electric discharge through carbon monoxide[56] or a mixture of carbon monoxide and carbon dioxide[57] in an ozoniser ($4CO \rightarrow C_3O_2 + CO_2$) and on irradiating a mixture of carbon monoxide and carbon dioxide with ultraviolet light[57].

IV. CHEMICAL PROPERTIES OF CARBON SUBOXIDE

The first investigators of carbon suboxide already noted its unsaturated character and tendency towards addition reactions. At the present time the most thoroughly investigated reactions of carbon suboxide are those with various nucleophilic reagents: amines, alcohols, mercaptans, etc. It must be supposed that in this case the addition begins with the penetration of the unshared electron pair of the nucleophilic reagent into the electron gap of the extreme carbon atom of carbon suboxide:

The proton can add either to the oxygen or the carbon atom. In the first case the unstable enol isomerises to the carbonyl form. The fact that addition to oxygen is possible is confirmed, for example, by the participation of carbon suboxide in organometallic synthesis[60].

While the mechanism of addition to ketones has been frequently discussed in the literature[58,59], the same process involving carbon suboxide has been almost entirely neglected[60]. There is hardly any point in considering the problem of whether addition takes place at the carbonyl or ethylene bond, since the extreme carbon atom of carbon suboxide is simultaneously a carbonyl and an ethylenic atom. In any case, it is the atom subject to primary nucleophilic attack.

1. Reactions with Hydroxy- and Mercapto-Compounds

Carbon suboxide reacts with water and alcohols, forming malonic acid and its esters respectively:

$$2\,ROH + O{=}C{=}C{=}C{=}O \rightarrow ROCOCH_2COOR\ .$$

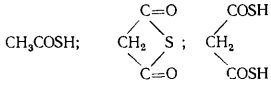
At room temperature the reaction of carbon suboxide with water is fairly slow but is accelerated at 60–70°C in the presence of catalytic amounts of hydrochloric acid. The yield of malonic acid is quantitative[61]. This reaction has been used to prepare 4-D-malonic acid. On carrying out the reaction of carbon suboxide with deuterium oxide in solution in benzene[62] or carbon tetrachloride[63], deuteriated malonic acid was obtained. On the other hand, when the reaction was carried out in deuterium oxide at 50°C, the final product was only deuteriated acetic acid[64].

Methyl and ethyl alcohols react with carbon suboxide even at room temperature. Starting with propyl alcohol, heat and catalysts are required[61]. Phenol reacts only in the presence of catalysts[61,65]. Nitro-alcohols can be "malonylated" with the aid of carbon suboxide only when aluminium chloride is used as the catalyst[50]. Reactions of carbon suboxide with hydroxylamine and oximes, involving the mechanism common to hydroxy-compounds, have been described[47,66].

In the reaction with hydroxy-compounds acid catalysts were mainly used: sulphuric acid, *p*-toluenesulphonic acid[65], and hydrogen chloride[61]; their role probably consists in the additional polarisation of the carbonyl group of carbon suboxide and hence in an increase of the electrophilicity of the carbonyl carbon:

The effect of basic catalysis on addition reactions of carbon suboxide has not been considered, although some experiments on those lines have been performed. Hegar[51] carried out the reaction of carbon suboxide with aqueous solutions of phenol and butanol in the pH range 1–14 at 0°C. Under these conditions he obtained exclusively the phenyl ester of malonic acid, the maximum yield occurring at pH 11. It has recently been established that in the reaction of carbon suboxide with alcohols the corresponding alkoxides are good catalysts. The yield of malonate esters is then nearly quantitative[67]. We believe that both these findings confirm the applicability of basic catalysis to reactions of carbon suboxide with weak nucleophilic reagents, in which there is a possibility of the formation of an anion with much more pronounced nucleophilic properties.

With diols carbon suboxide forms polyesters, the molecular weight of which is several thousands[34,52]. Carbon suboxide reacts fairly readily with formic and acetic acids, mixed anhydrides of malonic acid being formed[42]. The reaction of carbon suboxide with anhydrous oxalic acid is accompanied by the evolution of carbon monoxide and dioxide and leads to the formation of the lactone of β-hydroxyisopropylmalonic acid, a solid product, whose structure has not been established, being produced with malonic acid[18,66].



Mercaptans react with carbon suboxide under somewhat more severe conditions than do alcohols. The corresponding esters of dithiomalonic acid are formed[52]:

However, when diethylaminoethanol and diethylaminoethanethiol are "malonylated" with the aid of carbon suboxide the

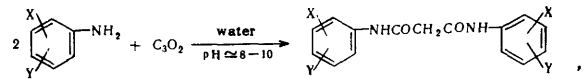
reaction takes place much more readily with the mercaptan[69]. These data are satisfactorily consistent with analogous work in the chemistry of keten[58] and also with work on the introduction of the malonyl acid group into proteins with the aid of carbon suboxide[70], which can probably be accounted for by the marked nucleophilic properties of the SH group[71].

Depending on the relative amounts of the reagents, the reaction of carbon disulphide with carbon suboxide gives rise to a number of compounds[68,72]:

2. Reactions with Primary Amines

In consequence of their pronounced nucleophilic properties, amines react extremely readily with carbon suboxide:

This group of reactions of carbon suboxide has been investigated more thoroughly than others, which makes it possible to follow at least qualitatively the effect of the properties of the amine on its reactivity with respect to carbon suboxide. Since carbon suboxide is a Lewis acid and amines are bases, the reaction can be regarded as an acid–base process. Then the basicity of the amine can be regarded as a criterion of its reactivity. This makes it possible to estimate to some extent the effect of substituents in the amine on the course of the reaction[73].

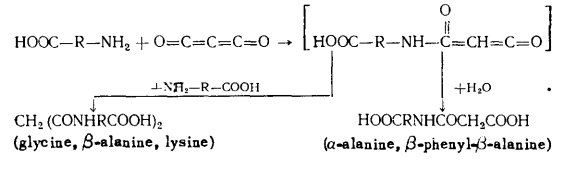


Unsubstituted primary amines. These react with carbon suboxide under mild conditions and with almost quantitative yields. The reaction is a rule performed in an indifferent solvent at the normal temperature or below 0°C. The reactions of carbon suboxide with acyclic, alicyclic, and aromatic amines have been investigated[74,75]. As was to be expected, the phenyl group lowers somewhat the rate of reaction, which, however, does not prevent the use of the reaction between carbon suboxide and aniline for the quantitative determination of the latter[48].

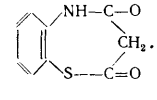
Substituted primary amines. Pauw[74] showed that the reaction of carbon suboxide with *o*-, *m*-, and *p*-alkylanilines, -halogenoanilines, and -alkoxyanilines results in high yields of the corresponding malonic acid diamides[76]. On introduction into the benzene ring of electrophilic substituents, the reduction of the basicity of the amine becomes so appreciable that, for example, *o*-, *m*-, and *p*-aminoacetophenones and aminobenzoic acid esters virtually do not react with carbon suboxide in the absence of catalysts[75]. The reaction of carbon suboxide with *o*- and *p*-sulphoanilines and *o*- and *p*-nitroanilines could not be achieved even on prolonged heating and in the presence of various catalysts[74,77]. In the series of C-substituted aliphatic amines, reactions of carbon suboxide with β-substituted ethylamines[78], βγ-halogenopropylamines[79], and amino-acids and their esters[74,78,80,81,82] have been carried out:

where X = Cl, Br, OH, OR, SH, SR, ArC=O, COOR, COOH, C≡N, and CH_2=(allylamine).

The acylation of amines with carbon suboxide is as a rule performed in an organic solvent. However, as a result of the difference between the rates of the reactions of amines and water, it is in many cases possible to use water successfully as the reaction medium[77]:



where

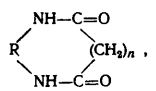


X	*o*-, *m*-, *p*-COOH	*o*-, *m*-, *p*-OH	*m*-, *p*-COOH
Y	H	H	*p*-, *m*-OH

The "malonylation" of halogenoalkylamines (β-chloroethylamine, etc.), which are unstable in the form of the free bases, takes place with high yields when the base is produced from the aqueous solution of its salt by adding alkali during the reaction[78].

Aliphatic amino-acids also readily react with carbon suboxide in aqueous media at pH 8–10.[78,80,81,82]. However, when α-alanine and β-phenylalanine were "malonylated", it proved possible to isolate from the reaction medium only the monoamides of malonic acid[73,78]. It should be noted that the formation of monoamides has been observed in the acylation of amino-acids in which the amino-group is linked to a secondary carbon atom. This course of the reaction may be associated with the fact that the presence of the substituent (methyl or phenyl) gives rise to steric hindrance to the reaction of the intermediate aldoketone with a second amino-acid molecule. As a result, the rates of the reactions with a second amino-acid molecule and water become comparable:

When the C-substituent of the amine is itself reactive with respect to carbon suboxide (OH, SH), it may be expected that the reaction will take place in several ways. However, whereas, as stated above, β-hydroxyethylamine and β-mercaptoethylamine, which are fairly strong bases, react with carbon suboxide via the amino-group, in reactions involving the "malonylation" of *o*-aminothiophenol, in which the basicity of the amino-group is greatly reduced, a cyclic addition product (2,3-benzo-1-thia-4-azacycloheptane-5,7-dione) is obtained[73,83]:



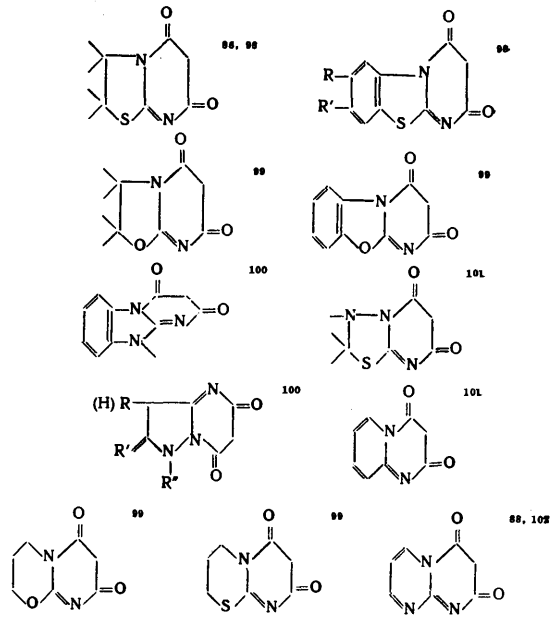
Secondary amines. As a result of their high basicity, it would seem that these should react with carbon suboxide fairly readily in accordance with the general mechanism. However, Pauw[74] failed to identify the products of the reaction of carbon suboxide with dimethyl- and diethyl-amines. Subsequently this reaction ceased to attract the attention of investigators. The reaction of carbon suboxide with secondary cyclic amines (cyclic imines) has been more widely investigated. Ethyleneimine reacts with carbon suboxide, giving *NN'*-malonylbisethyleneimine in good yield only in "absolute" ethyl ether between -60° and -70°C.[64] At higher temperatures there is a possibility of the formation of polymeric products[51]. It is noteworthy that attempts to "malonylate" ethyleneimine by the usual method (malonyl dichloride in the presence of triethylamine

in benzene) proved unsuccessful[85]. Higher polymethyleneimines, up to heptamethyleneimine inclusive, also react fairly readily with carbon suboxide; the yields of products range from 60% up to quantitative[84,86]. When the reaction is performed in the presence of water, there is a possibility of the formation of *N*-acetyl derivatives. Thus in the "malonylation" of ethyleneimine the formation of a product undergoing rapid decomposition, possibly *N*-acetylethyleneimine, was observed[51,73], the yield of *N*-acetylpiperidine being 82%.[86]

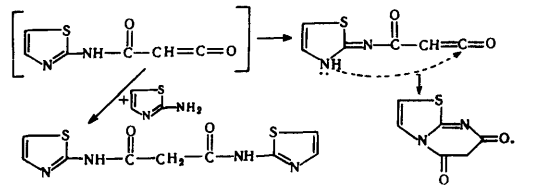
Substituted oxazolidines and thioazolidines react with carbon suboxide similarly[83,87]. The yields range from 50 to 80%, thiazolidine and 2,2-dimethylthiazolidine undergoing "malonylation" even in an aqueous medium. All these compounds are fairly strong bases ($pK_b < 10$). With still less basic amines ($pK_b > 10$), for example benzo-condensed heterocycles, the reaction is carried out in the presence of catalysts — sulphuric acid[51] and aluminium chloride[73,84]. Under these conditions 1,2,3,4-tetrahydroquinoline reacts with carbon suboxide fairly rapidly, the yield of products being 72%,[84] while without catalysts the yield of *NN'*-malonylbistetrahydroquinoline is only about 30% and the reaction takes several days[88]. Diethyl malonate also reacts in the presence of aluminium chloride but under more severe conditions. The product is 1,8-malonyl-1,2,3,4-tetrahydroquinoline[89].

Tertiary amines. Diels and Hansen[72] showed that quinoline, codeine, nicotine, and certain other heterocyclic compounds with a tertiary nitrogen atom react with carbon suboxide, forming coloured products of unknown structure. The powerful catalytic action of tertiary amines (particularly pyridine and triethylamine)[51] on the polymerisation of carbon suboxide has been frequently noted. Quaternary ammonium bases have a similar effect[51].

Diamines. In contrast to diols, these react with carbon suboxide, forming either linear polyamides or cyclic diamides, depending on the reaction conditions. When the reaction was carried out in ethereal solutions with gradual addition of carbon suboxide to the reaction mixture, cyclic addition products were obtained even with hexa- and deca-methylenediamines[74,90,91]:



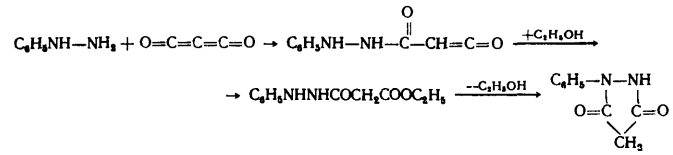
where R = $(CH_2)_n$ with n = 2–6 and 10. Under more severe conditions (heat, pressure), the products are polyamides[34,51]:



$$[-NH-RCOCH_2CO-]_n,$$

where R = $(CH_2)_6$ and $(CH_2)_{10}$.

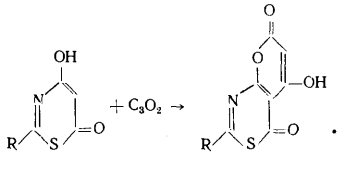
Amino–imino tautomers. Recently the capacity of carbon suboxide to react with compounds capable of amino–imino tautomerism with formation of various heterocyclic systems condensed with 2,4-dioxopyrimidine has been attracting much attention. Syntheses of heterocyclic systems of this kind using malonic ester and malonyl dichloride have been described, but the reactions often require severe conditions[92–95]. In certain cases, when diethyl malonate is used as the "malonylating" agent, only linear acylation products were obtained[93], while carbon suboxide gives cyclic products, for example with 2-aminothiazole[88,96,97]. The study of the reaction of carbon suboxide with a number of amino–imino tautomers led to the synthesis of the following heterocyclic systems[88,98–102]:



In the reaction involving the introduction of the malonyl group with carbon suboxide into certain amino–imino tautomers it was noted that the formation of cyclic products is accompanied by the formation of linear malonic acid diamides. Thus in the reaction of carbon suboxide with 2-aminothiazole the yields of the cyclic and acyclic products were 42.5 and 57.5% respectively[103]. Only the linear diamides were obtained in the reaction of carbon suboxide with 3-aminopyrazoles[100]. This course of the reaction can be satisfactorily explained by the different degrees of aromaticity of the initial heterocycles and hence their different capacities for isomerisation and cyclisation in the stage involving the formation of the intermediate aldoketen:

3. Reactions with Hydrazine and its Derivatives

The first studies on the reaction of carbon suboxide with hydrazines were performed by Van Alphen[90]. The aim was to prepare pyrazolidine-3,5-dione. However, with hydrazine itself, a polymeric product, probably of a linear structure, was obtained. Initially it was possible to obtain a cyclic addition product only with *N*-phenylhydrazine. The reaction proceeds through a stage involving the formation of *N*-malonylphenylhydrazine, the cyclisation of which yields 1-phenyl-3,5-dioxopyrazolidine. This mechanism of the reaction has been confirmed by other workers[91]:

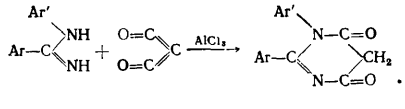


Later Van Alphen also obtained a series of 1,2-disubstituted 3,5-dioxopyrazolidines via carbon suboxide [104]. Reactions leading to the formation of 3,5-dioxopyrazolidines are also known for other "malonylating" agents (malonyl dichloride, diethyl malonate) [105,106], but yields are fairly low.

Reactions of carbon suboxide with substituted hydrazines [107,108] and hydrazobenzene [108] have been described comparatively recently. It has been stated that the reactions can take place without catalyst at temperatures close to 0°C. In the reaction of carbon suboxide with unsubstituted pyrazolidine cyclic addition of carbon suboxide with formation of 1,2-(3,5-dioxopyrazolidino)pyrazolidine also takes place [109].

4. Reactions with Amides and Diamides

It was believed that, in view of their greatly reduced basicity, amides are unreactive with respect to carbon suboxide. However, Ziegler [88] showed that the reactions of benzamide and 3,4-dimethylbenzamide with carbon suboxide on heating for several hours at 60–80° in tetrahydrofuran give bismalonyl derivatives in 65% yield. The reaction with the amides of thioacids takes place in a different way. In contrast to the usual amides, they react in the thiol form with formation of 2-substituted 4-hydroxy-1,3--thiazin-6-one. [88,110]

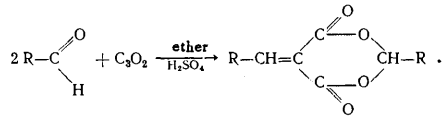


According to Ziegler, on heating with an excess of carbon monoxide, there is a possibility of further addition of carbon suboxide with formation of hydroxypyrone structures, which in turn can again combine with carbon suboxide:

Diamides (urea and thiourea) are acylated with carbon suboxide to barbituric and thiobarbituric acids. Van Alphen observed this only with the aid of qualitative reactions for barbituric acid [90], but after improvement of the method the yields reached 75–85% [91,110] and 56%. [91] *N*-Acetylthiourea reacts in the thiol form with formation of 2-acetyl-4-hydroxy--1,3-thiazin-6-one (yield 90%). [110]

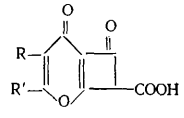
5. Reactions with Amidines

The interaction of carbon suboxide with amidines in which the basicity of the NH groups is approximately the same (for example, with an *N*-arylbenzamidine) leads to the formation of high yields of 1,2-aryl-4,6-dioxotetrahydropyrimidines [111–114]:



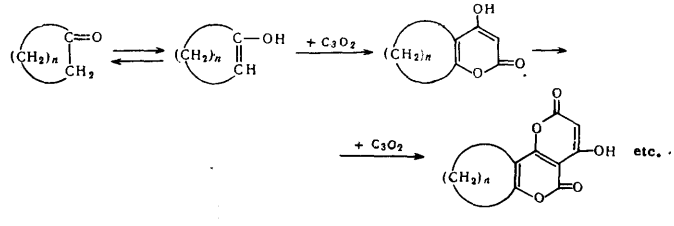
Unsubstituted amidines can react with carbon suboxide according to different mechanisms. Benzamidine reacts with carbon suboxide only via one amino-group, forming *NN'*-malonylbisbenzamidine, while *p*-toluamidine reacts via the amino- and imino-groups, yielding 2-(*p*-tolyl)--1,6-dioxotetrahydropyrimidine [112]. The use of malonyl dichloride [115] and dialkyl malonates [116,117] in these syntheses instead of carbon suboxide results in lower yields.

6. Reactions with Schiff Bases

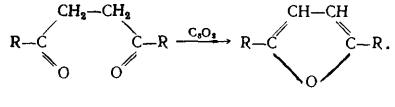


The study of these reactions was undertaken with the aim of preparing azetidine-2-ones containing an active keten grouping, which would make possible their use in the synthesis of biologically active substances with β-lactam rings. However, the reaction of carbon suboxide with benzylideneaniline takes place only under severe conditions (heating to 200°) which leads to the autocondensation of the intermediate aldoketen; only a complex compound with cyclobutane rings forms [118].

7. Reactions with Carbonyl Compounds



While keten readily reacts with aldehydes to form β-lactones [120], carbon suboxide behaves in a different way in reactions with aldehydes [51,119]. The reactions have been performed with benzaldehyde, *p*-toluic aldehyde, *p*-chlorobenzaldehyde, and cinnamaldehyde. In all cases high yields were obtained of the arylidene esters of substituted malonic acids, whose structure was demonstrated by synthesis and by infrared spectroscopy:



On reaction with carbon suboxide, β-diketones and β-keto-esters form compounds with the general formula [121]:

The probable mechanism of this reaction is the interaction of carbon suboxide with the enol form of the dicarbonyl compound and the subsequent addition of a second carbon suboxide molecule to the hydroxypyrone. A similar addition of carbon suboxide to cyclic ketones, which tend to enolise if only to a slight extent, has been described by Ziegler [88]. However, he also attributes the cyclopyrone structure to products of further addition of carbon suboxide:

Like keten [118], in reactions with γ-diketones carbon suboxide behaves as a dehydrating agent, which leads to the closure of the furan ring [51]:

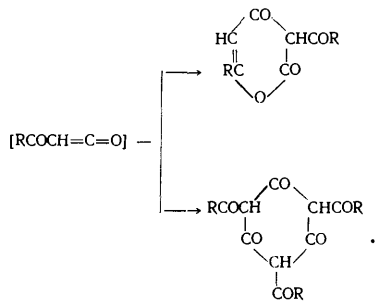
8. Carbon Suboxide in the Friedel–Crafts Reaction

In the presence of equimolar amounts of anhydrous aluminium chloride carbon suboxide enters into the Friedel–Crafts reaction with benzene, naphthalene, and their homologues [122,123], with formation of aryl methyl ketones:

$$ArH + C_3O_2 \rightarrow [R{-}COCH{=}C{=}O] \xrightarrow[-CO_2]{+H_2O} Ar{-}\overset{\overset{O}{\|}}{C}{-}CH_3 .$$

Although it proved impossible to isolate the intermediate aldoketen, convincing proof of its existence has been secured. Without preliminary hydration, the reaction mixture with benzene was treated with aniline or absolute alcohol. Benzoylacetanilide and ethyl benzoylacetate were then isolated [124]:

$$\left[\begin{matrix}O\\ \|\\ C_6H_5{-}C{-}CH{=}C{=}O\end{matrix}\right] \begin{matrix}+ C_6H_5NH_2 \rightarrow C_6H_5COCH_2CONHC_6H_5\\ + C_2H_5OH \rightarrow C_6H_5COCH_2COOC_2H_5 .\end{matrix}$$



9. Reactions with Organometallic Compounds

The participation of carbon suboxide in organomagnesium [125-128] and organolithium [129] syntheses has been described. Depending on the reaction conditions and the relative amounts of the reactants, β-diketones [127,129] or methyl ketones [125,126,128] can be obtained:

1. $C_3O_2 + 2\,Mg\begin{matrix}R\\X\end{matrix} \rightarrow XMgO{-}\overset{R}{\underset{|}{C}}{=}C{=}\overset{R}{\underset{|}{C}}{-}OMgX \xrightarrow{2H_2O} R(OH)C{=}C(OH)R \rightarrow$
$\rightarrow RCCOCH_2COR$

2. $C_3O_2 + Mg\begin{matrix}R\\X\end{matrix} \rightarrow XMgO{-}\overset{R}{\underset{|}{C}}{=}C{=}O \xrightarrow[-CO_2]{H_2O} R{-}COCH_3 .$

It has been shown [125,126] that the intermediate aldoketen can react further by another mechanism with formation of cyclic dimers and trimers:

The capacity of carbon suboxide to enter into the Reformatskii reaction has been demonstrated by Dashkevich and Siraya [130]:

$$Zn + BrCH_2COOC_2H_5 + C_3O_2 \rightarrow C_2H_5OCOCH_2{-}C(ZnBr){=}C{=}O \xrightarrow{H_2O} \rightarrow C_2H_5OCOCH_2{-}COCH{=}C{=}O.$$

Since it proved impossible to isolate the aldoketen, the latter was hydrated, decarboxylated, and the acetoacetic ester obtained was subjected to ketone decomposition:

$$C_2H_5OCOCH_2COCH{=}C{=}O \xrightarrow{H_2O} C_2H_5OCOCH_2COCH_3 \rightarrow CH_3COCH_3 + CO_2 + C_2H_5OH.$$

Data on the reaction of carbon suboxide with sodium alkoxides in the corresponding alcohol [67] were presented above.

It has been shown that, as the size of the alcohol radical increases, there is a corresponding increase in the amount of the sodium derivative of the dialkyl malonate formed:

$$RONa + C_3O_2 \rightarrow ROCOCNa{=}C{=}O \xrightarrow{HOR} ROCOCHNaCOOR,$$

where R = C_3H_7, C_4H_9, C_6H_{13}, C_7H_{15}, and C_8H_{17}. With ethyl and methyl alcohols, dialkyl malonates were obtained exclusively.

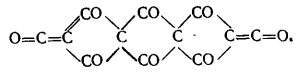
10. Reactions with Halides and Oxidation and Reduction of Carbon Suboxide

The addition of hydrogen halides to carbon suboxide results in the formation of malonyl halides [1]. From the reaction with ClBr in carbon tetrachloride the dichloride of dibromomalonic acid was isolated [124].

The oxidation and reduction of carbon suboxide have virtually not been investigated. In the attempt to reduce carbon suboxide with molecular hydrogen on nickel or palladium a mixture of products, consisting mainly of propene, together with acetic acid and small amounts of propane and water, was obtained [131] instead of the expected reduction products — propane-1,3-diol or propane.

According to the results of Staudinger, who studied the oxidation of ketens, carbon suboxide does not react with oxygen [132]. On cautious oxidation of carbon suboxide with a 2% solution of potassium permanganate, it proved possible to isolate a small amount of mesoxalic acid, which was identified via its phenylhydrazone [73]:

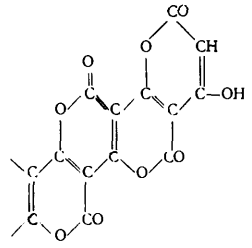
$$O{=}C{=}C{=}C{=}O \xrightarrow{2\%\ KMnO_4} \underset{OH}{\overset{O}{C}}{-}\underset{OH}{\overset{OH}{C}}{-}\overset{O}{C} .$$



11. Polymerisation of Carbon Suboxide

The polymerisation of carbon suboxide was first observed by Diels [1]. The polymer which he described consisted of an amorphous powder whose colour ranged from dark red to black and which was readily soluble in water. Subsequently it has been frequently reported that the formation of the carbon suboxide polymer as a side-product accompanies all prolonged reactions of carbon suboxide, particularly at an elevated temperature and in the presence of catalysts.

Special experiments have also been made on the polymerisation of carbon suboxide. It has been shown that pure carbon suboxide is fairly stable (does not polymerise at 0° over a period of several weeks [51]), whereas the insufficiently purified compound polymerises over a period of only several hours. The effect of various catalysts on the rate of polymerisation has been studied. Organic bases (pyridine, triethylamine, quaternary ammonium bases), sulphuric acid, aluminium chloride, boron trifluoride [51,52], and phosphorus pentoxide [1,66] have been tested. When catalysts are added to liquid carbon suboxide, the polymerisation takes place vigorously, often with explosion; in a solvent the reaction takes place smoothly and gradually. Pyridine and triethylamine proved to be the best catalysts [51]. The polymer is also obtained in good yield (80%) when solutions of carbon suboxide in halogen-containing solvents are γ-irradiated [133].



The problem of the structure of the carbon suboxide polymer has been the subject of lively discussion from the

moment of its discovery until the present time. Diels suggested that the red carbon suboxide polymer has a polycyclobutanedione structure[68]:

(I)

Later investigations of Schmidt and coworkers established that the polymer molecule includes also five- and six-membered lactone rings[134]. Ziegler suggested a poly-α-pyrone structure for the polymer[135]:

(II)

On the basis of the study of the infrared spectra of the polymer and its methyl ether, Hegar[51] rejects both structures (I) and (II), noting also that none of the polymers obtained had the composition $[C_3O_2]_x$. However, Blake and coworkers[136-138], who investigated the structure of the carbon suboxide polymer, again proposed a structure analogous to structure (II).

In the examination of the structures proposed one must bear in mind that the above investigators were scarcely likely to deal with identical compounds, since the conditions used in the preparation of the polymer were not the same. While Diels[1,68] and Hegar[51] obtained the carbon suboxide polymer at 0°C in the presence of chemical catalysts, Blake and coworkers[136] and other investigators[115] carried out the polymerisation at temperatures of the order of 100°C. Probably this is why the properties of the carbon suboxide polymers are so different[48]. It is also possible that the investigators dealt with structures analogous to both structure (I) and structure (II). Nor can one exclude the possibility of the formation of mixed structures, which may occur, for example, on further addition of carbon suboxide to the products of its interaction with enols; in this reaction two structures have been found to form, as in polymerisation — one with a carboxy-group analogous to structure (I)[51] and one with a polypyrone group, analogous to structure (II).[88]

In conclusion it should be noted yet again that further development of the chemistry of carbon suboxide is extremely promising both from the theoretical and practical points of view.

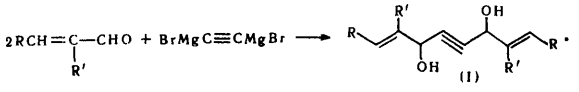
SYNTHESIS AND SOME PROPERTIES OF αω-DISUBSTITUTED (DIFUNCTIONAL) POLYENES

L. A. Yanovskaya

CONTENTS

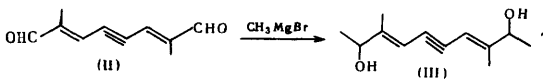
I. Introduction 400
II. Synthesis of polyenes with the same substituents at the ends of the chain 400
III. Synthesis of polyenes with different substituents at the ends of the chain 406
IV. Some properties of polyenes 407

I. INTRODUCTION



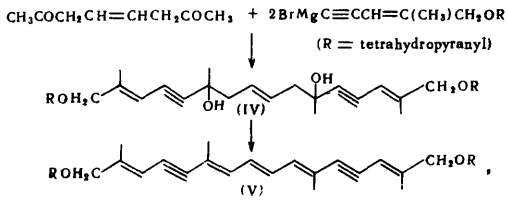
αω-Disubstituted (difunctional) polyenes are fairly widely distributed in nature. They include, for example, various branched and unbranched dicarboxylic acids (crocetin, bixin, corticrocin, descrocetin), which are the normal metabolites of certain plants and micro-organisms, polyene diketones (capsorubin – one of the pigments of cayenne, etc.). Many disubstituted difunctional polyenes are the degradation products of polyene antibiotics, such as, for example, fumagillin, lagosin, tetrin, etc. Finally, difunctional polyenes serve as the starting materials in the synthesis of other important natural compounds, for example, carotenoids (β-carotene, lycopene, etc.). In this connection synthetic methods have been investigated and developed for individual representatives of substances of this type, in the first place those with the isoprenoid structure; some of these have been described in reviews devoted to advances in the synthesis of carotenoids and vitamin A [1-3]. However, a complete description of the synthetic methods for αω-disubstituted (difunctional) polyenes has not been given so far. And yet in recent years considerable new advances have been achieved in this field, as a result of which the principal types of difunctional polyenes have become fully available. The advances in the synthetic field led to a number of theoretical findings based on the study of many properties of these compounds, particularly studies concerning the effect of the terminal substituents in the polyene chain on one another.

The present review is devoted to the advances in the synthesis of αω-disubstituted (difunctional) polyenes and certain properties of polyenes.



II. SYNTHESIS OF POLYENES WITH THE SAME SUBSTITUENTS AT THE ENDS OF THE CHAIN

Glycols

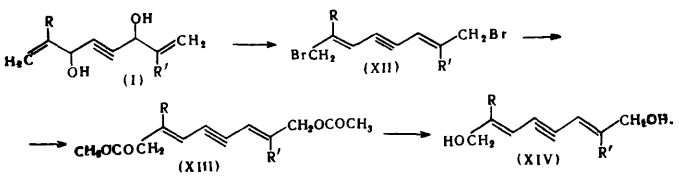


Primary and secondary glycols of the polyene and polyenyne series might serve as convenient starting compounds for the synthesis of other disubstituted (difunctional) polyenes, and therefore much attention has been devoted to their synthesis. The first and oldest method of preparing glycols consists in organometallic synthesis. This procedure leads mainly to secondary glycols. Best results have been obtained in the reaction of the simplest αβ-unsaturated monoaldehydes with the Iotsich complex. Thus when acrolein[4], methacrolein[5-11] or tiglic aldehydes[12] are allowed to act on bis(bromomagnesium)acetylene in ether, octa-1,7-dien-4-yne-3,6-diol (I, R = R′ = H), 2,7-dimethylocta-1,7-dien-4-yne-3,6-diol (I, R = H, R′ = CH_3), and 3,8-dimethyldeca-2,8-dien-5-yne-4,7-diol (I, R = R′ = CH_3) were obtained in yields of the order of 70%:

Dialdehydes and Grignard reagents can also be used in this reaction[12,13]. For example, the reaction of methylmagnesium bromide with 2,7-dimethylocta-2,6-dien-4-yne-1,8-dial (II) gave 3,8-dimethyldeca-3,7-dien-5-yne-1,9-diol (III):

However, attempts to synthesise primary glycols using the reaction between a Grignard reagent with the appropriate functional group and a diketone[14],

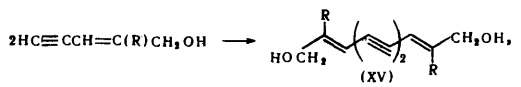
were not very successful because dehydration of compound (IV) gave the bistetrahydropyranyl ether (V) in a yield of only 8%.



The attempt to use for the synthesis of glycols the Grignard reaction between hex-4-en-1-yn-3-ol (VI) or hex-3-en-1-yn-5-ol (VII) and acetaldehyde was also unsuccessful. Although the corresponding reaction products, oct-6-en-3-yne-2,5-diol (VIII) and oct-5-en-3-yne-2,7-diol (IX) are formed in high yields[15], selective hydrogenation of the glycol (IX) by chemical or catalytic methods gave octa-3,5-diene-2,7-diol (X) in a very low yield. The hydrogenation

of the glycol (VIII) took place smoothly, but the anionotropic rearrangement of the glycol (XI) gave mainly octa--4,6-diene-2,3-diol instead of the desired glycol (X):

$$\begin{array}{lll} CH_3CH{=}CHCH(OH)C{\equiv}CH & \rightarrow & CH_3CH(OH)CH{=}CHC{\equiv}CH \\ (VI) \quad \downarrow & & (VII) \quad \downarrow \\ CH_3CH{=}CHCH(OH)C{\equiv}CCH(OH)CH_3 & \rightarrow & CH_3CH(OH)CH{=}CHC{\equiv}CCH(OH)CH_3 \\ (VIII) \quad \downarrow & & (IX) \quad \downarrow \\ CH_3CH{=}CHCH(OH)CH{=}CHCH(OH)CH_3 & & CH_3CH(OH)(CH{=}CH)_2CH(OH)CH_3. \\ (XI) & & (X) \end{array}$$

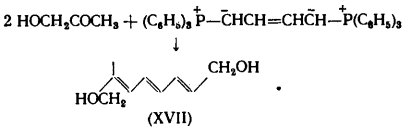


Thus organometallic synthesis can be used conveniently only for the synthesis of the simplest secondary glycols, based on monoaldehydes and the Iotsich reagent.

Anionotropic rearrangement is used for the preparation of primary glycols[5,7-9], but this frequently does not take place smoothly. Comparatively recently a new method has been proposed for the conversion of secondary glycols into primary glycols[11], in which the secondary glycol (I) is converted into the primary dibromide (XII) by the action of phosphorus tribromide[10] or hydrobromic acid[6,11]; the dibromide (XII) is then converted into the diacetate (XIII) by treatment with sodium acetate and the product (XIII) is hydrolysed with alkali to give the primary glycol (XIV). All the conversions take place readily and the yield of the glycol (XIV) is fairly high:

It should be noted incidentally that this promising method for the conversion of secondary glycols into primary glycols has so far been developed only for a few isolated cases.

A second synthetic method, which is suitable for the preparation of both primary and secondary glycols, is based on the oxidative coupling of primary or secondary enyne alcohols. Thus the corresponding primary enyne glycols (XV) were obtained in a high yield from pent-2-en--4-yn-1-ol or 2-methylpent-2-en-4-yn-1-ol[14]:



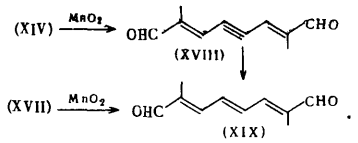
where R = H or CH_3.

The oxidative coupling reaction is used particularly extensively for the synthesis of secondary glycols[15-18]. For example, the oxidative coupling of the readily available but-3-yn-2-ol[17,18] gave the diacetylene glycol (XVI), the reduction of which led to the glycol (X):

$$HC{\equiv}CCH(OH)CH_3 \rightarrow HOCH(CH_3)(C{\equiv}C)_2CH(CH_3)OH \rightarrow (X).$$
(XVI)

Despite the ready availability of the initial enyne alcohols and the high yields of the glycols, this method has one important disadvantage: the selective reduction of the diacetylene system often constitutes a very difficult problem. Therefore, despite the obvious advantages of this method for the synthesis of glycols, preference is given at the present time to organometallic synthesis.

Quite recently yet another synthetic procedure for primary polyglycols has been described[19] — the Wittig reaction between 2-butene-1,4-diylidenebis(triphenylphosphorane) and hydroxyacetone, but the yield of the product (XVII) was only 10%:

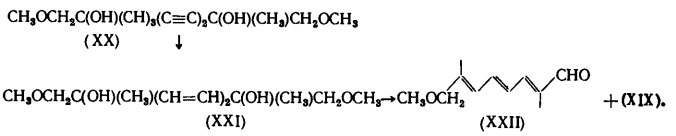


Dialdehydes

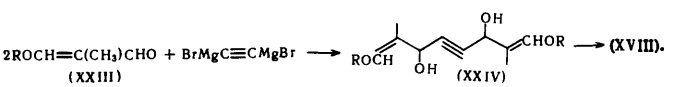
Dialdehydes are the most important starting compounds for reactions whereby substances of other classes can be obtained. Only the successful discovery of readily accessible and simple methods for the synthesis of dialdehydes of the polyene and polyenyne series could lead to the ready availability of the principal types of difunctional polyenes. In this connection, the interest shown by many investigators in this problem is fully justified.

The first synthetic procedure for dialdehydes was based on the oxidation of primary polyene glycols or polyenyne glycols with subsequent selective hydrogenation of the triple bonds. Each of the modifications proposed differed from the others by the method of synthesising the initial glycols (see above).

The oxidation of glycols of type (XIV) or (XVII) by the Oppenauer method or with t-butyl chromate is unsuccessful. Excellent results are, however, obtained in the presence of activated manganese dioxide[6-10], the yields of dialdehydes of type (XVIII) or (XIX) reaching 85–95%:

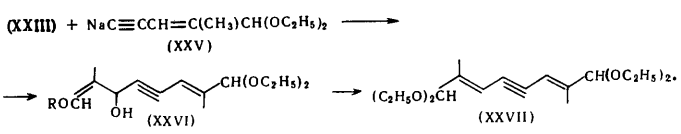


However, this universal method is not very suitable for the preparation of large amounts of dialdehydes because of the necessity to use extremely large amounts of manganese dioxide and solvent. Furthermore, the scope of this method is also restricted by the low availability of the starting compounds, because, as pointed out above, only the simplest glycols can be regarded as readily available.



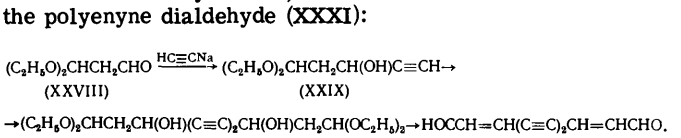
The hydrogenation of enyne dialdehydes to polyene dialdehydes takes place best in the presence of Lindlar's catalyst[7,20]. The *cis*-isomers produced in this process are isomerised to the *trans*-form on standing, on boiling in benzene solution, or under the action of traces of iodine or ultraviolet light.

The second method which was developed to prepare polyene dialdehydes consists in the synthesis of divinyl ethers, which are then hydrolysed to the dialdehydes. For example, oxidative dimerisation of 1-methoxy-2-methylbut-3-yn-2--ol[21,22] gives 1,8-dimethoxy-2,7-dimethylocta-3,5-diyne--2,7-diol (XX), the reduction of which with lithium aluminium hydride leads to the *trans-trans*-dienediol (*trans*-XXI), while hydrogenation in the presence of palladium poisoned with quinoline leads to the *cis-cis*-dienediol (*cis*-XXI).

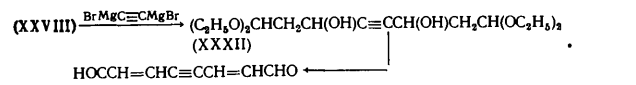


However, dehydration and hydrolysis of both dienediols resulted in a mixture of the dialdehyde (XIX) and the monoaldehyde (XXII):

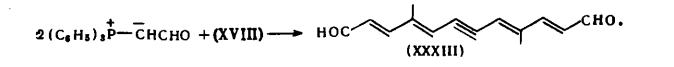
It has also been suggested that the aldovinyl ether (XXIII) be condensed with the Iositch complex[23,24] and that the resulting divinyl ether (XXIV) be hydrolysed to the dialdehyde (XVIII):



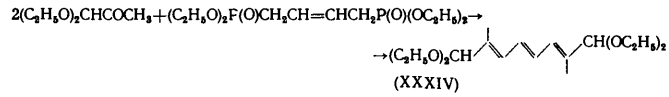
In another modification of this method[23,24] the aldovinyl ether (XXIII) is condensed with the sodio-derivative of the diethyl acetal of 2-methylpent-2-en-4-ynal (XXV) to give the hydroxy-acetal (XXVI), the latter being hydrolysed with the formation of the bisacetal (XXVII) without isolating in a pure form the intermediate dialdehyde (XVIII):



The method described above gives satisfactory yields of the final products, but it is not general.

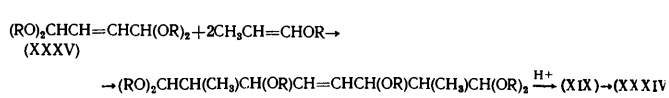


The third method for the synthesis of dialdehydes is also non-general. In this procedure $\beta\beta$-diethoxypropionaldehyde (XXVIII) is condensed with sodium acetylide or the Iositch reagent[25]. The hydroxy-acetal (XXIX) obtained in the first case is subjected to oxidative dimerisation to the dihydroxy-bisacetal (XXX) and the latter is hydrolysed with simultaneous dehydration, which leads to the formation of the polyenyne dialdehyde (XXXI):



In the second case the resulting dihydroxy-bisacetal (XXXII) is also hydrolysed with simultaneous dehydration:

The fourth method for the synthesis of dialdehydes is based on the Wittig reaction. It was found[26] that formylmethylenetriphenylphosphorane reacts with the dialdehyde (XVIII), the product being 4,9-dimethyldodeca-2,4,8,10-tetraen-6-yne-1,12-dial (XXXIII):



However, despite the fact that according to spectroscopic data the yield of compounds (XXXIII) was 50%, the amount of the dialdehyde isolated from the reaction mixture was only 15%, this being due, according to the authors, to the difficulty of separating compound (XXXIII) from triphenylphosphine oxide. Incidentally, the attempt[27] to increase the yield of compound (XXXIII) by using in the reaction with the dialdehyde (XVIII) formylmethylene(*p*-diethylaminophenyl)diphenylphosphorane, the oxide formed from which is readily soluble in dilute hydrochloric acid, was unsuccessful: the yield of the dialdehyde (XXXIII) was only 12%. A patent[19] describes the synthesis of the bis(diethyl acetal) of 2,7-dimethylocta-2,4,6-triene-1,8-dial (XXXIV) in the reaction between the diphosphonate (obtained from 1,4-dichlorobutene and triethyl phosphite) and the acetal of methylglyoxal:

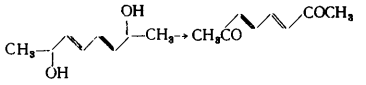
However, these data have not been confirmed so far. Furthermore, the method described is to some extent non-general.

Until recently, despite the many attempts made, there was no simple general and reliable method for the synthesis of polyene dialdehydes, based on readily available starting materials. Such a method was developed on the basis of the reaction of divinyl ethers with acetals of aldehydes. It involves three stages: (1) the conversion of the dialdehyde into the bisacetal, (2) the condensation of the bisacetal with two moles of vinyl ether [catalysts $BF_3(C_2H_5)_2O$, $ZnCl_2$, etc.], and finally (3) hydrolysis of the resulting dialkoxy-bisacetal with simultaneous removal of the alkoxy-groups by heating with a solution of sodium acetate in acetic acid, or with phosphoric acid, etc. Usually all three stages are carried out in succession without isolating and purifying the products and thus they are in fact combined into a single stage. This method was first used for the synthesis of isoprenoid dialdehydes[28-36] from the bisacetal of but-2-ene-1,4-dial (XXXV):

The dialdehyde (XIX), which is a key product of fundamental importance, was obtained in this way. The repetition of this procedure with the bisacetal (XXXIV) using ethyl vinyl ether gave 4,9-dimethyldodeca-2,4,6,8,10-pentaenedial and subsequently crocetin dialdehyde. This synthetic procedure was proposed[37-39] for the preparation of unbranched dialdehydes of the type $OHC(CH{=}CH)_nCHO$. It is noteworthy that all the stages of the synthesis often take place with very high yields and lead to the formation of pure products.

Since bisacetals of but-2-ene-1,4-dial are nowadays readily available[37-38], the above method may be regarded as ideal for the synthesis of polyene dialdehydes. Here we have a harmonious combination of ready availability of the starting materials and the ease of the synthetic procedure and the isolation and purification of the product, which makes this method superior to all others. The method is also flexible and universal. Thus polyene dialdehydes have now become fully available.

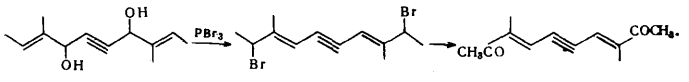
It is noteworthy that both maleic and fumaric bisacetals react with ethyl vinyl ether equally readily[37-39], the condensation of maleic bisacetal (increase in size) being



accompanied by a complete conversion of the *cis*-configuration into the *trans*-configuration[37]. In contrast to this, the condensation of the bisacetal of *cis-cis*-muconic dialdehyde[25] is not accompanied by complete isomerisation and leads to a mixture of isomeric dialkoxy-bisacetals. However, hydrolysis of the dialkoxy-bisacetals results, as a rule, in the formation of only the pure *trans*-isomers.

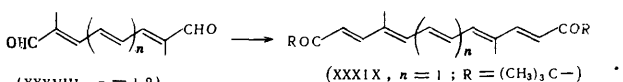
Asymmetric condensation (increase in the chain length) of the bis(dimethyl acetal) of fumaric dialdehyde using ethyl vinyl ether and butyl vinyl ether was achieved by Makin[39], but the yields of products were only 16–20%:

$$(CH_3O)_2CHCH{=}CHCH(OCH_3)_2+CH_2{=}CHOCH_3\rightarrow$$
$$\rightarrow(CH_3O)_2CHCH{=}CHCH(OCH_3)CH_2CH(OCH_3)_2.$$



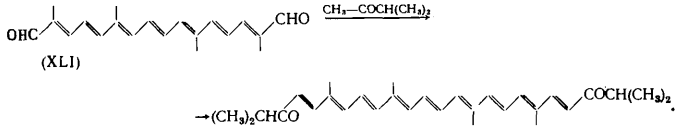
Diketones

Three procedures have been proposed for the synthesis of polyene diketones. The first is based on the oxidation of secondary glycols, using activated manganese dioxide[15]. For example, the oxidation of the secondary glycol (XXXVI) gives the diketone (XXXVII) in 91% yield (when aluminium t-butoxide was used, the yield fell to 5%):



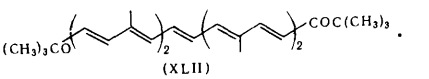
(XXXVI) (XXXVII)

Secondary glycols are also converted into diketones by a reaction involving the initial conversion into bromides (with isomerisation), this being followed by oxidation with 2-nitropropane in an alkaline medium[11]:



The oxidative method for the synthesis of diketones suffers from the same disadvantages as the oxidative method for the synthesis of dialdehydes (see above) and its scope is also restricted by the availability of the initial glycols.

The second method for the synthesis of polyene diketones is based on the Claisen condensation[40-43] in the presence of aluminium t-butoxide[14,41,42], an alcoholic solution of potassium hydroxide[43], and piperidine or piperidinium acetate[44-47]. In most cases this procedure leads to fairly high yields of diketones. Thus the condensation of 2,7-dimethylocta-2,4,6-triene-1,8-dial (XXXVIII, n = 1) with pinacoline in the presence of aluminium t-butoxide gives the diketone (XXXIV, n = 1) in 35% yield. Under the same conditions hexaene diketones (XI, n = 2) were obtained in yields of 40–50% from the dialdehyde (XXXVIII, n = 2) and acetone or pinacoline[41,42]:



(XXXVIII, n = 1,2) (XXXIX, n = 1; R = $(CH_3)_3C-$)
(XL, n = 2; R = CH_3, $(CH_3)_3C-$)

The condensation of isopropyl methyl ketone with crocetin dialdehyde (XLI) in the presence of alcoholic potassium hydroxide at room temperature also takes place with high yields (70–80%)[43]:

(XLI)

However, the condensation of the dialdehyde (XXXVIII, n = 1) with tiglylidenepinacolone gave the diketone (XLII) in a yield of only 1–2%:[42]

(XLII)

The Claisen condensation was also used in the synthesis of the natural polyene diketone canthaxanthin[42], the results also being satisfactory.

Since at the present time polyene dialdehydes are readily available, the above method for the synthesis of polyene diketones is undoubtedly convenient and simple.

Finally the third method for the synthesis of polyene diketones consists in the Wittig reaction between acylmethylenetriphenylphosphoranes and polyene dialdehydes[48]:

$$OHC(CH{=}CH)_nCHO+2(C_6H_5)_3\overset{+}{P}-\overset{-}{C}HCOR\rightarrow RCO(CH{=}CH)_{n+2}COR$$

(XLIII) n=2, 3, 4; R=CH_3, C_6H_5
n=2, 3, 4

The reaction takes place readily on heating acetylmethylenetriphenylphosphorane or benzoylmethylenetriphenylphosphorane with dialdehydes (XLIII) in benzene or toluene. The yields of polyene diketones reach 60–68%. The polyenes thus obtained are entirely in the *trans*-configuration. When the initial aldehydes are available, both the Wittig reaction and the Claisen condensation can be successfully used for the synthesis of polyene diketones.

We may conclude that at the present time polyene diketones are also fully accessible.

Dicarboxylic Acids and Their Esters

A number of synthetic procedures have been proposed for polyenedicarboxylic acids. The first, oldest method is based on the condensation of monocarboxylic acid esters with diethyl oxalate in the presence of alkaline reagents[49-51]:

$$C_2H_5OOCCOOC_2H_5+CH_3(CH{=}CH)_mCOOC_2H_5\rightarrow C_2H_5OOCCOCH_2(CH{=}CH)_mCOOC_2H_5\rightarrow$$
(XLIV) (XLV)
$$\rightarrow C_2H_5OOCC(OCOCH_3){=}CH(CH{=}CH)_mCOOC_2H_5\rightarrow$$
(XLVI)
$$\rightarrow C_2H_5OOCCH(OCOCH_3)(CH{=}CH)_mCH_2COOC_2H_5\rightarrow HOOC(CH{=}CH)_nCOOH$$
(XLVII) (XLVIII)

The condensation of the polyene ester (XLIV) with diethyl oxalate into the keto-diester (XLV) takes place in yields of 65–70% with the lower members of the series (XLIV, n = 1, 2), but with higher members (n = 4–6) the yields fall to 10–27%. The acetylation of the keto-diester (XLV) with acetic anhydride to give the compound (XLVI) takes place smoothly as a rule, but the reduction of the compound (XLVI) with aluminium amalgam or zinc dust in a mixture of pyridine and acetic acid is sometimes not smooth, for example in the case of compound (XLVI, n = 6), and is accompanied by hydrogenolysis with formation of the diester of dihydrodescrocetin[51]. Finally treatment of the compound (XLVII) with a solution of alkali gives the polyenedicarboxylic acid (XLVIII) containing one double bond more than the initial monocarboxylic acid ester (XLIV). The dicarboxylic acids (XLVIII, n = 3, 4, 5, 7) were obtained by this method. The main disadvantage of the method is the large number of stages. Furthermore, the method is not general — the attempts to extend it to the synthesis of branched higher polyene acids (crocetin, bixin) were unsuccessful.

The second method for the synthesis of polyenedicarboxylic acids consists in the oxidative dimerisation of acetylenemonocarboxylic acids with subsequent alkaline isomerisation of the resulting diacetylenedicarboxylic acids into polyenedicarboxylic acids[52,53]. The first complete synthesis of corticrocin (XLVIII, $n = 6$) was achieved by this method. For this purpose, the diacetylenedicarboxylic acid (L) was obtained by the oxidative coupling of hept-2-en-6-ynoic acid (XLIX), the salt of corticrocin being obtained by boiling the acid (L) with an aqueous solution of potassium hydroxide:

$$\underset{\text{(XLIX)}}{HC{\equiv}CCH_2CH_2CH{=}CHCOOH} \rightarrow \underset{\text{(L)}}{HOOCCH{=}CHCH_2CH_2(C{\equiv}C)_2CH_2CH_2CH{=}CHCOOH} \rightarrow \rightarrow \text{(XLVIII, } n = 6)$$

This comparatively simple procedure gives, however, very low yields of the final product, mainly due to the stage involving the isomerisation of diacetylene. Furthermore, the initial polyenynoic acids are also usually not readily accessible.

A more convenient modification is the direct dimerisation of the enynoic acids or their esters with subsequent selective hydrogenation of the resulting acetylenedicarboxylic acids or their esters[14,25]. For example:

$$HC{\equiv}C(CH{=}CH)_nCOOC_2H_5 \rightarrow \underset{\text{(LI)}}{C_2H_5OOC(CH{=}CH)_n(C{\equiv}C)_2(CH{=}CH)_nCOOC_2H_5} \rightarrow$$

$$\rightarrow \underset{\text{(LII)}}{C_2H_5OOC(CH{=}CH)_n(CH{=}CH)_{\overset{cis}{2}}(CH{=}CH)_nCOOC_2H_5} \rightarrow \underset{\text{(LIII)}}{C_2H_5OOC(CH{=}CH_2)_{n+2}COOC_2H_5}.$$

Polyenedicarboxylic acids with central *cis*-bonds can be obtained by this procedure. The diethyl esters of 4,6-*cis*-*cis*-deca-2,4,6,8-tetraene-1,10-dioic acid (LIII, $n = 1$) and 6,8-*cis*-*cis*-corticrocin (LIII, $n = 2$) were obtained in this way.

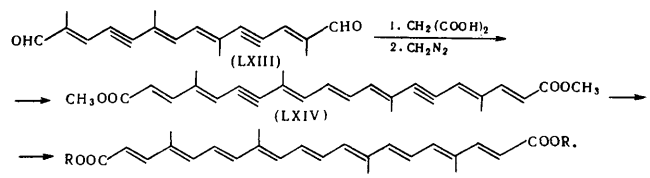
It is noteworthy that on hydrogenation of compound (LI, $n = 2$) in the dark at a weight ratio substance : catalyst = = 0.5, the *cis*-*cis*-isomer (LII, $n = 2$) forms, while at a weight ratio substance : catalyst = 1.5 the product is the diethyl ester of *cis*-*cis*-corticrocin, which is also produced by the isomerisation of (LII, $n = 2$).[25] The use of this modification leads to high yields of the final products, but its application is restricted by the availability of the initial enyne esters.

Yet another modification of the synthetic procedure has been proposed for the preparation of polyenedicarboxylic acids[54]. Thus dimersiation of pent-2-en-4-ynol yields the primary glycol (LIV), which is converted into the dibromide (LV) under the action of phosphorus tribromide. On treatment under copper cyanide, the latter yields the dinitrile (LVI). Hydrolysis of compound (LVI) with a solution of hydrogen chloride in methanol yields the dimethyl ester (LVII), which is converted by alkaline isomerisation into the dimethyl ester of dodeca-2,4,8,10-tetraen-6-yne-1,2-dionic acid (LVIII). When the compound (LVIII) is hydrogenated in the presence of Lindlar's catalyst and isomerised, the dimethyl ester of dodeca-2,4,6,8,10-pentaenedioic acid (LIX), fully in the *trans*-configuration, is obtained:

$$\rightarrow \underset{\text{(LVI)}}{NCCH_2CH{=}CH(C{\equiv}C)_2CH{=}CHCH_2CN} \rightarrow \underset{\text{(LVII)}}{CH_3OOCCH_2CH{=}CH(C{\equiv}C)_2CH{=}CHCH_2COOCH_3} \rightarrow$$

$$\rightarrow \underset{\text{(LVIII)}}{CH_3OOC(CH{=}CH)_2C{\equiv}C(CH{=}CH)_2COOCH_3} \rightarrow \underset{\text{(LIX)}}{CH_3OOC(CH{=}CH)_6CO}.$$

All the stages of the synthesis take place with fairly high yields, but, as a whole, the synthesis is inconvenient in view of the large number of stages and the limited availability of the initial compound.



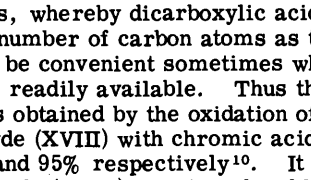
In a procedure similar to that described above[54] the ester of the tetracarboxylic acid (LX), obtained by the reaction of the dibromide (LV) with the potassiomalonic ester, is hydrolysed and decarboxylated to the dicarboxylic acid (LXI) and the latter is isomerised to give corticrocin (XLVIII, $n = 6$). This modification suffers from the disadvantage characteristic of the synthesis involving the dinitrile formation stage (see above) and in addition it is inconvenient because in the last two stages the yields of products are low:

$$\text{(LV)} + KHC(COOC_4H_9\text{-}t)_2 \rightarrow$$

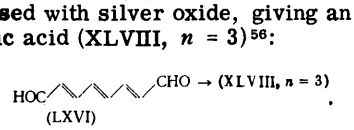
$$\rightarrow \underset{\text{(LX)}}{(t\text{-}C_4H_9OOC)_2CHCH_2CH{=}CH(C{\equiv}C)_2CH{=}CHCH_2CH(COOC_4H_9\text{-}t)_2} \rightarrow$$

$$\rightarrow \underset{\text{(LXI)}}{HOOCCH_2CH_2CH{=}CH(C{\equiv}C)_2CH{=}CHCH_2CH_2COOH} \rightarrow \text{(XLVIII, } n = 6).$$

The third method of synthesising polyenecarboxylic acids is based on the Doebner reaction applied to polyene and polyenyne dialdehydes[14,41,42,54]. The first complete synthesis of bixin (LXII) was achieved in this way[14]:

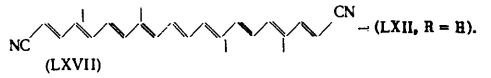


For this purpose, the enyne dialdehyde (LXIII) is condensed with malonic acid by heating in pyridine in the presence of piperidine, the resulting acid is esterified with diazomethane, the dimethyl ester of 6,7,14,15-bisdehydrobixin (LXIV) being obtained in 20% yield (in two stages); its hydrogenation in the presence of Lindlar's catalyst gave the dimethyl ester of *trans*-bixin (LXII), probably via the intermediate *cis*-forms.



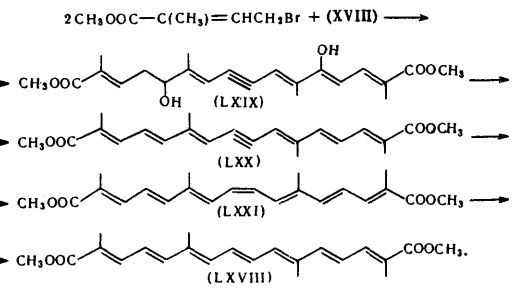
2,2'-bisnorcrocetin was obtained similarly by the condensation of 2,7-dimethylocta-2,4,6-triene-1,8-dial with ethylidenemalonic acid in the presence of trimethylbenzylamine oxide at room temperature[41]. However, attempts to condense 2,9-dimethyldeca-2,8-diene-4,6-diyne-1,10-dial with malonic acid were unsuccessful[54].

The Doebner reaction can probably be sometimes successfully employed in the synthesis of polyenedicarboxylic acids, because at the present time the corresponding dialdehydes are readily available.



The fourth synthetic procedure for polyenedicarboxylic acids consists in the oxidation of the corresponding glycols and dialdehydes, whereby dicarboxylic acids are obtained with the same number of carbon atoms as the initial compound. It can be convenient sometimes when the initial compounds are readily available. Thus the dicarboxylic acid (LXV) was obtained by the oxidation of the glycol (XIV) or the dialdehyde (XVIII) with chromic acid mixture in yields of 30% and 95% respectively[10]. It is interesting that the dialdehyde (XVIII) is not oxidised by silver oxide:

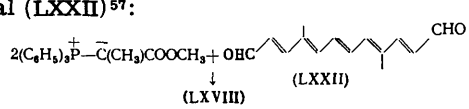
On the other hand, octa-2,4,6-triene-1,8-dial (LXVI) is smoothly oxidised with silver oxide, giving an 88% yield of the dicarboxylic acid (XLVIII, $n = 3$)[56]:



The fifth method of synthesis of polyenedicarboxylic acids consists in the hydrolysis of dinitriles. It also yields polyenedicarboxylic acids with the same number of carbon atoms and can find limited application when the dinitriles are available. Thus norbixin (LXII, R = H), with a fully *trans*-configuration, was obtained on cautious hydrolysis of the dinitrile (LXVII)[55]:

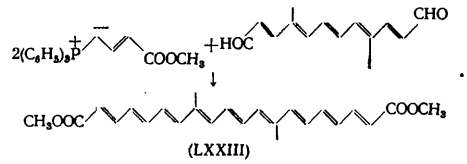
→ (LXII, R = H).

The sixth method is based on the Reformatsky reaction between polyene and polyenyne dialdehydes and bromo--acid esters. The syntheses of the dimethyl ester of crocetin (LXVIII) and methyl bixin (LXII) were achieved in this way[7,8,13]. For example, the acetylenic dialdehyde (XVIII) is made to undergo the Reformatsky reaction with methyl γ-bromotiglate in tetrahydrofuran under carefully selected conditions, the glycol (LXIX) being obtained in high yield. Dehydration of the glycol (LXIX) with *p*-toluenesulphonic acid gives the dimethyl ester of 8,8′-dehydrocrocetin (LXX). On hydrogenating the compound (LXX) and then isomerising the dimethyl ester of 8,8′-*cis*--crocetin (LXXI) by irradiation with ultraviolet light in the presence of iodine, the dimethyl crocetin ester (LXVIII), fully in the *trans*-configuration, is obtained:

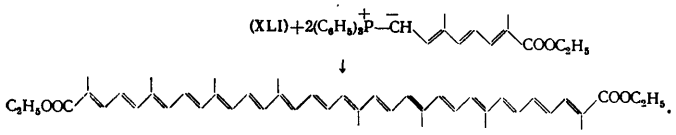


A bottleneck in the application of the Reformatsky reaction to the synthesis of polyenedicarboxylic acids is the stage involving the dehydration of the resulting hydroxy--esters, in which the yields are frequently very low [for example, the dehydration of compound (LXIX) gave compound (LXX) in a yield of only 1%].

The seventh method of synthesis of polyene dicarboxylic acids is based on the Wittig reaction between polyene or polyenyne dialdehydes and alkoxycarbonylmethylenediphenylphosphoranes or the diethyl esters of alkoxycarbonylmethylphosphonic acids, or their derivatives. Isler[57] was the first to apply the Wittig reaction in the synthesis of isoprenoidpolyenedicarboxylic acids. Thus a number of norbixin esters (LXII) were obtained in high yields (75–85%) on boiling a benzene solution of crocetin dialdehyde (XLI) with alkoxycarbonylmethylenetriphenylphosphoranes:



The use of α-alkoxycarbonylethylidenetriphenylphosphoranes permits the introduction not only of the alkoxycarbonylmethylene group but also of a methyl side-group. The dimethyl ester of crocetin (LXVIII) was thus obtained in 80–95% yield from α-methoxycarbonylethylidenetriphenylphosphorane and 4,9-dimethyldodeca-2,4,6,8,10-pentaene--1,12-dial (LXXII)[57]:



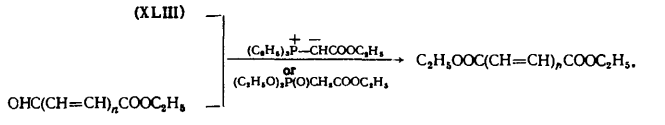
The esters of 8,8′-dehydrocrocetin and 10,10′-dehydronorbixin were obtained similarly[58].

Phosphoranes obtained from unsaturated ω-halogeno--acids can also be used in the synthesis of polyenedicarboxylic acids. For example, it has been proposed that the dimethyl ester of crocetin (LXVIII), the dimethyl ester of norbixin (LXII, R = CH_3), and dimethyl ester of 4,4′-desmethylnorbixin (LXXIII) be synthesised by the condensation of the corresponding dialdehydes with phosphoranes obtained from the methyl esters of γ-bromodimethylacrylic, γ-bromocrotonic, and γ-bromotiglic acids[59–62]:

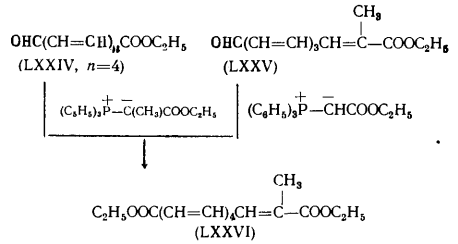
The yields of the final products reach 75–80%.

However, the use of the phosphoranes derived from the methyl ester of 4-methyl-6-bromosorbic acid and the ethyl ester of 2,6-dimethyl-8-bromo-octa-2,4,6-trienoic acid[63] results in much lower yields of the final product (of the order of 15%). For example,

A convenient modification of the Wittig reaction has been described in patents[19,64], where it is suggested that phosphonates be used instead of phosphoranes. Thus a solution of the diethyl ester of an ethoxycarbonylmethylphosphonic acid in dimethylformamide is treated with sodium alkoxide and then crocetin dialdehyde (XLI) is introduced into the reaction mixture, which leads to a high yield of the diethyl ester of norbixin (LXII, R = C_2H_5):



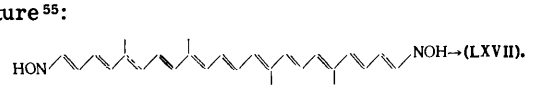
The dimethyl ester of crocetin (LXVIII) has been obtained similarly from the dialdehyde (XIX) and diethyl (3-methoxycarbonylbut-2-en-1-yl)phosphonate:



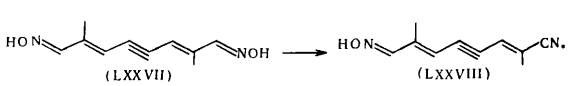
The principal advantage of the procedure involving phosphonate esters consists in the exceptional ease with which the final products are isolated, frequently by simple dilution of the reaction mixture with water, while the compounds formed in the presence of phosphoranes are often difficult to purify from triphenylphosphine oxide.

Both modifications of the Wittig reaction have been used for the synthesis of unbranched polyene acids[25,37,65,66]:

For example the diethyl esters of descrocetin and corticrocin have been synthesised in this way.



In the reaction of ethoxycarbonylvinylmethylenetriphenylphosphorane with unbranched dialdehydes the yields of the final products are only 9–13%, which is much lower than in the reaction where unbranched isoprenoid dialdehydes or ethoxycarbonylmethylenetriphenylphosphorane are used. However, this is frequently compensated by the fact that more readily available lower polyene dialdehydes serve as the starting materials in the reaction. The use of esters of aldehydo-acids (LXXIV) permits the synthesis of esters of asymmetric dicarboxylic acids[65]. The diethyl ester of 2-methyldodeca-2,4,6,8,10-pentaene-1,12-dioic acid (LXXVI), a degradation product of natural fungichromin, was obtained by the reaction of the aldehyde (LXXIV, n = 4) with α-ethoxycarbonylethylidenetriphenylphosphorane or the aldehyde (LXXV) with ethoxycarbonylmethylenetriphenylphosphorane:

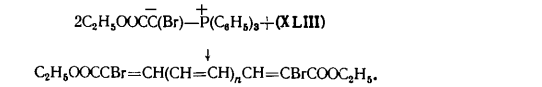


The study of the stereochemistry of the Wittig reaction with unbranched aldehydes and esters of aldehydo-acids[38,65,66] showed that in all cases the reaction is stereospecific, the *trans*-isomers of the polyenedicarboxylic acid esters being formed exclusively. On the basis of the analysis of the above data, one may conclude that the synthesis based on the use of phosphonates is the most convenient because of the ease with which it can be carried out, the ease of isolating the final products, and because of the high yields of the diesters. The application of this synthesis in practice made a wide variety of polyenedicarboxylic acid esters of different structures readily available.

Dinitriles

Comparatively recently the dinitriles of polyenedicarboxylic acids were almost unknown. Only the dinitrile of bixin (LXVII), obtained by the dehydration of bixin dialdehyde dioxime with acetic anhydride, was described in the literature[55]:

Recently the same procedure was used to prepare octa-2,4,6-triene-1,8-dinitrile[56] from the dioxime of octa-2,4,6-trienedial. However, this procedure cannot be regarded as sufficiently satisfactory, because the preparation and isolation of the dioximes of unsaturated aldehydes often constitute a very complex problem. Furthermore, the conversion of dioximes into dinitriles is not always possible. Thus dehydration of the dioxime (LXXVII) leads only to the hydroxyimino-nitrile (LXXVIII)[10]:

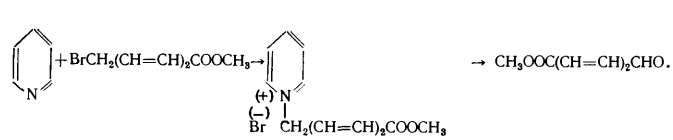


The second method of synthesising dinitriles, based on the Wittig reaction between cyanomethylenetriphenylphosphorane or diethyl cyanomethylphosphonate with polyene dialdehydes, is much more promising[25]. This procedure has been successfully applied in the preparation of a number of polyene-dinitriles (LXXIX):

As in the synthesis of the esters of polyenedicarboxylic acids, the employment of phosphonates greatly facilitates the isolation of the dinitriles from the reaction mixture and their purification. The yields of the dinitriles are quite satisfactory, reaching 50–70%. Thus polyene dinitriles too can now be regarded as fully accessible compounds.

Esters of $\alpha\alpha'$-Dibromopolyene Acids

Earlier these compounds were unknown. The possibility of their synthesis arose when the readily accessible synthetic procedure for dialdehydes had been developed and ethoxycarbonylbromomethylenetriphenylphosphorane began to be used in the Wittig reaction[25]:

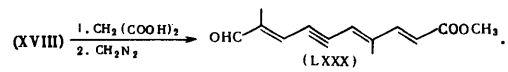


The yields of the final products range from 63 to 90%.

III. SYNTHESIS OF POLYENES WITH DIFFERENT SUBSTITUENTS AT THE ENDS OF THE CHAIN

Until recently polyenes with different substituents at the ends of the chain were relatively unknown and virtually no methods for their synthesis were developed. General methods for the synthesis of acetals of the type $(R'O)_2CH-R-Y$, where Y is a functional group and R a polyene chain, were found only in very recent years, which made it possible to develop general synthetic procedures for polyenes substituted in a wide variety of ways, based on the increase in the length of the polyene chain by condensation with vinyl ethers, with subsequent conversion of the aldehyde group into any other functional group by the Wittig reaction or other reactions. Thus polyene series with various substituents at the ends of the chain, which were formerly difficult to obtain or altogether unknown, became available.

Esters of Aldo-Acids and Their Acetals



The synthesis of the lowest member of the series of polyene aldo-acids was achieved as follows[67]:

However, this method of synthesis was not extended to higher members of the series.

The ester of the aldo-acid (LXXX) was obtained in 10% yield by the Doebner condensation of the dialdehyde (XVIII)

with malonic acid and subsequent esterification with diazomethane:

New synthetic procedures for aldo-acid esters (LXXXI) became available when the reaction involving an increase in the chain length of the acetals of aldo-acids by condensation with vinyl ethers was proposed[65,68,69]:

$$(RO)_2CH(CH{=}CH)_nCOOC_2H_5 + CH_2{=}CHOC_2H_5 \rightarrow$$
$$\rightarrow (RO)_2CHCH_2CH(OC_2H_5)(CH{=}CH)_nCOOC_2H_5 \rightarrow OHC(CH{=}CH)_{n+1}COOC_2H_5.$$
(LXXXI; n=1–4)

A similar reaction was used to prepare the ethyl ester of 5-formyl-2-methylhexa-2,6-dienoic acid[68,69] and for the synthesis of asymmetrically substituted polyene aldo-acids[65]:

$$(RO)_2CH(CH{=}CH)_nCH{=}C(CH_3)COOC_2H_5 + CH_2{=}CHOC_2H_5 \rightarrow$$
$$\rightarrow (RO)_2CHCH_2CH(OR)(CH{=}CH)_nCH{=}C(CH_3)COOC_2H_5 \rightarrow OHC(CH{=}CH)_{n+1}CH{=}C(CH_3)-.$$
$$-COOC_2H_5 \quad (n=1-3)$$

These modifications of the synthesis were quite realistic and easy to carry out, because a simple method had been developed for the preparation of the initial acetals of aldo-acids by the Wittig reaction between readily available monoacetals of glyoxal and but-2-ene-1,4-dial (fumaric dialdehyde) and ethoxycarbonylmethylenetriphenylphosphorane (or better the diethyl ester of ethoxycarbonylmethylphosphonic acid)[65,70,71]:

$$(C_2H_5O)_2CH(CH{=}CH)_nCHO \rightarrow (C_2H_5O)_2CH(CH{=}CH)_nCH{=}C(R)COOC_2H_5.$$
(n=0, 1, 2) (n=0, 1, 2; R=H, CH_3)

Acetals of symmetrical and asymmetric aldo-acids were thus obtained in high (up to 70%) yields; these acids could also be hydrolysed to the corresponding aldehydes in the presence of phosphoric acid.

An unusual method for the synthesis of the ethyl ester of 10-formyldeca-2,4,6,8-tetraenoic acid (LXXXI, n = 3), based on the reaction of octa-2,4,6-triene-1,8-dial (XLIII, n = 3) with an equimolar amount of ethoxycarbonylmethylenetriphenylphosphorane in benzene solution, which involves preferentially one of the aldehyde groups, was proposed quite recently by Kovalev et al.[72] This method is particularly promising for the synthesis of higher asymmetrically substituted polyenes, because the dialdehyde (XLIII, n = 3) is very readily available, and the acetal can be smoothly obtained from the ester of the aldo-acid (XXXI, n = 3).

The development of a general method of synthesis of monoacetals of dialdehydes and esters of aldo-acids has opened up wide possibilities for the synthesis of other polyenes substituted with various functional groups.

Aldo-Nitriles and Their Acetals

The starting material for the synthesis of a number of polyene aldo-nitriles and their acetals has been the monoacetal of fumaric dialdehyde, the reaction of which with the diethyl ester of cyanomethylphosphonic acid gave a 70% yield (with cyanomethylenetriphenylphosphorane the yield was much lower) of the acetal of 5-cyanopenta-2,4-dien-1-al (LXXXII) as a mixture of *cis-trans*-isomers (in this case the Wittig reaction is not stereospecific)[25,73]. The increase in the chain length of the compound (LXXXII) in the usual way using ethyl vinyl ether with subsequent hydrolysis of the ether-acetal (LXXXIII) and the simultaneous removal of the methoxy-group led, however, to 7-cyanohepta-2,4,6-trien-1-al (LXXXIV, n = 3), which was fully in the *trans*-configuration as a result of isomerisation during the chain growth process and hydrolysis. It is noteworthy that the hydrolysis of the mixture of the *cis-trans*-isomers of compound (LXXXII) also gave a product which was fully in the *trans*-configuration:

$$(CH_3O)_2CHCH{=}CHCHO \rightarrow \underset{(LXXXII)}{NC(CH{=}CH)_2CH(OCH_3)_2} \rightarrow$$
$$\rightarrow \underset{(LXXXIII)}{NC(CH{=}CH)_2CH(OCH_3)CH_2CH(OCH_3)(OC_2H_5)} \rightarrow \underset{(LXXXIV,\ n=3)}{NC(CH{=}CH)_nCHO}.$$

Compound (LXXXIV, n = 4) was obtained by the reaction of the octatrienedial (XLIII, n = 3) with an equimolar amount of cyanomethylenetriphenylphosphorane[72]. A general method was thus developed and aldo-nitriles and their acetals have become readily accessible.

Aldo-Ketones and Their Acetals

The method of synthesis of the acetals of aldo-ketones was outlined using as an example the reaction of the monoacetal of fumaric dialdehyde with acetylmethylenetriphenylphosphorane, where the dimethyl acetal of 6-formylhexa-3,5-dien-2-one (LXXXV) was obtained in high yield[25]:

$$(CH_3O)_2CHCH{=}CHCHO + (C_6H_5)_3\overset{+}{P}-\overset{-}{C}HCOCH_3 \rightarrow \underset{(LXXXV)}{(CH_3O)_2CH(CH{=}CH)_2COCH_3}.$$

The reaction of equimolar amounts of the octatrienedial (XLIII, n = 3) with acetylmethylenetriphenylphosphorane was used for the preparation of 10-formyldeca-3,5,7,9-tetraen-2-one[72]:

$$(XLIII,\ n=3) + (C_6H_5)_3\overset{+}{P}-\overset{-}{C}HCOCH_3 \rightarrow OHC(CH{=}CH)_4COCH_3.$$

Esters of Keto-Acids

The hydration of hepta-2,4-dien-6-ynoic acid by heating with dilute sulphuric acid in the presence of mercury sulphate[52] leads to 6-oxohepta-2,4-dienoic acid:

$$HC{\equiv}CCH{=}CHCH{=}CHCOOH \rightarrow CH_3CO(CH{=}CH)_2COOH.$$

When the starting compounds are available, this method can be used in principle for the synthesis of keto-acids. When aldo-esters are available, the synthesis of esters of polyene keto-acids by the reaction between acetylmethylenetriphenylphosphorane and aldo-esters becomes of general importance. The ethyl esters of the keto-acids (LXXXVI) were obtained in this way[25,72]:

$$C_2H_5OOC(CH{=}CH)_nCHO + (C_6H_5)_3\overset{+}{P}-\overset{-}{C}HCOCH_3 \rightarrow \underset{(LXXXVI)}{C_2H_5OOC(CH{=}CH)_3COCH_3}.$$

Esters of Cyano-Acids

The general method for the synthesis of esters of cyano-acids (LXXXVII) is based on the reaction of cyanomethylenetriphenylphosphorane or diethyl cyanomethylphosphonate with esters of aldo-acids (LXXXI)[25,72,73]:

$$(C_6H_5)_3\overset{+}{P}-\overset{-}{C}HCN + (LXXXI) \rightarrow \underset{(LXXXVII)}{NC(CH{=}CH)_nCOOC_2H_5}.$$

In addition, esters of cyano-acids have been obtained in high yields by the reaction of aldo-nitriles (LXXXIV) with diethyl esters of ethoxycarbonylmethylphosphonic acid (or the corresponding phosphorane)[72,73]:

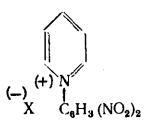
$$(\text{LXXXIV}) + (C_2H_5O)_2P(O)CH_2COOC_2H_5 \rightarrow (\text{LXXXVII}).$$

The compounds formed are fully in the *trans*-configuration.

Esters of Nitro-Acids

The general method for the synthesis of these esters[74] is based on the condensation of aldo-acid esters with nitromethane followed by the dehydration of the hydroxynitro-compounds (LXXXVIII) formed:

$$\underset{(n=0-3)}{C_2H_5OOC(CH{=}CH)_nCHO} + CH_3NO_2 \rightarrow \underset{(\text{LXXXVIII})}{C_2H_5OOC(CH{=}CH)_nCH(OH)CH_2NO_2} \rightarrow \underset{(\text{LXXXIX})}{\rightarrow C_2H_5OOC(CH{=}CH)_{n+1}NO_2}.$$



To achieve the dehydration, the hydroxynitro-compounds (LXXXVIII, n = 0–2) are converted into halogenonitro-derivatives, which can be dehydrohalogenated by treatment with sodium acetate, without isolation. In the synthesis of the ethyl ester of ω-nitronona-2,4,6,8-tetraenoic acid (LXXXIX, n = 3) it is best to carry out the dehydration directly by passing the compound down an alumina column. The yields of the nitro-acid esters are satisfactory. The nitro-esters (LXXXIX, n = 1–3) of the *trans*-series, which were formerly unknown, were obtained in this way.

Amino-Aldehydes

A general method for the synthesis of ω-dimethylamino-polyenals (XC) and ω-*N*-methyl-*N*-phenylpolyenals (XCI) with fairly high yields (50–70%) has been described[75-77]:

$$\underset{(\text{XCII})}{[RR'N(CH{=}CH)_nCH{=}NRR']X} \xrightarrow{OH^-} \underset{\substack{(\text{XC},R=R'=CH_3)\\(\text{XCI},R=CH_3;\ R'=C_6H_5)}}{RR'N(CH{=}CH)_nCHO}.$$

However, a general procedure for the synthesis of compounds (XCII) has not been developed. Thus compound (XCII, n = 2) is most conveniently obtained by the reaction of secondary amines with an alcoholic solution of 1-(2′,4′-dinitrophenyl)pyridinium halide at 60–70°:[76,77]

$$\xrightarrow{RR'NH} (\text{XCII}, n = 2).$$

Compound (XCII, n = 3) can be obtained by the reaction[75]:

$$\underset{(n=2)}{(\text{XC}) \text{ or } (\text{XCI})} \xrightarrow[H^+]{HC{\equiv}CMgBr} HC{\equiv}C(CH{=}CH)_2CHO \xrightarrow[RR'NH\cdot HClO_4]{RR'NH} (\text{XCII}, n = 3, X = HClO_4).$$

For this purpose, the amino-aldehyde (XC, n = 2) or (XCI, n = 2) is allowed to react with ethynylmagnesium bromide, after which the product is hydrolysed with sulphuric acid. The resulting hepta-2,4-dien-6-ynal is treated with a mixture of dimethylamine and dimethylammonium perchlorate or of *N*-methylaniline and *N*-methylanilinium perchlorate, compounds (XCII, R = R′ = CH, n = 3) (yield 38%) or (XCII, R = CH_3, R′ = C_6H_5, n = 3) (yield 93%) being obtained.

Finally the following synthetic procedure has been developed for compounds of the series (XCII, n = 4–6, X = $HClO_4$)[75]:

$$\underset{(n=2-4)}{(\text{XCI})} \xrightarrow[2.\ H^+]{1.\ CH_3OCH{=}CHC{\equiv}CMgBr} \underset{(\text{XCIII})}{CH_3OCH{=}CHC{\equiv}C(CH{=}CH)_nCHO} \xrightarrow{H_2} \underset{(\text{XCIV})}{CH_3O(CH{=}CH)_{n+2}CHO} \xrightarrow[RR'NH\cdot HClO_4]{RR'NH} (\text{XCII}, n = 4-6, X = HClO_4).$$

The amino-aldehydes (XCI, n = 2–4) are condensed with 1-methoxybut-2-en-4-ynylmagnesium bromide, the product is hydrolysed with a solution of tartaric acid, and the resulting enyne methoxy-aldehydes (XCIII) are hydrogenated in the presence of Lindlar's catalyst. Treatment of the unstable polyene methoxy-aldehydes (XCIV) with secondary amines and the corresponding perchlorates yields the required compound (XCII). The above reaction constitutes at the present time the only way of synthesising compounds of this type. Despite the satisfactory yields at all stages, this procedure is inconvenient because of the large number of stages involved.

Amino-Acid Esters

The Wittig reaction between amino-aldehydes and diethyl ethoxycarbonylmethylphosphonates has been proposed for the synthesis of amino-acid esters[73]. For example:

$$(\text{XCI}, n = 2) + (C_2H_5O)_2P(O)CH_2COOC_2H_5 \rightarrow RR'N(CH{=}CH)_3COOC_2H_5,$$

where the yield is 40% for R = R′ = CH_3 and 70% for R = CH_3 and R′ = C_6H_5. Isomers which are fully in the *trans*-configuration are formed.

Hydroxy-Aldehydes

The hydroxy-aldehydes of the polyene series are the enol forms of dialdehydes of the type of glutaconic aldehyde and are known in the form of salts and benzoates (XCV). The sodium salts of hydroxy-aldehydes (XCVI, n = 1–3) are formed on heating dimethylaminopolyenals (XC) with aqueous methanolic sodium hydroxide solution[75]:

$$(\text{XC}) \rightarrow \underset{(\text{XCVI})}{NaO(CH{=}CH)_nCHO}.$$

The salts (XCVI, n = 1, 2) are formed in 90–95% yields, while the yield of the salt (XCVI, n = 3) is low. The dimethylaminopolyenal (XC, n = 4) does not hydrolyse under these conditions at all. Although the compounds (XC, n = 3, 4) are capable of undergoing hydrolysis on heating with a solution of potassium hydroxide in a mixture of water and 1-methylpyrrolidone, the compounds (XC, n = 5, 6) are no longer hydrolysed under these conditions. The change in the reactivity of dimethylaminopolyenals (XC) with increase in the number of double bonds can be explained by the weakening of the electronic effect (+M-effect) of the dimethylamino-group of the aldehyde group with increasing chain length:

$$\underset{(\text{XC})}{(CH_3)_2\ddot{N}{-}(CH{=}CH)_n{-}CH{=}O}.$$

The benzoates (XCV) are formed when benzoyl chloride is allowed to react with pyridine solutions of potassium salts of hydroxy-aldehydes[75]:

$$\underset{(n=2,3,4)}{KO(CH{=}CH)_nCHO} + C_6H_5COCl \rightarrow \underset{(\text{XCV})}{C_6H_5COO(CH{=}CH)_nCHO}.$$

ωω-Dichloro-Aldehydes

A number of unbranched ωω-dichloropolyenals (XCVII) have been described[78,79]. In their synthesis the readily available ωω-dichloroacrolein is converted into an acetal which is then allowed to react with ethyl vinyl ether, according to the general procedure for the synthesis of polyenals:

$$Cl_2C{=}CHCH(OC_2H_5)_2 \xrightarrow{CH_2{=}CHOC_2H_5} Cl_2C{=}CHCH(OC_2H_5)CH_2CH(OC_2H_5)_2 \xrightarrow{H^+} \rightarrow Cl_2C{=}CHCH{=}CHCHO \xrightarrow{HC(OC_2H_5)_3} Cl_2C{=}CHCH{=}CHCH(OC_2H_5)_2 \rightarrow \rightarrow Cl_2C{=}CH(CH{=}CH)_nCHO.$$

(XCVII)

The chain growth reaction is performed in the presence of zinc chloride and boron trifluoride-ether and the hydrolysis is carried out by heating with a 15% solution of sodium acetate in 85% acetic acid: ωω-dichloropolyenals (XCVII, n = 1–4) are obtained in a yield of 70–90%.

ωω-Dichloro-Alcohols

A series of ωω-dichloropolyene alcohols (XCVIII) have been obtained[79] by the reduction of ωω-dichloropolyenals (XCVII) with lithium aluminium hydride (yield 40–50%):

$$(XCVII) \rightarrow Cl_2C{=}CH(CH{=}CH)_nCH_2OH.$$
$$(XCVII),\ n = 1{-}4)$$

ωω-Dichloro-Acids

ωω-Dichloropolyene acids (XCIX) have been obtained by the oxidation of ωω-dichloropolyenals (XCVII) with silver oxide[78], the yield being 30–37%:

$$(XCVII) \rightarrow Cl_2C{=}CH(CH{=}CH)_nCOOH.$$
$$(XCIX)$$

In addition, another method has been proposed for the synthesis of these acids[73]. In this procedure ωω-dichloropolyenals (XCVII) are converted into esters of ωω-dichloro--acids (C) by reaction with the diethyl ester of ethoxycarbonylmethylphosphonic acid and then compound (C) is subjected to alkaline hydrolysis, which results in a high yield of ωω-dichloro-acids (XCIX) containing one double bond more than the initial ωω-dichloropolyenals (XCVII):

$$(XCVII) + (C_2H_5O)_2P(O)CH_2COOC_2H_5 \rightarrow \underset{(C)}{Cl_2C{=}CH(CH{=}CH)_{n+1}COOC_2H_5} \rightarrow (XCIX).$$

It is quite evident from the data presented above that a wide variety of polyenes with different substituents at the ends of the chain have now become accessible.

IV. SOME PROPERTIES OF POLYENES

Those properties of substituted polyenes with different functional groups which have been investigated to elucidate the effect on them of the length of the polyene chain or the effect on the properties of the functional group due to the substituents in the ω-position will be considered in this section. It is noteworthy that in the literature there still persists a quite definite view on this subject, which arose as a result of a comparison of the reactivities of saturated compounds, on the one hand, and of mono-olefins and dienes, on the other. In the first place this view is in conflict with the well known and long established analogy between the behaviour of certain saturated and unsaturated compounds in reactions, which gave rise to the concept of vinylogy — the transfer of the mutual influence of atoms along a system of conjugated double bonds, the concept having now become firmly established in organic chemistry. The principle of vinylogy proved very fruitful and made it possible to explain many facts. However, within the framework of synthetic chemistry the limits of the application of this principle to the series of aliphatic conjugated polyenes have not been investigated and it has been assumed *a priori* that the principle of vinylogy is applicable to all $X(CH{=}CH)_nY$ systems, regardless of the chain length and the structure of the end groups. This hypothesis is still to be found in monographs and text books on theoretical organic chemistry.

Wide acceptance of this view has been favoured both by studies of the properties of $X(CH{=}CH)_nY$ systems, where n = 1 or 2 or X and Y are the conjugated groups (as in cyanine and polymethine dyes), and the results of the first quantum-mechanical calculations, which showed that, when the length of the polyene chain increases, an equalisation of bond orders and hence of the lengths of double and single bonds apparently takes place. However, the use of various methods (the molecular orbital–linear combination of atomic orbitals method, the valence bond method, and the free electron method) in subsequent quantum-mechanical calculations demonstrated unambiguously that in the ground electronic state polyenes are systems with an alternating charge density, the density maxima corresponding to the double bonds in the classical formula.

We shall examine further the results of studies on the transfer of the mutual influence of atoms along the chain.

Polarographic Reduction of Polyenes

The polarographic reduction of the polyenals $CH_3(CH{=}CH)_nCHO$ (n = 1–5)[80–82] in aqueous dioxan buffer solutions has been investigated in the pH range 1–11. The dependence of the half-wave potential and the ratio $id/Cm^{2/3}t^{1/6}$ on the pH of the medium and the number of double bonds has also been studied. The investigators adopted the following mechanism for the reduction at a dropping mercury electrode:

$$CH_3(CH{=}CH)_nCHO + H^+ + e \rightleftarrows CH_3(CH{=}CH)_n\dot{C}HOH \rightarrow \rightarrow CH_3(CH{=}CH)_nCH(OH)-CH(OH)(CH{=}CH)_nCH_3.$$

In the range pH 1–11 one distinct polarographic wave was observed and, over a narrower pH range, a second wave of the same height as the first occurred at pH values which were lower the greater was the number of double bonds. The ratio $id/Cm^{2/3}t^{1/6}$ for the first and second waves is approximately the same and independent of the pH and the number of double bonds. The half-wave potentials of both waves are displaced towards less negative potentials with increase in the number of double bonds, the increment per double bond becoming smaller as the chain length increases. Thus the difference between the half--wave potentials of crotonic and sorbic aldehydes is 0.23 V, while that between the values for deca-2,4,6,8-tetraenal and dodeca-2,4,6,8,10-pentaenal is only 0.07 eV. The same has also been found for the half-wave potential of the second wave.

Thus accumulation of double bonds facilitates the polarographic reduction of polyenals, but the introduction of each new double bond makes an increasingly smaller contribution to the polarographic behaviour of the molecule. The diffusion coefficient D of polyenals, calculated from the Ilkovič equation, also tends to decrease to a definite limit:

n	1	2	3	4	5
D, 10^6 cm^2 s^{-1}	6.1	5.3	5.1	4.3	4.2.

Dipole Moments of Polyenes

The dipole moments of the dimethylaminopolyenals $(CH_3)_2N(CH{=}CH)_nCHO$ (n = 0–4) in benzene solution have been determined at 25° [83] and the following values (dipole moments μ in Debye units) have been found:

n	0	1	2	3	4
μ	3.86	6.24	7.62	8.24	8.50.

It is evident that the dipole moments increase with chain length, but the difference between the values of μ for adjacent members decreases, i.e. the dipole moment tends to a limit.

On the basis of the data obtained and the calculation of the charge transfer from end to end along the system of conjugated double bonds using various stereochemical models, it was concluded [83] that each end-group has a restricted sphere of action, extending approximately over three double bonds.

Infrared Spectra

Infrared spectroscopy is widely used to characterise substituted polyenes with different functional groups (see, for example, Lapitskii et al. [56]), but few papers dealing with the effect of the number of double bonds or the relative positions of the functional groups on the infrared spectra of polyenes have been published. In 1948 the infrared spectra of the dimethylpolyenes $CH_3(CH{=}CH)_nCH_3$ (n = 2–6), the polyenals $R(CH{=}CH)_nCHO$ (R = CH_3, α-furyl, n = 1–4), and the corresponding azines were investigated in the range 1440–1900 cm^{-1} to elucidate the effect of the accumulation of conjugated double bonds on absorption in the region corresponding to double bond vibrations. On the basis of their data, the investigators concluded that the vibration bands associated with the double bonds are displaced towards lower frequencies with increase in the number of double bonds, the charge per double bond decreasing with the number of such bonds [84].

The infrared spectra of compounds of the type $X(CH{=}CH)_nCOOC_2H_5$ with all the double bonds in the *trans*-configuration, where X = CH_3 (n = 1–4), $COOC_2H_5$ (n = 1–7), CHO (n = 1–4), NO_2 (n = 1–4), and OC_2H_5 (n = 1, 2), were investigated recently [85], special attention being devoted to the problem of the mutual influence of the end-groups via the system of conjugated double bonds. The CO stretching frequencies in the spectra of these compounds are presented in Table 1 as a function of the number of double bonds. Table 1 shows that in the spectra of the compounds investigated the CO stretching frequencies due to the ethoxycarbonyl group approach one another as the length of the polyene chain increases: the maximum differences between the frequencies amount to 24 cm^{-1} for n = 1, 16 cm^{-1} for n = 2, 7 cm^{-1} for n = 3, and only 3 cm^{-1} for n = 4. Hence the authors concluded that the mutual influence of atomic groups in the ground electronic state of the molecule decays rapidly with increase in the length of the intervening chain of conjugated bonds.

TABLE 1. CO vibration frequencies in the compounds $X(CH{=}CH)_nCOOC_2H_5$ (in carbon tetrachloride, values of ν in cm^{-1}).

n	R					
	CH_3	NO_2	CHO		$COOC_2H_5$	OC_2H_5
1	1724	1735	1733	1704	1730	1711
2	1718	1727	1725	1695	1721	1711
3	1714	1721	1718	1688	1715	
4	1715	1717	1716	1688	1714	
5					1713	
6					1713	
7					1714	

It has also been established that the intensity of the infrared absorption bands in the region of 1600 cm^{-1} (vibrations of the polyene chain) is determined mainly by the number of double bonds (increasing with the latter) involved in the vibrations, the relation between the absolute integral intensity of the absorption bands in the region of 1600 cm^{-1} and the number of double bonds being linear. On the basis of the experimental data and a comparison of the experimental and calculated relative intensities of the absorption bands in the region of 1600 cm^{-1}, it was concluded [85] that there is an alternation of charges at carbon atoms along the polyene chain.

Yukhnovski [86], who compared the frequencies and the integral intensities associated with the nitrile group in β-phenyl-substituted trans-α-cyanostilbenes and the corresponding benzonitriles, also concluded that the effect of substituents on the frequency and integral intensity of the band due to the nitrile group in compounds of the type *trans*-$RC_6H_4CH{=}CH(C_6H_5)CN$ weakens with increase in the length of the conjugation chain.

Raman Spectra

The Raman spectra of the diethyl esters of the polyene-$\alpha\omega$-dicarboxylic acids $C_2H_5OOC(CH{=}CH)_nCOOC_2H_5$ (n = = 1–8) have been analysed [87]. The frequencies ω of the most intense lines of the Raman spectra of acetone solutions of these compounds are presented in Table 2 (exciting light–the Hg*e* mercury blue line, frequency μ = 22 938 cm^{-1}). The lines with the frequencies ω_1 and ω_2 characterise the vibrations of the polyene chain and the line with the frequency ω_3 characterises the behaviour of the carbonyl group. The spectra of the diesters with n = 6–8 contain overtones, because these absorption bands and the exciting lines occur in the resonance region.

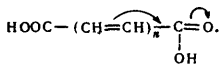


TABLE 2. Principal frequencies (in cm^{-1}) of the Raman spectra of $C_2H_5OOC(CH{=}CH)_nCOOC_2H_5$.

n	ω_1	ω_2	ω_3	n	ω_1	ω_2
1	1210	1664	1733	5	—	1570
2	1135	1644	1726	6	1142	1562
3	1139	1621	1721	7	1140	1550
4	1139	1596	1717	8	1137	1540

Analysis of the vibration frequencies of the polyene diesters led to the conclusion[87] that, in the first place, there is a comparatively small change in the vibration frequencies of the polyene chain as its length increases and examination of compounds in the range from $n = 3$ to $n = 8$ shows that in long chains of conjugated double bonds there is no appreciable "equalisation" of the multiple bonds. In the second place, since with increase in chain length the addition of each new unit has a smaller effect on the frequencies, the mutual influence of the atomic groups becomes weaker as the length of the intervening chain of conjugated double bonds becomes greater.

pK_a Values of Polyenoic Acids

To elucidate the effect of electron-acceptor substituents on the pK_a values of polyenoic acids, the latter were determined for $CH_3(CH=CH)_nCOOH$ and $HOOC(CH=CH)_nCOOH$ ($n = 1-4$).[88] The data obtained are presented in Table 3. The lower pK_a values of dicarboxylic acids compared with the monocarboxylic acids when $n = 1$ and 2 can be explained by the enhanced acidity of the dicarboxylic acid due to the $-M$-effect of the second carbonyl group:

The appreciable increase of the pK_a on going from muconic acid to octa-2,4,6-triene-1,8-dioic acid indicates a weakening of the $-M$-effect, i.e. a rapid decay of the effect of the electron-acceptor carboxy-group on the pK_a.

Ultraviolet Spectra

The relation between the length of the polyene chain and the positions and intensities of the bands in the electronic absorption spectra has attracted the attention of investigators for a long time. The studies in this field were made in 1935 by Hausser and Kuhn[89-92], who investigated the ultraviolet spectra of the polyenals $CH_3(CH=CH)_nCHO$ ($n = 1-3$), the polyenemonocarboxylic acids $CH_3(CH=CH)_nCOOH$ ($n = 1-4$), α-furylpolyenals and α-furylpolyenoic acids ($n = 1-3$), and also the diphenylpolyenes $C_6H_5(CH=CH)_nC_6H_5$ ($n = 1-7$). It was established that (1) the introduction of each new double bond causes a shift of the band towards the visible part of the spectrum and (2) the magnitude of the shift decreases with the number of double bonds.

Subsequently the ultraviolet spectra of polyenes were investigated by a number of workers. Thus one may refer to the work of Blout and Fields[93], who investigated the polyenals $CH_3(CH=CH)_nCHO$ ($n = 1-7$), the dimethylpolyenes $CH(CH=CH)_nCH_3$ ($n = 1-7$), the ω-furylpolyenals ($n = 0-6$), and certain azines. In other investigations dimethylpolyenes[94-96], *NN*-dimethylaminopolyenals[75], ferrocenylpolyenes[97], etc. were studied. All these investigations confirmed the principal conclusions of Hausser and Kuhn. Furthermore, a comparative study of the spectra of ω-dimethylaminopolyenals, the sodium salts of ω-hydroxypolyenals, and $[(CH_3)_2N(CH=CH)_nCH=N(CH_3)_2]HClO_4$ led to the conclusion[75] that the spectra of the linear polyenes $X(CH=CH)_nY$ differ in principle from the spectra of polyene cyanine dyes and from the spectra of polyene molecules with charges at the end of the chain, of the type $\bar{O}(CH=CH)_nCHO$.

TABLE 3. pK_a values for certain polyenoic acids (in 50% aqueous alcohol).

n	$CH_3(CH=CH)_nCOOH$ pK_a	$HOOC(CH=CH)_nCOOH$ pK_{a_1}
1	4.66	2.98
2	4.62	2.70
3	5.37	5.01
4	5.42	5.11

There exist very numerous data on the ultraviolet spectra of isoprenoids with different functional groups, such as vitamin A and carotenoids, because the spectra are widely used to characterise compounds of this kind. However, the presence of methyl side-groups and in many cases the complexity of the end-groups make the interpretation of the optical properties difficult, but several empirical equations relating the position of the absorption bands to the structure of polyenes of this kind have been postulated[98-100]. In this connection we shall examine the studies dealing with unbranched polyenes with different functional groups. Table 4 lists the principal absorption maxima of the unbranched polyenes.

Analysis of the ultraviolet spectra of linear polyenes led to the following conclusions[101].

1. The replacement of the methyl group in a dimethylpolyene by an electron-donor or an electron-acceptor substituent causes a bathochromic shift, which increases in the following sequence of substituents:

$$OC_2H_5 < COOC_2H_5 < CHO \leqslant COCH_3 < NO_2.$$

TABLE 4. Principal absorption maxima of polyenes (solvent – alcohol, other solvents indicated in brackets, literature references indicated in footnotes).

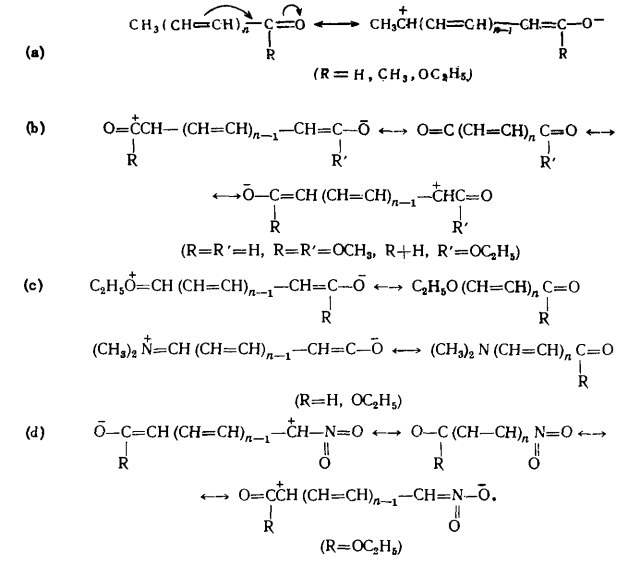
[a]Ref. 101; [b]Ref. 93; [c]Ref. 102; [d]Ref. 103; [e]Refs. 104 and 105; [f]Ref. 106; [g]Ref. 107; [h]Ref. 108; [i]Ref. 109; [j]Ref. 110; [k]Ref. 74; [l]Ref. 73.



2. The replacement of the methyl group in the series $CH_3(CH=CH)_nR$, where R = CHO or $COOC_2H_5$, by electron-acceptor groups in which one carbon atom is linked by a multiple bond to the atom of another element (CHO, $OCCH_3$, $COOC_2H_5$, CN) gives rise to very slight hypsochromic or bathochromic shifts, whose absolute magnitude does not exceed 10 nm (see also Refs. 111 and 112).

3. The replacement of the methyl group in CH_3. $.(CH=CH)_nCOOC_2H_5$ by the nitro-group results in an appreciable bathochromic shift (30–59 nm).

4. The replacement of the methyl group in the series $CH_3(CH=CH)_nR$, where R = CHO or $COOC_2H_5$, by an electron donor group causes an appreciable bathochromic shift (29–75 nm).

In the last two cases the bathochromic shift increases as the double bonds accumulate.

The observed features were explained by the nature of the polarisation of the molecules in the excited state[101]:

In case (a) the electrons in the molecule in the excited state are displaced in the direction indicated by the arrow and therefore the introduction of the CO group is equivalent to the introduction of yet another double bond. When a second chromophore of the type of CO is introduced into the ω-position in the molecule, simultaneous polarisation of both CO groups is unlikely and therefore the observed displacement of the band is similar to that which occurs on introduction of a single substituent [case (b)]. In case (c) the free electron pair of nitrogen or oxygen participates in conjugation, which makes a considerable contribution to the excited state of the molecule, the mobility of the electrons of the auxochromes and the decrease of the polarisation energy becoming more pronounced as the chain length increases. Finally, as a result of the considerable difference in the polarisation energies of the ethoxycarbonyl and nitro-groups, in case (d) polarisation probably occurs preferentially at the group for which the polarisation energy is smaller, which can alter the principal absorption maximum, compared with the corresponding monosubstituted polyenes.

UBIQUINONES (COENZYME Q)

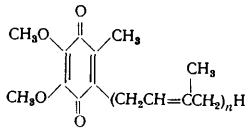
G. I. Samokhvalov and E. A. Obol'nikova

CONTENTS

I. Discovery and natural sources of ubiquinones 414

II. Determination of the structure of ubiquinones 414

III. Synthesis of ubiquinones 415



IV. Conversion products of ubiquinones 418

V. Biosynthesis of ubiquinones 419

VI. Role of ubiquinones in electron transport in oxidative phosphorylation. Hypotheses concerning the possible mechanism of the process 421

VII. Certain biological and therapeutic functions of ubiquinones in animals and in man 424

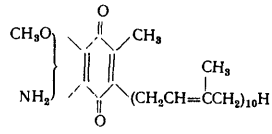
The studies carried out in recent years demonstrate the outstanding role of substituted quinones, ubiquinones (coenzyme Q) (I), in intracellular electron transport coupled with oxidative phosphorylation [1-8]:

(I)

The data on this new group of coenzymes are collected in the present review and certain hypotheses concerning the participation of quinones in intermediate reactions in oxidative phosphorylation are considered.

I. DISCOVERY AND NATURAL SOURCES OF UBIQUINONES

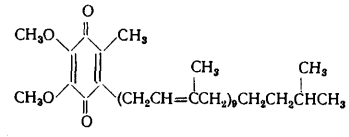
At the end of 1955 a group of investigators at the University of Liverpool carried out experiments designed to elucidate the mechanism of the effect of vitamin A in growth processes and in cases of xerophthalmia [9]. They isolated from the mucus membrane of the horse intestine a substance, the spectrum of which had characteristic absorption maxima at 272 and 400 nm. [10,11] Somewhat later the same investigators isolated chromatographically from the non-hydrolysable fraction of liver lipids and other mammalian tissues (under normal conditions and under conditions of vitamin A deficiency) other analogous fractions which were denoted by the letters SA, SB, and SC. [12-16] It was further elucidated that the substance in fraction SA is identical with that isolated from the intestine and that it is indeed present in human and animal liver, kidneys, spleen, blood, and pancreas and is localised within the cell [17-22]. It was established that the substance of the fraction SA contains a cyclic group of the quinone type and a side-chain with a definite number of double bonds. The compound was given the name "ubiquinone", which indicates its chemical type and wide distribution in nature [17,18,20].



Simultaneously with the investigations in Liverpool, Swiss chemists of the Hofmann-La Roche Company [23,24] isolated two ubiquinones from pig heart and from yeast after processing a large amount of natural material. The first ubiquinone had a side-chain of ten isoprenoid units in position 6 — ubiquinone(50) or UQ_{10} — and the second a side-chain of six isoprenoid units — ubiquinone(30) or UQ_6. Soon the same investigators achieved the synthesis of UQ_6 and UQ_{10} and also of their homologue UQ_9 and showed that these quinones are identical with the natural compounds [24,25].

In 1957 yet another group of investigators, from Wisconsin University, published their work on the isolation from beef heart mitochondria of a substance with properties characteristic of quinones and called coenzyme Q_{275} (quinone with an ultraviolet absorption maximum at 275 nm) [26,27]. Soon, in collaboration with the American chemists of the Merck Company (New Jersey), the investigators from Wisconsin demonstrated the identity of coenzyme Q_{275} with the ubiquinones discovered by the workers of the Liverpool school and in Switzerland [28-30].

At the Fourth International Biochemical Congress in Vienna in 1958 the reports of all the groups of investigators were presented and the identity of the compounds confirmed. In 1961 the Committee on Enzymes of the International Biochemical Union [31] recommended the name "ubiquinone" to unify the terminology for this class of substances, in view of the fact that the nature of this cofactor had already been established.

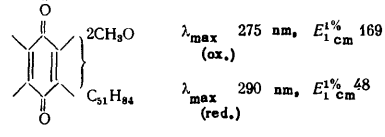


Natural ubiquinones (UQ_6, UQ_7, UQ_8, UQ_9, and UQ_{10}) have been found in various tissues of animals [10-13,15,16,19,24-26,32-38] and plants [39,40] and in micro-organisms [23,28,41-46]. UQ_6, [23,28,45,46] UQ_7, [28,45,47] and UQ_8 [28,45,47] are encountered almost exclusively in micro-organisms, only traces being found in animals [47]. UQ_9 [25,28,37,38,40,45,47] and particularly UQ_{10} [11,14,21,24-26,34-41,44,45,47] are distributed mainly in animals and in higher plants [48], and UQ_9 is found in vegetable oil [30] and in aloe [37]. The heart tissue of rhesus monkeys contains UQ_{10}. These animals are suitable objects for UQ_{10} tests in various diseases. UQ_{10} has been found in the nerve tissue of the frog. This fact can be used in the investigation of the role of UQ_{10} in neurology. UQ_{10} has also been found in tumour tissues in man and in rodents [49]. In man UQ_{10} has been isolated from heart tissue and other organs [38,50]. A comparative estimate of the content of ubiquinone(50) in various organs showed that the organism of the adult man contains 0.5–1 g of UQ_{10}.

Micro-organisms are capable of synthesising all the natural homologues of ubiquinones (UQ_6–UQ_{10}). [24,28,38,45] The cells of *Ochromonas mathamensis* produce UQ_{10} and those of *Polyporous schweinitzii* both UQ_9 and UQ_{10}. [49] An analogue of UQ_{10}, rhodoquinone with one free amino-group (II), [51] has been isolated from a culture of *Rhodospirillum rubrum*:

(II)

Another representative of the group of ubiquinones has been isolated from the cells of *Gibberella fujckuroi* and *Penicillum stipitatum* [52,53]. Identification of this compound, obtained from two types of culture, showed that the tenth isoprenoid residue of the side-chain is saturated. This new compound, called UQ_{10}(H-10), has the structure (III): [53-55]



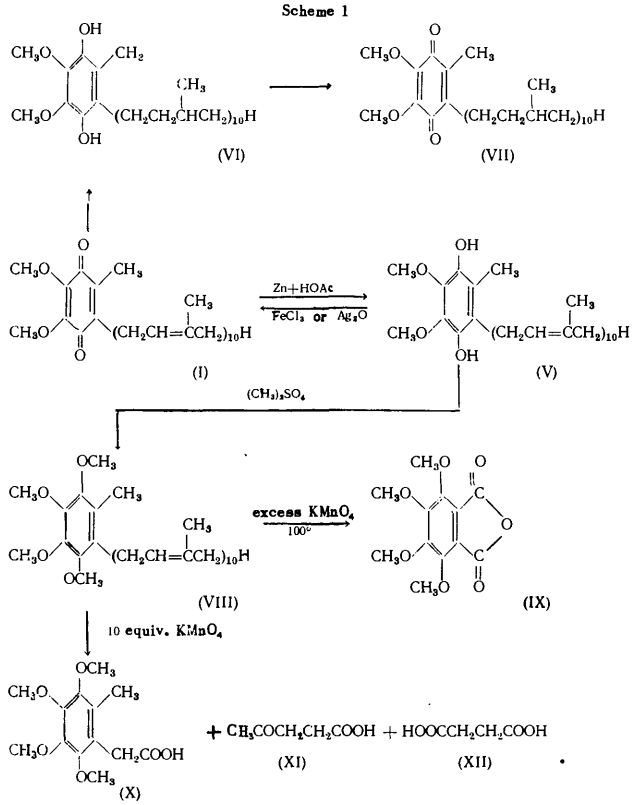
(III)

II. DETERMINATION OF THE STRUCTURE OF UBIQUINONES

1. Ubiquinone(50) (UQ_{10})

The general formula found [29] for UQ_{10} is $C_{59}H_{90}O_4$; the following partial formula (IV) has been put forward on the basis of the displacement of the ultraviolet maximum from 275 to 290 nm after reduction under mild conditions:

(IV)



Determination of the O–Alk residues showed the presence of two methoxy-groups. Since it was suggested that the UQ_{10} molecule contains the benzoquinone ring, the two CH_3O groups could occupy three different positions. Comparison of the ultraviolet spectra of UQ_{10} in the quinone and

hydroquinone forms with those of aurantiogliocladin[56] (2,3-dimethoxy-5,6-dimethyl-1,4-benzoquinone) revealed their close similarity. However, on the basis of these data, one cannot finally conclude that UQ_{10} is a derivative of 2,3-dimethoxy-5-methylbenzoquinone, because the ultraviolet spectra of 2,6-dimethoxy-3,5-dimethyl- and 2,5-dimethoxy-3,6-dimethyl-1,4-benzoquinones[57,58] differ only slightly from the ultraviolet spectra of the isomeric aurantiogliocladin.

Chemical conversions (Scheme 1) suggested that one of the substituents in the *p*-quinone ring of UQ_{10} is a polyisoprenoid chain[28,29]: on catalytic reduction of UQ_{10}, 11 moles of hydrogen are absorbed; eicosahydroquinone (VI) is formed and after oxidation is converted into eicosahydro-UO_{10} (VII). Oxidation of UQ_{10} with alkali and potassium permanganate leads to the formation of levulinic, acetic, and succinic acids. The isoprenoid nature of the side-chain of UQ_{10} has been confirmed by nuclear magnetic resonance[59] and a difference between the protons of the methyl groups of the ring and the isoprenoid chain has been demonstrated. Together with other evidence, the NMR data confirm to a large extent (but do not provide the final proof) the positions of the two CH_3O groups, one CH_3 group, and of the isoprenoid chain of ten units.

The positions of all the substituents in the quinone ring of UQ_{10} were finally demonstrated by oxidative degradation. Dimethylhydro-UQ_{10} (VIII) was obtained in a crystalline form by the reduction of UQ_{10} (I) to the hydroquinone (V) and exhaustive methylation. Oxidation of compound (VIII) with potassium permanganate in aqueous alkaline solution at 100° gave, after sublimation, tetramethoxyphthalic anhydride (IX). Oxidation of compound (VIII) with potassium permanganate in acetone gave 2-methyl-3,4,5,6-tetramethoxyphenylacetic (X), levulinic (XI), and succinic (XII) acids.

Scheme 1

Another group of investigators, who studied independently the structure of UQ_{10},[9,24] subjected ubiquinone(50) to reductive acetylation followed by oxidative degradation of diacetylhydro-UQ_{10} and isolated acetone and levulinic aldehyde in the form of 2,4-dinitrophenylhydrazones and also 3,6-diacetoxy-4,5-dimethoxy-2-methylphenylacetic acid, which was characterised via its *p*-toluidide derivative.

Thus chemical conversions and spectroscopic data carried out by different investigators showed that UQ_{10} is 2,3-dimethoxy-5-methyl-6-[3-methyl-2-butenylenakis--(3-methyl-2-butenylene)]-1,4-benzoquinone.

2. Ubiquinones(30), (35), (40), and (45) (UQ_6–UQ_9)

The ultraviolet spectra of various natural ubiquinones[60] are the same, but the extinction coefficient is inversely proportional to the length of the carbon chain (decrease of the mole fraction of the chromophore). Qualitatively the infrared spectra of ubiquinones are also the same[24]. Each of the natural ubiquinones is characterised by a different value of R_f in paper and thin-layer chromatography[61,62] and also by a different redox potential[63,64]. The molecular weight of ubiquinone homologues has been determined by the esterification of the OH group of the corresponding [^{14}C]-ubiquinols with acetic anhydride followed by the measurement of the ^{14}C radioactivity in the acetate derivatives[65]. These results confirm that each quinone differs from the succeeding homologue of the given group by one isoprene unit (I, n = 6–10). Thus the ubiquinones isolated from natural sources have been characterised as UQ_6 (*Saccharomyces cerevisiae*), UQ_7 (*Torulopsis utilis* A), UQ_8 (*Azotobacter vinelandii*), and UQ_9 (*Torulopsis utilis* B).[28]

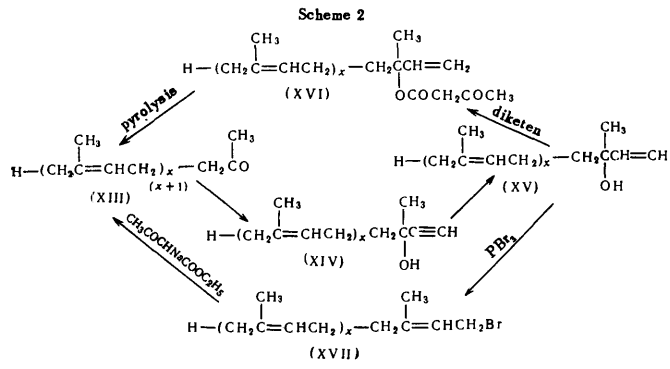
III. SYNTHESIS OF UBIQUINONES

1. Synthesis of the Polyisoprenoid Side-Chain

Formula (I) shows that ubiquinones contain an unsaturated side-chain with a variable number of isoprenoid units linked to one another "head to tail". The double bonds in the side-chain have the *trans*-configuration. The corresponding unsaturated terpenoid alcohols [of type (XV), see Scheme 2 and Table 1] with the all-*trans*-configuration of the double bonds, necessary for the synthesis of ubiquinones, were obtained by methods developed in recent years in the chemistry of isoprenoids.

Condensation of acetone (XIII, x = 0) with sodium acetylide in liquid ammonia followed by partial hydrogenation of the product (XIV, x = 0) gives methylbutenol (XV, x = 0).

Scheme 2



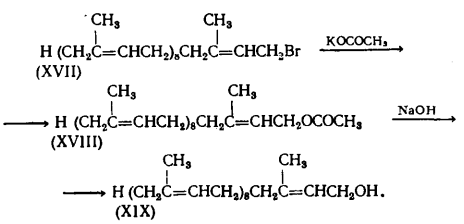


TABLE 1.

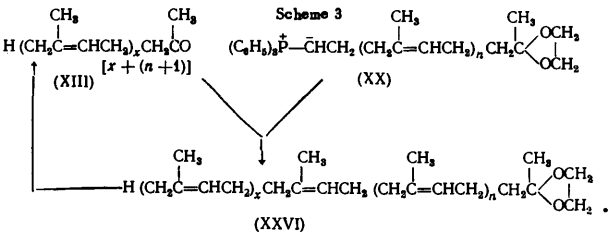
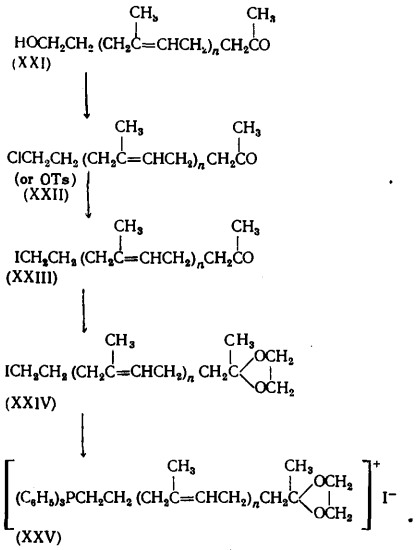
x	Ketones	Tertiary alcohols
0	C_5-ketone (A)	C_5-alcohol (methylbutenol)
1	C_8-ketone (methylheptenone)	C_{10}-alcohol (L)
2	C_{13}-ketone (GA)	C_{15}-alcohol (N)
3	C_{18}-ketone (FA)	C_{20}-alcohol (GL)
4	C_{23}-ketone (GGA)	C_{25}-alcohol (FL)
5	C_{28}-ketone (FGA)	C_{30}-alcohol (FN)
6	C_{33}-ketone (FFA)	C_{35}-alcohol (FGL)
7	C_{38}-ketone (FGGA)	C_{40}-alcohol (FFL)
8	C_{43}-ketone (FFGA)	C_{45}-alcohol (FFN) (isosolanesol)
9	C_{48}-ketone (FFFA)	C_{50}-alcohol (FFGL)

A = acetone, G = geranyl, F = farnesyl, L = linalo-ol, N = neralidol.

When the latter is condensed with diketen[66] and the resulting acetoacetate (XVI, $x = 0$) is pyrolysed, methylheptenone (XIII, $x = 1$) is obtained. Repetition of similar operations gives geranylacetone (XIII, $x = 2$) via linalo-ol (XV, $x = 1$); the new double bond in geranylacetone has the *trans*-configuration to the extent of two thirds and the *cis*-configuration to the extent of one third. Subsequent increase of chain length by one isoprenoid unit gives rise to farnesylacetone (XIII, $x = 3$).



One of the methods of synthesis of isoprenoid ketones consists in the preparation of primary bromides (XVII) from the corresponding tertiary vinyl carbinols (XV) and subsequent condensation with sodioacetoacetic ester[67]. The isoprenoid ketones (XIII) obtained in this way after ketonic hydrolysis contain 85% of the *trans*- and 15% of the *cis*-forms. Subsequent sixfold increments of the chain length of *trans*-geranylacetone (XIII, $x = 2$) by the C_5-unit [68,69] with separation of the stereoisomers gives the *trans*-C_{43}-ketone (XIII, $x = 8$). The latter is converted in the usual way into the primary C_{45}-bromide (XVII, $x = 8$), which is also obtained from the natural alcohol solanesol (XIX).[69,70] This bromide can be converted, via the C_{48}-ketone (XIII, $x = 9$), into the *trans*-tertiary alcohol (XV, $x = 9$) and the corresponding primary C_{50}-alcohol[69]. Treatment of the C_{45}-bromide (XVII, $x = 8$) with potassium acetate followed by hydrolysis of compound (XVIII) gives the C_{45}-alcohol (XIX) which is identical with the natural solanesol, as shown by the determination of the melting point of a mixed sample and a comparison of the corresponding X-ray diffraction patterns[25,69].

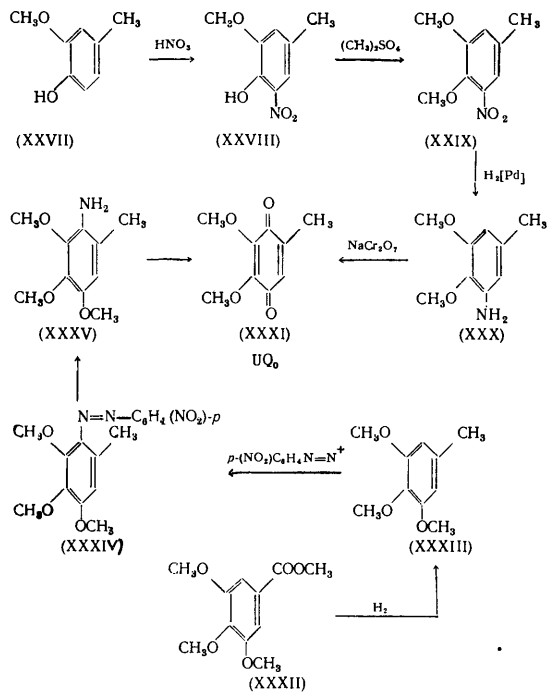


Another method of synthesising polyisoprenoid ketones consists in a gradual increase of the length of the carbon chain by mono-, di-, or tetra-isoprenoid units using difunctional compounds in the Wittig olefin addition reaction[71-73] (Scheme 3).

Isoprenoid ketones of the type of methylheptenone (XIII, $x = 1$), *trans*-geranylacetone (XIII, $x = 2$), and *trans*-farnesylacetone (XIII, $x = 3$) can be made to undergo the olefin addition reaction using the phosphorane (XX).[71-73]

Scheme 3

The bifunctional stereoisomeric phosphoranes (XX, $n = 0$ and $n = 1$) are synthesised from acetylpropanol (XXI, $n = 0$) [71] and the di-isoprenoid C_{10}-keto-alcohol (XXI, $n = 1$) respectively[72,73]: the OH group is replaced by iodine [compound (XXIII)], the carbonyl group is protected by the formation of the ethyleneketal (XXIV), the phosphonium salt (XXV) is formed, and the phosphorane is finally produced by further reaction with sodium methoxide in dimethylformamide:



The resulting ethyleneketals (XXVI) with the carbon chain lengthened by five and ten carbon atoms respectively and the isoprenoid ketones (XIII, $x = n + 1$) obtained from them by the hydrolysis of the ketal group are formed as a mixture of *cis*- and *trans*-isomers with respect to the new double bond, in proportions of 60 : 40. Individual *trans*-isomers required for subsequent syntheses are obtained by vacuum fractionation in the case of geranylacetone (XIII, $x = 2$) and farnesylacetone (XIII, $x = 3$). The *trans*-isomers of successive isoprenoid ketone homologues are isolated by crystallisation at low temperatures[65].

2. Synthesis of UQ_0

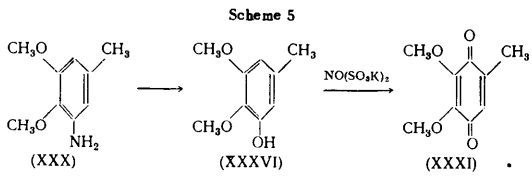
2,3-Dimethoxy-5-methyl-1,4-benzoquinone (XXXI) — the ubiquinone chromophore — has been called UQ_0 and its position in the series of ubiquinones is analogous to the position of menadione among vitamins K. However, the corresponding biological similarity between UQ_0 and menadione has not been observed[74]. UQ_0 was synthesised long before the discovery of the ubiquinone group[75] (Scheme 4).

Creosol (XXVII), obtained by the reduction of vanillin over $Pd/BaSO_4$ using the Rosenmund method[76], is converted into nitrocreosol (XXVIII),[77] the methylation of which gives 5-nitrohomoveratrol (XXIX). The reduction of the latter to 5-aminohomoveratrol (XXX) and oxidation

Scheme 4

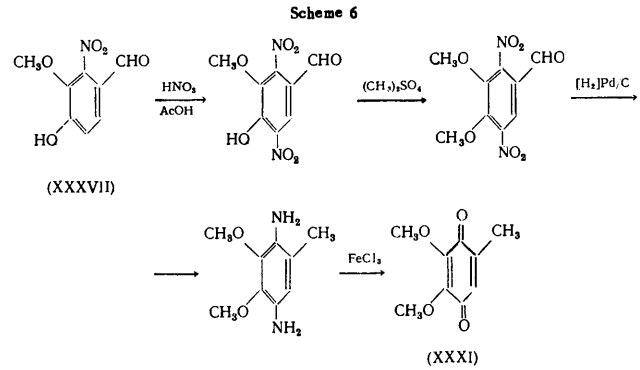
of the amine with sodium dichromate in sulphuric acid yield 2,3-dimethoxy-5-methylbenzoquinone (XXXI).

An alternative synthesis of UQ_0, from the ethyl ester of trimethylgallic acid, was described after the discovery and determination of the structure of ubiquinones[78]. Trimethylgallate (XXXII), obtained by the methylation of gallic acid[79], is reduced over a copper–chromium catalyst to 3,4,5-trimethoxytoluene (XXXVIII). Coupling with *p*-nitrophenyldiazonium salt and subsequent reduction of the diazo-compound (XXXIV) lead to trimethoxytoluidine (XXXV), which is oxidised to 2,3-dimethoxy-5-methylbenzoquinone (XXXI).



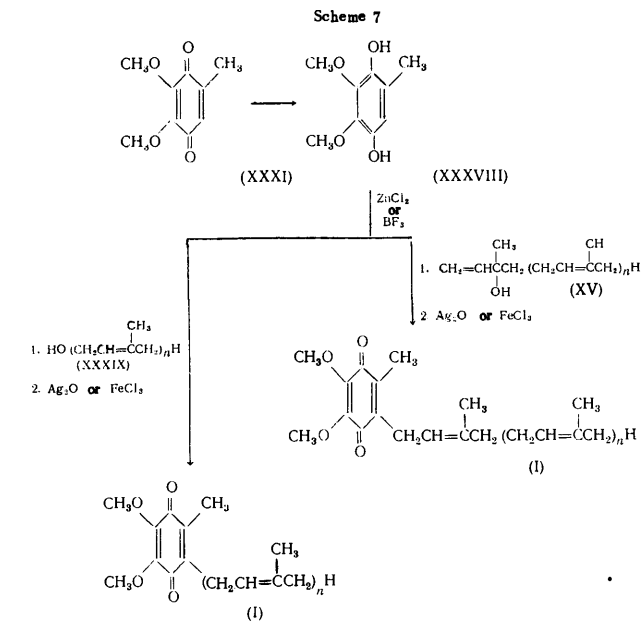
Other syntheses of UQ_0 described in the literature are modifications of the procedures already given above. It has been suggested[80] that 2,3-dimethoxy-5-methylphenol (XXXVI), obtained from aminohomoveratrol (XXX), be oxidised to 2,3-dimethoxy-5-methyl-1,4-benzoquinone (XXXI) with the aid of potassium nitrosodisulphonate (Fremy's salt) (Scheme 5).

In addition UQ_0 (XXXI) can be obtained from nitrovanillin (XXXVII) [8] by the series of conversions shown in Scheme 6.



3. Synthesis of UQ_1–UQ_{10}

The ubiquinones UQ_1–UQ_{10} have been synthesised[23,25,67,82–87] by the condensation of 2,3-dimethoxy-5-methylhydroquinone (XXXVIII) with the tertiary (XV) or primary allyl



Scheme 5

Scheme 6

Scheme 7

alcohol (XXXIX) to give the corresponding substituted hydroquinones (Scheme 7). Zinc chloride or boron trifluoride-ether or the two together are used as catalysts for this reaction. The hydroquinones are oxidised with silver oxide or ferric chloride to give the ubiquinones (I) (see Table 2).

The identity of the synthetic and natural products has been established by determining the melting points of mixed samples, by ultraviolet and infrared spectroscopy, by paper and thin-layer chromatography, and by X-ray diffraction. The last method proved to be exceptionally accurate for the identification of crystalline isoprenoid homologues[25].

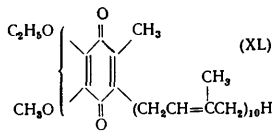


TABLE 2.

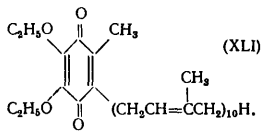

Synthetic quinone	M.p.	λ_{max} = 275 nm in petroleum ether		Synthetic quinone	M.p.	λ_{max} = 275 nm in petroleum ether

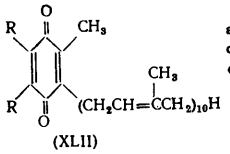
IV. CONVERSION PRODUCTS OF UBIQUINONES

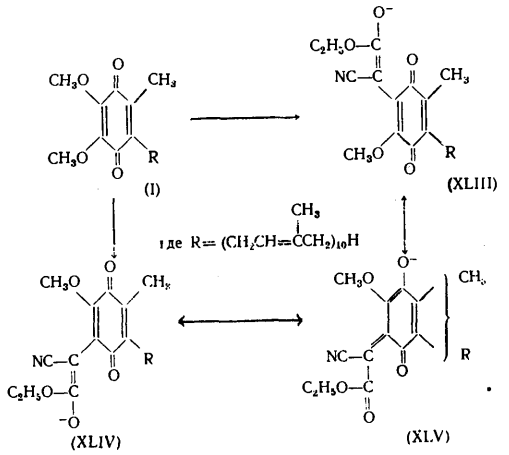


1. Products of the Nucleophilic Replacement of the Methoxy-Groups

The isolation of ubiquinones consists mainly in the hydrolysis of the test substance with hot alcoholic alkali, extraction of the non-hydrolysable lipids, purification of the extracts by column chromatography with the appropriate adsorbent, and crystallisation from polar solvents[32,33]. When ethanol is present in the hydrolytic process, there is a possibility of the nucleophilic replacement of the methoxy--groups, the amounts of the resulting monoethoxy- and diethoxy-derivatives, (XL) and (XLI), depending on the temperature and the duration of hydrolysis[50].

(XL)

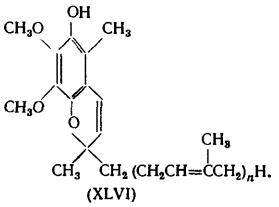
(XLI)



The capacity of the methoxy-groups of the ubiquinones to undergo nucleophilic replacement permits an approach to the synthesis of higher alkoxy-homologues (XLIIa), derivatives containing nitrogen and sulphur [(XLIIb) and (XLIIc) respectively], and the ubiquinone (XLIId) with a radioactive methoxy-group.

(XLII)

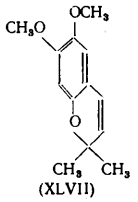
a) R=R'O; b) R=R'NH—, R'R"N—;
c) R=R'S—; d) R=$C^{14}H_3O$—;
e) R=$(CH_3)_2CHCH_2CH_2O$—;
f) R=$(CH_3)_2CHO$—.



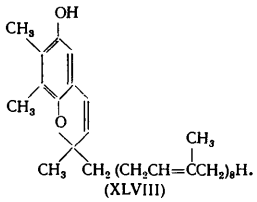
The di-isopentyloxy- and di-isopropoxy-homologues [(XLIIe) and (LXIIf) respectively], which are of definite interest in connection with the determination of the role of UQ_{10} in various enzymic systems, have been synthesised in this way[88].

The determination of UQ_{10} in human urine (a modification of the Craven reaction) is based on this principle[50]. The blue colour produced by the reaction of UQ_{10} with cyanoethyl acetate is due to the conversion of UQ_{10} (I) into compounds (XLIII), XLIV), and (XLV):

(I) (XLIII) (XLIV) (XLV)



2. Ubichromenols



Ubichromenol is the trivial name given to the ubiquinone isomer in which the third carbon atom of the side-chain forms a chromen ring with the quinone oxygen [compound (XLVI)]:

(XLVI)

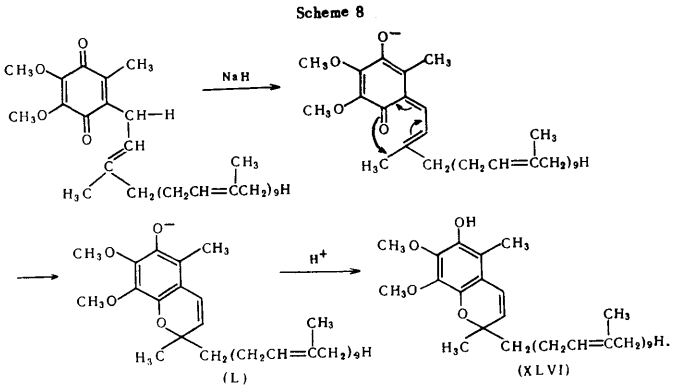
The nomenclature of ubichromenols is derived from the corresponding ubiquinones. The compound which is the isomer of ubiquinone(50) is called ubichromenol(50) although its side-chain contains only 46 carbon atoms. Ubichromenol(50) (XLVI, n = 9) has been isolated from the kidneys and liver of humans[89] and from the liver of rats suffering from vitamin A deficiency (the substance which was initially denoted by the letters SC [15,34,90-96]).

The structure of ubichromenol(50) was established in a study of its spectroscopic properties[91], by comparing them with those of two known chromens: ageratochromen (XLVII) [97] and solanochromen (XLVIII):[98]

(XLVII)

(XLVIII)

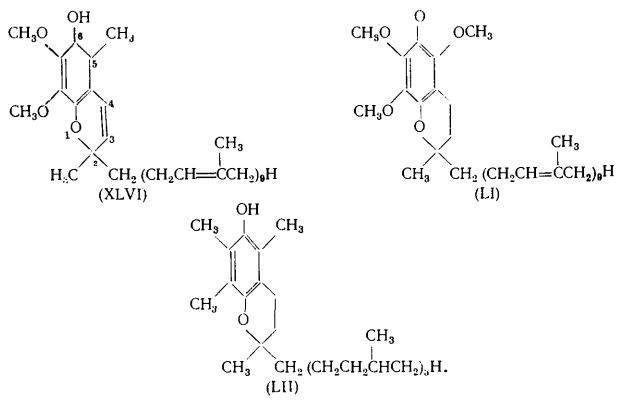
Thus it was shown that ubichromenol(50) (XLVI) is 2,5-dimethyl-7,8-dimethoxy-2-{[3-methyl-2-butenyloctakis--(3-methyl-2-butenylene)]methyl}-3-chromen-6-ol[91].



Ubichromenols can be obtained from ubiquinones by passing the latter through an alumina column with subsequent elution using various solvents with[93] and without[94,99] dilute hydrochloric acid. This reaction led to many doubts as to whether ubichromenol as such is a natural component of animal origin or whether it is formed as a result of isomerisation in the organism or during isolation[92,100-103].

Biosynthetic studies using the [2-^{14}C]lactone of mevalonic acid demonstrated convincingly that ubichromenol has a common precursor with ubiquinone and is a product of biosynthesis in the rat organism[104,105]. Furthermore, ubichromenol(50), isolated from human kidneys, is optically active[95,106], while the compound obtained by the cyclisation of UQ_{10} is racemic.

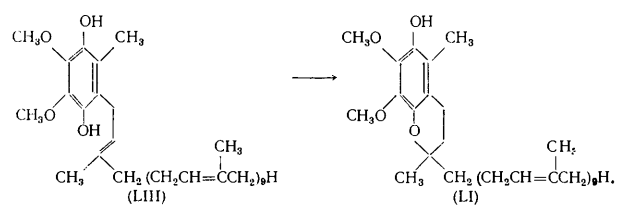
The synthesis of 6-chromenol (XLVI) in high yield has been achieved by the cyclisation of UQ_{10} under the influence of sodium hydride[107] (Scheme 8).



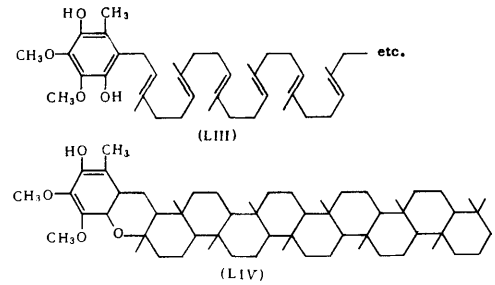
The elimination of a proton from the first carbon atom of the side-chain and the withdrawal of electrons towards the quinone oxygen in position 4 lead in all probability to the intermediate (XLIX) which is stabilised by the electron shift. The formation of the bond between the quinone oxygen in position 1 and the 3-carbon atom in the side-chain yields the 6-hydroxy-anion of 6-chromenol (L). When this intermediate is protonated, ubichromenol(50) (XLVI) is formed.

Scheme 8

Ubichromenols can also be obtained on a preparative scale from ubiquinones in the presence of pyridine [108].



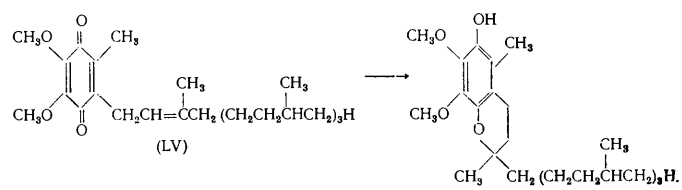
Certain common features in the structure of α-tocopherol (LII) and ubichromenol (XLVI) as well as its analogue saturated with respect to the 3,4-bond [ubichromanol (LI)] led to the investigation of the vitamin activity of these compounds.



However, it was found [109] that, while ubichromenol exhibits a definite vitamin E activity, ubichromanol (LI), which would appear to be more similar to α-tocopherol (LII), does not. In this connection, ubichromenol may be regarded as a non-specific antioxidant [110,111].

3. Ubichromanols

Interesting observations were made by Folkers in the preparation of the corresponding chromanol (LI) from ubiquinol(50) (LIII): [50]

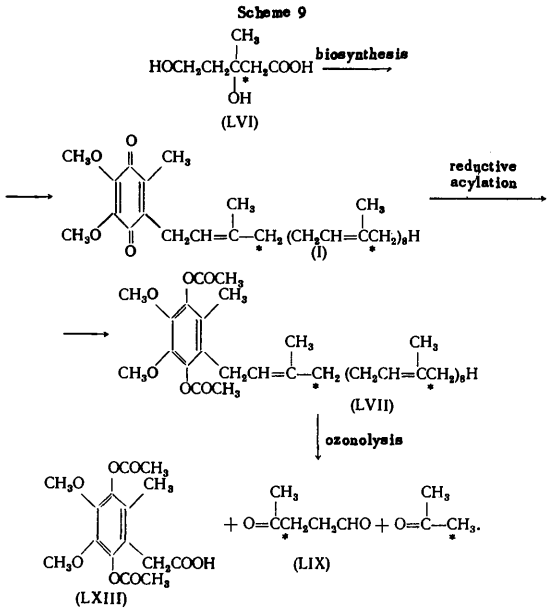


When ubiquinol(50) is treated with potassium bisulphate under conditions which are well known to be suitable for the preparation of 6-chromanols, the corresponding chroman (LI) is formed [112]. However, under the action of stannous chloride [113], instead of the expected product (LI) a mixture of substances was obtained in which, according to NMR spectroscopic data, there are protons characteristic of saturated hydrocarbons instead of the protons characteristic of the isoprenoid chain, and the *p*-hydroxy-group is absent. The authors believe that, as a result of the high reactivity of the isoprenoid side-chain, intramolecular condensation of the isoprenoid residues of compound (LIII) takes place in this case with formation of compound (LIV):

Different degrees of cyclisation of compound (LIII) were responsible for the formation of a mixture of substances.

The formation of the chromanol from hexahydroubiquinone(20) (LV) takes place in the usual way on boiling the quinone in glacial acetic acid in the presence of an excess of stannous chloride:

The double bond of the first, unsaturated isoprenoid unit of the phytol residue of compound (LV) becomes localised on formation of 6-chromanol; there are no other unsaturated centres which would favour the cyclisation of the side-chain of hexahydro-UQ_4. Hexahydroubiquinone(20) is the most convenient member of the ubiquinone group for various biological tests [114].

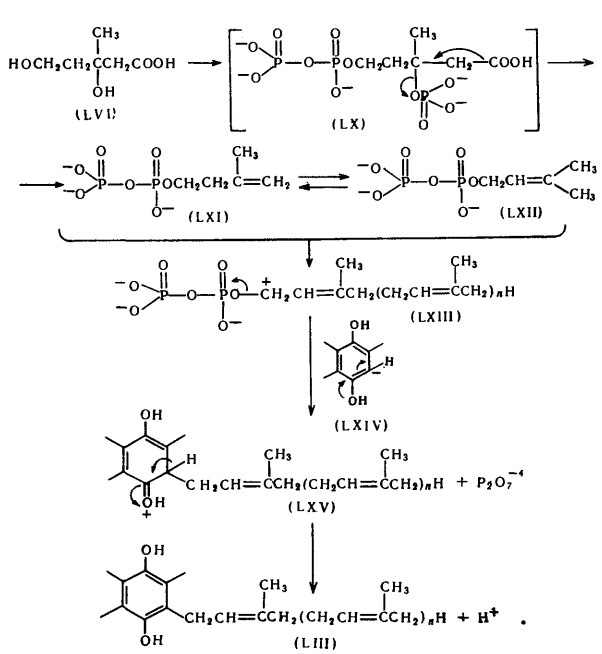


V. BIOSYNTHESIS OF UBIQUINONES

In order to assess the physiological significance of ubiquinones, to which an important function in the oxidative processes in the cell is attributed [115], it is important to know whether the living organism can itself synthesise them or whether they have to be supplied from the outside.

1. Biosynthesis of the Isoprenoid Side-Chain

Experimental studies *in vitro* and *in vivo* showed that [2-^{14}C]mevalonate [104,105,116,117] and [2-^{14}C]acetate [118-121] are incorporated only in the side-chain of the ubiquinone. The limited role of mevalonic acid in the biosynthesis of ubiquinones was confirmed by the oxidative degradation of labelled UQ_9. [122,123] A specimen of [^{14}C]UQ_9, obtained biosynthetically from [2-^{14}C]mevalonic acid (LVI), was acylated reductively to diacetyl[^{14}C]dihydro-UQ_9 (LVII), which was then subjected to selective degradation by ozonolysis. Radioactive levulinic aldehyde (LIX) and acetone were isolated from the reaction mixture as the corresponding dinitrophenylhydrazones (Scheme 9).

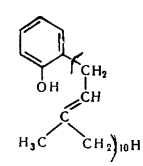


Scheme 9

3,6-Diacetoxy-4,5-dimethoxy-2-methylphenylacetic acid (LVIII), formed from the aromatic ring of the ubiquinone molecule, was isolated in the crystalline form and did not contain the radioactive label.

The above results are consistent with the postulated biosynthesis of terpenoids such as squalene [124] and carotenoids [125], according to which the polyisoprenoid side-chain of ubiquinone can be built up as a result of successive increments by one C_5-unit (Scheme 10). Mevalonic acid (LVI) [126] is converted in three stages into the derivative (LX) with three phosphate residues. As a result of decarboxylation and dephosphorylation, the latter yields isopentenyl pyrophosphate (LXI) [127,128] — "active isoprene" or the "structural C_5 unit" [129]. Δ^3-Isopentenyl pyrophosphate is capable

Scheme 10



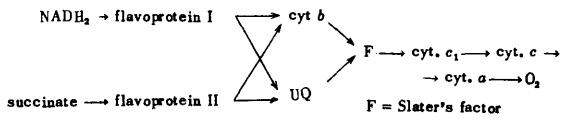
of isomerising to dimethylallyl pyrophosphate (LXII), [128-130] which is the terminal unit in isoprenoid polymers. Successive increments of the chain length of dimethylallyl pyrophosphate by C_5 units leads to isoprenoids with a carbon chain of increasing length, such as geranyl pyrophosphate (LXIII, n = 1), farnesyl pyrophosphate (LXIII, n = 2), etc. Geranylgeranyl pyrophosphate (LXIII, n = 3) [131] and the free alcohol solanesol [132], corresponding to the C_{45}-pyrophosphate (LXIII, n = 8), have been found in animal tissues. These compounds are probably synthesised in the same way as the lower representatives of this group.

Comparatively recently the polymer with twenty isoprenoid residues (C_{100}) has been found in human kidneys and has been given the name dolichol [133,134]. In this connection, one may assume that in the animal organism there are a number of enzymes which are responsible for the formation of polyisoprenoid homologues which are then used for the synthesis of squalene, the side-chains of ubiquinones, vitamins K_2, and other isoprenoids.

2. Biosynthetic Pathways for Ubiquinones

The discovery of allyl pyrophosphate as an alkylating agent in the biosynthesis of polyterpenoids became the basis for the development of a possible mechanism of the addition of the isoprenoid chain to the appropriate hydroquinones [128,129,135,136]. It is suggested that the alkylation of the unknown hydroquinone precursor (LXIV) with allyl pyrophosphate (LXII) involves the formation of an intermediate (LXV), which loses a proton and is converted into ubiquinol (LIII). On the basis of this hypothesis, it is quite likely that in the formation of ubiquinone itself the animal organism can use as donors of aromatic rings certain benzoquinone derivatives supplied with food or synthesised by the intestinal microflora. In this connection, a study has been made of a number of radioactive compounds containing aromatic rings to elucidate their possible participation in the formation of the ubiquinone chromophore. These were aromatic amino-acids [137,138] {[^{14}C]phenylalanine [139-142] and [^{14}C]tyrosin [141]}, vitamin E, [117,143] (labelled with tritium by Wilzbach's method [144]), and also 2,3-dimethoxy-5-methylbenzoquinone, 3-hydroxy-2-methoxy-5-methylbenzoquinone (fumigatin), and 2,3-dihydroxy-5-methylhydroquinone, labelled selectively in position 5. [145] Only [^{14}C]phenylalanine was found to be incorporated into the UQ_9 molecule in rats [146,147].

2-Decaprenylphenol, a biosynthetic precursor of ubiquinone containing simultaneously the aromatic ring and the isoprenoid side-chain, has been isolated recently from the lipid fraction of *Rhodospirillum rubrum* [148], which contradicts the above hypothesis that the incorporation of the isoprenoid side-chain is one of the last stages in the biosynthesis [149].



It is believed that this precursor can be obtained by the enzymic decarboxylation of *p*-hydroxybenzoic acid [150,151] after the latter had been first alkylated with decaprenyl pyrophosphate. *p*-Hydroxybenzoic acid is formed biosynthetically from shikimic acid [152].

It has been shown experimentally that, in the biosynthesis of ubiquinone, methionine [149,153] and formate [154] can serve as donors of methyl groups in the *O*-methylation reaction. Furthermore, formate is a source of the methyl group in the benzene ring [154].

VI. ROLE OF UBIQUINONES IN ELECTRON TRANSPORT IN OXIDATIVE PHOSPHORYLATION. HYPOTHESES CONCERNING THE POSSIBLE MECHANISM OF THE PROCESS

Ubiquinones are localised in the mitochondria in animal and higher plant cells at relatively high concentrations (NAD : cyt. $a \simeq$ UQ : cyt. $a \simeq 15$). This suggested that they participate in the electron transport system of the respiratory chain. Experimental data show that, on incubation under anaerobic conditions with substrates such as succinate and $NADH_2$, endogenous ubiquinone in mitochondrial preparations is reduced to ubiquinol while under aerobic conditions the latter is reoxidised to the quinone [155,156] (the redox potential is +0.122 V [157]). Furthermore, the extraction of ubiquinone bound in mitochondria with organic solvents results in loss of enzymic activity, which can be restored by the addition of ubiquinone [158]. In the attempts to determine the function of ubiquinone in electron transport these two findings were the subject of thorough investigations in non-phosphorylating systems [26,158-164]. The results of the determination of the concentration of ubiquinone in mitochondria [165], the kinetics of oxidation–reduction reactions [166-168], and the study of the effect of inhibitors [166] and of the effect of the extraction of ubiquinone on enzymic activity [158,169-174] led to certain hypotheses concerning the role of ubiquinone in the respiratory chain [175].

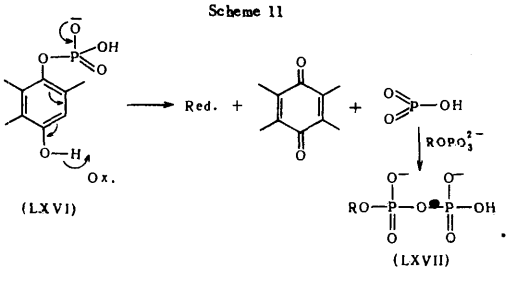
In the "reconstructed" respiratory chain described by Green [176] in the plenary lecture at the Fifth International Biochemical Congress ubiquinone precedes cytochrome *b*, the entire electron flux passing through ubiquinone. However, later studies in Green's laboratory [177] and Doeg's data [178] showed that ubiquinone and cytochrome *b* provide two alternative pathways for the electron flux [8]:

Comparison of the data on the kinetics of the oxidation–reduction reactions of ubiquinone in mitochondria with the overall rate of electron transport favours the second view [159,166,175,179].

One of the most important achievements of modern biochemistry is the demonstration of the central metabolic role of adenosine triphosphate (ATP) as the universal donor of chemical energy in the cell. The continuous renewal of ATP is an oxidation reaction, in which electron transport is coupled with phosphorylation — with synthesis of ATP. In the animal cell this process is localised in intracellular granules (mitochondria) where all the enzymes required for respiratory phosphorylation and part of the oxidative cell enzymes are to be found. A number of attempts have been made to determine the redox state of ubiquinone in mitochondria as a function of various phosphorylating conditions, in which the effect of inorganic phosphate and ATP was examined [4,168,179-181].

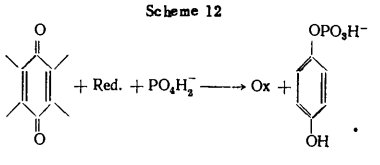
The studies of Todd and coworkers [182] showed that oxidation of quinol phosphates (LXVI) *in vitro* can result in the formation of the "active metaphosphate" (LXVII) which forms pyrophosphate from inorganic phosphate and adenosine diphosphate from adenosine monophosphate (Scheme 11). [183,184]

This scheme constitutes to some extent a model of oxidative phosphorylation. The formation of quinol phosphate from quinone in the presence of inorganic phosphate can be represented by Scheme 12.



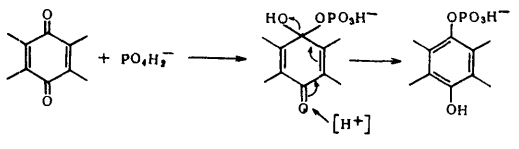
Wieland proposed a simple mechanism for such "reductive phosphorylation" [185] (Scheme 13).

However, many attempts to carry out this reaction with benzo- or naphtho-quinones under various laboratory conditions proved unsuccessful.

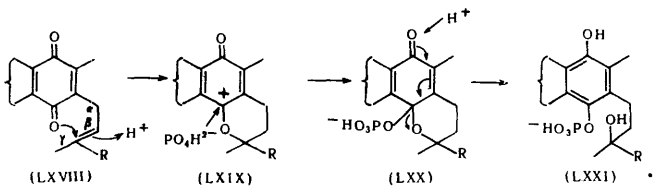


Clark and Todd [186] examined hypothetical ways of obtaining quinol phosphates from quinones in the series of ubiquinones and vitamins K (Scheme 14).

Quinones of type (LXVIII) have a tetrasubstituted quinone ring and a trisubstituted $\beta\gamma$-double bond in the side-chain. The addition of a proton at the β-position leads to a tertiary carbonium ion (LXIX), which is converted into compound (LXX) as a result of nucleophilic attack by the phosphate dianion (HPO_4^{2-}). The reduction of compound



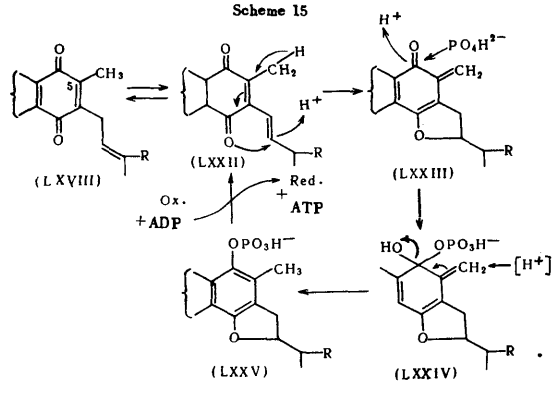
Scheme 11



Scheme 12

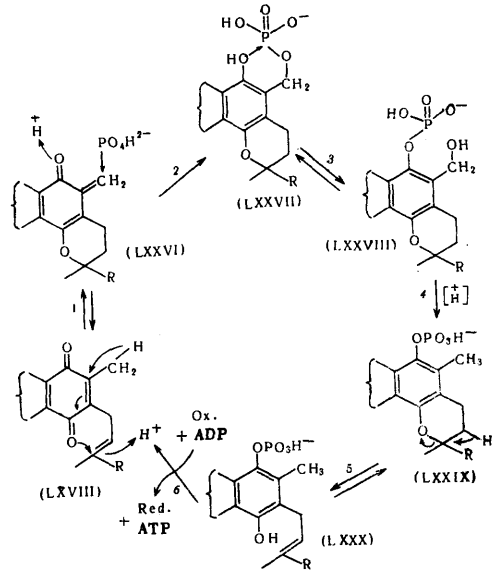
Scheme 13

Scheme 14



(LXX) and the subsequent opening of the chroman ring result in the formation of the corresponding quinol phosphates (LXXI). It is suggested that compound (LXXI) is then dehydrated and a $\beta\gamma$-double bond forms as in (LXVIII).

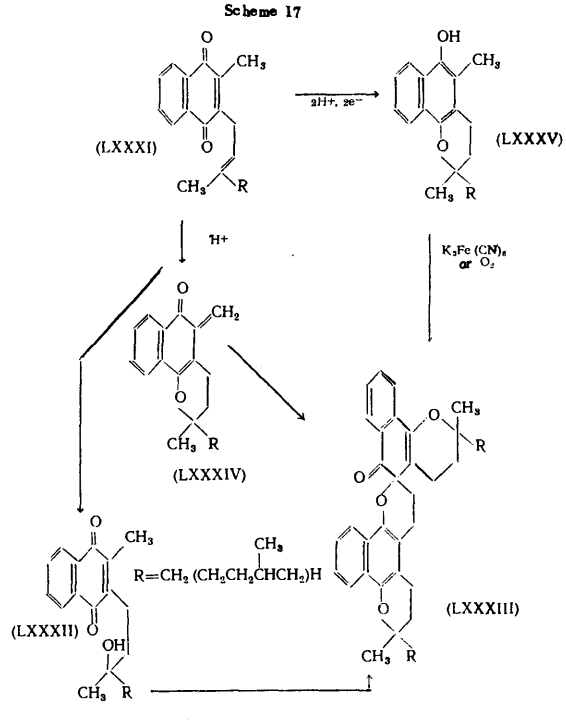
The mechanism of the synthesis of quinol phosphates proposed by Todd presupposes the formation of a phosphorus centre in position 4, whereas in biologically active systems this should be located in position 1. The latter was confirmed by a number of workers who demonstrated the phosphorylating role of 6-naphthochromanol phosphate [54,187,188]. Chmielewska [189] noted that ubiquinones and vitamins K with the methyl group in position 5 can occur in an active *ortho*-quinonoid form. The latter exhibits an enhanced capacity for nucleophilic addition reactions. Accordingly, Chmielewska suggested a consecutive series of reactions to account for the participation of quinones in oxidative phosphorylation (Scheme 15).



5-Methylquinone (LXVIII) is converted, via the isomerisation product (LXXII), into the *ortho*-quinonoid form (LXXIII), stabilised by the heterocyclic ring. The addition of the phosphate dianion to compound (LXXIII) yields compound (LXXIV), from which the quinol phosphate (LXXV) is then formed. The oxidation of compound (LXXV) is accompanied by the synthesis of ATP and leads to the recovery of the initial quinone, thereby completing the phosphorylation cycle. Chmielewska's hypothesis presupposes the 1,2-addition of the phosphate residue to the quinone oxygen [(LXXIII) → (LXXIV)]. The complexity of the 1,2-addition in such systems renders this mechanism unlikely.

On the basis of purely theoretical considerations, Vilkas and Lederer [190] modified Chmielewska's mechanism and proposed their own version of the mechanism of the addition of inorganic phosphate to methylene quinones (Scheme 16). This scheme presupposes the formation of methylene quinones or quinone methides (LXXVI, reaction 1) with a pyran ring and not a furan ring as suggested by Chmielewska [189], which is confirmed by the existence of chromans in the series of ubiquinones and vitamins K. According to this mechanism the phosphoric acid residue is not fixed at the quinone oxygen but in the 1,4-position of the conjugated quinone methide $O{=}C{-}C{=}CH_2$, with formation of benzyl phosphate (LXXVII, reaction 2). The intramolecular migration of the phosphate residue to the phenolic hydroxyl (LXXVIII, reaction 3) and the reduction of compound (LXXVIII) results in the formation of 6-chromanol phosphate (LXXIX, reaction 4). Ring opening results in the formation of the quinol phosphate (LXXX, reaction 5), which on being oxidised produces ATP and is converted into the initial quinone (LXVIII, reaction 6).

Scheme 15

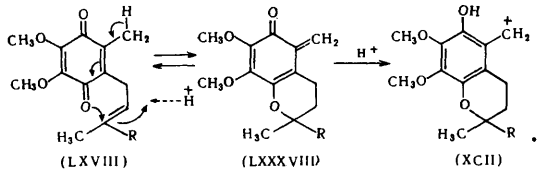


Scheme 16

The key feature of Lederer's theoretical considerations consists in the assumption of the 1,4-addition of the phosphate residue to the quinone methide postulated by Chmielewska. Both authors consider the presence of the methyl group in position 5 of the quinone ring and of the $\beta\gamma$-double bond to be important for the phosphorylation process [191].

In recent years the first two stages of the mechanism, i.e. the formation of quinone methides of chromans (reaction 1) and 1,4-addition to these compounds (reaction 2), have been confirmed experimentally. The studies of Folkers' group [192,193] showed (Scheme 17) that vitamin $K_{1(20)}$ (LXXXI) gives rise to a hydroxyquinone (LXXXII) under the influence of sulphuric acid.

Scheme 17

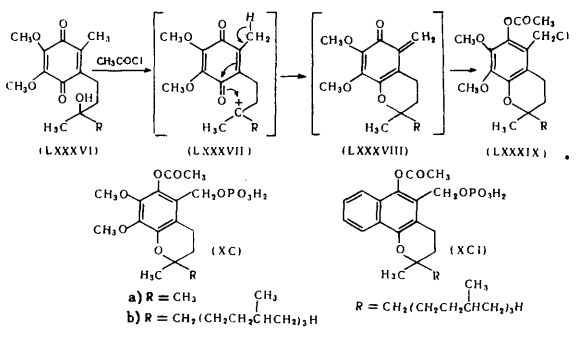


Further reactions in the presence of sulphuric acid gave an oily substance, to which the authors attributed the structure of the dimer (LXXXIII) and showed that the formation of such a compound can be accounted for only by the preliminary formation of the quinone methide (LXXXIV).

Experimental confirmation of the formation of quinone methides was also obtained in Lederer's studies [191,194], in which the dimer (LXXXIII)† was isolated in a crystalline form and its structure was established by mass-spectrometry. It has been shown by means of model reactions that under acid conditions vitamin $K_{1(20)}$ can isomerise to the chromanyl quinone methide (LXXXIV).

Folkers and coworkers [192,193,195,196] obtained 5-phosphomethyl-6-chromanyl acetates (XC, a, b; XCI), the mechanism of the synthesis of which presupposes the intermediate formation of quinone methides and 1,4-addition to the latter (Scheme 18).

When acetyl chloride is allowed to act on γ-hydroxyhexahydro-UQ_4 (LXXXVI), the product is probably the cation (LXXXVII), which is converted via the quinone methide (LXXXVIII) into 5-chloromethyl acetate (LXXXIX). The 1,4-addition is confirmed by the synthesis from compound (LXXXIX) of three new 5-phosphomethyl derivatives (XC, a, b; XCI) [192,196] with the aid of silver dibenzyl phosphate and subsequent selective debenzylation.

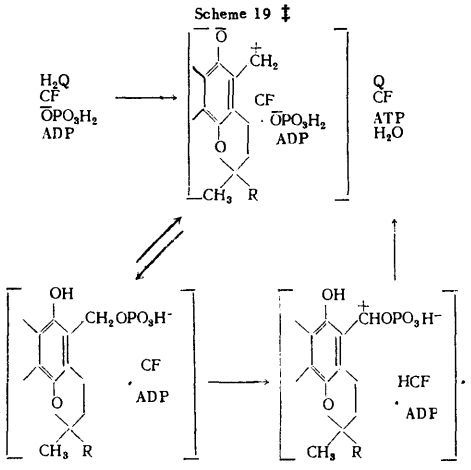


After analysis of the experimental data obtained, Folkers et al. [196] put forward their version of the synthesis of the "active phosphate". The addition of a proton to the double bond of the first isoprenoid unit of the side-chain of compound (LXVIII) results in an electron shift accompanied by cyclisation and the elimination of a proton from the 5-methyl group:

(LXVIII) (LXXXVIII) (XCII)

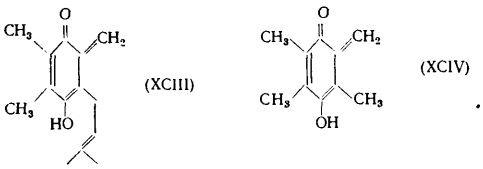
This is the principal factor in acid catalysed isomerisation. Evidently compounds (LXVIII) and (LXXXVIII) are equivalent in the molecular sense. The addition of a proton to the quinone methide (LXXXVIII) yields the carbonium ion (XCII). The authors believe that this protonated quinone methide (XCII) is a more likely form of quinone methide in chemical reactions in enzymic and non-enzymic processes. The carbonium ion (XCII), which has a deficiency of electrons in the 5-methyl position, is capable of interacting with the phosphate anion. In this connection, the authors suggest the following sequence of reactions, which account for the participation of quinones in oxidative phosphorylation (Scheme 19). Experimental confirmation of this mechanism would render unnecessary the subsequent stages of Lederer's mechanism given above.

Scheme 18



(LXXXVI) (LXXXVII) (LXXXVIII) (LXXXIX)

(XC) (XCI)

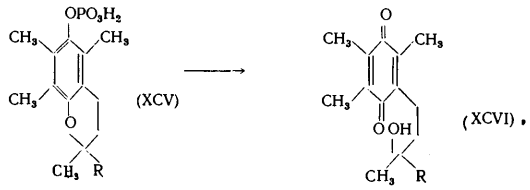


a) R = CH_3 CH_3

b) R = $CH_2(CH_2CH_2CHCH_2)_3H$ $R = CH_2(CH_2CH_2CHCH_2)_3H$

Scheme 19 ‡

Scott put forward a number of new postulates concerning the intermediate compounds in oxidative phosphorylation in the quinone series [197]. On the basis of observations of NMR signals from deuteriated methanol, he suggests the formation of quinone methides without a chroman ring, of the type (XCIII) and (XCIV):



(XCIII) (XCIV)

In Scott's view, such quinone methides are more likely to be in equilibrium with the corresponding quinones than the quinone methides (LXXVI) derived from chromans proposed by Lederer. Furthermore, Scott demonstrated the complexity of the formation of the hydroquinone phosphate (LXXX) from chromanyl phosphate (LXXIX) (Scheme 16) and the reversibility of this reaction, although he does not exclude the probability of a process of this kind in the presence of enzymes. He suggests that direct oxidation of chromanyl phosphate be taken into consideration, and illustrates this using as an example the oxidation of (±)-α-tocopherol phosphate (XCVa) and the phosphate ester

† A dimer of this type can be obtained by oxidising naphthochromanol with potassium hexacyanoferrate(III) [191] or oxygen [233].

‡ CF is the mitochondrial substrate-coupling factor. Scheme 19 is based on the formulae given by R.E.Erickson, A.F.Wagner, and K.Folkers, [J.Amer.Chem.Soc., 85, 1535 (1963)](Ed. of Translation).

of 2,2,5,7,8-pentamethyl-6-chromanol (XCVb) to the corresponding hydroxyquinones (XCVIa, b) in the presence of cerium sulphate.

(XCV) (XCVI),

where R = $C_{16}H_{33}$ (a) and R = CH_3 (b).

The mechanisms quoted above, i.e. hypotheses which explain the chemical reactions of quinones in oxidative phosphorylation, are to a large extent speculative, since none of them has been adequately confirmed experimentally. So far they are working hypotheses, whose validity will have to withstand the test of time.

VII. CERTAIN BIOLOGICAL AND THERAPEUTIC FUNCTIONS OF UBIQUINONES IN ANIMALS AND IN MAN

The role of ubiquinones in intracellular mitochondrial electron transport was considered above.

UQ_{10} has been identified as a component of the liver aldehyde oxidase [198]. This enzyme — which is a xanthine oxidase found only in the homogenate of the soluble fraction of rabbit liver and probably of cytoplasmic origin — has been isolated recently in a crystalline form [198]. The purified enzyme contains two molecules of flavine-adenine dinucleotide, eight iron atoms, two molybdenum atoms, and two UQ_{10} molecules per mole of protein.

The studies of Leonhäuser et al. [199] showed that UQ_{10} is present in microsomes.

The 6-chromanol derived from hexahydroubiquinone(20) has been most widely used in studies designed to elucidate the therapeutic action of compounds of the ubiquinone group in animals and in man. This chromanol facilitates the breeding of rats [114], enhances the mobility of sperm cells in chickens [200], and has a favourable effect on monkey dystrophy [201]. It has yielded satisfactory clinical results in the therapy of certain forms of anaemia in infants [202].

Therapeutic and prophylactic tests recently established that hexahydroubiquinone(20) in the quinone form is active in rabbit dystrophy [203,204]. Furthermore, the study of α-tocopherol deficiency in rhesus monkeys yielded interesting comparative data for UQ_{10} and vitamin E. It was found that UQ_{10} as such markedly increases the number of reticulocytes and the amount of haemoglobin [205]. These are the first data concerning the activity *in vivo* of members of the ubiquinone group in the quinone form.

---o0o---

During the preparation of the manuscript for the press interesting papers were published on the chemistry of ubiquinones, menaquinones, and tocopherylquinones [206-211,232,233], and yet another natural member of the ubiquinone group, containing 25 carbon atoms in the side-chain (UQ_5) was isolated [212]. Papers were published on the synthesis of the hydroxy-analogues of ubiquinones [213,214] and a definite view concerning the structure of rhodoquinone was established [215].

The discovery of 2-decaprenylphenol [148], the biosynthetic precursor of ubiquinone, and its next analogue 2-decaprenyl-6-methoxyphenol [216], led to a revision of the biosynthesis of ubiquinones. Further studies of this biosynthetic pathway for the cyclic component showed that the ring in ubiquinone, menaquinone, plastoquinone, and α-tocopherylquinone is synthesised from shikimic acid [217-219].

The participation of ubiquinone in electron transport was examined by a number of workers [220-224], and it has been suggested that ubiquinone can have a function other than that of electron carrier [225].

The role of ubiquinones in oxidative phosphorylation was discussed [226,227] and hypotheses have been put forward concerning the impossibility of the participation of ubiquinone methines as intermediates in oxidative phosphorylation [228,229]. Studies on the biological importance of ubiquinones were published [230,231].

SPECTRA OF ORGANIC MOLECULES IN THE FAR AND VACUUM ULTRAVIOLET

O. V. Agashkin and A. E. Lyuts

CONTENTS

1. Introduction 428

2. Chromophores in the vacuum ultraviolet region 428

3. The spectra of saturated hydrocarbons 429

4. Hydrocarbons containing double and triple bonds 430

5. Saturated compounds containing nitrogen, oxygen, and halogens 432

6. Complex chromophores 436

7. Application of absorption spectra in the far and vacuum ultraviolet to the analysis of the composition and structure of materials. 438

1. INTRODUCTION

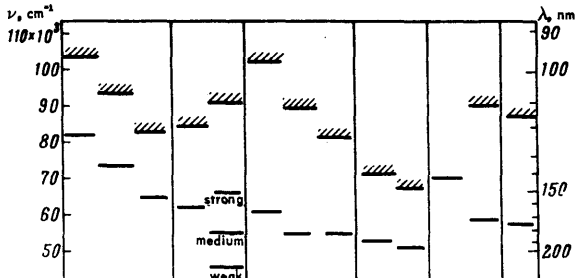
When we study absorption in the visible, the ultraviolet, or the Schumann regions of the spectrum, we are observing a single process: the transfer of electrons to higher energy levels under the influence of light. However, for purely historical reasons, the unnatural classification of electronic spectra by wavelength is still retained. At first, only the visible region was experimentally accessible. Later, when quartz optics and photocells were developed, we became acquainted with the ultraviolet region. Lastly, by using diffraction techniques and LiF and CaF_2 optics, we were able to reach the vacuum ultraviolet region. This is a relatively recent achievement; the technical difficulties still act as a psychological barrier against the widespread application of vacuum ultraviolet spectra in structural problems involving polyatomic molecules. At least two psychological factors militate against the adoption of the vacuum region by chemists. The first is the widespread belief that the necessary techniques are extremely complex and inaccessible. The second, and more important, obstacle is that we know a great deal about the origin of absorption bands in the near ultraviolet and in the visible region, whereas we know practically nothing of the nature of bands in the Schumann region. Thus, the frequent temptation to look beyond the limits of 220 nm is usually demolished by the commonsense question: what shall we learn about this molecule by going further into the short-wavelength region? There are no correlations at all, in this region, between the position and intensity of bands on the one hand and structure on the other hand. Even the spectra themselves are so few that no attempt has been made to classify them systematically.

The aim of the present article is to review the most important results obtained by applying absorption spectra in the far and vacuum ultraviolet to the solution of problems in molecular structure. We hope to convince the reader that the vacuum region is not altogether barren from the chemist's point of view, that the new spectra can be treated as extensions of many existing spectra, and lastly that the techniques involved in recording these spectra have now reached a level comparable to those of the near ultraviolet and infrared region, so that all these regions can now be exploited on an equal footing.

Electronic spectra in the vacuum ultraviolet do not constitute an isolated aspect of theory. To understand these spectra and to make practical use of them, we need a basic knowledge of spectroscopy and of quantum chemistry. Existing textbooks on these subjects are quite good, and deal with the subject at quite different levels. Readers wishing to familiarise themselves with the basic theory are referred to the book by Barrow[1]. A group of three books[2,3,4], read in conjunction, would give a firmer grasp of the subject. Readers approaching spectroscopy from a chemical background will perhaps find the books by Jaffe and Orchin[5] and by Murrell[6] best suited to their needs.

The minimum background knowledge needed to read the present article is the following. We shall assume familiarity on the part of the reader with the form of the complete energy spectrum of a molecule, with the properties of the states giving rise to this spectrum, with possible inter-state transitions, and with the reasons for intensity differences between the observed bands. An appreciation of the origin of the fine structure of electronic bands will be important, as well as the ability to extract from it information on molecular structure. Lastly, it will be necessary to understand some other effects associated with the absorption of light. The review articles by Mason[7] and by Ramsay[8] give a very compact account of all these problems.

The order of presentation of the subject matter will be as follows. We shall first of all discuss the possibility of establishing a relationship between the characteristics of absorption in the far and vacuum ultraviolet and characteristic structural elements. We shall then examine in detail the individual spectra of various classes of organic compounds. Electronic transitions will be designated according to Mulliken's classification[9] and also by the localised orbitals classification[3].



The spectra obtained up to 1944 were classified in the review articles by Sponer[10] and by Platt and Klevens[11]. The fullest account of subsequent work is given by Turner[12]. The books by Phillips[13] and by Rao[14] include a factual summary and a bibliography of vacuum spectra.

2. CHROMOPHORES IN THE VACUUM ULTRAVIOLET REGION

Electronic spectra are widely used in the study of problems of chemical structure, particularly when chromophoric groups are present in the molecules and characteristic frequencies exist. We shall try to establish whether the concept of a chromophore can in any sense be carried over to the new region. It is immediately apparent that by no means every absorption in the vacuum ultraviolet can be ascribed to the presence of a known chromophore in the molecule. In particular, it is obvious that any organic molecule with saturated bonds absorbs light in this region, whereas not every such molecule contains a chromophoric group in the usual meaning of the word. The term chromophoric is applied to those groups or atoms in a molecule which give rise to absorption by the molecule at the longest wavelengths. The definition is not too loose, since it has been known for a long time that a chromophore does not always produce a colour. We shall retain the term auxochromic for those groups which shift the spectrum towards longer waves. However, a given group can behave either as a chromophore or as an auxochrome in different molecules. For example, in the ethane molecule the C–C bond is a chromophore, and the C–H bonds are auxochromic in the most favourable case. In methane, the C–H bonds are fully chromophoric.

However, this is not merely a matter of terminology. The chromophore concept is a fruitful one if it can be shown that a characteristic absorption is associated with each chromophore. This idea is illustrated in Table 1, which summarises existing information on the longest-wavelength allowed transitions of a series of organic mole-

TABLE 1. Chromophores.

cules, each of which is the simplest carrier of that chromophore and could therefore stand at the head of a whole family of related compounds. The first impression gained from the Table is definitely unfavourable. Matters improve slightly if the chromophores are classified by transition type: this brings order into the groups in which only one type of long-wavelength transition is possible.

In the paraffin series transitions of the type $\sigma \rightarrow \sigma^*$ only are possible. These transitions occupy the shortest wavelength region. Unsaturated compounds give bands associated with $\pi \rightarrow \pi^*$ transitions, close to the lower absorption edge of the paraffins. All three long-wavelength bands of acetylene are due to these transitions. For oxygen-containing saturated compounds, the transitions of lowest energy will be $n \rightarrow \sigma^*$ transitions. These transitions may turn out to be forbidden (as in methanol), depending on whether the highest filled states taking part in the transition are $2p$ or $2s$. The $n \rightarrow \sigma^*$ transitions localised at an amino nitrogen atom occur at even longer wavelengths. In alkyl halides $n \rightarrow \sigma^*$ transitions are peculiar. They are undoubtedly forbidden, which suggests that an appreciable fraction of $n(2p)$ states takes part in the transition. In ketones, aldehydes, and carboxylic acids, competition of absorption in the long-wavelength region is possible between the $\pi \rightarrow \pi^*$, $n \rightarrow \pi^*$, and $n \rightarrow \sigma^*$ transitions. Within the limits of Table 1, it is impossible to demonstrate any regularities for these compounds: we shall discuss their spectra in greater detail in the subsequent Sections. At this point, however, it is important to draw attention to the behaviour of the ionisation potentials. They follow the long-wavelength allowed transitions very closely indeed. In some cases the relationship between ν_{max} for the long-wavelength band and the ionisation potential is not merely monotonic, but actually linear.

We shall now turn to the published spectroscopic data, following the classification given in Table 1.

3. THE SPECTRA OF SATURATED HYDROCARBONS

The highest filled orbitals in saturated hydrocarbons are bonding σ-orbitals. In these systems absorption can occur only by transitions of the molecule to the σ^* antibonding state or to Rydberg levels. The simplest member of this series is methane. A knowledge of its spectrum should resolve the problem of the absorption associated with the chromophore C–H in all compounds containing this chromophore. Clearly, we can only talk about the absorption region, since in saturated compounds the electrons are not localised in an individual bond but belong to the whole molecule to an appreciable extent. Figs. 1*a* and 1*b*, taken from the work of Duncan[16] and of Weissler[25], give some idea of the full spectrum of methane. The total oscillator strength, measured by the area between the long-wavelength absorption edge and the onset of ionisation, is 6.1: this is practically the same as the theoretical limit, since the higher molecular orbitals contain just six $2p\sigma$-electrons. This means that all possible transitions for electrons of the valence shell ($N \rightarrow V$ and $N \rightarrow R$ transitions) are concentrated in that interval. From this point of view, the band with a maximum at 1250 Å is due to a $\sigma \rightarrow \sigma^*$ transition, whilst the shorter-wavelength region of the spectrum relates to forbidden Rydberg series converging towards the ionisation potential (12.99 eV).

Unfortunately, the chromophore carrier C–C (ethane) has not been studied in the same detail. We only know[17] that its long-wavelength absorption maximum lies at 1350 Å. This is undoubtedly an $N \rightarrow V$ transition, involving excitation of one of the σ-electrons of the C–C bond to the antibonding σ^* state. Further increase in the number of carbon atoms in the straight-chain alkane series causes the band associated with this transition to shift towards longer wavelengths (Fig. 2). Curve *a* of Fig. 2, based on

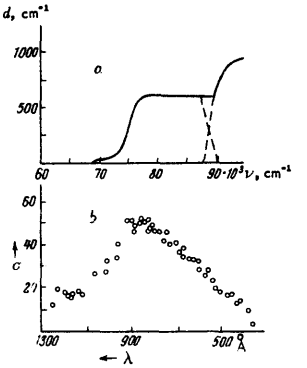

Fig. 1. Absorption spectrum of gaseous methane:
a) absorption coefficients of methane in the region 60 000–95 000 cm^{-1};[16] *b*) absorption cross-sections of methane in the region 1300–500 Å.[25]

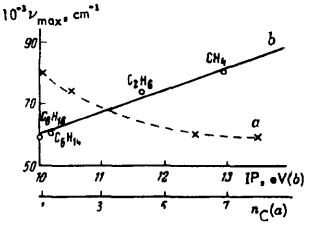

Fig. 2. Relation between the frequency of the long-wavelength absorption maximum of saturated normal hydrocarbons and (*a*) chain length and (*b*) ionisation potential.

experimental data[18,26,27], justifies the conclusion that the wavelength of the absorption maximum for straight-chain alkanes remains practically constant beyond C_6. Despite the scarcity of experimental data, this conclusion seems reasonable, because delocalisation of bonding σ-electrons can extend only over a limited region. Further lengthening of the hydrocarbon chain ceases to affect the distribution of charge among the bonds, and therefore also the absorption spectrum. It is important to remember the linear relationship between ionisation potential and the frequency of the long-wavelength absorption maximum, which suggests that the energy of the highest occupied orbital increases monotonically with the length of the chain. Evidently, when the number of carbon atoms is large enough the energy diagram of the molecule can be described by zones similar to those of a dielectric. Furthermore, branched hydrocarbons absorb at higher wavelengths than their straight-chain isomers[18]. Cyclic hydrocarbons also give spectra at longer wavelengths than the straight-chain linear hydrocarbons, but in this case the wavelengths of the maxima and the oscillator strengths are a function of strain in the ring[28,29]. This is the reason why straight-chain hexane and heptane are often used as solvents in the far ultraviolet. According to Platt and coworkers[30], 0.3 mm layers of these compounds are transparent down to 1705 Å: this is adequate in a large number of cases.

4. HYDROCARBONS CONTAINING DOUBLE AND TRIPLE BONDS

Here we have to deal with two types of $N \rightarrow V$ transition. The first of these originates in exactly the same way as the transition discussed above. The second, on the other hand, is associated with $\pi \rightarrow \pi^*$ excitation. We can predict some of the features of absorption arising from this particular transition on the basis of current ideas. Firstly, this absorption should occur at longer wavelengths, if only because π-bonding is weaker than σ-bonding, and, secondly, the transition should be symmetry allowed.

Let us consider the spectrum of the simplest carrier of the C=C chromophore (ethylene), shown in Fig. 3. The envelope of the fine structure in the region 1400–2000 Å is a very broad band with a maximum at 1620 Å. This is the band which is assigned to an $N \rightarrow V$, $\pi \rightarrow \pi^*$ transition. Studies of its long-wavelength slope[19] revealed a vibrational structure, which becomes diffuse as the dissociation limit (1620 Å) is approached. The absorption showing fine structure, which forms the maximum of the diffuse band and begins at 1750 Å, is caused by an $N \rightarrow R$ transition, where R is the first Rydberg state. The system of doublets denotes transitions to different vibrational levels of this Rydberg state. By using deuteriated materials, Wilkinson and Mulliken[19] were able to show that the long-wavelength components of the doublets correspond to the vibrations of the C=C bond, whereas the short-wavelength components

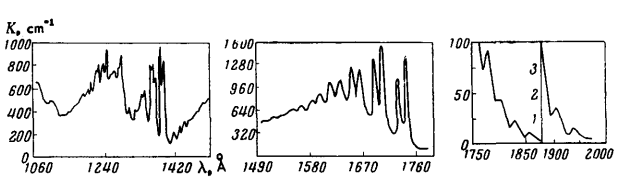

Fig.3. Absorption spectrum of gaseous ethylene[31].

are the even transitions of the oscillations associated with the torsional vibration $\tau_{H-C-H'}$. The higher terms of the Rydberg series lie at 1322, 1247, and 1225 Å, and converge towards the ionisation limit at 10.45 eV, in good agreement with the values of ionisation potential obtained by other methods[26,27].

Let us now return to the $N \rightarrow V$ transition. The long-wavelength side of the band has a vibrational structure whose intensity distribution shows that excitation of the molecule produces an anomalously large increase in the C–C distance: the strongest components of the structure give[19] $\Delta v > 10$. Theoretical analysis[32] of the vibrational structure gives $r_{C-C} = 1.69$ Å as compared with 1.335 Å for the ground state[19]. In the spectrum of tetradeuterioethylene we find, in addition to the stretching vibration bands, bands which can only be ascribed to τ_{H-C-H} vibrations. The difference between the vibrational quantum numbers for these transitions is again very large, which suggests, by the Franck–Condon principle, a very large difference in the angle between the HCH planes in the upper and lower electronic states. This difference is close to 90°. It is difficult to overemphasise the importance of these conclusions. They mean, effectively, that the V-state of ethylene is non-planar. Analysis of many spectroscopic results led Walsh[33] to the conclusion that (1) the planes of the methylene groups are mutually perpendicular; (2) the C–H and C–C bonds form a pyramid at each of the carbon atoms; (3) each carbon atom lies slightly outside the plane passing through the bisector of the H–C–H angle of the opposite methylene group. The first of these conclusions can be readily understood without detailed analysis of the experimental data. Antibonding in the π^*-state is a maximum for the planar configuration of the nuclei, when the carbon $2p$-orbitals are mutually parallel. The repulsion energy will be a minimum, by symmetry considerations, when these orbitals are oriented at right angles to each other. Under these conditions the planes of the methylene groups also will diverge by about 90°. The resulting molecular orbital will no longer be a pure π^*-orbital, and the total bonding will increase to a maximum. Thus, the potential energy of the ethylene molecule, both in the ground and in the excited states, is a periodic function of the angle between the planes of the methylene groups (Fig. 4). The two curves are out of phase by 90°. This means that excitation brings the system into a state of maximum repulsion energy. If the lifetime of the excited

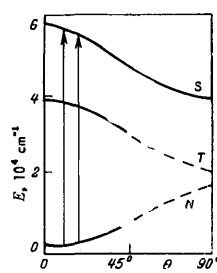

Fig.4. Variation of the potential energy of ethylene with the angle of twist between the planes of the methylene groups for the ground (N), singlet (S), and triplet (T) excited states[7].

state is long enough, the molecule, having dissipated the excess of energy, will be in a state of zero vibrational energy and non-planar nuclear configuration. Such a molecule will behave in a very unusual way in a number of reactions. Equally important is the fact that, when returning to the electronic ground state, the molecule can adopt (with equal probabilities) either the original nuclear configuration or a configuration involving a 180° rotation. With ethylene itself this is immaterial, but if we consider instead *trans*-dichloroethylene, say, we can expect to obtain a new substance, *cis*-dichloroethylene, as a result of this process. The *cis-trans* isomerisation reaction of ethylene derivatives is a very common one. This is evidence that we are indeed dealing with a long-lived excited state, which is a triplet in this case[34]. The Rydberg states correspond to planar nuclear configurations[18], and when a molecule is excited to these states there is no significant change in the shape or in the reactivity of the molecule.

Let us now consider what happens to the $N \rightarrow V$ transition when the ethylene molecule is perturbed in various ways. The introduction of an alkyl substituent into ethylene causes a shift of the band towards longer wavelengths. Longer alkyl substituents give an enhanced shift, but the effect tapers off when the number of carbon atoms in the radical is large (Fig. 5). Similar changes are found in the ionisation potential. Increasing the number of alkyl substituents has exactly the same effect[35-37]. In every case we can envisage a delocalisation of the π-electrons, leading to an increase in the energy of the ground state and a decrease in the energy of the excited state.

A second vinyl or carbonyl group, not conjugated with the first, has practically no effect on the absorption characteristic associated with the $N \rightarrow V$ transition in a C=C double bond[38]. The intensities of non-interacting C=C groups present in the same molecule are additive[39]. All these observations open the way for analytical applications of spectra in the far ultraviolet, at least to alkenes. Table 2 can be used as a key to analytical applications.

Cyclic alkenes are a special group of alkenes. If we compare a linear and a cyclic alkene having the same number of carbon atoms, the cyclic compound is usually found to absorb at shorter wavelengths than the linear compound, the difference increasing with the amount of strain in the ring. The integral intensities or oscillator strengths for the transitions decrease as the strain increases[29,40]. If the molecule contains more than one unsaturated bond, and

TABLE 2. Average position and maximum intensity of the absorption bands (Å) of olefin vapours[39].

Alk-1-enes	1750±25	11800±1200

2-Alkylalk-1-enes	1875±15	8900±1200

conjugation between these bonds is established, the spectrum is so strongly shifted towards longer wavelengths that it can appear in the near ultraviolet and thus fall outside the frequency range relevant to the present article. A great deal of relatively recent information on the spectra of unsaturated conjugated systems and of alkenes can be found in Turner's[12] and Mason's[7] reviews, and in the monographs by Rao[14], Murrell[6], and Phillips[13].

The chromophore C≡C is in many ways similar to the previous one. The longest-wavelength transition is again the $N \rightarrow V$ transition from a bonding π-state to an antibonding π^*-state. The electronic structure is still more complicated in this case because the π-states are doubly degenerate. If we choose the Z axis in the direction of the bond, we can consider filled π_x and π_y states, and free antibonding π_x^* and π_y^* orbitals. Ignoring singlet–triplet transitions, we can set up four combinations of these states, but not every one of these can be realised. If the molecule in the excited state is linear, three of the four combinations lead to forbidden transitions and only one can be realised. If, on the other hand, the excited molecule is bent, three allowed transitions are possible, one of which should be relatively weak, by analogy with the corresponding forbidden transition for the case of a linear upper state[41]. This transition should be modified by two types of vibration: by C≡C stretching vibrations and by bending vibrations arising from changes in the H–C–C angle. The spectrum indicates a decrease in the H–C–C angle and an increase in the C–C internuclear distance in the first excited state. Fig. 6 shows the spectrum of gaseous acetylene. Four absorption bands are found in the range 1400–2400 Å. The band with the longest wavelength has a vibrational structure with a red shift, indicating that the internuclear distance increases during excitation. King and Ingold[42] have made a vibrational analysis of the structure. They found evidence for two vibrations: a C≡C stretching vibration with a frequency of 1385 cm^{-1} (as compared with 1974 cm^{-1} in the ground state) and a scissor bending vibration of frequency 1049 cm^{-1} (as compared

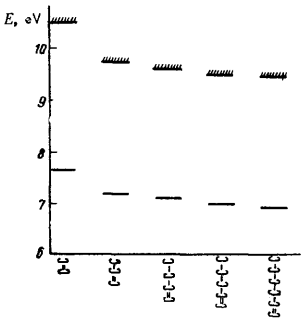

Fig. 5. Relationship between the frequency of the long-wavelength absorption maximum and ionisation potential in the olefin series.

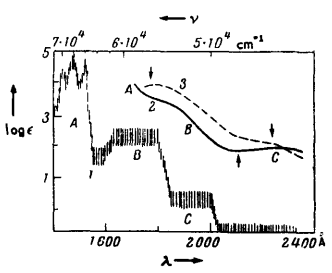

Fig. 6. Absorption spectra[45] of acetylene vapour (curve 1) and of hexane solutions of oct-1-yne (curve 2) and oct-2-yne (curve 3).

with 612 cm^{-1} for the ground state). The transition was found to be polarised at right angles to the plane of the bent molecule, whence it follows that the configuration of the nuclei in this particular excited state has a centre of symmetry. This means that the equilibrium configuration is bent in the *trans* direction. The other two $N \rightarrow V$ transitions correspond to excitation to linear states[43] with an even greater increase in C–C internuclear distance, since the corresponding frequency is lowered to 800 cm^{-1}. Relatively recently Wilkinson carried out a more careful vibrational analysis using deuteriation, and was able to confirm the earlier conclusions[44]. Absorption at wavelengths shorter than 1500 Å is associated with $N \rightarrow R$ transitions. Analysis of this region has shown that the fine structure of the spectrum can be reduced to two Rydberg series converging to a single ionisation limit at about 92 000 cm^{-1}.

Alkylation of acetylene lowers the frequency of all the bands due to $N \rightarrow V$ transitions. At the same time, the intensity of these bands increases. Fig. 6 shows the spectra of two octyne isomers. Bands having the same origin are labelled with the same letter. Other examples have confirmed that alkylation decreases the frequency and increases the intensity. An even stronger red shift and increase in intensity are obtained when hydrogen is replaced by a heteroatom (particularly nitrogen)[46], or by a second $-C{\equiv}CH$ group[47].

The changes occur in the same sense for all bands associated with $N \rightarrow V$ transitions. In the case of heteroatoms, the anomalously large increase in intensity may be due to charge transfer of non-bonding electrons to the free π-orbitals.

The hydrocyanic acid molecule, being isoelectronic with acetylene, should have a similar spectrum: this is confirmed by the work of Herzberg and Innes[48]. However, in this case there are two transitions giving a ben configuration of the molecule: the $\Sigma^+ \rightarrow \Sigma^-$ transition with a band in the region of 1600–2000 Å, and the $\Sigma^+ \rightarrow \Delta$ transition whose absorption lies in the region of 1550–1700 Å.

5. SATURATED COMPOUNDS CONTAINING NITROGEN, OXYGEN, AND HALOGENS

The spectroscopic properties of these compounds are largely determined by the properties of the heteroatoms. The most characteristic feature of their electronic structure is the presence of non-bonding electrons occupying the highest filled levels. We shall consider first the nitrogen compounds.

1. The Chromophore $-\overset{|}{N}-$

We were able to list only five papers on the electronic spectra of aliphatic amines. Yet, these spectra should be a fruitful field of study in short-wave spectroscopy. The simplest carrier of the chromophore is ammonia. Because it has three equivalent N–H σ-bonds and a non-bonding electron pair, ammonia should give rise to a very simple spectrum consisting of one $N \rightarrow Q$ transition, one $N \rightarrow V$ transition at a shorter wavelength than the previous one, and a series of Rydberg transitions. Thompson and Duncan[49] studied the frequency range from 45 000 to 120 000 cm^{-1} and discovered four ammonia bands in this region, which they assigned to Rydberg transitions of the non-bonding pair. Sun and Weissler[25] found a continuum similar to the methane continuum at the short-wavelength end of this range, possibly arising from $N \rightarrow V$ transitions of the electrons localised at the N–H σ-bonds. If this is the case, one of the bands found by Thompson and Duncan[49] should be assigned to the $N \rightarrow Q$ transition. It was recently shown that this interpretation is not definitive: if the four transitions are arranged in a single Rydberg series, the series converges to a potential of 11.58 eV, whereas photoionisation experiments give[50] 10.154 ± 0.01 eV. Vibrational and rotational analysis led Walsh and Warsop[51] to conclude that if the Q-branch frequencies of purely electronic transitions are considered, the Rydberg series including only three transitions (2168, 1434, and 1330 Å) converges towards a reasonable limit (10.1 eV). This is a series of transitions to the 3*s*, 4*s*, and 5*s* atomic states. The other two transitions at 1665 and 1286 Å can be combined into an $n \rightarrow n'p$ series, where n' is the principal quantum number, which takes the values 3 and 4. Vibrational analysis confirmed Walsh's theoretical prediction[52] that ammonia is planar in excited states. The strongest argument is provided by deuteriation experiments. The ratio of the w_{e_2} frequencies for ammonia and ND_3 is the same as the value calculated by the product rule if both molecules have D_{3h} symmetry and the vibration being considered belongs to class A_2''. Another important effect of excitation is an increase in length of the N–H bond. However, in the limiting case involving ionisation of the molecule the N–H bond should be shorter than in the ground state of the neutral molecule because the electron repulsion energy is decreased. Since we expect these changes to be continuous, we may think that, as the excitation energy increases in the sequence 3*s*, 4*s*, 5*s*.... NH_3, the bond length increases more and more slowly and eventually starts to decrease. All this is difficult to reconcile with identity of configuration in all excited states, including the ground state of the $\overset{+}{N}H_3$ ion†. The increase in length of the N–H bond was confirmed for the first excited state by Douglas[54] on the basis of an analysis of the rotational structure (1.08 Å as against 1.01 Å in the ground state). Douglas also showed that practically all electronic transitions in ammonia show signs of predissociation, and we must therefore assume strong interaction between singlet and unstable triplet states. It would appear that, somehow, there is no room for the $N \rightarrow Q$ transition in the range we are discussing. It is possible, however, that this transition falls into the long-wavelength region with alkylated ammonias.

Förster and Jungers[55] recorded the spectrum of methylamine and its deuterium derivatives in the region 2500–2000 Å. They observed a single electronic transition in this region, with a resolved vibrational structure, which can be described by the formulae

$$\begin{aligned}
CH_3NH_2 \quad & \nu = 41\,680 + v_1 \times 650 + 1000 \ cm^{-1} \\
CD_3NH_2 \quad & \nu = 41\,780 + v_1 \times 600 + 870 \ cm^{-1} \\
CH_3ND_2 \quad & \nu = 42\,540 + v_1 \times 515 + 1000 \ cm^{-1} \\
CD_3ND_2 \quad & \nu = 42\,580 + v_1 \times 500 + 825 \ cm^{-1}.
\end{aligned}$$

Thus, the electronic transition giving rise to the band at the highest wavelength is modified by two vibrational frequencies. One of these is strongly affected by deuteriation at the nitrogen atom, the other by deuteriation at the carbon atom. This allows us to ascribe the frequency 650 cm^{-1} to

† See also Duncan's comments[53] in connection with the force constants of the bending vibrations of the planar and the pyramidal structure.

scissor bending vibrations of the N–H bond, and 1000 cm^{-1} to vibration of the methyl group. The corresponding frequencies in the ground state are 783 and 1127 cm^{-1}. Since no other frequencies appear in the vibrational structure, we are dealing with an $N \rightarrow R$ transition of non-bonding electrons to the nearest Rydberg state.

It would nevertheless be very surprising if no room were found for the $N \rightarrow Q$ transition among the long-wavelength transitions in alkylamines: the transition should be strong, since the transition moment in this case is large[56].

Tannenbaum and coworkers[23] have systematised the spectroscopic data on alkylamines (see Fig. 7). They found three broad overlapping bands in the range 45 000–65 000 cm^{-1}. The maximum of the band at the shortest wavelength lies outside the above limits with primary and secondary amines, and can be seen only in tertiary amines. The long-wavelength band, on the other hand, is visible only in primary amines: it strongly overlaps the middle band in secondary amines and is quite invisible in tertiary amines because of the intense middle band. Table 3 gives a fuller account of the influence of structure on the spectroscopic characteristics of an amine.

It can be seen from Table 3 that the long-wavelength band is not markedly affected by substitution. This confirms the suggestion that the long-wavelength transition is the first Rydberg transition of non-bonding electrons of the nitrogen atom to the 3s atomic state of nitrogen. The second transition in the amine series is sensitive to substitution, and can therefore be interpreted as an $N \rightarrow Q$ transition of the non-bonding electrons to the antibonding σ^*-orbital. The decrease in frequency of the second band maximum and the sharp increase in intensity upon alkylation suggest that in this case the n-electrons are excited to antibonding orbitals localised mainly at C–N bonds. Thus, as far as the second transition is concerned, we can envisage charge transfer of n-electrons, leading to a decrease in binding energy and dipole moment in the excited state of alkylamines.

There is another way of testing whether these bands have been correctly assigned to n-electron transitions. When alkylamines are dissolved in acids, the proton of the acid is taken up by the nitrogen, forming a salt and binding the n-electrons. Under these conditions, absorption in the region under discussion vanishes completely[23]. Dissolution of alkylamines in water or alcohols causes a characteristic short-wavelength shift in both bands, resulting from the formation of a hydrogen bond which lowers the energy of the n-electrons.

The relationship between the spectroscopic characteristics of alkylamines and the basicity of the nitrogen atom is particularly important. Fig. 8 shows the n-electron levels in the two lowest unoccupied orbitals relative to the first ionisation energy, taken as $E = 0$. It is evident that the energy of the n-electrons increases with alkylation. This is accompanied by a decrease of the frequency of maximum absorption for the $n \rightarrow \sigma^*_{C-N}$ transition. It is natural to assume that the basicity of the nitrogen increases in this series. Measurements of the ionisation constant confirm that the basicity increases from ammonia to secondary amines, but the measured basicity of tetriary amines turns out to be anomalously low. It is believed that the increase in basicity is cancelled out by steric hindrance to proton addition. Hence it is reasonable to distinguish intrinsic basicity, resulting from the electronic structure of the molecule, from the realisable basicity, which is determined by the steric factors of the reaction as well as by the electronic structure. It is obvious that the spectroscopic characteristics of an isolated molecule should correlate with the intrinsic basicity. This may be the reason for the lack of reasonable correspondence between the pK_B values and the spectroscopic characteristics of cyclic

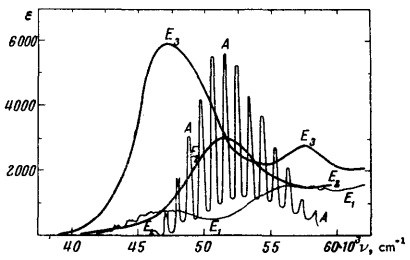

Fig. 7. Absorption spectra of gaseous ammonia (A), ethylamine (E_1), diethylamine (E_2), and triethylamine (E_3)[23].

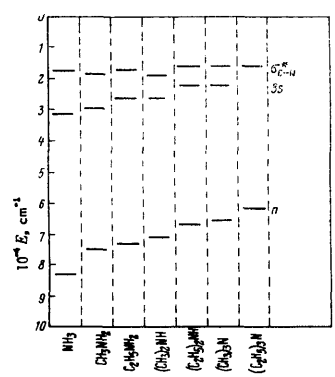

Fig. 8. Ground and nearest excited states of various aliphatic amines[23,26,27].

amines[57]. We should consider yet another factor which may limit the realisable basicity. The non-bonding electron pair of the nitrogen in amines occupies a hybrid orbital, formed by the superposition of s- and p-atomic orbitals. If the s-character is predominant, the resulting orbital is localised close to the nucleus and therefore resides within the van der Waals sphere of the atom. In the opposite limit, when the n-electrons are effectively in a pure p_Z state (e.g. in the pyridine molecule), the electron density distribution is more diffuse and part of the electron cloud can extend beyond the van der Waals sphere. However, the most directional orbital of the carbon atom will be an sp^3-hybrid bonding orbital. This maximises the probability of direct contact between the interacting species — the first step in the process of proton addition. In this sense, the hybrid strength or the value of the homopolar dipole moment is an important characteristic of the basicity[3]. Thus, we can say that the basicity of an amine should increase as the ionisation potential decreases and as the homopolar dipole increases. Information on the homopolar dipole may possibly be obtained by analysing the intensities of the $n \rightarrow \sigma^*_{C-N}$ transitions in different amines, assuming that the orbital of the n-electrons can be approximated by the combination $a2s + b2p$ and estimating the ratio a/b. In general, the intensity of $n \rightarrow \sigma^*$ transitions is surprisingly sensitive to structural changes. For example, axial or equatorial methyl groups at C_2 in cyclic amines cause absorption at practically the same frequencies, but the maximum intensities of the corresponding bands differ by a factor of three or four[58]. These anomalous changes in intensity suggest the presence of some specific intramolecular interactions (between the methyl group and n-electrons) which only an equatorial methyl group can undergo. Changes in ring strain also give rise to remarkable changes in band intensity. The oscillator strength for the $n \rightarrow \sigma^*_{C-N}$ transition[57] is 0.11 for piperidine and 0.05 for pyrrolidine. The intensities fall off appreciably when amines are dissolved in polar solvents, the effect increasing with the polarity of the solvent[57,58]. The bands also suffer a short-wavelength shift, which can be taken to indicate that n-electrons are involved in the transition.

The great sensitivity of the spectroscopic characteristics of amines towards structural changes in the molecules and towards the properties of the medium justifies our hope that spectroscopic studies will soon become a standard method of investigating this large and important class of compounds.

In conclusion we note that the tendency to form planar configurations in the excited state should persist in alkylamines. This cannot fail to have a significant effect, particularly in the isomerisation of cyclic amines, alkylation, and above all in the preparation of amides.

2. The Chromophore -O-

The chromophore -O- is common to water, alcohols, and ethers, but the attention given to these compounds by research workers has differed widely. About 90% of the papers on the electronic spectra of oxygen-containing saturated compounds relate to water. The remaining 10% are shared between ethylene oxide and all other alcohols and ethers. This state of affairs is quite reasonable, since water, being the simplest of all carriers of the chromophore, is the natural touchstone of theory. A preliminary idea of the absorption spectrum of water can be obtained by considering, in Mulliken's approximation, the molecular orbitals of the ground and of the lowest excited state. According to Mulliken[59,60], the ground state of the H_2O molecule, ignoring the $(1s)^2$ electrons, can be represented as follows:

Orbitals	$(2sa_1)^2$	$(yb_2)^2$	$(za_1)^2$	$(2xb_1)^2$	$^1A_1$
Localisation	O	HOH	HOH	O	
Ionisation potential, (eV)	32	18	17	12.7	

The second line shows the atom or group at which the state orbital is localised. The third line gives the energy of these orbitals or ionisation potential calculated in the zeroth approximation (except for the last). Thus, the highest orbital is the orbital of non-bonding $(2xb_1)^2$ electrons, which are localised mostly at the oxygen atom. The nearest excited state can be obtained from the ground state by moving one of the electrons $(2x)$ to the first Rydberg $3s$ atomic orbital of the oxygen, leading to the state $(2sa_1)^2(yb_2)^2(za_1)^2(2xb_1)(3sa_1)$. This state can be a triplet $^3A_1$ or a singlet $^1A_1$. The band observed[21] at 1667 Å can be assigned to a transition of the molecule to this state. The anomalously large width of this band is ascribed to predissociation, leading to $O + H_2$ $(^1\Sigma^+_g)$[59], but an alternative interpretation is possible[61]. The region below 1250 Å shows a series of absorption bands: these can be combined in a Rydberg series, whose members have a vibrational and rotational structure. By analysing the fine structure for H_2O and D_2O, Bell[61] was able to estimate the changes in bond length and bond angle accompanying excitation. Absorption at 1240 Å lengthens the O–H bond by 0.065 Å and increases the angle by 5.2°. The corresponding value for the band system at 1219 Å is 0.067 Å. Bell's analysis also shows that the oxygen n-electrons are bonding, whilst the 3s and 3p atomic orbitals are to some extent antibonding in the water molecule. Bell considers this to be the cause of the continuum at 1655 Å.

In the alkyl derivatives of water only the long-wavelength transition can be associated with the oxygen atom. Alkylation brings about several interesting changes. Replacement of hydrogen by methyl lowers the transition frequency by 5500 cm^{-1} and decreases the intensity by an order of magnitude. Increasing the length of the radical by one unit raises the intensity but has little effect on the frequency. Further increase in the length of the radical lowers the intensity again, but for a secondary alcohol with the same number of carbon atoms the intensity is higher. These changes are summarised in Table 4.

The intensity of this band begins to increase with chain length[30] in the spectra of alcohols with still longer straight-chain hydrocarbon radicals.

Replacement of hydroxylic hydrogen by an alkyl group causes a sharp increase in the intensity of the long-wavelength transition. Also, this transition is accompanied by

TABLE 4.[21]

Substance	Frequency, cm^{-1}	ϵ	f	Ionisation potential, eV
Water	60000	1480	0.0460	12.59
Methanol	54500	150	0.005	10.86
Ethanol	55100	320	0.008	10.50
1-Propanol	54600	240	0.006	10.15
2-Propanol	55300	620	0.015	10.09

a clear vibrational structure in the spectra of ethers. Methyl ether and ethyl ether show this behaviour most clearly (Fig. 9)[62]. The first band has structure with spacing of about 400 cm^{-1}, which can be ascribed to C–O–C bending vibrations in the excited state. The structure of the second band of methyl ether includes the frequencies 2100 and 1300 cm^{-1}, corresponding apparently to stretching and bending vibrations of the methyl group[22,62]. This means that the second band is generated by a transition to antibonding levels of the alkyl substituents, and not to oxygen atomic levels. The spectrum of ethylene oxide[63] is strongly displaced towards short wavelengths as compared with non-cyclic ethers. The bands of 1,3-dioxan occur at shorter wavelengths than those of 1,4-dioxan[64]. This allows us to conclude that in 1,3-dioxan the two oxygen atoms are independent. Another interesting observation is that absorption in 1,4-dioxan is stronger than in tetrahydropyran, but not by a factor of two, as would have been expected if the oxygen atoms had been independent (see Fig. 10). A vibrational band structure observed in cyclic ethers can be assigned to deformation of the ring

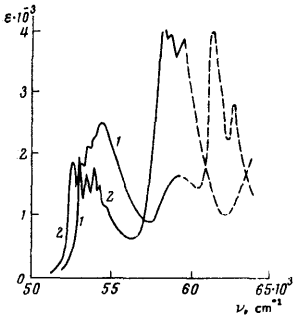

Fig. 9. Absorption spectra of gaseous ethyl ether (curve 1) and methyl ether (curve 2)[62].

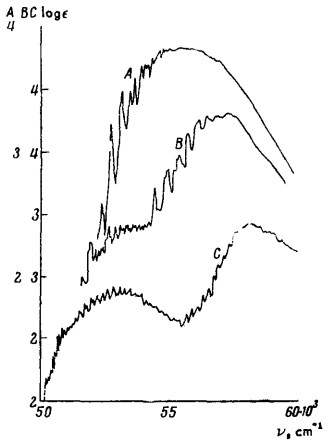

Fig. 10. Absorption spectra of gaseous 1,4-dioxan (*A*), tetrahydropyridine (*B*), and tetrahydrofuran (*C*)[65].

(frequencies in the region of 200 cm^{-1})[65,66]. The absence of one of the bands from the dioxan spectrum is ascribed to the higher symmetry of this compound. Furthermore, because of the presence of a centre of symmetry, the electronic band of 1,4-dioxan cannot show out-of-plane vibrations. The whole of the experimental data on the vacuum spectra of alcohols and ethers suggests that the long-wavelength bands are due to a transition involving non-bonding electrons. The $N \rightarrow V$ transitions in these compounds are concentrated in the region 500–1300 Å, and are weakly perturbed by the proximity of the hydrocarbon part of the molecule to the oxygen atom. In particular, the absorption by methyl, ethyl, n-propyl, and n-butyl alcohols has a maximum at 800 Å, and the intensity ratio of the bands is in strict proportion to the ratio of the number of C–H bonds (3 : 5 : 7 : 9), with a slight discrepancy in the case of n-propyl alcohol[67].

The identification of $n \rightarrow 3s$ and $n \rightarrow \sigma^*$ transitions is a controversial problem in saturated oxygen-containing compounds, as it is in aliphatic amines. This is because the first term of the Rydberg series is not described as a rule (see, for example, Walsh and Warsop[51]) by the Rydberg formula, and therefore the position of the first transition cannot be determined rigorously. The $n \rightarrow \sigma^*$ transition also is to be expected in the long-wavelength part of the spectrum.

Tsubomura[56] and others consider that the absorption spectra of water, alcohols, and ethers can be given a unified interpretation by postulating that: (1) the long-wavelength band is due to an $n \rightarrow \sigma^*$ transition where the n-orbital is a pure $2p$ atomic orbital of oxygen; (2) σ^*_{C-O} lies below σ^*_{H-O}; (3) the matrix element of the Hamiltonian for the σ^*-orbitals is small. If these assumptions are correct — and several arguments can be put forward in favour of the last two — the orbitals σ^*_{C-O} and σ^*_{O-H} in these spectra are non-interacting, but the σ^*-orbitals in water and in the ethers interact strongly owing to degeneracy. This explains why the first transition occurs at longer wavelengths in the ethers than in the alcohols. Calculation of the oscillator strengths for water, alcohols, and ethers, based on the same postulates, leads the authors to conclude that the values should decrease in the sequence water, ethyl ether, ethanol. The observed values are 0.084, 0.041, and 0.013 respectively. The qualitative agreement between calculation and experiment indirectly confirms the validity of the assumptions (including the first). Thus there are arguments in favour of both the $N \rightarrow Q$ and the $N \rightarrow R$ [62] interpretation of the long-wavelength transition. There can be no doubt, however, that the nature of this transition is molecular rather than atomic, since its characteristics are strongly dependent on the nature of the substituent groups. Thus it is meaningful to envisage some composite molecular orbital as the upper state of the first transition.

3. The Halogen Atom Chromophore

The electronic structure of the C–Hal bonds is very similar to that of the C–O bond. However, the observed absorption may lie in the far ultraviolet (70 000 cm^{-1} for CF_4 [20]) as well as in the near ultraviolet (40 000 cm^{-1} for CH_3I [7]). This absorption is due to transitions from n-electron levels. As in the case of alcohols, the intensity is low (see Table 5). The long-wavelength transition can be interpreted as an $n \rightarrow \sigma^*$ transition with the same justification as in the case of the oxygen-containing compounds.

6. COMPLEX CHROMOPHORES

We have so far considered only chromophores which absorb in the far and vacuum ultraviolet. In this sense, the chromophores were simple ones. We shall now discuss the short-wavelength absorption of the familiar chromophores, which we shall term complex because they absorb both in the near and in the far ultraviolet. The simplest of these is the carbonyl group in saturated systems.

The C=O Chromophore

The simplest carrier of this chromophore is formaldehyde, whose ground state can be described as

$$[(1s_C)^2(1s_O)^2(2s_O)^2(\sigma_{CH})^2(\sigma_{CH})^2(\sigma_{CO})^2(\pi_{CO})^2(n_O)^2]\,A_1.$$

Transitions to the following excited states are possible:

$$\ldots(\pi_{CO})^2(n_O)(\pi^*),\quad A_2$$
$$\ldots(\pi_{CO})(n_O^2)(\pi^*),\quad B_1$$
$$\ldots(\pi_{CO})^2(n_O)(\sigma^*).\quad B_2$$

These transitions give rise to absorption bands at relatively long wavelengths. The next transition (towards shorter wavelengths) may be due to excitation of an electron from one of the bonding σ-levels, either σ_{CH} or σ_{CO}. An analysis of the symmetry of the initial and of the final state is needed to establish which of these transitions actually occurs, and with what intensity. Remembering that the formaldehyde molecule has C_{2v} symmetry, we can ascribe a definite symmetry also to the electronic configurations of the various states, which gives us a basis for applying the selection rules. These rules tell us that the $A_1 \rightarrow A_2$ transition is forbidden by symmetry, since all three components of the dipole moment of the transition are equal to zero, whilst the $A_1 \rightarrow B_1$ and $A_2 \rightarrow B_2$ transitions are allowed. If we allow also for spin conservation, the $^1A_1 \rightarrow {}^3A_2$ transition must have the lowest intensity, because the spin of the electron changes. Table 6 [1] lists the approximate positions of typical absorption bands for formaldehyde and symmetrical ketones, the oscillator strengths, and assignments of the bands to the appropriate transitions.

Formaldehyde, in particular, has the following set of absorption bands[7]: 3100 Å (ε = 5), 1749 Å (ε = 18 000), and 1555 Å (ε = 23 000). Their assignment presents no difficulty if we remember that none of these bands are caused by singlet–triplet transitions. With other symmetrical ketones, however, the situation may be more complicated, and further investigation is needed to distinguish $N \rightarrow Q$ and $N \rightarrow V$ transitions. In this respect, a characteristic property of the transitions, such as the shift in the maximum absorption frequency on going from the gas to a solution, can be of considerable help, if the ketone molecules become solvated by molecules of the solvent. Under these conditions the $n \rightarrow \pi^*$ and $n \rightarrow \sigma^*$ bands are shifted towards shorter wavelengths, whilst the $\pi \rightarrow \pi^*$ band moves towards longer wavelengths[14,68].

Let us return to formaldehyde. The band at 1749 Å is diffuse, possibly as a result of predissociation. This band is fairly confidently assigned[69,70] to the $n \rightarrow \sigma^*$ transition. The band at 1555 Å has a clear vibrational structure whose spacing (1250 cm^{-1}) is probably related to stretching vibrations of the C=O group in the excited state[69]. This band is confidently assigned[70] to a $\pi \rightarrow \pi^*$ transition. Rydberg absorption begins at 1397 Å. The two series which are observed converge to an ionisation potential of 10.83 ± 0.01 eV.

Alkyl substituents shift the $n \rightarrow \sigma^*$ transition towards longer wavelengths (1749 Å for formaldehyde, 1816 Å for acetaldehyde, 1950 Å for acetone)[7]. The $\pi \rightarrow \pi^*$ transition does not show a definite trend (1555 Å for formaldehyde, 1650 Å for acetaldehyde, 1540 Å for acetone). The ionisation potential rises continuously with alkylation and with the length of the alkyl chain.

Acetone and other aliphatic ketones show yet another band in the 1500–1700 Å region, whose assignment raises special difficulties. Its intensity increases with the degree of branching at the α carbon atom[71,72], whilst at the same time the band shifts towards longer wavelengths. Holdsworth and Duncan[71] analysed the behaviour of this band, and concluded that a $\sigma_{C-C} \rightarrow \sigma^*_{C-O}$ transition with charge transfer was involved. This assignment is supported by two additional arguments. Firstly, if we arrange the molecular states of acetone and, say, ethane on a single energy scale (ethane being chosen as the simplest model of an alkyl substituent containing the C–C bond), we find that the transition $\sigma_{C-C} \rightarrow \sigma^*_{C-O}$ falls exactly in the region of 55 000–60 000 cm^{-1} (see Fig. 11). Secondly, the intensity of the $n \rightarrow \sigma^*$ transition decreases[71] in the aliphatic ketone series as the intensity of the transition under discussion increases. Similar effects are found in cyclic ketones[73,74].

The carbonyl group in amides, acids, and esters is no longer an isolated chromophore. The absorption spectra of these compounds cannot be treated as an additive combination of the spectra of the elementary chromophores. The spectrum of formamide, in particular, consists of a broad band with a maximum at 1717 Å and a weak band with a maximum at 1345 Å.[75] The broad band has a fine structure some of whose components can be combined into a Rydberg series converging at 10.2 eV. The spectrum of dimethylformamide is similar to that of formamide but displaced towards longer wavelengths[75]. Nagakura assigned

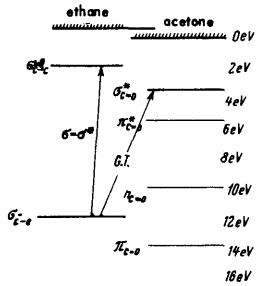

Fig. 11. Diagram of possible charge transfer in carbonyl compounds.

these bands[76] on the basis of the calculated electronic spectrum of formamide. Using the same calculation, the band at 1717 Å is shown to be associated with charge transfer and the band at 1345 Å with a $\pi \rightarrow \pi^*$ transition. Another paper by Nagakura and coworkers[77] gives the absorption spectra of formic and acetic acids and of ethyl acetate as well as the calculated electronic spectrum of formic acid. According to their calculation, the formic acid band with a maximum at 1590 Å is of $\pi \rightarrow \pi^*$ type to the extent of 46.2% and has 44.7% of charge-transfer character.

The  Chromophore

Aromatic compounds have attracted, not surprisingly, most of the attention of theoretical chemists. Benzene itself has undoubtedly been the object of practically every variant of the quantum-chemical methods. The basic difference between benzene and the chromophores discussed above is that the $2p\pi$ electrons in benzene cannot be localised at any individual carbon atom. All six $2p\pi$ electrons belong to the molecule as a whole. According to Pauli's principle, they should be distributed among three orbitals. Since these electrons are the least firmly bound in the molecule, their transitions should give rise to the long-wavelength part of the benzene spectrum. The simplest variant of the quantum-chemical calculation of the states of a π-electron system (the Hückel method) leads to a ground state in which the six π-electrons are distributed over two levels, the upper level being degenerate. The lower of the two nearest excited states is also doubly degenerate. Fig. 12 shows the energy diagram of the states and the shape of the corresponding molecular orbitals. The long-wavelength spectrum of benzene, reproduced in Fig. 13, is in fact determined by transitions to the

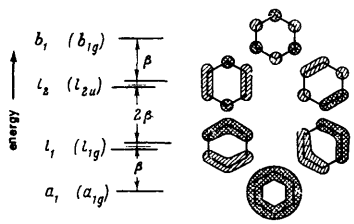

Fig. 12. Energy level diagram and orbital shapes in the benzene molecule[1].

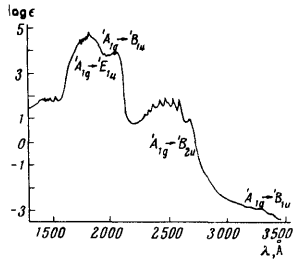

Fig. 13. Absorption spectrum of benzene[1].

two nearest excited states. The transition giving the longest wavelength is evidently forbidden on the grounds of change in multiplicity. The 2500 Å band is associated with the $^1A_{1g} \rightarrow {}^1B_{2u}$ transition, forbidden by symmetry. The allowed $^1A_{1g} \rightarrow {}^1E_{1u}$ transition gives a band at 1800 Å, which is diffuse owing to predissociation. At still shorter wavelengths we find a fine structure caused by Rydberg absorption, and further still we find another Rydberg series[78]. Both these series converge to an ionisation potential compatible with the values obtained by other methods[26]. Platt and Klevens[79] studied the effect of alkyl substitution on the spectrum of benzene, and found that the 1800 Å band is gradually shifted towards longer wavelengths by alkylation in the sequence toluene, *o*-, *m*-, and *p*-xylene. The intensity of the observed band increases in the same order. The influence of lower symmetry on the spectrum of an aromatic system was investigated by El-Sayed[80]. As expected, the spectra of pyridine, pyrimidine, and pyrazine turned out to be more complex, but each of the changes, relative to the benzene spectrum, follows naturally from the lower symmetry which removes the degeneracy from an initially degenerate state. A review article by Stevenson[81] is devoted to the effect of chemical substitution on the electronic spectra of aromatic compounds, but, of course, it deals mainly with the near ultraviolet.

We have thus surveyed the spectra of practically all the most important organic chromophores. We must stress the fact that care was taken to avoid discussing substances in which several chromophores interact so strongly that they behave as a combined chromophore in which the characteristics of the components are lost. With this important exception, we may conclude that the chromophore concept remains a fruitful one in the far and vacuum ultraviolet. In other words, we can assign to each isolated functional group a fully characterised band or set of bands in the absorption spectrum which is an analytical criterion of this chromophore. Furthermore, we know in practically every case the qualitative and quantitative effect of the immediate environment, provided that it does not destroy the "isolation" of the chromophore being considered. The impact of intramolecular interactions on short-wavelength electronic spectra is undoubtedly of much greater interest, but unfortunately it is still too early to consider this topic: the fund of published data is too small. It should be remembered, however, that the far ultraviolet region is being intensively investigated at present, and the results should be available before long.

Our next question is: are the far and vacuum ultraviolet regions already of use to the chemist at the time of writing? In this connection we shall consider several examples of the practical application of short-wavelength electronic absorption spectra.

7. APPLICATION OF ABSORPTION SPECTRA IN THE FAR AND VACUUM ULTRAVIOLET TO THE ANALYSIS OF THE COMPOSITION AND STRUCTURE OF MATERIALS

The far and vacuum ultraviolet regions are the only source of information on electronic absorption spectra which can be applied to determining the composition of mixtures and the structure of compounds containing only saturated bonds (and which therefore do not absorb in the near ultraviolet and visible regions). Fig. 14 shows the spectrum of cholestanol[82]. The structural elements of this compound are cyclohexane and the hydroxy-group. Neither cyclohexane nor cyclohexanol have an absorption comparable to that of cholestanol. It follows that the excess absorption of cholestanol (as compared with cyclohexanol) can be ascribed to the quaternary carbon atom.

The isolated ethylene group gives an even more characteristic absorption. Cyclohexene and the sterols containing a cyclohexene ring (such as cholesterol and stigmasterol) give a band with a maximum at 180 nm (Fig. 15)[82]. Increasing the degree of substitution at the ethylene bond produces a monotonic shift of the band towards longer wavelengths, up to 200 nm.

The problem of the electronic structure of five-membered unsaturated heterocycles can be solved quite easily with the help of absorption spectra in the far ultraviolet.

Two structural variants of these compounds are possible. In the first the diene system does not interact with the heteroatom; in the second conjugation occurs between the n-electrons of the heteroatom and the π-electrons of the double bond. In the first case the absorption spectrum should be simply the sum of the spectra of the diene system and of the n-electrons. For example, the spectrum of thiophen should be indistinguishable from a superposition of the spectra of cyclohexadiene and tetrahydrothiophen. If the second variant is the correct one, the spectrum will have nothing in common with the superposition. Experiment settles the question unambiguously in favour of the second alternative. Thus, spectra in the far ultraviolet have confirmed the aromaticity of thiophen and selenophen[83].

Spectra in the vacuum ultraviolet have helped to characterise the main intermolecular interactions in solid ammonia, water, and methane. By comparing the spectra of the gaseous and of the solid compounds, it was found that hydrogen bonds play a very important role in the first two compounds, but are absent in the third[84].

Another very important aspect is that spectra in the far and vacuum ultraviolet provide information about a great

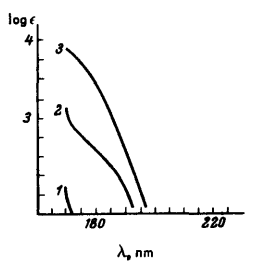

Fig. 14. Absorption spectra of cyclohexane (curve 1), cyclohexanol (curve 2), and cholestanol (curve 3)[82].

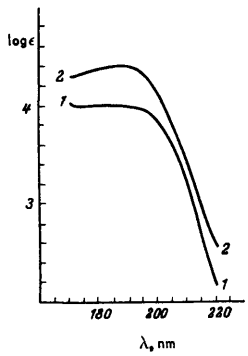

Fig. 15. Absorption spectra of cholesterol (1) and stigmasterol (2)[82].

number of molecular transitions. This adds substantially to the reliability of quantum-chemical calculations of the electronic structures and of the spectra themselves. The more we can check the predicted transitions the more realistic is the result of the calculation. Between three and five bands in the region 1500–2200 Å have been found in styrene, benzaldehyde, acetophenone, and benzonitrile. Satisfactory agreement with the observed spectra was obtained in a calculation which allowed for interaction between the ground state, a partially excited configuration, and a configuration including intramolecular charge transfer. The contribution of the charge-transfer configuration was 58% for styrene, and 68% for benzaldehyde (for the bands in the region of 2300 Å). The same investigation provided information about the electron affinity of the C=C and C=O groups.

In conclusion, we should mention another important field of application of the vacuum ultraviolet region: the determination of adiabatic ionisation potentials. In addition to the absorption spectra, which enable the Rydberg series to be observed and analysed, photoionisation spectra are also valuable in this context[26,27,86].

It should be understood that the applications listed here are only a very small fraction of the field and are given simply as illustration. The reader is referred to the bibliographic handbook published by Comstock in 1960 for a fuller review of the literature on this subject[87].

The analytical application of vacuum ultraviolet spectra in chemistry has been discussed in review articles by Kaye[88], and by Jones and Taylor[39].

References to the techniques and experimental methods can be found in the reviews by Price[89], Tousey[90], Lüscher[91], Inn[92], and Romand and Vodar[93].

VI. Semiconductor (electron–hole) properties of ionic crystals and their chemical composition 449

I. INTRODUCTION

An understanding of the effect of composition on the properties of chemical compounds of different types is essential in the development of new materials having prescribed properties. The problem is usually tackled with compounds of simple, known composition and structure, and the results are then applied to the more complex materials used in industry.

The classical theory of ionic lattices provides a satisfactory explanation of many of the physical properties of ionic crystals, such as the compressibility, polarisability, dielectric constant, wave propagation, spectra of characteristic ionic vibrations, etc., and gives practical formulae which can be used to evaluate these parameters. However, there is as yet no unified theory dealing from a single standpoint with the effect of composition on the thermal, mechanical, optical, and dielectric properties of solids.

Satisfactory theoretical explanations are available for a number of crystal properties not involving disturbance of the continuity of the lattice, but we lack a comprehensive theory of the mechanical disintegration, melting, or electrical breakdown of crystals, allowing the strength of the material to be calculated exactly and without assumptions, and giving values consistent with experiment.

The earliest theories were developed to explain individual properties of the solid state, usually without reference to each other: for example, the theory of specific heat or the theory of electrical breakdown, and also the theory of the elastic properties of crystals, without reference to the chemical composition of the material. Phenomena such as electronic and ionic electrical conduction, losses, breakdown, diffusion, etc. were not among the topics proper to solid state theory.

An essential stage in the development of a unified theory of the solid state is to compare the properties of crystals, to correlate them, and to establish a relationship between properties and composition.

The correlations between various properties of ionic crystals have been discussed extensively.

Kurnakov[1] suggested that the dynamics of changes in properties of the material should be observed on at least two parameters, because one property may be insensitive to the interaction in question under the particular conditions of the experiment.

Simple correlations were found between the composition and structure on the one hand, and the physical properties on the other hand, of organic compounds and polymers.

According to Butlerov's theory of the structure of organic compounds, the physical properties of materials depend on their composition and structure. For example, in one homologous series of saturated hydrocarbons increase of molecular weight raises the boiling point; the melting point also increases with the number of atoms in the molecule, and so does the density of the hydrocarbons at the boiling point[2-4].

Special structural features of monomers leading to the preparation of polymers with prescribed properties have been pointed out. For example, the addition of fluorine is known to enhance the thermal and chemical stability of polymeric molecules, although the resistance to radiation is sometimes lowered. A high proportion of cyclic groupings consisting of benzene rings in the polymer molecule raises the thermal and the radiation-chemical stability of the polymer. Hence, methods of preparation of polymer molecules with the highest possible content of fluorine atoms or of groupings containing benzene rings are now being intensively studied in polymer chemistry.

A study of the properties of ionic crystals and of their dependence on composition and structure is of practical importance for the description of inorganic materials in general and ceramics and glasses in particular. Materials of different physical structure can be obtained by controlling the composition and the treatment of a ceramic body. Ceramic materials have different mechanical, thermal, and electrical properties according to their composition and structure. The rules which control the relationship between the composition, structure, and properties of ceramics have not been adequately investigated.

Ceramic materials are a multiphase system, including a crystalline phase, an amorphous phase, and a gas phase (the pores). The composition, structure, and relative amounts of the phases determine the properties of ceramic materials in a complicated way.

The crystalline phase largely determines the physical properties of ceramics. Hence, studies of the properties of ionic crystals have great practical importance. The crystalline phase consists of chemical compounds and of solid solutions of the components found in many ceramic materials.

The most advanced dielectric properties are found in ceramics based on gemstone spinels ($MgO.Al_2O_3$), forsterite ($2MgO.SiO_2$), periclase (MgO), perovskite ($CaO.TiO_2$), clinoenstatite ($MgO.SiO_2$), etc.

Ionic crystals have found the most varied practical applications, as in the production of optical systems, in crystal counters, amplifiers, etc. A study of the properties of ionic crystals should advance our understanding of the fundamental properties of corrosion resistant, structural, and other ceramic materials, and of the relationship between the composition and properties of these materials.

It should also provide a scientific basis for the rational specification of their composition and method of treatment.

A solid is a quantum-mechanical system of strongly interacting particles. The individual properties of the particles in a solid are largely lost and replaced by new, collective properties which characterise the solid as a whole. The basic properties of the solid are determined by its chemical composition, physical structure, and by external conditions. The energy of interaction between the component particles of the solid, which controls its physical properties, is determined by the position of the constituent elements in the Periodic Table.

It is interesting to examine the way in which the physical properties of the simplest ionic crystals depend on the position of the components in the Periodic Table (i.e. on their atomic weight and atomic number). The bonding between particles in crystals is most conveniently expressed by the energy needed to remove each ion to an infinitely large distance from all the other ions. This quantity is termed the crystal lattice energy.

The early work was done on compounds which had been chosen without regard for similarities or differences between the properties of anions and cations, or for periodicity in their parameters. This has caused difficulties in comparing the results obtained by different workers, particularly since even individual workers have reported measurements made under different conditions.

Comparison of the results of different workers (particularly on the kinetics of various processes in ionic crystals) is further complicated by the choice of a single measurement temperature for compounds of different composition having different Debye temperatures. In such a case the crystal lattices are in different relative states of breaking up and of approaching fusion. In all probability, the properties of ionic compounds of different composition should be compared at their respective Debye temperatures or at a common relative temperature T_m/T_f, where T_m and T_f are the measurement temperature and the melting point of the crystal respectively.

The observed trends have led to attempts to generalise and to relate the properties of ionic compounds to their composition in terms of the lattice energy, free volume, ionic radii, atomic numbers of the component atoms, etc.

The present article aims to establish a correlation between various properties of ionic compounds taking the lattice energy as the characteristic parameter controlling the properties of ionic crystals. This parameter is thermodynamic and, therefore, macroscopic. In solid state theory the parameter is expressed in terms of ionic radii and ionic charges, and is therefore associated with the microscopic structure and composition of the compound.

In practice, the structures and composition of single crystals are always different from the ideal. It has been assumed[5] that the defects of a real crystal and their concentration are directly related to the lattice energy.

Ionic structures are close packed, so that ionic motion in the crystal is possible only by jumps into neighbouring vacant lattice sites. Motion of an ion by jumps in a given direction is accompanied by the transfer of vacancies of that ion in the opposite direction. The activation energy attending the motion of ion vacancies is a very important quantity which determines the displacement of ions and their vacancies from one equilibrium position to the next. This quantity increases, as a rule, with the ionic radius, but the potassium ion in sylvite is exceptional in having a very small activation energy[5]. As the lattice energy decreases, the activation energy needed to transfer an ion or vacancy from one position to the next also decreases. Hence we may conclude that a correspondence exists between the macroscopic description of these processes in terms of the lattice energy and the microscopic description in terms of the activation energy for the motion of ions and vacancies in the solid.

The properties of bodies obey an internal relationship which can be expressed by the equation of state for a real, inhomogeneous solid. To set up the equation of state of a solid body we need information on all the internal parameters of the system.

The observed correlation between the properties of ionic crystals and the lattice energy[5] can be described thermodynamically in terms of the expression for the free energy of an inhomogeneous body. Ignoring the vibrations of the ionic nuclei, the free energy of an ideal crystal consists of the energy density of the statistical lattice plus the zero-point vibration energy[1]. The equation of state of an ideal crystal, describing the relationship between pressure, volume, temperature, thermal and mechanical properties, can be derived from the expression for the free energy. The free energy at low temperatures is determined by the internal energy, i.e. by the potential energy of the interacting ions at 0°K, which we call the crystal lattice energy.

Like many other properties of a crystal, the entropy also is related to the lattice energy. Hence the free energy in the linear approximation is expressed in terms of the lattice energy[7].

In the theory of crystal lattices the free energy is used to define the linear temperature expansion coefficient and the isothermal compressibility, which are related to other mechanical, thermal, optical, and electrical characteristics of the crystal. Hence, the relationship between various physical characteristics of a solid and changes in its free energy can be established thermodynamically[6].

It follows from what has been said that the relationship between the normal mechanical, thermal, optical, and electrical properties and the free energy can be replaced by a relationship between those properties and the lattice energy, the latter being simpler to determine. The lattice energy is proportional to the product of the valencies and inversely proportional to the sum of the ionic radii and depends only on the chemical composition and structure. Expressions for the properties of bodies in terms of the lattice energy reflect their dependence on chemical composition.

The free energy of a real solid differs significantly from the ideal value on account of the energy stored in defects. The defect structure is one of the properties of real crystals. Like other properties, the defect structure of crystals, characterised by the concentration of defects, is related to the lattice energy and under different measurement conditions this relationship can upset in various ways the dependence on lattice energy of a basic characteristic[8].

When defects form, energy is absorbed by the crystal and the internal energy increases. At the same time, point defects raise the configurational entropy of the system. Hence, the free energy of the system can decrease at high temperatures as a result of the increase in entropy[9] The excess of internal energy arising from the formation

of point defects in the ionic lattice increases with the concentration of defect pairs. The concentration of defects increases with deformation, irradiation, and increase of temperature. It decreases with radiational and thermal annealing.

The establishment of a correlation between various characteristics of ionic crystals in terms of the lattice energy alone is of practical importance, since it would enable a comparison of the changes in properties of ionic compounds resulting from changes in chemical composition. A satisfactory classification of the different ionic compounds according to their properties can be based on a single parameter: the lattice energy. When the relationship between the properties is known, the lattice energy can be used to determine many other properties of ionic crystals of practical importance.

II. CRYSTAL LATTICE ENERGY AND SURFACE ENERGY OF IONIC CRYSTALS

The stability and the strength of a crystal depend on the magnitude of the forces acting between the particles, and on the crystal lattice energy which is determined by these forces. For ionic crystal lattices of the same structural type, the energy of the bond between the particles is determined by the chemical composition. The energy of the crystal lattice is a valuable index of the energy level of the system.

In the classical Born–Madelung theory of ionic crystals [10,11] the interaction energy is determined by the electrostatic interaction between all the ion pairs. The interaction energy is calculated taking account of the electrostatic Coulombic attraction energy e^2/r (for charges of different sign) and of repulsive forces (for charges of the same sign). The energy of the repulsive forces due to the electron shells of the ions, B/r^n, is then computed.

In the calculation of the forces of attraction and repulsion acting between a cation and an anion the energy of the ionic lattice is given by the formula

$$U = -\frac{N}{2}\left[\frac{A\,\eta_1\,\eta_2\,e^2}{r_0} - \frac{B}{r_0^n}\right] \qquad (1)$$

where A is the Madelung constant, which depends on the crystal structure, η_1 and η_2 are the valencies of the ions of which the lattice is composed, r_0 is the shortest distance between the centres of oppositely charged lattice ions, n is the exponent in the expression for the potential of the repulsive forces, B depends on the crystal structure and on the structure of the ion, and N is the number of ions in the crystal. The magnitude of the repulsive force is determined by the distribution and by the number of electrons in the outer shells. The exponent n is greater for Na^+ ions, which have 8 electrons in the outermost shell, than for Li^+ ions, which have only 2 electrons.

The complete expression for the crystal lattice energy, including quantum-mechanical corrections, is an additive function of the energy of the electrostatic attraction forces, the energy of the repulsive forces, the energy of the van der Waals cohesive forces between ions, and the zero temperature vibrational energy. The vibrational energy of a lattice consisting of N atoms at absolute zero is $9h\nu N/4$, where ν is the residual radiation frequency and h is Planck's constant.

Thus, the full expression for the lattice energy at 0°K of an alkali metal halide crystal per mole can be written [2]

$$U = N\left[\frac{\eta^2 e^2 A}{r_0} + \frac{C}{r_0^6} - B(r_0) - {}^9/_4 h\nu\right] \qquad (2)$$

where U is the lattice energy, η^2e^2A/r_0 the part of the energy arising from electrostatic attraction, η the lowest valency found in the lattice, C/r_0^6 the van der Waals energy, and $B(r_0)$ the potential energy due to the repulsive forces in the lattice.

Calculations of the lattice energy by formulae (1) and (2) involve serious difficulties in the determination of the value of r_0 by X-ray diffraction and in the computation of the quantities A and n.

Kapustinskii [12], using Born and Mayer's quantum-mechanical expression for the lattice energy, derived an equation for the energy of a crystal lattice not involving A or n:

$$U = 287.2\,\frac{\Sigma m \eta_C \eta_A}{R_A + R_C}\left(1 - \frac{0.345}{R_A + R_C}\right), \qquad (3)$$

where Σm is the number of ions in the molecule and η_A, η_C, R_A, and R_C are the valencies and the radii of the anion and the cation respectively.

The majority of inorganic compounds are not usually ionic. In ionic crystals we observe a continuous transition from ionic to covalent bonds, but there is no satisfactory criterion for determining the degree of polarity.

Sarkisov [13] proposed that the lattice energy of ionic compounds should be calculated on the basis of the electron gas concept, in which the ionic bond is, effectively, replaced by a covalent bond. Any crystalline inorganic compound is envisaged as an assembly of cores of interacting atoms: the chemical bond between the atoms is created by an electron cloud formed by the delocalisation of the valency electrons of the metal atoms and of an equivalent number of peripheral electrons from the non-metal atoms. The chemical bond in a lattice of the NaCl type is described as a strongly polar covalent bond. The electron cloud of the bond between the sodium and chlorine atomic cores consists of two electrons, made up of one valency electron from the sodium and one peripheral electron from the chlorine. In homopolar crystals the maximum density of the electron cloud of the bond is located exactly half-way between the neighbouring nuclei, and in typically ionic crystals it suffers a maximum displacement towards the non-metal. When this shift occurs, the electron cloud cannot be considered to belong exclusively to the non-metal, but the motion of the electrons must be treated in the field of the two positively charged cores of the interacting atoms.

Thermochemically, the lattice energy is defined by the Born–Haber cycle.

The lattice energy of chemical compounds varies in accordance with the periodicity of the properties of their constituent elements in the Periodic Table. Fig. 1 shows the change in lattice energy with composition for the alkali metal halides. An increase in the size of the ions (and therefore in the size of the unit cell) is accompanied by a decrease in lattice energy. Replacing the anion whilst keeping the cation constant, or replacing the cation whilst keeping the anion constant, produces a monotonic change in lattice energy. This substitution causes the lattice energy to decrease as the sum of the atomic numbers of anion and cation ($Z = Z_C + Z_A$) increases, and to approach a constant value for large Z. However, if we go to the halides of

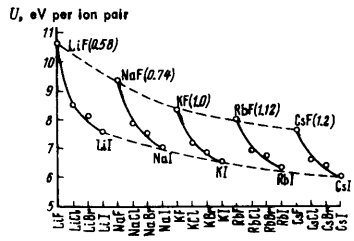

Fig. 1. Variation of lattice energy with composition for the alkali metal halides. (The numbers in brackets denote the cation to anion radius ratio.)

another metal or to the compounds of metals with other halogens we land on a different curve.

There are several rules which describe the change in lattice energy of a chemical compound with composition. Increase of ionic charge raises the lattice energy. The lattice energy of alkali halide crystals, consisting of singly charged ions, is 100–200 kcal mole^{-1}. The lattice energy of metal oxides such as MnO, FeO, NiO, and others, composed of doubly charged ions, is ~ 900 kcal mole^{-1}.

Compounds of the cations of secondary subgroups, with 18 electrons in the outer shell, have a greater lattice energy than compounds with ions of the same period but having the inert gas structure, thus [5]:

$$U_{CuCl} > U_{KCl};\ U_{ZnBr_2} > U_{CaCl_2}.$$

This rule probably follows from the smaller size of the ions in the secondary subgroups, and particularly from the influence of the polarisation energy, which is evident also from the following rule. The lattice energy of the halides of secondary subgroup elements is much less sensitive to anion radius than that of the main subgroup elements. If the radius of the anion increases, the lattice energy should decrease. However, the polarisation energy also increases, and in the secondary subgroup elements this has a much more profound effect than in the main subgroup elements.

Quantum-mechanical corrections to Born's theory have enabled us to calculate the vibrational energy of the crystals at 0°K and the contribution to the attractive energy from van der Waals dipole–dipole or dipole–quadrupole interaction, amounting to several per cent of the total lattice energy. In silver halides this additional term in the interaction energy is very much greater because of their large polarisability, and reaches 14% in AgBr. The correction for the van der Waals interaction forces in these compounds is greater for the heavier elements, which experience a greater polarisation. The correction for zero-point energy is greater for compounds composed of light elements, which have a higher Debye characteristic frequency. Therefore, a change in composition in the alkali and alkaline-earth metal halide series is accompanied by a change in the role of a given type of chemical bond in the compound, which in turn induces a change in the properties of the compound.

The lattice energy is linearly related to the heat of formation [10]. Oxides having a low heat of formation (and therefore a low lattice energy) are likely to be semiconductors. These include Ag_2O, CuO, NiO, CoO, FeO, CdO, HgO. Oxides with a high lattice energy and heat of formation (CaO, MgO, ZnO, BeO, BaO, SrO) are dielectrics of high electrical and mechanical strength.

The rates of processes depending on the thermal mobility of atoms in diatomic and polyatomic systems are related to interatomic interactions. The rates of processes depending on the thermal motion of atoms are functions of lattice energy.

The most stable structures are obtained by forming compounds of tetravalent elements. The oxides of Group II elements of the Periodic Table, BeO, MgO, CaO, SrO, BaO, have high lattice energies, heats of formation, melting points, and also good electrical and mechanical properties.

The lattice energy determines: (a) the tendency to form stable heteropolar lattices; (b) the mechanical strength of the compounds; (c) the stability of the compounds towards melting, but not necessarily towards dissociation, and (d) the solubility in aqueous solutions. However, the lattice energy cannot completely define the stability of the system. Polarisation and depolarisation phenomena must also be taken into account: these can have a considerable influence on the ionic radius and therefore on the course of various processes. Lattice energy depends on the crystal structure [14].

The lattice energy is lowest for lattices of the caesium chloride type, and highest for wurtzite. This increase in lattice energy corresponds to a decrease in the ionic radius from 1–0.7 (for a caesium chloride type lattice) to a value below 0.4 (wurtzite). The modern theory of the crystal lattice and well-known experimental results provide the data needed to compare the properties of ionic lattices with their energetic and structural characteristics [15].

The surface particles of a solid experience considerable forces of attraction from particles in the interior. This attraction is not compensated by attractive forces from particles in the surrounding medium. Hence, the particles on the surface have a greater potential energy than the particles in the interior of the body. The excess energy of the surface particles can be determined by transferring particles from the interior to the surface. When a crystal is broken into pieces the work required to transfer particles to the surface has to be expended [15].

The specific surface free energy is measured by the work done in creating 1 cm^2 of surface layer by an isothermal process and is different for different crystal faces. For crystals of the rock salt type, the specific surface energy of the cubic face, $\sigma_{(100)}$, is lower than that of the rhombic dodecahedral face, $\sigma_{(110)}$, or of the octahedral face, $\sigma_{(111)}$. If molecules of active substances are adsorbed on the surface of a solid the specific surface energy of the face decreases. The surface energy of crystals decreases after irradiation.

The surface energy has a considerable effect on the course of many processes taking place at the interface between two solids, especially on phenomena involving the formation or disappearance of a surface, diffusion, adsorption, etc. By its physicochemical nature, the surface energy is a manifestation of interaction forces and of chemical bonding between particles, and can be calculated by applying the formulae for the lattice energy.

The surface energy is small compared with the lattice energy. To divide one mole of rock salt into small cubes

of linear dimensions of the order of one micron, thus imparting to it a surface area of 1.62×10^6 cm^2, requires the expenditure of only 0.0057 cal, whereas the lattice energy is [16] 183 kcal mole^{-1}.

The surface energy is relatively unaffected by changes in composition. Hence, pronounced changes in properties with chemical composition must be associated with lattice energy rather than with surface energy, the latter being relatively insensitive to the composition of the material [15].

III. CORRELATION BETWEEN PROPERTIES OF IONIC CRYSTALS AND LATTICE ENERGY

The properties of ionic structures are interrelated, but the rules which govern these relationships have as yet been theoretically established in only a few cases. Hence, until quite recently, the various properties were investigated in most cases separately. During the last decade complex studies of different properties and of their interplay have become more frequent [15,16].

On heating, applying mechanical or electrical stress, or on dissolution, the bonds between the particles in an ionic crystal are overcome, which leads to the collapse of the lattice. The energy needed to break down the lattice depends on the forces between the particles which form the lattice. An increase in lattice energy leads to enhanced mechanical, electrical, and thermal stability in ionic compounds. These results were obtained from measurements on single crystals and compacts pressed from powdered oxides, sulphides, and halides of metals of Groups I and II.

The lattice energy determines the physicochemical properties of a crystal involving separation of the ions, their motion in the lattice, and changes in interaction forces between the ions.

The plastic properties of solids are described by the dislocation theory. The mechanical properties of real crystals vary in a regular manner with lattice energy, which characterises the ideal lattice. This correlation exists because structural defects, their concentration and mobility, and dislocations are all determined by the same structure and are related to its energetics [17].

The polarisability and the chemical bonding between ions depend on the nature of the ions. In a series of metal halides of a single type the polarisability decreases on going from rubidium to lithium compounds and increases as the anionic radius increases from fluorine to iodine [18].

Changing the structural type of the rubidium fluoride lattice, which has the caesium chloride structure at normal temperature and pressure, does not disturb the overall regularity. Associated with changes in the polarisability and concentration of the ions, the dielectric constant and its electronic and ionic components are found to increase or decrease as the lattice energy increases.

The electrical conductivity of ionic compounds in the solid state is determined by the motion of cation vacancies both in the intrinsic and in the impurity region. The heat of activation for electrical conduction, measured from the temperature coefficient of conductivity, increases as the lattice energy increases, whilst the magnitude of the conductivity decreases. The temperature of onset of intrinsic conduction in ionic compounds is shifted upwards as the lattice energy increases.

Dielectric loss arising from conduction at low or at high frequencies behaves similarly. An explanation has been given [19] of observed discrepancies from the general pattern, due to impurities, including the formation of vacancy aggregates, the distribution of impurities throughout the crystal, etc.

The specific heat and the heats of fusion, sublimation, evaporation, and dissociation increase as the lattice energy of ionic compounds increases, whilst the linear thermal expansion coefficient decreases [5].

The electronic component of the dielectric constant of alkali metal halide crystals increases as the polarisability of the halogen is increased (keeping the metal constant) and the lattice energy is decreased.

The replacement of magnesium by calcium, strontium, etc. in titanates produces an increase of dielectric constant, accompanied by a decrease of the binding energy of the particles in the lattice [19].

In crystals, the physical phenomena determined by the elastic vibrations of ions are related to the lattice energy. The specific heat per g-atom of compounds of metals of Groups I and II decreases as the lattice energy increases. The melting points of alkali metal halide crystals increase with the lattice energy. The fundamental vibration frequency of the lattice ions of the compounds of metals from Groups I and II also increases with the lattice energy.

The surface energy has a substantial effect on many processes occurring at the contact between two solids. The surface energy can be considered, physicochemically, as the manifestation of the interaction forces between particles and of the chemical bond between them. Hence, the crystal lattice energy and the surface energy of a solid in a vacuum are interrelated. Any increase in specific surface energy is accompanied by an increase in lattice energy. A successful attempt has been made [20] to relate the surface resistance of solid dielectrics to the value of the surface energy.

High values of the lattice energy and surface energy in ionic compounds cause hydrophilicity and increase the surface conductivity. They also degrade, in general, the favourable electrical properties of ionic dielectrics. The highest surface resistivity is found in materials having a structure intermediate between those of materials with ionic and with atomic bonds (for example, in fused quartz).

When the binding energy of ions in the lattice increases, the electrical conductivity and dielectric losses of ionic crystals decrease.

Some crystal properties, e.g. thermal conductivity, specific heat, elastic moduli, etc., are determined not so much by the lattice energy as by its derivatives with respect to various parameters. Due to the simple relationship between the properties of ionic crystals and the lattice energy, the various properties are also simply interrelated. A knowledge of the lattice energy allows a complicated evaluation of the properties of ionic compounds of a given series. Compounds with a high lattice energy have more desirable properties in practice. For example, beryllium and magnesium compounds are more refractory and have a higher mechanical and dielectric strength than barium or zinc compounds [19,21-29].

However, not all the properties and characteristics of ionic crystals can be simply correlated with lattice energy. Processes in which ionic compounds are broken down to

atoms or radicals rather than ions do not show a simple correlation. For example, the stability of azides towards thermal decomposition increases from lithium to caesium azide, i.e. on going from compounds with higher towards compounds with lower lattice energy [30]. The heat of formation increases from lithium towards caesium [31]. In this case the failure of the rule according to which the stability of ionic compounds should increase with the lattice energy can be explained as follows. Azides decompose into atoms as a result of electron transfer from the anion to the cation. Hence the elementary act is ionisation of the anion, followed by the collapse of the lattice. The sign of the ionisation potential is opposite to that of the lattice energy, and its magnitude varies more markedly than the lattice energy from cation to cation. When the azides are decomposed into ions (e.g. in aqueous solutions) their stability is found to increase in the same sense as the lattice energy [32].

Departures from the simple correlation between lattice energy and various physicochemical characteristics are observed also when the compound includes chemical bonds of different types and strengths. Among such compounds we find, for example, the crystal hydrates, in which coordinate bonds are present as well as ionic bonds. The stability of these compounds towards mechanical, thermal, chemical, and electrical breakdown increases with the number of water molecules present in the lattice, because this increases the strength of the bond between the particles of the lattice.

The weak van der Waals bond between the layers of layered structures explains the low strength of these materials towards cleavage along the layers. When such a body is fractured across the layers, against the large coulombic interaction forces, the strength is found to be high [17,18,20,33].

The exceptions which we have considered allow us to formulate more precisely the rule for the stability in a series of chemical compounds of a single type: when the compounds are broken down into their structural units (for example, ions in the case of an ionic lattice), the stability is found to vary in the same order as the strength of the bond between the structural units.

Homopolar lattices can form a strong framework made up of covalent bonds (diamond lattice). Unlike compounds having an ionic lattice, homopolar compounds retain their dielectric properties in the melt. The main physicochemical and electrical properties of solids with a homopolar lattice depend on the parameters of their constituent atoms (radius, deformability of electronic shells, etc.). Thus, for example, in Group IV carbon (diamond) is a good insulator, silicon (which crystallises in the diamond lattice) is a semiconductor, and tin has the electrical properties of a metal. The quantity equivalent to the lattice energy of ionic crystals is, in homopolar materials, the energy of atomisation, i.e. the energy needed to dissociate the atoms forming the homopolar lattice (or the energy needed to convert these materials into a monatomic vapour).

The physicochemical properties of homopolar structures are determined by the heat of atomisation and depend on the parameters of the constituent atoms [34-39].

In a molecular lattice, as well as in crystals with mixed ionic and covalent bonds in comparable proportion, no simple correlation is found between the overall binding energy and the physicochemical characteristics of the material. Most practically useful materials are compounds of this type.

The lack of simple, unique correlations between the physicochemical properties and the energy of the bond between the particles of compounds having chemical bonds of different types probably follows from the fact that the role of the various bonds is different under different external interactions. Some processes reflect one type of chemical bond, other processes reflect the other.

The physicochemical properties of liquid and of gaseous organic compounds have been compared with their dielectric strength. In the alkane series the dielectric strength increases with the strength of the bonds between molecules, and is practically independent of the strength of the intramolecular bonds. From these results, the electrical breakdown of organic dielectrics has been visualised as a process which begins with the breaking of intermolecular bonds. As the energy becomes concentrated in a discharge channel, breakdown may involve the breaking of intramolecular bonds [39].

The fact that the properties of real crystals depend on defects as well as on the lattice energy stems from the influence of the energetics of the crystal lattice on the behaviour of defects (in particular, of dislocations). Dislocation theory shows that the size and mobility of a dislocation are determined by the forces between the constituent particles of the crystal. The density of dislocations in crystals grown from the melt decreases as the crystal lattice energy increases.

The influence of defects and of the lattice energy on the electrical properties of ionic crystals has been established in the case of electrical conductivity. In ionic crystals, current is carried almost exclusively by cation vacancies [40]. Under these conditions, the conductivity is determined by the number of cation jumps per unit time. This number is proportional to the probability of a cation adjacent to the vacancy having sufficient energy for the jump. The concentration of vacancies in the crystal is proportional to

$$\exp\left(-\frac{W}{2kT}\right),$$

where W is the work of formation of a vacancy pair.

This quantity is related to the energy of the crystal lattice, and this accounts for the dependence of the electrical conductivity of alkali metal halide crystals on lattice energy.

As the lattice energy increases, both the electrical conductivity and the conductance losses in alkali metal halide crystals decrease.

The relation which exists between the defect structure and the energy of a crystal lattice leads us to expect that the laws derived for single crystals will be found to be equally applicable to the polycrystalline substances used in technology. In polycrystalline samples of oxides and halides of Group II elements, prepared by pressing followed by heat treatment, the electrical conductivity and the dielectric losses decrease as the lattice energy increases, and at the same time the activation energy increases.

Ceramic materials and minerals in which the binding energy between ions is large have a high thermal and chemical stability and high mechanical and dielectric strength.

The stability towards neutron bombardment of the properties of beryl, quartz, phenacite, chrysoberyl, barium titanate, and other minerals decreases in the following

order: beryllium–oxygen, silicon–oxygen, aluminium–oxygen, titanium–oxygen, zirconium–oxygen, and barium–oxygen. The decrease in radiation stability of the oxides is accompanied by a corresponding increase in cation radius: Be (0.34 Å), Si (0.39 Å), Al (0.57 Å), Ti (0.64 Å), Zr (0.87 Å), Ba (1.43 Å).

Replacement of the cation in this sequence also lowers the ionic bond character and the lattice energy per ion [41-43].

IV. STORED ENERGY IN IONIC CRYSTALS

The energy absorbed by crystals during mechanical or heat treatment, or irradiation, causes heating or the formation of various types of damage to the lattice: this increases the internal energy of the crystal and the elastic deformation energy. In particular, after irradiation a crystal has an excess of free energy (over the equilibrium value) which is termed latent or stored energy. The amount of stored energy is related to the radiation-induced defects: it can be used as a measure of the number of these defects, and it controls the change in physical and chemical properties of the material.

Compounds having a relatively large effective atomic number form crystals of relatively low lattice energy. When subjected to a given dose of radiation, these crystals absorb more energy than crystals with a high lattice energy.

Because defects are annealed more rapidly in crystals of low lattice energy, the stored charge at room temperature is smaller than in crystals with a higher lattice energy.

If the energy of formation of a defect is known, the number of defects can be determined by measuring the total stored energy. If the number of defects is known, the energy of formation of a single defect can be calculated. Provided the irradiation is carried out at low temperature, when the annealing of defects is suppressed, the stored energy is a measure of the energy of formation of the given number of defects. Radiation damage to solids is in some respects analogous to the influence of plastic deformation, and is attended by similar changes in properties. In contrast to cold working, radiation damage has the following characteristics: (1) it causes a different type of microscopic damage to the lattice; (2) radiation damage is more extensive than the damage caused by plastic deformation; and (3) radiation damage appears in a microscopic volume, and is not crystallographically oriented [41].

After a high integral dose of neutron irradiation, spallation of the crystals was observed. The minimum dose of radiation needed for significant breakdown of the crystals into blocks increases with the stability of the crystals (i.e. with the lattice energy). For quartz and for lithium fluoride the dose was, respectively, 1×10^{19} and 8×10^{17} neutrons cm^{-2}. [42]

The energy stored in rock salt after 6.64% relative plastic deformation at room temperature and a maximum stress of 1.02 kg mm^{-2} was 0.4 J g^{-1}. Less than 10% of this energy is stored in point defects [43].

The stored energy increases the free energy and weakens the cohesion of the lattice. Hence, the Debye temperatures (calculated from X-ray diffraction data) of undeformed and deformed crystals of rock salt are 260–290° and 150–170° respectively [44,45].

When the concentration of F-centres was increased from 2.5×10^{17} to 6.5×10^{17} cm^{-3} by irradiation with X-rays the stored energy was found to increase linearly [46], with a tendency towards saturation at higher doses.

On annealing NaCl crystals containing stable vacancy complexes, maxima were observed on the curve of heat evolution versus temperature. These corresponded to the annihilation of mobile defects at the lower temperatures and to dissociation of the vacancy complexes at the higher temperatures [47,48]. The stored energy was measured in crystals which had been irradiated with 4.3 MeV protons in a flux of 1.5×10^{14} protons cm^{-2} s^{-1}, with X-rays, and with γ rays from ^{60}Co. Single crystals of CaF, SrF_2, BaF_2, LiF, NaCl, KCl, KBr, and KI, and of solid solutions in the KCl–KBr system, were investigated. The measurements were made by annealing and also, in the case of the alkali metal halides (with the exception of LiF), by dissolution in water as well as by annealing.

Fig. 2 shows the temperature variation of the rate of evolution of heat from NaCl crystals, heated after the stated dose of ^{60}Co γ radiation. As the dose was increased, the amount of energy stored in the crystal increased, and the first (low-temperature) peak grew. The stored energy was greater in the crystals with the higher lattice energy. The amount of energy stored increases with dose of radiation. In crystals with a large lattice energy the stored energy accumulates faster than in crystals with a smaller lattice energy.

Several times more energy is stored in alkali metal halide crystals than in copper crystals, probably because of energy scattering by the free electrons in copper. The difference may be associated with the nature of radiation damage in alkali metal halides under X-ray irradiation. The defects are formed in these crystals by ionisation processes, which consume 99% of the absorbed energy. In copper the radiation damage occurs mainly by elastic interactions between the particles and the atoms of the material.

The energy stored upon irradiation can be as much as 7% of the lattice energy in NaCl. The energy stored in NaCl after irradiation at room temperature can be 200 times higher than the energy stored under maximum plastic deformation. As the temperature is lowered the amount of stored energy increases. Irradiation is a much more powerful agency than plastic deformation [49-52].

In NaCl + Ca crystals irradiated with X-rays the stored energy increases with increase of the calcium content. The position of the peak rate of heat evolution of the temperature axis shifts towards lower temperatures when the concentration of impurity is increased. This result is in keeping with the hypothesis that the activation energy for

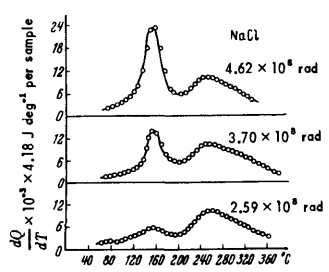

Fig. 2. Variation of the rate of evolution of heat with temperature on heating NaCl crystals irradiated with γ rays [46].

annealing radiation damage is smaller in the presence of impurities [52].

The stored energy after irradiation in solid solutions is less than in the original, pure crystals. Hence, crystals of solid solutions are more stable to radiation than pure crystals.

The amount of free energy which can be stored in the structure is determined by the experimental conditions and by the composition of the compound. As the bond energy increases, the energy storage capacity (i.e. the free energy) of the crystal increases. Substances having a high lattice energy and able to store the energy dissipated by mechanical or thermal treatment, or by irradiation, can be used as memory elements for external interactions giving rise to excess free energy.

The radiation-induced changes in the properties of materials with ionic bonds vary in the same sense as the stored energy. The amount of energy stored after relatively low doses of radiation or by quenching is of the same order of magnitude as in systems containing impurities or in solid solutions. Thus, solid-state reactions, whose characteristics show a correlation with the free energy in ionic compounds, are influenced by irradiation in the same way as by heat treatment.

The postulated strong influence of the after-effects of irradiation on the rate of processes determined by free-energy changes, and the expectation of a significant change in the properties of substances with bonds of the ionic type, were not confirmed by experimental measurements. The changes taking place in the material during irradiation are determined by the amount of energy absorbed: this increases as the lattice energy of the crystal is decreased. A compound with a low bond energy absorbs more energy in the radiation field and is weakened to a greater extent than a compound with a higher lattice energy. The energy absorbed exceeds the stored energy by two or more orders of magnitude. Hence, radiation technology should be based on the effects occurring during irradiation rather than after irradiation [41].

V. DISSOLUTION AND EVAPORATION OF ALKALI METAL HALIDES

When alkali metal halides come into contact with water or unsaturated aqueous solutions the following processes can occur: diffusional or diffusion-kinetic dissolution, hydrate formation, dissociation, and crystallisation from solution. The probability and rate of each of these processes depend on the bond energy of the chemical compound being dissolved, on the nature of the solvent, and on the dissolution conditions.

When a crystal dissolves and the system passes from an ordered to a disordered state the energy of the system increases. The ordered state of the particles in the crystal corresponds to a minimum in potential energy.

The heat of solution Q_{sol} is made up of the heat needed to break down the crystal structure, including the lattice energy U (taken with the negative sign) and the heat of interaction of the solute with the solvent ($H > 0$), which is evolved on dissolution. Thus, we have approximately

$$Q_{sol} = H - U. \qquad (4)$$

On dissolution in water with formation of hydrates the quantity Q_{sol} [*H*? (Ed. of Translation)] is termed the heat of hydration.

Fig. 3 shows the variation of the heat of hydration of the alkali metal halides, taken as the sum of the heats of hydration of the ions, with the lattice energy. The expected linear relationship (4) is satisfactorily supported by the experimental data (see Fig. 3).

The chemical stability of ionic compounds increases with increase of lattice energy [5]. The monotonic relationship between solubility and thermal effect is infringed if compound formation with water takes place [5]. If the salts dissolve without forming hydrates, and dissolution occurs with absorption of heat, i.e. $\Delta H > 0$, the solubility decreases with increase of lattice energy as shown in Fig. 4. For compounds which form crystal hydrates the thermal effect on dissolution increases with increase of lattice energy.

For aqueous salt solutions, if $\Delta H > 0$, we also have $T\Delta S > 0$, where ΔS is the increase in entropy of the system resulting from dissolution [53]. The thermal effect on dissolution of these systems, coupled with the condition $T\Delta S > \Delta H$, automatically controls the dissolution. The large increase in entropy of the system during dissolution of a crystal lowers the free energy of the system and therefore favours the dissolution process. The entropy increase ΔS attending dissolution in water of the alkali metal halides which do not form hydrates is smaller, the higher the lattice energy. This accounts for the decrease in solubility illustrated in Fig. 4.

Crystals of alkali metal halides can dissolve in water and in aqueous solutions in the diffusional regime when the rate of dissolution is determined exclusively by diffusion, and in the diffusion-kinetic regime, which depends on the structure of the crystal [54].

The difference in the dissolution mechanism of crystals along different crystallographic directions gives rise to

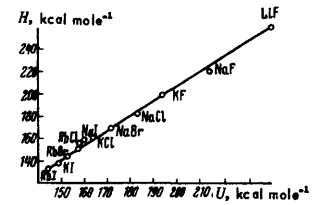

Fig. 3. Variation of the heat of hydration of alkali metal halides, taken as the sum of the heats of hydration of the ions, with lattice energy.

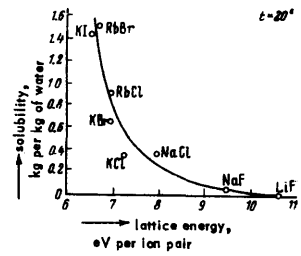

Fig. 4. Solubility of the alkali metal halides in water at 20° against lattice energy.

anisotropy in the rate of dissolution. The rate of dissolution of a crystal in the mild solvents recommended for etching is probably more under the control of the reaction by which particles are transferred from the crystal into the solution than under the control of diffusion into the bulk of the solution [31,55].

In the diffusion-kinetic regime the rate of dissolution of a crystal becomes anisotropic. At room temperature the highest rate of dissolution is observed on the (110) face, and the lowest on the (100) face. The ratio of the rates $v_{(110)}$ and $v_{(100)}$ increases [with lattice energy? (Ed. of Translation)] [31]. The rate of dissolution is highest when the reticular density of the ions on the crystal face is highest and the energy of the bonds between the ions is lowest. The rate of dissolution is lowest on the (110) face, which has the highest density of ions, but on the other hand the bonds between the ions on the (100) face are the strongest [sic]†. Thus, the rate of dissolution in this case correlates satisfactorily with the bond energy of the ions, but not with their density. In the (110) plane the rate of dissolution is greatest, the ionic density is less than on the (100) face, and the bonds between neighbouring ions are less strong than on the (100) face. Therefore, we again note a satisfactory correlation between the rate of dissolution and the energy of the bond between the particles [31].

The dissolution anisotropy of crystals increases with increase of surface energy and of lattice energy. The rates of contact melting of the various faces of crystals display a similar relationship to that of the rates of dissolution of the faces: the rate of contact melting of the crystals is a maximum on the (110) face and a minimum on the (100) face [7-9]. The ratio of the dissolution rates, $v_{(110)}/v_{(100)}$, for a given undersaturation increases with the crystal lattice energy. Therefore, the transition to the diffusion-kinetic dissolution mechanism takes place at lower concentrations in the aqueous solutions used as solvents [31] when the lattice energy of the crystals is greatest. When the crystals are dissolved in doubly distilled water the anisotropy $v_{(110)}/v_{(100)}$ of the rate of dissolution increases with the lattice energy and with stirring rate of the solution.

In radiation chemistry and technology it is important to know the dissolution mechanisms of materials during and after irradiation. The damage to the structure of an irradiated crystal leads to an increased density of dissolution centres and to a higher rate of dissolution under certain conditions. The (100) and (110) faces, which contain ions of both kinds, were chosen for comparison: the (111) plane contains only ions of a single kind.

The interionic distance on the (110) face is greater than on the (100) face by a factor of $\sqrt{2}$, and the bond energy is accordingly lower. The density of defects is greater on faces with a lower bond energy. Because of its lower bond energy and higher defect concentration, the (110) face dissolves faster than the (100) face [56].

Because of the bond energy differences in the various crystal planes, in practice a crystal always breaks along a (100) cleavage plane, whose bond energy is lower than that of alternative planes. This is because the bond energy between ions in neighbouring (100) planes is decreased by the relatively large interplanar spacing. Irradiation of a crystal with soft X-rays, which are absorbed in a thin layer, increases the linear rate of dissolution of the (100) face without affecting the rate of dissolution of the more defective (110) face. For any given rate of arrival of the solvent flow at the surface undergoing dissolution, and for each crystal composition, we can define a limiting undersaturation σ_0 of the solvent. The linear rate of dissolution of a (100) crystal face is affected by irradiation only if the relative undersaturation is less than σ_0.

The value of σ_0 increases with lattice energy. To remain in the region of low dissolution rate, in which the rate is a function of the previous dose of radiation, the degree of undersaturation of the solvent must be lowered in proportion to the energy of the chemical bond [55].

These results justify the general conclusion that the linear rate of dissolution should be structure-sensitive at low dissolution rates and low undersaturations of the solvent [31].

Fig. 5 shows curves for the relative linear rate of dissolution of an irradiated (100) face (v_0/v_n, where v_n is the rate before irradiation) for various values of the relative undersaturation σ and for crystals of different chemical composition after irradiation with a dose of 10^5 rad of 8 keV X-rays. Irradiation and dissolution were both carried out at room temperature.

The largest increase in rate of dissolution is found in crystals with high lattice energy. This result agrees with the hypothesis that radiation-induced defects, which increase the rate of dissolution, are more permanently retained in the lattice of compounds with more stable chemical bonds [55].

The deviation from the general rule (of the ratio v_0/v_n increasing with lattice energy) shown by KI and KBr crystals at $\sigma \geq 0.006$ is ascribed to transition from the diffusion-kinetic dissolution regime to the diffusion-limited regime.

For each ion of a compound it is possible to select dissolution conditions and a solvent such that the parameters of the dissolution process (e.g. the rate of dissolution) are

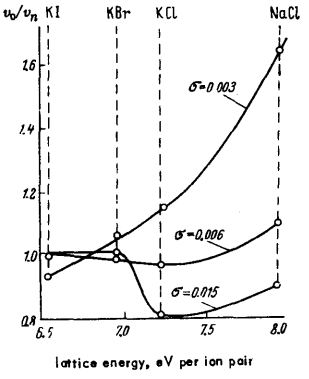

Fig. 5. Ratio of the linear dissolution rate v_0 of an irradiated (100) face to the rate of dissolution of a non-irradiated (100) face at different values of the relative undersaturation, σ, for crystals of different chemical composition after irradiation with 10^5 rad of 8 keV X-rays.

† Presumably the author means: The rate of dissolution *should be* lowest on the (110) face which has the *lower* density of ions compared with (100) but on the other hand the bonds between the ions on the (100) face are the strongest (Ed. of Translation).

sensitive to external interactions (e.g. to irradiation [55]). Thus, the linear rate of dissolution under specific conditions is a measure of the radiation stability of an ionic compound. Irradiation increases the density of defects in the material, loosens its structure, and increases the rate of dissolution. These effects are more marked in compounds of relatively high bond energy, since these can store radiation effects more successfully. High-energy compounds undergo changes in properties after irradiation because of the rapid annealing of radiation-induced defects. It can be assumed that the density of radiation defects will be greater in compounds with a lower bond energy, and that their properties will show relatively greater changes than those of compounds with a higher lattice energy.

Hence, it is important to investigate the dissolution mechanism and the characteristics of the process during irradiation of the solid to be dissolved.

The dependence of the time [sic], rate of melting, and rate of evaporation of a solid upon temperature is of scientific interest in the description of radiation damage (thermal spike), of the thermodynamics and theory of the solid state, and of the thermal decomposition of solids, etc.

The rate of thermal disintegration of a solid varies with experimental conditions, pressure, dose of radiation, and also with the structure of the solid (including structural defects).

The temperature dependence of the rate of evaporation v_{ev} of a solid in a vacuum is given by the expression

$$\log v_{ev} = A_1 - B_1/T, \quad (5)$$

where A_1 and B_1 are constants, and T (°K) is the evaporation temperature, or

$$v_{ev} = v_0 \exp(-E/RT)$$

where E is the heat of evaporation and R is the gas constant.

The temperature dependence of the vapour pressure P of metal oxides and of alkali metal halides is described by the approximate formula

$$\log P = A - \frac{B}{T} \quad (6)$$

where A and B are constants [57,58].

At higher temperatures the rate of evaporation increases, and the evaporation time τ decreases exponentially; the effect is analogous to an increase of stress during mechanical fracture.

The temperature dependence of the vapour pressure and the heats of evaporation of NaCl, KCl, KBr, and KI have been measured in the pressure range 10^{-1}–10^{-7} mmHg by the surface ionisation method. The heat of evaporation and the entropy were calculated from the results. The heat of evaporation and entropy for a temperature of 298° were also evaluated [58].

Fig. 6 shows graphs of $\log P = f(1/T)$. In the temperature range 1000–600°K the vapour pressure P (and therefore also the rate of evaporation) increase exponentially with specimen temperature.

The heat of evaporation of a substance and the entropy of solid compounds increase when the temperature is raised [59]. An increase of lattice energy also raises the heat of evaporation, lowers the entropy of the solid, and raises the entropy of the vapour. The vapour pressure and the rate

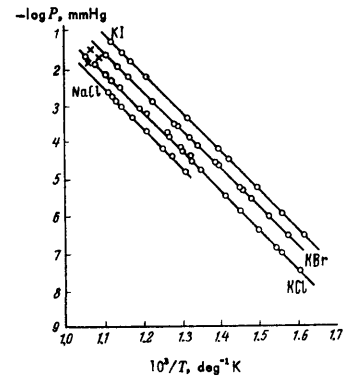

Fig. 6. Variation of $\log P$ with $1/T$. [57]

of evaporation of single crystals in a vacuum increase exponentially with temperature [59]. The evaporation coefficient, defined as the rate of evaporation from 1 cm² in 1 s divided by the rate of molecular collisions from the saturated vapour on 1 cm² in 1 s at the same temperature, is independent of temperature over a certain interval.

The higher the evaporation coefficient, the greater is the number of molecules evaporating from the surface and the weaker is the bond between particles.

At elevated temperatures the heat of evaporation decreases somewhat. Because of the different in the rates of evaporation from different crystal faces, stepped and mosaic structures are found after evaporation.

A similar behaviour is observed in tension: as the stress σ is increased, the heat of activation of the rupture process decreases according to the equation $U = U_0 - \gamma\sigma$, and the rate of tensile deformation increases exponentially [59].

The rate of evaporation of molybdenum and tungsten in a vacuum is increased by 80% or more on applying a field of 10^6 V cm^{-1}. The effect of strong electric fields (10^6 V cm^{-1}) on the rate of evaporation of the alkali metals is not yet known.

The evaporation of metals, oxides, and alkali metal halides in a vacuum and the mechanical failure of these materials show the same type of behaviour. As the driving force (temperature or tensile stress) increases, the rate of breakdown increases exponentially and the time of breakdown correspondingly decreases. Temperature increase lowers the heat of activation for evaporation and also the heat of activation of the process of failure in tension; the formation energy of the breakdown process decreases with increase of excess stress [59].

VI. SEMICONDUCTOR (ELECTRON–HOLE) PROPERTIES OF IONIC CRYSTALS AND THEIR CHEMICAL COMPOSITION

The electronic properties and other characteristics of crystals show a regular dependence on the lattice energy. The electronic properties can be discussed by treating the crystal as a system of interacting ions. We shall define the electronic levels in the isolated atoms by taking the energy of a free electron at rest in a vacuum as zero. The lowest unoccupied level of a free Na ion, corresponding to

the 3*s* state, is located below the zero level by an amount equal to the ionisation energy of 5.12 eV. The highest occupied level for the Cl^- ion is a 3*p* level, located below the vacuum level by an amount equal to the electron affinity of the Cl atom (4 eV).

Thus, the free 3*s* level lies below the occupied 3*p* level by 1.12 eV. As the free Na^+ and Cl^- ions are brought closer together, and the fraction of the chemical bond energy due to Coulombic interaction increases, the relative positions of the energy levels begin to change at a certain interionic distance, beyond which they become inverted. With further decrease of the interionic distance, the highest occupied 3*p* levels of the Cl^- ions are found to lie below the free 3*s* levels of Na^+.

When the distance between neighbouring ions reaches a value equal to the lattice parameter, by which time the wave functions of nearest ions of the same sign have begun to overlap, the discrete electronic levels of the atoms spread out into bands. The lattice parameter determines the band gap and the width of the bands. The levels corresponding to pairs of ions of the same kind overlap to form an energy band. The energy level diagram for electrons in crystals depends on the lattice parameter and on the energy spectrum of the lattice on the one hand, and on the electronic structure and levels of the atom on the other hand. For example, the lower (filled, or valence) band of an NaCl crystal is associated with the highest filled 3*p* levels of Cl^-, whilst the empty upper band of energy levels of the crystal corresponds to lowest unoccupied 3*s* levels of the Na^+ ions (Fig. 7).

The interaction between the atoms of a solid is reflected most strikingly by the energy conditions of the outer electrons of the atoms having the highest energy and exposed to the fields of neighbouring atoms situated at a distance a_0 apart.

The energy levels of the inner electrons for $r \leqslant a_0$ either do not split at all (1*s*) or split very slightly (2*s*). In this sense the crystal can be treated as a giant molecule, consisting of a large number of atoms and having the system of energy levels described above. The inner electrons of these atoms behave almost as though the atoms were isolated, whilst the outer electrons belong to the whole molecule-crystal. The energy of the electrons can lie within the regions shown hatched in Fig. 7 (the energy bands).

The valence electrons in atoms have several allowed levels, and therefore several bands of allowed electron energies are usually formed in crystals. The width of the forbidden energy gap is comparable to that of the allowed d bands. As the lattice energy decreases in Fig. 7, the width of the allowed energy bands increases and that of the forbidden gap decreases.

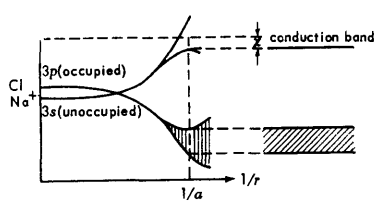

Fig. 7. Splitting of the different atomic levels under the influence of the field of neighbouring atoms.

The filling of the energy bands by electrons must satisfy Pauli's exclusion principle and at the same time minimise the energy of the system: hence, the lowest levels of the valence band are filled by electron pairs.

In real crystals the number of atoms, n, in 1 cm^3 is of the order of 10^{22}–10^{23}. The number of levels in each band must also be of the same order. The total width of the band is a few eV, and therefore the distance between adjacent levels is as low as $\sim 10^{-22}$ eV.

These effects give rise to some experimental observations interrelating the electron–hole transitions and properties in alkali metal halide crystals with the energetics of the ionic lattice in general, and with the chemical composition of a compound.

When the crystal lattice energy decreases, the width ΔE of the forbidden gap of electron energies also decreases, and the dielectric constant ϵ of the crystal increases. In alkali metal halides with *F*-centres the Mott relationship $\epsilon^{-2} \simeq \Delta E$, which was proposed for extrinsic semiconductors, is approximately obeyed.

The systematic increase of ϵ with decrease of lattice energy follows from the increasing polarisability of the anions on going from fluorides to iodides and of the cations on going from lithium to caesium, and also from the weakening of the Coulombic binding in the structure and from the increasing contribution of van der Waals interactions to the chemical bonding in these compounds. The dielectric properties and the stability deteriorate on going from lithium fluoride towards caesium iodide, as the ionic character of the chemical bond decreases.

The optical refractive index and the absorption coefficient over a wide range of radiation energies decrease as the lattice energy increases. The short-wave edge of the fundamental absorption and the maxima of the fundamental and additional absorptions in the infrared, visible, and ultraviolet regions of the spectrum for crystals activated by impurities are shifted towards shorter waves in this series of compounds by moving towards greater lattice energies whilst keeping the cation constant.

Some physical processes in crystals are not directly related to the lattice energy. For example, the scattering of phonons, photons, and high-energy particles at the atoms of which the crystal is composed. These processes are determined by the cross-section of the scattering centres, by the ionic radius, by the number of electrons, etc. As the radius of the ions in the compound increases the lattice energy decreases whilst photon, phonon, and particle scattering increases. Thus, a decrease in lattice energy is accompanied by enhanced absorption of radiation and of phonons, and by a decrease in the thermal conductivity and velocity of sound in the crystals.

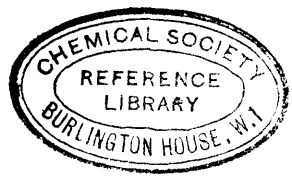
This correlation allows us to extend to these properties the classification of the properties of ionic structures by means of a single parameter: the crystal lattice energy.

The properties of structures including other chemical bond types can likewise be classified in terms of a characteristic energy. Thus, in covalently bound semiconductors we note a correlation between various properties and the energy of atomisation or the heat of formation of the compound.

A classification of the properties of various glassy polymers can be based, as in the case of crystals, on the force binding together the structural units which give rise to the

polymer and into which the polymer breaks down when it decomposes. Increase of binding energy between the structural units of the glasses is accompanied by an increase in the temperature and heat of the glass transition, and of the thermal, mechanical, and chemical stability of the glass, as well as by a decrease in the loss angle and the electrical conductivity, and by a shift of the region of anomalous dispersion of the dielectric constant and of the losses towards higher temperatures.

The stability of solids towards radiation varies with chemical bond type. Chemical bonds can be placed in the following order of decreasing stability towards the action of ionising radiation: metallic, ionic, covalent, and (the least stable) molecular.



The available fund of experimental data allows us correctly to evaluate changes in the properties of compounds due to changes in chemical composition, and to arrive at a general picture of the rules which determine the influence of the chemical bond in a solid on the properties of the solid.

The classification of compounds on the basis of the chemical bond can give guidance in the search for new dielectrics and semiconductors, and in the determination of their properties. It may be less complicated to treat the properties of materials in terms of the chemical bond than to calculate them on the basis of band theory.

ORIENTATION OF NUCLEOPHILIC ATTACK AT AN ACTIVATED DOUBLE BOND

A.N. Nesmeyanov, M.I. Rybinskaya, and L.V. Rybin

CONTENTS

I. Introduction 453

II. Mechanism of nucleophilic reactions of an ethylenic bond activated by electron-acceptor groups 453

III. Orientation of nucleophilic attack at the double bond of the X–CH=CH–Y system 455

I. INTRODUCTION

An explanation for the regularities in cyanoethylation and condensation with $\alpha\beta$-unsaturated carbonyl-containing compounds (a particular type of which is known as the Michael condensation) has been sought frequently since the time they were discovered up to the present (see earlier reviews [1-4]). The investigators were interested in a simple and cheap path of synthesis for compounds of the most varied types, many of which became available even on an industrial scale.

The main condition for the successful use of ethylene compounds in these reactions is the presence of electron-acceptor groups which activate the double bond. However, the problems of a detailed study of the influence of electron-acceptor groups on the condensation from a quantitative standpoint received attention comparatively recently. The influence on the mechanism and rate of reaction of the introduction in series with the alkene bond of additional electron-acceptor groups and of their nature has also been little studied, although even now it is clear that this influence is undoubtedly great, as the example of tetracyanoethylene has shown. The latter, as is well known, not only reacts readily with nucleophilic reagents, forming addition and substitution products, but is also the strongest of the known π-acids, capable of giving a stable anion-radical, isolated in the form of salts with various cations [5,6].

In the present brief review an attempt is made to generalise some of the properties of $\alpha\beta$-substituted ethylene systems in which the double bond is under the inconsistent action of two electron-acceptor groups. Such systems can be symmetrical (identical electron-acceptor groups) or unsymmetrical (different groups), the interest being greatest in unsaturated compounds with electron-acceptor groups conjugated with the double bond. An explanation of the regularity in the direction of the attack of the nucleophilic agent for unsymmetrical $\alpha\beta$-diactivated ethylenes is also a subject of this review.

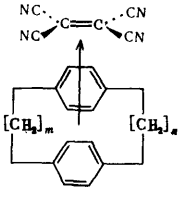
These problems are mainly considered by the example of the compounds RCOCH=CHX, where X is CN, CO_2R, NO_2, SO_2Ar, COAr, etc. In connection with this in the present review the preparation and reactivity of compounds of this type will receive most attention.

II. MECHANISM OF NUCLEOPHILIC REACTIONS OF AN ETHYLENIC BOND ACTIVATED BY ELECTRON-ACCEPTOR GROUPS

The mechanism of the reaction of an activated double bond with nucleophilic reagents was predicted theoretically by Ingold [7] and confirmed experimentally by several authors [8-14]. According to this mechanism the rate-determining stage is the addition of the nucleophilic reagent to the β-carbon atom of the double bond relative to the electron-acceptor substituent, which can be written in general form:

$$X{-}CH{=}CH_2 + Z^- \underset{}{\overset{\text{slow}}{\rightleftharpoons}} X{-}\bar{C}H{-}CH_2{-}Z \overset{+H^+\ \text{fast}}{\rightleftharpoons} XCH_2CH_2Z.$$

The reaction rate is given by the equation:



$$\frac{-d[XCH=CH_2]}{dt} = k[XCH=CH_2][Z^-].$$

The reactivity of monoactivated ethylenes with nucleophilic reagents is usually linked with the polarisation of the double bond[15] in these compounds, or, what is the same thing, with the presence of an appreciable positive charge on the β carbon atom of the double bond. From this standpoint the high reactivity (see Table 1) of the $\alpha\beta$-substituted† ethylenes of the *trans*-series is astonishing since the double bond in these compounds should be polarised comparatively weakly, as can be judged from the low intensity of the absorption band of the double bond in the infrared spectrum and the high intensity in the Raman spectrum[16].

The available information on the kinetics of the reaction of monosubstituted and $\alpha\beta$-disubstituted ethylenes, although meagre, allows some comparisons to be drawn. Table 1 gives data on the kinetics of the addition of methanol to an activated double bond, which show that the reaction rate is much greater than that for disubstituted ethylenes.

In this connection it is desirable to consider the molecule diagrams calculated by Shvarts[20] by the molecular orbital method for five cyano-substituted ethylenes. Table 2 gives some data from these calculations.

In examining these diagrams the positive charges on the ethylenic carbon atoms and the values of the energies of the lower vacant orbitals must be compared. Clearly the double bond is most polarised in the unsymmetrical compounds *1* and *2* (see Table 2). In these instances a considerable positive charge is concentrated on the β-carbon atoms in relation to the electron-acceptor groups. In compounds *3* and *5* there is no polarisation of the double bond (there is a small positive charge on both ethylene carbon atoms), but the level of the first vacant orbital lies considerably below that for *1* and *2*. This difference appears distinctly in the disubstituted alkenes *2* and *3*, the first of which is characterised by a strongly polarised double bond with the maximal value of the positive charge on all five cyano-substituents of the ethylenes and a higher level of the energy of the lower vacant orbital of the last four. An especially low energy level was calculated for tetracyanoethylene, in which it is close to the energy of the atomic orbital. Hence it can be seen that the accumulation of cyano-groups around the double bond lowers the energy of the first vacant orbital. This agrees well with the ability of tetracyanoethylene to form π-complexes and to give radical-anions by accepting one electron[5,6]. We note that π-π-complexes of tetracyanoethylene with *para*-cyclophanes are so stable that they could be isolated in the crystalline state[22].

orange for $m = n = 4$; red for $m = n = 6$, red-black for $m = 3$, $n = 4$.

Rather stable π-complexes are also formed by $\alpha\beta$-disubstituted ethylenes. According to Merrifield and Phillips[23], who studied complexes of maleic anhydride and *p*-quinone with pyrene (CH_2Cl_2, 22°) spectrophotometrically, the equilibrium constants for the formation of the complexes are 17.6 and 14.4 respectively. For tetracyanoethylene with the same π-base the constant is 29.5.

At the same time α- and $\alpha\alpha$-substituted ethylenes should show a very weak tendency to π-complex formation. Actually, even methylenemalononitrile forms a very weak complex with anthracene (benzene, 23°), the equilibrium constant for the formation of the complex being close to zero[24].

Unfortunately, the necessary quantitative data on the reactions of these compounds with nucleophilic reagents do not exist at present, so strict comparison with calculated data is impossible. Such comparisons would be especially interesting for methylenemalononitrile and fumarodinitrile. However, the difference in the positive charges and energy levels of the first vacant orbitals for the two types of substituted ethylenes (α and $\alpha\alpha$, or $\alpha\beta$ and $\alpha\alpha\beta\beta$) suggests that their reactions with nucleophilic reagents may have some differences in mechanism.

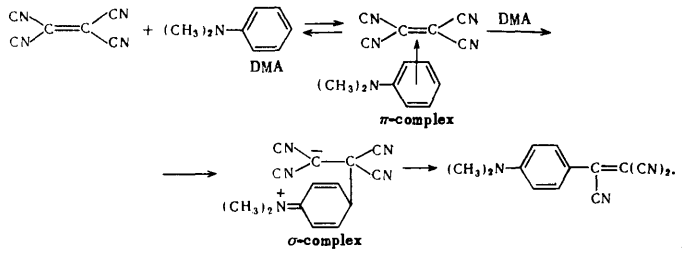
A possible hypothesis is that a not inconsiderable part (possibly the main part) in the mechanism of the $\alpha\beta$- and $\alpha\alpha\beta\beta$-substituted double bond is played by the ability to form π-complexes which subsequently rearrange into σ-complexes and then into the final product.

The correctness of this suggestion is confirmed by a series of experimental results. Actually tetracyanoethylene[5,6], tricyanovinyl chloride[25], dicyanobis(ethoxycarbonyl)ethylene[26], maleic anhydride[23], and esters of fumaric acid[27-29] have been separately shown to be capable of

TABLE 1. Data on the reaction kinetics for the addition of methanol to an activated double bond.

Alkene	K_{25}, litre mole^{-1} min^{-1}	Activation parameters
trans-$C_6H_5COCH{=}CHCN$[17]	425 (25°)	ΔE=13.5±1.3 kcal mole^{-1} ΔS=−11 e.u.
trans-$C_6H_5COCH{=}CHCOC_6H_5$[18]	182 (25°)	
$CH_2{=}CHCN$[13]	0.722 (25°)	ΔE=18.7 kcal mole^{-1} ΔS=−7.2 e.u.
$CH_2{=}CHCOCH_3$[19]	23.3 (19°)	

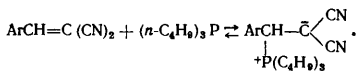
TABLE 2. Calculation of the molecular orbitals of cyano-substituted ethylenes*



No.	Skeleton and charges on the carbon atoms of the double bond**	Energy of the lowest vacant orbital	Order of the ethylenic bond
1	−0.016 / +0.106	α−0.487β	1.886
2	−0.024 / +0.184	α−0.382β	1.802
3	+0.056 / +0.056	α−0.241β	1.784
4	+0.030 / +0.106	α−0.148β	1.704
5	+0.062 / +0.062	α−0.058β	1.638

* This table gives data calculated using Pullman and Pullman's parameters[21]

** The black circles denote CN groups, the lines C–H bonds.

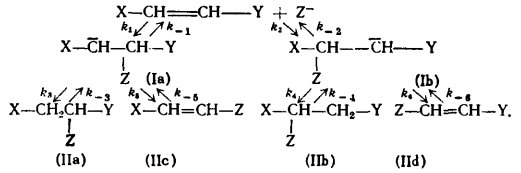


† In speaking of substituted ethylenes we will be thinking of ethylenes containing electron-acceptor substituents as well as the double bond.

forming π-complexes and of reacting with nucleophilic reagents. Rappoport and coworkers [30] have experimentally confirmed the formation of a π-complex which is an intermediate in the reaction of tetracyanoethylene with dimethylaniline. On investigating this reaction spectrophotometrically they found the rapid and reversible formation of a π-complex (K_{equil} = 15 litre mole^{-1}), which, they think, is converted into a σ-complex and then into the final product. This can be represented schematically:

Here it should be noted that a very low activation energy (5.7 kcal mole^{-1}) is found for the π-complex → σ-complex stage. Foster and Hanson suggested a similar mechanism for the reaction of tetracyanoethylene with indole [31].

On the other hand, of the α- and $\alpha\alpha$-substituted ethylenes, as noted above, even methylenemalononitrile forms a weak complex. In this connection it is interesting to consider the reaction of arylmethylenemalononitriles with tributylphosphine. In a spectrophotometric investigation of the kinetics of these reactions Rappoport and Gertler [32] observed the direct conversion of these compounds into an addition compound, having, according to the infrared spectra, the structure of a bipolar ion, which corresponds to the σ-complex:



It was found that the addition product readily dissociates into the initial components. The authors did not observe any intermediate products within the sensitivity limits of the method.

Hence, on the basis of the above evidence it seems logical to suggest that the observed increase in reaction rate with methanol for $\alpha\beta$-disubstituted ethylenes in comparison with monosubstituted ones (see Table 1) can be due to the reaction with the disubstituted ethylenes proceeding through the intermediate formation of a π-complex.

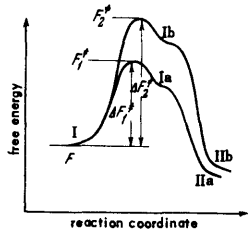
III. ORIENTATION OF NUCLEOPHILIC ATTACK AT THE DOUBLE BOND OF THE X–CH=CH–Y SYSTEM

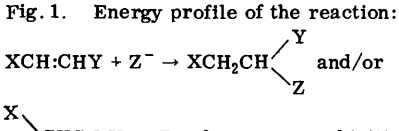
When ethylenes unsymmetrically substituted at each side react with nucleophilic reagents the orientation of the nucleophilic attack must be determined. The scheme of reaction of nucleophilic reagents with compounds of the type XCH=CH–Y, where X and Y are electron-acceptor groups, can be represented in the general form as follows:

In this, there are different probabilities of the formation of two carbanions (Ia) and (Ib). Kinetic investigations of reactions of this type undertaken by various authors [18] and by us [17,33] agree with these suggestions‡.

The stabilisation path of these carbanions will depend on several factors and above all on the nature of X and Y, on the nature of the nucleophilic substance, and on the surrounding medium. The stabilisation directions most frequently realised are§: (1) the addition of a proton or any positive species, as a result of which addition products (IIa) and (IIb) are formed; (2) ejection of an anion or neutral molecule and formation of substitution products (IIc) and (IId); (3) hydrolytic breakdown when the nucleophilic reagent is the OH^- ion. Naturally, the first stabilisation path of carbanions (Ia) and (Ib) predominates in systems where X and Y are electron-acceptor groups incapable of readily leaving in the form of anions (for example, RCO–, COOR). On the other hand, for X and Y which are easily removed in the form of stable anions (NO_2, halogens) the second path is possible. Naturally, for some examples of systems which we will consider mixed stabilisation of carbanions can occur (for example, where X is a group readily leaving as an anion and Y is not.

Let us consider additions and their energetic profile (Fig. 1), that is, that part of the general scheme by which products (IIa) and (IIb) are formed. According to the theory of the transition state, the ratio of the amounts of two kinetically controlled reaction products (P) formed from a single initial substance depends solely on the difference between the free energy levels of the two transition states and is not connected with the free energy level of the principal state (it is suggested that the reaction includes





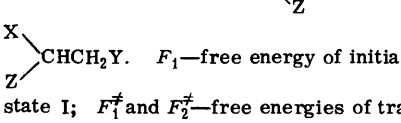


Fig. 1. Energy profile of the reaction:

and/or

F_1—free energy of initial state I; $F_1^{\neq}$ and $F_2^{\neq}$—free energies of transition states leading to the carbanions (Ia) and (Ib).

‡ The kinetic data also do not contradict the intermediate formation of a π-complex.

§ In the present work we shall consider only some of the possible stabilisation paths. For a detailed discussion of this problem see the paper of Patai and Rappoport [34].

the same kinetic expressions for the formation of both products)

$$P = \frac{k_1}{k_2} = e^{\frac{F_1^{\neq} - F_2^{\neq}}{RT}}.$$

In our particular instance the direction of attack of the nucleophile will be determined by the ratio k_1/k_2, and evidently to form a judgement about it the transition states leading to the carbanions (Ia) and (Ib) must be considered and an attempt made to evaluate their relative free energies $F_1^{\neq}$ and $F_2^{\neq}$. According to Hammond's hypothesis [35] the transition states can suggest by their structure the final products of a given stage, that is, the carbanions (Ia) and (Ib)¶ in our example and in the first rough approximation can be limited to comparison of the relative stability of the carbanions themselves, $X\overline{C}H-CHYZ$ (Ia) and $XZCH-\overline{C}HY$ (Ib) and this, in turn, for lack of other data, has to be judged from dissociation constants or from the rate constants for deuterium exchange of substituted methanes $X-CH_3$ and $Y-CH_3$. Here it is suggested that the stability of the anions depends primarily on the capability of the group directly adjoining the anionic centre to delocalisation of the negative charge. Such an approach is of course a considerable simplification, above all because it starts from these assumptions: the transition states which are formed either by the addition of negatively charged species to the double bond, or as a result of the dissociation of C–H bonds in saturated hydrocarbons, can be comparable in their structure†, that is:

$$X-CH=CH-Y+Z^- \rightleftarrows X-\overset{\overset{|}{Z}}{\overline{C}H}-CH-Y \rightleftarrows X-CH_2-\underset{\underset{|}{Z}}{CH}-Y.$$

Moreover, this approach makes no allowance whatsoever for the fact that steric factors for groups ZYCH in (Ia) and ZXCH in (Ib) and solvents (especially strongly solvating anions) can have a significant influence on the formation of carbanions. Furthermore, the possibility of interaction between the groups themselves which enter into the carbanion and the formation of cyclic transition states can be of great importance. However, this approach can be useful to a certain extent since it is valid for many reactions, which will be considered below.

It is noteworthy that for most substitutions where the heterolysis of the C–X or C–Y bond in the stabilisation of carbanions (Ia) and (Ib)—with the formation of the products (IIc) and (IId)—takes place very readily (where the group leaving is a halogen or NO_2), the energy profile can relate solely to what has been discussed. However, a more complex example is presented by substitutions in which the heterolysis of the C–X(Y) bond proceeds slowly. Fig. 2 shows the generalised picture of the energy profile for such reactions.

There are several experimental facts which agree with the above ideas on the orientation of attack by a nucleophile at an ethylenic double bond activated at each side. We will restrict discussion mainly to those instances for which the dissociation constants of the corresponding substituted methanes or the rates of their deutero-exchange are known.

¶ According to the results of most of the kinetic investigations, the addition of nucleophilic reagents at an activated double bond leading to the formation of carbanions is the limiting stage of the process [7–14]. The rapid second stage of protonation proceeds in practice with a low activation energy [36].

† Possibly a more complete introduction to the transition state in these examples can be given by a study of the secondary α-isotopic effect [37,38].

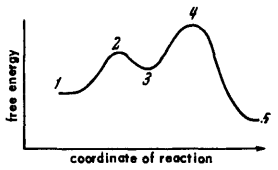

Fig. 2. Energy profile of the reaction: XCH=CHY + Z^- → XCH=CHZ and/or ZCH=CHY where the heterolysis of the C–X(Y) bond is slow.
1) Initial state; 2) transition state leading to carbanion 3; 4) transition state of heterolysis of the C–X(Y) bond; 5) final state.

On comparing the dissociation constants of nitromethane ($K_{CH_3NO_2} = 6 \times 10^{-11}$) [39] and acetic acid ($K_{CH_3CO_2H} = 10^{-24}$) [39] (see Table 3), it can be predicted that β-nitroacrylic acid will add on nucleophilic reagents in the following manner:

$$NO_2CH=CHCOOH + HZ \rightarrow NO_2CH_2\underset{\underset{|}{Z}}{CH}COOH.$$

In fact, Shechter and coworkers [42] have shown that this acid adds on methanol and water with the formation of products of this structure. It is important to note that the addition of methanol proceeds very easily even in the absence of basic catalysts.

On studying the deuterium exchange of *cis*- and *trans*-arylsulphonylacrylic acids in D_2O–NaOD medium by NMR spectra, Montanari and coworkers [43] found that the β-H is exchanged first, then the α-H, and addition products with deuterium oxide (III) and (IV) are formed:

$$ArSO_2CH=CHCOOH \rightarrow ArSO_2CD=CHCOOH \rightarrow ArSO_2CD=CDCOOH$$
$$\downarrow D_2O \qquad \downarrow D_2O$$
$$ArSO_2CD_2\underset{\underset{|}{OD}}{CH}COOH \qquad ArSO_2CD_2\underset{\underset{|}{OD}}{CD}COOH.$$
$$\text{(III) } 20\% \qquad \text{(IV) } 80\%$$

In H_2O–NaOH solution (III) exchanges all the deuterium atoms for hydrogen, but (IV) under the same conditions retains one deuterium atom, which rules out alternative structures for the β-hydroxy-acids in which after the exchange one or two deuterium atoms respectively should remain. Although in the sulphonyl-substituted methane series the dissociation constant is known only for dimethylsulphone ($K_{CH_3SO_2CH_3} = 10^{-23}$) [39] there will be no great error in taking the dissociation constant for $CH_3SO_2C_6H_5$ to be close to this value.

TABLE 3. Dissociation constants for substituted methanes.

Substituted methane	Dissociation constant of the C–H bond	Reference	Substituted methane	Dissociation constant of the C–H bond	Reference
CH_3NO_2	$6.1 \cdot 10^{-11}$	39	$(CF_3)_2CFH$	10^{-20}	40
CH_3COCH_2COOR	$2.1 \cdot 10^{-11}$	39	$CH_3SO_2CH_3$	10^{-23}	39
$(CF_3)_3CH$	10^{-11}	40	CH_3COOH *	10^{-24}	39
$CH_2(CN)_2$	$6.5 \cdot 10^{-12}$	39	$CH_3COOC_2H_5$	$10^{-24.5}$	39
$CH_2(COOC_2H_5)_2$	$5 \cdot 10^{-14}$	39	CH_3CN	10^{-25}	39
$C_6H_5COCH_3$	10^{-19}	41	CH_3CONH_2 *	10^{-25}	39
CH_3COCH_3	10^{-20}	39	$CF_3(CF_2)_2CF_2H$	10^{-30}	40

* Here, naturally we refer to constants for dissociation with the formation of the anions $^-CH_2CO_2H$ and $^-CH_2CONH_2$ and not $CH_3CO_2^-$ and $CH_3\overline{CONH}$.

Trichloromethylnitroethylene[3,3,3-trichloro-1-nitroprop-1-ene] also exhibits an extremely electrophilic double bond and with nucleophilic reagents it gives addition products [44-49] of the expected structure:

$$CCl_3CH{=}CHNO_2 + HZ \rightarrow CCl_3\underset{\underset{Z}{|}}{C}HCH_2NO_2$$

where HZ = amines, alcohols.

By the action of hydrogen chloride upon it, Dornow and coworkers [50] obtained an α-chloro-oxime, for the formation of which they proposed the following mechanism:

$$CCl_3CH{=}CHNO_2 + HCl \longrightarrow CCl_3\underset{\underset{Cl}{|}}{C}HCH_2NO_2 \longrightarrow$$

$$\longrightarrow CCl_3{-}\underset{\underset{Cl}{|}}{C}H{-}CH{=}\overset{+}{N}\begin{matrix}O^-\\ \diagdown\\ \diagup\\ OH\end{matrix} \xrightarrow{HCl} CCl_3CHCl{-}CH{=}NOH.$$

Perfluoroalkylnitroethylenes react‡ in an analogous fashion [51,52]:

$$R_fCH{=}CHNO_2 + HZ \longrightarrow R_f\underset{\underset{Z}{|}}{C}HCH_2NO_2,$$

where $R_f = CF_3$, C_3F_7, and HZ = $CH_2(CO_2R)_2$, C_2H_5OH, p-$NH_2C_6H_4CO_2H$, CH_3NO_2, or RMgX.

By studying the addition of water and ammonia to β-trifluoromethylacrylic acid and its derivative (V), Walborsky and coworkers [53,54] explained their results by the ability to stabilise the neighbouring anionic centre in the transition state being less for the CF_3 group than for the CO_2H, CO_2R, or $CONH_2$ groups. McBee and coworkers carried out an analogous work [55]:

$$CF_3CH{=}CHCOOR + HZ \longrightarrow CF_3\underset{\underset{Z}{|}}{C}HCH_2COOR.$$

(V)

Knunyants and Cheburkov [56] and McBee and coworkers [57] found that the methyl ester of 3-methyl-4,4,4-trifluorocrotonic acid (VI) adds on nucleophilic reagents as follows:

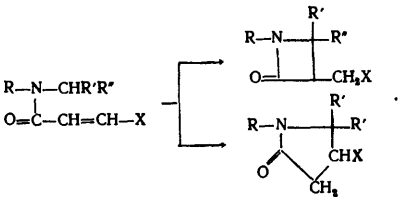
$$\begin{matrix}F_3C\\ \diagdown\\ H_3C\end{matrix}\!\!>C{=}CHCOOCH_3 + HZ \longrightarrow \begin{matrix}F_3C\\ \diagdown\\ H_3C\end{matrix}\!\!>\underset{\underset{Z}{|}}{C}{-}CH_2COOCH_3.$$

(VI)

As Table 3 shows, the attachment of CF_3 groups sharply raises the acidity of the hydrogen atoms in the α-position. In accordance with this ethyl $\beta\beta$-bis(trifluoromethyl)acrylate (VII) reacts according to the scheme [58]:

$$\begin{matrix}F_3C\\ \diagdown\\ F_3C\end{matrix}\!\!>C{=}CHCOOR + HZ \longrightarrow \begin{matrix}F_3C\\ \diagdown\\ F_3C\end{matrix}\!\!>\underset{\underset{Z}{|}}{C}H{-}CHCOOR.$$

(VII)



On determining the relative rate of formation of anions from deuterohaloforms, Hine and coworkers [59] found that in their ability to accelerate this reaction the halogens are arranged in the following order: I ~ Br > Cl > F. Slaugh and Bergman [60] came to similar conclusions in studying the kinetics of deuterium exchange in haloforms. This suggests that fluorine atoms stabilise neighbouring anionic centres worse than the other halogens. In this connection it is interesting to note that dichlorodifluoroethylene and chlorotrifluoroethylene add on nucleophilic reagents thus [61-63]:

$$CF_2{=}CCl_2 + HZ \rightarrow ZF_2C{-}CHCl_2$$
$$CF_2{=}CFCl + HZ \rightarrow ZF_2C{-}CHClF\ .$$

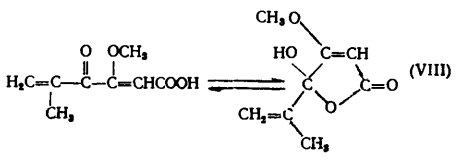
The following results evidently also fit into the framework of the rule being considered [64]:

$$(AlkO)_2\overset{O}{P}{-}CH{=}CHCOOR + H{-}\overset{O}{P}(OAlk)_2 \rightarrow ROCOCH_2CH\left[\overset{O}{P}(OAlk)_2\right]_2.$$

Bose and coworkers [65] observed an interesting dependence of cyclisation upon the nature of substituent X in β-substituted acrylamides. They found that in cyclisation instead of the γ-lactams usually obtained, β-lactams are formed when X = CO_2R or p-$NO_2C_6H_4$:

The most extensive study of the orientation of the addition of nucleophilic reagents was made for the RCOCH=CHX system, where X represents an electron-acceptor group; therefore we will consider these examples in somewhat greater detail. It is noteworthy that there is a general method of making most of these compounds, based on the reaction known as β-ketovinylation§.

β-Ketovinylation can be effected in two ways, which differ in principle. The first is based on nucleophilic substitutions, mainly in β-chlorovinyl ketones¶ and in β-acylvinyltrimethylammonium salts. In the second, which has been comparatively little developed, nucleophilic addition to the triple bond of ethynyl ketones is employed [73-75]:



$$\begin{matrix}RCOCH{=}CHCl & [\text{or } \overset{+}{N}(CH_3)_3] & \xrightarrow{X^-}\\ RCOC{\equiv}CH & \xrightarrow{HX} & \end{matrix} \rightarrow RCOCH{=}CHX\ .$$

Note that as the present authors have shown in various papers it is best to use β-acylvinyltrimethylammonium salts for the ketovinylation of anions [76-80].

The chemistry of the β-acylacrylic acids† started to develop extremely rapidly after it had been observed that antibiotic action was exhibited by a series of compounds containing the grouping

$$-CO-\underset{\underset{|}{}}{C}=C-COOH,$$

especially penicillic acid (VIII): [154]

(VIII)

‡ Andreades [40] gives $K = 10^{-30}$ for $CF_3[CF_2]_5CF_2H$. Evidently it can be assumed that the dissociation constants of CF_3CH_3 and $C_3F_7CH_3$ will be even smaller.

§ The term ketovinylation implies the introduction of the residue RCOCH=CH into the molecule. This term was proposed by Kochetkov [66].

¶ The chemistry of the β-chlorovinyl ketones has been presented in several reviews [66-71] and in a book [72].

† Preparation described elsewhere [81-153].

Since many authors thought that the antibiotic action of these compounds is based on the ability of easily adding on the active SH–, and possibly >NH, groups of bacterial enzymes, the β-acylacrylic acids and their derivatives were studied intensively in pharmacology. They were actually shown to be active against a series of gram-positive and gram-negative bacteria[93,95,144,155-159] and in some instances they showed fungicidal activity[94]. The nucleophilic reactions of the β-acylacrylic acids take place very readily and were investigated for a wide range of nucleophilic reagents. On comparison of the dissociation constants of acetophenone ($K_{C_6H_5COCH_3} = 10^{-19}$) [41] and of acetic acid, its amide, and esters ($K_{CH_3CO_2H} = 10^{-24}$, $K_{CH_3CONH_2} = 10^{-25}$, and $K_{CH_3CO_2R} = 10^{-24.5}$), [39] it can be suggested that addition products of the following structure are formed:

$$RCOCH{=}CHCOOR' + HZ \rightarrow RCOCH_2\underset{\displaystyle Z}{\underset{|}{C}}HCOOR\ .$$

Actually in most of the investigations‡ it was found that as a result of the reaction of the β-acylacrylic acids or their derivatives with nucleophilic reagents, α-substituted β-acylpropionic acids are formed. For example, even in the first work on the investigation of the properties of β-benzoylacrylic acid[168] it was shown that it readily adds on water, sodium cyanide, ammonia, aniline, hydrogen halides§, and that the general scheme of reaction can be represented as above. Sodium sulphite also adds on similarly[92,170].

Cromwell and coworkers[171,172] studied the reaction of methyl β-benzoylacrylate with primary and secondary amines:

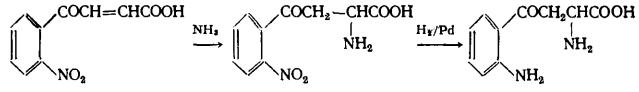
$$C_6H_5COCH{=}CHCOOCH_3 + HNR_1R_2 \rightarrow C_6H_5COCH_2\underset{\displaystyle NR_1R_2}{\underset{|}{C}}HCOOCH_3.$$

The study of the various conversions of the reaction products and above all their reduction to α-amino-γ-phenylbutyric acids, showed that amines add on in the α position to the methoxycarbonyl group.

The reaction of β-aroylacrylic acids with ammonia proceeds in a similar manner[149,152,168,173]. The structure of the addition product of β-benzoylacrylic acid and ammonia:

$$ArCOCH{=}CHCOOH + NH_3 \rightarrow ArCOCH_2\underset{\displaystyle NH_2}{\underset{|}{C}}HCOOH$$

was shown by the yield of the known β-benzoyl-α-hydroxypropionic acid under the action of nitrous acid:



$$C_6H_5COCH_2\underset{\displaystyle NH_2}{\underset{|}{C}}HCOOH \xrightarrow{HNO_2} C_6H_5COCH_2\underset{\displaystyle OH}{\underset{|}{C}}HCOON\ .$$

‡ The work of a group of French authors[160-167] somewhat contradicts these results; the French workers ascribe to the products of the addition of ammonia and amines the structure of β-acyl-β-aminopropionic acids, without giving, in essence, any evidence in support of their structures.

It is curious that in their earliest work[168] these very investigators held a contrary opinion about the orientation of the addition of amines.

§ The addition of hydrogen halides to αβ-unsaturated ketones can be considered as the proton-catalysed addition of weak nucleophilic reagents—halide anions[169].

The ability of β-aroylacrylic acids to add on ammonia was used in several studies to make *dl*-kynurenine and some of its derivatives[81,149-153]:

It is known that *l*-kynurenine—a natural α-amino-acid—plays an important part in the genetic formation of pigments in insects[174] and is also the main product of the metabolism of tryptophan in the organism of mammals and micro-organisms[174,175]. Kynurenine was first synthesised by Butenandt[176,177], who also established its structure.

It was shown that β-benzoylacrylamide also readily adds on aniline[178]:

$$C_6H_5COCH{=}CHCONH_2 + NH_2C_6H_5 \rightarrow C_6H_5COCH_2\underset{\displaystyle NHC_6H_5}{\underset{|}{C}}HCONH_2.$$

Bougault and Chabrier[179] investigated the reaction of β-benzoylacrylic acid with thiols and found that the orientation of nucleophilic attack is here the same as for amines

$$C_6H_5COCH{=}CHCOOH + RSH \rightarrow C_6H_5COCH_2\underset{\displaystyle SR}{\underset{|}{C}}HCOOH.$$

Additions of cysteine can also be classified as this type of reaction[95]. Reactions of β-aroylacrylic acids with alcohols have been somewhat less studied. Here reference can be made to the work of Lutz and Scott[180,181] and also to Rice's earlier paper[182], where it was assumed that methanol adds on in the α position to the carboxyl group:

$$ArCOCH{=}CHCOOH + CH_3OH \longrightarrow ArCOCH_2\underset{\displaystyle OCH_3}{\underset{|}{C}}HCOOH.$$

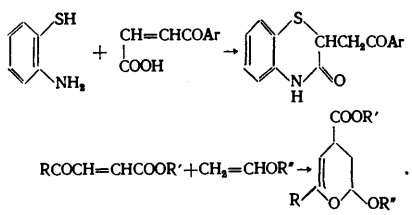
It was found[166,168] that in acid medium water adds on to β-benzoylacrylic acid with the formation of β-benzoyl-α-hydroxypropionic acid:

$$C_6H_5COCH{=}CHCOOH + H_2O \xrightarrow[H^+]{} C_6H_5COCH_2\underset{\displaystyle OH}{\underset{|}{C}}HCOOH\ .$$

At the same time aqueous alkali solutions bring about hydrolytic splitting of the double bond[85,167,168,183,184]:

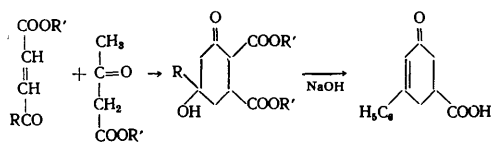
$$C_6H_5COCH{=}CHCOOH + H_2O \xrightarrow[OH^-]{} C_6H_5COCH_3 + CHOCOOH\ .$$

According to the generally accepted mechanism of similar reactions[185-189] the rate-limiting stage of the reaction is the addition of hydroxide ion to the double bond, as a result of which a carbanion (IX) is formed. The formation of acetophenone thus demonstrates that here the usual direction of nucleophilic attack is retained:



$$C_6H_5COCH{=}CHCOOR + OH^- \longrightarrow C_6H_5C\underset{\displaystyle OH}{\underset{|}{\bar{C}}}HCHCOOR \rightleftarrows$$

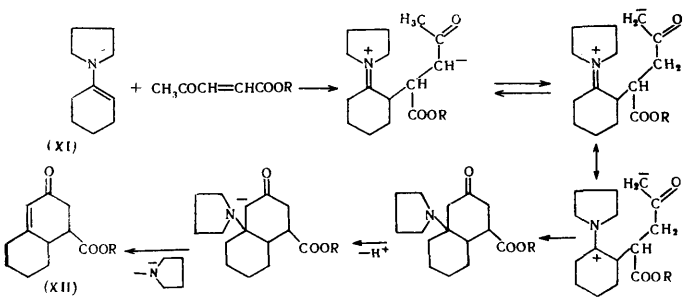
(IX)



$$\rightleftarrows C_6H_5COCH_2\underset{\displaystyle O^-}{\underset{|}{C}}HCOOR \longrightarrow C_6H_5C\bar{O}H_2 + CHOCOOR.$$

$$\qquad\qquad\qquad

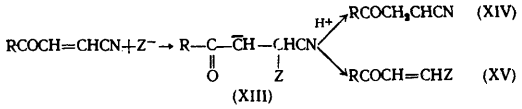
is known, and for many of these it is natural to postulate initial addition at the α-carbon atom of the double bond [193-194], for example:



Julia and Bonnet [190] proposed to use the condensation of β-acylacrylic acids (or esters) with acetoacetic ester in the presence of basic catalysts for the synthesis of substituted cyclohexenones. It was shown, by the example of β-benzoylacrylic ester, that the reaction proceeds through an intermediate cyclic addition product (X), which under the action of alkali leads to a 3-substituted 5-carboxycyclohex-2-en-1-one. The ester of this acid is readily dehydrogenated into an ester of 3-hydroxy-5-phenylbenzoic acid, which also confirms its structure:

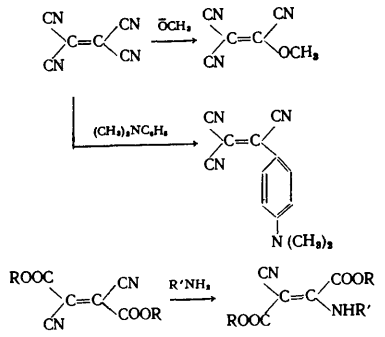
(X)

The diethylamide of acetoacetic ester reacts analogously [190]. In a brief communication Stork and Landesman [195] described the reaction of ethyl β-acetylacrylic acid with an enamine (XI), as a result of which a bicyclic product (XII) was isolated:

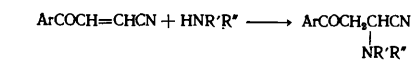


Hence all the known reactions of β-acylacrylic acids with nucleophilic reagents are characterised on the one hand by the ease with which they take place (apparently connected with the marked electron impoverishment of the ethylene bond in these compounds) and on the other by the invariable direction of attack by the nucleophile, which is probably explained by the stability of the carbanion of type

which is formed being greater than that of the carbanion



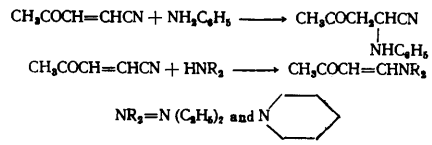
For β-cyanovinyl ketones [76] (the nitriles of β-acylacrylic acids) the expected direction of attack by the nucleophilic reagent:



(XIII)

is the same as for the β-acylacrylic acids.

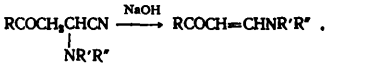
Let us remember that ($K_{C_6H_5COCH_3} = 10^{-19}$) [41] and ($K_{CH_3CN} = 10^{-25}$). [39] Actually in all the instances studied only one reaction product was observed in the reaction medium and this product contained the nucleophilic moiety in the β position to the carbonyl group, as was confirmed by thin-layer chromatography. However, unlike the β-acylacrylic acids, the intermediate carbanion (XIII) which is formed in attack by the nucleophile Z^- can be stabilised in two ways, giving addition product (XIV) as a result of protonation (Fig. 1 can represent the energy profile) and the substitution product (XV) as a result of possible heterolysis of the C–CN bond (energetic profile of Fig. 2). It is noteworthy that replacement of the CN group at an activated double bond has been observed repeatedly in the reactions of tetracyano-1,2-diethoxycarbonylethylene [5,196] and 1,2-dicyano-1,2-diethoxycarbonylethylene [197] with certain nucleophilic reagents:



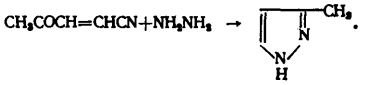
Nesmeyanov and Rybinskaya [178,198] showed that the reaction of β-cyanovinyl ketones with amines (primary and secondary) takes place very readily on simple mixing of the reagents in an appropriate solvent, as for β-acylacrylic acids. In this way aryl β-cyanovinyl ketones give an addition product in high yield. The method can serve as a preparative path for the synthesis of α-amino-γ-ketonitriles·

The structure of these compounds was shown by hydrolysis, which yielded known α-amino-β-benzoylpropionic acids.

However, methyl β-cyanovinyl ketone gives an addition product only with aniline [178], and the reaction is slower than for the aryl β-cyanovinyl ketones. Substitution products are formed with diethylamine and piperidine [198]:

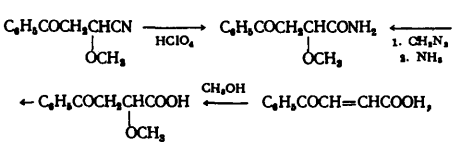


The latter is evidently explained by aliphatic amines being stronger bases than aniline, so that the equilibrium is more displaced towards the intermediate carbanion (XVI),



(XVI)

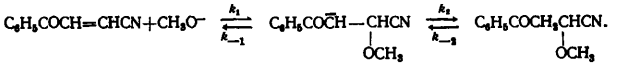
as a result of which the possibility of heterolysis of the C–CN bond is increased. It is therefore natural that the action of bases stronger than the amines (for example, alkalis) on the addition products should result in the loss of a molecule of hydrogen cyanide [178,198]:



It is interesting to note that β-cyanovinyl methyl ketone, like β-chlorovinyl methyl ketone [199], gives 3-methylpyrazole with hydrazine:

Nesmeyanov and coworkers [17] showed that in the presence of basic catalysts *cis*- and *trans*-β-cyanovinyl phenyl ketones [200] add on methanol to form β-benzoyl-α-methoxypropionitrile:

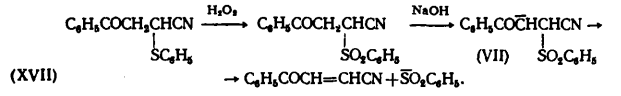
This was hydrolysed by 70% perchloric acid to give the β-benzoyl-α-methoxypropionamide:



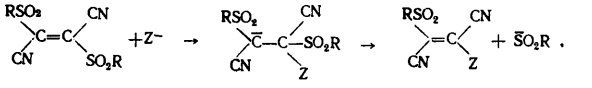
which was obtained by counter-synthesis from β-benzoylacrylic acid. Consequently the direction of the addition of methanol to β-cyanovinyl phenyl ketone is the same as to β-benzoylacrylic acid. The addition of methanol to *cis*- and *trans*-β-cyanovinyl phenyl ketones seemed a convenient method for the investigation of kinetics and mechanism [17]. Spectrophotometric studies of the kinetics showed that the reaction is reversible, but the equilibrium is strongly displaced to the side of the addition product and the equilibrium position is almost independent of the pH of the medium but dependent upon temperature (at 10° there is 90% addition, at 25°, 85%). It was found that the reaction is of first order in both *cis*- and *trans*-β-cyanovinyl phenyl ketones and first order in methoxide ion¶.

From a comparison of the second-order rate constants at 25°, k_1, *trans* = 425 litre mole^{-1} min^{-1} and k_1, *cis* = 260 litre mole^{-1} min^{-1} it is evident that there is a not very marked relation between the reaction rate and the geometrical isomerism in the β-cyanovinyl phenyl ketones.

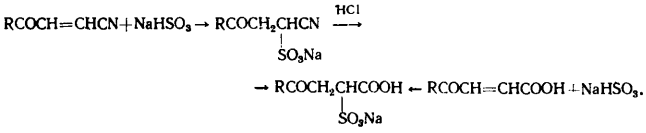
¶ See Table 1 for the activation parameters.



The experimental results agree with the reaction mechanism, which postulates a slow attack by the methoxide anion in the first stage with subsequent rapid protonation of the carbanion formed:

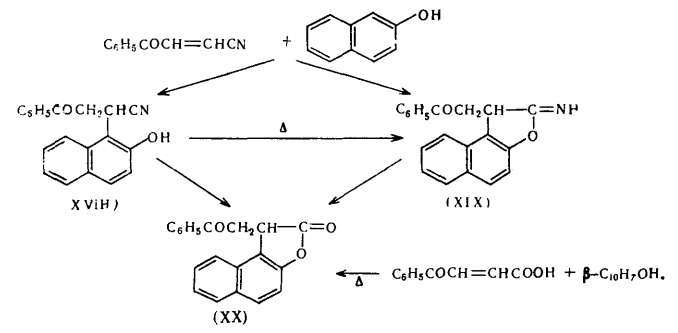


Alkyl and aryl β-cyanovinyl ketones add on thiophenol, the reaction being accelerated by the presence of bases, as a result of which β-acyl-α-phenylmercaptopropionitriles are formed in high yield [201]:

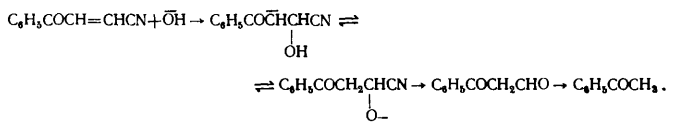


The structure was shown by the hydrolysis into the known β-aroyl-α-phenylmercaptopropionic acids. The β-acyl-α-phenylmercaptopropionitriles are oxidised by peroxide to the corresponding sulphones, which are more stable than the initial phenylmercapto-derivatives. It is interesting that when alkali acts on the latter there is an elimination of benzene sulphinic acid, which is evidently evidence that the heterolysis of the C–$SO_2C_6H_5$ bond in the carbanion (XVII) formed as intermediate is easier than the heterolysis of the C–CN bond:

Probably it is for the same reason that when 1,2-dicyano-1,2-disulphonylethylene reacts with nucleophilic reagents a sulphonyl group and not a nitrile group is replaced [202]:

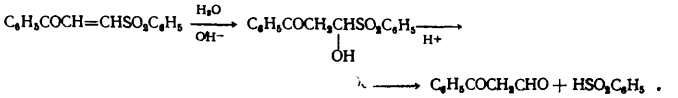


Aryl β-cyanovinyl ketones also add on sodium hydrogen sulphite very readily in aqueous alcoholic medium [176]. When the addition products are boiled with concentrated hydrochloric acid the monosodium salts of β-aroyl-α-carboxyethanesulphonic acids are formed, which can be obtained by direct synthesis from β-aroylacrylic acids [92,170]:

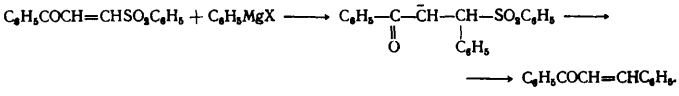


β-Cyanovinyl phenyl ketones react with 2-naphthol in the presence of catalytic quantities of calcium hydroxide [198]. When the reaction is carried out in 10 : 1 water–dioxan mixture in the cold in the presence of calcium hydroxide, β-benzoyl-α-(2-hydroxynaphthyl)propionitrile (XVIII) is formed. However, the same reaction at room temperature in 1 : 9 water–dioxan mixture with addition of catalytic amounts of calcium oxide gives a cyclic addition product, the imine of 1-*H*-1-phenacylnaphtho[2,1-*b*]furan-2-one (XIX). On hydrolysis with hydrochloric acid, (XVIII) and (XIX) are converted into 1-*H*-1-phenacylnaphtho[2,1-*b*]furan-2-one

(XX), which was also obtained by fusion of β-benzoylacrylic acid with 2-naphthol:

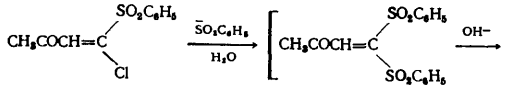


As might be expected, under the action of aqueous alkali β-cyanovinyl phenyl ketones decompose with the formation of acetophenone[78]:

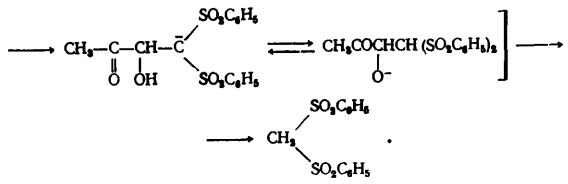


The addition of nucleophilic species in the β position to the carbonyl group is also characteristic for the αβ-unsaturated ketosulphones[73-75,80,203,204] $RCOCH{=}CHSO_2C_6H_5$ ($K_{C_6H_5COCH_3} = 10^{-19}$ and $K_{CH_3SO_2CH_3} = 10^{-23}$).[39,41] As already noted, there is a possibility of heterolysis of the C–SO_2R bond from the β position to a negatively charged atom in the intermediate carbanion. Therefore for αβ-unsaturated ketosulphones the formation of addition and substitution products is to be expected. However, the reactions of β-benzoylvinyl sulphone have only been investigated for a limited number of examples.

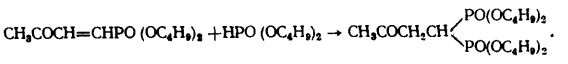
Kohler and Larsen[204] found that the addition of water is catalysed by bases. The addition product obtained decomposes into benzoylacetaldehyde and benzenesulphinic acid:



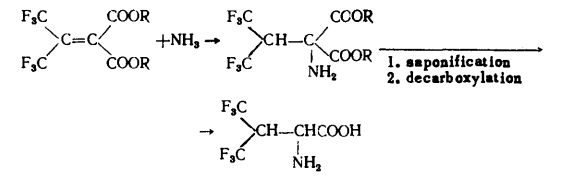
In the reaction with a Grignard reagent the main product is a chalcone[204]:



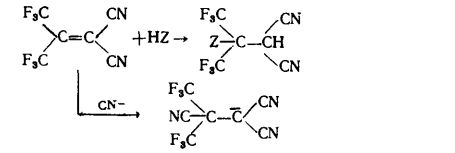
The same authors found that the addition product of hydrogen bromide has the structure of 2-benzoyl-1-bromoethyl phenyl sulphone[204]:



The following results[205] can evidently be classified as in agreement with the rule stated above (note that $K_{CH_2(SO_2CH_3)_2} = 10^{-14}$):[39]

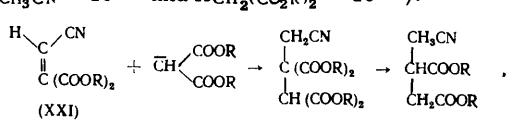


Note also the work of Kreutzkamp and Schindler[206], who showed that dibutyl 2-acetylvinylphosphonate adds on dibutyl phosphite to form tetrabutyl 2-acetylethane-1,1-diphosphonate:

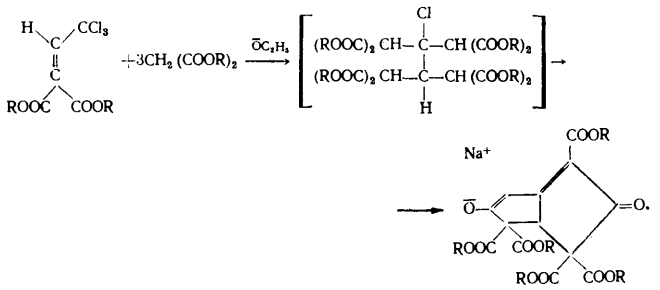


Hence the examples mentioned can serve as illustrations of the position stated above: that the direction of nucleophilic attack in XCH=CHY systems can be judged by comparison of the dissociation constants of the corresponding substituted methanes.

However, the above approach does not always fit the experimental facts. For example, it is inapplicable to ethylenic systems which contain several bulky substituents at the double bond, capable of delocalisation of the neighbouring anionic centre, mainly owing to the conjugation effect. As Ch'en and coworkers[207] showed, the reverse of the expected direction of attack of the nucleophile occurs for hexafluoroprop-2-ylidenemalonic ester with ammonia ($K_{(CF_3)_2CH_2} \simeq 10^{-20}$†, $K_{CH_2(CO_2R)_2} = 10^{-14}$).

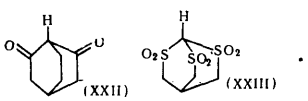


The structure of this product was convincingly demonstrated by conversion into hexafluorovaline, which was known already. At the same time, nucleophilic reagents add on in the expected direction to 1,1-dicyano-2,2-bis-(trifluoromethyl)ethylene, in which the ethoxycarbonyl groups have been replaced by more compact CN groups ($K_{CH_2(CN)_2} = 10^{-12}$).[39] As Middleton has shown[208] 1,1-dicyano-2,2-bis(trifluoromethyl)ethylene reacts with aniline, water, and cyanide ion as follows:



where Z = OH or NHC_6H_5.

Uchibayashi's results[209] also do not fit within the framework of the proposed hypothesis. He studied the reaction of cyanomethylenemalonic ester (XXI) with sodiomalonic ester ($K_{CH_3CN} = 10^{-25}$ and $K_{CH_2(CO_2R)_2} = 10^{-14}$):[39]



† Andreades[40] gives $K = 10^{-20}$ for $(CF_3)_2CFH$; it can be assumed that $K_{(CF_3)_2CH_2}$ will be even less.

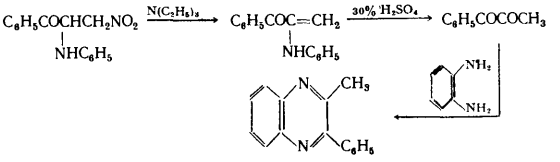
However, the replacement in this example of the cyano-group by the CCl_3 group‡, which is considerably less capable of stabilising a negative charge, leads to a product with the expected orientation of attack by a nucleophile[210-215]:

These examples show the great importance of secondary steric effects for the type of reaction being investigated[216]. Actually, if the electron-acceptor substituents, which delocalise the negative charge mainly by a conjugation effect, cannot occupy a planar position in the transitional complex owing to interference with the sides of other groups, then the stabilisation of the anionic centre of such substituents is much worse, which can also lead to orientation of the attack of the nucleophile opposite to what is expected. Naturally, secondary spatial effects do not play a large part for groups which stabilise the anionic centre mainly by an induction effect (such as $CHal_3$, SO_2R, etc.). Probably for these very reasons bicyclo[2,2,2]octane-2,6-dione (XXII) is devoid of acidic properties[217], although it is a 1,3-diketone, whereas the trisulphone (XXIII) exhibits high acidity[218]:

It is noteworthy that the addition of the bulky anion of malonic ester to the carbon atom of cyanomethylenemalonic ester (XXI), which is already carrying two carboxyl groups[209], shows that primary steric effects play such a small part in this type of reaction[216]. The minor part played by these effects is also demonstrated by the example already given of the addition of amines to esters of β-trifluoromethylacrylic (V), β-trifluoromethylcrotonic (VI), and ββ-bis-(trifluoromethyl)acrylic (VII) acids. Whereas introduction of a CH_3 group into the β position of the first of the esters mentioned has no effect on the orientation in the addition, replacement of the methyl group by CF_3 in the second leads to a change in the direction of nucleophilic attack. Hence the orientation of nucleophilic addition is mainly due to electronic influences, not steric.

It was stated earlier that the approach to the problem of the orientation of nucleophilic attack from the position of a determination of the stability of carbanions from the dissociation constants of the corresponding substituted methanes is a crude simplification in many respects. Thus, in clear contradiction to this there is the example of the reactions of aryl β-nitrovinyl ketones. Although a comparison of $K_{CH_3NO_2} = 6.1 \times 10^{-11}$ and $K_{C_6H_5COCH_3} = 10^{-19}$ suggests that the direction of attack of nucleophilic reagents can be represented as follows:

$$RCOCH{=}CHNO_2 + HZ \rightarrow \underset{\displaystyle Z}{RCOCHCH_2NO_2},$$



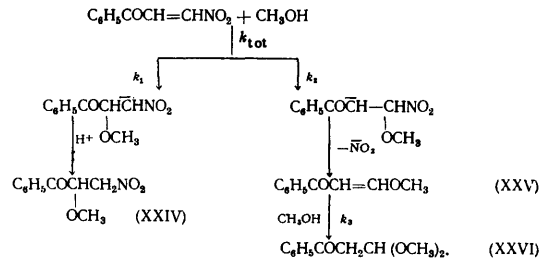
in reality, in addition to the products of the expected direction, products of the reverse orientation (and sometimes solely of the reverse orientation) are formed; it can be noted that for methanol[33,78] and aniline[219] both products belong to the kinetically controllable type.

Our own studies have repeatedly shown enhanced electrophilic nature of the ethylenic bond in these compounds. It was established that the reaction of aryl β-nitrovinyl ketones with aniline is exothermic[219]. As a result a mixture of the aryl α-anilino-β-nitroethyl ketone and the β-anilinovinyl aryl ketone is formed and the ratio of the products in the mixture depends on the nature of the substituent in the benzene ring:

$$ArCOCH{=}CHNO_2 + NH_2C_6H_5 \rightarrow \underset{\displaystyle NHC_6H_5}{ArCOCHCH_2NO_2} + ArCOCH{=}CHNHC_6H_5.$$

As Table 4 shows, the introduction of electronegative substituents (*p*-NO_2, *p*-Br) facilitates attack by the nucleophilic reagent at the β-carbon atom, and of electron donor ones (*p*-CH_3) at the α position.

Unfortunately, the dissociation constants of acetophenones substituted in the nucleus have not been determined. However, it is known that their enolisation, which is catalytically based, varies in the order H < *p*-Hal < *p*-NO_2.[220] The products liberated are kinetically controllable and cannot be interconverted. Thus under the action of bases α-anilino-β-nitroethyl phenyl ketone loses nitric acid, as a result of which α-anilinovinyl phenyl ketone is formed, the structure of which is shown by hydrolysis to methyl phenyl diketone:



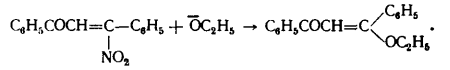
The dual direction of attack of the nucleophile was also observed by the example of the reaction of *trans*-phenyl

TABLE 4. Proportions of the products of the reaction of aryl 2-nitrovinyl ketones with aniline.

Ar	Proportions of the products of the reaction, mole %	
	aryl 1-anilino-2-nitroethyl ketone	aryl 2-anilinovinyl ketone
p-$CH_3C_6H_4$	> 95	< 5
C_6H_5	92	8
p-BrC_6H_4	60	40
p-$NO_2C_6H_4$	0	100

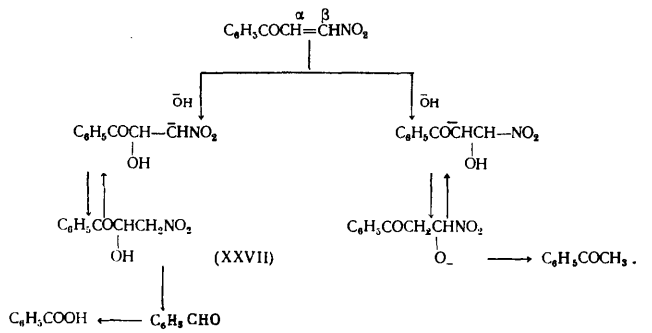
‡ Even if in this reaction chlorine atoms are first replaced by malonic ester residues, then this would have little effect on the capability of the $-CCl[CH(CO_2R)_2]_2$ group to stabilise the neighbouring anionic centre in comparison with the CCl_3 group.

β-nitrovinyl ketone with methanol[78]. The reaction can be represented as follows:



It takes place very readily and does not require a basic catalyst. Kinetic studies[33] showed that the reaction is pseudounimolecular in *trans*-phenyl β-nitrovinyl ketone and its overall rate (k_{tot}) considerably exceeds the rate of addition of methanol to other αβ-disubstituted ethylenes (see Table 5). It appeared that the reaction of β-nitrovinyl phenyl ketone proceeds irreversibly in both directions.

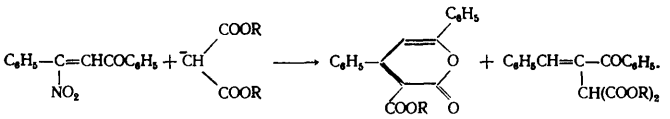
Moreover, it was found that the rate of formation of α-methoxy-β-nitroethyl phenyl ketone (XXIV) (α orientation), ($k_1 = 2.05 \times 10^{-3}$ min^{-1}) is only twice the rate of formation of β-methoxyvinyl phenyl ketone (XXV) (β orientation), ($k_2 = 0.92 \times 10^{-3}$ min^{-1}). Conversion of (XXV) into benzoylacetaldehyde dimethylacetal (XXVI) took place much more slowly ($k_3 = 9.1 \times 10^{-5}$ min^{-1}).



It was shown that the formation of β-methoxyvinyl phenyl ketone (XXV) is not connected with the elimination–addition mechanism which presupposes the intermediate formation of ethynyl phenyl ketone, since the ultraviolet absorption of the latter in standard buffer solution did not change in 24 h. After this period β-nitrovinyl phenyl ketone is almost completely converted into (XXIV) and (XXVI), and consequently the mechanism shown below does not take place:

The alternative mechanism of α elimination (HNO_2) with subsequent reaction of the carbene formed with methanol also seems improbable, since Smith and Davis[221] have shown that β-nitrobenzalacetophenone (which does not have an α-H close to the NO_2 group) reacts with the ethoxide ion to give β-ethoxybenzalacetophenone:

In the hydrolytic decomposition of β-nitrovinyl phenyl ketone the main products isolated were benzaldehyde and benzoic acid (products of α orientation of the OH^- ion), and there were traces of acetophenone (β orientation):[78]



Here it is suggested that an intermediate α-hydroxy-ketone (XXVII) is formed, which on breaking down by a type of retrobenzoin decomposition[222-224], is capable of giving benzaldehyde.

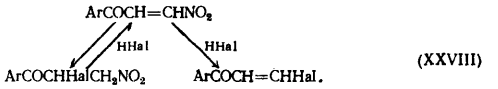


TABLE 5. Data on the kinetics of reactions with methanol of *trans*-αβ-disubstituted alkenes in standard buffer solution (0.0024 M CH_3CO_2H–0.0024 M CH_3CO_2Na) at 25°.

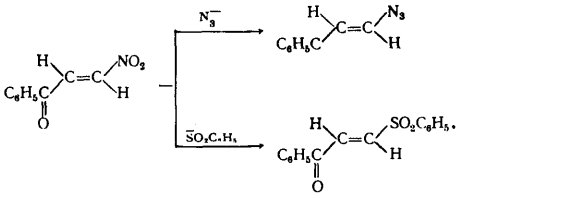
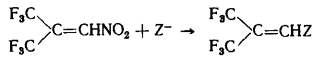
Alkene	k, min^{-1}	Ref.
$C_6H_5COCH=CHNO_2$	2.98×10^{-3}	33
$C_6H_5COCH=CHCOC_6H_5$	2.0×10^{-5}	18
$C_6H_5COCH=CHCN$	1.8×10^{-5}	17

A dual direction of attack by a nucleophile was also observed by Smith and Davis[221] in the example of the reaction of β-nitrobenzalacetophenone with sodiomalonic ester:



Aryl β-nitrovinyl ketones add on hydrogen chloride and bromide to form mainly aryl α-halo-β-nitroethyl ketones (XXVIII):[225]

Among the products of the reaction of β-nitrovinyl phenyl ketone with hydrogen chloride, *trans*-β-chlorovinyl phenyl ketone was observed. The formation of these products confirms the possibility of dual orientation of the attacking reagent.



Note that when these hydrogen halides are passed for a long time into a solution of aryl β-nitrovinyl ketones the reaction is complex and leads to the formation of isoxazoles.

However, when *trans*-β-nitrovinyl phenyl ketone reacts with sodium azide or sodium benzenesulphinate[226] in aqueous alcoholic medium only products of replacement of the nitro-group which retain the *trans*-configuration are formed:

Hence the above examples of the reaction of the aryl β-nitrovinyl ketones contradict the orientation rule. Evidently these contradictions are due to several factors, which are not taken into account in the simplified approach to the orientation problem. Of such factors mention must first be made of the mutual influence of the groups entering the carbanion. The fact that these groups have an important influence is to some extent confirmed by the rather great sensitivity of the results of the reactions to the nature of the attacking nucleophile (compare the reactions with CH_3OH and $NH_2C_6H_5$ with those with N_3^- and $\overline{SO_2C_6H_5}$). The explanation of these anomalies is best provided by the hypothesis of the intermediate formation of π-complexes, the rearrangement of which into carbanions

is influenced by the nature of the groups entering into the carbanions. A noteworthy point is that the orientation rule is invalid for nitro-compounds in which the nitro-groups are replaced. It should be noted that, as already demonstrated[227], an anomalous course of reaction is also observed for $\beta\beta$-bis(trifluoromethyl)nitroethylene; $K_{CH_3NO_2} = 10^{-11}$, $K_{(CF_3)_2CFH} = 10^{-20}$: [39,40]

The nitro-group is known to be very easy to remove in nucleophilic substitution. Possibly its removal starts even before the π-complex is completely rearranged into the carbanion.

Furthermore, the influence of solvation can be of some significance and should be especially great for a solvent which strongly solvates anions (protonic solvents). The role of the solvent appears particularly clearly in the ionisation of $\geq$C–H acids activated by electron-acceptor groups. For example, nitromethane in aqueous medium with OH^- ions reacts 10^6 times more slowly than phenol, but in dimethylformamide proton transfer for both these acids is diffusion-controlled[228].

The decrease in the rate of ionisation of $\geq$C–H acids in proton-containing solvents is connected with the reconstruction of the solvate sheath, due to a change in the electronic structure on going from a neutral molecule to a mesomeric anion, unlike –OH or $>$N–H acids where there is no significant rearrangement of the electronic structure[228].

If it is assumed that this hypothesis is correct for the formation of anions by the ionisation of $\geq$C–H acids, then evidently it can be taken that solvation can also have considerable influence in the formation of carbanions by the addition of a nucleophilic reagent to a carbon–carbon double bond.

Naturally in $\alpha\beta$-disubstituted ethylenes different electron-acceptor groupings at the two ends of the ethylenic bond will be solvated differently. It can therefore be expected that the rate of formation of carbanions from these ethylenes will also show the influence of effects due to the rearrangement of the solvate sheaths. The difference in these effects can lead to some levelling of the rates of formation of the carbanions, in both the α and the β directions. Possibly such influence of the solvent will show particularly strongly in the reactions of substituted nitroethylenes.

In conclusion we must note that the problem of the orientation of nucleophilic attack at the double bond in XCH=CHY systems is too complex for it to be fully covered in the present review. Moreover, unfortunately this problem has not been studied systematically and with a purposeful direction. For this reason the present review only attempts to consider certain aspects of the problem.

I. INTRODUCTION

Many papers have been published on the synthesis and study of the properties of unsaturated organoelemental compounds of the elements of Group IV of the Mendeleev Periodic System. Practical interest in these compounds arose in connection with the need to create new types of polymers. The investigation of the structure and reactivity of such compounds is of great theoretical importance since there is a specific interaction between carbon–carbon multiple bonds and the elements, an interaction which brings about the appearance of anomalous properties.

There is special interest in the unsaturated derivatives of the elements of the carbon subgroup since it is in this very series, situated at the heart of the Periodic System, that we can expect both an analogy with the purely carbon compounds, and also a considerable difference connected with the electronic structure of the atoms of the Group IV elements. Vinyl and allyl derivatives of silicon, germanium, tin, and lead have been studied most fully. The absence of reliable methods for the preparation of the ethynyl derivatives until recently retarded investigation in this field. It was only in the nineteen-forties, with the development of the chemistry of acetylene, that the first information appeared on the synthesis of alkynylsilanes[1,2]; the more systematic investigation of the alkynylsilanes started much later[3].

The first communication on the preparation of organogermanium compounds containing an acetylenic bond was published in 1958.[4] The first organotin acetylene derivatives were obtained in 1954.[5] A large number of acetylene derivatives of silicon, germanium, and tin are now known.

The present review considers only the acetylene derivatives of silicon, germanium, tin, and lead having a triple bond in the α or β positions to the atom of the element. Organoelemental compounds with a triple bond in the α position show most markedly the mutual influence of the π-electrons of the triple bond and the electrons of the element atoms.

The prop-2-ynyl derivatives of the Group IVb elements (C≡C in the β position) are interesting because they allow the influence of the elements on the prop-1,2-dienyl–prop-2-ynyl isomerism to be studied. The prop-1,2-dienyl derivatives formed as a result of the isomerisation are electronic analogues of ethynyl compounds (sp-hybridisation) [sic (Ed. of Translation)]; the resulting intramolecular interaction with the atoms of the Group IV elements should give effects analogous to those found with ethynyl groups [sic (Ed. of Translation)]. Therefore the preparation and properties of prop-2-ynyl compounds will also be considered within the bounds of our review.

This review describes in succession the synthesis and the chemical and physical properties of the ethynyl and

prop-2-ynyl derivatives of silicon, germanium, tin, and lead from literature sources, including work up to the middle of 1966.

II. PREPARATION OF ETHYNYL DERIVATIVES OF SILICON, GERMANIUM, TIN, AND LEAD

1. Preparation of Ethynyl Derivatives from the Alkali Metal Acetylides

This method allows compounds containing a triple bond in the α position to the element to be obtained:

$$(a)\quad R_{4-n}EX_n + MC{\equiv}CR' \rightarrow R_{4-n}E(C{\equiv}CR')_n,$$

where $n = 1, 2, 3,$ and 4; R = alkyl, aryl, H; X = Cl, Br; M = Na, Li.

$$(b)\quad 2R_3EX + MC{\equiv}CM \rightarrow R_3E{-}C{\equiv}C{-}ER_3.$$

Judging from the literature the method has certain limitations. Thus, with sodium acetylide in liquid ammonia alkynylsilanes and alkynylgermanes are not formed, evidently owing to ammonolysis of the alkyl- or aryl-silicon (or germanium) halides[10]. On the other hand all the organotin and organolead halogen derivatives react rapidly with NaC≡CR under these conditions[5-10] with the formation of disubstituted acetylenes ($R_3E{-}C{\equiv}C{-}ER_3$).

Quan and Cadiot[11] made a detailed investigation of the reaction of alkali metal acetylides with Ph_3SnX. They found that when triphenyltin iodide was used in this reaction and this was carried out rapidly, monosubstituted ethynyltriphenyltin(IV) was obtained.

The reaction of sodium acetylide with silicon and germanium halides was effected under other conditions. Thus in a patent[12] Boldebuch described the condensation of sodium acetylide with chloro(ethoxy)silanes in pyridine, with the formation of $(C_2H_5O)_{4-n}Si(C{\equiv}CH)_n$.

Beerman and Hartmann[5] obtained compounds of the type of $Ph_3E{-}C{\equiv}C{-}EPh_3$ by the reaction of monosodium acetylide with bromotriphenylsilane or triphenyltin bromide at 200°C. An analogous compound was obtained with lithium acetylide (through PhLi) in tetrahydrofuran[13].

Symmetrical organogermanium compounds with an acetylene bridge were obtained[14] by the reaction of sodium acetylide with chlorotriphenyl-and chlorotriethyl-germanium in tetrahydrofuran.

Davidson and Henry[15] prepared tetraethynylsilane, tetraethynylgermanium, diethynyldiphenylsilane, diethynyldiphenylgermanium, di-n-butyldiethynylgermanium, and ethynyltriphenylgermanium by the reaction of the corresponding germanium and silicon chlorides with sodium acetylides in tetrahydrofuran.

A patent[16] describes the preparation of ethynyl derivatives of tin, $R_{4-n}Sn(C{\equiv}CH)_n$, by the reaction of tin chlorides with alkali metal acetylides in ether, hexane, or benzene.

West and Kraihanzel[17] proposed a similar method for preparing

$$(CH_3)_3Sn(C{\equiv}CH).$$

Reaction with alkali metal acetylides has also been used for the preparation of poly-yne derivatives of tin and lead[11,18,19]. When the reaction is carried out in ether or hydrocarbons, then only the monosubstituted compounds are formed[17,18]. When the reaction is carried out in liquid ammonia the yield of mono- and di-substituted compounds depends on the ratio of the initial substances[11].

Some authors[20-27] have used the reaction of sodium and lithium acetylides of monosubstituted acetylenes with halogen derivatives of silicon, germanium, and tin for the preparation of compounds of the type $R_{4-n}E(C{\equiv}CR')_n$ and $R_3E(C{\equiv}C)_2R'$, where R = alkyl, aryl; and E = Si, Ge, or Sn.

For the preparation of $Pb(C{\equiv}CR)_4$ through the corresponding lithium acetylide rubidium hexachloroplumbate(IV) was used as the initial organolead compound[20] [sic (Ed. of Translation)].

2. Preparation of Ethynyl Compounds of Silicon, Germanium, Tin, and Lead Through Magnesium Bromide Derivatives of Acetylenes

$$R_{4-n}EX_n + XMgC{\equiv}CR' \rightarrow R_{4-n}E(C{\equiv}CR')_n,$$
$$R_3EX + XMgC{\equiv}C{-}R'{-}C{\equiv}CMgX \rightarrow R_3E{-}C{\equiv}C{-}R'{-}C{\equiv}C{-}ER_3.$$

Vol'nov and Reutt[1] first obtained alkynylsilanes by organomagnesium synthesis; as a result of the reaction of tetraethoxysilane with phenylethynylmagnesium bromide they obtained triethoxy(phenylethynyl)silane and diethoxybis(phenylethynyl)silane, and by reaction of ethynylmagnesium bromide with silicon tetrachloride, hexaethynyldisiloxane. At that time the use of polar solvents for the preparation of ethynylmagnesium bromide was unknown and the reaction was effected in boiling xylene; consequently, the yields of the products were insignificant.

After Jones[28] had developed the method of making ethynylmagnesium bromide in tetrahydrofuran, many investigators used this reagent for the preparation of ethynyl derivatives of silicon, germanium, and tin. Petrov and coworkers[23,29,30] synthesised alkynylsilanes of the type $R_3SiC{\equiv}CH$ and $R_2Si(C{\equiv}CH)_2$ from ethynylmagnesium bromide in tetrahydrofuran. Sladkov and Luneva[31] obtained diethynylmethylphenylsilane, diethynyldiphenylsilane, ethyldiethynylphenylgermanium, diethynyldiphenylgermanium, and *p*-bis(ethynyldimethylsilyl)benzene by the reaction of the corresponding germanium and silicon chlorides with ethynylmagnesium bromide in tetrahydrofuran. This method was also used to prepare monoethynyl derivatives of germanium[32] ($R_3GeC{\equiv}CH$) and tin[11,14]; to obtain the tin derivatives a method of precipitating the products from the reaction medium was used.

Mazerolles and coworkers[33] obtained tetraethynylgermanium by the reaction of germanium tetrachloride with ethynylmagnesium bromide.

Organomagnesium derivatives of monosubstituted acetylenes were used to make organoelemental ethynyl derivatives of the $R_{4-n}E(C{\equiv}CR')_n$ type[26,32-41], where E = Si, Ge, Sn; R = alkyl, aryl, vinyl.

Petrov and Shchukovskaya[3] found that symmetrical Iotsich reagent reacts with chlorotrialkylsilanes to form the corresponding symmetrical acetylene derivatives of silicon $R_3Si{-}C{\equiv}C{-}SiR_3$. At the same time Frisch and Young[42] condensed ethynylenedimagnesium dibromide with dichlorodimethylsilane in the presence of CuCl and as a result isolated

$$Cl(CH_3)_2Si{-}C{\equiv}C{-}Si(CH_3)_2Cl.$$

This reaction was used by many investigators[5,6,11,16,40] to prepare $R_3E-C\equiv C-ER_3$, where R = alkyl, aryl; E = Si, Ge, Sn.

Shikhiev and coworkers[43] carried out a similar reaction with butadiynylenedimagnesium dibromide:

$$BrMg-C\equiv C-C\equiv CMgBr + 2\,R_3SiCl \rightarrow R_3Si(C\equiv C)_2SiR_3.$$

Recently Shostakovskii and coworkers[44-46] reported the preparation of organotin acetylene compounds by the reaction of stannanols [hydroxo(trialkyl)tin(IV) complexes (Ed. of Translation)] and dialkyltin oxides [oxodialkyltin(IV) complexes (Ed. of Translation)] with an excess of magnesium bromide derivatives of monosubstituted acetylenes:

$$R_3SnOH + BrMgC\equiv CR' \rightarrow R_3Sn-C\equiv CR',$$

where R′ = vinyl, alkyl, aryl.

$$(R_2SnO)_n + 2n\,BrMgC\equiv CR' \rightarrow n\,R_2Sn(C\equiv CR')_2.$$

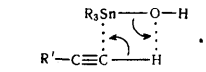
Alkynyl silanols are formed in the reaction of poly(diorganosiloxanes) with derivatives of ethynylmagnesium bromide[47-49]:

$$(R'R''SiO)_n + BrMgC\equiv CR \rightarrow R'R''(R-C\equiv C)SiOH.$$

3. Other Methods of Obtaining Ethynyl Organoelemental Compounds

a. Preparation through alkali metal derivatives of a triaryl- or trialkyl-tin. This preparation is based on the reaction of the sodium derivatives of tin with halogen derivatives of acetylene in liquid ammonia. Nothing has been published on the preparation of acetylene derivatives of silicon and germanium by this method and evidently this method is inapplicable for these compounds because the initial products may react with ammonia.

The reaction of sodium triphenylstannate(IV) or a sodium trialkylstannate(IV) with di-iodoacetylene produces the compound[5,10]: $R_3Sn-C\equiv C-SnR_3$.



Compounds of similar structure can be obtained by the reaction of sodium triarylstannates(IV) or trialkylstannates(IV) with iodo- or bromo-acetylene[50]; in the first stage the sodium derivative of tin reacts with the labile hydrogen at the acetylenic carbon with the formation of $R_3SnC\equiv CBr$, which subsequently reacts again with the sodium derivative to form a disubstituted acetylene:

$$R_3SnNa + BrC\equiv CH \rightarrow R_3SnC\equiv CBr \xrightarrow{R_3SnNa} R_3SnC\equiv CSnR_3.$$

Reactions with halides of monosubstituted alkynes proceed analogously, with formation of $R_3Sn-C\equiv CR$.[19,51,52] $R_3Pb(C\equiv CR)$ were obtained in the same way[52].

b. Reaction of organic oxygen and amino-derivatives of tin with acetylene. Investigations showed that hydroxotrialkyltin(IV) complexes react with acetylene compounds containing labile hydrogen at the carbon with the triple bond, to form ethynyl derivatives of tin[53-57]. As a result of the reaction, trialkylstannyl derivatives of acetylene, vinylacetylene, and alkyl- and aryl-substituted acetylenes were obtained. The reaction with acetylene requires the use of pressure (15-20 atg) and elevated temperature (100-120°C)[57]. With vinylacetylene and phenylacetylene the reactions take place at room temperature and ordinary pressure[56,57]; this is explained by the increase in acidity of the acetylenic hydrogen.

The mechanism of the reaction is explained by the donor-acceptor interaction of the unpaired electrons of oxygen of the hydroxyl group with the labile acetylenic hydrogen and by the $d\pi$-interaction between the tin atom and the triple bond[56,57]:

The use of trialkyltin halides in this reaction seemed possible[58]. The method consists in the successive reaction of the tin compound with powdered alkali (NaOH or KOH) and the acetylenic compound:

$$R_3SnX \xrightarrow{NaOH} [R_3SnOH] \xrightarrow{HC\equiv CR'} R_3SnC\equiv CR'.$$

A new method was developed[53,55,59] for the preparation of acetylenic derivatives of tin, consisting in the direct reaction of monosubstituted acetylenes with bis(trialkyltin) oxides:

$$(R_3Sn)_2O + 2\,HC\equiv CR' \rightarrow 2\,R_3SnC\equiv CR'.$$

The reaction mechanism is evidently the same as for the stannols and proceeds in two stages:

$$R_3SnOSnR_3 + HC\equiv CR' \rightarrow R_3SnC\equiv CR' + R_3SnOH,$$
$$R_3SnOH + HC\equiv CR' \rightarrow R_3SnC\equiv CR' + H_2O.$$

Lutsenko and Ponamarev[60] described the preparation of trialkyl(phenylethynyl)tin complexes from trialkyl(methoxy)tin complexes and phenylacetylene. This reaction is more difficult than that with the hydroxotrialkyltin compounds and requires heating to 100-110°C.

Several other interesting preparations of acetylenic organotin compounds have been proposed.

Luijten and van der Kerk[61] observed the formation of organotin compounds in the thermal decarboxylation of triaryltin(IV) cyanoacetates:

$$(C_6H_5)_3SnOCOCH_2CN \xrightarrow{-CO_2} (C_6H_5)_3SnCH_2CN.$$

This method was next extended to the tin derivatives of phenylpropiolic and but-2-yndioic acids[61]:

$$R_3SnOCOC\equiv C-C_6H_5 \xrightarrow{-CO_2} R_3SnC\equiv CC_6H_5,$$
$$R_3SnOCO-C\equiv C-OCO-SnR_3 \xrightarrow{-2CO_2} R_3SnC\equiv CSnR_3.$$

In studying the reactions of nucleophilic substitution in organotin derivatives of dimethylamine it was found[62,63] that the N-Sn bond is readily split by compounds which contain a labile hydrogen, for example, phenylacetylene and hex-1-yne; acetylenic derivatives of tin are formed:

$$R_3Sn-N(CH_3)_2 + HC\equiv CR' \longrightarrow R_3Sn(C\equiv CR').$$

III. PREPARATION OF PROP-2-YNYL DERIVATIVES OF SILICON, GERMANIUM, TIN, AND LEAD

Le Quan and Cadiot[64] first reported the preparation of monoprop-2-ynyl derivatives of silicon and tin by the reaction of prop-2-ynylmagnesium bromide with trialkylhalogenosilanes and stannanes. This method became general for the preparation of most of the prop-2-ynyl derivatives of silicon, germanium, tin, and lead[18,31,40,65-67]:

$$R_{4-n}EX_n + BrMgCH_2-C\equiv CH \longrightarrow R_{4-n}E(CH_2-C\equiv CH)_n,$$

where n = 1, 2; R = alkyl, aryl; E = Si, Ge, Sn, Pb.

The reaction of lithium triphenylstannate with 1-bromoprop-2-yne was also used for the preparation of triphenylprop-2-ynyltin[67]. Note that here the prop-2-ynyl derivative is not formed, but exclusively its allene isomer with 30% yield. At the same time, chlorotriphenyltin and prop-2-ynylmagnesium bromide form only 10% of the allene isomer with a total yield of reaction products of 80%.[67]

IV. CHEMICAL PROPERTIES OF ETHYNYL ORGANOELEMENTAL COMPOUNDS

There has been little investigation of the chemical properties of the organoelemental compounds of acetylene described above. The reactions of these compounds, both nucleophilic and electrophilic, depend strongly on the nature of the element (Si, Ge, Sn, Pb) linked with ethynyl or prop-2-ynyl groups.

The reactions are considered below in the following order: (a) reactions with splitting of the E–C bond; (b) additions at the triple bond; (c) replacement of the acetylenic hydrogen; (d) isomerisation.

a. Reactions with splitting of the E–C bond. Many investigators have found that the Si–C≡ bond in alkynylsilanes is hydrolytically stable towards dilute acids and alkalis[5,40,68,69]. Concentrated solutions of alkalis break the silicon–carbon bond[5,68,69].

On changing alkyl groups at the silicon atom the higher homologues of the alkynylsilanes are less stable to the action of acids than the lower[68].

Bis(triphenylsilyl)acetylene is stable to cold water but is hydrolysed by alkalis[5]. Ethynyltriphenylsilane differs from the trialkylethynylsilanes in being hydrolysed in the cold[23].

The hydrolytic stability of the E–C≡ bond decreases in the order Si > Ge > Sn > Pb with increase in the polarity of the E–C≡ bond.

The disubstituted acetylenes $R_3E-C\equiv C-ER_3$, where R = aryl and E = Ge or Sn are fairly stable to atmospheric moisture but are split under the action of dilute alkali[10,16], unlike their silicon analogues. On replacing a phenyl radical by alkyls the sensitivity to moisture decreases[5,10]. Monophenylethynyl derivatives of germanium are fairly stable to atmospheric moisture but are hydrolysed by aqueous alkalis[21]. Strong organic acids[13] break the Ge–C≡ bond. Corresponding tin compounds are less stable and the hydrolytic stability decreases on replacing the triphenylstannyl radical by trialkylstannyl radicals[11,14]. Similarly, in trialkylstannylacetylene the Sn–C≡ bond is less stable than in triarylstannylacetylenes[11].

With increase in the number of acetylene radicals the sensitivity of the compound to hydrolysis increases[39]. All acetylene derivatives are extremely sensitive to water[5,9,20] and rapidly decompose in moist air. On the basis of a study of the hydrolytic splitting of the Sn–C≡ bond in triphenylstannylacetylenes it has been shown[11] that the ethynyl group is weakly bound to the tin atom and in the empirical series found by Seyferth[70] it should occupy a place before the aryl radical as regards ease of removal: ethynyl > aryl > vinyl > alkyl[11].

The increase in polarity of the E–C≡ bond in ethynyl organoelemental derivatives that results from the increase in the electronegativity of the carbon atom at the triple bond should therefore facilitate both electrophilic attack at the carbon atom and also nucleophilic attack at the atom of element E.

Copper and silver ions break the E–C≡ bond. Thus, $R_3Ge-C\equiv CH$ is split by silver nitrate in alcoholic solution and by an ammoniacal solution of CuCl, with the formation of silver and copper acetylides[32]:

$$R_3GeC\equiv CH \xrightarrow[NH_4OH]{Cu+} Cu-C\equiv C-Cu.$$

Under analogous conditions the ethynyl derivatives of tin and lead are decomposed with the formation of the same acetylides[5,9,11].

Breaking of Sn–C and Pb–C bonds is also observed under the action of Grignard reagents[5,11,45]:

$$R_3SnC\equiv C-R' + RMgBr \rightarrow R_4Sn + R'-C\equiv CMgBr.$$

The rate at which the C–E bond is broken by halogens also increases from Si to Pb. The Sn–C and Pb–C bonds in $R_3Sn-C\equiv CH$ and $R_3Pb-C\equiv CH$ are readily broken even under the action of iodine at room temperature with the formation of di-iodoacetylene and the corresponding organoelemental compound[5,11]. Even at room temperature bromine breaks the E–C bond in the ethynyl derivatives of germanium, tin, and lead[5,32,36,41].

In the organoelemental acetylene compounds containing a triple bond in the β-position to a silicon, germanium, tin, or lead atom the prop-2-ynyl radicals are much less strongly bound to the element atom than acetylene radicals would be. They are much less resistant to moisture, alkalis, acids[32,40,65]. Just like allyl and benzyl derivatives, the unsaturated radical in prop-2-ynyl compounds also exhibits electron-acceptor properties. Therefore the $E-CH_2$ bond breaks down and becomes more labile, which is explained by the σπ-conjugation of the 1–2 and 3–4 bonds associated with the electromeric effect.

b. Additions. Little has been published about additions at the triple bonds of ethynyl derivatives of the Group IVb elements. Compounds of the type $R_3EC\equiv CER_3$ and $R_3EC\equiv CR'$, where R' = H, alkyl, aryl, react differently with halogens. Alkynylsilanes do not react with iodine[5] and add only two atoms of bromine even on boiling in CCl_4.[30,35,39] It has been reported[71] that four bromine atoms add to $R_3Si-C\equiv C-CH_3$ but then HBr is lost and $R_3Si-CBr_2-CBr=CH_2$ is formed. At −80°C bromine adds to the triple bond of $R_3Ge-C\equiv CH$ but breaks the Ge–C bond in $R_3Ge-CH_2-C\equiv CH$.[32]

Davidson and Henry[15] brominated tetraethylgermanium with bromine at room temperature and isolated $Ge(CBr=CHBr)_4$ from the products.

Disilyl-substituted acetylenes do not add hydrogen under ordinary conditions for the catalytic hydrogenation of the C≡C bond; under severe hydrogenation conditions cracking of the molecule occurs[43,72,73].

$R_3Si(C\equiv CR')$ compounds are catalytically hydrogenated, two or four hydrogen atoms being added[39,43,72,73]. The monoethynyl derivatives of germanium $R_3GeC\equiv CH$, $R_3GeC\equiv CR'$, and $R_3GeCH_2-C\equiv CH$ readily add hydrogen at 20°C in the presence of Raney nickel, with the formation of saturated compounds[32,34].

Silicon and germanium hydrides are added quantitatively to alkynylsilanes and alkynylgermanes in the presence of hydrogen hexachloroplatinate(IV)[74,75]:

$$R_3Si-C\equiv CH + R_3Si-H \rightarrow R_3Si-CH=CH-SiR_3$$
$$R_3Ge-C\equiv CH + R_3Ge-H \rightarrow R_3Ge-CH=CH-GeR_3.$$

Diazomethane adds to diethynyldiphenylgermanium(IV) to form diphenyldipyrazolylgermanium(IV)[15].

Some recent papers describe investigations of the chemical reactions of enyne and diyne organoelemental compounds of silicon, germanium, and tin. Alkylvinylacetylenes are known to add bromine almost exclusively at the double bond[76]. Trialkyl(but-3-en-1-ynyl)silanes add bromine mainly in the 1 : 4 position:

$$R_3Si-C\equiv C-CH=CH_2 \xrightarrow[-10^\circ]{Br_2} R_3Si-CBr=C=CH-CH_2Br.$$

When heated, such dibromo-compounds isomerise to form the dibromo-1,3-diene.

Triphenyl(but-3-en-1-ynyl)silane exhibits low reactivity towards electrophilic reagents, as the triphenylsilyl group is a strongly electrophilic substituent and by drawing off electrons from the enyne system it makes the latter inactive towards bromination. Different substituents in the but-3-en-1-ynyl group at the double bond also effect the direction of bromination. Thus the introduction of a methyl group into but-3-en-1-ynyl(trimethyl)silane leads to a change in the direction of bromination, facilitating the addition of bromine at the double-bond[77-79]:

$$(CH_3)_3Si-C\equiv C-\underset{\displaystyle CH_3}{\underset{|}{C}}=CH_2 \xrightarrow{Br_2} (CH_3)_3Si-C\equiv C-\underset{\displaystyle CH_3}{\underset{|}{CBr}}-CH_2Br.$$

In vinyl- and allyl-dimethyl(but-3-en-1-ynyl)silanes bromination proceeds perferentially at the vinyl and allyl groups[79].

It has been shown that germanium-enynes also add bromine in the 1-4 and (partly) 3-4 positions[30,80]. When heated, the dibromides obtained are isomerised into dibromodienes. The direction of bromination in substituted germanium-enynes is less dependent on the substituent at the double bond than in the silicon-enynes, since the R_3Ge group compensates to a greater extent the influence of the alkyl groups at the double bond[77], because the R_3Ge radicals are less electrophilic than the R_3Si radicals. It is assumed[77-79] that the increase (in comparison with alkylvinylacetylenes) in the ability to add bromine in the 1, 4 position possessed by the silicon- and germanium-enynes is apparently due to an additional positive charge on the first carbon atom owing to electron displacement due to interaction of the *d*-orbitals of silicon and germanium with the π-electrons of the triple bond:

$$R_3E \longrightarrow C\equiv C-C=C.$$

Bromine breaks the Sn-C bond in tin-enynes[26,37]. The triple bond is more active in the catalytic hydrogenation of vinylacetylene hydrocarbons[81]. Trialkyl(but-3-en-1-ynyl)-silanes[78,79] ($R_3Si-C\equiv C-\underset{\displaystyle R'}{\underset{|}{C}}=CH_2$) add hydrogen preferentially at the double bond in the presence of $Pd/CaCO_3$ forming two addition products:

$$R_3Si-C\equiv C-\underset{\displaystyle R'}{\underset{|}{CH}}-CH_3 \text{ and } R_3Si-CH=C=\underset{\displaystyle R'}{\underset{|}{C}}-CH_3.$$

The ratio of the acetylene and allene isomers depends on the radical R′: the more bulky the radical the more allene isomer is formed[82].

Under these conditions germanium-enynes[74] are hydrogenated much more slowly than the corresponding silicon-enynes. The main direction of the reaction is the addition of hydrogen at the double bond but a certain amount of a diene derivative is formed. The existence of all three possible isomers has been found with the aid of infrared spectra[74]:

$$R_3Ge-C\equiv C-\underset{\displaystyle R}{\underset{|}{CH}}-CH_3$$

$$R_3Ge-CH=C=\underset{\displaystyle R}{\underset{|}{C}}-CH_3$$

$$R_3Ge-CH=CH-\underset{\displaystyle R}{\underset{|}{C}}=CH_2.$$

Under these conditions tin-enynes are not hydrogenated[79].

The difference in the direction of the catalytic hydrogenation of silicon and germanium-enynes of hydrocarbons is explained[74,82] by the steric factors under the conditions of heterogeneous catalysis (the presence of the bulky R_3E groups).

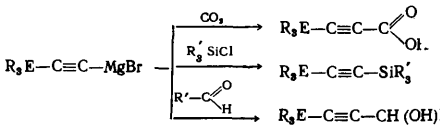
It is known[83,84] that alkylbut-3-en-1-ynes add alkyllithium complexes in the 1,4-position, with the formation of lithium derivatives of allene hydrocarbons. Under these conditions silicon-enynes and germanium-enynes form mixtures of isomeric allene and acetylene silicon hydrocarbons, the ratio of which depends on the structure of the enyne groupings and the nature of the radical in the alkyllithium[85-87].

Alkyl-lithium complexes break the Sn-C≡ bond in tin-enynes, with formation of tetra-alkyltin(IV) complexes[52,79,88].

From the above it is clear that nucleophilic (alkyl-lithium) and electrophilic (bromine, etc.) reagents break the Sn-C≡ bond. Zavgorodnii and Petrov[88] studied the stability of this bond in radical processes. It seemed that the triphenylmethyl radical adds to but-3-en-1-ynyltriethyltin(IV) mainly in the 3,4-position but to triethyl(3-methylbut-3-en-1-ynyl)tin(IV) in the 1,4-position, owing to steric factors[88] due to the presence of the methyl group. The same investigators also succeeded[88,90] in adding diazomethane to the above tin-enynes. The addition of diazomethane takes place at the double bond of the vinylacetylene residue, with formation of ethynylpyrazoline derivatives, from which cyclopropane compounds are subsequently formed:

$$(C_2H_5)_3Sn-C\equiv C-\underset{\displaystyle N}{\underset{\|}{C}}-\underset{\displaystyle NH}{\underset{\diagdown\diagup}{CH_2}} \rightarrow (C_2H_5)_3Sn-C\equiv C-\underset{\displaystyle CH_2}{\underset{\diagup\diagdown}{CH}}-CH_2+N_2.$$

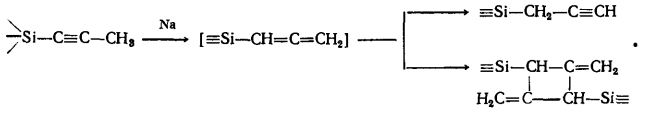
Petrov and coworkers also investigated electrophilic and nucleophilic additions to trialkylsilylalkadiynes[91,92]. It was shown[93] that with 1,3-diene silicon-hydrocarbons the first molecule of bromine adds to the triple bond in the α-position to the silicon atom; when heated, the resulting dibromo-compound isomerises into 1,3- and 3,4-dibromo-compounds. This was shown by infrared and NMR spectra. An investigation of the addition of lithium alkyl-lithium complexes to 1,3-diyne silicon-hydrocarbons showed[92] that, irrespective of the nature of the radical in the LiR, the addition proceeds at the 3,4-position with fixation of the alkyl radical at the quaternary carbon atom. The results of the bromination and addition of LiR to silicon-diynes, carried out by the author, agree with the following scheme for the direction of polarisation of silicon-diynes, due to the $d\pi$-conjugation effect:



$$R_3Si-\overset{\delta-}{C}\equiv\overset{2}{C}-\overset{3}{C}\equiv\overset{\delta+}{\overset{4}{C}}-R.$$

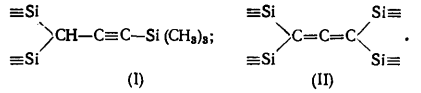
c. Substitutions. The hydrogen atom at the H-C≡ bond retains its activity in silicon and germanium-substituted acetylenes. The ethynyl derivatives of silicon

and germanium readily form organomagnesium derivatives[23,30,32,94]:



$$R_3E-C\equiv CH + R'MgX \rightarrow R_3E-C\equiv C-MgX + R'H.$$

These compounds can be used for the preparation of various germanium- and silicon-acetylene derivatives[30,32,95]:



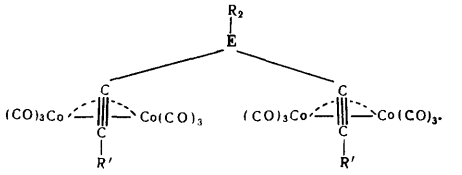
d. Isomerisation of acetylenic organoelemental compounds. Favorskii[96] investigated the isomerisation of acetylenic hydrocarbons; it has been discussed repeatedly[97,98].

There have been a few investigations[36,99,100] concerning the isomeric changes of acetylenic silicon hydrocarbons. Petrov and coworkers[36] obtained interesting results in an attempt to isomerise triethyl(prop-1-ynyl) silane into the allene isomer by the Favorskii reaction. Spectroscopic analysis of the products showed the presence of a cyclodimer and a little triethyl(prop-2-ynyl)silane:

West and coworkers[100] described the reaction of prop-1-ynyl-lithium with chlorotrimethylsilane, which led to the formation of a mixture of tri- and tetra-silyl derivatives:

(I) (II)

Thermolysis and photolysis of (I) leads to disproportionation and formation of an allene derivative.



Investigators[20,31,38,40,62-64,101,102] who have been engaged in the preparation of prop-2-ynyl derivatives of organo-silicon, -germanium, -tin, and -lead compounds have noted that a mixture of allene, prop-2-ynyl, and prop-1-ynyl isomers is formed in the reaction:

$$R_3E-CH_2-C\equiv CH; \quad R_3E-CH=C=CH_2; \quad R_3EC\equiv C-CH_3$$

where E = Si, Ge, Sn, Pb; R = alkyl, phenyl.

The structure of the isomers obtained was studied by molecular and radio-frequency spectroscopy, and by analytical gas chromatography[20,63,101,102]. The amounts of the isomers obtained depend on the temperature, the basicity of the solvent, the order in which the initial compounds are added, and their structure[38]. With increase in the atomic weight of the element the proportion of allene isomers increases (Si < Ge < Sn < Pb)[63]. For example, in the preparation of triphenyl(prop-2-ynyl)-lead, 90% triphenyl(prop-1,2-dienyl)-lead(IV) is formed[20]. Prop-2-ynyl derivatives are especially readily isomerised into allene ones on heating in electron-donating solvents[67]. Thus when triphenylprop-2-ynyltin was boiled in 95% ethanol for 12 min it was completely converted into the allene isomer[67].

e. Other reactions. Hübel and Hoogzand[103] reported that trialkylethynylsilanes undergo cyclic trimerisation. Thus trimethylsilylacetylene forms 1,2,4-tris(trimethylsilyl)benzene at 100°C in the presence of tetracarbonylcobalt(IV)[103]. Possibly this reaction takes place through a stage of formation of an intermediate complex. This was confirmed recently by information published about the production of stable complexes from dialkynyl derivatives of silicon and germanium with tetracarbonylcobalt at room temperature in petroleum ether[104]:

V. PHYSICAL PROPERTIES

$R_3EC\equiv CR'$ and $R_3EC\equiv CER_3$, where E = Si, Ge, Sn, are liquids which can be distilled when R = alkyl and solids when R = aryl. The boiling point rises from the derivatives of silicon to those of tin. All the compounds are readily soluble in most organic solvents. Most of the liquid acetylene derivatives of silicon, germanium, and tin are thermally stable; they can be readily distilled. Solid acetylene derivatives of silicon and germanium usually melt without decomposition as distinct from the tin and lead derivatives, which usually melt with decomposition.

The dipole moments of the silicon- and tin-enynes were measured[105,106]. The tin-enynes have a greater dipole moment than hydrocarbons and silicon-hydrocarbons of analogous structure. The dipole moments are always directed from the tin or silicon towards the acetylene grouping[106]. Stadnichuk and Petrov[80] calculated the dipole moment of triethylvinylacetylenegermane [but-3-en-1-ynyltriethylgermanium(IV)], which had a greater dipole moment than the silicon-enyne of analogous structure[80].

Many papers on the spectra of ethynyl compounds of Group IVb elements have been published recently. Usually the infrared spectra of the compounds obtained are used to identify the structure. The most complete information on the vibrational spectra of ethynyl organoelemental derivatives is given in Chumaevskii's review[107] and in the papers of Petrov, Shostakovskii, and their coworkers[37,44], Cadiot[11,40], Hartmann[5,10], and others[108,109].

Of the special spectroscopic studies, that of Shigorin and coworkers[110] deserves mention.

The greatest interest is in the position and intensity of the characteristic frequencies of the C≡C and ≡C–H stretching vibrations.

Study of the infrared spectra of acetylene derivatives of silicon, germanium, tin, and lead showed the shift and change in intensity of the absorption bands characteristic of the acetylene bond[13,108,109,111-116]. For example, the stretching vibration of the acetylene bond in the t-butylacetylene spectrum corresponds to a frequency of 2110 cm^{-1}, that for ethynyltrimethylsilane 2040 cm^{-1}, and for triethylethynylsilane[112] the analogous vibration appears at $\nu_{C\equiv C}$ = 2008 cm^{-1}. The intensity of the absorption bands of the acetylenic bond in these compounds increases on going from carbon to tin[113,114].

It is known[115,116] that in unsymmetrical disubstituted alkynes the frequency of the stretching vibrations of the C≡C bond is in the 2200–2260 cm^{-1} region. Replacement of the carbon atom in the α position to the triple bond by a silicon atom[117] shows a drop in the frequency of the C≡C vibration of 75 cm^{-1}, and replacement of silicon by tin[115,116] leads to a further drop in frequency of 20 cm^{-1}.

Stadnichuk and Petrov investigated the infrared spectra of germanium-enynes[80] and showed that the triple bond in these compounds corresponds to an absorption band of 2147 cm^{-1}, that is, the same as in the silicon-enyne[116].

On the basis of the results obtained the authors conclude that the displacement of the triple bond vibrational band in the ethynyl derivatives of silicon, iron [germanium? (Ed. of Translation)], and tin is connected with a change in the bond polarity, which in turn can be explained by the intramolecular interaction of the π-electrons of the acetylenic bond with the vacant d-orbitals of silicon, germanium, and tin. By calculating the relative force constants of the triple bond in the acetylene derivatives of silicon and tin, the authors[116] were able to show that the displacement of the band of the triple bond of these compounds in the infrared spectra is not connected solely with the increase in mass of the atom on going from carbon to tin.

The peculiar light absorption of the α-ethynyl compounds of the Group IVb elements has also been associated with $d\pi$-conjugation[118,119].

To explain the shortening of the Si–O and Si–X interatomic distances in comparison with the sum of the covalent radii of the elements forming the bond, Pauling[120] postulated in the 1940's the possibility of the participation of the d-orbitals of silicon in the formation of bonds. Carbon has only s- and p-orbitals in its outer shells, whereas the other elements of Group IVb have the closer d-orbitals, which can in principle participate in the formation of a chemical bond. When the molecule of an organoelemental compound contains multiple bonds in the α position to the element, it is possible for intramolecular interaction to occur, with displacement of the π-electrons and use of the vacant d-orbital of the element. The possibility of the participation of the d-orbitals in the formation of chemical bonds was given a theoretical basis by Craig and coworkers[121], Eaborn[122], and others[123].

Stone and Seyferth[123] and Webster[124] also concluded that $d\pi$-conjugation is possible.

Husk and West[125] observed that in the ion-radical of dodecamethylcyclohexasilane the electron is delocalised over the entire molecule, which also confirms the participation of the d-orbitals of silicon in conjugation. The hypothesis of $d\pi$-conjugation has become widely accepted. At the same time, the problem of $d\pi$-conjugation forms the subject of discussion since as yet there is no method which would allow this effect to be evaluated directly and all the evidence in support of this phenomenon is based on indirect proofs.

From the vibrational spectra of vinyl derivatives of the Group IV elements, Leites and coworkers[126] concluded that the frequency of the C=C group in carbon and organotin compounds is connected solely with a change in the inductive effect of the element. Note also that Bochvar and Gambaryan[127] made quantum-mechanical calculations of the contribution of the d-orbitals of silicon and germanium to the bond formation in the vinyl compounds of these elements and found that it was very small and comparable in magnitude with the energy contribution of the p-orbitals of the carbon atom in compounds of analogous structure.

However, most research chemists still maintain the view that there is $d\pi$-conjugation between the vacant d-orbitals of the silicon, germanium, and tin atoms and the π-electrons of the unsaturated bonds situated in the α position to the hetero-atoms. There is still no single opinion as to the relative value of the $d\pi$-interaction in the derivatives of Si, Ge, Sn, and Pb. Some authors think that the $d\pi$-conjugation diminishes in the order Si > Ge > Sn[128], others, that is it independent of the element[129].

Gastilovich and coworkers[110] carried out an interesting investigation of the infrared spectra of the compounds

$$(CH_3)_3—CH_2—C\equiv CH \quad (I)$$
$$(CH_3)_3SiC\equiv CH \quad (II)$$
$$(C_2H_5)_3Sn(C\equiv CH) \quad (III)$$

in the region of the stretching vibrations of the C≡C and ≡C–H groups and calculated the effect of the mass of the element (from C to Sn), the rigidity of the E–C bond (E = Si, Sn), and of the intermolecular interaction on anomalies in the spectra and showed that these factors are insufficient to explain the displacement and change in intensity of the frequencies of the C≡C stretching vibrations, which is observed in compounds (II) and (III). On the basis of these results conclusions were drawn about the intramolecular interaction of the π-electrons of the triple bond with the d-orbitals of the Si and Sn atoms, which also determines the frequency change.

Another approach to evaluation of the $d\pi$-interaction in ethynyl derivatives of Si, Ge, Sn, and Pb from their infrared spectra has been made by Cadiot[11]. The author started from Kross's results[130] on the electronegativities of the Group IVb elements calculated from the frequencies of the infrared vibrations of the phenyl nuclei connected with the element and found a linear dependence of electronegativity on the C≡C bond frequency in $(C_6H_5)_3E(C\equiv CR)$. In appeared that the change in $\nu_{C\equiv C}$ in the order Si > Ge > Sn > Pb is connected with the decrease in electronegativity from Si to Pb which had been proposed by other authors[80,115], Cadiot[11] showed that on the basis of the Bykov equation[131], which relates the wave number of bands in the infrared spectrum with the electronic charge of the C≡C bond ($\nu^{2\alpha}_{C\equiv C} = KA_{C\equiv C}$), it can be concluded that the decrease in frequency for the C≡C bond in $\gtrless E-C\equiv C$ in the series from C to Pb is connected with the decrease in the charge on this bond; this is a consequence of the partial overlap of the π-electron cloud and the d-orbitals of the element.

The ultraviolet spectra of the ethynyl derivatives of silicon, germanium, and tin have also been investigated[11,18,108,109]. A bathochromic shift and increase in intensity of the bands has been observed in comparison with the acetylene hydrocarbons of analogous structure.

Comparatively recently there have been papers on the proton magnetic resonance spectra of the ethynyl compounds of the Group IVb elements[11,18,26,80,101,102,132,133]. For example, Egorochkin and coworkers[134] investigated the NMR spectra of ethynyltrimethylsilane and ethynyltrimethylgermanium(IV). The proton chemical shifts for the carbon atom of the ethynyl group are displaced to weaker fields compared with the proton shifts in saturated radicals, which the authors explain by the intramolecular interaction of the C≡C bond with the element atom. The large shift of the π-electrons towards the silicon atom compared with the germanium analogue leads to a more significant decrease in the electron density at the protons at the triple bond of the ethynylsilicon compounds. This is due to a stronger displacement of the chemical shift for ≡C–H to weaker fields in ethynyltrimethylsilane.

The NMR spectra of prop-2-ynyl compounds of silicon and tin have been obtained[101,102]; the chemical shifts of the protons of the methylene and acetylene groups decrease with decrease in the electronegativity of the elements and

are greatly dependent on the substituents at the elements, on the solvents, and on the concentration of the solution.

Simonnin[133] also investigated the NMR spectrum of compounds of the type $R_3E-(C\equiv C)_m-CH_3$ and $R_3E(C\equiv C)_m-H$, where E = Si, Ge, Sn and $m = 1, 2, 3$, labelled with ^{13}C in the α, β, and γ positions. The greatest difference in the chemical shifts of the ethynyl proton was observed in compounds with a $^{13}C-H$ bond (up to 39%).

Fedin and coworkers[132] found, in studying the NMR spectra of diethyldiphenyl-silane and -germane, that the silicon and germanium in these compounds are acceptors of electrons in relation to the phenyl nuclei. In diphenyldiprop-2-ynylgermane and diphenyldiprop-2-ynylsilane the signals of the ethynyl protons are shifted to stronger fields, by 0.8×10^{-6} for silicon and by 0.5×10^{-6} for germanium, relative to hexamethyldisiloxane.

Cadiot and coworkers[11,18] observed the proton chemical shifts in the NMR spectra of ethynyl compounds of tin. They interpreted the results from the standpoint of $d\pi$-conjugation.

To conclude this part of the review it must be emphasised that the hypothesis of $d\pi$-conjugation has been extremely fruitful and has stimulated considerably investigations in the field of the synthesis of ethynyl compounds of the Group IVb elements. This is equally true of the investigation of the physical properties of these compounds, particularly the infrared absorption spectra. Despite the fact that the interpretation of the spectral properties from the viewpoint of $d\pi$-interaction was evidently unsound, as a result of the work of many authors we have now, a large collection of spectral data, which is used successfully in chemical investigations for identification and for finding the structure of the compounds obtained.

VI. ORGANIC POLYMERS OF SILICON, GERMANIUM, AND TIN, CONTAINING ACETYLENIC GROUPINGS

The introduction of silicon, germanium, or tin into a polymeric chain is of great interest since, being situated in the same subgroup as carbon, they should have properties analogous to those of carbon, yet having a different electronic structure they should display their own specific properties.

Since the silicon, germanium, and tin atoms exhibit acceptor properties and their d-orbitals can draw away the π-electrons of a multiple bond, there is particular interest in polymers in which atoms of silicon, germanium, and tin alternate with acetylenic groupings. Such polymers could be expected to show interesting electrophysical properties. The first indication that such polymers could be made came in 1962 [135,136,137].

Korshak and coworkers[136] suggested that organosilicon and organogermanium polymers with acetylenic bonds in the chain could be synthesised by polycondensation of dihalogeno-organoelemental compounds with the bis-sodium (or bromomagnesium) derivatives of alkadiynes:

$$n\,R_2ECl_2 + n\,(Na)\,BrMg-C\equiv C-R'-C\equiv C-MgBr\,(Na) \longrightarrow$$
$$\longrightarrow [ER_2-C\equiv C-R'-C\equiv C]_n + 2n\,Mg\,Br\,(Na)\,Cl$$
$$n\,R_2ECl_2 + n\,BrMgC\equiv CMgBr \longrightarrow [ER_2-C\equiv C]_n,$$

where E = Si or Ge; R = CH_3, C_2H_5, or C_6H_5; R′ = $-C_6H_4-$.

Later a patent[138] described the preparation of polymers of the type

$$[ER_2-C\equiv C-R'-C\equiv C]_n$$

by the reaction of dilithium derivatives of alkadiynes with halogen compounds of silicon, germanium, and tin.

Sladkov and coworkers[139] proposed the preparation of organotin polymers with acetylenic groupings by the polycondensation of dialkyldimethoxystannanes and bisacetylenes:

$$n\,CH_3O-\underset{\displaystyle R}{\overset{\displaystyle R}{Sn}}-OCH_3 + n\,HC\equiv C-R'-C\equiv CH \longrightarrow \left[\underset{\displaystyle R}{\overset{\displaystyle R}{Sn}}-C\equiv C-R'-C\equiv C\right]_n;$$

where R = CH_3, C_4H_9; R′ = $-C_6H_4-$, $-GeR_2-$, or $-SiR_2-$

The authors confirmed[137,139] the structure of the polymers obtained from their infrared and NMR spectra. The polymers react with bromine only at elevated temperature (70–100°C), whereupon two bromine atoms are added at each triple bond[137]:

$$[ER_2-C\equiv C]_n \xrightarrow{n\,Br_2} [ER_2-CBr=CBr]_n.$$

$$[ER_2-C\equiv C-R'-C\equiv C]_n \xrightarrow{2n\,Br_2} [ER_2-CBr=CBr-R'-CBr=CBr]_n.$$

Hydrogenation of the polymers (20°C, Raney nickel) leads to the preparation of polymers with completely saturated bonds.

The organosilicon and organogermanium polymers which have been obtained are thermally stable up to 450–550°C; the organotin polymers, up to 300–350°C.[137]

Investigation of the electrophysical properties of the polymers has shown that organoelemental polymers in which atoms of silicon, germanium, and or tin alternate with unsaturated bonds exhibit high electrical resistivity at room temperature (10^{11}–10^{13} Ω cm) but it decreases with rise in temperature. The activation energy for conductivity by the polymers lies in the range 0.64–1.04 eV.[137]

A photo-e.m.f. (10 mV mW^{-1}) is observed with almost all the polymers that have been obtained[137,140].

It has been shown[137,141] that many of these polymers can be used as active electrographical layers.

A patent[138] has proposed the use of organoelemental polymers (where the element is silicon, germanium, tin, antimony, etc.) with acetylenic groupings for the manufacture of semiconductor materials.

π-ALLYL COMPLEXES OF THE TRANSITION METALS

M. I. Lobach, B. D. Babitskii, and V. A. Kormer

CONTENTS

I. Introduction 477

II. Investigation of structure 477

III. Preparation and properties 479

IV. π-Allyl complexes in organic syntheses 491

I. INTRODUCTION

In the chemistry of organometallic compounds there is now great interest in the π-allyl complexes of transition metals. On the theoretical side this interest is explained by the unusual bond of the allyl ligand with the metal, which is an inherent feature of the bonds of both alkene and aromatic complexes (ferrocene, dibenzenechromium).

The results obtained in recent years show the considerable part played by π-allyl complexes as intermediates in various reactions of organic synthesis: they are extremely effective catalysts for stereospecific polymerisation and oligomerisation (both linear and cyclic) of alkenes and dienes.

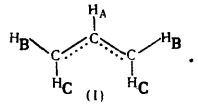
In these complexes the bond between the transition metal and the allyl ligand, analogous to the π-cyclopentadienyl and arene complexes, is multicentric: all three carbon atoms of the allyl group take part in the formation of the bond with the metal owing to the more or less complete delocalisation of the double bond.

According to Fritz [1], the ligand in the π-allyl complexes can be a π-allyl anion, radical, or cation. According to the molecular orbital theory, with the [approx.] sp^2-hybridised carbon atoms of the allyl group there are one bonding, one non-bonding, and one antibonding orbitals [1,2]. Of the three electrons of the allyl radical, two are in a bonding orbital and one in an antibonding orbital. In the allyl anion, there is a pair of electrons in [each of] these orbitals, whereas in the cation the two electrons are located in the bonding orbital. Complex formation proceeds by the transfer of these π-electrons to a vacant orbital of the metal†.

Because atoms of metals which form π-allyl complexes have lone pairs of *d*-electrons the possibility arises for formation of dative bonds by the interaction of these electrons with the antibonding orbitals of the π-allyl anions. Quantum-mechanical calculations show that the participation of the π-allyl ligand in a dative bond is less significant, unlike an alkenic ligand [3]. This, in particular, can explain the low stability of the so-called "pure" allyl compounds of the transition metals, that is, those in which there are no other stabilising ligands. In the presence of ligands such as CO, Cl, or C_5H_5 the stability of the complexes increases, this being explained by the lower energetic level of the antibonding orbitals of these ligands (in comparison with π-allyl) which also capture the *d*-electrons of the metal, forming a dative bond.

The first π-allyl complex was apparently made in 1952 by Prichard [4] in the reaction between a hydrocarbonyl of cobalt [hydrogen tetracarbonylcobaltate(−1)] and butadiene. The author erroneously ascribed to this compound the structure of a 1:1 addition compound $C_4H_7Co(CO)_4$. Later, Jonassen and coworkers [5] found that the reaction of hydrogen tetracarbonylcobaltate(−1) with butadiene is accompanied by the release of one molecule of carbon monoxide and suggested that in the product $C_4H_7Co(CO)_3$ the bond of the 1-methylallyl ligand with the metal is effected by one π- and one σ-bond [6]. Such a conception of the nature of the bonding of the allyl residue to the transition metal was viewed with suspicion after both Syrkin and coworkers [7] and Smidt and Hafner [8] obtained chloro-(π-allyl)palladium(II) $(C_3H_5PdCl)_2$. Soon after Heck and Breslow [9] used nuclear magnetic resonance to show the π-allyl structure of the compound $C_3H_5Co(CO)_3$.

π-Allyl complexes have now been obtained for all the transition metals of Groups IV–VIII except Hf, Re, Tc, and Os.



II. INVESTIGATION OF STRUCTURE

1. NUCLEAR MAGNETIC RESONANCE SPECTRA

The proton magnetic resonance method enabled slight differences in the structure of the allyl compounds of the transition metals to be observed. On the basis of their NMR spectra they can be classified into four types.

a. π-Allyl Compounds

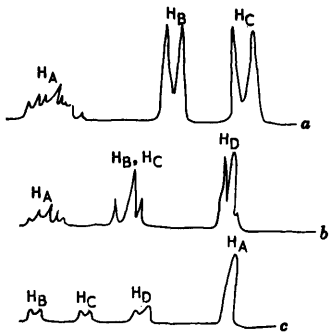
The NMR spectra of the π-allyl complexes of cobalt [9,10], manganese [10], palladium [11,12], nickel [12], and some other metals are characterised by the presence of three types of signal with ratio of intensities 1:2:2 (Fig. 1*a*). The interpretation of the NMR spectra also leads to a structure for the complexes in which, owing to the delocalisation of the π-electrons, hybridisation of the allyl carbon atoms (which are in the same plane) occurs. The hydrogen atoms H_A, H_B, and H_C in (I) are evidently coplanar with the carbon atoms:

(I)

The different chemical shifts for the H_B and H_C hydrogens suggests that they are at different distances from the metal, with the H_C protons, which are closer to the metal atom, showing a shift at higher field intensities, owing to the greater screening by the metal atom. The proton at the central carbon atom, H_A, is further from the metal atom than the H_B and H_C protons and is therefore characterised by the least chemical shift. A similar conclusion can be drawn from a comparison of the spin–spin coupling constants J_{AC} and J_{AB}, the first of which is always the greater. The interaction between the protons H_B and H_C is almost zero, a possible explanation for this, according to Gutowsky and coworkers' results [13], being that the angle $H_C\!-\!C\!-\!H_B$ is close to 125°C. The introduction of a polar substituent (for example, a chlorine atom) at the central atom of the allyl group leads to the observation of some interaction between the protons H_B and H_C (J_{BC} = 2 Hz) [14]. On replacing the H_A hydrogen by alkyl groups simple spectra are also obtained: the signal with chemical shift 4.5–4.9, which belongs to the H_A proton, disappears, and a peak with chemical shift τ = 7.7–7.9, corresponding to the allyl group protons attached to the central carbon atom of the π-allyl group, is observed [15].

The spectra of π-allyl complexes substituted at a terminal carbon atom of the allyl group are more complex,

† However, the problem of how many electrons (2, 3, or 4) leave the π-allyl ligand to form the bond with the transition metal is not so important, since this, in turn, is compensated by the degree of oxidation of the central atom.



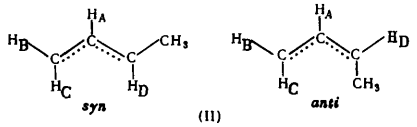


Fig. 1. NMR spectra of allyl compounds: *a*) π-allyl; *b*) σ-allyl; *c*) πσ-allyl.

the bands showing splitting due to the terminal alkyl group. For simplicity, we will discuss only 1-methyl-π-allyl (π-crotyl‡) complexes. The replacement of the H_B or H_C hydrogens of the π-allyl group leads to two isomeric complexes depending on the position of the methyl group in relation to the H_A hydrogen at the central atom of the π-allyl group—*syn*-(II) and *anti*-(II) respectively.

(II)

The spectra of $[(C_4H_7)Co(CO)_3]$ [10,16] and $(C_4H_7NiCl)_2$ [12] show five types of split peaks with the intensity ratio 1:1:1:3:1. The example of 1-methyl-π-allylcobalt-tricarbonyl showed that the spin–spin coupling constant J_{AD} is 10.5 Hz for the *syn*-isomer and 6.8 Hz for the *anti*-isomer [16]. Here the presence of the π-allyl structure is also confirmed by the equality of J_{AC} and J_{AB} for the *syn*-isomer and the similar values of J_{AB} and J_{AD} for the *anti*-isomer.

The possibility of *syn–anti*-isomerism is excluded for complexes with cyclic π-allyl ligands and therefore the NMR spectra of such compounds mainly contain three types of bands. Here it must be pointed out that the chemical shift for the H_A and H_B protons of (II) is quite close to the shift for the same protons of the unsubstituted π-allyl group of (I) [17]. The resonance lines of the methylene protons of a cyclic ligand appear at higher field strengths (τ = 8.5–9).

b. σ-Allyl Compounds

The σ-allyl compounds (III) are characteristic mainly of the non-transition elements. Of the transition metals, only Mn [10], Fe [18], W [19], and Mo [20] are known to form such compounds. In the NMR spectra of the compounds of this group four signals with the intensity ratio 1:1:1:2 are usually observed (Fig. 1*b*),

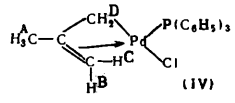
(III)

‡ sic (Ed. of Translation).

that is, the protons H_B and H_C are non-equivalent owing to the impossibility of rotation about the C=C bond. The signal from the H_A proton is split into a complex multiplet by the H_D and H_B nuclei, so that J_{CA} is considerably less than J_{AB}, as is usually observed for *cis–trans* hydrogen atoms in alkenes [21]. The signals from the H_B and H_C protons are split into a doublet by the H_A nucleus, but since these protons belong to the AC system both doublets overlap and three lines are usually obtained. Finally, the signal from the H_D protons is split into a doublet by the H_A nucleus.

c. "Dynamic" Allyl Compounds

The NMR spectra of compounds of this type show two signals with a 4:1 intensity ratio, that is, the CH_2 group protons have become equivalent. For the allyl compounds of non-transition metals (for example, magnesium [22]) this is explained by a rapid rearrangement of the type:



$$\overset{1}{CH_2}=\overset{2}{CH}-\overset{3}{CH_2}MX \rightleftarrows XM-\overset{1}{CH_2}-\overset{2}{CH}=\overset{3}{CH_2}.$$

An analogous NMR spectrum was obtained at elevated temperatures for addition compounds of π-allyl- (or π-methyl-allyl-)palladium chloride with triphenylphosphine [23-26], dimethyl sulphoxide [25-27], and triphenylarsine [26]; of π-allyl-nickel chloride with triphenylphosphine [23]; of π-allylnickel bromide and cyanide with triethylphosphine [28]; and also for allyl compounds of thorium and zirconium [23,27,29]; and for complexes $C_3H_4RRh(X_2)[P(C_6H_5)_3]_2$ and $C_3H_5Pt(X).[P(C_5H_5)_3]_2$, [30] where R = H, CH_3; X = Cl, Br.

The equivalence of the CH_2 groups in the complexes mentioned above can be explained as follows: as a result of the deficit in *d*-electrons necessary for the formation of dative bonds between the metal and the π-allyl ligand it becomes possible for the latter to rotate around the axis passing through the metal atom and the centre of the CCC plane. According to the results of Wilke and coworkers [23] the energy barrier of this rotation is 10–15 kcal.

d. πσ-Allyl Compounds

These intermediate structures were observed for the 1:1 addition compound of π-methylallylpalladium chloride with triphenylphosphine [24-25]. In the NMR spectrum of this compound (IV) there are four signals with intensity ratio 1:1:2:3 (Fig. 1*c*):

(IV)

The signals from the protons H^B, H^C, and H^D are split into doublets by the interaction with the phosphorus atom.

2. INFRARED AND ULTRAVIOLET SPECTRA

Fritz [1] made the first detailed study of the infrared spectra of a series of π-allyl complexes of palladium and nickel.

Weak bands at 3079, 3040, 3010, and 2907 cm^{-1} were assigned to stretching vibrations of the CH_2 (ν_{CH_2}) and CH (ν_{CH}) bonds. The stretching vibrations at lower wave

numbers are due to the C–H_C bonds (I) situated close to the metal atoms. For $(C_3H_5NiCl)_2$ and $(C_3H_5PdBr)_2$ these absorption bands were observed at lower frequencies (2865 and 2849 cm^{-1} respectively)[12].

The interpretation of bands belonging to the vibrations of the carbon skeleton of the π-allyl group is of the greatest value in determining the structure of the complexes. Lanpher[31] showed that the allyl anions have an absorption band in the 1500–1560 cm^{-1} region: in the π-allyl complexes of the transition metals coordination leads to a displacement of the C–C asymmetric stretching vibrations (ω_{CC}) into the 1450–1470 cm^{-1} region[1,12,32]. The bands at 1021 and 511 cm^{-1} were attributed to the symmetric stretching vibrations of the C–C bonds (ω_{CC}) and the deformation vibrations of the C–C–C carbon skeleton (Δ_{CCC}) of the allyl group respectively. The bands at 1450–1470, 1021, and 511 cm^{-1} are characteristic of π-allyl systems. For the π-crotyl and π-methylallyl complexes of palladium and nickel Δ_{CCC} appears in the 520–567 cm^{-1} region[1,12,33] and for the complexes with cyclic ligands[1] it is at ~ 585 cm^{-1}.

The absorption bands at 1381, 1226 and 1191 cm^{-1} are attributed to the in-plane bending [scissoring] vibrations of the CH_2 (δ_{CH_2}) and CH (δ_{CH}) bonds and those at 981, 965, 940, 911, and 763 cm^{-1} to the out-of-plane bending [wagging] vibrations of the CH_2 (γ_{CH_2}) and CH (γ_{CH}) bonds.

Lupin and coworkers[34] dealt with the interpretation of the vibrational frequencies of the Pd–Cl bond in bridging allyl complexes.

The comparative instability of π-allyl complexes towards ultraviolet radiation greatly limits the possibility of studying them by this method. The limited information on the ultraviolet spectra of certain π-allyl complexes, mainly those of nickel and palladium[35–37], has not yet been satisfactorily explained.

3. X-RAY STRUCTURAL INVESTIGATIONS

X-Ray structural investigations of π-allylpalladium chloride, carried out by several investigators[38–43] have confirmed the structure proposed on the basis of the NMR and infrared spectra, in which the double bond of the allyl group is completely delocalised and the group is bonded with the metal directly by a π-bond analogous to the bond between the cyclopentadienyl ring and a metal atom.

It is expedient to give only the results of the analysis of three-dimensional projections of the $(C_3H_5PdCl)_2$ molecule[39–41] since they are much more accurate than the results of Rowe[43] and Porai-Koshits[38], who studied two-dimensional projections of crystals of the complex. Fig. 2 shows the intramolecular distances and angles for bis-(π-allylpalladium chloride). It was shown that, in contrast to other results[38,43], the plane of the three carbon atoms of the allyl groups is not perpendicular to the plane of the bridging system, $(PdCl)_2$: the angle between these planes is 108°C, and the central carbon atom of an allyl group is 0.05 Å above and the terminal carbon atoms are 0.04 and 0.09 Å below the plane of the palladium atoms [sic: presumably palladium and chlorine atoms is meant]. The large angle between the C–C–C carbon atoms of the allyl group (128.6°C ± 3.3°C) agrees well with the fact that in $(C_3H_5PdCl)_2$ it behaves as a bidentate ligand.

An X-ray structural analysis made by Smith[42] at −140°C confirmed in the main Oberhansli and Dahl's results[39–41]. However, according to Smith's results the three carbon atoms

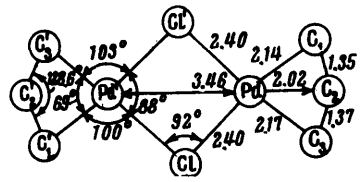


Fig.2. Intramolecular distances and angles in $(C_3H_5PdCl)_2$.

of the π-allyl group are at an equal distance from the palladium atom. The low-temperature investigation also established that all five hydrogen atoms lie in the same plane as the carbon atoms.

These have also been X-ray diffraction studies of bis-(π-methylallyl)nickel[44], cyclo-octenylnickel acetylacetonate[45], π-allylpalladium acetylacetonate[46], cyclo-octa-2,4-dienylpalladium acetylacetonate[47,48], the addition product of π-methylallylpalladium chloride and triphenylphosphine (VI)[49], π-allyl-π-cyclopentadienylpalladium[50], and π-allylirontricarbonyl iodide[51].

4. MEASUREMENT OF DIPOLE MOMENTS

The dipole moments found for π-allyl-π-cyclopentadienylnickel (0.78 D)[12,52] or π-cyclopentadienyl-π-cyclopentenylnickel (1.16 D)[53] agree well with the sandwich structure proposed for them. The appreciable dipole moment observed for dicarbonyl-π-cyclopentadienyl-π-cyclopentenylchromium (3.49 D)[54,55] indicates the asymmetric structure of the complex with the carbonyl groups in the *cis*-position.

The appearance of appreciable dipole moments in the π-allylhalogeno-complexes of nickel (1.3–1.6 D) and palladium (2.1–2.2 D) which are symmetrical in the crystalline state[7,8,12,52,56,57] suggests that evidently the centrosymmetrical configuration of these complexes undergoes considerable deformation in solution. Syrkin and coworkers[7] attributed the dipole moment of $(C_3H_5PdCl)_2$ in benzene to partial dissociation into the monomer, whereas Fischer and Bürger[12,52,57] suggested that the appearance of a dipole moment in these dimeric complexes can be explained by the angular displacement of the bridging halogen atoms. Moreover, during the dissolution of these compounds reorientation of the two allyl ligands from the *trans*-to the *cis*-position is possible (Fig. 3), which also can significantly affect the value of the dipole moment.

The first, and still the only, example of mirror [optical] isomerism in a transition metal π-allyl complex was described by Corradini and coworkers[58].

III. PREPARATION AND PROPERTIES

Owing to the great variety of both π-allyl complexes themselves and of methods for preparing them, it is desirable to examine the latter for each metal separately.

1. COMPLEXES OF TITANIUM, ZIRCONIUM, THORIUM, VANADIUM, NIOBIUM, AND TANTALUM

π-Allylbis-(π-cyclopentadienyl)titanium can be obtained by the reaction of bis-(π-cyclopentadienyl)titanium halides

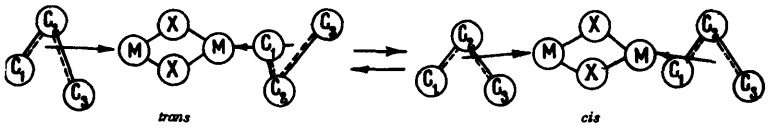

Fig.3. *cis–trans* Isomerism of halogeno-(π-allyl) complexes. M = Ni or Pd; X = Cl, Br, or I.

with allylmagnesium chloride in tetrahydrofuran solution[59,60]. The substance isolated by recrystallisation from *n*-pentane at −80°C consists of purple crystals, m.p. 118°C (decomp.). This complex and its pentane solutions are stable for a few months at room temperature in the absence of oxygen but in air rapid oxidation occurs. Reaction with octanol is accompanied by the liberation of propene in 80% yield: in methylene or allyl chlorides, $(C_5H_5)TiCl_2$ is formed. The compound is paramagnetic. The π-allyl structure has been advanced solely on the basis of infrared spectra. 1-Methyl- and 1,3-dimethyl-π-allyl-bis-(π-cyclopentadienyl)titanium have been prepared by the reaction of $(C_5H_5)_2TiCl_2$ with isopropylmagnesium bromide in the presence of buta-1,3-diene and penta-1,3-diene respectively[61].

The reaction of allylmagnesium chlorides with titanium, zirconium, thorium, vanadium, niobium, and tantalum salts [halides (Ed. of Translation)] gave the corresponding "pure" allyl compounds[23,29].

2. CHROMIUM COMPLEXES

Kurras and Klimsch[62] and Oberkirch[63] obtained tris-(π-allyl)chromium by the reaction of anhydrous $CrCl_3$ with allylmagnesium halides in ether at a temperature not exceeding −18°C. It forms red-black plates, which melt with decomposition at 77–79°C. According to cryoscopic measurements, the compound is monomeric. Solid tris-(π-allyl)chromium is extremely unstable and decomposes at −16°C, but the compound can be stored as a solid and in solutions for some time at −80°C. Bis-(π-allyl)chromium(III) was observed in the decomposition products: it is a dimer with a metal–metal bond[64]. The interaction of $(C_3H_5)_3Cr$ with hydrogen halides leads to the formation of bis-(π-allyl)chromium halides[63,65]. The latter can also be obtained as a result of the action of halogens on $(C_3H_5)_3Cr$, the course of the reaction depending considerably on the polarity of the solvent[63]. For example, $(C_3H_5)_3Cr$ and iodine in ether give bis-(π-allyl)chromium iodide, but when the reaction takes place in toluene the reaction leads only to chromium(II) halides.

When a mixture of $[(C_5H_5)Cr(CO)_3]_2$ and butadiene is irradiated with ultraviolet rays for 6 h in the presence of small amounts of mercury metal dicarbonyl-1-methyl-π-allyl-π-cyclopentadienyl is formed[66,67]. In this complex the 1-methyl-π-allyl ligand is in the *syn*-form but the CO groups are in the *cis*-position[35].

A compound similar in structure with a π-cyclopentadienyl ligand is obtained in low yield by the reaction of bis-(π-cyclopentadienyl)chromium, carbon monoxide, and hydrogen at 65–68°C.[54,55] The complex is stable in air and readily dissolves in polar organic solvents. Its NMR spectrum has four signals with intensity ratio 5:1:2:4, which agrees with the π-allyl structure of the complex. The presence in the infrared spectrum of two close absorption bands at 1894 and 1818 cm^{-1} shows the *cis*-position of the CO groups.

3. COMPLEXES OF MOLYBDENUM AND TUNGSTEN

When σ-allyl complexes of molybdenum and tungsten, which are obtained in high yields by the reaction of the sodium salt $Na^+[M(CO)_3(C_5H_5)]^-$ with an excess of allyl chloride, are subjected to ultraviolet irradiation in a vacuum, π-allyl complexes of these metals are formed[19,20]:

$$(\pi\text{-}C_5H_5)\,M\,(\sigma\text{-}C_3H_5)\,(CO)_3 \xrightarrow{uv} (\pi\text{-}C_5H_5)\,M\,(\pi\text{-}C_3H_5)\,(CO)_2 + CO.$$

Dicarbonyl-π-allyl-π-cyclopentadienylmolybdenum (or tungsten) differs from the initial complexes with π-allyl ligands in having considerably greater thermal stability and also great resistance to oxidation by oxygen.

According to King's results[68], in the complex $[(\pi\text{-}C_5H_5).(C_7H_7)Mo(CO)_2]$, obtained from $[(C_7H_7)Mo(CO)_2]I$ and cyclopentadienylsodium, the bonding of the molybdenum with the cycloheptatrienyl ligand has a π-allyl nature. The author came to this conclusion as a result of a comparison of the NMR spectra of this compound and of $[\pi\text{-}C_5H_5)(\sigma\text{-}C_5H_5)Fe(CO)_2]$[69].

King also succeeded in obtaining the complex $[(\pi\text{-}C_3H_5).(C_9H_7)Mo(CO)_2]$ from tricarbonylindenylmolybdenum and allyl chloride[70].

Murdoch[71] obtained new π-allyl complexes of molybdenum and tungsten, not containing π-cyclopentadienyl groups, in good yield from the tetraethylammonium salts of the halogenopentacarbonyl complexes of these metals and the allyl halides:

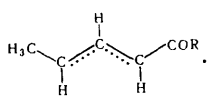
$$2\,[(C_2H_5)_4N]^+[MX(CO)_5]^- + 3\,R{-}C_3H_4Y \rightarrow [(C_2H_5)_4N]^+[M_2Y_3(R{-}C_3H_4)_3(CO)_4]^- + 6\,CO + R{-}C_3H_4X + [(C_2H_5)_4N]^+X^-,$$

where X = Cl, Br, or I; Y = Cl or Br; R = H or CH_3; and M = Mo or W.

These complexes are yellow crystalline substances, readily soluble in polar solvents. In air, the tungsten complexes are always less stable than the molybdenum.

The complex anions have a dimeric structure with halogen bridges between the metal atoms. Reaction of the molybdenum complexes with pyridine, 2,2′-bipyridyl, and ethylenediamine leads to the formation of monomeric complexes, for example, $R{-}C_3H_4Mo(CO)_2(C_5H_5N)_2Y$.[72] The latter work also describes the replacement of the halogen bridges Y by the groups OCH_3, OC_2H_5, SC_6H_5, and OH.

There are indications of the possibility of obtaining dimeric bis-(π-allyl)molybdenum and tetrakis-(π-allyl)-molybdenum and tungsten by the reaction of allylmagnesium chloride with molybdenum pentachloride and tungsten pentabromide[63,73,74].

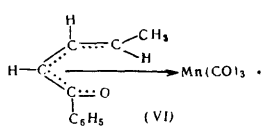


4. MANGANESE COMPLEXES

Two main methods for obtaining π-allyl complexes of manganese are known: (a) from the alkali salts of pentacarbonylmanganese and allyl halides[10,75,76]; (b) by the addition of $HMn(CO)_5$ to dienes[10].

In both instances complexes of the general formula allyl–$Mn(CO)_5$ are formed in the first stage of the reaction, these complexes containing σ-allyl ligands. On heating these compounds one molecule of carbon monoxide is lost and tetracarbonyl-π-allylmanganese complexes are formed. The infrared spectra show that the π-allyl complexes differ from the σ-allyl complexes in the presence of an absorption band at 1505 cm^{-1} and the absence of an intense absorption band at 1620 cm^{-1}, which is ascribed to the stretching vibrations of the non-coordinated double bond[10].

The above methods were used to prepare manganese π-allyltetracarbonyl complexes with the following ligands: allyl, 1-methylallyl, 2-methylallyl, 1-chloroallyl, and 1,1-dimethylallyl[10].



Recently Bannister and coworkers[77,78] reported another way of making π-allyl complexes of manganese. They found that phenyl-or methyl-pentacarbonylmanganese reacts readily with butadiene, forming a 1 : 1 addition product with the ligand of structure (V; R = CH_3, C_6H_5):

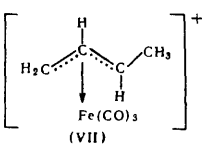
(V)

The mechanism of these processes was studied by Green and Hancock[79].

An interesting reaction took place on heating the complex with R = phenyl to the melting point (~ 108°C). Slow release of a molecule of carbon monoxide gave a new complex (VI) [from the allyl $Mn(CO)_4$ species (Ed. of Translation)] in which, according to the authors[80]§ the ligand was a five-electron system analogous to the three-electron system described below for tricarbonyl-π-oxapropenylcobalt.

(VI)

5. IRON COMPLEXES



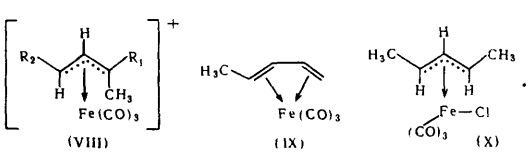
π-Allyl complexes or iron can be obtained in various ways, of which the two most general are: the action of strong acids on the π-(1,3)-dienecarbonyl complexes of iron, and the reaction of allyl halides with iron carbonyls—$Fe(CO)_5$, $Fe_2(CO)_9$, and $Fe_3(CO)_{12}$.

a. Action of Strong Acids on π-(1,3)-Dienecarbonyl Complexes of Iron

Impastato and Ihrman[81] found that tricarbonylbutadieneiron reacts at room temperature with anhydrous hydrogen chloride to give the 1 : 1 addition product of tricarbonylbutadieneiron and HCl in up to 45% yield. An investigation of the infrared spectra made by the authors showed that this compound is tricarbonyl-(1-methyl-π-allyl)iron chloride. The compound was also obtained by the reaction of tetracarbonylbutadieneiron with hydrogen chloride[82]. In the first stage of this reaction an intermediate cationic carbonyl complex $[Fe(CO)_4(C_4H_7)]^+ Cl^-$ is formed, which, on losing CO, is readily converted into tricarbonyl-(1-methyl-π-allyl)iron. The opinion in the literature as to the geometric configuration of this complex is divided. Impastato[81] and Heck and Boss[83] ascribe to the π-crotyl ligand the *anti*-configuration, whereas Murdoch and Weiss[82] consider the *syn*-form is correct.

When a benzene solution of the complex is boiled or the crystalline product is heated above its melting point (58–60°C), it decomposes to give $Fe(CO)_3(C_4H_6)$ and $FeCl_2$, with the simultaneous liberation of carbon monoxide and a mixture of butenes. The poor solubility of the complexes in water and their good solubility in organic solvents indicates the covalent nature of the bonding of the halogen with the metal.

The tricarbonyl-π-allyliron halides can be converted into salts containing the corresponding cations on treatment with $AgClO_4$ or $AgBF_4$,[84] for example, (VII)



(VII)

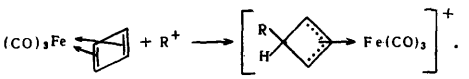
The formation of cations proceeds without change in the configuration of the allyl ligand. The tricarbonyl-π-allyliron cationic complexes can also be obtained by treating tricarbonyldieneiron complexes in nitromethane solution with such acids as $HClO_4$, $HSbCl_6$, etc.[84,85]

Note that in the protonation of tricarbonylbutadieneiron, for example, with HBF_4, the tricarbonyl-(1-methyl-π-allyl)iron cation (VIII; $R_1 = R_2 = H$), having the opposite geometrical configuration to that of cation (VII), is formed.

The same behaviour is observed in the preparation of π-allyl complexes from tricarbonyl penta-1,3-dieneiron (IX).

(VIII) (IX) (X)

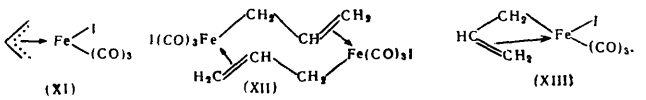
Study of the NMR spectrum of the chloride (X), produced when (IX) is treated with hydrogen chloride, showed that there is only one type of proton in the methyl groups. The salt obtained from (X) by reaction with $AgClO_4$, had an analogous NMR spectrum. On the other hand, in the complex made by reaction of (IX) with perchloric acid the protons of the methyl groups gave two doublets (7.86 and 8.35 τ)[85]. This feature suggests that here a complex of another configuration (VIII; $R_1 = H$, $R_2 = CH_3$) is formed



The fluoroborates of the tricarbonyl-(1,1-dimethyl-π-allyl)iron cation (VIII; $R_1 = CH_3$, $R_2 = H$) and the tricarbonyl-(1-methyl-3-phenyl-π-allyl)iron cation (VIII; $R_1 = H$, $R_2 = C_6H_5$) were obtained in a similar fashion from tricarbonyl-(2-methylbutadiene)iron and tricarbonyl-(1-phenylbutadiene)iron respectively.

Treatment of a salt of tricarbonyl-(1-methyl-π-allyl)-iron with water gives significant amounts of butan-2-one,

§ This reference appears to be entirely in error; the work referred to is to be found in Ref. 77 (Ed. of Translation).



whereas pentan-2-one was obtained from the tricarbonyl-(1,3-dimethyl-π-allyl)iron salt.

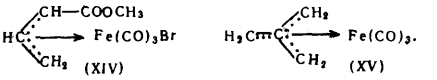
A cationic complex analogous to (VII) but with a π-cyclobutenyl group was recently isolated by Fitzpatrik and coworkers[86] by the reaction of tricarbonylcyclobutadiene-iron with electrophilic reagents:

b. Reaction of Allyl Halides with Iron Carbonyls.

$Fe(CO)_5$. When pentacarbonyliron is heated with allyl iodide the reaction leads to the formation of tricarbonyl-π-allyliron iodide[87], but the analogous reactions with allyl chloride and bromide could not be affected[12,87]. Later, Heck and Boss[83] found a convenient method of obtaining tricarbonyl-π-allyliron complexes, by ultraviolet irradiation of pentane solutions of the allyl halide and $Fe(CO)_5$. The iodo-complexes can also be obtained by the exchange reaction of the corresponding chloro-complex with sodium iodide or lithium iodide in acetone solution[82,83]. In turn, the bromo- and chloro-complexes were obtained by exchange reaction from the iodo-complex and the corresponding tetra-alkylammonium salts in chloroform[88]. Plowman and Stone[87] suggested that the iodo-complex in solution consists of a mixture of monomer and dimer, and on the basis of spectra they gave the monomer formula (XI) and the dimer formula (XII) with bridging allyl groups.

(XI) (XII) (XIII)

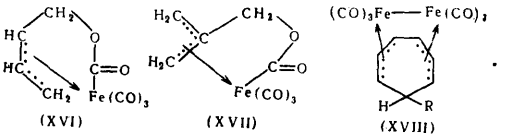
However, Nesmeyanov and coworkers[88] consider that the differences observable in the proton magnetic resonance spectra of $Fe(CO)_3(C_3H_5)I$ and the usual π-allyl complexes can be explained by some distortion of delocalisation and approach to structure (XIII), but not by the presence of dimers.



All the tricarbonyl-π-allyliron complexes react readily with triphenylphosphine, with replacement of one molecule of carbon monoxide by $(C_6H_5)_3P$,[83,88] but the product from π-$C_3H_5Fe(CO)_3Cl$ is extremely unstable, unlike its bromo- and iodo-analogues. According to Murdoch and Luncen[89] the loss of the halogen from the tricarbonylallyliron iodide in the presence of such anionic complexes as $[Mn(CO)_5]^-$ and $[(C_5H_5)Fe(CO)_2]^-$, and also its electrolytic reduction, takes place with the formation of the dimer of tricarbonyl-allyliron, which is readily split at the Fe–Fe bond to give a paramagnetic species $(C_3H_5)Fe(CO)_3$. Nesmeyanov and coworkers[88] detached the iodine from $[(C_3H_5)FeI(CO)_3]$ by treating it, in an inert atmosphere, with silver nitrate in nitromethane solution with the minimal quantity of methanol: this gave tricarbonylallyliron nitrate in 50% yield.

$Fe_2(CO)_9$. Allyl and 1-methylallyl halides react with $Fe_2(CO)_9$ at moderate temperatures, according to the equation[90]:

$$H_2C{=}CH{-}CH_2X + Fe_2(CO)_9 \rightarrow \pi\text{-}C_3H_5{-}Fe(CO)_3X + Fe(CO)_5 + CO.$$

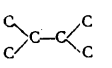


Similarly, methyl γ-bromocrotonate gave bromotricarbonyl-(1-methoxycarbonyl-π-allyl)iron (XIV), and 1,3- and 2,3-dibromoprop-1-ene gave the two isomeric bromotricarbonyl-(1-bromo-π-allyl)iron and bromotricarbonyl-(2-bromo-π-allyl)iron.

Reaction of 3-chloro-(2-chloromethyl)propene with $Fe_2(CO)_9$ for 12 h at room temperature leads to tricarbonyl-(trimethylenemethane)iron (XV)[91]. Protonation of the complex with strong acids, for example, 96% H_2SO_4, gives the tricarbonyl-π-methylallyliron cation, from which on further treatment with HCl the covalent chlorotricarbonyl-(π-methylallyl)iron was obtained.

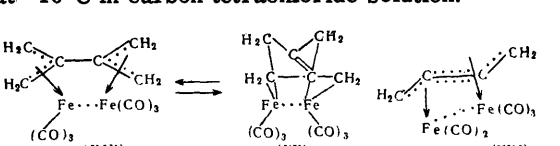
(XIV) (XV)

A new type of compound was discovered by Murdoch[92], who observed that the product of the reaction of 4-chloro-but-2-en-1-ol and nonacarbonyldi-iron contained neither alcoholic nor chloro-groups. The same product, but in greater yield, was obtained from but-2-ene-1,4-diol and $Fe_2(CO)_9$. On the basis of chemical, analytical, and spectroscopic studies it was given the structure (XVI):



(XVI) (XVII) (XVIII)

The complex (XVII), isomeric to (XVI), was obtained from $Fe_2(CO)_9$ and 2-hydroxymethylprop-1-en-3-ol. Similar reactions of 2,3-dimethylbut-2-en-1,4-diol and hex-3-en-2,4-diol with $Fe_2(CO)_9$ led to the corresponding dimethyl derivative of complex (XVI). The reaction of (XVI) with triphenylphosphine gives a complex in which one CO group is replaced by a $(C_6H_5)_3P$ group.



In reactions of $Fe_2(CO)_9$ with cycloheptatriene, 7-methoxy-cyclohepta-1,3,5-triene, cyclo-octa-1,3,5-triene[93], and cyclo-octatetraene[93–95], Pettit and coworkers always obtained orange-red crystalline complexes in which the $Fe_2(CO)_9$ grouping was attached to the corresponding cyclic diene. Investigation of the NMR and nuclear γ resonance [Mössbauer] spectra showed the equivalence of the two $Fe(CO)_3$ groups and it was therefore assumed that these compounds were new bis-(π-allylenironcarbonyl) complexes. Formula (XVIII) illustrates the structure of cyclopentatriene–$Fe_2(CO)_6$ (R = H) and its methoxy-derivative (R = OCH_3).

$Fe_3(CO)_{12}$. By the reaction of allene with $Fe_3(CO)_{12}$, Nakamura and coworkers[96] obtained a compound of composition $[(C_3H_4)Fe(CO)_3]_2$. From chemical investigations and studies of the infrared and NMR spectra it was found[97] that this compound has the skeleton

and is a second example of a bi-π-allylene compound.

Investigation of the NMR spectra of hexacarbonyl-(2,2′-bi-π-allylene)di-iron (XIX) showed[97] that the complex is in tautomeric equilibrium with a new complex of non-allyl type (XX); the equilibrium is established rather rapidly even at −10°C in carbon tetrachloride solution:

(XIX) (XX) (XXI)

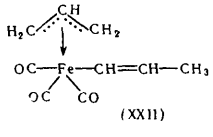
The reaction of 1,4-dibromobut-2-yne, and also of 1,4-dichlorobut-2-yne or 1,4-diacetoxybut-2-yne, with $Fe_3(CO)_{12}$ in the presence of zinc dust at 60°C gave a red crystalline substance, $Fe_2(CO)_5(C_4H_4)$ [96,98]. The most probable structure for this compound is (XXI) with two π-allyl groupings arranged at an angle to one another.

c. Special Methods of Making π-Allyl Complexes of Iron

The σ-allyliron complexes $\pi\text{-}C_5H_5Fe(CO)_2\text{-}\sigma\text{-}C_3H_5$ and $\pi\text{-}C_5H_5Fe(CO)_2\text{-}\sigma\text{-}C_4H_7$, like the analogous molybdenum compounds, liberate one molecule of carbon monoxide under the action of ultraviolet radiation and are converted into the corresponding π-allyl complexes in high yields [18].

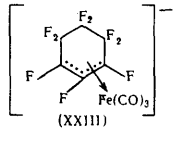
π-Allyl complexes of iron were recently obtained [99,100] with, in addition to carbonyl groups attached to the metal, one nitrosyl group. The carbonylnitrosylallyl complexes of iron are readily obtained from the corresponding sodium salts:

$$Na[Fe(CO)_3NO] + C_3H_5X \rightarrow NaX + \pi\text{-}C_3H_5Fe(CO)_2NO + CO.$$



Complexes of this type can be obtained by the addition of $HFe(CO)_3(NO)$ to a conjugated diene, for example:

$$HFe(CO)_3NO + C_4H_6 \rightarrow \pi\text{-}C_4H_7Fe(CO)_2NO + CO.$$



A method based on the reaction of halogenotricarbonyl-π-allyliron complexes or their phosphinic complexes with nitrogen(II) oxide has been proposed. A triphenylphosphine complex with a nitrosyl group can be obtained directly from $(C_4H_7)Fe(CO)_2(NO)$:

$$\pi\text{-}C_4H_7Fe(CO)_2NO + P(C_6H_5)_3 \rightarrow \pi\text{-}C_4H_7Fe(CO)(NO)[P(C_6H_5)_3] + CO.$$

Tris-(π-allyl)iron was obtained in 10–35% yield by the reaction of allylmagnesium chloride with iron(III) chloride or acetylacetonate at −80°C. [73,74,101] Reaction of trisallyliron with carbon monoxide at +10°C gives a compound which has been given the structure (XXII) on the basis of its infrared spectrum [23,101]:

(XXII)

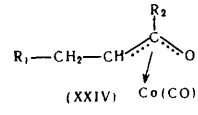
(XXIII)

It is also reported [102] that tricarbonyl(perfluorocyclohexadiene)iron treated with caesium fluoride gives a caesium salt with a (π-perfluorocyclohexenyl)tricarbonylferrate anion (XXIII).

6. COBALT COMPLEXES

There are two main methods for preparing π-allyl complexes of cobalt.

a. Addition of Hydrocobalttetracarbonyl to Diene Hydrocarbons



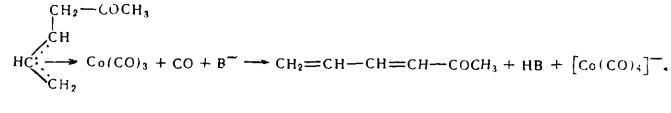
(1-Methyl-π-allyl)cobalttricarbonyl $Co(CO)_3(C_4H_7)$, obtained by Prichard [4] by the reaction of hydrogen tetracarbonylcobaltate(−1) with butadiene in isopropyl alcohol was, as mentioned above, the first π-allyl compound. $KCo(CO)_4$ [5] and $Co_2(CO)_8$ [10] can be used instead of $HCo(CO)_4$ if glacial acetic acid is used as the reaction medium. Aldridge and coworkers [6] showed that $Co(CO)_3(C_4H_7)$ is formed as a mixture of *syn* and *anti* forms in the ratio 6 : 4. The intermediate product in these reactions is the complex $Co(CO)_4(C_4H_7)$, which readily loses a molecule of carbon monoxide and is converted into tricarbonyl-1-methyl-π-allylcobalt [10].

The reactions of $HCo(CO)_4$ with 2-methylbuta-1,3-diene, penta-1,3-diene, and 2,3-dimethylbutadiene [32] proceed similarly. The reaction of penta-1,4-diene is accompanied by rearrangement of the alkadiene and leads to the formation of *syn* and *anti* isomeric forms of (1-ethyl-π-allyl)cobalttricarbonyl and of the 1,3-dimethyl complex. The yield of the latter does not exceed 10–15%. [103]

When the reaction is carried out under a pressure of carbon monoxide, some oxidation products, such as hex-5-enal and 2-methylcyclopentanone, [104,105] are formed as well as the (1-ethyl-π-allyl)cobalttricarbonyl. The yield of the complex decreases as the pressure is raised.

Addition of butadiene to the $[CoH(CN)_5]^{3-}$ ion gives the tetracyano-1-methyl-π-allylcobalt anion $[Co(CN)_4.(C_4H_7)]^{2-}$. [106,107] This process, as with hydrogen tetracarbonylcobaltate(−1), proceeds through the formation of the σ-allyl complex $[Co(CN)_5(C_4H_7)]^{3-}$.

When unsaturated aldehydes and ketones react with hydrogen tetracarbonylcobaltate(-1) under hydroformylation conditions the products are, according to the mechanism suggested by Goetz and Orchin [80], the so-called π-oxapropenyl complexes of type (XXIV). In this way the complex (XXIV; $R_1 = CH_3$, $R_2 = H$) was obtained from but-2-enal and the more stable complex (XXIV; $R_1 = H$, $R_2 = CH_3$) from butenone.



(XXIV)

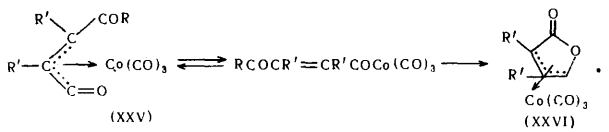
Heck [108,109] found a way of obtaining substituted π-allyl complexes with an acyl group in the side-chain. These products are formed in the reaction of butadiene, $NaCo(CO)_4$, and alkyl or acyl halides in ethereal solution. The rate of the process depends on the reactivity of the halide. Tetracarbonylacylcobalt and tetracarbonylalkylcobalt complexes are formed in the first stage of the reaction, and then, by reaction with butadiene, are converted into active tricarbonylacylcobalt complexes.

1-Substituted tricarbonyl-π-allylcobalt complexes, obtained in the reaction of dienes with tetracarbonylalkylcobalt or tetracarbonylacylcobalt complexes, exist in *syn* and *anti* forms. For example, the complex from tetracarbonylmethylcobalt and *cis*-penta-1,3-diene is found in the *syn*, and that from 2,3-dimethylbutadiene, in the *anti* configuration. π-Allyl complexes have also been obtained by reactions with 2-methylbutadiene, 4-methylpenta-1,3-diene, and *trans*-1-methoxybutadiene in methyl sorbate [108].

The structure of the complexes formed was studied using their reactions with bases (dicyclohexylethylamine, sodium methoxide, or potassium t-butoxide) in the presence of carbon monoxide [110]. The bases evidently detach a proton from the α-methylene group (in relation to the carbonyl), which leads to the liberation of a tricarbonylcobalt group; this adds CO and forms a stable tetracarbonylcobaltate anion, for example:

On reaction with $CH_3Co(CO)_4$ and a base, *cis*-penta-1,3-diene gives

$$CH_3—CO—C(CH_3)=CH—CH=CH_2,$$



but *trans*-penta-1,3-diene gives:

$$CH_3—CO—CH=CH—CH=CH—CH_3.$$

When disubstituted acetylene is used instead of a diene in the reaction with a carbonylacylcobalt complex, then from the intermediate complex

$$C—R—CO—CR'=CR'—COCo(CO)_3,$$

which is essentially mainly in the form of a π-acrylic complex (XXV), a 2,3-dialkyl-π-(2,4-penteno-4-lactonyl)cobalttricarbonyl complex (XXVI) is obtained [111]:

(XXV) (XXVI)

As Heck has shown [112], the addition of acyl or alkyl tetracarbonylcobaltates(-1) to $\alpha\beta$-unsaturated aldehydes and ketones leads to tricarbonyl-(1-acyloxy-π-allyl)cobalt complexes, the triphenylphosphine derivatives of which have been characterised.

The carbonyl-π-allyl complexes of cobalt are usually characterised as their triphenylphosphine derivatives, which are more stable. The reaction of $Co(CO)_3(C_3H_5)$ with $(C_6H_5)_3P$ is accompanied by the formation of yellow crystalline dicarbonyl-π-allyltriphenylphosphinecobalt and the liberation of carbon monoxide. [113-115] Kinetic investigations showed that the rate of this reaction is independent of the phosphine concentration when the latter exceeds 0.06 M. [114] The replacement of the hydrogen atom at the central carbon atom of the π-allyl group by electron-donating or electron-accepting groups increases the reaction rate. On the other hand, replacement of a hydrogen atom at the first or third carbon atoms of the π-allyl group by an electron-accepting substituent decreases the reaction rate by a factor of almost 30. [112]

Tetracarbonyl-σ-allylcobalt reacts differently with triphenylphosphine [113-115]. Liberation of carbon monoxide is not observed but an acyl complex is formed:

$$CH_2=CH—CH_2COCo(CO)_3P(C_6H_5)_3$$

tricarbonyl(but-3-enoyl)(triphenylphosphine)cobalt, which can also be obtained by the reaction of allyl bromide with $NaCo(CO)_4$ and CO in the presence of triphenylphosphine.

In the reaction with triphenylphosphine as unusual type of metal–organic bond is clearly evident in the tricarbonyl-π-allylcobalt complexes, since compounds with a σ-bond (tetracarbonylalkylcobalt complexes) give acylcobalt derivatives with $(C_6H_5)_3P$ [115] but the cyclo-octatetraene ligand is displaced from a π-complex, tricarbonylcyclo-octatetraenecobalt [116].

The reaction of π-allylcobalttricarbonyl complexes with trimethylolpropan phosphite [? trimethylene propenyl phosphite (Ed. of Translation)] has been shown by Heck [117] to proceed by replacement of two molecules of carbon monoxide:

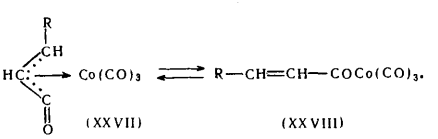
$$C_3H_5Co(CO)_3 + 2\,PO_3C_6H_{11} \rightarrow C_3H_5Co(CO)(PO_3C_6H_{11})_2 + 2\,CO.$$

Bis(trimethylolpropan phosphite) derivatives were also obtained from 2-chloro-π-allyl-, 1-acetyl-π-allyl, and 1-benzoylmethyl-3-methoxy-π-allyl-tricarbonylcobalt complexes.

All these compounds are crystalline, from yellow to orange in colour, and fairly stable in air.

b. Reaction of the $[Co(CO)_4]^-$ Anion with Allyl Halides

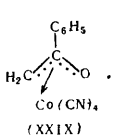
This method was used to make tricarbonyl-π-allylcobalt [9,10,113,114], and the 1-methyl- [9,10,113], 1- and 2-chloro- [10], 2-methyl-, 2-bromo-, 2-phenyl-, and 1-methoxycarbonyl- [114] π-allyltricarbonylcobalt complexes from allyl and 1-methylallyl halides, 2,3- and 1,3-dichloropropene, 2-phenylallyl bromide, and methyl 3-bromocrotonate respectively. The reaction was carried out with a slight excess of $KCo(CO)_4$ or $NaCo(CO)_4$.



When there is an excess of the allyl halide, for example, C_3H_5Br, the reaction proceeds in another direction:

$$2\,C_3H_5Co(CO)_3 + 4\,C_3H_5Br \rightarrow 3\,C_6H_{10} + 2\,CoBr_2.$$

Tricarbonyl-π-allylcobalt complexes are also readily obtained by decomposition of acyl tetracarbonylcobaltates formed in the reaction of $NaCo(CO)_4$ with allyl halides in the presence of carbon monoxide [9,113,118]:

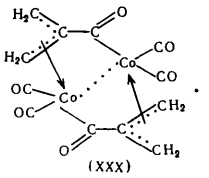


$$NaCo(CO)_4 + CH_2=CH—CH_2Cl + CO \xrightarrow{-NaCl} CH_2=CH—CH_2COCo(CO)_4 \xrightarrow{-2Co} \rightarrow C_3H_5Co(CO)_3.$$

When vinylacetyl chloride is used instead of allyl halides the reaction proceeds in the absence of carbon monoxide [9,113]. The reaction of $NaCo(CO)_4$ with acrylyl, crotonyl, or sorbyl chloride in the presence of carbon monoxide leads to the formation of an equilibrium mixture of π-acrylyl complexes (XXVII) and acyl complexes (XXVIII) [113,119,120]. On adding triphenylphosphine a complex of (XXVIII) with one molecule of $(C_6H_5)_3P$ was isolated:

(XXVII) (XXVIII)

π-Allyl anions with cyano-groups, already mentioned above, can also be obtained by the reaction of allyl halides with the pentacyanocobaltate(II) anion $[Co(CN)_5]^{3-}$. [106,107] The reaction of pentacyanocobaltate(II) with phenacyl bromide led to a complex which was given a structure of the π-oxapropenyl type (XXIX).

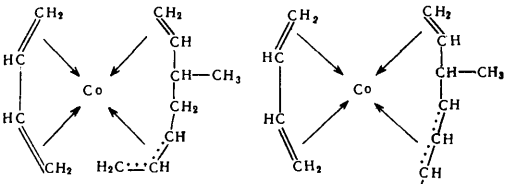


(XXIX)

In addition to these two general methods for the prepartion of π-allyl complexes of cobalt, some other synthetic routes must be noted.

Carbonyl-π-allyl-π-cyclopentadienylcobalt bromide was made by the reaction of allyl bromide with $Co(CO)_2(C_5H_5)$ [121]. Heck [122] showed that in this reaction not only $[Co(CO)(C_3H_5).(C_5H_5)]Br$ but also a little π-allyl-π-cyclopentadienylcobalt bromide is formed. With allyl iodide the main product was also an ionic complex, but more of the covalent $CoI(\pi\text{-}C_3H_5)(C_5H_5)$ was present (10%). With allyl chloride only carbonyl-π-allyl-π-cyclopentadienylcobalt chloride is formed. The treatment of a benzene solution of octacarbonylcobalt with allene at 40°C leads to a carbonyl-π-allylacylcobalt complex (XXX) [123], the structure of which

was established on the basis of NMR and infrared spectra, and by bromination.



(XXX)

Tris-(π-allyl)cobalt $(C_3H_5)_3Co$ was obtained by the reaction of an ethereal solution of allylmagnesium chloride and cobalt acetylacetonate at −80°C (yield 45–50%)[73,74]. With cobalt chloride the yield did not exceed 20%. The compound is thermally unstable and decomposes rapidly, even at 0°C.

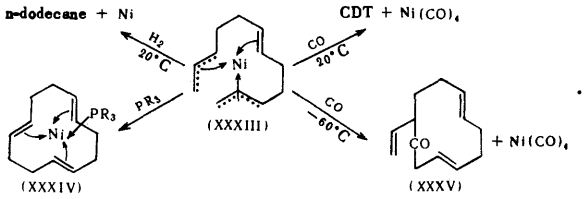
There are indications that the reaction of $(C_3H_5)_3Co$ with hydrogen halides leads to the formation of bis-(π-allyl)-cobalt halides[65]. The product of the reaction of $(C_3H_5)_3Co$ with CO at −35°C is π-allylcobalttricarbonyl[23].

By the reaction of an ethanol solution of $CoCl_2$ with sodium tetrahydroborate in the presence of butadiene Natta and coworkers[124] obtained a complex of composition $CoC_{12}H_{19}$, to which they ascribed one of the following structures:

(XXXI) (XXXII)

The compound melts at ~ 37°C, dissolves in hydrocarbons with the formation of red solutions, and is insoluble in water. On reaction with carbon monoxide two tricarbonyl-π-allyl complexes were isolated: $(C_4H_7)Co(CO)_3$ and $(C_8H_{13})Co(CO)_3$. The latter, in turn, was made from $Co_2(CO)_8$ and 3-methyl-hepta-1,4,6-triene in acetic acid solution.

7. NICKEL COMPLEXES

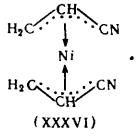


The following types of π-allyl complexes of nickel are known: bis-(π-allyl), bis-(π-allylnickel halides), π-allyl-π-cyclopentadienyl, and also complexes with cyclic π-allyl ligands.

a. Bis-(π-Allyl) Complexes

The simplest complex of this class, bis-(π-allyl)nickel, $(C_3H_5)_2Ni$, was first obtained by Wilke[23,29,125-128] by the reaction of an ethereal solution of allylmagnesium chloride with anhydrous nickel bromide at −10°C. 1-Methylallyl, 2-methylallyl, and phenylallyl complexes were obtained in a similar manner[73,74,129,130]. $(C_3H_5)_2Ni$ is readily soluble in hydrocarbons and stable in relation to water. It ignites in air. On reduction with hydrogen it liberates propane and metallic nickel is left. The reaction of $(C_3H_5)_2Ni$ with compounds which exhibit electron-donating properties is accompanied by the formation of biallyl. In addition to biallyl, in the presence of carbon monoxide or triphenylphosphine, nickelcarbonyl and $[(C_6H_5)_3P]_4Ni$ is formed[125,126,128].

Under certain conditions and at reagent ratios of 1 : 1 for bis-(1-methyl-π-allyl)nickel and bis-(2-methyl-π-allyl)-nickel their addition product with triphenylphosphine of composition $Ni(\pi\text{-}C_4H_7)(\sigma\text{-}C_4H_7).[P(C_2H_5)_3]$ was isolated[23,129].



Wilke and coworkers[128,131] obtained compounds of general formula $C_{12}H_{18}Ni$ as an intermediate product in the preparation of cyclododecatriene (CDT) from butadiene. On the basis of the infrared spectra this complex was assigned structure (XXXIII) in which three molecules of butadiene form a chain of 12 carbon atoms with a *trans* double bond and two allyl groupings:

(XXXIV) (XXXIII) (XXXV)

Reaction of (XXXIII) with electron donors (carbon monoxide, phosphine, butadiene) leads to ring closure, and when phosphine is used detachment of the cyclododecatriene does not take place (XXXIV). With carbon monoxide at −60°C the reaction is quite different, tetracarbonylnickel and vinylcycloundecadiene (XXXV) being formed. When hydrogen reacts with (XXXIII) n-dodecane is formed[125,128,131].

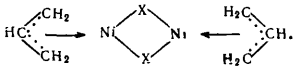
According to Schrauzer[132], complexes of nickel with acrylonitrile (XXXVI), acrolein, cinnamonitrile, and fumaronitrile, which are obtained by the reaction of tetracarbonylnickel with corresponding unsaturated compounds, can be classified as π-allyl complexes:

(XXXVI)

b. Bis-(π-Allylnickel Halides)

Bis-(π-allylnickel halides) are obtained by the reaction of tetracarbonylnickel with allyl halides[12,52,57]:

$$2\,Ni(CO_4) + 2\,RX \rightarrow [RNiX]_2 + 8\,CO.$$



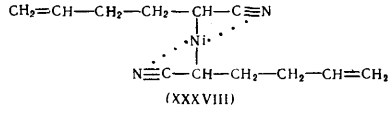
Benzene is the most suitable solvent for this reaction[12].

The reaction of tetracarbonylnickel with allyl halides in an alcoholic medium leads to the dimerisation of the allyl residues[133]. Thus, hexa-1,5-diene is obtained from allyl halides and octa-2,6-diene (7.8%) and 3-methylhepta-1,5-diene (22%) from a mixture of crotyl chloride and 3-chloro-but-1-ene.

Both in the dimerisation and in the formation of π-allyl complexes, the reaction evidently proceeds through the formation of an intermediate compound, $R-[(C_3H_4)NiX(CO)]$[35,134].

Bis-(π-allylnickel halides) can also be obtained by the reaction of allyl halides with other complexes of nickel(0), such as bis(cyclo-octadiene)nickel(0), cyclododecatriene-nickel[135] or by reaction of bis-(π-allyl) complexes of nickel with hydrogen halides in ethereal solution at −80°C[65,129].

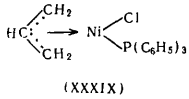
According to Fischer and Bürger [12,52,57] bis-(π-allylnickel halides) have structure (XXXVII) with halogeno-bridges.



(XXXVII)

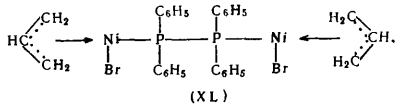
They are readily soluble in organic solvents to give dark red solutions. In water saturated with nitrogen bis-(π-allylnickel halides) form orange-red solutions which are stable for a short time but which decompose on long standing, with the formation of metallic nickel.

Chiusoli and Merzoni [136] found that during the carbonylation of methanol solutions of $(C_3H_5NiBr)_2$ methyl vinylacetate is formed. A mixture of acetylene and carbon monoxide acts on $(NiXC_3H_5)_2$ to give, in addition to tetracarbonylnickel, derivatives of hexa-2,5-dienoic acid, depending upon the nature of the solvent; for example, in ether at ~ 0°C the following reaction takes place [137]:



$$(C_3H_5NiBr)_2 + 10\,CO + 2\,C_2H_2 \rightarrow 2\,CH_3{=}CH{-}CH_2{-}CH{=}CH{-}COBr + 2\,Ni(CO)_4.$$

The reaction of bis-(π-allylnickel bromide) with methyl acrylate in benzene solution at room temperature leads to the formation of methyl hexa-2,5-dienoate and methyl hex-5-enoate [138,139]. Acrylonitrile reacts with $(C_3H_5NiBr)_2$ with the separation of a complex which has been given the structure (XXXVIII):



(XXXVIII)

The reaction of bis-(π-allylnickel halides) with triphenylphosphine leads to the breaking of the halogeno-bridges [23,29,140]. The complexes thus formed (XXXIX):

(XXXIX)

were also obtained by the reaction of allyl chloride with $Ni(CO)_3[P(C_6H_5)_3]$ [141]. The reaction of tetraphenyldiphosphinedinickelhexacarbonyl [μ-(tetraphenyldiphosphenylene)bis(tricarbonylnickel)(Ed. of Translation)] with allyl bromide leads to the π-allyl complex (XL) with a diphosphinic bridge [142]:

(XL)

Bogdanović and coworkers [140] obtained π-allylmethylnickel by the reaction of $(C_3H_5NiBr)_2$ with methylmagnesium chloride in ether (-78°C). This product is extremely unstable and even at -60°C it changes into bis-(π-allyl) nickel. π-Allylmethylnickel-triphenylphosphine was made in a similar fashion from complex (XXXIX).

Wilke and coworkers [28] obtained bis-(π-allylnickel cyanide) in methanol starting from $(C_3H_5)_2Ni$ and HCN or $(C_3H_5NiBr)_2$ and KCN.

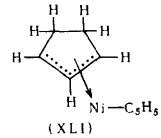
c. π-Allyl-π-Cyclopentadienyl Complexes of Nickel

π-Allyl-, and also 1-methyl-π-allyl-π-cyclopentadienyl complexes of nickel are obtained from the corresponding bis-(π-allylnickel halides) and cyclopentadienylsodium [12,52]:

$$(C_3H_5NiBr)_2 + 2\,NaC_5H_5 \rightarrow 2\,C_3H_5NiC_5H_5 + 2\,NaBr.$$

In addition, the same products are obtained by the reaction of bis-(π-cyclopentadienylnickel) with the corresponding allylmagnesium halides [10,143], for example:

$$C_3H_5MgCl + (\pi\text{-}C_5H_5)_2Ni \rightarrow C_5H_5MgCl + C_3H_5NiC_5H_5.$$



1-methyl-π-allyl-π-cyclopentadienylnickel was also obtained by the reaction of $(C_5H_5)_2Ni$ with butadiene and consisted of a mixture of *syn*- and *anti*-isomers [144]. The reaction of 1-methylallyl chloride with the potassium salt of π-cyclopentadienylnickelcarbonyl leads to the formation of the same complex [144]:

$$C_4H_7Cl + K[C_5H_5NiCO] \rightarrow C_4H_7NiC_5H_5 + CO + KCl.$$

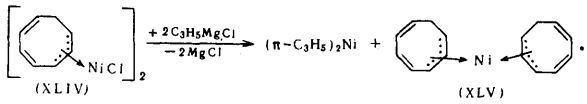
All the π-allyl-π-cyclopentadienyl complexes of nickel are readily soluble in most organic solvents. These compounds rapidly decompose in air. Cryoscopic measurements in benzene have shown that the complexes have a monomeric structure.

d. Complexes with Cyclic π-Allyl Ligands

A π-allyl complex of nickel with a cyclic ligand was first obtained by Fischer and Werner [53,145] by the reaction of tetracarbonyl nickel with cyclopentadiene in n-hexane solution. However, it was incorrectly given the structure of bis(cyclopentadiene)nickel, $(C_5H_6)_2Ni$. [53] It was later found, from infrared and NMR spectra, that this compound is a π-cyclopentadienyl-π-cyclopentenyl complex (XLI) [1,17,146-150].

(XLI)

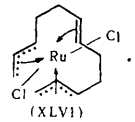
Dubeck and Filbey [149] prepared it by reduction of $(C_5H_5)_2Ni$ with sodium amalgam in methanol solution, and also by the reaction of cyclopentenylmagnesium bromide, C_5H_5Na, and anhydrous $NiBr_2$ at -10°C.



Reaction of bis-(π-cyclopentadienyl)nickel with tetrafluoroethylene gave a π-allyl complex of structure (XLII), which was proposed on the basis of an examination of the ^1H- and ^{19}F-NMR spectra [151]. Complexes analogous to (XLII) were also obtained by the reaction of $(C_5H_5)_2Ni$ with chlorotrifluoroethylene and hexafluorobut-2-yne [149,151]. The product of the reaction of $(C_5H_5)_2Ni$ with octafluorocyclohexa-1,3-diene was represented as the π-allyl complex (XLIII) on the basis of spectroscopic data [152]:

(XLII) (XLIII)

Nickel compounds with cyclobutenyl [39,40,153-157] and cyclopropenyl [158,159] ligands must also be classified as complexes of the π-allyl type. A series of cyclic π-allyl nickel complexes has been isolated in Wilke's laboratory [23,129]—bis-(π-cyclohexenyl)nickel, bis-(π-cycloheptenyl)nickel, bis-(π-cyclo-octenyl)nickel, and also the corresponding π-enylnickel chlorides formed from them on treatment with HCl. The reaction of cyclo-octatetraenylnickel with HCl



at −80°C in toluene gave red crystals of bis-(π-cyclo-octatrienylnickel chloride) (XLIV)[23], which when treated with allylmagnesium chloride yielded bis-(π-cyclo-octatrienyl)nickel (XLV) and bis-(π-allyl)nickel, instead of the expected π-allyl-π-cyclo-octatrienylnickel:

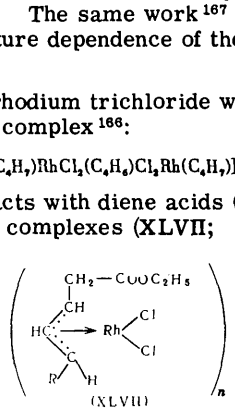
(XLIV) (XLV)

8. COMPLEXES OF RUTHENIUM, RHODIUM, AND IRIDIUM

Two π-allyl complexes of ruthenium are known at present. Complex (XLVI) was obtained by the reaction of ruthenium(III) chloride and butadiene in 2-methoxyethanol solution at 100°C.[160,161] It is a monomer in benzene. Complexes of rhodium and iridium with butadiene were obtained in the same way.

(XLVI)

The reaction of $RuCl_3$ in alcoholic solution with 2-methylbuta-1,3-diene leads to the formation of the dimeric dichloro-(2,7-dimethylocta-2,6-dien-1,8-ylene)ruthenium, to which Porri and coworkers[162] ascribed a π-allyl structure.



The diamagnetic cyclododeca-1,5-dienylrhodium dichloride, the first π-allyl complex of rhodium(III), was obtained by Paiaro and coworkers[163,164] from $RhCl_3.3H_2O$ and cyclododeca-*trans*-1,*trans*-5,*trans*-9-triene in boiling ethanol. The polymeric nature of the substance is shown by its insolubility in the usual organic solvents, and its ability to dissolve in dilute ammonia and to react with Lewis bases (CO, amines, alkenes) with the formation of monomeric complexes $C_{12}H_{19}RhCl_2B$, where B is the base.

Dimeric bis-(π-allyl)rhodium chloride was prepared by Shaw and coworkers[165] by the reaction of $[RhCl(CO)_2]_2$ with allyl chloride in methanol containing a little water. The reaction of the complex with pyridine, thallium(I) acetylacetonate, and cyclopentadienylthallium led to the corresponding monomeric compound. Treatment of $[(\pi\text{-}C_3H_5)_2RhCl]_2$ with allylmagnesium chloride gives trisallylrhodium[166], which was also obtained by the reaction of anhydrous $RhCl_3$ with C_3H_5MgCl at 0°C.[167] The same work[167] also gave information on the temperature dependence of the NMR spectra of $(C_3H_5)_3Rh$.

The reaction of rhodium trichloride with butadiene in ethanol leads to the complex[166]:

$$[(C_4H_7)RhCl_2(C_4H_6)Cl_2Rh(C_4H_7)].$$

$RhCl_3.3H_2O$ also reacts with diene acids (sorbic, vinylacrylic) to form the complexes (XLVII; R = H, CH_3)[168]:

(XLVII)

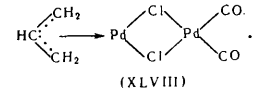
Corresponding monomeric complexes were obtained from (XLVII) with 2,2-bipyridyl, ethylenediamine, or carbon monoxide.

π-Allyl-π-cyclo-octa-1,5-dienerhodium was made by the reaction of $[C_8H_{12}RhI]_2$ with an excess of allylmagnesium bromide at 0°C.[169]

Wilkinson and coworkers[170] recently reported the preparation of the complexes

$$R—C_3H_4RhCl_2[PC_6H_5)_3],$$

the NMR spectra of which were studied by Volger and Vrieze[30].



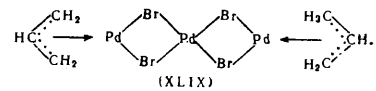
CHEMICAL SOCIETY REFERENCE LIBRARY BURLINGTON HOUSE, W.1

9. PALLADIUM COMPLEXES

A. Preparation

a. Reactions with allyl halides. Yellow bis-(π-allylpalladium bromide) is obtained when palladium sponge is heated with allyl bromide[12,56]. However, in experiments with allyl chloride and iodide, and also with crotyl bromide, π-allyl palladium compounds were not obtained.

The reaction of a solution of allyl chloride in 50% acetic acid with palladium chloride at 30°C leads to the formation of bis-(π-allylpalladium chloride)[171,172]. At room temperature methylallyl chloride gives a red complex sparingly soluble in organic solvents, $(C_4H_8PdCl_2)_2$. When this is boiled in water it decomposes to metallic palladium and bis-(π-methylallylpalladium dichloride). Dent and coworkers[33] found that these complexes can be obtained almost quantitatively by the action of carbon monoxide on a mixture of Na_2PdCl_4 and allyl chlorides in methanol at atmospheric pressure and room temperature. In the presence of palladium and calcium chlorides in addition to π-allylchloride complexes of palladium a compound insoluble in the usual organic solvents could be isolated, to which the authors ascribed the structure (XLVIII) on the basis of the infrared spectra.



(XLVIII)

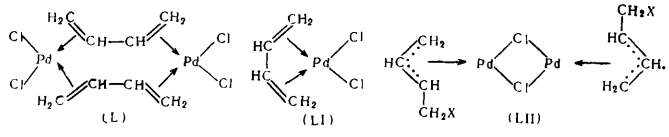
Subsequently Shaw and coworkers[173] showed that in the absence of CO and H_2O allylpalladium chloride cannot be prepared by Dent's method.

b. Reactions with allyl alcohol, alkenes and acetylenes. Bis-(π-allylpalladium chloride) was first obtained independently by Syrkin and coworkers[7] and by Smidt and Hafner[8,174] by the reaction of palladium chloride with allyl chloride in acid medium at room temperature.

Dimeric $(C_3H_5PdCl)_2$ is a yellow crystalline substance readily soluble in polar solvents and also in dilute aqueous acids and alkalis. The report by Syrkin and coworkers[7] on the preparation of a second dark green form of $(C_3H_5PdCl)_2$ at temperatures below 10°C was not confirmed in work by other investigators[175].

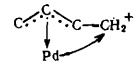
When allyl alcohol reacts with $PdBr_2$ in hydrobromic acid solution under the same conditions, bis-(π-allylpalladium bromide) is formed[176]. On increasing the $PdBr_2$ concentration a complex of composition $C_6H_{10}Pd_3Br_4$ is also formed, for which structure (XLIX) has been proposed:

(XLIX)



The reaction of alkenes with various palladium compounds (for example, $PdCl_2$, Na_2PdCl_4, and $[PdCl_2(C_6H_5CN)_2]$) is a most general and convenient method for obtaining π-allyl complexes of palladium.

For most alkenes the reaction with palladium chloride passes through the stage of formation of π-complexes of the type $[(alkene)PdCl_2]_2$, which lose HCl at a higher temperature, being changed into π-allyl complexes. Raising the reaction temperature to 50–100°C allows the π-allyl complexes to be obtained directly.

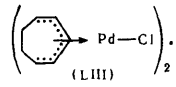


The Table gives the complexes prepared from the corresponding alkenes.

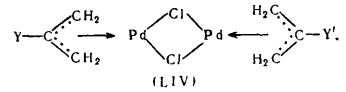
In the reaction of propene with an acetic acid solution of $PdCl_2$ saturated with sodium acetate a yellow complex of composition $C_6H_{11}PdCl$ is formed [180]. Study of the chemical properties and infrared and NMR spectra of the product showed that it is bis-(3-*syn*-ethyl-1-*syn*-methyl-π-allylpalladium chloride) [181]. The same complex is produced in the reaction of hex-1-ene with $PdCl_2$.

Some π-allyl complexes can be obtained by treatment of bis(benzonitrile)palladium chloride with dienes. The product of the reaction with butadiene was earlier given the structures (L, LI) [182-184]. However, Shaw [185] showed that butadienepalladium chloride is a π-allyl complex with halogen bridges (LII; X = Cl). Recently Donati and Conti [186] obtained the π-complex $(C_4H_6PdCl_2)_2$ by the reaction of butadiene with $(n\text{-}C_5H_{10}PdCl_2)_2$ at −40°C. At temperatures above −20°C the complex is converted into a π-allyl complex (LII; X = Cl).

Treatment of (LII) with methanol converts it into the less stable methoxy-derivative (LII; X = OMe). The methoxy- and also the ethoxy-π-crotylpalladium complexes are best obtained by passing butadiene into an alcoholic suspension of $Na_2[PdCl_4]$. Hence it is possible to obtain complexes from a large number of 1,3-dienes, such as 2-methylbutadiene, 4-methylpentadiene, 2,3-dimethylbutadiene, 2,4-dimethylpenta-1,3-diene, 1,1,4,4-tetramethylbutadiene, sorbic acid, and methyl sorbate [36,185,187]. It was also found [36] that methoxy-π-allyl palladium chloride treated with an ethanol solution of hydrogen chloride readily forms the corresponding ethoxy-derivative. The authors suggest the intermediate formation of a carbonium ion of type



the considerably stability of which was explained (by analogy with the stability of α-ferrocenylcarbonium ions) by the participation of the palladium atom in the stabilisation of the neighbouring cationic centre.

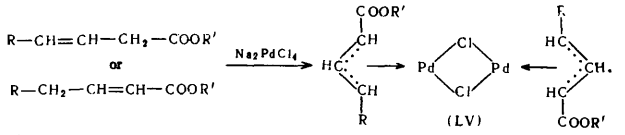


Cycloalkenes also react with palladium salts: cyclohexene [172,188], cycloheptene [188], cyclododecene [189], and their methyl derivatives, and also methylcyclo-octene [189]. The yields of the complexes increase with the number of carbon atoms in the ring, and here π-alkene complexes are formed initially, which are converted into π-allyl complexes with various degrees of ease. It has been noted [188], however, that cyclopentene gives a stable alkene complex which is not converted into a π-allyl compound. π-Allyl complexes are formed much more readily in the reaction of palladium salts with cyclic 1,3-dienes [190-192].

Robinson and Shaw [37] obtained dimeric methoxy-π-cyclohexenylpalladium chloride from cyclohexa-1,3-diene at room temperature. The stability of the product was much less than that of the corresponding acyclic complex [36].

A complex of composition $(C_7H_9PdCl)_2$ was obtained from cyclohepta-1,3-diene, and on the basis of the infrared spectra Robinson and Shaw [37] gave it the formula (LIII), where the palladium atom is associated with five atoms of the cycloheptadienyl ligand, as occurs in the π-cyclopentadienyl complexes.

π-Allyl complexes have also been obtained by passing allene or methyl-, dimethyl-, or tetramethyl-allenes through a methanol suspension of $Na_2[PdCl_4]$ [14,187]. The π-allyl complexes isolated had substituents at the central carbon atom of the π-allyl group $\left(\text{LIV; } Y = Y' = -C\begin{matrix}=CH_2\\ CH_2Cl\end{matrix}\right)$.

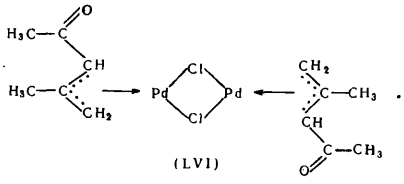


However, when allene is introduced into a methanol solution of dichlorobis(benzonitrile)palladium(II), then in addition to the above product about the same amount of the methoxy-derivative $\left(\text{LIV; } Y = Y' = -C\begin{matrix}=CH_2\\ CH_2OCH_3\end{matrix}\right)$ [193] is formed; the 2-methoxy-derivative is not formed. The reaction of $[PdCl_2(C_6H_5CN)_2]$ with allenes can also be effected in benzene or benzonitrile solutions [194]. The nature of the products formed depends on the method of preparation. When allene is introduced into a benzene solution of dichlorobis-(benzonitrile)palladium(II) the product is bis-(2-chloro-π-allylpalladium chloride) (LIV; Y = Y′ = Cl). In benzonitrile solution this complex with two 1-(chloromethyl)vinyl substituents at the central carbon atom in the π-allyl group is

TABLE. Bis[dichloro(π-allyl)palladium(II)] complexes

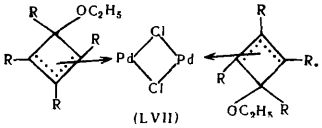
Initial alkene	Organic residue of the π-allyl complex	Reference
2-Methylpropene	2-methyl-π-allyl	172,177
2-Methylbut-1-ene 2-Methylbut-2-ene	1,2-dimethyl-π-allyl	177,178
2-Methylpent-1-ene 2-Methylpent-2-ene	1-ethyl-2-methyl-π-allyl	177,178
3-Methylpent-2-ene	1,2,3-trimethyl-π-allyl	177
2,3-Dimethylbut-1-ene 2,3-Dimethylbut-2-ene	1,1,2-trimethyl-π-allyl	177,178
2-Methylhex-2-ene	2-methyl-1-propyl-π-allyl	177
3-Ethylpent-2-ene	2-ethyl-1,3-dimethyl-π-allyl	177
2,4-Dimethylpent-2-ene	1-isopropyl-2-methyl-π-allyl	177
2,5-Dimethylhex-2-ene	1-isobutyl-2-methyl-π-allyl	177
2,4,4-Trimethylpent-1-ene (di-isobutene)	2-neopentyl-π-allyl	172,1
2,4,4-Trimethylpent-2-ene (di-isobutene)	1-t-butyl-2-methyl-π-allyl	177
Tri-isobutene (mixture of isomers)	mixture of isomers of composition $(C_{12}H_{21}PdCl)_2$	172
α-Methylstyrene	2-phenyl-π-allyl	172,179
β-Methylstyrene	1-phenyl-π-allyl	172
$\alpha\beta$-Dimethylstyrene	1-methyl-1-phenyl-π-allyl or 2-phenyl-1-methyl-π-allyl	172
Methylstilbene	1,2-diphenyl-π-allyl	172

obtained. On addition of solid $[PdCl_2(C_6H_5CN)_2]$ to a benzene solution of allene a mixed complex was obtained (LIV; Y = Cl, Y' = $-C\begin{matrix}CH_2\\CH_2Cl\end{matrix}$). The mechanism of the above reactions of allene hydrocarbons has been discussed by Heck[195] and Schultz[193].



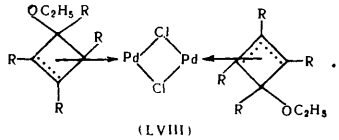
A π-allyl complex with an alkoxycarbonyl group at a terminal carbon of the allyl group was obtained in the reaction of $\alpha\beta$- or $\beta\gamma$-unsaturated carboxyl-containing esters with an alcoholic solution of $Na_2[PdCl_4]$[196]:

(LV)



A compound of type (LV) can also be obtained by heating esters in the presence of palladium chloride or by adding the esters to a benzene solution of dichlorobis(benzonitrile)palladium(II).

A complex with a carbonyl group was first observed by Syrkin and coworkers[7] in the reaction of palladium chloride with mesityl oxide. Parshall and Wilkinson[197] showed that the complex has the structure (LVI) and is better obtained from $Na_2[PdCl_4]$:



(LVI)

Mention must also be made of the complexes of palladium with four-membered cyclic π-allyl ligands. Such complexes can be obtained by the reaction of diphenylacetylene with alcoholic solutions of $PdCl_2$, $Na_2[PdCl_4]$, or $[PdCl_2(C_6H_5CN)_2]$[198-203], an orange-red complex of composition $C_{30}H_{25}OPdCl$ always being formed. Guy and Shaw[204] proposed for it a π-cyclobutenyl structure (LVII):

(LVII)

On treating the complex with hydrochloric acid a tetraphenylcyclobutadiene complex is obtained, $[(C_6H_5)_4C_4PdCl_2]$[199,200,202,204], from which treatment with ethanol gave an insoluble yellow substance of the same composition as complex (LVII) but with somewhat different chemical and physical properties. X-Ray diffraction examination, by Dahl and Oberhansli[39,40,205], confirmed the structure proposed by Guy and Shaw (LVII) and showed that both complexes are geometrical isomers (*exo*- and *endo*-), differing in the arrangement of the ethoxy-group in the cyclobutenyl ring. The complex obtained from tetraphenylcyclobutadiene palladium dichloride is the dimeric di-μ-chlorobis-(1-*exo*-ethoxy-1,2,3,4-tetraphenylcyclobutenylpalladium) (LVIII: R = C_6H_5).

(LVIII)

A substance with hydroxo groups was obtained on treating a dimethylformamide solution of $[(C_6H_5)_4C_4PdCl_2]$ with water[206].

In addition to diphenylacetylene, the compounds dichloro-(diphenylacetylene) and methylphenylacetylene react with palladium compounds, for example, $[PdCl_2(C_6H_5CN)_2]$[204,207].

The preparation of π-cyclopentadienylethoxy-π-tetraphenylcyclobutenylpalladium[157,208] and of a complex with the triphenylcyclopropenyl ligand[209] has been reported.

c. Reaction with allyl Grignard compounds. On mixing a benzene solution of chlorobis-(benzonitrile)palladium with 150% excess of an ethereal solution of allylmagnesium chloride, a bright yellow substance of composition $(C_6H_5CN)(C_3H_5)PdCl$ is formed. It is stable in air at room temperature but decomposes on heating to 115°C or over[210].

Bis-(π-allyl)palladium and bis-(π-methylallyl)palladium are obtained by the reaction of anhydrous palladium chloride with allyl- and methylallyl-magnesium chloride respectively in ethereal solution at −40°C.[73,74,129]

Bis-(π-allyl)palladium is a yellow crystalline substance, m.p. 31°C, readily soluble in organic solvents, and does not react with alcohol or water. When hydrogen chloride is passed into an ethereal solution of bis-(π-allyl)palladium (−80°C) π-allylpalladium chloride is formed quantitatively. The latter is also formed by reaction of bis-(π-allyl)palladium with palladium(II) chloride[129].

B. Chemical Properties

a. Reactions leading to breaking of the halogen bridges. On treatment with cyclopentadienylsodium, bis-(π-allylpalladium chloride) gave a diamagnetic substance $(C_5H_5)(C_3H_5)Pd$ which was stable in air for a long time at low temperature[10,211]. The chemical properties of the product were studied in detail by Nesmeyanov and coworkers[212]. Reactions of π-allyl-π-cyclopentadienylpalladium with many electrophilic and nucleophilic reagents in acid, neutral, or alkaline media led to rapid removal of the cyclopentadienyl ligand. In the presence of an alkali metal halide the main product of the reaction was the bis-(π-allylpalladium halide). NaC_5H_5 reacts in an analogous fashion with the dimeric alkoxy-π-allylpalladium chlorides[36,185] and with complexes with cyclic allyl ligands[37,146-148,150,157,190].

$[(C_3H_5)(C_5H_5)Pd]$, just like $[(C_5H_5)(C_6H_9)Pd]$, on reacting with isopropyl or cyclohexyl isocyanide forms $[Pd(^iPrNC)_2]$ and $[Pd(C_6H_{11}NC)_2]$ respectively[213]. The reaction of $[(C_5H_5)(C_6H_9)Pd]$ with $AsCl_3$ or $SbCl_3$ proceeds by the reaction:

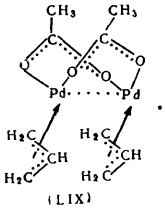
$$2\,C_5H_5PdC_6H_9 + AsCl_3 \rightarrow (C_6H_9PdCl)_2 + 2\,C_5H_5AsCl_2$$

with the formation of bis-(π-cyclohexenylpalladium chloride)[213].

A characteristic reaction of the π-allyl complexes with chlorine bridges is the breaking of the bridge by amines[36,37,187], which results in the formation of complexes of general formula [(allyl)PdCl(amine)]. Usually these compounds lose the amine easily, giving the initial complexes. Cryoscopic measurements have shown the monomeric structure of the compounds with the amines.

The infrared spectra of the products of addition of pyridine to $[(C_3H_5)PdCl]_2$ and $[(C_6H_{11})PdCl]_2$ had bands at 517 and 520 cm^{-1} respectively, owing to the retention of the π-allyl grouping in them[181]. With increase in the basicity of the amine there is an increase in the tendency of the complexes to decompose with separation of metallic palladium.

Moiseev and coworkers[181] consider that this decomposition is the result of the alkylation of the amine by the allyl grouping connected to the palladium atom:



$$\pi\text{-}C_3H_5PdClNR_3 \rightarrow Pd + Cl^- + \overset{+}{N}R_3\text{—}C_3H_5.$$

However, it is possible that alkylation precedes the isomerisation of the complex, in which the π-allyl group is converted into a σ-bound ligand. A similar π–σ change of an allyl ligand is observed in the reaction of π-allyl complexes with triphenylphosphine[23-26] and dimethyl sulphoxide[25-27,175]. It was shown[24-26] that this change precedes the formation of an intermediate compound in which one π- and one σ-bond is present.

The Pd–Cl bond is covalent in all the monomeric complexes described in this section.

Compounds with an ionic Pd–Cl bond were obtained in using bidentate amines such as ethylenediamine and 2,2-bipyridyl (bipy)[214]. When bis-(π-allylpalladium chloride) or bis-(π-crotylpalladium chloride) reacts with these amines, taken in twofold molar excess, complexes are formed which are readily soluble in methanol and water. When the stoichiometric amount of 2,2′-bipyridyl is taken, a compound of the type $[(C_3H_5)Pdbipy]^+[(C_3H_5)PdCl_2]^-$ is obtained, in which a π-allyl ligand is present in both the cation and the anion. The preparation of other salts with the $[(C_3H_5)PdCl_2]^-$ anion has been described[215].

b. Replacement of the halogeno-bridges. Replacement of the chlorine bridges in π-allyl complexes of palladium by bromo- or thiocyanato-groups takes place readily on treatment with the corresponding alkali metal salt in a polar solvent (acetone, alcohol, etc.)[8,36,37,187,200]. Complexes with bridging carboxylato-groups (acetato-, propionato-, benzoato-, and trimethylacetato-) were made by treating acetone solutions of dichlorobis-(π-allylpalladium) complexes with the corresponding silver salt[46,187,216]. Cryoscopic and ebullioscopic measurements in benzene showed that all the complexes are dimers. They are somewhat less stable than the corresponding chloro-complexes. X-Ray diffraction examination of bis-(π-allylpalladium acetate) showed[46] that it has the structure (LIX) with a weak bond between the palladium atoms. Carboxylato-bridges are easily replaced by other groups. For example, on treating the acetato-complex with dry HCl, dichlorobis-(π-allylpalladium) was obtained, and treatment with trifluoroacetic acid gave the trifluoroacetato-complex $[(C_3H_5)(O_2CCF_3)Pd]_2$.

(LIX)

With acetylacetone and sodium carbonate, monomeric π-allylpalladium acetylacetonates are formed, which were obtained earlier on treating π-allylpalladium chlorides with thallium acetylacetonate[36,187] and also with sodium acetylacetonate. The π-allylpalladium acetylacetonates thus obtained have sharp melting points and can be used for the identification of the π-allyl complexes. Furthermore, it has been shown[217] that the hydrogen of the acetylacetonato-ligand is capable of being replaced by bromine under the action of *N*-bromosuccinimide. The action of other electrophilic and nucleophilic agents leads to loss of the acetylacetonato-ligand.

c. Reactions leading to breaking of the bond between the palladium and the allyl ligand. When heated to 145°C, $[(\pi\text{-}C_3H_5)PdCl]_2$ decomposes violently, the main products being allyl chloride and metallic palladium[8,172]. The decomposition of bis-(3-ethyl-1-methyl-π-allylpalladium chloride)[181]:

$$(C_6H_{11}PdCl)_2 \rightarrow 2\,C_6H_{11}Cl + 2\,Pd$$

and of some other complexes[172] took place in a similar fashion. However, when complexes with four or more carbon atoms in the allyl ligand are heated without solvent in a high vacuum, conjugated dienes are obtained[218].

As Christ and Hüttel showed[219], the reaction of π-allylpalladium chloride complexes with methanol solutions of potassium hydroxide leads to the formation of metallic palladium and an alkene with the same number of carbon atoms as in the π-allyl ligand. Reduction of the complexes $[(C_3H_5)PdCl]_2$ and $[(C_6H_{11})PdCl]_2$ with a methanol solution of sodium methoxide gave propene and hexene respectively[181].

Smutny[220] studied the decomposition products of methoxy-substituted π-allylpalladium chlorides on boiling in alcoholic medium with sodium acetate or hydrogen at room temperature.

During the bromination of $[(\pi\text{-}C_3H_5)PdCl]_2$ and other π-allyl palladium complexes there is stepwise absorption of two bromine molecules at each allyl–PdCl grouping[181,221]. In the first stage there is oxidation of the π-allylpalladium chloride with the formation of an acido-complex of the palladium and allyl bromide. In the second, slower stage, bromination of the C_3H_5Br takes place, which uses up another molecule of bromine.

Prolonged boiling of $[(\pi\text{-}C_3H_5)PdCl]_2$ with water in the presence of oxygen leads to the formation of propene and acrolein[172]. The oxidation of bis-(σ-methylallylpalladium chloride) goes only as far as α-methylacrolein[172,177]. A little isobutyraldehyde is apparently formed by the reaction

$$(C_4H_7PdCl)_2 + 2\,H_2O \rightarrow 2\,CH_3\text{—}CH(CH_3)\text{—}CHO + 2\,Pd + 2\,HCl.$$

π-Allyl complexes with substituted allyl ligands are oxidised in acid solutions in the presence of palladium(II) chloride, chromic acid, or manganese dioxide, to give the $\alpha\beta$-unsaturated carbonyl compounds[177]. The polarographic reduction of π-allylpalladium halides has also been studied[222].

The carbonylation of $[(\pi\text{-}C_3H_5)PdCl]_2$, just like that of the analogous nickel complex, leads to the formation of but-3-enoyl chloride as the main product, when the reaction takes place in benzene. In methanol solutions, there is direct conversion of the chloride into methyl vinylacetate[223]. Similarly, methyl 2-methylbut-1-enoate and methyl pent-2-enoate were obtained from the π-methylallyl and π-crotyl complexes[224].

The carbonylation of complex (LII) in benzene solution together with dichlorobutene gives 1-chloropent-2-enoyl chloride, from which in methanol and ethanol the corresponding esters of these acids are obtained[225,226].

On reaction with carbon monoxide in methanol, the π-allyl complex with a methoxycarbonyl group at a terminal carbon atom of the organic ligand (LV; R′ = CH_3, R = H) gives dimethyl pent-2-endioate.

From all the above examples it is clear that the attack of carbon monoxide proceeds at the terminal, less substituted carbon atom of the π-allyl group of the complex. There is also a report of the carbonylation of π-allyl complexes (LIV)[227].

Two interesting reactions were described recently, which also involve breaking the bond between the palladium and the allyl ligand. The reaction of $[(C_3H_5)PdCl]_2$ with $Fe_2(CO)_9$ leads, as a result of the transfer of the allyl ligand from the palladium to the iron, ($\pi \rightarrow \pi$ transfer), to the formation of tricarbonyl-π-allyliron chloride[228]:

$$(C_3H_5PdCl)_2 + Fe_2(CO)_9 \rightarrow 2\,C_3H_5Fe(CO)_3Cl + 2\,Pd + 3\,CO.$$

Treatment of bis-(π-allylpalladium chloride) with metallic mercury gives the quantitative yield of allylmercury(II) chloride ($\pi \rightarrow \sigma$ transfer)[229]. This method was used by the authors for the synthesis of a series of substituted allylmercury halides. In this reaction, as in the reaction with carbon monoxide, the attack of the mercury atom takes place at the unsubstituted terminal carbon atom of the π-allyl group.

Tsuji and coworkers[230,231] showed that the reaction of π-allylpalladium chloride with nucleophilic reagents (ethyl malonate, ethyl acetate, etc.) also leads to the splitting of the π-allyl complex:

$$(C_3H_5PdCl)_2 + 2\,X\overline{C}H{-}COOC_2H_5 \rightarrow 2\,CH_2{=}CH{-}CH_2{-}CHX{-}COOC_2H_5 + Pd + PdCl_2$$

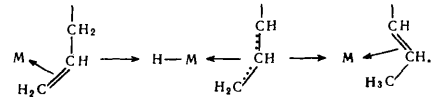
where X = $CO_2C_2H_5$ or $COCH_3$.

The decomposition of ethyl diazoacetate in the presence of the π-allylpalladium chloride dimer has been described by Armstrong[232].

10. PLATINUM COMPLEXES

There is little information about π-allyl complexes of platinum. Bis-(π-allyl)platinum was obtained by the reaction of platinum(II) chloride with allylmagnesium chloride in ether at 0°C.[73,74,129] It is a colourless crystalline compound, m.p. 41°C, with a very unpleasant odour. Treatment of $[(C_3H_5)_2Pt]$ in pentane with hydrogen chloride at −80°C leads to the formation of $[(C_3H_5)PtCl]_2$, the structure of which has been shown by its reaction with NaC_5H_5.[129] This gives the complex $[(\pi\text{-}C_3H_5)(\pi\text{-}C_5H_5)Pt]$ prepared earlier[148] by the reaction of propeneplatinum chloride with a mixture of allylmagnesium chloride and cyclopentadienylsodium. The compound is lemon-yellow and stable in air.

Another π-allyl complex of platinum was described[30] recently. $[(C_3H_5)PtCl\{P(C_6H_5)_3\}_2]$, obtained as follows:

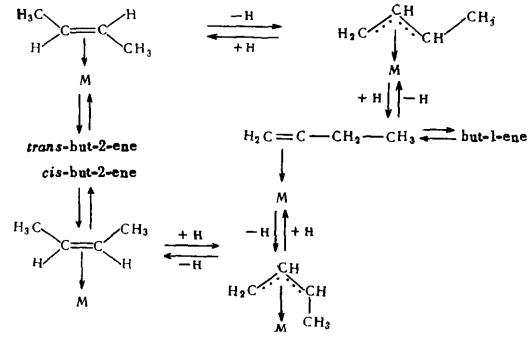


$$[(C_6H_5)_3P]_4Pt + C_3H_5Cl \rightarrow C_3H_5Pt[P(C_6H_5)_3]_2Cl + 2\,(C_6H_5)_3P.$$

IV. π-ALLYL COMPLEXES IN ORGANIC SYNTHESES

In this section we will discuss the participation of π-allyl complexes of the transition metals as intermediates in the isomerisation, oxidation, hydrogenation, carbonylation, and polymerisation reactions of unsaturated compounds.

1. ISOMERISATION OF ALKENES



When treated with iron carbonyls[233,234], or with hydrogen carbonylferrate[235,236] or carbonylcobaltate[237], alk-1-enes isomerise into alkenes with non-terminal double bonds. A possible mechanism was proposed for these reactions, isomerisation with participation of the intermediate π-allyl metal hydride complexes[233,234,238,239]:

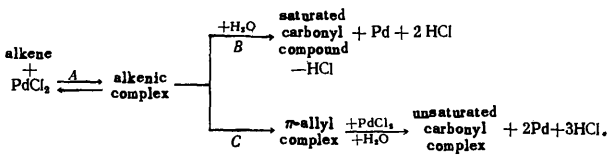
A similar scheme was proposed for the isomerisation of octenes[240] and of cyclo-octa-1,3-diene by iridium, palladium, and platinum compounds[241-244] and also of allyl alcohol to propionaldehyde by $Fe(CO)_5$.[85]

The isomerisation of alkenes by palladium salts evidently takes place analogously, with the formation of intermediate π-allyl complexes[245-247].

From the standpoint of the π-allyl mechanism Rooney and Webb[248] have explained the *cis–trans*-isomerisation of the monoalkenes. The general picture of the isomerisation of alkenes with the participation of π-allyl intermediate complexes can be represented as follows, for the example of the butenes:

The geometrical configuration of the alkene formed is determined by the structure of the intermediate π-allyl complex. The *syn*-isomer leads to *trans*-but-2-ene, and the *anti*-isomer gives *cis*-but-2-ene.

It is necessary to note that Davies[249], Harrod and Chalk[250], and Cramer and Lindsey[251] criticise the generality of the above scheme. For example, Cramer and Lindsey consider that the formation of π-allyl structures should lead sometimes even to inhibition of the isomerisation.



Asinger and coworkers[252] have proposed a method by which it is possible in some instances to confirm the π-allyl mechanism of the isomerisation of alkenes. When the isomerisation is carried out in a mixture with an alkene labelled with tritium, they think that the transfer of tritium will indicate the intermolecular hydride mechanism, but the absence of transfer, the intramolecular π-allyl mechanism.

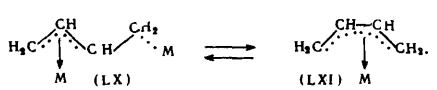
2. OXIDATION OF ALKENES

In studying the catalytic conversion of alkenes into compounds of the platinum group metals, Smidt and coworkers[253] showed that methylglyoxal is formed from allyl halides.

Hüttel and coworkers [172] obtained the same product in the oxidation of bis-(π-allylpalladium chloride). In support of the π-allyl mechanism there is the identity of the products obtained in oxidising most alkenes and the corresponding π-allyl complexes listed in the Table (p. 488).

Hüttel and Christ [177] proposed the following general scheme for these reactions:

Depending on whether saturated or unsaturated carbonyl compounds are formed this scheme gives an answer about the nature of the intermediate complexes. The course of the reaction in direction *B* or *C* is determined mainly by the nature of the initial alkene, and primarily by its degree of branching. For example, linear aliphatic alk-1-enes give only saturated ketones [253] but branched alkenes listed in the Table give unsaturated carbonyl compounds [177].



In the oxidation of the higher alk-1-enes by palladium chloride in anhydrous acetic acid containing sodium or potassium acetate, in the first stage π-allyl complexes are formed, which, as Vargaftik and coworkers have shown [254], are in equilibrium with the σ-allyl complex, the reaction of which with acetate ion give substituted allyl acetates:

$$R{-}CH{=}CH{-}CH_2PdCl + CH_3COO^- \rightarrow R{-}CH{=}CH{-}CH_2OCOCH_3 + Pd + Cl^-.$$

3. HYDROGENATION OF ALKENE DERIVATIVES

Kwiatek and coworkers who used the pentacyanocobaltate anion in aqueous solution to hydrogenate a series of organic compounds [255], later showed [107] that the intermediate products in these syntheses were cyano(allyl)cobalt complexes: whether they were π- or σ-complexes was mainly determined by the cyano:cobalt ratio. When butadiene was hydrogenated with a catalyst of low CN:Co ratio, *trans*-but-2-ene was mainly formed, but at high ratios but-1-ene was obtained. The authors explain these results by the formation of an intermediate cyano(methylallyl)cobaltate, in which at high CN:Co ratio the allyl ligand is connected to the cobalt atom by a σ-bond, and at low ratios by a π-allyl bond. The corresponding butene was obtained from these complexes on their reaction with the hydride $[CoH(CN)_5]^{3-}$.

The hydrogenation of buta-1,3-diene by transition metal compounds can, in the general example, pass through intermediate complexes of two types [248]:

On addition of hydrogen to these, the *syn*- and *anti*-forms of methyl-π-allyl complexes will be formed, which, in accordance with the above scheme, for the isomerisation of alkenes will give all three isomeric butenes.

4. CARBONYLATION OF ALLYL HALIDES

The carbonylation of allyl halides in the presence of nickel carbonyl was first described by Chiusoli [256-258]. On carrying out the reaction in water or alcoholic medium the corresponding acids or their esters were isolated:

$$R{-}CH{=}CH{-}CH_2Cl + CO + R'OH \xrightarrow{Ni(CO)_4} R{-}CH{=}CH{-}CH_2{-}COOR' + HCl.$$

The main product obtained from allyl chloride was vinylacetic acid, that from crotyl chloride, pent-3-enoic acid, etc.

In later work, Chiusoli and coworkers [259-262] showed the possibility of π-allyl complexes, $(\pi\text{-}C_3H_5)NiX(CO)$ where X = halogen, participating in these reactions as intermediates.

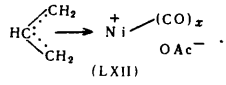
The carbonylation of allyl halides in the presence of acetylene is a reaction important for the synthesis of organic substances [127,258-267]. Here the π-allyl complexes formed as a result of the reaction of $Ni(CO)_4$ with the allyl halides then react with carbon monoxide in the presence of acetylene, with a molecule of acetylene being introduced between the allyl residue and the carbon monoxide. Hexa-2,5-dienoyl chloride is isolated under carbon monoxide pressure. In aqueous medium, in addition to hexa-2,5-dienoic acid a little phenol was obtained which shows that cyclisation takes place [263].

When the carbonylation of allyl halides is carried out in the presence of substituted acetylenes in water–acetone solution, cyclisation predominated with the formation of carboxyl derivatives of cyclopentenone and cyclohexenone [268,269].

Some of their derivatives behave similarly to the allyl halides in the carbonylation. Thus 1-chloro-4-cyanobut-2-ene gives 5-cyanopent-3-enoic acid, from which caprolactam can be obtained by hydrogenation, or caprylic acid in the presence of acetylene [258]. In the presence of acetylene 1,8-dichloro-octa-2,6-diene gave tetradeca-2,5,9,12-tetraen-1,14-dioic acid.

Prop-2-ynyl chloride also undergoes carbonylation in the presence of $Ni(CO)_4$ and water [270]. The main products are buta-2,3-dienoic and itaconic acids.

The identity of the products obtained from allyl chloride or allyl alcohol [271] and from bis-(π-allylpalladium chloride) [223] also supports the π-allyl mechanism of the carbonylation of allyl compounds with palladium catalysts ($PdCl_2$) at elevated temperatures. At room temperature allyl chloride gives 3,4-dichlorobut-3-enoyl chloride, and not but-3-enoyl chloride.

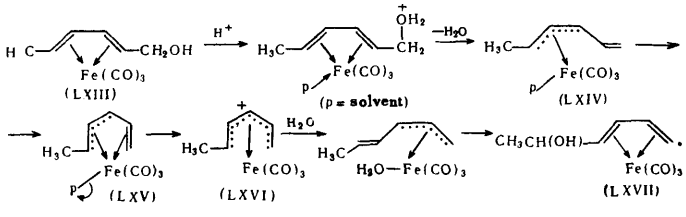


It has been shown that [272,273] that bis-(π-allylpalladium chloride) is an active catalyst for the carbonylation of allyl halides, giving alkenoyl chlorides as the main products, in high yields.

Of the other catalysts for the carbonylation of allyl derivatives, mention may be made of rhodium compounds [271] and platinum compounds [274].

5. SOME OTHER REACTIONS IN WHICH π-ALLYL INTERMEDIATE COMPLEXES PARTICIPATE

$\alpha\beta$-Unsaturated aldehydes and ketones are obtained in the hydroformylation of conjugated and non-conjugated

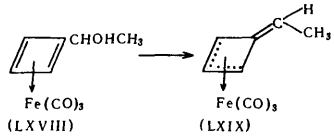


alkadienes in the presence of hydrogen tetracarbonylcobaltate(-1). Under the conditions of the reaction these aldehydes and ketones are easily reduced by the hydrogen tetracarbonylcobaltate(-1) through an intermediate π-oxapropenyl complex of type (XXIV) to saturated aldehydes and ketones[80]. The same complex evidently participates in the reaction for the formation of 1,2-dibenzoyloxystilbene from benzoyl chloride or bromide and tetracarbonylnickel in tetrahydrofuran or hexane solution[275]. As Bauld has shown[276], the reaction of allyl acetate with $Ni(CO)_4$ proceeds through the stage of complex (LXII), the structure of which is analogous to that of complex (XXXIX), and leads to biallyl:

(LXII)

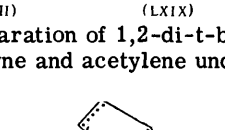
Bicinnamyl is obtained in the same way from cinnamyl acetate.

Mahler and coworkers[277,278] showed that some of the reactions of tricarbonyldieniron complexes can be satisfactorily explained by starting from the formation of π-allyl complexes. For example, the action of strong acids on tricarbonyl(hexa-*trans*-2,*trans*-4-dien-1-ol)iron (LXIII) gives the intermediate π-allyl complexes (LXIV, LXV) and then tricarbonyl-*syn*-1-methylpentadienyliron cation (LXVI)[274], which on hydrolysis is converted into tricarbonyl(hexa-*trans*-3,5-dien-2-ol)iron (LXVII)[275]:



(LXIII) (LXIV) (LXV) (LXVI) (LXVII)

Pettit and coworkers[279] proposed a π-allyl structure (LXIX) for the intermediate product formed on treating complex (LXVIII) with hydrochloric acid followed by solvolysis in methanol.



$Co_2(CO)_4[C_2H{-}C(CH_3)_3]_2(C_2H_2)$ (LXX).

Mills and Robinson[280] used X-ray structural analysis and NMR spectroscopy to show the π-allyl nature of the intermediate product:

(LXVIII) (LXIX)

obtained in the preparation of 1,2-di-t-butylbenzene from 3,3-dimethylbut-1-yne and acetylene under the influence of cobalt carbonyl:

(LXX)

6. POLYMERISATION AND OLIGOMERISATION OF ALKENES AND ALKADIENES

Catalysts based on π-allyl complexes of nickel have been studied in most detail.

Wilke found that bis-(π-allyl)nickel brings about the cyclic trimerisation of butadiene into cyclododeca-1,5,9-triene[23,125,127]. Bis-(π-methylallyl)nickel and bis-(π-crotyl)nickel behave in the same manner[129,281].

π-Allylnickel halides initiate the stereospecific polymerisation of butadiene[130,282-285]. The microstructure of the polymer formed is determined by the nature of the halogen in the π-allyl complex: compounds which contain chlorine lead to *cis*-1,4-polymers, whereas iodine complexes are capable of forming polybuta-1,4-dienes. It has been shown radiochemically that the π-allylnickel ligands of the initial complexes entered into the composition of the polymer[286].

The products of the reaction of π-allylnickel halides with Lewis acids (halides of B, Al, Ti, Sn, V, Mo, and W) exhibit high activity in the polymerisation of butadiene[130,282,283,285,287]. In this, irrespective of the halogen in the π-allyl complex or in the Lewis acid, polybutadienes with a high proportion of *cis*-1,4-links are formed[283].

Active catalysts for the polymerisation of butadiene are also formed in the reaction of bis-(π-crotyl)nickel with the halides of various metals[130,281,282,287]. The proportion of links of different configurations in the polymers obtained under the influence of these systems is determined by the nature of the halogen in the metal halide[281,282].

The products of the reaction of π-cyclopentadienyl(π-cyclopentyl)nickel with Lewis acids act similarly[288,289].

Propene and ethylene are dimerised extremely rapidly in the presence of catalytic systems consisting of bis-(π-allyl)nickel or bis-(π-allylnickel halides), aluminium halides or alkylaluminium halides, and trialkylphosphines[23,29,290,291]. It has been shown[23,29] that the basicity of trialkylphosphines affects the structure of the dimers formed.

Bis-(π-allylnickel bromide) polymerises cyclobutene with opening of the double bond: a polycyclobutylenamer is formed[284]. There is also a report of the polymerisation of acetylene in the presence of bis-(π-allylnickel bromide)[138,139]. Crystalline 1,2-polyallene was obtained in the presence of $Ni(\pi\text{-}C_3H_5)_2$, $[NiBr(\pi\text{-}C_3H_5)]_2$, and $[Ni(\pi\text{-}CH_2CHCN)_2]$[292].

Bis-(π-allyl)cobalt iodide polymerises butadiene to *cis*-1,4-polymer[23,29,128,290].

The π-allyl cobalt complex of composition $CoC_{12}H_{19}$ described by Natta and coworkers[124] is a catalyst for the linear dimerisation of butadiene and 3-methylhepta-1,4,6-triene. The same dimer is also formed by the action of tris-(π-allyl)cobalt[23,29,290,293].

1,2-Polybutadiene is formed in the presence of tris-(π-allyl)chromium[23,29,63,128,281,290]. The products of the reaction of $(\pi\text{-}C_3H_5)Cr$ with $NiCl_2$ or TiI_4 bring about the formation of *cis*-polybuta-1,4-diene, but with $NiBr_2$ the *trans*-1,4-polymer is obtained[281].

Bis-(π-allyl)chromium iodide, like bis-(π-allyl)nickel, catalytically trimerises butadiene into cyclododeca-1,5,9-triene[23,29,63,128]. In the presence of $(\pi\text{-}C_3H_5)_2CrCl$ butadiene is converted into a polymer[63]. Furthermore, it must be mentioned that at room temperature and moderate pressure (15 atm) $(\pi\text{-}C_3H_5)_3Cr$ polymerises ethylene into linear high-molecular-weight polyethylene, analogous to the polyethylene obtained with Ziegler catalysts[63].

Bis-(π-allyl)palladium converts butadiene solely into linear oligomers, whereas its addition products with electron donors gives cyclic dimers[23,129].

Tris-(π-allyl)iron gives a mixture of cyclic and aliphatic oligomers, and also polymerises but-2-yne into hexamethylbenzene[101].

An examination of the mechanism of the polymerisation of diene hydrocarbons with participation of π-allyl complexes allowed ideas of primary importance to be formulated about the formation of the links of a polymeric chain as a function of the direction of attack of the active centre of the monomer molecule[283,294-296]. The polymerisation of butadiene in an aqueous medium under the influence of the rhodium compounds has been examined from the aspect of a π-allyl mechanism[297-299].

---oOo---

Several new papers on the subject of the present review have appeared whilst the latter was being written.

The reaction of π-allylpalladium chlorides with electron donors has been investigated by NMR and infrared spectra[300-302]. Hegarty and Kitching[303] have interpreted the ultraviolet spectra of π-allyl complexes of palladium in various solvents. Several papers[304-307] have described the preparation of π-allyl complexes of palladium. Moiseev and coworkers[308] investigated the thermal decomposition of six π-allyl complexes of palladium.

Wilkinson and coworkers[309] prepared new allyl complexes of rhodium. The results of an X-ray diffraction study of bis-(π-allyl)rhodium chloride have been reported[310].

Nesmeyanov and coworkers[311] studied the decomposition products of carbonyl-π-allyl complexes of iron. King[312,313] has studied the π-allyl complexes of molybdenum and iron.

The participation of π-allyl complexes of the transition metals as intermediate products in isomerisations has been discussed[314-317]. A patent[318] deals with the polymerisation and copolymerisation of alkenes under the influence of the π-allyl complexes of Cr, Mo, W, and Zr.

I. INTRODUCTION

The catalytic dehydrogenation to alkenes and alkadienes of alkanes containing 2 to 5 carbon atoms is a promising method for the preparation of unsaturated hydrocarbons. In recent years there has been greatly increased interest in the preparation of alkenes and alkadienes by the catalytic dehydrogenation of low-molecular-weight alkanes at low pressures of the starting materials, because thermodynamic calculations have shown that under these conditions considerable yields of useful products should be obtained. Notwithstanding a certain complexity in the technological design of dehydrogenation processes at low hydrocarbon pressures (that is, under vacuum or with the use of solvents), the application of such processes results in substantial economic gains. It is for this reason that, in the United States and Western Europe, the production of bivinyl by Houdry's method has been developed as the most economic method of dehydrogenation[2]; in this method n-butane is dehydrogenated under vacuum in a single stage[1]. In the USSR the problem of using this method is under consideration[3,4].

A large amount of experimental information on the catalytic dehydrogenation of hydrocarbons at low pressures is now available, and this merits a special review; in our opinion such a review provides an essential supplement to modern informative reviews[5-7] on the dehydrogenation of hydrocarbons. The present review considers problems of the thermodynamics of the dehydrogenation of C_2–C_6 hydrocarbons at low pressures, as well as catalysts and the operating conditions for industrial applications of the process.

II. THERMODYNAMIC CALCULATIONS OF HYDROCARBON DEHYDROGENATIONS

Thermodynamic calculations permit us to select the optimal conditions for carrying out a reaction. Using such calculations, we can calculate whether a given reaction could proceed in such a way as to give a useful product in sufficiently high yield to warrant its practical application, and also the most favourable temperatures and pressures for carrying out the reaction. An increase in the temperature of a process and reduction in pressure result in an increase in the degree of equilibrium dehydrogenation, and therefore favour an increased yield of alkenes or alkadienes[5,8].

Using experimental data on the dehydrogenation of alkanes in the presence of chromium catalysts, Frey and Huppke[9] determined the equilibrium constants for the dehydrogenation of n-butane to each of the isomeric butenes, and of propane to propene, and ethane to ethylene. Using the data of these workers, Zharkova[10] determined the dependence of $\lg k_{equil}$ on temperature. Dement'eva and coworkers[11,12] calculated the dependence of the degree of dehydrogenation of n-butane, isobutane, and propane on

temperature and pressure. Moreover, using experimental results on the dehydrogenation of n-butenes to buta-1,3-diene on chromium(III) oxide at 404–534°C, these workers also calculated the equilibrium constants of this reaction for the temperature range mentioned. Kassel[13] and Pitzer[14] calculated the equilibrium constants for the dehydrogenation of butane and the equilibrium composition at various temperatures. Aston and coworkers[15] calculated equilibrium constants for the dehydrogenation of n-butane to n-butene and buta-1,3-diene at 25–1227°C, and of individual n-butenes and their mixture to buta-1,3-diene over the same temperature range. The difference between the values of k_{equil} found experimentally[9] and the calculated values[15] is due to experimental errors in the investigation of a mixture with components present in low concentrations.

Balandin and coworkers[16] made a thermodynamic calculation of equilibria in the butene–butadiene system, and found that the yields of butadiene increase with decreasing pressure, the most favourable results being obtained at a temperature of 550–600°C and a pressure below atmospheric.

Using published data[6,17], Bogdanov[18] derived an equation for determining the equilibrium composition in the dehydrogenation of n-butane to n-butenes and buta-1,3-diene in the presence of an inert gas or water vapour as diluent. The author regards the dehydrogenation of n-butane as consisting of two successive reactions: n-butane is first dehydrogenated to n-butene (a mixture of isomers of but-1-ene, *cis*-but-2-ene, and *trans*-but-2-ene), and the butenes are then dehydrogenated to buta-1,3-diene. For this reason, the equilibrium constants for these reaction were calculated for each isomer separately, and the values found were then used to calculate the overall equilibrium constant (Table 1).

The values of the constants obtained are in satisfactory agreement with the corresponding values obtained by other workers. Dilution of n-butane with an inert gas greatly improves conversion into n-butenes and buta-1,3-diene. At 527°C and with a 1 : 5 molar dilution of butane with inert gas, the conversion of butane into butenes and butadiene reaches 62.5%, compared with 36.7% without dilution. At 527°C and a 1 : 10 dilution with inert gas the conversion of n-butenes to buta-1,3-diene is 28.7%, compared with 10% without dilution[18]. Dilution of a butane–butene mixture (30% of n-butenes and 70% butane) with an inert gas also increases the degree of conversion into butadiene. Thus, at 600°C and a 1 : 5 dilution, conversion increases from 13.8% without dilution to 34.3%, that is, by a factor of two and a half. The authors point out that dilution with hydrogen leads to a sharp fall in conversion.

TABLE 1. Temperature dependence of the equilibrium constants for the dehydrogenation of n-butane to n-butenes (total isomers) and of n-butenes to buta-1,3-diene[18].

Temperature, °C	k_{equil} (dehydrogenation of n-butane to n-butenes)	k_{equil} (dehydrogenation of n-butenes to buta-1,3-diene)
427	0.0111	0.000680
527	0.154	0.0102
627	1.21	0.0851
727	6.35	0.462

In a thesis, Khodakov[19] derived an equation for calculating the equilibrium conversion of n-butane into butenes (mixture of isomers) and an equation for the calculation of the equilibrium conversion of n-butane with allowance for side-reactions, that is, when the process is not selective.

As with C_4 hydrocarbons, in the dehydrogenation of isopentane, a reduction in pressure and an increase in temperature also increases the yield of isoprene.

Ghosh and Roy[20] studied the reaction equilibrium in the dehydrogenation of 3-methylbut-1-ene at 330–450°C and a pressure of 10–35 mmHg on an aluminochromium catalyst with the addition of oxides of vanadium and molybdenum. These workers determined the equilibrium constants at the temperatures mentioned and calculated the dependence of free energy change on temperature for the dehydrogenation of isopentane to methylbutene, and of methylbutenes to isoprene. Shuikin and coworkers[21,22] calculated the equilibrium constants and the degree of dehydrogenation for the conversion of isopentane into methylbutenes at 327–627°C and atmospheric pressure. Bogdanov and Bol'shakov[23,24] made a detailed thermodynmaic calculation for the dehydrogenation of isopentane, methylbutenes, and isopentane–methylbutene mixtures at 427–727°C. The equilibrium constants and compositions of the equilibrium mixtures were calculated over the given temperature range at atmospheric pressure and at inert gas dilutions of 1 : 1 to 1 : 10 (molar). Calculations analogous to those used for the dehydrogenation of butane, butenes, and their mixtures were used to determine the overall equilibrium constant k' for the dehydrogenation of isopentane to methylbutenes (mixture of isomers); this constant was taken as the sum of the equilibrium constants of the dehydrogenation of isopentane to 2-methylbut-1-ene (k_1'), 3-methylbut-1-ene (k_2'), and 2-methylbut-2-ene (k_3'):

$$k' = k_1' + k_2' + k_3'.$$

The overall equilibrium constant for the dehydrogenation of methylbutenes to isoprene, k'', is calculated from the equation:

$$\frac{1}{k''} = \frac{1}{k_1''} + \frac{1}{k_2''} + \frac{1}{k_3''},$$

where k_1'', k_2'', and k_3'' are the equilibrium constants for the dehydrogenation to isoprene of 2-methylbut-1-ene, 3-methylbut-1-ene, and 2-methylbut-2-ene respectively. The calculated equilibrium constants were used to determine the composition of the equilibrium mixtures formed in the dehydrogenation of isopentane to methylbutenes and isoprene. The degree of conversion of isopentane into methylbutenes and isoprene was calculated from the composition of the equilibrium mixtures (Table 2).

The figures in Table 2 clearly show that dilution of isopentane with an inert diluent at atmospheric pressure, or a corresponding reduction of total pressure in the system, greatly increases the conversion of isopentane into methylbutenes and isoprene. Thus, at 527°C and a molar dilution of 1 : 5 the conversion into methylbutenes and isoprene reaches 80.8%, compared with 57.8% without dilution. Temperature change greatly influences the nature of the isopentane conversion. At temperatures below 600°C isopentane is converted mainly into methylbutenes, but at higher temperatures the conversion of isopentane into isoprene increases sharply, and smaller amounts of the methylbutenes are formed. At very high temperatures, particularly at very low pressures, isoprene is the main dehydrogenation product.

TABLE 2. Effect of an inert diluent on the conversion of isopentane into methylbutenes and isoprene at various temperatures.

Temperature, °C	Dilution of isopentane, molar ratio	Conversion of isopentane, % into methylbutenes	into isoprene	into methylbutenes + isoprene	Temperature, °C	Dilution of isopentane, molar ratio	Conversion of isopentane, % into methylbutenes	into isoprene	into methylbutenes + isoprene
427	1:0	19.1	0.1	19.2	627	1:0	74.8	15.0	89.8
	1:5	37.9	0.7	38.6		1:5	61.9	35.3	97.2
	1:10	47.1	1.0	48.1		1:10	52.5	46.3	98.8
527	1:0	55.9	1.9	57.8	727	1:0	50.9	47.4	98.3
	1:5	73.3	7.5	80.8		1:5	28.4	71.3	99.7
	1:10	75.0	11.9	86.9		1:10	20.1	79.6	99.7

Fridshtein and Chechik[25] made a thermodynamic calculation for the isopentane–methylbutenes–isoprene–hydrogen system over the temperature range 450–650°C for pressures of 1, 0.3, and 0.2 ata. These workers determined the equilibrium constants for the dehydrogenation of isopentane and isopentane–methylbutene mixtures to isoprene, and also the equilibrium composition of the dehydrogenation products (Fig. 1). These calculations showed that a significant yield of isoprene and methylbutenes can only be obtained at a temperature higher than 550°C and a pressure lower that 0.3 ata.

It follows from calculations of the equilibrium composition of mixtures in the dehydrogenation of methylbutenes (mixture of isomers) and isopentane–methylbutene mixtures to isoprene[23] that a reduction of pressure in the system, or dilution of the starting material, significantly increases the degree of conversion into isoprene (Fig. 2).

The work of Chang and coworkers[26] is also of interest; they established the relationship between the individual methylpentenes formed when isopentane is dehydrogenated under vacuum, and they give the equilibrium constants and equilibrium composition of the reaction products at 427–627°C at a residual pressure of 100 mmHg and also at atmospheric pressure (Fig. 3). Reduction of the pressure increases the yield of isoprene; thus at 602°C and 100 mmHg it is thermodynamically possible almost completely to decompose isopentane to yield 51.7% of methylpentenes and 46.5% of isoprene. These results are in good agreement with calculations made by other workers[23–25].

With C_6 hydrocarbons, a thermodynamic calculation for the dehydrogenation reaction has only been made for one isomer—neohexane[27].

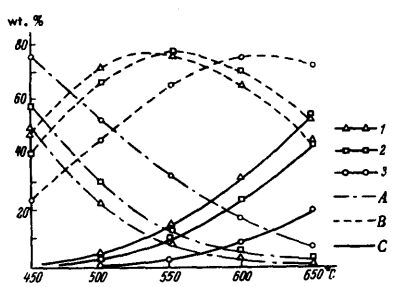

Fig. 1. Equilibrium composition of products of dehydrogenation of isopentane at different pressures: 1) 0.2 ata, 2) 0.3 ata, 3) 1.0 ata; *A*) isopentane; *B*) methylbutenes; *C*) isoprene.

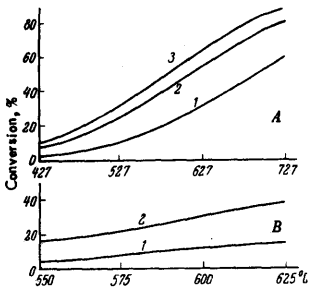

Fig. 2. Effect of an inert diluent on the conversion of methylbutenes into isoprene (*A*) and isopentane–methylbutene mixtures (70 : 30) into isoprene (*B*) as a function of temperature: 1) without dilution; 2) dilution 1 : 5; 3) dilution 1 : 10.

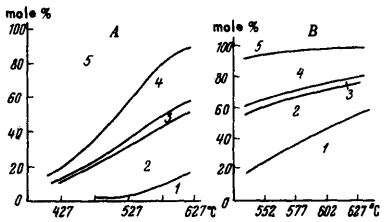

Fig. 3. Equilibrium composition of dehydrogenation products of isopentane at atmospheric pressure (*A*) and at a residual pressure of 100 mmHg (*B*): 1) isoprene; 2) 2-methylbut-2-ene; 3) 3-methylbut-1-ene; 4) 2-methylbut-1-ene; 5) isopentane.

Thus the thermodynamic data show convincingly that the most suitable conditions for the dehydrogenation of alkanes and alkenes to give alkadienes are high temperatures (~600–700°C) and low pressures (~100 mmHg).

Thermodynamic calculations do not, of course, give any indications of reaction rates, but only indicate the most suitable conditions for the reaction. It is therefore necessary to find catalysts which increase the rate of a given reaction and suppress side-reactions which reduce the yield of required products.

It is also useful to examine the behaviour of petroleum hydrocarbon fractions at high temperatures and low pressures in the absence of catalysts. It has been shown in a number of papers on the thermal cracking and pyrolysis of alkanes under reduced pressure that at 400–800°C the hydrocarbons are cleaved at the C–C bonds[28–48]. Dehydrogenation takes place to only a slight extent.

At high temperatures, ethane[28–35] and ethylene[36] give a number of saturated and unsaturated C_1–C_4 products.

When propane is subjected to a cracking process at 590°C and a pressure of 20 mmHg, it is decomposed to a slight extent (up to 10%) and the sum of the $H_2 + C_3H_6$ products formed is equal to the sum of the $CH_4 + C_2H_4$ products[37]. When the degree of decomposition increases, the predominating reaction is demethanisation, that is, the amount of $CH_4 + C_2H_4$ formed is greater than the amount of $H_2 + C_3H_6$ produced.

TABLE 3. Composition of issuing gas in the thermal cracking of isopentane (820°C, 109 mmHg, $\tau_{contact}$ = 0.015 s).

Composition of gas	Content, %	Composition of gas	Content, %
iso-C_5H_{12}	19.0	C_3H_6	12.4
α-C_4H_8	0.7	C_3H_8	0.4
β-C_4H_8	6.0	C_2H_2	0.2
iso-C_4H_8	5.6	$C_2H_4+C_2H_6$	16.0
C_4H_6	0.4	CH_4	23.1
n-C_4H_{10}	0.4	H_2	17.0
iso-C_4H_{10}	0.1	coke(CO_2)	0.2

The main reaction that occurs in the cracking of butane[40] is decomposition into methane and propene, and to a lesser degree into ethane and ethylene. Dehydrogenation proceeds to only a slight extent[40-42]. Reports on the kinetics and mechanism of thermal decomposition of butane have been published[43,44]. Isobutane[40] decomposes preferentially into 2-methylpropene and hydrogen (580°C, 20 mmHg), smaller proportions decomposing into methane and propene, and into ethane and ethylene.

When the cracking of propane is initiated by the addition of 1–3% of azomethane, dehydrogenation predominates over demethanisation[45]. The reverse is true for isobutane[45]. In the sensitised cracking of butane, the direction of the reaction and the ratio of the products are the same as in ordinary cracking.

Isopentane is cracked[46-48] preferentially into C_2 and C_3 hydrocarbons; butenes are formed to a lesser extent (Table 3).

The thermal decomposition of hydrocarbons is a free-radical chain reaction. The predominant decomposition of the hydrocarbon molecules at the C–C bond in contrast to decomposition at the C–H bond (dehydrogenation) under thermal-cracking conditions is due to the lower energy of the C–C bond compared with the C–H bond[49]. Catalysts can change the direction of the thermal decomposition reaction so that dehydrogenation of alkanes and alkenes to alkadienes becomes the predominant reaction.

III. CATALYSTS FOR THE DEHYDROGENATION OF ALKANES AND ALKENES AT LOW PRESSURES

The extensive patent literature that has appeared over the past 25 to 30 years is evidence of the great amount of work that has been done in the selection and study of catalysts for the dehydrogenation of alkanes and alkenes to alkadienes at low pressures. More than 100 patents giving proposed catalysts for these processes have been published during this period, mainly in the United States, but also in England, France, the Federal German Republic, and other countries. Most of the catalysts refer to the preparation of butadiene and isoprene from the corresponding alkenes; the minority have been proposed for producing these diene hydrocarbons from the alkanes n-butane and isopentane. Reduction of pressure is achieved either by dilution with water vapour or an inert gas or by evacuation. The composition of the catalysts varies with the method used to reduce the pressure.

Several types of catalysts have been developed for the dehydrogenation of mono-alkenes diluted by water vapour. The ones that have been used most extensively are those proposed by the firm Standard Oil Development, based on oxides of metals of Group II of the Periodic System: Mg [50-60], Zn [61,62], Be [61-64]; their composition includes iron(III) oxide, and also copper(II) oxide as a stabiliser and potassium oxide as a promoter. The general composition of catalysts of this type may be expressed as follows (parts by weight): $MO:Fe_2O_3:CuO:K_2O = 80:20:5:5$, where M = Mg, Zn, or Be. Of such catalysts, Catalyst 1707 has been used industrially; it has the following composition (wt.%): 72.4 MgO; 18.4 Fe_2O_3; 4.6 CuO; 4.6 K_2O.[51-57] Various modifications of these catalysts were examined in the course of their development[50,51,55,61,65-67]. CaO and SrO [50,51,56] have been proposed as promoters, and oxides of Ag, Zn, Cd, Th, Co, and Mn [51] as stabilisers. Iron(III) oxide has been replaced by MnO_2.[61]

The Shell Development Company and others have done work on the selection of catalysts based on iron(III) oxide with potassium compounds as promoters[68-77] and also with the inclusion of oxides of Cr, Bi, Ti, Al, and compounds of Cu, Pb, and Li. The catalysts of this type that have been most widely used are Contact Shell 105 (9 Fe_2O_3, 4 Cr_2O_3, 6 K_2CO_3) and Contact Shell 205 (Contact Shell 105, but with a higher content of K_2CO_3).[1]

For the dehydrogenation of butenes to butadiene, the firm I. G. Farbenindustrie used a catalyst consisting of more than 50% of ZnO and oxides or salts of Cr, V, Mo, U, W, etc.[78-81]; zinc oxide has also been used with other additives[82].

Schulze and coworkers (Phillips Petroleum Company)[83-85] patented a bauxite catalyst for this process; this consists of bauxite and the oxide or hydroxide of Ba, Mg, Sr, or Cr; they also patented catalysts containing combinations of Al_2O_3 with oxides or hydroxides of Ba, Mg, and K [86]. Bauxite catalysts have also been tried in processes in which the starting material is diluted with inert gases[87-89].

Britton and Dietzler (Dow Chemical Company) and other workers (Esso Research Company) have made a new type of catalyst (nickel phosphate catalyst) for the dehydrogenation of alkenes in the presence of water vapour[90-95]. A similar catalyst has been developed in Czechoslovakia[96,97]. Its composition may be represented by the formula $Ca_8Ni(PO_4)_6$. The addition of small amounts of Cr_2O_3 and graphite improves the properties of this catalyst[90,92-95].

There are references[98] to the use of graphite and carbon as catalysts; these have been tried for n-butenes diluted with water vapour, N_2, and CO_2. Silver vanadate[99] and metals of Group VIII (Ni) [100] have been used as catalysts in this process with CO_2 as the diluent, and CaO has been used with N_2 as the diluent[101], but these catalysts have not found extensive use.

All the catalysts described have been tried in the dehydrogenation of n-butenes to butadiene under various conditions (550–800°C, space velocity 100–800 h^{-1}), the alkenes being diluted with water vapour in the ratio 1:7 to 1:15. The use of a CaNi–phosphate catalyst requires the introduction of large quantities of water vapour (the ratio of n-butenes to water vapour is 1:20). The operating life without regeneration of Type 1707 and CaNi–phosphate catalysts is 0.5–1 h; catalysts based on Fe_2O_3 can be

used without regeneration for 8–12 h, and bauxite catalysts for 6 h. Regeneration is effected by means of superheated steam, alone or mixed with air. On Catalyst 1707 the yield of butadiene calculated on the butenes passed through is 28 to 30%, and the selectivity is 68 to 85%; the catalyst is stable and does not lose its activity or selectivity over a period of several months. Iron and bauxite catalysts give a lower conversion of n-butenes into butadiene (20–26% and 20% respectively).

On a CaNi–phosphate catalyst butenes are converted into butadiene in 30–35% yield; under production conditions this catalyst gives a butene conversion of 35% with a selectivity of 86–88%. Thus, the use of a CaNi–phosphate catalyst ensures high yields of butadiene, based on butenes passed through and decomposed, although it requires regeneration more frequently and is more expensive than catalysts based on iron oxide. The useful life of a CaNi–phosphate catalyst is 6–7 months, and that of an iron catalyst 2–3 months.

All the types of catalysts encountered in patents for use in the dehydrogenation of n-butenes in the presence of water vapour have also been used for the dehydrogenation of methylbutenes to isoprene: this includes Type 1707 catalyst[59], iron[77], zinc[82], bauxite[83], and CaNi–phosphate catalysts[90,94,97]. The best yields of isoprene (over 40%) were obtained with a CaNi–phosphate catalyst over the temperature range 640–650°C, with a space velocity of 0.9–1.0 h^{-1}, a 1 : 17 dilution with water vapour, and a contact time of 5–10 min[97]. 2,3-Dimethylbutane was dehydrogenated to 2,8-dimethylbutadiene on the same catalyst[94].

The catalytic dehydrogenation of alkanes to unsaturated hydrocarbons in the presence of water vapour has not been widely used: the available information consists of isolated references[102,103] indicating that n-butane is converted into a mixture of butenes and butadiene in 20% yield on an aluminochromium catalyst containing V_2O_5 or MoO_3.

In the dehydrogenation of alkanes, alkenes, and their C_4–C_5 mixtures under reduced pressure, aluminochromium catalysts[104–118] containing about 20% of Cr_2O_3, sometimes with the addition of 1–5% of BeO, SiO_2, and K_2O, are mainly used[96,119–121]. These catalysts are notable for their high activity, long-term stability, and the simplicity with which they are prepared. Thus, in the dehydrogenation on an aluminochromium catalyst (80% Al_2O_3, 20% Cr_2O_3)[113] of a butane–butene mixture containing 62% of butenes, the yield of butadiene is 18–21% (590–600°C, 50 mmHg, contact time 0.2 s). A chromium–vanadium oxide catalyst[122] has also been used for the dehydrogenation of butane–butene mixtures. In the dehydrogenation of monoalkanes under reduced pressure, apart from aluminochromium catalysts, catalysts consisting of Al_2O_3 in a mixture with V_2O_5 and Ag[123], or oxides of Ti, Zr, Ce, Hf, Th[124] and V, Ce, Ta[125], have been used. When the first of these catalysts[123] is used, butenes are converted into butadiene in 35% yield (660°C, 97 mmHg, 482 h^{-1}).

In some instances, the partial pressure of the starting hydrocarbon was reduced by dilution with hydrogen[126,127].

Several papers on the dehydrogenation of hydrocarbons under the conditions mentioned above deal with catalysts of practical interest, but do not propose any fundamentally new catalysts.

Thus, the search for active and selective catalysts for use in the dehydrogenation of alkanes and alkenes at low pressures, which has long been in progress, is still being intensively pursued at the present time.

IV. DEHYDROGENATION OF BUTANE AND BUTENES TO BUTADIENE

The dehydrogenation of butane, butenes, and their mixtures to buta-1,3-diene at low pressures of the initial hydrocarbons has been studied at fairly high temperatures. In addition to the main dehydrogenations, in which butane is converted into a mixture of butene isomers, and the butenes to butadiene, the process is accompanied by a number of side-reactions, such as isomerisation, formation of saturated and unsaturated C_1–C_3 hydrocarbons, as well as coke formation on the catalyst, which necessitates its regeneration. These reactions are undesirable since they lower the yield of the required product, buta-1,3-diene. The extent to which they occur depends on many factors, including the composition of the catalyst, the degree of hydrocarbon conversion, and the conditions under which the process is carried out.

Fedorov and coworkers[128] studied the dehydrogenation of but-2-ene diluted with nitrogen on different catalysts. On the best of these, magnesium oxide, the yield of butadiene was 25–29%.

Balandin and coworkers[16,129–131] studied the dehydrogenation of butenes to butadiene on chromium catalysts at low pressure, the starting material being diluted with nitrogen and carbon dioxide. When a 1 : 7.5 dilution with carbon monoxide was used at 600°C the yield of butadiene was 34.2 with a selectivity of 75%. It was found that the following side-reactions occurred, in which carbon dioxide reacted with butene and with hydrogen:

$$C_4H_8 + 4\,CO_2 = 8\,CO + 4\,H_2,$$
$$H_2 + CO_2 = H_2O + CO.$$

The side-reactions play only a small part here, since the yield of butadiene increases with increasing dilution. Experiments in which butenes were dehydrogenated on a chromium catalyst at a residual pressure of 180 mmHg showed that, when the temperature is increased from 550° to 600°C, the yield of butadiene increases from 14 to 28–29%, that is, by a factor of two[16]. In addition to the dehydrogenation of butene[131], reactions occur in which the initial butene and the butadiene formed are decomposed and hydrogenated. But-1-ene and but-2-ene are dehydrogenated at about the same rate[130]. Experiments with a mixture of butene and butadiene show that the decomposition of butadiene increases with temperature and also with its concentration in the initial mixture.

Grosse and coworkers[132] dehydrogenated n-butenes on an aluminochromium catalyst at 600°C and 190 mmHg. Under these conditions a lower yield of butadiene per pass was obtained (18–23%).

Balandin and coworkers[131] studied the kinetics of dehydrogenation of butene on a chromium catalyst at low pressure. The kinetic equation has the following form:

$$V = k\,\frac{[C_4H_8]}{[C_4H_8] + \Sigma Z_n [A_n]},$$

where k is the dehydrogenation rate constant; Z_n is the relative adsorption coefficient of a compound; and A_n is its partial pressure.

The apparent activation energy of butenes and bivinyl at a residual pressure of 180 mmHg with a contact time of 0.3 s was 26.3–27.9 kcal $mole^{-1}$ at 551–660°C, and 34.3–34.7 kcal $mole^{-1}$ at 535–559°C.

This reaction has also been studied by Shcheglova and Pshezhetskii[133] at 450–500°C and butene partial pressures of 0.05–0.3 atm, nitrogen being used as a diluent; they found that the kinetics of dehydrogenation of n-butenes on an aluminochromium catalyst correspond to the equation:

$$W = kC_2^{0.5}$$

where C_2 is the concentration of butene.

The value found for the activation energy was 27 ± 1 kcal mole^{-1}. They showed that the addition of 10% of hydrogen has no effect on the rate of dehydrogenation of butene, but 20% of hydrogen slightly reduces the rate. The addition of butadiene did not significantly reduce the rate of dehydrogenation. However, the relative adsorption coefficients of butene, butadiene, and hydrogen on an aluminochromium catalyst indicate that butadiene has a high adsorption coefficient, that is, on a catalytically active surface butadiene is more strongly adsorbed than butene, but hydrogen is adsorbed to about the same degree as butene; the adsorption coefficients of butene, butadiene, and hydrogen at 560°C are in the ratios 1 : 9.5 : 0.82.[131] Thus the presence of butadiene must have an appreciable effect on the rate of dehydrogenation.

When butadiene is dehydrogenated on a mixed oxide catalyst[134] in the presence of water vapour the ratio of the relative adsorption coefficients for butene, butadiene, and hydrogen is found to be 1 : 4.9 : 0.8 at 580°C, and 1 : 3.7 : 0.8 at 600°C.

Beakberger and Watson[135] found that, with Catalyst 1707, and water vapour as a diluent, the rate of the reaction may be expressed by the following equation:

$$W = \frac{k\left(P_{C_4H_8} - \frac{P_{C_4H_6} \cdot P_{H_2}}{k_{equil}}\right)}{(1 + k_{C_4H_8} \cdot P_{C_4H_8} + k_{C_4H_6} \cdot P_{C_4H_6} + k_{H_2} \cdot P_{H_2} + k_A P_A)^2}$$

where k is the rate constant; k_{equil} is the equilibrium constant of the dehydrogenation reaction; $k_{C_4H_8}$, $k_{C_4H_6}$, k_{H_2}, k_A are the equilibrium adsorption constants for C_4H_8, C_4H_6, H_2, and aromatic compounds respectively; and P is the partial pressure. The activation energy of this process, with water vapour as the diluent, was 17 kcal mole^{-1}.

For the same n-butene dehydrogenation on an oxide-type industrial catalyst with water vapour as diluent, Tyuryaev and Kolobikhin[136] give another kinetic reaction of the form: $r = kP^n_{C_4H_8}$, where $P_{C_4H_8}$ is the partial pressure of the butenes, and $n = 0.35$ (found by a graphical procedure).

The mechanism of dehydrogenation of butane and butene has also been studied by means of radioactive carbon, ^{14}C.[137,138] A mixture (1 : 1) of butane and butene, diluted with water vapour (1 : 9) was dehydrogenated on a chromium catalyst at 635°C. The results of the experiment show that the formation of butadiene is mainly due to the dehydrogenation of butene:

$$C_4H_{10} \rightarrow C_4H_8 \rightarrow C_4H_6.$$

It was then shown[137] that, in addition to dehydrogenation, a reaction occurs in which hydrogen is exchanged between butane and butene, that is, hydrogenation of butene and dehydrogenation of butane occur at the same time. The rates of dehydrogenation of butane to butene (W_1), to butadiene (W_2), and of butene to batadiene (W_3) on a chromium catalyst are related by the following ratios: $W_1 : W_2 : W_3 = 20 : 1 : 1000$.

$$C_4H_{10} \xrightarrow{W_1} C_4H_8 \xrightarrow[W_3]{} C_4H_6$$

Thus butadiene is formed from butene, and there is virtually no conversion of butane into butadiene.

When the reaction is carried out on an aluminochromium catalyst at a pressure of 250 mmHg and a temperature of 600°C, that is, under conditions favouring the dehydrogenation of butane[138], more than 96% of the butadiene formed is derived from butene. The ratio of the reaction rates then is: $W_1 : W_2 : W_3 = 18 : 1 : 25$.

The ratio $W_1 : W_2$ is therefore the same for dehydrogenation on a chromium as on an aluminochromium catalyst. Carbon and resinous products are formed by the decomposition of butene and, to a greater extent, of butadiene[138,139]. If the process is carried out in the presence of water vapour, a large amount of carbon dioxide is formed, and no coke is deposited since the greater part of the carbon deposited on the catalyst is oxidised to CO and CO_2 by the water-gas reaction. The reaction rates for the formation of CO_2 from C_4H_6, C_4H_8, and C_4H_{10} are in the ratio 60 : 4 : 1 [137]; this shows that the formation of CO_2 is the result of a secondary bivinyl-conversion reaction. Kolobikhin and Tyuryaev[140] studied the reaction for the conversion of butadiene in the presence of water vapour on a catalyst used for the dehydrogenation of n-butenes. They showed that the main reactions are the hydrogenation of butadiene and its decomposition to give coke. The greater part of the coke reacts with water vapour to form CO and CO_2. Coke deposition appears to be the main cause of the reduction of catalyst activity.

Beakberger and Watson[135] and Kearby[141] carried out experiments on the dehydrogenation of n-butenes on Catalyst 1707 and its modifications, water vapour being used as diluent. In addition to butadiene and hydrogen, the dehydrogenation products also contained low-molecular alkenes and alkanes (propene, ethylene, propane, ethane, methane) and carbon dioxide. At 665°C, with butenes at a space velocity of 500 h^{-1} and a water-vapour dilution of 1 : 14, the yield of butadiene is 28%, based on the amount of butene passed through, and 74% based on the amount decomposed. Results of the industrial use of Catalyst 1707 and of catalysts based on iron oxide (Shell-105 and Shell-205) are also given in articles by Reidel[142], Reilly[143], and Kearby[5]. Britton and Dietzler[144] obtained better yields of butadiene on a catalyst of composition $Ca_8Ni(PO_4)_6$ containing 1–2% of chromium(III) oxide. When a high water-vapour dilution was used (molar ratio of water vapour to butene 20 : 1) on a laboratory apparatus, the yield of butadiene was 93–97% based on n-butenes consumed, the conversion being 20–45% (525–650°C, space velocity 100–200 h^{-1}). Increasing the duration of the cycle from 1 to 2 h reduces the conversion of n-butene by 2–3%. The conversion increases as the space velocity decreases.

Thus, on this catalyst the dehydrogenation is characterised by high yields and selectivity. However, a disadvantage is the high yield of carbonyl compounds (4% of the butene obtained) and acetylene hydrocarbons (1%) [143].

Data on the industrial use of calcium–nickel–phosphate, termed Dow B, are given in papers by several authors[143,145,146]. At 620–680°C, a butene space velocity of 125–175 h^{-1}, and a molar ratio of water vapour to n-butene of 20 : 1, butadiene was obtained in 90–94% yield with a conversion per pass of 45–55%.[146]

Diaconescu and coworkers[147] dehydrogenated butenes on a catalyst consisting of a mixture of oxides of magnesium, iron, copper, and potassium (73.5; 18.0; 4.3; 4.2% respectively) and a catalyst based on calcium and nickel

phosphates (PO_4 58.0; Ca 33.3; Ni 6.6; Cr_2O_3 2.17). The best yields of butadiene were obtained on a calcium–nickel–phosphate catalyst.

Recently great attention has been paid in the Soviet Union to the single-stage dehydrogenation of n-butane to butadiene. Single stage dehydrogenation greatly simplifies the technological arrangement as compared with the two-stage process, since it is no longer necessary to separate the butenes from the products of the first dehydrogenation stage. Moreover, the large amount of water vapour used in the dehydrogenation of the butenes to butadiene is saved. The single-stage method is advantageously carried out by dehydrogenatiny butane–butene mixtures, since fresh butane is sent for dehydrogenation with the recirculating butane–butene mixture that remains after separation of the butadiene from the reaction products. A large number of patents, but only a small number of papers, have been published on the direct preparation of butadiene from n-butene. A method for the preparation of bivinyl in one stage was first studied by Pshezhetskii and coworkers[148]. A butane–butene mixture containing 32–38% of butenes was dehydrogenated on an aluminochromium catalyst. At a temperature of 600°C and a pressure of 100–150 mmHg, the yield of butadiene was 14–15%, based on the amount of mixture passed through, and 60–68% based on the amount consumed. Dehydrogenation of pure n-butane under the same conditions gave 10.9 to 12.4% of butadiene based on the amount of butane passed through.

Balandin and coworkers[149] obtained 31% of butadiene, based on the amount of butenes passed through, or 15.7% based on the amount of butane–butene mixture (57 : 43) passed through at 600°C, 180 mmHg, and a contact time of 0.82 s.

Komarewsky[150] dehydrogenated butane on a selective dehydrogenation catalyst at 540–650°C and pressures of from 35 to 753 mmHg. The conversion to butadiene was 12.2% of butane per pass, with only slight carbon deposition (0.2%). By recirculation, 74% of butadiene can be obtained with only 2.3% of coke being deposited on the catalyst. Dehydrogenation of a technical butane–butene fraction of cracking gas (containing 35.7% of butenes) on a chromium catalyst at 180 mmHg and 600°C gave a butadiene yield of 31–35.5% based on the amount of butene passed through, or 9–10% based on the total flow[151].

Bogdanova and coworkers dehydrogenated butane–butene mixtures on an oxide catalyst in the presence of water vapour[152]. When the butene content of the initial mixture is increased from 41.4 to 65%, the yield of butadiene based on the total flow increases from 16.9 to 24.1%, but the yield based on the amount of butene passed through decreases from 40.8 to 38.4%. The yield of butadiene based on butene passed through increases in comparison with the yields obtained in experiments with pure butene because butane acts as a diluent, lowering the partial pressure of the butenes. On this catalyst butane is dehydrogenated only to a slight extent.

The catalysts K-3 and K-5 were found to be insufficiently active and selective in the dehydrogenation of a butane–butene mixture (60 : 40) at 600°C [18] (molar dilution with nitrogen 1 : 4 to 1 : 5). Under these conditions the yield of butadiene was 15–17% based on mixture passed through, and 70–75% based on mixture consumed. In the presence of hydrogen, a significantly lower amount of butadiene was obtained per pass. At the same time the yield of butadiene based on the amount of raw material decomposed increases because the thermal decomposition of butadiene, which is accompanied by the elimination of hydrogen, is inhibited. Worse results were obtained when methane, ethylene, or propene was used as a diluent. In experiments on the dehydrogenation of butane–butene mixtures containing 33% of butene at 600°C and 140 mmHg, 19% of butadiene was obtained[153]. Blowing the catalyst with hydrogen at high temperature improves the characteristics of the process (the yield of butadiene increases, the catalyst becomes more selective, and less coke is deposited). This is due to desorption at high temperature of the water formed when the catalyst is reduced by hydrogen.

Lyubarskii and coworkers[154] studied the kinetics of dehydrogenation of n-butane on an aluminochromium catalyst containing 6% of chromium(III) oxide at 460–500°C and partial butane pressures of from 0.1 to 1 atm, with nitrogen as diluent[154]. It was found that the reaction is inhibited by butene; a small amount of butene in the starting gas greatly reduces the degree of conversion of butane. Admixture of hydrogen has little effect on the rate of dehydrogenation. The kinetics of dehydrogenation are represented by the equation:

$$W = k_1 \frac{C_1}{C_2^{0.5}}$$

where C_1 is the concentration of butane, and C_2 is the concentration of butenes.

The effective rate of dehydrogenation of butane with allowance for reversibility of the reaction is expressed by the following equation[7]:

$$W_{\text{eff}} = k_1 \frac{C_1}{C_2^{0.5}} - k_2 C_2^{0.5} C_{H_2},$$

where C_{H_2} is the concentration of hydrogen.

The activation energy for the dehydrogenation of n-butane to butenes with nitrogen as diluent was 40 ± 1 kcal mole^{-1} at 460–500°C.

The conditions have been established[153] for the single-stage dehydrogenation of butane on Catalyst K-117; these are: a temperature of 590°C, a pressure of 150 mmHg, an operating cycle of 7 min, a space velocity of 400–600 h^{-1}, and a 67 : 33 butane–butene mixture.

On the industrial scale, the single-stage dehydrogenation of butane to butadiene has been effected by Houdry's method. The results of operations on the first semi-industrial and industrial plants for the dehydrogenation of butane and butane–butene mixtures have been described[155,156]. Butane was dehydrogenated on chromium(III) oxide–aluminium oxide catalysts at 580–590°C, at a residual pressure of 130 mmHg and a space velocity of 1–1.5 h^{-1}. The total duration of the cycle is 20 to 25 min, with a contact time of 7–10 min. The yield of butadiene is 32.7% based on the butane passed through. Later, the single-stage process was perfected and adopted industrially in the United States[157,158], the German Federal Republic[159], and France[160]. Dehydrogenation is carried out under vacuum on an aluminochromium catalyst. The duration of the dehydrogenation and regeneration cycles is 7–10 min. The amount of heat adsorbed in the endothermic dehydrogenation is balanced by the heat evolved in the burning of the coke deposited on the catalyst during regeneration. To ensure thermal balancing in the process, the catalyst is mixed with an inert material with a high heat

capacity, such as alundum, kaolin, refractory brick, etc. Fresh butane being fed into the dehydrogenation process is first mixed with the recirculating butane–butene mixture obtained after the butadiene has been removed from the dehydrogenation products of the initial mixture. The following are the optimal parameters for the process and the yield of butadiene reported in the literature[158]: temperature 600–607°C, pressure 100–150 mmHg, space velocity 2 h^{-1}, yield of butadiene 50–55%.

Bol'shakov has reviewed the literature on the single-stage dehydrogenation of butane to butadiene in reactors with an adiabatic regenerative cycle[161].

V. DEHYDROGENATION OF ISOPENTANE AND PENTENES

In the catalytic dehydrogenation of isopentane, three alkene isomers with the iso-structure are formed: 3-methylbut-1-ene, 2-methylbut-1-ene, and 2-methylbut-2-ene, and these are converted into isoprene. Table 4 gives data on the dehydrogenation of individual pentenes, with both the normal and iso-structure, and their mixtures.

Both Grosse and coworkers[132], and Mamedaliev and coworkers[162], concluded that the degree of dehydrogenation of methylbutenes is independent of the position of the double bond. On cannot agree with Grosse's conclusion, since the dehydrogenation of individual methylbutenes was studied with different contact times. Gorin and coworkers[163] established that 3-methylbut-1-ene is dehydrogenated to a lesser degree than two other methylbutenes under the same conditions. This conclusion has been confirmed by the work of Bogdanova and coworkers[164], in which higher yields of isoprene were obtained in the dehydrogenation of 2-methylbut-2-ene. Having studied the isomerisation of methylbutenes under dehydrogenation conditions, these workers suggested[164] that isoprene is mainly formed from 2-methylbut-2-ene, and to a lesser extent from 2-methylbut-1-ene, but 3-methylbut-1-ene isomerises to the two other methylbutenes. They studied the dehydrogenation of individual methylbutenes to isoprene with water vapour as a diluent and showed that the activation energies for the dehydrogenation of all three isomers are similar (20.9–22.1 kcal $mole^{-1}$).

TABLE 4. Data on the dehydrogenation of individual pentenes and their mixtures.

Starting alkene	Catalyst	Pressure (mmHg) or water vapour dilution	Temperature, °C	Space velocity (h^{-1}) or contact time, s	Yield of alkadiene, wt. % of raw material	Reference

Balandin and coworkers have studied the dehydrogenation of methylbutenes in the presence of water vapour[165,166]. It was found that the greatest yields of isoprene were obtained when the methylbutenes were diluted with water vapour in the ratio 1 : (2.3–3.3) by weight. With lower dilution ratios the yield of isoprene decreases, and the amounts of light hydrocarbons and carbon dioxide formed increase. In addition to the main reaction in which the methylbutenes are dehydrogenated to isoprene, demethanisation also occurs with the formation of butene and butadiene; the methylbutenes are hydrogenated to isopentane and isoprene is decomposed with the formation of light hydrocarbons and carbon dioxide. At 600°C and a space velocity of 5 h^{-1}, in the presence of water vapour, the yield of isoprene is 30.6% of the methylbutenes passed through. The activation energy for the dehydrogenation of a mixture of methylbutenes to isoprene was 23.3 kcal $mole^{-1}$.[165]

Mamedaliev and coworkers[170] dehydrogenated a mixture of methylbutenes in a semi-technical apparatus with a 0.5 litre reactor using K-16 Catalyst at 540°C and a space velocity of 2 h^{-1}, with water vapour as a diluent in the ratio of 7–10 moles per mole of starting material; they obtained a catalysate containing 23% of isoprene. The yield of isoprene on the methylpentenes passed is not stated. Kearby[141] dehydrogenated 2-methylbut-2-ene at a somewhat higher temperature (665°C) in the presence of Catalyst 1707 and water vapour (in the ratio 1 : 14) as a diluent and obtained a high yield (35.5%) of isoprene with a selectivity of 71%. Britton and Dietzler obtained a similar yield on calcium–nickel–phosphate catalyst at 635°C, the starting hydrocarbons being diluted with water vapour[144].

The dehydrogenation of normal pentenes has been studied by Grosse and coworkers[132], by Guyer[123], and by Bogdanova and others[169].

A number of workers have carried out the dehydrogenation of isopentane. Bogdanova and coworkers[171] have shown that, on an oxide catalyst at 580–620°C, and with a space velocity of feed of 5.5 h^{-1} and a 1 : 3 dilution with water vapour, comparatively low yields (4–8%) of isoprene are obtained. Mamedaliev and coworkers[172,173] studied the dehydrogenation of an isopentane fraction on Catalyst K-5 at 600–615°C with hydrogen as diluent; they found that the best yields of dienes (8.2–8.8%), on the basis of isopentane passed through, are obtained when the isopentane is diluted 1 : (3–4) with hydrogen. Higher yields of isoprene have been obtained on a catalyst developed at the All-Union Research Institute for Synthetic Rubber (VNIISK)[174]. The process was carried out at a low partial pressure of isopentane, obtained by using nitrogen as a diluent. It was shown that an increase in temperature or an increase in the degree of dilution leads to an increased content of diene hydrocarbons in the catalysts. The yield of diene hydrocarbons at 575°C, a space velocity of 1.1 h^{-1}, and a 1 : 4 dilution with nitrogen is 14.5%. High yields of isoprene (26–28.5% based on isopentane passed through) were obtained by Kolupaeva and coworkers[175] in the dehydrogenation of isopentane on an aluminochromium catalyst, previously activated in a stream of hydrogen, at a temperature of 600°C, a pressure of 100 mmHg, and a space velocity

of 0.4 h^{-1}. They showed that when the pressure is reduced the proportion of isoprene in the reaction products is increased in comparison with the proportion of the isopentanes. The yield of normal C_5-hydrocarbons is less than 1%. The studies mentioned here were made in a flow system with a stationary catalyst layer.

Chang and coworkers[26] studied the kinetics of dehydrogenation of isopentane on aluminochromium oxide catalysts in a fluidised bed at 500–600°C and a pressure of 100–500 mmHg. Although the equilisation of concentrations in the fluidised bed leads to inhibition of the process and an increase in the proportion of side-reactions, fairly high yields of isoprene were obtained per pass: at 600°C, 100 mmHg, and a contact time of 2.2 s, the yield of isoprene was 15.8% based on the amount of isopentane passed through. These workers found that the observed activation energy of the dehydrogenation reaction was 44 kcal $mole^{-1}$. The kinetics of dehydrogenation of isopentane have also been studied by Shirokov[176], using an aluminochromium catalyst at 471–521°C and 0.2–1 atm. He found that the kinetics of the reaction could be represented by the following equation:

$$W = k\frac{C_1}{C_2^{0.4}},$$

where C_1 and C_2 are the concentrations of isopentane and methylbutenes at the reactor outlet. The activation energy of the process was 38 kcal $mole^{-1}$, a value differing only slightly from the more recent values given above[26].

Like butadiene, isoprene can be prepared from isopentane by two methods: single-stage and two-stage. In the two-stage method, isopentane is dehydrogenated to methylbutenes on one catalyst; the methylbutenes are then separated from the reaction products and dehydrogenated on another catalyst to isoprene. The isolation of the methylbutenes from the catalysate is a complex problem because of the closeness of the boiling points of the components and the difficulty of separating the azeotropic mixtures formed. Isoprene can be obtained in one stage by the dehydrogenation of isopentane–methylbutene mixtures. The process is carried out on a single catalyst and it is not necessary to separate the methylbutenes from the isopentane. The difficulty of the single-stage process lies in the selection of suitable catalysts and in finding the conditions under which the dehydrogenation of isopentane to methylbutenes proceeds simultaneously with the dehydrogenation of the methylbutenes to isoprene; the conversion of isopentane into methylbutenes must not be less than the conversion of methylbutenes into isoprene. Isoprene is separated from the catalysate obtained in the dehydrogenation of isopentane–methylbutenes mixtures, and isopentane is added. The quantity of isopentane is adjusted so that the conversion of isopentane exceeds the conversion of methylbutenes. The isopentane–methylbutenes mixture is again subjected to dehydrogenation. The extent to which the process is single-stage (φ) is determined[177] by the ratio of the concentration of methylbutenes in recycle (σ') to the concentration of methylbutenes in the initial isopentane–methylbutene mixture (σ):

$$\varphi = \frac{\sigma'}{\sigma} \times 100.$$

A value of φ necessary for operation of the single-stage process may be achieved at certain ratios of the process parameters. A number of workers have obtained the ratio of conversion of isopentane and methylbutenes needed for single-stage dehydrogenation (Table 5); isopentane is consumed in the formation of isoprene, but at the same time there is a slight increase in the amount of methylbutenes[174]. The results of Mavity and Zetterholm[167] and those of Fridshtein and coworkers[174] on the dehydrogenation of methylbutenes and mixtures of methylbutenes and isopentane show that the yields of isoprene increase with decreasing pressure, or increasing dilution with nitrogen, and also with increasing temperature, and when the isopentene content of the starting material is increased. But as the temperature is increased, or the content of methylbutenes in the mixture is reduced, the selectivity of the process is reduced, and more coke is formed[174,178]. Increasing the contact time beyond 0.6 s does not increase the yield of isoprene, because this also increases the rate of secondary reactions (dimerisation and decomposition of isoprene, and coke formation). Isopentane has been dehydrogenated in a single-stage by Houdry's method[179] on a semi-technical apparatus with recycling of the unreacted products. The mixture subjected to dehydrogenation contained 16.6% of methylbutenes; the yield of isoprene was 12.1 wt.% based on the amount of mixture passed through, and 51.8 wt.% based on the amount converted.

To determine the optimal conditions for the dehydrogenation of isopentane–methylbutenes mixtures when the process is operating in one stage, Bol'shakov[180] studied the effect of temperature, space velocity, pressure, and content of methylbutenes in the mixture on the main characteristics of the process on Catalyst K-N. Table 6 gives his results.

In the same paper, Bol'shakov reported that when the partial pressure of the hydrocarbons is reduced by dilution with an inert gas such as nitrogen, the main characteristics of the single-stage process are impaired in comparison with dehydrogenation under vacuum. Thus, when nitrogen was used as a diluent, the yield of isoprene was 15% based on the amount of mixture passed through, and 50% based on the amount of mixture converted, the process being 100% single stage; under similar conditions but with the application of reduced pressure, the yield of isoprene increased to 17.7% based on the amount passed through, and 65% based on the amount of mixture converted, the process being single stage to the extent of 116%.[180]

Gorin and coworkers made a somewhat different approach to the dehydrogenation of isopentane–methylbutene mixtures[163]. In order greatly to simplify the two-stage scheme for the preparation of isoprene from isopentane, these workers proposed that dehydrogenation conditions

TABLE 5. Dehydrogenation of isopentane–methylbutene mixtures under single-stage conditions (according to data from different authors).

should be so chosen that the ratio of methylbutenes to isopentane in the catalysate after separation of isoprene would be the same as the ratio of these compounds in the initial mixture. After separation of the isoprene from the reaction mixture, the mixture obtained can be sent for dehydrogenation having been mixed with a fresh portion of isopentane–methylbutene mixture of the same composition obtained in the first stage of the dehydrogenation of isopentane. The experiments showed that, at 580°C and a pressure of 190 mmHg, dehydrogenation of n-butane and butene [sic. pentane and pentene? (Ed. of Translation)] on a catalyst gives a catalysate containing 15–18% of isoprene (Table 7). The ratio of the methylpentenes to the isopentane in the initial mixture is the same as that in the catalysate (40 : 60).

Bogdanova and coworkers [171] studied the dehydrogenation of a prepared mixture of isopentane and methylbutene ($C_5H_{10} : C_5H_{12} = 1 : 1$) and of a catalysate (ratio 1 : 1.3) obtained on an aluminochromium catalyst after the first stage of the dehydrogenation of isopentane. These workers consider that the best results are obtained at 600–620°C, with a space velocity for the mixture 5–6 h^{-1} and a 1 : 3 dilution with water vapour. Under these conditions, the yield of isoprene is 38–40% based on isopentenes passed through and 88–92% based on the amount of mixture reacting.

Satisfactory results have also been obtained in the dehydrogenation of isopentane–methylbutene mixtures (60 : 40) diluted with benzene in the molar ratio 1 : 3. [163] Isopentane–methylbutene mixtures (70 : 30) have also been diluted with nitrogen–hydrogen mixtures [174] containing 0 to 50% of hydrogen. In the presence of hydrogen, the concentration of unsaturated hydrocarbons changes little, but the concentration of alkadienes decreases, as does also the degree of coke formation. Thus, as might be expected, the presence of hydrogen in the starting mixture has an inhibitory effect on the formation of isoprene.

A very important characteristic of the isopentane dehydrogenation process is the amount of coke deposited on the catalyst, which is determined by the temperature and duration of the experiment [181]. The amount of coke deposited increases with the methylbutene content of the mixture, and the coke is removed by the hydrogen. Tyuryaev and Balashova have suggested the following mechanism for coke formation [181]: isoprene → cyclic dimer → ... (polycondensation, decomposition, dehydrogenation)... → polycyclic hydrocarbons.

VI. DEHYDROGENATION OF C_6-HYDROCARBONS

Alkadienes have been prepared from C_6-alkanes and mono-alkenes on catalysts used for the dehydrogenation of butane and butenes to butadiene, the hydrocarbon being diluted with water vapour, hydrogen, or nitrogen [27,182–184].

Nazarov and coworkers [182] found that, on Catalysts K-12, K-16, and K-18, which are used for the conversion of butenes to butadiene, at temperatures of 600–675°C, space velocities of 1000–2000 h^{-1}, and a 1 : 8 water-vapour dilution, 2,3-dimethylbut-2-ene is converted into 2,3-dimethylbuta-1,3-diene. The yield of alkadiene on Catalyst K-16 is 20–23% based on the quantity of alkene passed through, and 40–50% based on the amount that reacts. Under similar conditions [181], on this catalyst, 2-methylpent-3-ene gives 10–13% of diene hydrocarbons (isoprene and 2,3-dimethylbuta-1,3-diene), calculated on the amount of hydrocarbon passed through.

A group of workers [183,184] dehydrogenated 2,3-dimethylbutane and its mixtures with 2,3-dimethylbut-1-ene and 2,3-dimethylbut-2-ene (containing 54% of alkenes) on Catalyst K-5 at 630°C, a space velocity of 2 h^{-1}, and 1 : 4 hydrogen dilution. These workers pointed out that the yield of alkenes and alkadienes (12–14% of starting material) does not depend on the position of the double bond in 2,3-isomers present in the starting mixture. When a mixture of 2,3-dimethylbutane with 2,3-dimethylbutenes (40%) diluted 1 : 8 by volume with water vapour is dehydrogenated on Catalyst K-16, a yield of 12–12.2% of alkadienes is obtained [184]. Timofeeva and coworkers [185] studied the dehydrogenation of 2,2-methylbutane on an aluminochromopotassium catalyst at 500°C, a space velocity of 0.72 h^{-1} at atmospheric pressure, with helium as an inert diluent. Comparison of the results showed that dilution increases the yield of 3,3-dimethylbut-1-ene in comparison with dehydrogenation at atmospheric pressure from 8–9 to 10–12%. Other workers, who carried out the reaction in vacuum on an aluminochromium catalyst also obtained ~10 wt.% of alkene [186].

Thus, in the dehydrogenation of the C_6 hydrocarbons described above, because of side-reactions, fairly low yields of unsaturated dehydrogenated products are obtained, although higher yields are thermodynamically possible. It is well known that the equilibrium yield of dehydrogenation products increases with increasing molecular weight [5–7].

---o0o---

Certain conclusions can be drawn from the literature survey on the conversions of alkanes and alkenes at low pressures.

It is thermodynamically more advantageous to dehydrogenate alkanes and alkenes for the purpose of obtaining alkadienes at temperatures above 600°C and very low pressures. However, because of technological difficulties and increased cracking at high temperatures, the process cannot be carried out under these conditions. It is therefore expedient to carry out the dehydrogenation at 550–600°C and a pressure of 100–200 mmHg. Low partial pressures are obtained by evacuation, or by the use of inert diluents.

The use of nitrogen, methane, or carbon dioxide as a diluent greatly increases the volume of the contact gas, and this makes the condensation and separation of the reaction products very complicated. Water vapour has a number of advantages compared with the diluents mentioned above: it can be easily separated from the reaction products, it also serves as a heat carrier, and since it reacts with coke deposited on the catalyst, no special regeneration of the catalyst is necessary. In the dehydrogenation of mono-alkenes and alkadienes in the presence of water vapour, the most active catalysts were found to be those based on oxides of magnesium, iron, zinc, and phosphates of calcium and nickel. Other catalysts, even those that are active dehydrogenation catalysts, for example, aluminochromium catalysts, are rapidly deactivated in the presence of water vapour. For this reason, dehydrogenations of alkane and alkene hydrocarbons and their mixtures on aluminochromium catalysts are carried out in the presence of inert diluents, such as nitrogen, or under vacuum. The use of low pressures produced by evacuation in the dehydrogenation process is more effective than dehydrogenation in the presence of diluents, although operation under vacuum requires that the plant should be hermetically sealed to prevent air being sucked in. Most of the catalysts described in the literature for the dehydrogenation of alkanes, alkenes, and their mixtures at low pressures are not sufficiently selective. Further development of these processes therefore requires that a search should be made for new and more effective catalysts.

Kinetic studies of the dehydrogenation processes considered here have permitted elucidation of the most probable mechanism for the reactions and, in a some instances, have made it possible to select the optimal conditions for the process. However, a number of kinetic studies have been made at an unsatisfactory level, and the kinetics of the processes dealt with require extensive study with the use of the most modern methods.

The dehydration of C_4–C_5 hydrocarbons at low pressures has been widely adopted in the synthetic rubber industry, and a tendency has been noted to extend work still further in the field of single-stage dehydrogenation under vacuum of alkanes or mixtures of alkanes and alkenes to give alkadienes.

CALCULATION OF THE ACTIVATION ENERGY OF CHEMICAL REACTIONS ON THE BASIS OF THE ADDITIVITY PRINCIPLE

F.B.Moin

CONTENTS

1. Introduction 511
2. Structure of activated complexes of chemical reactions 512
3. Additivity of the energy of an activated complex 513
4. Radical substitutions 514
5. Activity of radicals and molecules 515
6. Molecular reactions 517
7. Nature of the activated bond 519

1. INTRODUCTION

A great mass of experimental data has now accumulated in the literature on chemical kinetics and urgently requires generalisation and classification. However, to appraise this mass of disconnected and often contradictory facts is quite a complex task, made difficult by the fact that the theoretical premises and the methods of calculation of the kinetic parameters for most chemical reactions are still in an "embryonic" state.

The now generally accepted theoretical treatment of the nature of the elementary act of a chemical reaction is based on the "activated complex" method developed by Eyring[1] and by Evans and Polanyi[2]. It is based on the concept that the configuration of the atoms of a system, whilst changing continuously during the course of a reaction, passes through some critical intermediate configuration, which has received the name of "activated complex" or "transition state". A quite important concept introduced in this method is the potential-energy surface with a saddle point corresponding to the "transition state". The height of this point in comparison with the initial system gives the activation energy of the chemical reaction.

In its quantitative aspect the activated complex method frequently allows the pre-exponential factors in the Arrhenius equation to be calculated satisfactorily[3]. The accuracy of the results thus obtained is approximately one order of magnitude.

As regards calculations of activation energy, the results obtained so far have been much more modest. The most developed theory is that for the simplest system of three hydrogen atoms, which corresponds to reaction (1):

$$H\cdot + H_2 \rightarrow H_2 + H\cdot \qquad (1)$$

Many studies[4-12] have been devoted to quantum-mechanical calculations of system (1), but it is only very recently that the use of computer techniques has allowed agreement

with the experimental results to be reached[12]: the calculated value is $E = 6.2$ kcal†, and the experimental activation energy is ~7 kcal.[13]

The difficulty of direct quantum-mechanical calculations of activation energy stimulated the creation of the so-called "semiempirical" method, proposed by Eyring and Polanyi[13] and somewhat modified by Sato[14]. In this method the well-known London formula for the energy of a three-electron system[15] is used in conjunction with empirical curves of the Morse type for the potential energy of diatomic molecules[16]. However, here agreement with experiment is reached by the introduction into the formulae of an arbitrary parameter, the value of which is selected to "fit" the calculated activation energy to the experimental value. Hence "the semiempirical method introduces considerable uncertainty into activation energy calculations, in which it is material that the inaccuracy in the determination of E is theoretically completely uncontrollable"[17].

Matters are even worse for multi-electron atoms and molecules, especially when p-electrons participate in the elementary act. Here the picture of the interaction is complicated by the specific arrangement of the electron clouds and the transfer to this system of the conclusions and analyses made on the basis of the semiempirical method for 1s-electrons is quite inadmissable.

Hence the problem of the direct theoretical calculation of the activation energy of chemical reactions remains unsolved. Because of this, various empirical relations between activation energies and various factors characterising the reacting molecules or radicals have become important. These relations connect indirectly the rate of a chemical reaction with the structure of the molecule and the thermodynamics of the reaction. The clearest connection between the activation energy E and the exothermicity ΔH is for radical substitutions of type (2):

$$R\cdot + R'X \rightarrow RX + R'\cdot \qquad (2)$$

It was found empirically[17-21] that on changing either R or R′ the value of E is a linear function of ΔH (Polanyi's rule). This makes it possible to express the dependence of E on ΔH in the following generalised form:

$$E = a + b\Delta H \qquad (3)$$

where a and b are constants for a given homologous series.

By generalising much experimental material, Semenov[17] concluded that Eqn. (3) can be written in the form (4) with sufficient approximation:

$$E = 11.5 - 0.25\,\Delta H \qquad (4)$$

for exothermic reactions, and as (4′) for endothermic:

$$E = 11.5 + 0.75\,\Delta H. \qquad (4')$$

Relations (4) and (4′) allow the activation energy of radical reactions to be evaluated with an accuracy of 2–3 kcal. These relations are satisfactory for various atoms and radicals, but not for halogen atoms and reactions of type (1) involving H and D atoms. However, since the reactions which satisfy this relation are all radical reactions there is great interest in seeking more general relationships which are applicable to a wider class of reactions, both radical and molecular.

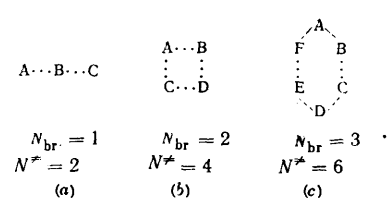
† For brevity, here and subsequently we write kcal instead of kcal mole^{-1}.

The principles described below allow the activation energy of the most varied reactions, both radical and molecular, to be determined with good accuracy.

2. STRUCTURE OF ACTIVATED COMPLEXES OF CHEMICAL REACTIONS

The principal feature of every chemical reaction is that during it some chemical bonds are broken and others are formed. In homolytic reactions the breaking of the bonds takes place in such a way that the atoms which form the bond do not acquire electrical charges. This signifies that the electron pair of the chemical bond is divided and each electron remains at its "own" atom. Consequently, in the rupture of every chemical bond two free valencies arise, which can either be used in the same elementary act for the formation of other bonds, or remain unutilised.

The breaking of some and the formation of new bonds proceeds gradually during the continuous change of the coordinates of the atoms in the system. The energy maximum of the system corresponds to the transition state, in which there are weakened breaking bonds and also even weakened new bonds. Hence in the activated complex instead of the bonds which are being broken and formed we have other weaker bonds, which we will conventionally term "activated" subsequently.



To understand the nature of the elementary chemical act it is necessary to find the structure of the activated complex. For radical reactions (2) the activated complex has the form A...B...C, where the dots denote activated bonds. For molecular reactions of a different type four-membered and six-membered cyclic complexes have been proposed[22]. Hence the number of activated bonds can be different. When the valency of the atoms of a system is constant, it can be shown that the number of activated bonds satisfies the following simple relationship:

$$N^{\neq} = 2N_{br} - \frac{\Delta n}{2} \qquad (5)$$

where N_{br} is the number of bonds broken during the course of the reaction, and Δn the change in the number of free valencies.

From this relation clearly Δn is always even, that is, only pairs of free valencies can appear or disappear during the course of the reaction. When there is a single free valency in the initial system then it cannot disappear (the "indestructibility of the free valency").

Let us consider what happens with $\Delta n = 0$. Here $N^{\neq}$ equals 2, 4, and 6 for $N_{br} = 1$, 2, and 3 respectively. The structure of the activated complexes for these instances is shown in scheme (A):

(A)

Activated complex (*a*) corresponds to radical reactions, (*b*) and (*c*) to molecular ones.

For $\Delta n \neq 0$ two variants are most frequently encountered: $N_{br} = 1$, $\Delta n = \pm 2$ [scheme (B)]:

$$\begin{array}{cc} A\cdots B & \begin{array}{c} A\cdots B \\ \diagdown C \diagup \end{array} \\ \Delta n = 2 & \Delta n = -2 \\ N^{\neq} = 1 & N^{\neq} = 3 \\ (d) & (e) \end{array} \qquad (B)$$

Activated complex (*d*) corresponds to dissociation of the molecule into two radicals, (*e*) to the reaction of the molecule with a biradical.

In the schemes shown for the activated complexes the species A, B, etc. can be either atoms or radicals consisting of a few atoms.

The schemes described include only activated bonds. In reality, in addition to these bonds the activated complex also has ordinary chemical bonds which enter into the composition of the reacting components A, B, etc. However, only the activated bonds determine whether chemical reactions occur since the other bonds are unchanged during the course of the reaction.

Hence the structure of the activated complex can be represented in the usual way employed for molecules. The main differences are that activated bonds denoted by dots are much weaker than chemical bonds and their number does not obey the usual valence rules. These differences arise because the activated bond is not the usual two-electron bond. It is easily seen that the total number of electrons participating in all the activated bonds is:

$$m = 2N_{br} + n_0$$

where n_0 is the number of unpaired electrons of the initial system which participate in the reaction, and therefore the number of electrons taking part in one activated bond does not equal zero in the general case. However, despite the major difference in the nature of the activated and ordinary chemical bonds, the above method of representing the structure of the activated complex gives good results and (as will be shown later) allows the activation energies of the most diverse chemical reactions to be calculated with reasonable accuracy.

3. ADDITIVITY OF THE ENERGY OF AN ACTIVATED COMPLEX

The principle of the additivity of the bond energies of the atoms in molecules is well-known; according to it the atomisation energy of a molecule equals the sum of the mean energies of the bonds between the various atoms:

$$V = \sum Q. \qquad (6)$$

This principle allows the heats of various types of chemical reaction and certain thermodynamic properties of substances to be calculated.

From the theoretical standpoint the validity of the additivity principle signifies that the interaction of the atoms which are not directly connected to one another can be neglected. This possibility is not obvious.

On considering a molecule as a multi-electron system and rigorously solving the corresponding Schrödinger equation, we also have to include in the Hamiltonian operator terms which describe the interaction of electrons belonging to different valence bonds. It is known[23] that allowance for this interaction leads to an increase in the energy of the system, in other words, electrons which are not paired with one another are repulsed. Under certain assumptions the energy of the molecule can be represented[24] by the approximate additive formula:

$$E = \sum Q_{ij} + \sum A_{ii} - \frac{1}{2}\sum_{i \neq j} A_{ij} \qquad (7)$$

where Q_{ij} is the coulombic energy of all the electron pairs, A_{ii} the exchange energy of the paired electrons which form the bond, A_{ij} the exchange energy of pairs of electrons which do not form a bond.

In Eqn. (7) there are terms which describe the interaction of electrons of different valence bonds. Hence quantum mechanics leads with known approximation to the idea of the additivity of the energy of the molecule, but with allowance for the repulsion of non-bonded atoms. The fact that the usual additive scheme for the calculation of energy gives good results is evidence that these additional terms can be neglected.

Note that there is a class of molecules where the atoms which are not directly connected have a quite significant effect—these are the molecules with conjugated multiple bonds. Conjugation lowers the energy of the molecule and in Eqn. (6) it is then necessary to introduce a corresponding correction allowing for the presence of conjugation[25]:

$$V = \sum Q + \Delta Q_{conj}.$$

Another factor which greatly affects the energy of certain molecules is the deformation of the valence angles in cyclic structures. This increases the energy of the molecule and in Eqn. (6) it is necessary to introduce the deformation energy (strain energy)[26]:

$$V = \sum Q - \Delta Q_{def}.$$

An analysis of many experimental results on the chemical kinetics led us to conclude that the additivity principle can be extended to the bond energies of the atoms in the activated complex[27,28]. This makes it possible to calculate the activation energy of a variety of chemical reactions.

For the change from the initial system to the activated complex energy equal to ΣQ_{br} must be expended in breaking some of the chemical bonds. During this, activated bonds are formed and energy is released, equal to $\Sigma Q^{\neq}$. Therefore the activation energy of the chemical reaction, which is equal to the energy expended in going from the initial system to the activated complex, can be represented by the following equation:

$$E = \sum Q_{br} - \sum Q^{\neq}; \qquad (8)$$

in other words, the activation energy equals the sum of the energies of bonds which are broken minus the sum of the energies of the activated bonds.

Eqn. (8) is applicable both for the forward and for the reverse reaction. Since the activated complex for the elementary acts of the forward and reverse reactions is the same, the corresponding difference in activation energies will equal the difference between the energies of the bonds broken in the forward and reverse reactions, that is, the exothermicity:

$$E - E' = \sum Q_{br} - \sum Q'_{br} = \Delta H.$$

Eqn. (8) allows the activation energy of a chemical reaction to be calculated when the energies of the activated bonds are known.

The most rigorous path for the determination of the value of $Q^{\neq}$ consists in the direct quantum-mechanical calculation of the activated complex. However, as noted above, quantum chemistry has not yet achieved the necessary accuracy in calculating the activated complex in even the simplest instances.

Another way consists in using reliable experimental data on the kinetics of certain reactions to calculate the energies of the activated bonds by Eqn. (8). The energies of the activated bonds thus found allow the activation energies of many other chemical reactions to be calculated.

We show below the applicability of the additivity principle in the calculation of activation energies for radical reactions, and then also for molecular reactions. The necessity for considering radical and molecular reactions separately stems from the different requirements as regards the accuracy of the activation energy calculations. For molecular reactions, which usually have an activation energy E of between 20 and 65 kcal, an accuracy of 3–4 kcal in the calculation seems quite satisfactory. However, with radical reactions, for which a value of E of ~10 kcal or less is characteristic, it is desirable to carry out the calculations with an accuracy of ~1 kcal. This is also responsible for some differences in the corresponding calculation procedures.

Strictly speaking, Eqn. (8) gives us an expression for the "microscopic" activation energy, determinable as the difference in the zero energy levels of the activated complex and the initial system. In practice, however, we will be dealing with experimental activation energies determinable from the slope of the curve giving the temperature dependence of the reaction rate constant in Arrhenius coordinates.

As Temkin has shown[29], the experimental activation energy corresponds to the statistical determination of this quantity as the difference between the mean energies of the reacting molecules and the initial ones. At moderately high temperatures the "microscopic" and "statistical" activation energies are almost the same. The difference between them—a quantity of the order of RT—usually lies within the limits of experimental error. Therefore subsequently we will assume that the experimental activation energy is equal to the energy barrier of the reaction.

4. RADICAL SUBSTITUTIONS

For the radical substitution (9):

$$R\cdot + R'X \rightarrow RX + R'\cdot \qquad (9)$$

the activated complex, which is of the form R...X...R', belongs to type (*a*) (see p. 512). In this reaction one chemical bond is broken, R'–X, and in the activated complex there are two activated bonds, R...X and R'...X.

Before turning to the calculation of activation energy, we will give the following definition: the energy for the breaking of an activated bond $Q_{R\ldots X}$ is that part of the heat change $D_{R\ldots X\ldots R'}$ of the dissociation of the activated complex with formation of the free radicals R' and R'' and the atom X at 0°K in the gas phase which is associated with one activated bond:

$$R\ldots X\ldots R' \rightarrow R\cdot + X + R'\cdot \qquad (10)$$

Since in this reaction there is the simultaneous breaking of two activated bonds, the above definition is actually within the framework of our postulated principle for the additivity of the activation energy of the complex. The essense of this principle comprises the following two assumptions:

1. The energy for the dissociation of the activated complex equals the sum of the energies for the breaking of the activated bonds:

$$D_{R\ldots X,\ldots R'} = Q_{R\ldots X} + Q_{R'\ldots X}. \qquad (11)$$

2. The energy for the breaking of an activated bond $Q_{R\ldots X}$ is independent of the radical R'' and is therefore constant and characteristic of the RX molecule.

These assumptions are generally true only to a certain approximation. The nature of a substituent can influence to a certain extent the bond energies of the atoms in the molecule. Hence the nature of the radical R'' can change the energy of the activated bond $Q_{R\ldots X}$ within certain limits. However, we assume that this influence is small and can be allowed for in the appropriate way.

To calculate the activation energy of reaction (9) it is necessary to know the energy consumed in going from the initial system to the activated complex. For this purpose we will divide this change into two stages. First let the chemical bond R'–X be broken with the formation of atom X and radical R''. Then let a reaction take place, the reverse of reaction (10). In this, the energy released is equal to $D_{R\ldots X\ldots R'}$. Hence the activation energy of reaction (9) is

$$E = Q_{R'-X} - (Q_{R\ldots X} + Q_{R'\ldots X}) \qquad (12)$$

which agrees with general Eqn. (8). However, it must be remembered that the quantities in Eqn. (12) are energies for the breaking of bonds.

For the reverse reaction the activation energy is expressed by a similar relation:

$$E' = Q_{R-X} - (Q_{R\ldots X} + Q_{R'\ldots X})$$

so that the difference in these quantities:

$$E - E' = Q_{R'-X} - Q_{R-X} = \Delta H$$

equals the heat of reaction.

To calculate the activation energy by Eqn. (12) the energies of the activated bonds $Q_{R\ldots X}$ and $Q_{R'\ldots X}$ must be known. These quantities can be determined with the aid of the same equation from experimental data on the activation energies of certain reactions[27]. Table 1 gives the energies thus calculated for some activated bonds, together with the corresponding experimental data used for the calculations.

Note that to calculate each of the quantities $Q_{R\ldots X}$ the experimental value of the activation energy of the corresponding reaction is used. Consequently the accuracy of the calculation of $Q_{R\ldots X}$ depends on the reliability of the experimental results used. Therefore the quantities used in Table 1 are not, strictly speaking, definitive and could be refined subsequently.

The values given in Table 1 for the energies of the breaking of the bonds in molecules are recommended for use in calculating activation energy, since these particular values are used for calculating the energies for the breaking of activated bonds.

An illustration of the applicability of Eqn. (12) for calculating the activation energy of radical reactions is given by Table 2, in which calculated activation energies are compared with corresponding published values. Clearly,

TABLE 1. Energies for the breaking of bonds in molecules and activated complexes at 0°K.

Bond	Q_{R-X}, kcal	Ref.	$Q_{R\ldots X}$, kcal	Calculated for the reaction	E_{expt}, kcal	Ref.

$CF_3+\Delta\text{-}C_6H_{10} \rightarrow CF_3H+\Delta\text{-}C_6H_9$	5.1	4.7	48

the difference between the calculated and experimental values usually does not exceed 0.5–0.7 kcal.

If it is assumed that the accuracy of the experimental determination of activation energies of radical reactions is comparatively moderate (1–2 kcal), the approximation obtained must be considered good.

The additivity rule is obeyed by the reactions of various radicals with the most varied molecules. Exceptions are the reaction of free halogen atoms and reactions of type (1) with the participation of H and D atoms. It is remarkable that these particular reactions do not obey the Semenov relation. Possibly, here the direct interaction of radicals R and R′, not allowed for in Eqn. (12), is significant.

It is interesting to note that there is a clear linear correlation between the energies of breaking of the activated and the ordinary chemical bond (Fig. 1). The dependence of $Q_{R\ldots H}$ on Q_{R-H}, where R is a hydrocarbon radical, can be expressed by the simple relation:

$$Q_{R\ldots H} = 0.83\,(Q_{R-H} - 45)\ \text{kcal}\ . \qquad (13)$$

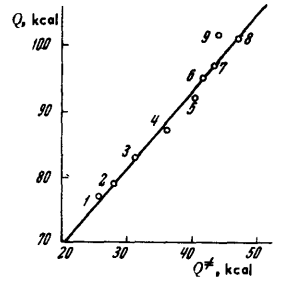

Fig. 1. Relation between the energies for breaking bonds between the atoms in the molecule and in the activated complex of radical reactions:
1) H–C_3H_5; 2) H–CH_3CO; 3) H–$C_6H_5CH_2$; 4) H–t-C_nH_{2n+1}; 5) H–s-C_nH_{2n+1}; 6) H–n-C_nH_{2n+1} ($n \geq 3$); 7) H–C_2H_5; 8) H–CF_3; 9) H–CH_3 (from the data of Table 1).

This relation allows the energy of an activated bond to be evaluated approximately in those instances when the experimental data needed for more accurate calculation are not available.

Note, however, that the accuracy of the results obtainable in this calculation (2–3 kcal) is somewhat worse than when using tabulated data.

Relation (13) agrees with the Polanyi rule and with the Semenov relation. In this connection we will examine several reactions in which radical R is changed but the R′X molecule remains the same. On substituting Eqn. (13) for $Q_{R\ldots X}$ and $Q_{R'\ldots X}$ in Eqn. (12) we obtain:

$$E = A - 0.17\Delta H, \qquad (14)$$

where $A = 74.7 - 0.66Q_{R-X}$.

We have arrived at a relation close to that of Semenov, Eqn. (4). Since $Q_{R\ldots X}$ for alkanes has a value of ~90 to 100 kcal, here A = 9–15 kcal.

An interesting feature of Eqn. (14), equally true of the Semenov relation (4), is that since the coefficient of ΔH is small, change in energy of the bond being broken (or the heat of reaction) has comparatively little effect on the value of the activation energy.

However, for the same reason the use of these relations for the reverse calculation of thermal effects (or bond energies) with the aid of data on activation energies leads to considerable errors. For example, an inaccuracy in Eqn. (14) of 3 kcal gives an error of ~18 kcal in the determination of ΔH. Therefore in using relations (4) and (14) extreme care must be taken and it can only be used for direct calculations of activation energy.

5. ACTIVITY OF RADICALS AND MOLECULES

From the above, three quantities must be known to calculate the activation energy of radical reactions: $Q_{R'-X}$, $Q_{R\ldots X}$, and $Q_{R'\ldots X}$.

However, often all these quantities are unknown. Therefore there is interest in those modifications of the additivity principle which would allow less information to be used. The following two corollaries of Eqn. (12) are useful for this purpose.

First corollary (relative activities of radicals). Let us consider two reactions for different radicals R_1 and R_2 with the same substance RX. The activation energies of these reactions, according to Eqn. (12), are:

$$E_1 = Q_{R-X} - (Q_{R_1\ldots X} + Q_{R\ldots X})$$
$$E_2 = Q_{R-X} - (Q_{R_2\ldots X} + Q_{R\ldots X}).$$

On subtracting one equation from the other we obtain:

$$E_1 - E_2 = Q_{R_2\ldots X} - Q_{R_1\ldots X}. \qquad (15)$$

In other words, *the difference in the activation energies for the reactions of two given radicals* R_1 *and* R_2 *with the same substance* RX *is independent of the nature of this substance and is a constant quantity*. This difference is determined by the energies of the activated bonds $Q_{R_1\ldots X}$ and $Q_{R_2\ldots X}$, and the greater the energy of the activated bond the less the activation energy.

Hence the energy of an activated bond can serve as a quantitative characteristic of the activity of a given radical. If we conventionally take the activity of any one radical (for example, CH_3) as zero, then the difference $Q_{R_i\ldots X} - Q_{CH_3\ldots X}$, or the equal difference between the corresponding activation energies, will characterise the *relative* activity (α) of the radicals in comparison with the radical CH_3. By the relative activity of a radical (in relation to CH_3) we understand the difference between the activation energies of the reactions of CH_3 and this radical with the same substance.

Table 3 gives a series of radicals in order of increasing activity. The relative activities in this table were calculated from the data in Table 1.

It must be pointed out that this determination of the relative activity of radicals differs from Semenov's proposal[17]. By relative activity this author[17] means the difference in the heats of the corresponding reactions, and not the difference in activation energies.

Naturally, between these two determinations‡ it is easy to find an unambiguous relation according to Polanyi's rule since the series of radical activities given in Table 3 can in principle be obtained from the corresponding Semenov series.

An illustration of the accuracy which is achieved with the first corollary of the additivity principle is provided in Table 4, which gives published data on the reactions of the hydrogen atom and the CF_3 radical with various substances. Obviously the difference $E_1 - E_2$ is constant with an accuracy of 0.2–0.3 kcal and agrees with that calculated in Table 3.

TABLE 3. Relative activity of radicals in reactions of the type $R_i + RH \rightarrow R_iH + R$.

Radical R_i	$CH_2{=}CH{-}CH_2$	$C_6H_5CH_2$	C_6H_5	CH_3	H	CF_3	O	OH
Relative activity, α	—17.9	—12.5	—0.6	0	0.7	2.9	3.9	4.9

‡ Semenov also mentioned[17] the possibility of compiling series of activities of free radicals from activation energies (as has been done by the author of this review) (Russian editorial note).

TABLE 4. Activation energies for the reactions of H· and CF_3 with various substances.

Substance	$H + RH \rightarrow H_2 + R$		$CF_3 + RH \rightarrow CF_3H + R$		$E_1 - E_2$
	E_1	Reference	E_2	Reference	
C_2H_6	9.7	62	7.5	49	2.2
C_3H_8	8.2	33	6.2	48	2.0
$n\text{-}C_4H_{10}$	7.1	34	5.3	48	1.8
$iso\text{-}C_4H_{10}$	6.8	35	4.7	49	2.1
$(CH_3)_4C$	9.3	36	7.6	48	1.7
CH_3COCH_3	9.0	57	6.9	58	2.1

By using the relative activities of the radicals, the activation energies of reactions of a given radical with any substance can be calculated if the activation energy of the reaction of another radical with the same substance is known:

$$E_1 = E_2 + \alpha_2 - \alpha_1.$$

For calculation by this equation only one quantity E_2 need be known.

The series of relative activities of the radicals can be quite useful for classifying the available experimental data on the kinetics of radical reactions. It allows the reliability of the available data to be evaluated and clearly unreliable values to be rejected. An important point is that in this method it is necessary to have the minimal information, namely: the value of only one activation energy of any radical of this series with the substance of interest. From this standpoint the second corollary is quite useful.

Second corollary (relative reactivities of substances). Let us consider two reactions of a single radical R with two different molecules R_1X and R_2X. The activation energies of these reactions, according to the additivity principle, are:

$$E_1 = Q_{R_1-X} - (Q_{R\ldots X} + Q_{R_1\ldots X})$$
$$E_2 = Q_{R_2-X} - (Q_{R\ldots X} + Q_{R_2\ldots X}).$$

Subtracting one equation from the other, we obtain

$$E_1 - E_2 = Q_{R_1\ldots X} - Q_{R_1\ldots X} - (Q_{R_2-X} - Q_{R_2\ldots X}) \qquad (15a)$$

that is, *the difference in the activation energies of reactions of the same radical with two given substances is independent of the nature of this radical and is a constant*, which can be determined solely by the quantities characteristic for the molecules taken: $Q_{R-X} - Q_{R_1\ldots X}$.

The values of $Q_{R_i-X} - Q_{R_i\ldots X}$ can therefore serve as a quantitative characteristic of the reactivity of a given substance. If it is conventionally assumed that the reactivity of one particular substance (for example, H_2) equals zero, then the difference of corresponding activation energies gives the *relative* reactivity of the different substances in comparison with hydrogen. Hence by the relative reactivity of a given substance (relative to H_2) we mean the difference between the activation energies for the reaction of H_2 and of this substance with the same radical.

As for the activity of the radicals, our determination of the relative reactivity differs from Semenov's proposal[17]; however, Polanyi's rule here allows us to establish a single-valued relation between them.

Table 5 gives a series of relative reactivities β for certain substances which we have obtained from an analysis of many experimental results, including those given in Table 2.

TABLE 5. Relative reactivity of R_iH molecules in reactions of the $R + R_iH \rightarrow RH + R_i$ type (kcal).

Substance R_iH	H_2	CH_4	C_2H_6	C_3H_8	C_4H_{10}	C_6H_6	CH_3CHO
Relative reactivity, β	0	1.0	4.6	5.6	6.7	7.3	7.8

TABLE 6. Activation energy for various radicals with CH_4 and C_2H_6.

Radical, R	$R+CH_4 \rightarrow RH+CH_3$		$R+C_2H_6 \rightarrow RH+C_2H_5$		$E_1 - E_2$, kcal
	E_1, kcal	Reference	E_2, kcal	Reference	
H	13.0	59	9.7	32	3.3
OH	9.0	45	5.5	45	3.5
CH_3	14.3	38	10.4	39	3.9
CN	—	—	—		3.7 [60]
CF_3	11.0	47	7 5	49	3.5

Table 6 gives published data which illustrate the second corollary of the additivity principle. They suggest that the difference in activation energies of the reactions of CH_4 and C_2H_6 molecules with various radicals is constant, irrespective of the nature of the radical, and agrees within 0.2–0.3 kcal with the value $E_1 - E_2 = 3.6$ kcal calculated from the data of Table 5.

By using a series of relative reactivities β_i of substances the activation energy for the reaction of a given radical with any substance can be calculated when the activation energy of a reaction of this radical with even a single substance of this series is known:

$$E_1 = E_2 + \beta_2 - \beta_1.$$

It is necessary to know only one value E_2 for calculation by this relation. A series of relative reactivities can be useful for a comparative evaluation of experimental data from the reactions of one radical with different molecules.

6. MOLECULAR REACTIONS

The additivity principle postulated for radical reactions can be extended to the reactions of saturated molecules. This makes it easy to calculate the activation energies of corresponding reactions. Such calculations are especially important since in distinction from radical reactions molecular reactions have as yet no relations for evaluating the activation energy. The existing theories of the rate of molecular reactions [61] in essence do not even mention the problem of the calculation of activation energy and only discuss the possibility of determining the pre-exponential factors.

The activated complex of most molecular reactions belongs to one of two types (*b*) and (*c*) (see scheme A), that is, in these reactions two or three chemical bonds are broken and four or six activated bonds respectively are formed.

The activated bond energies needed for calculating the values of E by Eqn. (8) can be determined with the aid of reliable experimental data on the kinetics of certain reactions.

Since in molecular, as opposed to radical, reactions several chemical bonds are broken simultaneously it is desirable to use the mean energies of the bonds between atoms of different elements. This somewhat reduces the accuracy of the calculation but considerably broadens the region of its use.

Table 7 gives the mean bond energies of the atoms in the molecules at 0°K and the corresponding mean energies of the activated bonds. The values of Q are taken from Moelwyn-Hughes [63], but we have rounded them off to whole numbers to simplify the calculations. Naturally, these quantities are not sufficiently precise and their value can be judged solely from how well they allow the activation energies of chemical reactions to be calculated.

Just as for molecules, the mean energy of an activated bond is that part of the heat of atomisation of an activated complex associated with one activated bond. When there are ordinary chemical bonds as well as the activated bonds in the activated complex then in the calculation of the heat of atomisation they are given the mean energies of bonds in molecules.

Hence we will use Eqn. (8) to calculate the activation energies of molecular reactions, taking Q_{br} and $Q^{\neq}$ in this equation to be *mean* bond energies, with one exception, which will be mentioned below. As stated above, the deformation of valence angles in rings leads to a departure from additivity by the strain energy of the ring:

$$V = \sum Q - \Delta Q_{def.} \qquad (16)$$

Because of this the energy for the rupture of a C–C bond in rings is considerably less than the mean energy of a C–C bond in alkanes; it is 50, 60, and 72 kcal for cyclopropane, cyclobutane, and cyclopentane, respectively [26]. This shows that the equality

$$Q_r \simeq Q - \Delta Q_{def.}$$

where Q_r is the energy of rupture of the C–C bond in cyclanes, is obeyed with sufficient accuracy for our purposes.

TABLE 7. Mean bond energies in molecules and activated complexes at 0°K.

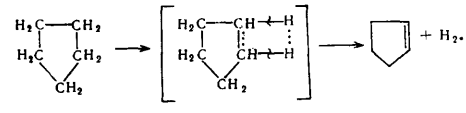
Bond	Q, kcal	$Q^{\neq}$, kcal
H—H	103	45
C—H	99	45
σ– C—C in alkanes	79	28
π– C ⋯ C in alkenes	61	17
π– C ⋯ C in acetylene	56	9
σ– C—O	80	18
π–C ⋯ O	88	27
O—H	105	55
C_{prim}—Cl	76	18
C_{sec}—Cl		25
C_{tert}—Cl		32
C_{prim}—Br	63	16
C_{sec}—Br		21
C_{tert}—Br		26
C_{prim}—I	47	8
C_{sec}—I		16
C_{tert}—I		24
H—Cl	102	40
H—Br	87	33
H—I	70	23
Correction for conjugation $\Delta Q^{\neq}_{conj.}$	—	12

Then Eqn. (16) can be written in the form

$$V = \sum_{n-1} Q + Q_r \qquad (17)$$

which is formally similar to the general equation (6), but in which one value of the mean energy is replaced by the bond rupture energy.

Hence if during the course of a reaction bonds forming part of a ring are broken then in Eqn. (8) for the calculation of E one energy of rupture of a C–C bond in a ring is substituted for the corresponding activated bond energy.



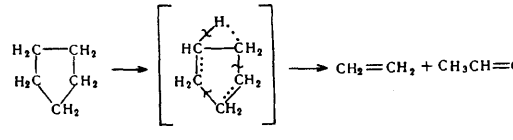
When there is a system of conjugated double bonds in an *activated complex* then the energy of *each* conjugated activated bond must be increased by the quantity $\Delta Q^{\neq}_{conj}$, equal to 12 kcal. Here it does not matter, to the first approximation, which double bonds are conjugated: C=C or C=O.

The author found the value of this correction, like the activated bond energies, by selection from many experimental results on kinetics. We do not make a correction for conjugation in the initial system since it is usually comparatively small and does not affect the calculated activation energy within the limits of error of the calculation.

As Fig. 2 shows, there is a linear relation between the energies of the C–H bonds in the molecules and in the activated complexes, in agreement with Eqn. (13). The existence of this relation allows the energy of the activated bonds to be determined when the energy of the bonds in the molecule differs considerably from the mean value shown in Table 7. For example, for activated bonds in cyclopropane, cyclobutane, and cyclopentane we obtain 4, 12, and 22 kcal respectively. In calculating activation energies it is recommended that the mean energies of the bonds of atoms in molecules given in Table 7 be used, since the activated bond energies found agree with these values.

We will illustrate the calculation of activation energies by examples.

1. The dehydrogenation of cyclopentane:



In this reaction two C–H bonds are broken and four activated bonds are formed: two C–H, one H–H, and one π-C–C. According to Eqn. (8) the activation energy is:

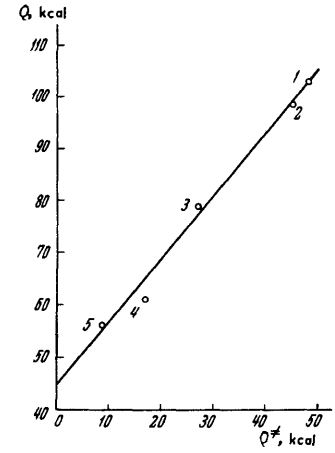
$$E = 2 \times 99 - (2 \times 45 + 45 + 17) = 46 \text{ kcal.}$$

The experimental value of E is 44 kcal.[64]

2. The decomposition of cyclopentane:

In this reaction three bonds are broken: two σ-C–C bonds in the five-membered ring and one C–H bond. In the activated complex there are six activated bonds: two C–H, two σ-C–C, and two π-C–C. Here the activated double bonds are conjugated.

$$E = 72 + 79 + 99 - (22 + 28 + 2 \times 45 + 2 \times 17 + 2 \times 12) = 52 \text{ kcal.}$$



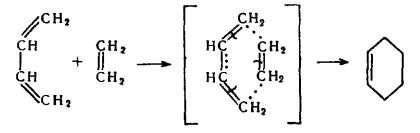


Fig. 2. Relation between the mean C–H bond energies in the molecule and activated complex for molecular reactions.

The experimental activation energy is 49.6 kcal.[64]

3. The Diels–Alder condensation:

During this reaction three π-C–C bonds are broken and a system of six activated bonds is formed: four π-C–C and two σ-C–C bonds. The three activated double bonds are conjugated:

$$E = 3 \times 61 - (4 \times 17 + 2 \times 28 + 3 \times 12) = 23 \text{ kcal.}$$

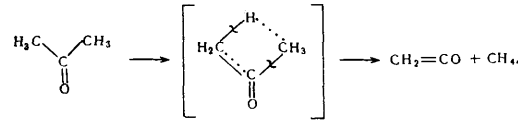
The experimental value of E is 26.7 kcal.[87]

In exactly the same way we calculated the activation energies of a large number of reactions of very different types. Table 8 gives the corresponding data.

These results show that calculated values of the activation energy agree well with the experimental values of E throughout the whole range of activation energies (25 to 70 kcal). The mean deviation does not exceed 2–3 kcal.

The additivity principle seems valid for reactions of the most varied types with molecules of different structure.

The additive scheme of calculating activation energy can be used for revealing the mechanism of a reaction and for obtaining a more accurate structure for the activated complex. A marked difference between the calculated and experimental activation energy suggests that the reaction does not proceed in the manner assumed. For example, in the decomposition of acetone under certain conditions the main products are keten and methane[99] and a molecular mechanism can be proposed for this reaction:



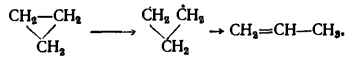


TABLE 8. Activation energies of molecular reactions.

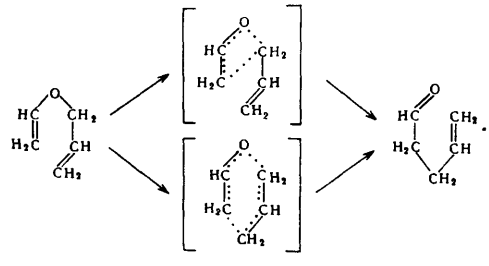

Reaction	E_{calc}, kcal	E_{exp}, kcal	Ref.
Cyclopentane → H_2 + cyclopentene	46	44.0	64
Cyclopentane → C_2H_4 + C_3H_6	52	49.6	64
d-Pinene → dipentene	43	43.7	65
Vinylcyclopropane → cyclopentene	51	50	66
Ethyl acetate → C_2H_4 + CH_3COOH	44	47.8	67
Isopropyl acetate → C_3H_6 + CH_3COOH	44	45	70
Ethyl formate → C_2H_4 + HCOOH	44	44.1	70
Isopropyl formate → C_3H_7 + HCOOH	44	44	70
Ethyl propionate → C_2H_4 + C_2H_5COOH	44	48.5	69
Cyclobutene → buta-1,3-diene	34	32.5	68
1-Methylcyclobutene → 2-methylbuta-1,3-diene	34	35.1	71
1,2-Dimethylcyclobutene → 2,3-dimethylbuta-1,3-diene	34	36	72
Cyclobutane → $2C_2H_4$	65	62.5	73
Methylcyclobutane → C_2H_4 + C_3H_6	65	62	74
Isopropylcyclobutane → C_2H_4 + alkene	65	62.6	75
Isopropenylcyclobutane → C_2H_4 + diene	53	51	76
Isopropenylcyclobutane → 1-methylcyclohexene	47	51	76
1-Chloroethane → HCl + C_2H_4	55	56.6	77
1-Chloropropane → HCl + C_3H_6	55	55	78
2-Chloropropane → HCl + C_3H_6	48	50.5	79
2-Chlorobutane → HCl + C_4H_8	48	49.6	80
2-Chloro-2-methylpropane → HCl + isobutene	41	41.4	81
Allyl vinyl ether → pent-4-enal	30	30.6	82
Allyl isopropenyl ether → allylacetone	30	29.3	83
CH_2=CH–O–C_2H_5 → C_2H_4 + CH_3CHO	47	43.8	84
CH_2=CH–O–$CH(CH_3)_2$ → C_3H_6 + CH_3CHO	47	43.6	85
3,7-Dimethylocta-1,6-diene → 3-isopropyl-1,2-dimethylcyclopentane	34	35.2	86
1,3-Butadiene + C_2H_4 → cyclohexene	23	26.7	87
2(Buta-1,3-diene) → vinylcyclohexene	23	23.1	88
2(Penta-1,3-diene) → dimer	23	25.4	89
Hepta-1,5-diene → 3-methyl-1,5-hexadiene	29	32.5	90
1-Bromoethane → HBr + C_2H_4	51	52.3	91
1-Bromopropane → HBr + C_3H_6	51	50.7	92
2-Bromopropane → HBr + C_3H_6	46	47.8	93
2-Bromo-2-methylpropane → HBr + isobutylene	41	41.0	94
1-Iodoethyl → HI + C_2H_4	53	53.7	95
2-Iodopropane → HI + C_3H_6	45	45.3	96
2-Iodobutane → HI + C_4H_8	45	47.9	97
2-Iodo-2-methylpropane → HI + isobutylene	37	36.4	98

However, the activation energy calculated by this mechanism (43 kcal) differs considerably from the experimental value (68 kcal), which compels us to reject the molecular mechanism in favour of a chain mechanism with loss of CH_3 as the first stage.

An analogous picture is observed for the isomerisation of cyclopropane into propene. The activation energy calculated by an additive scheme for a molecular mechanism is 38 kcal. The experimental value of E = 65.0 kcal [100] differs considerably from the calculated value. Obviously here the reaction proceeds through the formation of an intermediate biradical:

In several instances the additivity principle allows one of several proposed activated complexes for a single reaction to be chosen. For example, for the isomerisation of allyl vinyl ether into pent-4-enal two activated complexes, four-membered and six-membered, can be written:

Calculation gives E = 51 kcal for the four-membered complex, and E = 30 kcal for the six-membered. The experimental value [82], E = 30.6 kcal, shows that the reaction proceeds by the second path.

7. NATURE OF THE ACTIVATED BOND

A characteristic feature of the above approach to the calculation of activation energy is the hypothesis that an activated complex can be considered as a molecule the atoms of which are linked to one another by activated bonds. It is essential that the activated bonds introduced in this way have constant energies and the energy of the transition state is obtained by simple summation of the energies of all the activated bonds. The theoretical interpretation of the additivity principle involves explaining the nature of the activated bond and developing methods of calculating it.

Within the framework of the Heitler–London approximate quantum theory the energy of a two-electron bond is given by the expression:

$$Q = A + \alpha \qquad (18)$$

where A and α are the coulombic and exchange integrals.

Since the activated bond, as we have seen, is not the ordinary two-electron bond it is interesting to find, from the standpoint of the Heitler–London theory, a corresponding expression for the energy of an activated bond.

For the radical reactions of substitution (9) the activated complex can be considered as a three-electron system with an energy expressed by the London formula:

$$V = A + B + C - \left\{\frac{1}{2}[(\alpha-\beta)^2 + (\beta-\gamma)^2 + (\gamma-\alpha)^2]\right\}^{1/2}. \qquad (19)$$

On the other hand, according to Eqn. (11), Eqn. (20) is valid:

$$V = Q_{R\ldots X} + Q_{R'\ldots X}. \qquad (20)$$

The applicability of the additivity rule signifies that direct interaction of radicals R and R′ within the activated complex can be neglected (this is equivalent to the condition $C = 0$, $\gamma = 0$). Moreover, since the activated bonds are independent, for simplicity the radicals R and R′ can be put identical. Then $A = B$, $\alpha = \beta$, $V = 2Q_{R\ldots X}$, and from Eqn. (19) we obtain Eqn. (21):

$$Q_{R\ldots X} = A + 0.5\,\alpha. \qquad (21)$$

Here, as already shown [101], the curve giving the dependence of $A + 0.5\alpha$ on the interatomic distance shows a minimum at the point corresponding to the dimensions of the activated complex, which makes it possible in principle to calculate the length of the activated bond and consequently also the pre-exponential factor in the Arrhenius equation.

However, it is easy to show [102] that Eqn. (21) has a more general character and is applicable not only to a radical but also to molecular reactions, the activated complex of which can be considered as a multi-electron system, the energy of which is obtained by solution of the corresponding secular equation. In particular, for a four-membered complex of type (*b*), considered as a four-electron system, the same London equation can be written, in which $A = A_1 + A_2$; $B = B_1 + B_2$; $\alpha = \alpha_1 + \alpha_2$; $\beta = \beta_1 + \beta_2$.

The applicability of the additivity principle in this instance shows that the interaction of non-neighbouring

atoms can be neglected, that is, here also we have $C = 0$ and $\gamma = 0$. Assuming, as before, that all four activated bonds are identical, we obtain $A = 4A_1$, $V = 4Q^{\neq}$ and Eqn. (19) is changed into the following equation:

$$Q^{\neq} = A_1 + 0.5\,\alpha_1 .$$

which is identical with Eqn. (21).

For a six-membered complex the position is somewhat complicated by the absence of a clear analytical expression for the energy of a six-electron system. However, here it is possible to use the result of a calculation of the energy of a benzene molecule, where all six π-bonds are also identical. If the interaction of non-adjacent atoms is neglected, then for the energy of the system we have[103] Eqn. (22):

$$V = \sum A + 2.61\,\alpha . \qquad (22)$$

Since here the activated complex consists of six identical bonds, Eqn. (23) which is similar to that obtained earlier, is valid for $Q^{\neq}$:

$$Q^{\neq} = A + 0.435\,\alpha . \qquad (23)$$

Hence from the standpoint of the approximate quantum theory, which represents the energy of a chemical bond as the sum of coulombic and exchange integrals, the energy of an activated bond can be represented approximately by Eqn. (19). Since the exchange integral constitutes the main part of the energy of a covalent bond, an activated bond is considerably weaker than an ordinary one. It must also be borne in mind that the quantities A and α which enter into the expression of the energy of an activated bond have another (lesser) value than in the molecule. This is because the distance between the atoms in the activated complex is greater than in the molecule.

Note that although the energies of various activated bonds can be calculated by quantum-mechanical methods using Eqn. (19), such calculations can hardly give results which agree numerically with experiment. The approximations which form the basis of the London formula used in deriving relation (19) are too rough for such agreement.

Therefore the problem of a more correct quantum-mechanical treatment of the additivity principle and a development of methods for calculating the energy of activated bonds are extremely pressing§.

---o0o---

The above-mentioned principle of the additivity of the energy of the activated complex directly connects the reactivity of different molecules and radicals with their structure. It allows a simple and graphical interpretation of the activation energy of most varied reactions to be given—including extremely complex reactions which are at present inaccessible to other theories. The additive scheme of calculation makes it possible to determine the activation energy of various chemical reactions very easily and with an accuracy sufficient for practical purposes.

This work shows that to a certain extent a formal approach to the nature of an activated complex which considers it by methods used for ordinary molecules is sufficiently well-founded, both qualitatively and quantitatively.

The purely empirical concept of an activated bond which exhibits a definite energy evidently has a very real significance.

The most important task standing now in this direction is that of defining more accurately the physical essence of the nature of the activated bond and of providing a theoretical basis for and understanding the additivity principle. This is an extremely complex quantum-mechanical problem the solution of which will facilitate to a great extent an understanding of the essence of the elementary chemical act.

§ After the manuscript of the present article had been submitted to the Editors, Szabo's paper[104] appeared, in which an attempt was made to calculate the activation energy by the equation $E = \Sigma Q_{br} - \alpha \Sigma Q_{form}$, outwardly similar to our Eqn. (8), where α is a coefficient empirically selected for each type of reaction. Unlike Eqn. (8) here the second term depends *solely* on the bonds formed. The additivity of the energy of the activated complex is not discussed in Szabo's paper.

III. Future prospects in the application of the most important methods for separating zirconium and hafnium 532

I. INTRODUCTION

The separation of the chemical elements zirconium and hafnium, which are encountered in nature only in the presence of one another in isomorphous crystals and whose chemical properties are extremely similar, was carried out by de Hevesy and Coster more than forty years ago[1], but the industrial application of processes for the separation of zirconium and hafnium and the production of these metals began much later, in the nineteen-fifties, in connection with the development of nuclear weapons (particularly naval weapons) and the production of nuclear energy[2]. Unlike most other fields of application of zirconium and its compounds—in ferrous and non-ferrous metallurgy, chemical plant construction, the manufacture of ceramics, refractories, glass, and enamels, industrial catalysis, etc.[2-6]—where it is possible to use zirconium without the expensive preliminary purification from hafnium, the chain reactions of nuclear fission require "reactor grade" zirconium, with the minimal possible hafnium concentration. "Reactor grade" zirconium is used chiefly in the form of alloys, as constructional material for nuclear reactors. Here use is made of the exceptionally favourable combination of properties shown by zirconium—the low effective capture cross-section for thermal neutrons, equal to 0.18 barn, compared with a figure of up to 3.5 barn for the natural mixture of zirconium and hafnium containing 1–3 wt. % of the latter, and the high mechanical strength and corrosion resistance at temperatures of up to 550°C in aggressive media.

Although the properties of hafnium and its compounds have been insufficiently studied, it is to be expected, by analogy with zirconium, that hafnium should find fairly extensive application in such fields of modern technology as electrical engineering, radio engineering, metallurgy, the optical industry, etc. The small scale of world production (several dozen tons per year) and the comparatively high cost of hafnium, however, together with the possibility of replacing it in most instances by the more readily available zirconium, has meant that up to the present most hafnium is used in nuclear technology. In contrast to zirconium, hafnium is capable of intensive absorption of thermal neutrons (capture cross-section 115 barn), and this, together with the high corrosion resistance and mechanical strength of the metal and its alloys at both low and elevated temperatures and with exposure to radiation, makes it valuable as a material for the control rods of nuclear reactors. The use of hafnium in assemblies providing protection against irradiation by thermal neutrons is also of considerable importance. The possibility of using hafnium dioxide and boride in the field of nuclear energy has recently been studied.

With increase in the scale of production and decrease in the cost, hafnium and its compounds are beginning to be used in the other branches of industry and technology noted above; the consumption of hafnium for these purposes is still relatively low, however. Extremely promising applications are the use of hafnium as constructional material for jet engines and guided missiles, in view of the ability of hafnium to absorb and give up heat more than twice as rapidly as zirconium or titanium, and also its use for alloying with refractory metals[2]. With time, hafnium will probably find application in the manufacture of chemical apparatus, and hafnium compounds may be used as catalysts. At the present time, numerous studies are being carried out to find new branches of modern technology, in which the use of hafnium might be promising. In connection with the features described above, the scale of the production of "reactor grade" zirconium and hafnium is increasing rapidly. Thus in 1950 the largest producer of these metals—the United States industry—produced 9 tons of "reactor grade" zirconium and several kilogrammes of hafnium, whereas the corresponding figures for 1959 were 1350 tons and 30 tons respectively[2].

A large number of methods for the separation of zirconium and hafnium have been proposed and tested, such as fractional crystallisation, precipitation, sublimation, distillation, or rectification; selective dechlorination of the oxides, reduction of the chlorides, or electrolysis; adsorption; ion exchange; selective liquid extraction; etc. It should, however, be noted that up to the present, even the best of the methods which are described in the literature and used in industry are comparatively complex due to the extensive difficulties associated with the problem of separating elements whose properties are so similar†.

Several fairly extensive reviews have been devoted to the problems of separating zirconium and hafnium, but one of the most complete Soviet reviews[7] appeared more than ten years ago and is naturally somewhat out of date. Works

† The similarity in the properties of zirconium and hafnium is due to the similarity in their atomic dimensions (the atomic radii are R_{Zr} = 1.45 Å and R_{Hf} = 1.44 Å) and the similarity in the configuration of the valency electrons ($4d^2 5s^2$ for zirconium and $5d^2 6s^2$ for hafnium)[4].

by foreign authors[5,6,8-11] say little about results obtained by Soviet research workers, so that it has become necessary to compile a new review containing information on the present state of this problem in the Soviet Union and abroad.

Modern technology, for the industrial separation of mixtures of zirconium and hafnium, uses chiefly the methods of liquid extraction, and also in some instances the methods of cation exchange and fractional crystallisation of potassium fluorozirconates and fluorohafnates. In the present review, most attention is paid to these methods, particularly the extraction method. The description of many other methods, chiefly older versions of methods for separating zirconium and hafnium, is omitted. This material can be found elsewhere[5-10], together with bibliographies of the original papers on these methods. In view of the extensive nature of the topic and space restrictions, the present paper gives only the fundamental principles and a brief description of the technological processes for the separation of zirconium and hafnium. More detailed information on the theory of these processes is given in a number of monographs and original papers, to which reference is made at appropriate points in the text. General information on the present state of the chemistry of aqueous solutions of zirconium and hafnium, necessary for an understanding of the hydrometallurgical processes involved in the separation of these elements, together with bibliographies, can also be found elsewhere[12-15].

II. METHODS FOR SEPARATING ZIRCONIUM AND HAFNIUM

1. Fractional Crystallisation

This method of separation makes use of comparatively small differences in the solubilities of individual compounds of zirconium and hafnium[4-6,11]: the oxide chlorides or oxide bromides, citrates, acetylacetonates, and the double oxalates, sulphates, or fluorides with ammonium or potassium. The efficiency of separation by fractional crystallisation is therefore low. Systems containing the double fluorides (fluorozirconates or fluorohafnates) of potassium or ammonium were the first to be used for the separation of zirconium and hafnium, and these methods, as noted above, have to some extent retained their importance to the present day.

In the fractional crystallisation of the double fluorides (fluorozirconates and fluorohafnates) of potassium or ammonium, the hafnium salts, which are more soluble than the zirconium salts, concentrate in the mother-liquors, and the zirconium in the crystals is gradually purified from hafnium. Several hundred recrystallisations are required in order to obtain pure hafnium from the usual raw material. On the other hand, modern versions of this method make it possible to obtain a "reactor grade" zirconium salt, containing not more than 0.05% hafnium impurity, in a much smaller number of recrystallisations (12–18). Thus this method, despite the simplicity of the individual crystallisations, is now used only for the preparation of "reactor grade" zirconium.

In a version of the method developed in the Soviet Union by Sazhin and Pepelyaeva[16] for the preparation of "reactor grade" zirconium dioxide and hafnium concentrates by recrystallising the fluorozirconates and fluorohafnates, the finely ground zirconium concentrate is sintered with potassium fluorosilicate at 650–700°C to give a sinter of potassium fluorozirconate and fluorohafnate with silicon dioxide. The sinter is finely ground, the fluorozirconate and fluorohafnate are leached out with dilute hydrochloric acid at 85°C, and the extract is left to stand. Cooling of the clarified solution gives crystals of K_2ZrF_6 containing 1.5–2.5% K_2HfF_6; the crystals are compressed, washed with water, and subjected to fractional crystallisation. This is carried out using a countercurrent scheme with 16–18 stages; the hafnium is concentrated in the mother-liquors, and the zirconium in the crystals. The original potassium fluorozirconate crystals containing hafnium impurity are passed to the first stage of the crystallisation and are successively recrystallised from mother-liquors containing an ever-decreasing percentage of hafnium impurity. The crystals are dissolved at 80–90°C, and recrystallise on cooling. In the last two stages, distilled water is used for the dissolution. The mother-liquors from the first and second stages are removed from the crystallisation cycle; precipitation with ammonia from these mother-liquors gives a 6% hafnium concentrate, which is taken for subsequent enrichment by extraction or ion exchange. The final K_2ZrF_6 crystals contain down to 0.01% K_2HfF_6. Similar processes for the separation of zirconium and hafnium were tested by Kawecki[17] in the USA and by the Knaaks[18] in the German Democratic Republic. The development of the theory of these processes is still continuing. Recently, Egerev and coworkers[19] published new data obtained in physicochemical studies of the K_2ZrF_6–K_2HfF_6–H_2O system by the solubility method; these data give more complete information on the regular features of the processes involved in the separation of zirconium and hafnium by fractional crystallisation of potassium fluorozirconates and fluorohafnates.

A new version of the method of fractional crystallisation was recently patented in Japan[20]. Dissolution of pyridinium chlorozirconate in chlorine water at 60°C with subsequent cooling and separation of the resulting crystals increases the hafnium concentration (calculated on the sum Zr + Hf) by a factor of 3 compared with the original concentration.

2. Fractional Precipitation

Methods for separating zirconium and hafnium by fractional precipitation for the most part make use of differences in the solubilities of compounds of these elements, and also of differences in the stabilities of their complexes. In the large number of versions of these methods[4-11], studies have been made of separation by organic compounds (benzoic, tartaric, salicylic, and mandelic acids, and their derivatives) and by inorganic compounds—phosphoric acid, sodium hexacyanoferrate(II), hydrogen peroxide, ammonia, etc. The results of studies carried out over many years have shown that the methods of fractional precipitation are tedious and that the separation process is time-consuming; the degree of enrichment achieved in one stage of the fractionation is comparatively small. Thus even the most effective of these methods—certain versions of the phosphate and hexacyanoferrate(II) methods—are not now used in large-scale industrial production, although under certain conditions they can still be used in preparative laboratory work for the separation of zirconium and hafnium. Some versions of the phosphate and hexacyanoferrate(II) methods of separation are described below.

Phosphate method. (a) In Larsen's method[21], a 2–5% solution of phosphoric acid in 10% sulphuric acid, and a 2–5%—calculated as $(Zr, Hf)O_2$—solution of zirconium and hafnium sulphate in the same acid are added from spray jets with constant stirring to a 10% solution of sulphuric acid at 70–75°C. This gives a compact phosphate precipitate which settles readily, and in which the hafnium is concentrated. The precipitate is filtered off and washed with water. The resulting liquid paste is cooled with ice and treated with a cold solution of sodium hydroxide and sodium peroxide. The mixture is heated at 50–70°C until all the zirconium and hafnium is precipitated as the hydrated peroxides of these elements. The precipitate is filtered from the sodium phosphate solution and dissolved in sulphuric acid, and a new cycle of the phosphate precipitation is carried out. After seven successive cycles of this process, with precipitation of 55% of the total $(Zr, Hf)O_2$ from solution in each cycle, the concentration of HfO_2 in the concentrates is increased by a factor of more than 7, from 13% to 93%. With raw material containing 2–3% HfO_2, zirconium dioxide almost free from hafnium is left in the mother-liquor after two successive fractional precipitations of the phosphates from solution.

(b) In Peters' method[22], the zirconium and hafnium hydroxides are dissolved with heating in dilute (1 : 3) hydrochloric acid, and the resulting solution is treated with $NH_4H_2PO_4$ solution at 40°C. The resulting precipitate of zirconium and hafnium phosphates is washed with distilled water to remove phosphate ion, and dissolved with stirring in 10% oxalic acid solution at room temperature. The resulting solution is heated to 40–60°C and treated with a quantity of oxalic acid equal to that used for the dissolution. The solution is then heated on the water-bath at 40–60°C for a prolonged period varying from several days to several weeks. This is necessary for "aging"—the formation of a stable oxalato-complex of zirconium and hafnium. This complex is then subjected to fractional decomposition by the dropwise addition, with stirring at 70°C, of a solution of the precipitant—a mixture of hydrochloric acid and a solution of ammonium oxalate saturated in the cold. After some time an opalescence appears; this is eliminated by adding ammonium oxalate solution, after which the addition of the precipitant solution is continued until a turbidity appears. The addition of the precipitant is then stopped and the solution is stirred for a further 2 h. To increase the efficiency of the separation of zirconium and hafnium, a "seed" consisting of a fine crystalline nucleus of freshly-precipitated hafnium phosphate is added to the solution before the start of crystallisation. The resulting precipitate is separated from the mother-liquor, filtered, washed, and dissolved in 10% oxalic acid, from which the zirconium and hafnium hydroxide is precipitated.

The degree of separation of zirconium and hafnium by this method, when the "aging" of the complex is effective, is fairly high: from ~ 9% hafnium concentrates the first fraction gave 85% concentrates, and the sixth or seventh fractions gave zirconium dioxide containing down to 0.01% HfO_2. The chief disadvantage of the method is the time required for "aging" of the oxalato-complex.

The hexacyanoferrate(II) method. In the fractional precipitation of zirconium and hafnium hexacyanoferrate(II) from acid solutions of their mixtures in the presence of complex-forming reagents, hafnium is concentrated in the precipitate, since its hexacyanoferrate(II) complexes are less stable and less soluble than the zirconium complexes. The compositions of zirconium and hafnium hexacyanoferrates(II) were studied by Ionova and Tananaev[23], Savenko and Sheka[24], and others; the compositions depend on the conditions of preparation.

In Prandtl's method[25], freshly precipitated zirconium and hafnium hydroxides are dissolved in dilute sulphuric acid, the solution is boiled, and treated with ammonium sulphate and a solution of oxalic acid, saturated in the cold. The resulting solution, containing zirconium and hafnium in the form of anionic complexes, for example, $[ZrO(SO_4)_2]^{2-}$ and $[HfO(SO_4)_2]^{2-}$, is treated with sufficient sodium hexacyanoferrate(II) solution to give partial precipitation of zirconium and hafnium hexacyanoferrates(II). The precipitation is carried out at room temperature (according to Aleksandrov and coworkers[26], it is better to carry out the precipitation at 60°C). The hexacyanoferrate(II) precipitate, which is enriched in hafnium, is left to stand for a prolonged period and then separated from the solution; treatment with hot NaOH solution is then carried out to precipitate zirconium and hafnium hydroxides. These are washed with hot water, dissolved in dilute sulphuric acid, and passed to the next stage of the hexacyanoferrate(II) concentration of hafnium. According to Prandtl, 1% raw material after 6 precipitation cycles gives 95% hafnium concentrates.

Although stable results on the separation of zirconium and hafnium were not achieved in Prandtl's experiments, the higher efficiency of the hexacyanoferrate(II) process compared with most other processes based on fractional precipitation led to further studies of this method. Schumb and Pittman[27] put forward a slightly modified version of the hexacyanoferrate(II) process, the chief difference being that the precipitation of the hexacyanoferrates(II) is carried out from a solution of zirconium and hafnium oxide chlorides to which concentrated sulphuric acid has been added (the other components of the reaction mixture are the same as those in Prandtl's version). The sodium hexacyanoferrate(II) solution is added even more slowly—dropwise; the hexacyanoferrate(II) precipitates are filtered off and decomposed not with NaOH but with ammonia. When this version of the hexacyanoferrate(II) method is used, a 12% hafnium concentrate gives an 80% concentrate after four precipitation cycles.

Thus the hexacyanoferrate(II) method makes it possible, after a comparatively small number of fractional precipitations, to obtain high-percentage hafnium concentrates. One specific disadvantage of this method is that partial decomposition of sodium hexacyanoferrate(II) by sulphuric acid during the hexacyanoferrate(II) precipitation leads to the liberation of HCN vapour into the atmosphere, so that the process must be carried out with efficient ventilation, and also to contamination of the precipitates with iron.

3. Fractional Distillation

This method of separation is based on the use of the difference in the boiling points of various zirconium and hafnium compounds. Earlier, tests were carried out on methods for separating these elements by sublimation of their tetrafluorides and tetrachlorides[28] or by distillation of the tetrafluorides from solution in molten potassium fluorozirconate and fluorohafnate[28], or of the tetrachlorides at an elevated pressure of ~ 10 atm.[29] Although the efficiency of these methods was found to be comparatively low, the idea of using sublimation to separate zirconium

and hafnium has not been abandoned completely: comparatively recently, a sublimation separating apparatus of the column type was patented [30].

More effective methods of separation are those based on fractional distillation of complex compounds—products of the reaction of zirconium and hafnium tetrachlorides with phosphorus(V) chloride and, more particularly, phosphoryl(V) chloride. The compositions of the zirconium complexes are as follows—with PCl_5: $ZrCl_4.PCl_5$ and $2ZrCl_4.PCl_5$ [31,32]; and with $POCl_3$: $ZrCl_4.2POCl_3$, $ZrCl_4.POCl_3$ [33,34], and $2ZrCl_4.POCl_3$. [31] The compositions of the hafnium complexes are analogous to those of the zirconium complexes, for example: $HfCl_4.2POCl_3$ and $HfCl_4.POCl_3$ [34,35]. It has also been suggested [36] that the products of the reaction with $POCl_3$ are not individual chemical compounds, but only azeotropic mixtures.

Although the difference in the boiling points of the complexes formed by phosphoryl(V) chloride with zirconium and hafnium tetrachlorides is comparatively small (360° and 355°C respectively) [31], effective separation of zirconium and hafnium can be achieved when the number of plates in the fractionating column is sufficiently large. Litton [37] carried out the fractional distillation of a mixture of commercial zirconium tetrachloride and phosphoryl(V) chloride in columns, each containing 50 plates; the hafnium concentrated in the distillate. Four successive fractional distillation cycles gave concentrates containing 98.5% HfO_2 in $(Zr, HF)O_2$, with a direct yield of hafnium equal to 25%. The concentration of HfO_2 in the residues in the still, calculated on the total $(Zr, Hf)O_2$, was 1.5–2%. The final distillate was dissolved in methanol, and hafnium hydroxide was precipitated with ammonia. The method involving fractional distillation of the complex compounds (or mixtures) of zirconium and hafnium tetrachlorides with phosphorus chlorides has now been fairly well studied. Thus Nisel'son [38], in one column with 50 plates, obtained zirconium containing less than 0.05% hafnium from a starting material in which the concentration was 1%; the yield of zirconium amounted to ~ 40%.

It has been reported [6] that an assembly has been planned for separating zirconium and hafnium by this method, with a continuously operating packed column of stainless steel, capable of an annual production of 18 tons of metallic zirconium containing less than 0.1% hafnium.

Ogburn and Fischer [39], using a high-efficiency glass apparatus, obtained zirconium containing ~ 0.01% hafnium from an original concentrate containing 3% hafnium.

The study of the possibility of separating mixtures of zirconium and hafnium tetrachlorides without the addition of phosphorus compounds is also of considerable interest. A satisfactory solution of this problem would make it possible to use the products of the separation of zirconium and hafnium for direct conversion into the metals. Thus in recent years, papers on the separation of zirconium and hafnium tetrachlorides by fractional distillation under pressure [40-42] or by extractive fractional distillation [40,43,44] have again appeared, at a higher technical level than earlier papers.

Extractive fractional distillation is carried out in columns irrigated with melts in which $ZrCl_4$ and $HfCl_4$ are readily soluble (NaCl, KCl, $SnCl_2$, $ZnCl_2$, etc., and their mixtures). The vapour in the upper part of the columns is enriched in hafnium; zirconium is concentrated in the melt leaving the section of the column adjoining the still. The temperature conditions for some systems are as follows: 350–500°C in the lower section of the columns and 330–350°C in the upper section (melt of NaCl and KCl); 470°C in the lower section of the columns and 250–450°C in the upper section of the columns ($SnCl_2$ melt). The efficiency of extractive fractional distillation is still comparatively low, however. For example, for an $SnCl_2$ melt, the separation factor in the column is only 2.

Laboratory experiments on fractional distillation under pressure have been carried out at 20–30 atm [31] at temperatures of ~ 450°C in the rectifying section of the columns; under these conditions the $ZrCl_4$ and $HfCl_4$ in the column are present partly in the liquid state and partly in the vapour state‡. The properties of gaseous and liquid zirconium and hafnium tetrachlorides have been studied [41,42]. The fractional distillation of a mixture of zirconium and hafnium tetrachlorides containing ~ 0.3% $HfCl_4$ gave 69–88% $ZrCl_4$ containing less than 0.03% hafnium, together with 7–11% hafnium concentrates in the first distillate fraction. In large-scale experiments in a column with metal packing [45], fractional distillation of mixtures of zirconium and hafnium tetrachlorides with an initial $HfCl_4$ concentration of ~ 1.5–2.5% gave zirconium containing less than 0.05% hafnium, in yields of more than 50%.

Advantages of the fractional distillation method for separating zirconium and hafnium are the comparatively high capacity of the apparatus and the possibility of achieving extensive purification of the products and establishing a continuous process. The introduction of this method in industry, however, particularly the version involving fractional distillation under pressure, first requires the solution of a number of complex problems, associated chiefly with the development of apparatus for carrying out the process—the selection of materials resistant to aggressive media at high temperatures and pressures, the design of fairly complex apparatus, etc.

4. Selective Dechlorination of Zirconium Tetrachloride

Thermodynamic calculations [46,47], carried out for the conversion of zirconium and hafnium tetrachlorides into the corresponding oxides by reaction with oxygen according to the equations

$$ZrCl_{4\,(gas)} + O_2 \rightleftarrows ZrO_2 + 2\,Cl_2$$

$$HfCl_{4\,(gas)} + O_2 \rightleftarrows HfO_2 + 2\,Cl_2$$

showed that the conversion of zirconium tetrachloride into the dioxide is possible, whereas the analogous process for hafnium tetrachloride is almost unrealisable. On this basis, Prakash and Sundaram [47] proposed a method for separating zirconium and hafnium by the selective dechlorination of zirconium tetrachloride with oxygen. A mixture of zirconium and hafnium tetrachlorides containing 2.54% HfO_2 in $(Zr, Hf)O_2$, previously purified from traces of silicon, iron, and titanium, was placed in a tubular quartz furnace from which it was sublimed at 300–325°C and carried by a stream of dry chlorine into the upper part of a vertical tubular furnace, into which a mixture of dry chlorine and oxygen was also passed. The mixture of gases entered the furnace from above; the white zirconium dioxide powder formed in the reaction was deposited in a collector connected to the foot of the reaction tube in the

‡ At atmospheric pressure, however, the sublimation temperatures of $ZrCl_4$ and $HfCl_4$ (335° and 314°C) are lower than the melting points (434° and 432°C respectively), and there is no need for rectification of the liquid phase.

furnace. The gas mixture passed into a condenser, where the unreacted chlorides—the hafnium concentrates—were deposited. At a chlorine: oxygen ratio of 1 : 1, a temperature of 500°C, and a duration of reaction equal to 2 h, the concentration of HfO_2 in the zirconium oxide deposited was 1.29% (half of the initial value) and the yield of zirconium oxide 90–97%; the volatile fraction contained more than 25% HfO_2.

It was thus shown possible to achieve partial separation of zirconium and hafnium in a single cycle by this method; a tenfold enrichment of the hafnium concentrates was achieved, but the purification of zirconium from hafnium was much less efficient.

Koemon Funaki and Kotaro Uchimura[48] studied the kinetics of the dechlorination of zirconium and hafnium tetrachlorides by oxygen. Their experiments confirmed that selective dechlorination of $ZrCl_4$ takes place. Contrary to the views previously expressed[46,47], however, these authors state that appreciable dechlorination of $HfCl_4$ also takes place, reducing the efficiency of the separation.

Later, it was suggested[49] that the selective dehalogenation be carried out in a continuously operating apparatus, preferably using zirconium and hafnium tetrachlorides as starting materials; the tetrabromides and tetraiodides can also be used. The process was carried out at 500–900°C, which is higher than the temperature in the first version of the method.

5. Selective Reduction of the Tetrachlorides by Metals

Although methods for the reduction of zirconium halides by aluminium and zirconium were developed fairly early[50–53], it was only some years later that research workers turned their attention to the marked difference in the abilities of $ZrCl_4$ and $HfCl_4$ to undergo reduction[54–57]. This indicated the possibility of using selective reduction of the tetrachlorides to separate zirconium and hafnium. This process was first developed by Newnham[55,56]; the original mixture of (Zr, Hf)Cl_4 containing 1.5% HfO_2 in (Zr, Hf)O_2 was reduced with zirconium in an evacuated vessel at 300–550°C. $ZrCl_4$ was reduced to $ZrCl_3$; the extent of the reduction of $HfCl_4$ was several times smaller. The hafnium tetrachloride and unreduced zirconium tetrachloride were sublimed off. A reduction temperature of 420°C and a duration of reaction equal to 8 h gave the sublimate with highest hafnium content—5.7%. It was found that the rate of reduction decreases considerably due to the formation of a sinter of the trichloride and unreacted zirconium powder. The reaction vessels were therefore subjected to repeated intensive agitation during the reduction; it was found that for the above temperature and duration of the process, this increased the concentration of hafnium in the sublimate to 29.4%, with a 95% yield of this element. The concentrates obtained were converted into hafnium dioxide by ion exchange or liquid extraction. The degree of reduction of $ZrCl_4$ to $ZrCl_3$ also amounted to 95%; the concentration of hafnium in the latter was reduced to 0.05%. The zirconium trichloride obtained was heated in a vacuum; disproportionation took place according to the reactions

$$2\,ZrCl_3 \rightleftarrows ZrCl_2 + ZrCl_4$$

$$2\,ZrCl_2 \rightleftarrows Zr + ZrCl_4.$$

A temperature of 540°C was found to be sufficient for complete disproportionation of $ZrCl_3$, but the disproportionation of the dichloride is more difficult. The $ZrCl_4$ was distilled off, and the $ZrCl_2$ was used as reducing agent in subsequent cycles.

A disadvantage of the reduction by zirconium is that $ZrCl_3$ begins to disproportionate even at 300°C, as a result of which the $HfCl_4$ being sublimed off is diluted with unreduced $ZrCl_4$. This disadvantage is eliminated if the reduction is carried out with aluminium powder at 300°C.[55] Moreover, at this temperature a melt of $ZrCl_3$ in $AlCl_3$ is obtained, and this prevents the formation of a sinter. Versions of this method, in general differing little from one another, were patented in several countries. The starting materials were (Zr, Hf)Cl_4 [58–61] or (Zr, Hf)I_4 [62,63] mixtures.

In the Soviet Union, the separation of zirconium and hafnium by selective reduction of their tetrachlorides was studied under laboratory conditions by Emel'yanov and coworkers[64,65], by Kozhemyakin and coworkers[66,67], and by others. The thermodynamic principles and kinetics of the process were studied, and the optimal conditions for carrying it out were determined. The results of the studies made it possible to develop a laboratory method for separating zirconium and hafnium. Using this method, it is possible to reduce the concentration of hafnium in (Zr, Hf)Cl_4 from 1–1.5% to 0.05% in one cycle, but the degree of reduction is comparatively low—not more than 70–75%; the concentration of hafnium in the concentrates obtained reaches 3–4%. With further increase in the degree of reduction, the concentration of hafnium in the purified $ZrCl_4$ and the hafnium concentrates increases; thus for 99% reduction of zirconium, the $ZrCl_4$ obtained contains 0.3–0.5% HfO_2, and the concentrates contain 25–29% HfO_2 (calculated on the total oxides).

Thus this method is of undoubted interest for further studies, particularly since its further development might make it possible to eliminate completely the hydrometallurgical processes of converting the (Zr, Hf)Cl_4, obtained by the chlorination of zirconium, into pure $ZrCl_4$ and $HfCl_4$, and then into the corresponding metals.

6. Electrolysis of Melts

After it had been shown, in the nineteen-twenties, that methods for separating zirconium and hafnium, based on the small difference in the mobilities of the ions of the two metals, had a low efficiency[68,69], the electrolysis method was not tested further for this purpose for a long time. It was only when the industrial production of zirconium by electrolysis was successfully developed that the attention of research workers was again drawn to this problem. The possibilities provided by the electrolytic separation of zirconium and hafnium can be illustrated by a recent paper devoted to the study of this problem[70]. The electrolysis vessel contained a mixture of 65% NaCl and 35% K_2ZrF_6. The electrolysis was carried out at 850°C in an atmosphere of argon previously purified from traces of nitrogen and oxygen. The initial current density at the cathode was 2 A cm^{-2}; the current strength was 10 A, and the potential difference 5 V. The graphite crucible in which the melt was placed was used as the anode, and the cathode consisted of rods of heat-treated molybdenum, nickel, and low-carbon steel. Metallic zirconium powder containing 0.05% hafnium was obtained in one cycle from fluorozirconate containing 0.6% hafnium. When the duration of electrolysis exceeded 2 h, the degree of separation began to decrease sharply; within this period, 40% of the metal taken was extracted. It was possible to extract a further 25% of the metal in additional cycles.

Smirnov and coworkers[71] showed that an even greater degree of purification of zirconium from hafnium can be achieved by the electrolysis of K_2ZrF_6 in an NaCl–KCl melt. The concentration of hafnium in zirconium is decreased by a factor of 20 at 700°C and by a factor of 70 at 650°C. The hafnium is concentrated in the electrolyte.

Although the efficiency of electrolysis as an independent method for the separation of zirconium and hafnium is comparatively low, the results obtained indicate the possibility of additional incidental purification of reactor zirconium during its industrial preparation by electrolysis.

Electrolytic refining in NaCl–KCl or LiCl–KCl melts can also be used to purify $HfCl_4$ from traces of iron, aluminium, etc.[72]

7. Adsorption and Ion Exchange

Sorption (chromatographic) methods for separating zirconium and hafnium are based on differences in the behaviour of these elements in molecular or ionic forms in processes of sorption or desorption on adsorbents or ion-exchange resins. The general theoretical principles of these processes are given in many papers and monographs[73,74].

(a) Partition chromatography. In the original version of this method[75,76], a cellulose mass impregnated with aqueous zirconium nitrate solution was treated with an eluant consisting of a mixture of diethyl ether and nitric acid (7 : 1). As a result of the difference in the constants for distribution between the aqueous and organic phases, zirconium was eluted more rapidly than hafnium. The degree of extraction of purified zirconium, containing less than 0.01% HfO_2, amounted to ~ 70%; the hafnium was concentrated in the last fractions. In a method developed by Chou and Tao[77] for the separation of zirconium and hafnium by paper chromatography, the combustible and explosive diethyl ether was replaced by less dangerous eluants consisting of mixtures of tributyl phosphate (TBP) with butanol and xylene (or benzene) in 8–10 M HNO_3. The authors reported complete separation of zirconium and hafnium.

Data on the separation of these elements by reversed-phase chromatography were published recently. Crawley[78] passed a solution of zirconium and hafnium in an eluant consisting of a mixture of 25% HNO_3 and 50% NH_4NO_3 through a column containing kieselguhr and TBP; up to 88% hafnium passed into the eluate. Better results were obtained by Fritz and Frazee[79], who used a stationary phase consisting of polytetrafluoroethylene (Teflon-6) treated with isobutyl methyl ketone previously brought into equilibrium with 3 M HSCN solution. A hydrochloric acid solution of the mixture of zirconium and hafnium was mixed with the eluant and placed in the upper part of the column, after which the zirconium was eluted with an aqueous solution of a mixture of NH_4SCN and $(NH_4)_2SO_4$. The hafnium was then eluted with a solution of $(NH_4)_2SO_4$ or H_2SO_4. Quantitative separation of zirconium and hafnium was achieved.

The methods of partition chromatography described above are unsuitable for industrial use. These methods, however, particularly those involving reversed-phase chromatography, can apparently be used for the laboratory preparation of small quantities of pure zirconium and hafnium, and for the analytical determination of the concentrations of these elements in their mixtures.

(b) Adsorption on silica gel. Methods for separating zirconium and hafnium on silica gel are based on differences in the degree of adsorption and desorption of various compounds of these elements. A recent paper[80] described a study of the mechanism of the sorption of zirconium from nitric acid medium on silica gel; the kinetics of sorption are determined by the rate of diffusion. There are no data indicating that the separation of zirconium and hafnium may take place by an ion-exchange mechanism (as has been shown for the sorption of various metals on silica gel[81]).

Work on the separation of zirconium and hafnium on silica gel was first published by Hansen and coworkers[82,83], and later by Beyer and coworkers[84]. In Beyer's method, a 20% methanol solution of $ZrCl_4$ containing 2–2.5% $HfCl_4$ was passed through a column of silica gel previously activated at 300°C. Hafnium was selectively sorbed by the silica gel, as a result of which the concentration of hafnium in the zirconium in the solutions leaving the column was reduced to ~ 0.3%. Subsequent elution with a 1.9–2.5 *N* solution of HCl in methanol also eluted chiefly zirconium. 7 *N* sulphuric acid was then passed through the column to elute the enriched hafnium concentrate. This was converted into the tetrachloride and the cycle was repeated. Two cycles of this process gave a 90% hafnium concentrate with a yield of hafnium equal to ~ 70%; pure hafnium was not obtained.

Zirconium and hafnium were also separated from solutions of their oxide chlorides in methanol by a frontal chromatographic process on silica gel[85]. From the original 3–15% hafnium concentrates the authors obtained purified zirconium dioxide containing ≤ 0.01% HfO_2, with a yield of zirconium equal to 70–75% of the original quantity (~ 0.23 kg ZrO_2 per kg silica gel) and hafnium concentrates containing more than 20% HfO_2.

The method of separation by adsorption was also tested in continuously operating columns[86]; zirconium dioxide containing only 0.01% HfO_2 was obtained from a raw material containing 2% HfO_2. On the basis of these results, a pilot-plant separating assembly was designed, capable of an annual production of 5 tons of zirconium, purified to a hafnium content of less than 0.01%.

In subsequent studies it was found possible to obtain higher degrees of separation under optimal laboratory conditions by altering the method of preparing the silica gel. Thus Koemon Funaki and coworkers[87] used silica gel, treated with alkali solution, to purify zirconium from hafnium. Waltenberger-Raźniewska[88] obtained an 80% yield of purified zirconium dioxide (HfO_2 content ≤ 0.01%) by using silica gel obtained by neutralising Na_2SiO_3 solution with hydrochloric acid in the presence of a considerable quantity of $Ni(NO_3)_2$.

c. Cation exchange. The differences in the stabilities of zirconium complexes and the corresponding hafnium compounds in sulphuric and certain other acids have been used successfully to separate these elements on cation-exchange resins. The first paper on the separation of zirconium and hafnium by cation exchange appeared in 1948.[89] Finely divided Dowex-50 resin—a polystyrene resin with active sulphonic acid groups—was treated with a solution of zirconium and hafnium oxide chlorides in 2 M perchloric acid; at this acidity, zirconium is present in solution chiefly in cationic form[90-92]; recently, the same has been proved for hafnium. About 80% of each metal was sorbed by the resin, which was then transferred to the

upper part of a column of the same resin (without metal) and eluted with 6 *N* hydrochloric acid. 99.9% HfO_2 was isolated from the first fraction of eluate in 66% yield relative to the original quantity. In this first work, milligramme quantities of zirconium and hafnium were used; Newnham[93], however, used this method to separate several grammes of the mixture. The yield of 99.9% HfO_2 amounted to only 42%.

Several versions of the cation-exchange process for separating zirconium and hafnium were subsequently developed in a series of papers by Lister and coworkers[94-97]. The efficiency of desorption by hydrochloric, perchloric, nitric, oxalic, and sulphuric acids was first studied; best results were obtained using sulphuric acid. Later, Benedict and coworkers[98] showed that a mixture of dilute nitric and citric acids is an effective desorbent, but sulphuric acid is much cheaper and is therefore more promising for preparative and particularly industrial use. The separation of zirconium and hafnium on desorption by sulphuric acid is due chiefly to the marked difference in the stabilities of the sulphato-complexes of hafnium and zirconium in solution. Thus according to Ryabchikov and coworkers[99,100], the stability of the sulphato-complexes of zirconium in solution under certain conditions is three times that of the hafnium complexes. Almost no separation of zirconium and hafnium takes place during sorption on cation-exchange resins from nitric acid solutions. This was confirmed by a study of the isotherms and kinetics of the cation-exchange sorption on the strongly acidic KU-2 sulphonic acid cation-exchange resin§ produced in the Soviet Union[101,102].

In Lister's method, to obtain zirconium purified from hafnium from a raw material containing 20% HfO_2 in $(Zr, Hf)O_2$, the original 0.01 M solution of zirconium oxide chloride in 2 *N* hydrochloric, nitric, or perchloric acid was passed through a column of Dowex-50 or Zeocarb-225 cation-exchange resin. 0.8–1.2 *N* H_2SO_4 was used for the subsequent elution. The first fraction contained 98–99% of the original quantity of zirconium, containing 0.01% hafnium. The hafnium remaining in the column was extracted with 0.05 *N* hydrofluoric or oxalic acid.

In another version of the method, the sorption of zirconium and hafnium was carried out from 0.8–1.2 *N* H_2SO_4 solution. Zirconium containing less than 0.05% hafnium was obtained from the first fractions of eluate. The separation of hafnium from zirconium on Wofatit[103] was found to be less efficient.

Lister also tested a semicontinuous separation process in a battery of two columns. A 0.01 M solution of zirconium nitrate in 2 *N* HNO_3 was passed through the first column, after which 0.8–1.5 *N* H_2SO_4 was passed successively through both columns. Up to 90% of the sorbed zirconium and less than 0.05% of the hafnium was extracted in the first fraction. Hafnium was then extracted by dilute hydrofluoric or oxalic acid in good yield, in the form of a high-percentage concentrate.

Other papers describe various versions of the cation-exchange method—separations on KU-2 resin using various mixtures as eluants: 0.025 M citric acid and 1 M perchloric or nitric acid[99], or hydrochloric acid containing organic solvents (acetone, isopropyl alcohol, ethyl methyl ketone, diethyl ketone, and acetylecetone[104]); separations by Lister's method have also been carried out using ion-exchange membranes[105]. Laskorin and coworkers[106] developed a new version of the ion-exchange process using the KU-2 sulphonic acid cation-exchange resin produced in the Soviet Union; the separation factors for zirconium and hafnium reached values of 5. The original sulphuric acid solutions contained 20–30 g litre^{-1} $(Zr, Hf)O_2$ and 0.65–0.75 M H_2SO_4; fluoride ions were added to the solution to give a ratio F: Zr = 0.7–1.0. When this solution was passed through a layer of KU-2 resin, as a result of the marked difference in the stabilities of the fluorosulphato-complexes of zirconium and hafnium, the hafnium and part of the zirconium were sorbed by the cation-exchange resin, and the remainder of the zirconium was left in the solution leaving the column. The elution was carried out with 0.65 M sulphuric acid. Zirconium hydroxide containing 0.01–0.08% HfO_2 in $(Zr, Hf)O_2$ was isolated from the first fraction of the eluate, and the second fraction gave a mixture of zirconium and hafnium, which was returned to a new separation cycle. The third fraction, containing hafnium, was passed through a column of RF phosphate cation exchanger¶; the hafnium was sorbed, and the dilute sulphuric acid solution was used for elution in a new ion-exchange cycle. The hafnium was washed from the RF exchanger with ammonium oxalate solution, from which hafnium hydroxide containing 99% HfO_2 in $(Hf, Zr)O_2$ was precipitated with ammonia. Further studies of the fluorosulphate process were carried out by Pepelyaeva and coworkers[107]. An advantage of this method over other ion-exchange methods is that partial separation of hafnium from zirconium also takes place in the ion-exchange sorption process; this makes it possible to increase considerably the capacity of the ion-exchange columns.

Laskorin and coworkers[108,109] also studied the separation of zirconium and hafnium in a moving layer of ion-exchange resin, in a continuously operating countercurrent chromatographic column. The cation-exchange resin with particle size 20–50 mesh moves down the column, and the original solution and eluant solutions move up the column. The cation-exchange resin suspension is moved from the lower to the upper sections of the column by means of an airlift. The concentrations of the original solution and the eluant solution (for the desorption of hafnium), because of subsequent dilution in the column, are greater than those for the batch process; the original solution contained 65 g litre^{-1} $(Zr, Hf)O_2$ and had a total acidity of 150 g litre^{-1}; 0.8–0.9 M H_2SO_4 was used as desorbent solution. Hafnium containing down to 1% zirconium passed to the lower section of the column, and zirconium containing less than 0.03% hafnium moved into the upper section. According to the authors, the capacity of the columns in the continuous countercurrent process is three times that for the batch process.

(d) Anion exchange. At sufficiently high concentrations of hydrofluoric acid, zirconium and hafnium form anionic complexes with different stabilities. This has provided the starting point for the development of most methods for separating these elements by anion exchange. Kraus and Moore[110] sorbed zirconium and hafnium from solutions of a mixture of fluorozirconates and fluorohafnates on the strongly basic resin Dowex-1; on elution with a mixture of acids (1 M HCl + 0.5 M HF) at a rate of flow

§ KU-2 is a monofunctional, strongly acid cation-exchange resin with $-SO_3H$ active groups, prepared by treating a swollen styrene–divinylbenzene copolymer with chlorosulphonic acid, then saponifying the sulphonyl chloride (Ed. of Translation).

¶ RF is a strongly acid cation-exchange resin with $-PO_3H_2$ functional groups (Ed. of Translation).

of eluant equal to 0.3 ml cm^{-2} min^{-1}, zirconium was concentrated in the first fractions, and more than 95% of the hafnium was concentrated in the last fractions. Better results were obtained by Huffman and Lilly[111] using Amberlite IRA-400 resin in the chloride form, at lower concentrations of eluant (0.2 M HCl + 0.01 M HF): the yield of purified zirconium was 70%, and that of purified hafnium containing 0.03% zirconium was 83%. Forsling[112], who studied the optimal conditions for the purification of zirconium from hafnium by anion exchange, achieved even better results on Amberlite IRA-400 resin by eluting with a mixture of 0.00008 M HF and 0.22 M HCl at a rate of flow equal to 0.04–0.15 ml cm^{-2} min^{-1}; the degree of extraction of purified zirconium amounted to 98%.

A number of papers describe the use of dilute sulphuric acid as desorbent. According to the data of Rajan and Gupta[113-115], who used finely divided Amberlite IRA-400 resin in the chloride form, the degree of extraction of zirconium dioxide purified from hafnium amounted to 94%, and the yield of spectroscopically pure hafnium amounted to 75%; the use of Dowex-2 resin gave 91.2% zirconium and 75% hafnium with the same purity; thus the efficiency of separation was approximately the same for these resins. Slightly less satisfactory results were obtained when resin fractions with a larger particle size were used. When hafnium concentrates were sorbed in a column of Amberlite IRA-400 resin in the SO_4^{2-} form and subsequently eluted with dilute sulphuric acid with varying concentration (first 0.25–0.5 N H_2SO_4 and then 3 N H_2SO_4), purified hafnium (less than 0.1% zirconium) was eluted first, followed by purified zirconium. The yield of purified hafnium was 93–95%. Huré and coworkers[116,117] also achieved effective separation of zirconium and hafnium from sulphate solutions using Dowex-2 and Amberlite IRA-400 resins, and also using Dowex-1 resin[118].

Yagodin and Orlov[119], using the weakly basic EDE-10P resin† and elution with 0.5 N sulphuric acid at a rate of 0.5 ml cm^{-2} min^{-1}, obtained in the first fraction a 30% hafnium concentrate, with 52% yield of the element, from an orginal 4% concentrate; zirconium dioxide containing less than 0.05% HfO_2 was obtained from the subsequent fractions. With the addition of KCl to the original fluorozirconate solutions, the order of elution of zirconium and hafnium was altered: 40–50% hafnium concentrates, with a hafnium yield of 60–90%, were obtained in the last fractions of the eluates from 8% hafnium concentrates.

In addition to the original fluorozirconate complexes, solutions of chloro-containing complexes of zirconium and hafnium in concentrated hydrochloric acid were also tested[120]. On desorption by the slow passage of 9 M hydrochloric acid, hafnium was eluted first in a fraction with extremely small volume, and effective separation of zirconium and hafnium was achieved.

Vinarov and Shul'gina[121] studied the conditions of separation of zirconium and hafnium on anion-exchange resins produced in the Soviet Union—the weakly basic AN-2F‡ and EDE-10P resins and the strongly basic AV-16§ and AV-17¶ resins. The best separation was achieved using AV-16 resin. Concentration of hafnium in the aqueous phase was observed during sorption on this resin from hydrochloric acid solutions. With sorption on these resins from hydrofluoric acid solutions and subsequent elution with dilute hydrochloric or sulphuric acid, the hafnium is concentrated in the eluates. Thus by sorption on AV-16 and elution with 1 N H_2SO_4, hafnium concentrates with a mean concentration of 50% and a direct yield of hafnium equal to 69% were obtained from the original 29% concentrates.

Thus it has not yet been possible to achieve on anion-exchange resins the high degree of separation of zirconium and hafnium achieved on cation-exchange resins. The good results recently obtained[122] by a combination of chromatography on silica gel and anion exchange on IRA-400 or Dowex-2 are therefore of interest. A two-stage chromatographic process gives purified zirconium dioxide containing less than 0.01% HfO_2, and an enriched hafnium concentrate (Hf : Zr = 40%), which is refined in an anion-exchange resin column to a zirconium concentration of 0.1%.

8. Selective Extraction by Solvents

The methods for separating zirconium and hafnium by selective extraction by solvents (liquid extraction) are the most common in modern technology. Many versions of these methods have been proposed. Examination of the mechanisms of the various extraction processes on the basis of Fomin's classification[123] shows that the methods which are most widely used in industry are those based on extraction by neutral organic reagents, with the formation of the corresponding solvates—selective extraction of hafnium thiocyanates by solvents, chiefly isobutyl methyl ketone (IBMK) and of zirconium nitrates by TBP. We shall examine these versions in most detail. Extraction processes taking place by cation-exchange or anion-exchange mechanisms are also being studied.

(a) Thiocyanate extraction. This method of separation is based on the difference in the distribution constants of the thiocyanato-complexes of zirconium and hafnium between aqueous and organic phases. The technological processes have been developed chiefly by empirical selection of conditions close to the optimal conditions, since there is very little information on the composition and properties of the thiocyanato-complexes of zirconium and hafnium in solution. The composition of the thiocyanato-complexes of zirconium and hafnium was established only recently. According to Golub and Sergun'kin[124], the composition of the thiocyanato-complexes of zirconium and hafnium in aqueous solutions is given by the formula $M(SCN)_n^{4-n}$, where $n = 1-8$. Vinarov and coworkers[125,126] established that the thiocyanato-compounds of zirconium

† EDE-10 is a polyfunctional strongly basic anion-exchange resin prepared by the condensation of polyethylenepolyamines with epichlorohydrin, and contains $-N(CH_3)_3$ groups (Ed. of Translation).

‡ AN-2F is a polyfunctional, weakly basic anion-exchange resin containing tertiary and secondary nitrogen groups. It is obtained by polycondensation of methyl derivatives of phenol with polyethylenepolyamines and formaldehyde (Ed. of Translation).

§ AV-16 is a polyfunctional, strongly basic anion-exchange resin prepared by the condensation of polyethylenepolyamines, pyridine, and epichlorohydrin. It contains secondary, tertiary, and quaternary (pyridinium) nitrogen groups (Ed. of Translation).

and hafnium which are most readily extracted by acetophenone (APH) from perchloric acid solutions contain the complex anion $[M(SCN)_6]^{2-}$, or under certain conditions have the formula $M(SCN)_4$. The extraction takes place by a solvate mechanism. Sinegribova and Yagodin[127] reported the compositions of the zirconium and hafnium compounds extracted by diisopentyl methylphosphonate (DPMP) from sulphuric acid solutions: $M(OH)_2(SCN)_2.2DPMP$, or $M(OH)_2(SCN)_2.2(DPMP.HSCN)$.

In the original version of the thiocyanate extraction proposed by Fischer and Chalybaeus[128], ammonium thiocyanate and sulphate were added to an aqueous solution of the mixture of zirconium and hafnium sulphates, and the mixture was shaken with diethyl ether in a separating funnel; the hafnium concentrated in the ether phase. Later, a repeated stepwise fractionation was developed[129]. The ether extract obtained as described above was washed with a solution of a mixture of ammonium sulphate and thiocyanate to achieve further selective removal of zirconium into the aqueous phase, after which the zirconium and hafnium were re-extracted with ammonium sulphate solution acidified with sulphuric acid. Zirconium sulphate enriched in hafnium was obtained from the re-extract and passed to the next stage of the fractional extraction. 70–90% concentrates were obtained after 6–8 fractionation stages from a raw material containing 0.5% HfO_2, and 99.6% hafnium specimens were obtained from 60–95% concentrates in an eight-stage extraction scheme.

The process described above for the thiocyanate extraction of hafnium from sulphate solutions is in general fairly efficient, but it also has a number of disadvantages: it is impossible to extract hafnium completely from the raffinates; formation of precipitates is often observed, leading to a decrease in the distribution constants; equilibrium is not established during the experiment in the sulphate scheme, so that the course of the process is influenced to a significant extent by the time for which the original solutions have been left to stand. The first attempts to carry out the thiocyanate extraction from hydrochloric acid solutions[128], however, led to a decrease in the efficiency of separation of zirconium and hafnium, since diethyl ether extracts zirconium preferentially from solutions of the chlorides, so that the presence of chloride ion decreases the degree of enrichment of hafnium in the extract. The use of ether as organic solvent also restricted the possible utilisation of the method on a larger scale, in view of the appreciable solubility of ether in water, its volatility, combustibility, and ability to form explosive mixtures with air.

Because of these features, Fischer and coworkers[130] patented another version of the thiocyanate extraction, in which the distribution of the thiocyanato-compounds of zirconium and hafnium was carried out in the absence of sulphate ions at a low concentration of chloride ions in the original solutions, as a result of which reproducible equilibrium was established in the system and precipitates were not formed. Although the authors, as before, used chiefly diethyl ether, they also noted the possibility of using certain other solvents for this process: n-butanol, cyclohexanone, n-butyl acetate, pentyl acetate, methyl propyl ketone, ethyl isopropyl ketone, and benzaldehyde. The distribution and separation of thiocyanato-compounds of zirconium and hafnium during extraction by hexanone was studied in detail[131].

The separation of zirconium and hafnium in a multistage countercurrent continuously operating apparatus has also been described[132]. The liquid phases are solutions of thiocyanic acid in water and in hexane. The solid salts—mixtures of zirconium and hafnium tetrachlorides or oxide chlorides—are introduced continuously into the middle stage of the distribution cascade. The aqueous phase or raffinate obtained contained purified zirconium with an Hf concentration down to 3×10^{-4}%,

Hoshino Yoshio[133] studied the distribution constants for zirconium and hafnium between an aqueous phase containing NH_4SCN, $(NH_4)_2SO_4$, and HCl, and 80 oxygen-containing solvents: ketones, alcohols, esters, and ethers. The highest distribution constants were obtained using alicyclic ketones. In some papers by Hoshino Yoshio and Ito Takuii[134,135], preference is given to extraction by cyclohexanone, which gives high values for the separation factor (β) for zirconium and hafnium (up to 250). The same solvent was previously used by Motov and Leshtaeva[136,137] to obtain zirconium dioxide purified from hafnium, together with hafnium concentrates (the values of β reached 140).

Yagodin, Kaplan, and coworkers[138-140] successfully separated thiocyanato-compounds of zirconium and hafnium by selective extraction by diisopentyl methylphosphonate (DPMP), diluted with benzene or xylene, from sulphuric or nitric acid solutions of zirconium and hafnium. Diviš[142] studied the selective extraction of the thiocyanato-compounds by methylcyclohexanone. No data on the industrial application of the above versions of the thiocyanate extraction have been published, however. We shall therefore not deal with these in more detail, but shall consider the method of separating zirconium and hafnium by selective thiocyanate extraction using isobutyl methyl ketone (IBMK, hexone), which is widely used at the present time[8,11,143-149]. Using this method, conditions have been found for effective extraction from hydrochloric acid solutions; this proved difficult in the first years after the development of the thiocyanate extraction by Fischer.

In one of the latest industrial versions of this method[8,11], a mixture of zirconium and hafnium tetrachlorides or oxide chlorides, obtained from "ore" raw material containing 2% HfO_2 in $(Zr, Hf)O_2$, is dissolved in water to which ammonium thiocyanate has been added. The concentrations of the components in the original solution are as follows: 1.3 M metal, 2.8 M NH_4SCN, and 1 N free acid; the IBMK extracting agent contains 2.8 M HSCN. The extraction, washing, and re-extraction are carried out in continuously operating countercurrent columns. The extract containing enriched hafnium concentrate and thiocyanic acid is washed with 3.5 M HCl; this is accompanied by additional removal of part of the zirconium. The hydrochloric acid wash solution is combined with a new portion of the original solution. The washed extract passes to a system of re-extraction columns, where the hafnium product is washed out with 5 N sulphuric acid. Ammonia is added to precipitate hafnium hydroxide containing small quantities of zirconium, titanium, boron, cadmium, etc.; if a pure product is required, further purification is carried out by re-pulping the product in hydrochloric acid, precipitating hafnium phthalate, re-pulping with aqueous ammonia, drying, and heating the hafnium hydroxide residue. The extracting agent and NH_4SCN (after regeneration from the ammoniacal solution) are used again.

The thiocyanic acid present in the raffinate is also extracted in a countercurrent system with pure IBMK, from which it is then re-extracted with water; the solution obtained is used for the preparation of the original solution for extraction, or the IBMK and HSCN are used

in a new extraction. Zirconium is regenerated by diluting the raffinate to a (Zr, Hf)O_2 concentration of ~ 12 g litre^{-1}, precipitating zirconium sulphate at pH 1.4–1.8 and 60–70°C, re-pulping the basic sulphate precipitate with aqueous ammonia, and heating the zirconium hydroxide. Purified zirconium dioxide and hafnium dioxide are obtained on the industrial scale by this method.

(b) Extraction by TBP and other alkyl phosphates. The method of extraction by TBP, first developed and used in France, is now being developed and extended on an increasing scale [6,11]. The method is based on the difference in the distribution constants of zirconium and hafnium nitrates in extraction by dilute TBP. Zirconium is extracted much more readily than hafnium, so that zirconium is concentrated in the extract, and hafnium in the raffinate. The theoretical principles of the separation of zirconium and hafnium by extraction using TBP are dealt with in a large number of papers by Huré, Korovin, Rozen, and others [75,76,150-154]. The extraction takes place by a solvate mechanism. The composition of the solvates formed during extraction may be different under different conditions. For the conditions usually employed in the separation of zirconium and hafnium, the mechanism of extraction can be represented as follows [75,76]:

$$(Zr, Hf)O^{2+} + 2H^+ + 4NO_3^- + 2\,TBP \rightleftarrows (Zr, Hf)(NO_3)_4 \cdot 2\,TBP + H_2O$$

or, with allowance for the hydration of zirconium and hafnium in the aqueous phase [150]:

$$[(Zr,Hf)(OH)_2]^{2+} + 2H^+ + 4\,NO_3^- + 2\,TBP \rightleftarrows (Zr,Hf)(NO_3)_4 \cdot 2\,TBP + 2H_2O\ .$$

From this it follows that the Zr : Hf ratio in the equilibrium organic phase in extraction from their mixtures is greater than that in the aqueous phase.

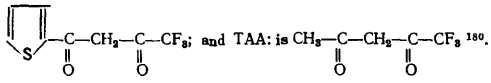
In the original version of the method, developed by Huré and Saint-James [155], the extraction was carried out with a mixture of TBP and white spirit (volume ratio 60 : 40), acidified to 1.6 M HNO_3; the original solution contained 30 g litre^{-1} Zr(Hf), 3 M HNO_3, and 3.5 M $NaNO_3$. The separation factor for the extraction was ~ 10. The washing was carried out with a mixture of 3 M HNO_3 and 3.5 M $NaNO_3$. The process was carried out in a system of mixing and settling vessels. Four extraction theoretical plates and two washing theoretical plates were required in order to obtain zirconium containing less than 0.02% hafnium, in 90% yield from the original ore raw material. The final aqueous phase contained 20–40% hafnium, relative to the total hafnium and zirconium.

The principles of the technology of the separation of zirconium and hafnium by extraction using TBP, developed at Harwell (England), are given in reviews by Hudswell and Hutcheon [75,76]. The extraction was carried out from an original solution of the nitrates, containing 80 g litre^{-1} zirconium and 1.6 g litre^{-1} hafnium in 8 M HNO_3. A 50% solution of TBP in xylene was used as extracting agent. A system of 4 extraction plates and 6 washing plates gave a high yield of zirconium with low hafnium concentration, together with ~ 25% hafnium concentrate. When kerosene (or decalin [156]) was used as diluent for the TBP, a third phase appeared, complicating the process.

Various extractors have been described [156-159] for the separation of zirconium and hafnium by extraction using TBP (vibrational columns, mixing and settling vessels, etc.). Much information has been published [147,159-173] on various versions of the extraction using these solvents. There are also a few data on extraction by TBP from sulphuric acid solutions [170]; the presence of thiocyanate ion is necessary. Hafnium is concentrated in the organic phase, but the separation factors are low.

Let us consider in slightly more detail one modern version of the extraction by TBP (the "nitrophos process"), developed in the USA. Initially, Cox and coworkers [159] used for the extraction a mixture of TBP and heptane (60 : 40), acidified to 0.65 *N* HNO_3; the original solution of zirconium and hafnium nitrates did not contain salting-out agents, and its acidity corresponded to ~ 5 M HNO_3. The separation factor was ~ 15. 14 working stages of the mixing and settling vessels (equivalent to 12 theoretical plates) gave zirconium containing less than 0.01% hafnium, together with a ~ 44% hafnium concentrate. The separation of zirconium and hafnium was carried out on the pilot-plant scale under slightly modified technological conditions [160].

An original solution of 1 M zirconium nitrate, with acidity 8 M HNO_3, and Hf : (Hf + Zr) ratio = 2%, was prepared. The solution was passed to the middle section of the column and moved downwards, in the opposite direction to a mixture of TBP and n-hexane (1 : 1), saturated beforehand with nitric acid by mixing with 8 M HNO_3. The extract then passed into the upper half of the column, where it was washed in a countercurrent process with 5 M HNO_3. The re-extraction was carried out in a special countercurrent column using de-ionised water. The re-extract contained purified zirconium with ≤ 0.006% hafnium, and the raffinate contained a 90–95% hafnium concentrate. The ratio of the volumes of solutions entering the system, the original organic solvent, the wash solution, and the re-extracting water was 1 : 3.6 : 0.6 : 0.9.



On the industrial scale, the "nitrophos process" is carried out in stainless steel columns. The concentration of zirconium nitrate in the original solution is 0.6 M, and the ratio of the volumes of the above solutions is 1 : 2.8 : 1.8 : 1.2. A mixture of saturated and unsaturated hydrocarbons is used to dilute the TBP.

Approximate calculations of the main data for extraction apparatus for the separation of zirconium and hafnium by extraction with TBP are given by Benedict and Pigford [174]. Granovskii, Komissarova, Nalimov, and others [175-177] have begun the development of a mathematical model for this process in order to determine its optimal conditions. The use of modern mathematical methods of optimisation in such complicated processes as the separation of zirconium and hafnium is undoubtedly extremely promising.

In addition to the improvement of the method of extraction by TBP, the search for other equally effective extracting agents is of interest. In particular, it has been suggested that zirconium and hafnium may be separated by extraction from nitrate solutions using other alkyl and aryl phosphates [166]. Separation by oxygen-containing solvents such as 3-methylbutanol, n-hexanol, methyl propylketone, etc. has been tried [178]; from 4 *N* HNO_3, these solvents extract 50–60% zirconium and hafnium, with separation factors of 6–9. In extraction by acetophenone from hydrochloric acid solutions with an acidity of 10 M, the maximal separation factors for zirconium and hafnium reach the value 5. All of these methods have as yet been little developed and are of no industrial importance.

(c) Extraction by fluorinated β-diketones. Thenoyltrifluoroacetone or thiophencarbonyltrifluoroacetone (TTA), trifluoroacetylacetone (TAA), and various

other fluorinated β-diketones react with zirconium and hafnium to form inner-complex compounds (chelates), soluble in benzene and various other solvents. The general formula for the fluorinated β-diketones can be written: $R-COCH_2-CO-CF_3$, where R represents various radicals; for example, TTA is:

and TAA: is $CH_3-C(=O)-CH_2-C(=O)-CF_3$ [180].

Complex formation by zirconium and hafnium with β-diketones has been studied by many authors [181-183]. The extraction of zirconium and hafnium can be represented in general form as follows:

$$Zr\,(Hf)^{4+}_{aq} + 4HK_{org} \rightleftarrows (Zr,Hf)\,K_{4\,org} + 4H^{+}_{aq}$$

where HK represents the fluorinated β-diketone and the subscripts aq and org denote the aqueous and organic phases. These reactions are often complicated by hydrolysis and polymerisation of the zirconium and hafnium ions. The differences in the distribution constants of zirconium and hafnium complexes make it possible to separate these elements by selective extraction [183-187]; zirconium is concentrated in the organic phase. According to Huffman [187], the separation factors obtained using a solution of TTA in benzene amount to 25; figures of 13-18 are obtained for various other extracting agents of the same class. Despite the fairly high separation factors, extraction by β-diketones cannot find extensive industrial application until these extracting agents become much more readily available.

(d) Extraction by liquid sorbents. Laboratory experiments on the separation of zirconium and hafnium by extraction using liquid sorbents of the cation-exchange (alkyl hydrogen phosphates) and anion-exchange (amines) types have been described in recent years. The mechanism of these separation processes is in principle similar to those on solid ion-exchange resins.

In extraction by solutions of alkyl hydrogen phosphates in organic solvents, salts of the cations being extracted (zirconium or hafnium) with the anions of the organic acids are formed.

Extraction by the acid esters of orthophosphoric acid—dihexyl, diheptyl, dioctyl, and diphenyl hydrogen phosphates—from sulphuric acid solutions showed that hafnium is concentrated in the organic phase [140,188]. In extraction by 50% solutions of these acids in xylene from a solution containing 20 g litre^{-1} Zr(Hf) in 2 N H_2SO_4, the separation factor reaches the value 12. Better results—separation factors up to 20—were achieved by extraction using di-2-ethylhexyl hydrogen phosphate. Zirconium is extracted preferentially from hydrochloric acid solutions [189].

In the extraction of zirconium and hafnium by solutions of amines, salts of the anions being extracted with organic cations are formed. For example, the mechanism of the extraction of zirconium and hafnium from solutions of their fluoro-complexes by trioctylamine (TOA) can probably be represented [190]:

$$2\,(NR_3H)\,HSO_{4\,org} + K_2MF_{6\,aq} \rightleftarrows (R_3NH)_2MF_{6\,org} + 2\,KHSO_{4\,aq}$$

where $R = C_8H_{17}$.

The study of extraction from hydrochloric acid solutions using primary, secondary, and tertiary amines [191,192] has shown that zirconium is concentrated in the organic phase. The separation factors vary over a wide range, from 1 to 89, depending on the conditions. Tertiary amines are the most selective. In extraction by a 0.1 M solution of TOA in cyclohexane from 7-9 M HCl solutions of zirconium and hafnium, the separation factor had values of 22-29. Decrease in temperature to ~ 10°C increased the separation factor to 70-89, but the degree of extraction was reduced. A sharp increase in the separation factor to 65-77 was achieved by adding HNO_3 to the original solution. In extraction by trioctylamine in xylene from sulphuric acid solutions with an acidity greater than 1 N, [140] zirconium was also extracted preferentially, with a separation factor of 10. In extraction from acidic solutions of fluorozirconate and fluorohafnate, the separation factor did not exceed 5.

Thus the use of liquid sorbents for the separation of zirconium and hafnium has proved effective, and continuation of these studies appears desirable.

III. FUTURE PROSPECTS FOR THE APPLICATION OF THE MOST IMPORTANT METHODS FOR SEPARATING ZIRCONIUM AND HAFNIUM

The above data make possible a comparative estimate of the future prospects for the industrial application of various methods for separating zirconium and hafnium. Since the present review did not give detailed technical-economic calculations on individual technological methods (for a number of methods these calculations have not been carried out), such a comparative estimate can obviously be made here only in the most general form. The basic criteria for the selection of methods or a combination of methods should be as follows: the highest separation factors, highest specific capacity of the apparatus, simplicity in the technological process and in the apparatus required, the possibility of carrying out a continuous process, low cost of the raw material and reagents used, and the possibility of obtaining them in the required quantities. Another important problem concerns the most rational way of introducing the separation of zirconium and hafnium into the general scheme for the production of these metals from the ore raw material.

If we examine on this basis the future prospects for the application of the above processes for the separation of zirconium and hafnium in industry (most of them can be used for small-scale preparative laboratory separation), it immediately becomes necessary to reject almost all methods of fractional crystallisation or precipitation, because of the low separation factors and the tedious and time-consuming nature of the technological processes, and also the inefficient (in present form) methods of selective dechlorination and electrolysis. Here an exception is the method developed by Sazhin and Pepelyaeva for the fractional crystallisation of potassium fluorozirconates and fluorohafnates, where the simplicity of the technology of separation and its successful combination with the method for opening zircon will evidently enable it, within a short time, to compete successfully even with other more effective separation processes, for the production of zirconium dioxide purified from hafnium. The method of selective reduction of the chlorides by metals is of considerable interest, since it uses zirconium and hafnium chlorides, obtained in the opening of zircon by the efficient chlorination method, and eliminates completely the intermediate hydrometallurgical stages in the production of zirconium and hafnium. This method, however, apparently still requires further technological development. The same

is true of the effective method of separation by fractional distillation under pressure, but the rapid development of this method can take place only after the optimal solution has been found to the problems of selecting constructional materials and a rational design of apparatus for the process. The method of separation on silica gel, although in general fairly effective, has an important disadvantage which makes its extensive industrial application difficult, namely the use of methanol, which is very toxic.

Of the ion-exchange methods, cation exchange on the sulphonic acid cation-exchange resins Dowex-50, KU-2, etc. has found most extensive application, thanks to the high separation factors, the availability of the resins and reagents used, and the possibility of setting up a continuous countercurrent process. The specific capacity of the ion-exchange apparatus (calculated on unit cross-sectional area or volume) and the concentration of zirconium and hafnium in the solutions obtained are usually low, however. Thus on the industrial scale of production it is necessary to have batteries of large-scale columns and to pass comparatively large volumes of solutions through these columns, and this naturally restricts the possible application of the ion-exchange method. This method, however, may even become the predominant method for the industrial separation of zirconium and hafnium, when conditions are found for the highly selective sorption of hafnium by ion-exchange resins. At present, however, the most promising field of application of the ion-exchange method for the separation of zirconium and hafnium is evidently to be found in the treatment of high-percentage hafnium concentrates and the refining of hafnium and zirconium specimens.

The methods of selective extraction by solvents, particularly IBMK and TBP, are widely used in industry. The advantages of these methods are the high separation factors, the high concentrations of the zirconium and hafnium solutions, the high specific capacity of the apparatus, the possibility of using continuously operating countercurrent extractors, etc. By selecting a suitable version, extraction methods can be used for the treatment of hafnium concentrates obtained by any of the existing methods for opening ore concentrates (zircon, etc.). The chief disadvantage of extraction methods is the relatively high cost of the reagents. Thus one of the most important tasks facing industries producing pure specimens of zirconium and hafnium must be the further improvement of the technology of extraction separation processes, including the search for the most readily available and at the same time highly efficient complex-forming reagents and extracting agents.

THE RADIOCHEMICAL PREPARATION OF ION-EXCHANGE MATERIALS

E.V.Egorov

CONTENTS

2. Resins 540
3. Fibres, fabrics, paper 541
4. Mineral-organic sorbents 542

The preparation of ion-exchange materials under the influence of ionising radiation is one of the few radiochemical processes which has found definite practical application. Thus homogeneous ion-exchange membranes have been obtained by grafting certain monomers on to various polymer-carriers under the influence of radiation[1-9]. These membranes have distinct advantages over those prepared by ordinary chemical methods. Moreover, ion-exchange resins prepared by the radiochemical method are in a number of instances not only better, but also cheaper, than ordinary standard ion exchangers[10].

The methods of radiation polymerisation, copolymerisation, and grafting have recently become fairly widespread, since they make it possible to prepare materials which differ from ordinary materials in their high purity, improved physicomechanical characteristics, and other valuable properties influencing their performance.

Grafting under the influence of radiation makes it possible in certain instances to obtain graft copolymers whose preparation is difficult or impossible by ordinary chemical methods. These copolymers can be used to prepare ion-exchange membranes with high mechanical strength, high selectivity, and low electrical resistance. All these features are responsible for the considerable interest in the radiochemical preparation of ion-exchange resins, the progress made in this field, and methods for its further development.

1. MEMBRANES

Most ion-exchange membranes are based on graft copolymers, so that it is convenient to examine briefly radiochemical methods for their preparation, and also the advantages and disadvantages of graft copolymers prepared under the influence of radiation, relative to ordinary copolymers.

The main radiochemical methods for the preparation of graft copolymers are as follows[11-26]: (*a*) direct grafting by irradiation of the polymer–monomer system; (*b*) grafting on to a polymer which is irradiated in a vacuum and then brought into contact with the monomer; (*c*) grafting on to a polymer irradiated in air with heating in a medium of the monomer; (*d*) intermolecular cross-linking of two polymers in the solid state, molten state, or solution; (*e*) grafting by the irradiation of emulsions or suspensions consisting of two polymers, or a polymer and a monomer; and (*f*) grafting under the influence of localised neutron irradiation.

It should be noted that in the preparation of graft copolymers by any of the above methods, block copolymers are also formed. As a rule, however, the relative quantity of block copolymers is extremely small; moreover, it is often impossible to decide whether a given copolymer should be described as a block copolymer or a graft copolymer[12,17]. The separation of block and graft copolymers also involves considerable methodological difficulties[27].

The efficiency of radiochemical grafting is determined by many factors, such as the nature of the polymers and monomers, the integral dose, the dose rate, temperature, the dimensions of the specimens being irradiated, the degree of crystallinity and phase state of the polymers, the rate of diffusion of the monomers in the polymers, the compatibility of the polymers making up the graft copolymers, the ability of the polymers to undergo swelling in the monomers, etc. The dependence of the rate of formation of graft copolymers on the above factors is so complex and varied that we can indicate only a few of the most general regular features, which may prove useful in an examination of problems related to the radiochemical preparation of ion-exchange membranes.

The preparation of graft copolymers by method (*a*) is at present the most widespread. The efficiency of the grafting is here determined chiefly by the quantity G_p/G_m where G_p/G_m are the yields of radicals on irradiation of the polymer and monomer respectively. The greater this quantity, the smaller the quantity of homopolymer formed. In this respect, the best system is the polyethylene–styrene system, for which $G_p/G_m \simeq 2-10$. The chief disadvantage of method (*a*) is that a large quantity of homopolymer is usually formed. The greater part of the ion-exchange membranes prepared by the radiochemical method are obtained, however, by this method.

One version of method (*a*) is vapour-phase radiochemical grafting, in which a large quantity of homopolymer is not formed[28-37]. Moreover, this method makes possible efficient grafting even when the quantity G_p/G_m is less than unity. The method of vapour-phase radiochemical graft polymerisation eliminates completely the possibility of capillary condensation in the pores and thus makes it possible to carry out grafting not only on organic polymers, but also on inorganic carrier-supports[28-34].

In grafting by method (*b*), almost no homopolymer is formed, but the rate of grafting is low, since the greater part of the macroradicals are destroyed on heating before they are able to initiate graft polymerisation. This method is seldom used to obtain ion-exchange membranes.

Method (*c*) is usually employed for surface grafting. By using sufficiently thin films and low irradiation dose rates, however, it is possible to introduce oxygen-containing groups throughout almost the entire volume of the polymer, and hence to achieve more or less uniform grafting. The disadvantages of the method include a slight deterioration in the physicomechanical properties of the carrier-polymer as a result of its radiochemical oxidation, and also the formation of an appreciable quantity of homopolymer under the influence of the $\cdot OH$ radicals produced by the thermal decomposition of polymeric hydroperoxides. It is possible, however, to avoid formation of the homopolymer by carrying out the decomposition of the hydroperoxides and the grafting in the presence of iron(II) salts[38]. This prevents the formation of the $\cdot OH$ radicals which inititate the homopolymerisation:

$$ROOH + Fe^{2+} \rightarrow RO\cdot + Fe^{3+} + OH^-.$$

Method (*c*) is fairly frequently used to obtain ion-exchange membranes.

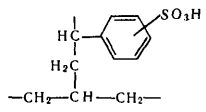
Method (*d*) is usually characterised by low yields of block and graft copolymers, and involves considerable methodological difficulties. Attempts have been made to use this method to prepare ion-exchange membranes[26,39,40], but because of the high integral doses (500 Mrad) and highly brittle nature of the product, these materials are significantly inferior to membranes prepared by methods (*a*) or (*c*).

Methods (*e*) and (*f*) are usually characterised by a high selectivity of graft (or block) copolymer formation, accompanied in most instances by only slight homopolymer formation. Nevertheless, these methods have not found practical application, not only in the preparation of ion-exchange membranes but also in the chemistry of graft copolymers in general, because of the marked experimental difficulties.

The problem of chemical bond formation during grafting is of considerable importance for the quality of membranes prepared by the radiochemical method. The chief method for detecting the presence of graft copolymers involves extraction of the homopolymers with suitable solvents. When the molecular chains of two different polymers are closely intertwined, however, removal of one of them by means of solvents may be impossible[41]. This forms the basis of the preparation of inter-polymer membranes, which have found extensive application in laboratory studies[42-44].

A more reliable method for the identification of graft copolymers is by fractional precipitation of the individual components from solutions containing a mixture of the homopolymers and graft copolymers[45,46]. This method has been used to prove the formation of a poly(ethylene-graft-styrene) system, which subsequently formed a basis for the preparation of membranes containing $-SO_3H$ and $-CH_2N^+(CH_3)_3$ groups, with improved properties influencing performance[47]. Methods which can be used in addition to fractional precipitation and selective extraction include the following[48,49]: fractional dissolution, selective precipitation, turbidimetric titration, adsorption chromatography and elution, ultracentrifuging, etc. In most work on the radiochemical preparation of ion-exchange membranes, however, these methods are not used, and the presence of graft copolymers is usually established merely on the basis of data obtained by selective extraction.

The radiothermoluminescence method[50-52] can apparently be used in certain instances to detect the presence of chemical bonds in graft copolymers.



The quality of membranes based on graft copolymers should be higher than that of membranes prepared from a mixture of homopolymers. These membranes have a greater homogeneity and uniformity of composition, higher chemical resistance and mechanical strength, and superior ion-exchange and electrochemical characteristics. For a given quantity of graft polymer, the properties of the system, particularly its homogeneity, will generally be better, the shorter the graft chains. Non-uniformity is one of the main disadvantages of ion-exchange membranes based on graft copolymers.

The distribution of a graft polymer within the volume of a carrier-polymer can be estimated by a microinterferometric method[53]. The superior properties of membranes prepared by the radiochemical method, and their greater uniformity compared with ordinary membranes may be due to the greater probability of formation of true graft copolymers during irradiation, compared with chemical initiation.

As already noted, the chief disadvantage of both ordinary membranes and membranes prepared under the influence of radiation is non-uniformity of composition. This may be due to the presence of amorphous and crystalline regions or regions with different degrees of orientation, and also to the varied supermolecular structures of the polymers on to which the grafting is carried out. Such important factors, determining the efficiency of graft polymerisation, as the yield of radicals, the degree of swelling, the rate of diffusion of the monomers, the reaction rate constants for termination of the growing polymer chains, and various others, differ significantly in the crystalline and amorphous regions. In most instances, the rate of grafting on amorphous polymer specimens is high, and the copolymers obtained are fairly homogeneous, but the generally unsatisfactory physicomechanical properties of these products prevents their extensive application. The degree of crystallinity may change during grafting; for example, it sometimes decreases with increase in the quantity of graft polymer[54]. For each specific system, there apparently exists a definite degree of crystallinity at which membranes with optimal physicomechanical and electrochemical properties are obtained. Studies in this direction are still in the initial stages.

When ion-exchange groups are introduced into a graft copolymer, its non-uniformity may increase. The formation of hydrophilic and hydrophobic regions in the membranes is accompanied by partial separation into layers, a decrease in selectivity, and an increase in the water-permeability of the membranes. The probability of this undesirable process is much smaller, however, for membranes prepared by radiochemical methods, and this ensures satisfactory properties influencing performance.

Most studies of the radiochemical preparation of cation-exchange membranes have been carried out using the poly(ethylene-graft-styrene) system. Direct irradiation, with ^{60}Co γ-radiation, of polyethylene films immersed in liquid styrene, followed by sulphonation of the poly(ethylene-graft-styrene) system with sulphuric or chlorosulphonic acids and subsequent hydrolysis with alkali has been used to prepare strongly acidic homogeneous membranes[9,40,47,55-64], apparently having the following structure:

The efficiency of grafting is increased considerably by preliminary vacuum-treatment of the polyethylene–styrene system[40,57] or by irradiation of the system in an atmosphere of nitrogen[47,58].

It has been shown[7,9,40,56] that the optimal quantity of polystyrene in the graft copolymer should not exceed 20–40 wt. %. Membranes containing more than 50 wt. % polystyrene, despite their low specific volume electrical resistance, are too brittle, and unsuitable for prolonged use.

To obtain copolymers with a high polystyrene content, a small quantity of divinylbenzene is sometimes added to the styrene; this decreases considerably the degree of swelling of the resulting membranes and improves their physicochemical properties[56,57].

To obtain homogeneous membranes, the styrene is grafted on to polyethylene powder, film, or granules, and the graft copolymers are then subjected to hot rolling. It is claimed[62] that this method has certain advantages over those described above, since it gives fairly homogeneous membranes, and this is extremely important not only in the radiochemical but also in the ordinary methods of preparation.

In all the work cited above[9,40,47,55-64], the irradiation was carried out at dose rates in the range 4–100 rad s^{-1}. The integral doses required to obtain graft copolymers with optimal composition varied from tenths of an Mrad to several Mrad.

The membranes obtained had the following characteristics: capacity 1.5–2.5 mg-equiv. g^{-1}; resistivity 50–200 Ω cm; selectivity 97–98%; and tensile strength 100–200 kgf cm^{-2}. The membranes were characterised by improved properties influencing performance. For example, the energy consumption for the desalination of water by electrodialysis was less for membranes prepared by the radiochemical method than for membranes prepared by ordinary methods (Fig. 1).

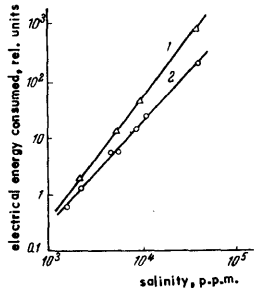


Fig. 1. Desalination of water. Dependence of the consumption of electrical energy on the salinity of the water[47]: 1) for ordinary membranes; 2) for membranes prepared by the radiochemical method.

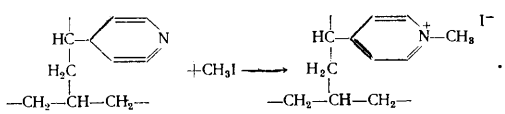
The efficiency of grafting was greater for high-density polyethylene[45,55] and when thicker films were used[40,45,55,65]. This may be due to a decrease in the reaction rate constant for bimolecular termination of the growing polymer chains or to a change from bimolecular termination to linear termination under these conditions.

The presence of stabiliser (diphenylamine) in the polyethylene film decreases the yield of graft copolymer and the efficiency of grafting[40]. It is therefore better to use non-stabilised polyethylene film.



The addition of other monomers, for example acrylonitrile (10–20 wt. %), sometimes increases the elasticity of the membranes considerably. Thus a sulphonic acid membrane based on the poly[ethylene-graft-(styrene-co-acrylonitrile)] system is elastic even in the dry state, whereas the analogous membrane based on poly(ethylene-graft-styrene) can be kept only in the swollen state[59].

Certain solvents, in particular methanol, increase considerably the efficiency of graft polymerisation and make it possible to decrease significantly the doses required to achieve the optimal degree of grafting[59,66].

Some data[40,55] indicate an increase in the efficiency of the grafting of styrene on to polyethylene with decrease in temperature, but other results[14,41] indicate the opposite. In the preparation of ion-exchange membranes, there is evidently in each specific instance an optimal temperature, determined by many of the parameters characterising the system being irradiated.

A number of anion-exchange membranes containing quaternary ammonium groups[47,55,56,61,62] or secondary and teriary amino-groups[61] have been prepared from poly(ethylene-graft-styrene) systems obtained by direction irradiation. The first stage usually involves chloromethylation with mono-chloromethyl ether at the boiling point in the presence of tin(IV) chloride as catalyst and this is followed by amination by heating with a 25% solution of trimethylamine in methanol[47]. These membranes have the following characteristics: capacity 1.5–2 mg-equiv. g^{-1}, resistivity 100–200 Ω cm, selectivity 95–97%, and tensile strength 150–300 kgf cm^{-2}.

Weakly basic and weakly acidic membranes can be prepared by grafting monomers such as 4-vinylpyridine[7,56,64] or acrylic acid[57] on to polyethylene. Treatment of the poly(ethylene-graft-4-vinylpyridine) system with alkylating agents leads to the formation of strongly basic membranes[7,56,64]:

Macromolecular compounds other than polyethylene can also be used as carrier-polymers for the preparation of membranes. Methods have been described for the preparation of membranes based on poly(vinyl chloride-graft-styrene)[57], poly(tetrafluoroethylene-graft-styrene)[57,61], poly[(ethylene-co-propylene)-graft-styrene][59], poly(tetrafluoroethylene-graft-acrylic acid)[67,68], and poly(tetrafluoroethylene-graft-4-vinylpyridine)[67,68] systems obtained by direct irradiation. When the polymer does not undergo swelling in the monomer (polytetrafluoroethylene–styrene), satisfactory results are obtained by periodic irradiation[57]. In this way it is possible to achieve a high degree of grafting throughout the entire volume of the polymer. The direct action of ^{60}Co γ-radiation on polytetrafluoroethylene film in aqueous acrylic acid solutions containing $FeSO_4$ as homopolymerisation inhibitor made it possible to graft 10–20 wt. % polyacrylic acid[67,68]. These films had a high homogeneity, underwent uniform swelling in water, and were suitable for use as cation-exchange membranes.

Weakly acidic and strongly basic membranes[69-71], with excellent properties influencing performance, were prepared by grafting methyl methacrylate, ethyl acrylate, and acrylonitrile from the vapour phase on to polyethylene films, followed by alkaline hydrolysis of the ester and nitrile groups to carboxylate groups, or by grafting 4-vinylpyridine and 2-methyl-5-vinylpyridine, followed by alkylation of the products. The grafting was carried out at room temperature in the absence of atmospheric oxygen under the influence of ^{60}Co γ-radiation, at a dose rate of 2 rad s^{-1}. The doses required to achieve extensive degrees of grafting did not exceed 1 Mrad. Thus irradiation with a dose of 0.4 Mrad was sufficient to give poly(ethylene-graft-4-vinylpyridine) containing 70% graft poly(4-vinylpyridine). The capacity of this membrane after alkylation amounted to ~ 4 mg-equiv. g^{-1}.[69]

The method of vapour-phase radiochemical grafting was used to prepare copolymers based on polyethylene powder (100 mesh), which was irradiated with ^{60}Co γ-radiation at 0.5 rad s^{-1} or with a beam of accelerated electrons at 6×10^4 rad s^{-1} at 80°C in the presence of the vapours of methyl acrylate, ethyl acrylate, 4-vinylpyridine, 2-methyl-5-vinylpyridine, styrene, and vinyl acetate[72,73].

The efficiency of grafting for equal doses was greater when γ-rays were used than when a beam of accelerated electrons was used. The degree of grafting decreased in the following order: methyl acrylate > styrene > ethyl acrylate > 4-vinylpyridine > 2-methyl-5-vinylpyridine > vinyl acetate. These graft copolymers were then converted at 120°C and a pressure of 200 kgf cm^{-2} into films with thickness 0.1–0.2 mm. Treatment of poly(ethylene-graft-4-vinylpyridine) and poly(ethylene-graft-2-methyl-5-vinylpyridine) films with a $CH_3I + CH_3NO_2 + (CH_3)_2CO + C_2H_5OH + O(C_2H_4)_2O$ mixture gave membranes of the quaternary pyridinium type with a capacity of ~ 2 mg-equiv. g^{-1}. Sulphonic acid membranes were prepared by sulphonating poly(ethylene-graft-styrene) with conc. H_2SO_4 in the presence of Ag_2SO_4 at 30–100°C. Carboxylic acid membranes were prepared by hydrolysing poly(ethylene-graft-methyl acrylate) and poly(ethylene-graft-ethyl acrylate) with a 1 *N* solution of KOH in alcohol. In almost all instances the functional groups of the graft copolymers were converted almost completely into ion-exchange groups. Copolymers with a very low concentration of the graft polymer were an exception.

It has been noted[60,74-77] that membranes with a high uniformity of composition cannot be obtained by direct grafting. Uniformity is achieved by preliminary radiochemical oxidation of the polymer, followed by grafting with heating†.

The method of preliminary irradiation of the polymer in a vacuum or in an atmosphere of an inert gas, followed by treatment of the irradiated product with monomer, has also been used to prepare ion-exchange membranes[60,77-80]. Thus irradiation of polyethylene film by ^{60}Co γ-rays in an atmosphere of nitrogen (integral dose 0.3 Mrad, dose rate

† It has also been noted[40], however, that the peroxide method is unsuitable for the preparation of a graft copolymer with a sufficiently high degree of grafting.

60 rad s^{-1}) followed by heating at 40°C in styrene gives a graft copolymer containing up to 30% polystyrene. Subsequent treatment of this film with chlorosulphonic acid and alkali gives a fairly uniform membrane with a capacity of 1.6 mg-equiv. g^{-1} and resistivity 250–300 Ω cm.[60] By altering the conditions of irradiation and grafting, it is possible to prepare membranes with varied physicochemical and physicomechanical properties.

Irradiation with ultraviolet light has also been used to obtain block copolymers for the preparation of ion-exchange membranes[81-83]. Thus the copolymerisation of dibutyl vinylphosphonate and acrylic acid has been carried out under the influence of ultraviolet light. This copolymer was dissolved in alcohol, a cross-linking agent (triallyl cyanurate) was added, and the solution was used to prepare a film, irradiation of which gave a membrane which was insoluble in water but underwent swelling to the extent of 10–40%, and had a capacity with respect to Fe^{3+} equal to 9–12 mg-equiv. g^{-1}.[82] Membranes with satisfactory properties influencing performance were obtained by ultraviolet irradiation of systems containing butyl vinyl sulphonate, vinyl acetate, and ethyleneglycol dimethacrylate[83] or salts of styrenesulphonic acid and acrylic or methacrylic acids[81].

Irradiation with accelerated electrons (dose 5 Mrad) of glass fibre in a solution containing ethyl acetate, polyethyl acrylate, and divinylbenzene[9,84] was used to prepare a reinforced homogeneous membrane. The ester groups were hydrolysed with concentrated alkali solutions.

Membranes obtained by the copolymerisation of styrene and tetrafluoroethylene have particularly high mechanical strength, chemical resistance, and heat resistance[9,61]. Ion-exchange groups are introduced into these membranes by the usual methods.

In the preparation of ion-exchange membranes, the use of radiation is not restricted to the initiation of block and graft copolymerisation. There are data indicating the promising possibilities of using radiation for the formation of three-dimensional insoluble structures containing ion-exchange groups[85]. Thus the irradiation, with ^{60}Co γ-rays (dose 10 Mrad), of films of a copolymer of styrene and butadiene, followed by treatment with conc. H_2SO_4, gave homogeneous membranes of fairly high quality[9,86]. The irradiation, by ^{60}Co γ-rays (dose 30–150 Mrad) and accelerated electrons (dose 150–500 Mrad), of block copolymers of salts of styrene sulphonic acid and acrylic acid was accompanied by the formation of membranes with a capacity of 3–10 mg-equiv. g^{-1}, which were insoluble but underwent swelling[81]. As already noted, the preparation of membranes by the irradiation of a mixture of polyethylene and polystyrene is not promising, because of the high values of the integral doses and the poor physicochemical characteristics of the membranes[40,87]. The same disadvantages are shown by membranes obtained by sulphonating polystyrene films, cross-linked by irradiation[88].

Irradiation of heterogeneous ion-exchange membranes may improve their properties. Thus the durability of membranes based on KU-2 resin‡ and polyethylene is increased by irradiation[40]. Radiochemical vulcanisation is a fairly promising process for heterogeneous membranes consisting of ion-exchange resins and rubbers, since it does not require the elevated temperatures necessary in ordinary vulcanisation, during which there is a considerable deterioration in the properties of the ion-exchange resins present in the membranes.

The radiochemical method can be used to prepare membranes which do not contain ion-exchange groups but which nevertheless exhibit extremely important properties. Thus the radiochemical cross-linking of poly(vinyl alcohol) or a mixture of poly(vinyl alcohol) with bifunctional monomers makes it possible to prepare chemically pure membranes, which may find application in biochemical processes[89].

The above data show that ion-exchange membranes prepared under the influence of radiation differ from ordinary membranes in their more uniform composition, increased thermal and chemical resistance, high mechanical strength, low electrical resistivity, increased selectivity, etc. Similar conclusions have been reached by others[90-94].

2. RESINS

Ionising radiation is used much less frequently in the preparation of ion-exchange resins than in the preparation of ion-exchange membranes, but the use of radiation in this field is fairly promising and makes it possible to obtain ion-exchange resins with improved physicochemical and physicomechanical properties.

One of the main stages in the preparation of polymerisation ion-exchange resins—the copolymerisation—can be effectively initiated by ionising radiation. This is true primarily of suspension (drop) copolymerisation, in which ion-exchange resins with regular spherical shape and almost any particle size from 1 μm to 2 mm can be obtained. Suspension copolymerisation under the influence of ionising radiation has the following advantages over the methods usually employed.

1. The copolymerisation can be carried out at room temperature and below, and this improves the conditions of heat transfer, improves the physicomechanical and physicochemical properties of the copolymer, decreases the probability of adhesion of the granules, and improves the stability of the suspensions. Radiation copolymers of styrene and divinylbenzene have greater mechanical strength and thermal stability than the ordinary copolymers[95]. Thus for a divinylbenzene content of up to 10 wt. %, the breaking stress for a copolymer prepared by irradiation amounts to 700 kgf cm^{-2}, whereas that for the ordinary copolymer is not more than 490 kgf cm^{-2}. The degradation temperature of the copolymer obtained by irradiation is 23 deg higher than that of the ordinary copolymer. Both types of copolymer show a decrease in breaking strength with increase in the divinylbenzene content above 10%, but the decrease is much less marked for the copolymer prepared by irradiation.

2. The absence of copolymerisation initiator from the system makes it possible to obtain copolymers with a high degree of purity. The use of ionising radiation makes it possible to reduce the number of components in the complex reaction mixture, which, in addition to monomers, usually contains initiators, stabilisers, and other substances which make it difficult to isolate the resulting copolymers in pure form[96,97]. This is particularly important in the preparation of nuclear grade resins[98-101] and

‡ KU-2 is a monofunctional, strongly acid cation-exchange resin with $-SO_3H$ active groups, prepared by treating a swollen styrene–divinylbenzene copolymer with chlorosulphonic acid, then saponifying the sulphonyl chloride (Ed. of Translation).

resins for analytical purposes[101], which should differ from ordinary standard ion-exchange resins by having a high degree of purity. For example, in nuclear grade resins the percentage concentration of impurities should not exceed the following values: iron 5×10^{-3}, copper 10^{-3}, and lead 10^{-4}.[101] Resins for analytical purposes must satisfy even stricter requirements; the percentage concentration of impurities should not exceed the following values: iron 10^{-4}, copper 8×10^{-5}, nickel 5×10^{-6}, lead 2×10^{-5}, and aluminium 1.5×10^{-3}; the total ash content should not exceed 4×10^{-2}%.[101]

3. Other conditions being equal, the maximal degree of conversion is greater when ionsing radiation is used than when chemical initiators are used, apparently due to an increase in the mobility of the macromolecular segments under the influence of radiation[102]. This feature is particularly important when the reaction mixture contains an appreciable (> 10–15%) quantity of cross-linking agent, for example, in the preparation of non-swelling macroporous resins, where in chemical methods of preparation ~ 20–30% divinylbenzene takes part in the copolymerisation for only one double bond[103].

Resins with a highly developed specific surface can be prepared under the influence of ionising radiation. For example, macroporous copolymers can be obtained by carrying out the radiation copolymerisation of styrene and divinylbenzene in granules of silica gel, which is then removed by dissolving it in concentrated alkali solution. This method of preparation makes it unnecessary to introduce into the reaction mixture the foaming agents or inert solvents which are usually employed in the preparation of macroporous ion-exchange resins[101–107]. In addition to silica gel, it is also possible to use other porous matrices whose chemical decomposition can be carried out fairly simply.

Since in many polymers irradiation leads to intensive cross-linking, it is sometimes possible to use irradiation instead of cross-linking agents. For example, linear buadiene–styrene copolymer is converted into a three-dimensional insoluble product by treatment with ^{60}Co γ-radiation (dose about 10 Mrad). Subsequent sulphonation of the resulting three-dimensional polymer with concentrated sulphuric acid leads to the formation of a strongly acidic cation-exchange resin[86]. It should of course be borne in mind that this cross-linking is effective for systems with a fairly high value of $G_{\text{cross-linking}}$. For systems with a low value of $G_{\text{cross-linking}}$, however, the doses required to obtain the necessary number of cross-linkages are too large. Thus the formation of the same number of cross-linkages as are present in a copolymer of styrene with 4% divinylbenzene requires irradiation of polystyrene with a dose of ~ 10 000 Mrad, and this is quite unacceptable.

The use of ionising radiation in the production of ion-exchange resins is not limited to the copolymerisation stage. In a number of instances irradiation produces various desirable properties in previously prepared resins. This is true primarily of sulphonic acid cation-exchange resins, whose functional groups are fairly stable towards radiation[108]. For example, specimens of the resins Dowex-50 (2–24% divinylbenzene) and Amberlite IR-120 (8% divinylbenzene), irradiated with ^{60}Co γ-radiation (dose 10–450 Mrad; dose rate 550 rad s^{-1}), were found to be much more stable towards hydrolysis at high temperatures than the original specimens. Non-irradiated ion-exchange resins at 180°C lost 25–30% sulphur and became almost completely soluble, whereas the stability of the resins towards hydrolysis under these conditions increased considerably after irradiation and the loss of sulphur was reduced to 10–15%.[109]

Irradiation has a definite influence on the selectivity of the sorption of various ions[108]. This feature can also be of some practical importance. For example, irradiated KU-2 resin shows an increase in selectivity for the caesium ion in the exchange of H^+ by Cs^+.[110] An analogous phenomenon was observed for the sorption of organic compounds, for example, phenol[111,112].

3. FIBRES, FABRICS, PAPER

Ion-exchange fibres and fabrics have recently become fairly widespread[113,114]. These materials can operate simultaneously as mechanical and ion-exchange filters. They are particularly promising for the technological development of continuous countercurrent processes[115]. Ion-exchange textiles show a combination of properties which sometimes makes them superior to ordinary resins[116]. They have a more highly developed surface than granulated resins, as a result of which ion-exchange processes take place at high rates on these materials. The use of ion-exchange fabrics makes it possible to carry out ion exchange on small-scale equipment of the filter-press type. This makes it possible to remove ions from a pulp and to carry out mechanical filtration, and this is almost impossible on ion-exchange columns. Ion-exchange fabrics can be used for the preparation of the framework of heterogeneous membranes.

The radiochemical method for preparing these materials is apparently more effective than other methods of preparation. The grafting of acrylic and methacrylic acids, methyl methacrylate and acrylonitrile (with subsequent hydrolysis), 4-vinylpyridine and 2-methyl-5-vinylpyridine (with subsequent alkylation), styrene (with subsequent sulphonation or amination) and various other monomers from the liquid or gaseous phase on to polyethylene, polypropylene, poly(tetrafluoroethylene), poly(vinyl chloride), poly(ethylene terephthalate), cellulose, and other fibres not only gives the fibres and fabrics ion-exchange properties but also in a number of instances leads to a marked improvement in their mechanical strength and thermal stability[33]. Grafting on to fibres usually takes place with high radiochemical yields; even at doses of 1–2 Mrad, the quantity of polymer grafted amounts to several dozen percent, and this gives fabrics with a total exchange capacity of 1–5 mg-equiv. g^{-1}.[117,118]

Fibres exhibiting weakly acidic or weakly basic properties are obtained by irradiating polyethylene and polypropylene fibres in air at room temperature and then heating with acrylic acid or 2-methyl-5-vinylpyridine. The total exchange capacity of fibres containing 40–50 wt.% graft polymers amounts to 2–3 mg-equiv. g^{-1}. The presence, in the fibres, of antioxidants of the substituted phenol and aromatic amine type decreases the efficiency of grafting[118].

The grafting of acrylic acid or acrylonitrile (followed by treatment with alkali) on to polypropylene fibres gives fibres with an exchange capacity in neutral solution up to 4 mg-equiv. g^{-1}.[74]

Ion-exchange fibres and fabrics can be prepared by surface grafting, whereas with ion-exchange membranes the grafting should take place throughout the entire volume of the irradiated polymer.

Cellulosic ion-exchange materials containing functional groups, in particular various papers, can be used successfully in analysis, particularly for the chromatography of biochemical materials: proteins, enzymes, nucleic acids, etc.[119]

Ion-exchange papers and fibres can be obtained by the radiation grafting of various monomers, containing ion-exchange groups, on to cellulose, or by the subsequent introduction of these groups into the graft copolymer. The radiochemical preparation of ion-exchange materials based on cellulose, however, is of much less practical importance than that based on synthetic fibres. This is due to the fact that the introduction of a comparatively small quantity of ion-exchange groups (1–2 mg-equiv. g^{-1}) into cellulose leads to a sharp increase in its ability to undergo swelling and to a deterioration in the physicomechanical properties. Moreover, the grafting of various vinyl monomers on to cellulose can hardly give sorbents with advantages over ordinary ion-exchange celluloses.

The radiation grafting of styrene on to cellulose under the influence of γ-radiation, followed by the introduction of ion-exchange groups into the graft polymer, makes it possible to obtain ion-exchange paper with a greater stability towards radiation than the original cellulose[120]. Thus on irradiation with a dose of ~ 50 Mrad, the tensile strength of pure cellulose decreases by 83%, whereas the corresponding figure for a copolymer containing ~ 35 wt.% graft polystyrene is only 47%.[121] When hydrophobic polymers such as polystyrene or poly(methyl methacrylate) (in quantities greater than 13–20 wt.%) are grafted on to cellulose, there is a marked change in the Rf values, the times required for separation, and the form of the spots in the molecular chromatography of aliphatic acids and dyes[120]. Ion-exchange papers can be prepared from materials other than cellulosic materials. For example, the grafting of acrylonitrile and acrylic acid on to polypropylene fibres under the influence of ^{60}Co γ-radiation makes it possible to obtain cation-exchange papers with a thickness of 0.2 mm, a capacity of 4 mg-equiv. g^{-1}, and a resistivity of 12 Ω cm (in 1 N NaCl)[74].

4. MINERAL-ORGANIC SORBENTS§

A number of ion-exchange materials consisting of an inorganic carrier-support and an organic fraction containing various functional groups capable of ion exchange have recently been prepared. These materials have certain advantages over ordinary ion-exchange resins. They show an increased thermal and radiochemical stability, a high rate of attainment of ion-exchange equilibrium, a low degree of swelling in the working solutions, and the ability to act as mechanical filters. The disadvantages of most of these materials generally include poor chemical stability and a lower exchange capacity on a weight basis than ordinary ion-exchange resins.

The mineral-organic products on which the subsequent preparation of the ion exchangers is based may be obtained by chemical[122,123] or chemical and mechanical[124] methods¶. For example, cation exchangers with capacities up to 0.5 mg-equiv. g^{-1} have been prepared by condensing dibenzyldichlorosilane with the hydroxyl groups of silica gel or aerosil and then sulphonating the products[125]. Cation exchangers with a capacity of 1 mg-equiv. g^{-1}, which are stable at 300°C and have found application as catalysts, have been prepared from silica gel and sulphonated benzyltrichlorosilane[126]. The reaction of silica gel with various aminosilanes gives anion exchangers with capacities up to 0.8 mg-equiv. g^{-1}, stable at temperatures above 200°C.[127]

The most universal method for the preparation of mineral-organic products, however, is the radiochemical method. It can be used for grafting on to surfaces which do not contain groups capable of undergoing condensation. It does not require mechanical subdivision and makes it possible to carry out grafting on highly dispersed materials. Finally, the radiochemical method can be used to obtain products with a high concentration of organic fraction, whereas this is generally difficult or impossible by chemical or chemical-mechanical methods.

Mineral-organic ion exchangers have been prepared by radiochemical vapour-phase graft polymerisation[10,128-131]. The mineral-organic products were made in the apparatus illustrated in Fig. 2. The inorganic carrier-support was placed in a thin-walled glass ampoule (*1*), and the liquid monomer was placed in the flask (*2*). The ampoule was separated from the flask by the glass filter (*3*). The apparatus was evacuated to a residual pressure of 10^{-5}–10^{-6} mmHg and sealed off. The ampoule was placed in the air thermostat (*4*) fitted with a window of thin aluminium foil (*5*) to permit irradiation. The flask containing the monomer was immersed in the water or oil thermostat (*6*), in which a temperature determined by the vapour pressure of the monomer in the system was maintained. The apparatus was rotated by means of a small motor (*7*). After irradiation by X-rays or a beam of accelerated electrons, the apparatus was opened and the homopolymer was separated from the mineral-organic product by extraction with a suitable solvent. The quantity of graft polymer usually amounted to 10–20 wt.%. When the graft polymer contained functional groups capable of ion exchange—for example, poly(acrylic acid)—the mineral-organic ion exchanger was obtained in a single stage. Otherwise, the functional groups were introduced into the graft polymer by further chemical reactions. Graft polystyrene was sulphonated or aminated, graft poly(4-vinylpyridine) was alkylated, and poly(vinylphosphonic dichloride) was hydrolysed with water. The following mineral-organic ion exchangers were prepared in this way: macroporous silica gel–sulphonated polystyrene; macroporous silica gel–aminated polystyrene; macroporous silica gel–alkylated poly(4-vinylpyridine); macroporous glass fibre–alkylated poly(4-vinylpyridine); "white soot" [powdered silica gel (Ed. of Translation)] (or aerosil)–sulphonated polystyrene;

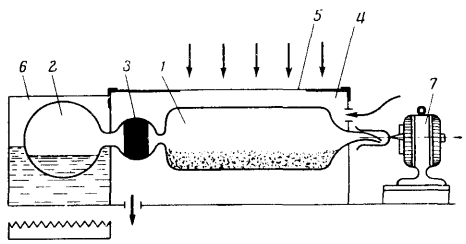


Fig. 2. Apparatus for vapour-phase radiochemical graft polymerisation[29].

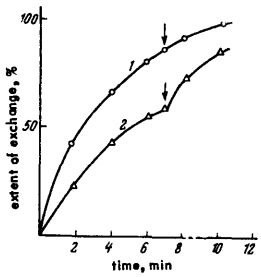
§ Since these sorbents are based on synthetic inorganic materials, it would be more correct to call them inorganic-organic sorbents.

¶ Methods for the preparation of mineral-organic products have been reviewed in detail by Morozov[34].



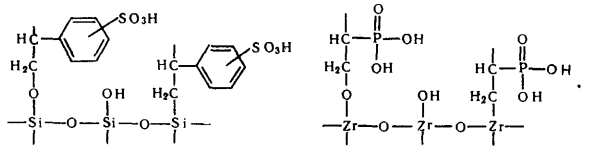


Fig. 3. Rate of exchange of H^+ by Cs^+:[130] 1) for a mineral-organic ion exchanger (macroporous silica gel–sulphonated polystyrene); 2) for KU-2-6 resin. The arrows mark the points at which the sorbents were removed from the solutions for 12 h.

"white soot" (or aerosil)–poly(acrylic acid); and zirconium oxide–poly(vinylphosphonic acid). The suggested structures of mineral-organic sorbents of the macroporous silica gel–sulphonated polystyrene and zirconium oxide–poly(vinylphosphonic acid) types are given below:

The ion exchangers obtained have a capacity of 1–2 mg-equiv. g^{-1} in neutral solutions, undergo slight swelling in water (5–10%), and have a highly developed specific surface, varying from several dozen to several hundred square metres per gramme. Most of them can also be used as mechanical filters. The rate of attainment of ion-exchange equilibrium in these ion exchangers is usually not limited by internal (gel) diffusion, as in ordinary resins (Fig. 3). The rate is very high even in dilute solutions. Thus the half-saturation time (the time required for 50% of the capacity of the resin to be realised) in the exchange of H^+ by Na^+ in 2×10^{-4} N NaCl amounts to only a few minutes for mineral-organic ion exchangers, compared with 30–40 min for KU-2-6 resin. Mineral-organic ion exchangers also have a high radiochemical stability. Thus an ion exchanger based on the system formed by macroporous silica gel with polystyrene containing $-CH_2N^+(CH_3)_3$ groups loses only 40% of its capacity on irradiation in water with a dose of 500 Mrad, whereas AV-17 anion-exchange resin†, which contains analogous groups, loses its ion-exchange properties completely under the same dose[132].

Finally, various mineral-organic ion exchangers show a high heat resistance, retaining their ion-exchange properties up to 300°C.

THE USE OF GAS CHROMATOGRAPHY IN THE STUDY OF POLYMERS

V. R. Alishoev and V. G. Berezkin

Chromatography is a physical method for the separation of compounds, in which the substances being separated are distributed between two phases, one of which is stationary,

while the other is mobile and filters through a layer of the stationary phase[1,2].

Gas chromatography is a form of chromatography in which the mobile phase is a gas. In a gas-chromatographic separation, the molecules of a compound being analysed are moved by a stream of carrier gas, so that gas chromatography can be used for the separation of only those compounds which can be transported without decomposition in the gaseous state. Thus the gas-chromatographic method cannot be used directly to separate non-volatile macromolecular compounds, and its application is restricted to volatile compounds with vapour pressures not less than several mmHg at the temperature of the separation. Accordingly, gas chromatography is used to determine the concentration of volatile products in polymers, or in compositions based on them. A common feature of these methods is that the polymer is introduced into the chromatography either in suspension or in solution in a suitable solvent. To facilitate calculations, a standard is usually added to the mixture introduced into the chromatograph. The polymer is retained in the column (a special short initial column, which is replaced at intervals, is often used to separate the polymer) and the solvent, standard, and volatile impurities present in the polymer are separated and detected.

A method has been developed for determining residual monomer and other volatile components in polymers based on styrene[3]. Dimethylformamide is used as solvent, and toluene is used as standard. The volume of sample taken is 5 μl. The sensitivity of the method corresponds to 10^{-6} g monomer in 1 g polymer.

Wilkinson and coworkers[4] developed a method for determining residual monomers in latices. Acetic anhydride, 2,2-dimethoxypropane, and cyclohexanone can be used as solvents. The first two solvents react with water and convert it into other compounds more convenient for chromatographic study. A separate initial column containing glass wool is used to separate the latex. The volume of sample used is 0.02–0.1 ml. The sensitivity is 0.01–0.05%.

A method has also been developed for determining free phenol and formaldehyde in phenolic resins[5].

Gratsianskaya and coworkers[6] were the first to use an analogous method for the quantitative determination of polymeric substances in a reaction system, for the example of the isomerisation of α-pinene into camphene, during which polymeric ompounds are also formed. A short initial column was used to separate the polymers. Cineol and menthol were used as internal standard. The concentration of polymer was determined from a comparison of the percentage concentration of standard in the prepared mixture and that determined by chromatographic analysis.

The application of gas chromatography to the direct study of polymers is possible only with a new type of approach, since the classical version of the analysis is impossible for non-volatile substances. In the study of polymers and other non-volatile compounds by gas chromatography, two approaches are possible in principle: (1) analysis of the polymers by the recently proposed method of "reversed" gas chromatography, and (2) analysis of macromolecular compounds from the products of chemical changes.

In the new method of "reversed" gas chromatography, in contrast to the usual version, the unknown system is the stationary liquid phase, on which known volatile compounds are separated[7]. The organic compounds used as stationary liquid phases are characterised by a definite spectrum of relative retention times for standard compounds. The spectra of the standard compounds change markedly with change in the nature of the stationary phase. Polymers can also be used as unknown stationary liquid phase; this can be used, in particular, to characterise their molecular weights. If the molecules of the polymer contain functional terminal groups differing from the main chain, there should be a definite relationship between the concentration of these groups (and hence the molecular weight of the polymer) and the retention times for standard compounds. This relationship for polyethyleneglycol maleate adipate[8] is given in Fig. 1.

The method of "reversed" gas chromatography can also be used to study phase changes in polymers, for example in polyethylene[9]. In the region of a phase change (fusion) the curves giving the dependence of the retention time or peak width on the column temperature show a maximum due to the change in the distribution constant resulting from the phase change (Fig. 2).

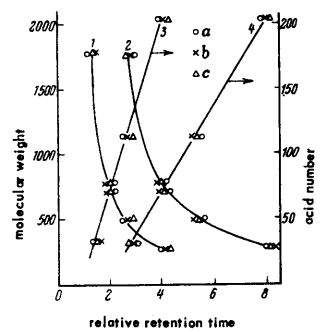

Fig. 1. Dependence of the relative retention times of ethanol (1, 3) and propanol (2, 4) on the number-average molecular weight and acid number of polyethyleneglycol maleate adipate; *a*), *b*), *c*) series of experiments.

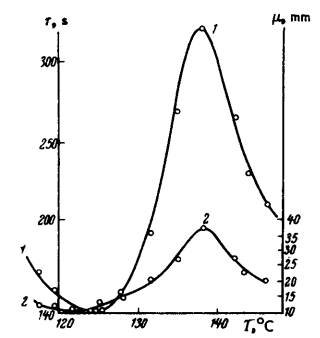

Fig. 2. Dependence of the retention time (1) and peak width (2) of n-tetradecane on the temperature of the column. The stationary phase is a mechanical mixture of polyethylene (1%) and glass beads.

The method of "reversed" gas chromatography can apparently also be used to determine the structure of polymers, the composition of copolymers, and other polymer characteristics which influence the change in the "gas–liquid" distribution constants for standard volatile compounds. An advantage of the method is that it makes possible the direct study of a polymer (without decomposing it) in small samples, but one restriction is the viscosity of the compounds being studied, which should not be too great at the temperature of the experiment[10]. "Reversed" gas chromatography can also be used to study the kinetics of chemical reactions[11], including polycondensation.

A method more widely used at present in the study of polymers characterises macromolecular substances by an indirect method—the macromolecular compound is characterised by the spectrum of volatile products formed by chemical changes. Here we must first mention the extensive application of the universal reaction of pyrolysis in the study of polymers, since the use of other chemical methods is often limited by the chemical inertness, the absence of functional groups, and the insolubility of many polymers of practical importance.

Disadvantages of the pyrolysis method include the complexity of the chemical reactions taking place during thermal degradation and the generally important part played by secondary reactions. The processes involved in the thermal degradation of polymers have as yet been insufficiently studied. Thus in general it is impossible to predict quantitatively the spectrum of volatile products from a knowledge of the structure and conditions of pyrolysis of the polymer; the opposite problem (the determination of the structure and composition of a polymer from the pyrolysis products), which is of considerable analytical interest, has not yet been solved theoretically.

The analyst's task is to establish an empirical correlation between the structure of a polymer and the spectrum of the products formed on pyrolysis. Since the composition of the pyrolysis products is determined by many factors (temperature, duration of pyrolysis, size of sample, etc.), the dependence on the structure of a polymer of the composition of the pyrolysis products becomes unambiguous only with strict standardisation of the conditions of pyrolysis, including some standardisation of the sample.

Thermal degradation followed by analysis of the degradation products has for long been used for the qualitative and quantitative analysis of macromolecular compounds and to establish their structures[12–15]. The use of the gas-chromatographic method for the analysis of the products has greatly increased the value of this method in the study of polymers, since in the complex mixture of products formed, only a few are characteristic of a given type of polymer. Thus for the analysis of volatile compounds, gas chromatography is in general a more selective method than spectroscopy and a simpler method than mass spectroscopy.

The use of gas chromatography for the analysis of pyrolysis products is due to the following fundamental advantages of gas chromatography as an analytical method: (1) the use of sensitive detectors makes it possible to carry out the analysis with small polymer samples of the order of one milligramme or several tens of microgrammes; (2) the high efficiency of separation on packed columns—1–3 thousand theoretical plates (t.p.)—or in capillary columns (20–60 thousand t.p.); (3) the time required for the analysis is short and usually varies from several minutes to several tens of minutes; and (4) standard chromatographic apparatus is used for the separation, and the pyrolysis unit consists of a small independent attachment fo the standard chromatograph.

The method of studying non-volatile compounds from the chromatographic spectrum of the volatile products is often called pyrolytic gas chromatography.

In the earliest work on the use of gas chromatography for the analysis of polymer degradation products[16–18], the pyrolysis was carried out in a special assembly, and the products were removed and analysed on a standard gas chromatograph. This method is convenient when the use of small samples (about 1–10 μg) is impossible because of the inhomogeneity of the specimen, to study the mechanism and kinetics of pyrolysis, to estimate the heat resistance of a material, when it is necessary to study the composition of the products at low degrees of conversion, etc.[19]

In a second version, the pyrolysis and the chromatographic separation are combined in a single instrument. This method for studying polymers by pyrolysis of a specimen in a special reaction vessel in front of the gas-chromatographic column in a current of carrier gas was first described by Lehrle and Robb[20]. This method has the following advantages: (1) the time required for the study is reduced considerably, since the pyrolysis and introduction of the sample are combined in a single short operation; (2) the study requires only small quantities of specimen (of the order of several milligrammes or even microgrammes); (3) for small samples (thin layers) the part played by secondary reactions is reduced; and (4) it is possible to carry out the pyrolysis under reproducible controlled conditions and to analyse both liquid and gaseous products.

An interesting intermediate version of the pyrolytic method was proposed by Swann and Dux[21]. The pyrolysis of the polymer being studied was carried out in an evacuated glass ampoule (weight of specimen 50 mg, duration of heating 15 min). The pyrolysis products were studied by gas chromatography; the ampoule was broken in a current of carrier gas in front of the column inlet.

An analogous method was used successfully for the quantitative determination of hydroxyethyl groups in hydroxyethyl–starch[22]. A sample of the substance being studied (0.001 g) was pyrolysed in a sealed capillary (9.0 × 0.1 cm) in a vacuum at 400°C for 10 min. The pyrolysis products were studied chromatographically. It was established that there is a linear relationship between the height of the acetaldehyde peak and the quantity of hydroxyethyl groups in the specimen being analysed.

A more widespread version of the pyrolytic method is that in which the cell for the pyrolysis is also the assembly for the introduction of the sample into the chromatographic column.

The layout of the apparatus in pyrolytic gas chromatography is characterised by considerable variety; the pyrolysis cells designed by foreign firms are extremely varied. The various pyrolysis cells can be divided into two design types. In pyrolytic reactors of the first type, the pyrolysis is carried out on a filament (spiral), which is heated rapidly by electric current. The heated spiral is placed in a flow chamber whose walls are at a temperature not exceeding the temperature of the subsequent chromatographic separation.

When these cells are used, the substance being studied is applied to the metallic filament (usually platinum or Nichrome). The spiral carrying the substance to be analysed is then placed in the gas stream, the cell is made airtight, the instrument is brought to operating conditions, and the spiral is heated. The resulting pyrolysis products are carried by the carrier gas into the chromatographic column, separated, and recorded by the detector. With cells of this type the design is simple, the specimen being studied can be heated rapidly to the required temperature, the pyrolysis is carried out in a stream of carrier gas, and the heating surface is small, so that the possibility of secondary reactions by the pyrolysis products is reduced. Cells of this type must satisfy the following requirements: (1) the cell colume must be as small as possible, since increase in its volume leads to a decrease in the efficiency of the subsequent chromatographic separation; (2) supplementary heating of the cell walls is required to prevent condensation of liquid pyrolysis products on the cold walls of the cell; alternatively, the cell can be placed in a thermostat; and (3) rapid and convenient replacement of the spirals carrying the substance being studied must be possible. Pyrolysis cells of this type can be used to carry out pyrolysis in various gaseous media, including reactive media, or in a vacuum.

The construction of a typical glass pyrolytic cell[23] is illustrated in Fig. 3. Cells of similar design are described by Janak[24], Jones and Moyles[25,26], and Mljenek[27]. These authors used chromatographs with an ionisation detector, since the total volume of products formed by pyrolysis on the spiral from very small samples is insufficient for detection by the simpler but less sensitive katharometer.

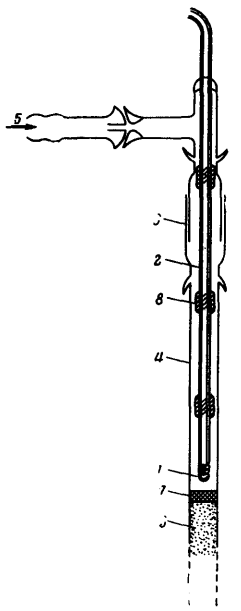

Fig.3. Glass cell for pyrolysis:
1) Nichrome spiral (0.2 Ω); 2) tungsten electrodes (diameter 1 mm); 3) sorbent; 4) column; 5) carrier gas inlet; 6) ground joint; 7) layer of asbestos; 8) glass insulation.

Franc and Blaha[28] worked with a pyrolysis cell in which platinum gauze was used instead of a spiral. This made it possible to increase the quantity of specimen being analysed, without increasing the weight of polymer per unit area of wire, so that it became possible to detect the pyrolysis products by means of a katharometer.

The temperature of the cell does not remain constant during the pyrolysis; Fig. 4 shows the change in the temperature of the cell and the concentration of volatile products with time in various experiments on the pyrolysis of a poly(propene oxide–tetrahydrofuran) copolymer. Thus the pyrolysis of the polymer actually takes place under conditions of rapidly changing temperature.

Kyryacos and coworkers[29] suggested the application of a higher voltage to the spiral at the start of pyrolysis in order to reduce the time required to heat the spiral to a given temperature.

The use of metallic filaments and spirals (platinum, Nichrome, etc.) as supports for the polymer film during pyrolysis is not the best arrangement, because of the possible catalytic activity of the metals. It has been shown[26] that for samples weighing more than one milligramme the filament material has a marked influence on the spectrum of products; the spectrum of pyrolysis products is simpler when a gold-plated filament is used than when a Nichrome filament is used. When smaller samples (20–30 μg) are used, however, the spectrum of pyrolysis products for polystyrene and poly(methyl methacrylate) are independent of the spiral material (Nichrome, platinum, gold-plated platinum). This undesirable factor for large samples can apparently be eliminated by using glass coated filaments.

It is sometimes convenient to place the sample for pyrolysis in a small boat of mica, quartz, or other more inert material, instead of directly on the spiral[30].

It has been reported[30] that when the pyrolysis of rubbers is carried out in a small mica boat heated with a Nichrome spiral, the gas-chromatographic spectra of the products are more characteristic (that is, greater differences are observed between them) than when the sample for pyrolysis is deposited directly on the spiral.

A method has also been described for studying non-volatile organic compounds by pyrolysis of a weighed specimen of the substance (5–30 μg) placed in a capillary

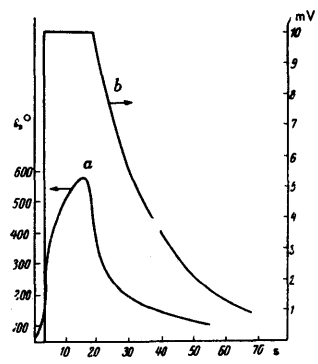

Fig.4. Change in the temperature of the spiral (*a*) and the concentration of volatile products (*b*) during pyrolysis.

(0.2 × 0.05 cm) sealed at one end[31]. The area and height of the peak were found to be linearly dependent on the size of the sample.

In pyrolysis cells of the second type, the specimen for pyrolysis is introduced into a high-temperature zone of a tubular reactor, where the thermal degradation takes place. An advantage of reactors of this type is the more effective standardisation of the thermal conditions, but a disadvantage is the possibility of secondary reactions by the pyrolysis products as a result of the increased time for which they are present in the hot zone.

Increase in the dimensions of the polymer sample being analysed makes it possible to supplement the gas-chromatographic method for the study of the degradation products with other physicochemical methods for the analysis of the residues from the pyrolysed polymer (chemical, spectroscopic, etc.).

Various methods for heating the specimen for pyrolysis have been described: (1) introduction of the small boat into a hot zone, heated to a high temperature[32]; (2) the use of an electric heater consisting of a platinum wire wound directly on to the boat or capillary[33,34]; (3) immersion of a U-shaped vessel containing the specimen in a bath of Wood's alloy (500–550°C);[35] and (4) induction heating of the specimen, mixed with a metal powder, by high-frequency currents[36].

An original assembly for the pyrolysis of polymers was proposed by Giacobbo and Simon[37,38]. The specimen for pyrolysis is deposited on a wire of ferromagnetic material (0.5 × 20 mm) and placed in a glass capillary in the stream of carrier gas. The ferromagnetic wire is heated rapidly to the Curie point in ~ 2×10^{-3} s by means of a high-frequency furnace. During pyrolysis of the polymer, the temperature of the wire remains constant at the Curie point. The temperature of pyrolysis can be varied to some extent by using different ferromagnetic materials. The method has been used to study the spectra of pyrolysis products from various amino-acids. This method of heating the specimen for pyrolysis was also used by Völlmin and coworkers[39].

Reactors using a heated filament have found wider practical application.

To obtain reproducible results and a characteristic spectrum of pyrolysis products, it is necessary to select the optimal parameters for the experiment, and these should be standardised precisely.

The thermal degradation of a polymer is sensitive to even slight changes in the conditions of pyrolysis. The decisive parameters in the rational design of a cell are as follows: (1) the size and geometric form of the specimen for pyrolysis; (2) the temperature conditions of the pyrolysis; (3) the duration of pyrolysis; and (4) the conditions of the chromatographic separation.

The polymer is deposited on the spiral of the pyrolysis cell by two main methods: (1) from solution by evaporation (for soluble substances) or from a suspension (for insoluble substances); and (2) small specimens (several milligrammes) of identical shape are placed directly inside the spiral.

A film can be obtained by immersing the spiral or filament in a dilute solution or suspension; Alternatively, a solution or suspension containing ~ 1 wt.% of polymer can be applied by means of a soft brush to one or two rings in the centre of the spiral, which is then dried; the drying can be accelerated using an infrared lamp[25].

Sometimes, the specimens for pyrolysis are first finely divided, and plasticisers and other soluble substances are removed by extraction[40]. It is sometimes recommended that the sample be deposited on the wire from alkaline or acidic solutions[38,41].

The removal of solvent and other volatile substances (gases, monomers, moisture, etc. dissolved in the polymers) can apparently be carried out conveniently by heating the polymer, before pyrolysis, at a temperature lower than that at which degradation begins.

In the study of the mechanism of pyrolysis, and sometimes in the study of the fine structural details of a polymer, the more complicated method of thin films is apparently the optimal method, since in thick films the low rate of diffusion, the increase in the part played by secondary reactions, and a number of other factors lead to distortion of the true rate of the process and a change in the qualitative composition of the pyrolysis products[25,42].

Jones and Moyles[26], in a study of the dependence of the composition of pyrolysis products on the size of the sample, demonstrated the advantages of working with small microgramme specimens. They give for comparison two chromatograms, obtained using milligramme and microgramme specimens of styrene homopolymer. The pyrolysis conditions were the same in both cases. The appearance of additional peaks on the chromatogram of the degradation products for the milligramme specimen indicates that the part played by secondary reactions is greater when large specimens are used. Since it is difficult in practice to obtain such a thin film, the degradation is usually carried out on thicker films, with the same thickness in all experiments. According to Voight[42,43], fluctuations of ±50% in the weight of sample produce no significant changes in the chromatographic spectrum of the pyrolysis products.

The structures of various amino-acids were investigated by pyrolysis of thin films of the acids[39]. The pyrolysis products were separated on capillary columns, and detected using a mass spectrometer fitted with a rapid scanning device.

A problem of practical importance concerns the possibility of applying the pyrolytic method to specimens which contain other components in addition to the polymer itself. When the polymer is insoluble in water and the other components soluble, it might be possible to prepare aqueous emulsions or suspensions of these specimens and to deposit them on a spiral and examine them in the usual way. The possibility of carrying out the direct study of industrial specimens was demonstrated by Jones and Moyles[26], who obtained identical chromatograms for the pyrolysis products from a specimen of pure polymer and a specimen containing various inert fillers. The polymer powder was mixed with the natural resin tragacanth (1 wt.%) and water, and applied to the filament in the form of a suspension for subsequent pyrolysis.

The pyrolysis may also be influenced by the carrier gas velocity, which determines the duration of contact between the pyrolysis products and the high-temperature spiral. It has been reported[44] that a decrease in the carrier gas velocity from 60 ml min^{-1} to 40 ml min^{-1} doubled the concentration of benzene in the products of the pyrolysis of polystyrene.

This effect is not always observed, however. Thus in the pyrolysis of atactic polypropylene in the range 320–935°C, the quantity of products did not change with change in the carrier gas velocity[45].

In the study of the structure of a polymer, the pyrolysis conditions should be chosen in such a way that the spectrum of polymer pyrolysis products obtained characterises unambiguously the material subjected to pyrolysis. To satisfy this requirement, it is apparently necessary that the final products be produced as a result of the minimal number of changes, that is, they should have a short "genealogy". It is then obviously easier to follow the relationship between the products of the change and the structure of the specimen being studied.

To reduce the part played by secondary reactions in the formation of the pyrolysis products, the temperatures used are usually not too high (400–800°C) and the time for which the products remain in the hot reaction zone is reduced.

An increase in the number of polystyrene pyrolysis products with increase in the temperature of pyrolysis has been demonstrated[44].

The optimal temperature of pyrolysis is determined by the nature of the analytical problem, the type of polymer studied, and the design of the pyrolysis cell. For example, in the determination of the monomeric composition of a copolymer, the optimal temperature is the temperature at which the relative yield of characteristic pyrolysis product varies most rapidly with change in the composition of the copolymer. The dependence of the percentage yield of methyl acrylate on the potential difference applied to the spiral (the voltage applied to the spiral determines its temperature) for copolymers of methyl methacrylate and methyl acrylate[46] is shown in Fig. 5.

The nature of the carrier gas also determines the conditions of pyrolysis to an appreciable extent. In the pyrolysis of atactic polypropylene, the temperature at which the gaseous pyrolysis products are liberated is about 200 deg higher in an atmosphere of nitrogen than in an atmosphere of hydrogen[47].

In the selection of conditions for the chromatographic separation, allowance must be made for the nature of the pyrolysis products. In the study of the composition of the pyrolysis products from hydrocarbon polymers, it is best to use non-polar phases, but in the study of hetero-atomic compounds it is best to use polar phases. In the analysis of volatile pyrolysis products, it is apparently best to use simultaneously two or three standard chromatographic columns containing phases with different polarities. In view of the wide range of boiling points among the pyrolysis products and also the complexity of the qualitative composition of the products, it is desirable, particularly in the study of the mechanism of thermal degradation, to use capillary columns combined with temperature programming[48]. A combination of pyrolysis in a vacuum and pyrolysis in contact with air has been used to determine the mechanism of the degradation of polystyrene and to identify the pyrolysis products in the range 300–420°C.[49]

It is convenient to express the results of the chromatographic analysis of the pyrolysis products in relative units, using the internal standard method, that is, in the form of line diagrams on coordinates S_i/S_{st} against $\lg(t_i/t_{st})$, where S_i and S_{st} are the areas of the peaks of the ith compound and the standard, and t_i and t_{st} the retention times of the ith compound and the standard. When the results are expressed in this form, it is possible to smooth out the changes due to fluctuations in the dimensions and weights of the specimens, the carrier gas velocities, temperature, etc.[30] Pyrograms obtained for various sample weights and various carrier gas velocities are given in Fig. 6. All these outwardly different pyrograms correspond to the same line diagram.

A large amount of factual material has now been obtained from the study of a wide variety of polymeric materials and non-volatile organic compounds by pyrolytic gas chromatography: Nitrocellulose, α-butyl methacrylate, poly(vinyl alcohol), poly(vinyl chloride), poly(methyl methacrylate),

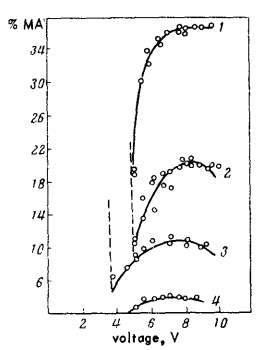

Fig.5. Dependence of the yield of methyl acrylate on the potential difference applied to the spiral for the pyrolysis of methyl methacrylate (MMA)–methyl acrylate (MA) copolymers. Polymer composition: 1) MMA : MA = 1 : 3; 2) MMA : MA = 1 : 1; 3) MMA : MA = 3 : 1; 4) MMA : MA = 9 : 1.

Fig.6. cellulose acetate, polyethylene, polypropylene, polyacrylonitrile, natural and synthetic rubbers, barbiturates, phenothiazines, amino-acids, various aromatic compounds, etc.

Let us consider the main fields of application of pyrolytic gas chromatography.

Identification of polymers. A large number of studies have shown that on pyrolysis under standard conditions various polymers give characteristic chromatographic spectra (pyrograms) of the pyrolysis products. An example is provided by the work of Groten[34], who found that almost all specimens of more than 150 different polymers tested gave different pyrograms. Distinct characteristic pyrograms were obtained for polymers with general formula $(CH_2-CHX)_n$, namely polystyrene, poly(vinyl acetate), polypropylene, and poly(vinyl chloride). Marked differences were observed in the pyrograms of cellulose esters (acetate, propionate, and butyrate), natural materials (silk, cotton, and wool), and the polyalkenes with similar structures: polyethylene, polypropylene, poly(3-methylbut-1-ene), and poly-(4-methylpent-1-ene)[34].

The pyrolytic spectra of a large number of plastics have been studied[50]. The specimens studied (0.2–0.5 mg) were subjected to pyrolysis at 650–750°C for 10 s; the pyrolysis products were separated on a column filled with a sorbent consisting of 5% silicone oil on Chromosorb W. It was noted that for polymers with similar structures, differences in the pyrograms are observed only in the peaks corresponding to the "heavy" products.

Janák[24,51] was the first to apply the method involving the identification of substances from the chromatographic spectra of the products of their pyrolysis on a heated spiral to non-volatile organic compounds (barbiturates, amino-acids, and other biochemical materials). Chromatograms for the products of the decomposition of the potassium salts of various amino-acids are given in Fig. 7. The spectrum of the decomposition products depends to a marked extent on the structure of the amino acids subjected to pyrolysis.

Interesting work on the pyrolytic study of proteins was carried out by Winter and Albro[52]. The observed differences in the pyrograms are related to differences in the structures of the materials taken for pyrolysis. For example, egg and serum albumins are characterised by different pyrograms, since the latter contains four times more cystine.

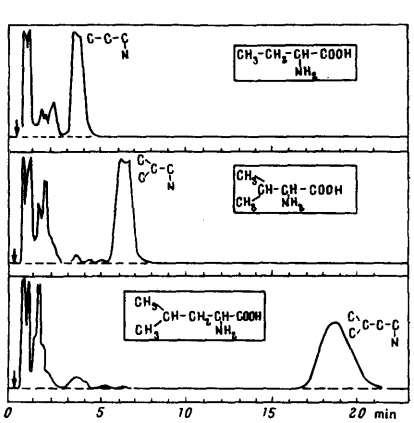

Fig. 7. Pyrograms for various amino-acids (stationary phase squalane, temperature of separation 30°C).

Pyrolytic methods were subsequently developed for the identification of non-volatile aromatic compounds[28,53], benzene clathrates[54], phosphates[55], and other compounds. The results obtained indicate that it is possible to identify polymers and non-volatile compounds from the chromatographic spectra of the products of their degradation under controlled pyrolysis conditions.

The pyrograms obtained in pyrolytic gas chromatography are sometimes figuratively described as "fingerprints", emphasising the empirical nature of the method. For the identification of a polymer, it is necessary to compare its pyrograms with the pyrograms of known specimens and to identify the spectrum. The interpretation of an analysed sample is possible only if the pyrogram of this material has been previously recorded. Inert fillers do not influence the pyrogram of a polymer[26].

In certain instances, definite conclusions regarding the nature and structure of a polymer can be reached merely on the basis of the volatile products obtained. For example, identification of the acid in the products of the pyrolysis of cellulose esters established the nature of the ester being studied.

The characteristic features of the structure of condensation polymers taken for pyrolysis can also be established from the composition of the pyrolysis products, particularly if the polymer contains phenyl groups. The influence of the structure of phenol-formaldehyde resin on its pyrolysis products[56,57] is shown in Fig. 8. It has been shown possible to identify phenolic resins with similar compositions but different degrees of curing[58]. It is pointed out that this identification is impossible by infrared spectroscopy. The analysis of natural and synthetic fibres has been described in detail[59–61].

The extensive application of pyrolytic gas chromatography is being held back, in our opinion, by the lack of standard pyrolysis cells and recommendations on standard conditions of testing.

Analysis of copolymers. In the study of copolymers, it is necessary to have the following information: (1) the concentration of original monomer units in the copolymer, and (2) the structure of the polymeric macromolecule.

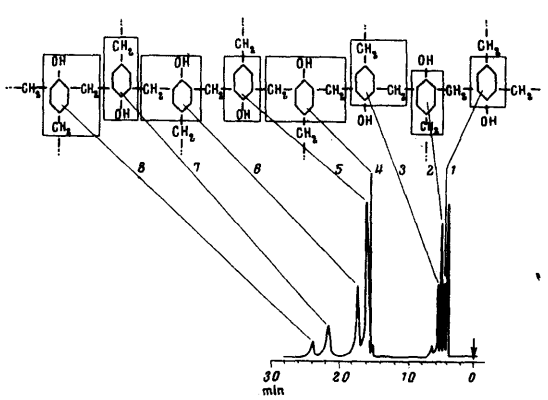

Fig. 8. Correlation between the pyrolysis products and the structure of the original phenol–formaldehyde resin. Temperature of pyrolysis 900°C; capillary column [length 100 m (100 cm? Ed. of Translation), diameter 1 mm]; temperature of separation 170°C; stationary phase polypropylene glycol.
1)–8): identified pyrolysis products.

With certain limitations, pyrolytic gas chromatography can provide this information.

The development of a method for determining the composition of a copolymer usually involves the following operations: (1) the recording of characteristic pyrograms for copolymer specimens with different compositions; (2) the selection of characteristic peaks on the pyrogram, whose magnitudes depend on the composition of the copolymer; and (3) the construction of a calibration curve from the data obtained.

Various copolymers whose compositions have been determined by pyrolytic gas chromatography[57] are listed in the Table, together with the methods of calculation.

An interesting feature is that the results of the determination of the compositions of block copolymers of ethylene and propylene show satisfactory agreement with the results obtained by infrared spectroscopy, and make it possible to determine the composition of the copolymer with an absolute error of 1–3%.[43]

For styrene copolymers it is convenient to select as characteristic peak the peak due to the monomer, the quantity of which (relative to the concentration of styrene in the copolymer) is almost independent of the temperature and of the composition of the copolymer over the range 545–640°C.[71]

The pyrolytic method has been used successfully for the analysis of graft copolymers. The error in composition in the analysis of graft copolymers does not exceed 5 rel.%.[72,73]

The method of pyrolytic gas chromatography is applicable to the analysis of the composition of copolymers even when the use of the classical methods of elementary analysis are restricted by the similarity in the elementary composition of the original monomers.

Esposito[74] proposed the use of the internal standard method in pyrolytic gas chromatography. A solution of the polymer taken as internal standard is suspended with a known quantity of the sample being studied and diluted with a solvent. The resulting solution of the polymers is deposited on a spiral and the pyrolysis is carried out in the usual way (the volatile products are separated by gas chromatography). The concentration of polymer (P) is determined from the formula $P = AB/C$, where A is the corrected area of the characteristic peak, C the area of the peak due to the substance formed by pyrolysis of the internal standard, and B the concentration of internal standard. Esposito[74] used ethyl methacrylate as internal standard. This internal standard method, however, is applicable only to soluble polymers.

It should be emphasised that the method of pyrolytic gas chromatography is sensitive not only to the composition of the copolymer, but also to its structure. This is understandable, since the rupture of chemical bonds in pyrolysis, generally speaking, is not restricted to the boundaries of the original monomeric units. Thus the pyrograms for copolymers with monomeric units alternating in disordered fashion (random copolymers) are in general not identical to the pyrograms of mechanical mixtures of the pure homopolymers, whereas the pyrograms for graft copolymers often correspond to the pyrograms for artificial mixtures of homopolymers with the same composition[72,73]. This result is not unexpected, since if the number of points in the chain of the original polymer at which grafting has taken place is small compared with the number of units in the main chain, the process can be regarded as the degradation of the homopolymers. Two different calibration curves obtained for random copolymers of methyl methacrylate and ethylene and for mechanical mixtures of the corresponding homopolymers[75] are given in Fig. 9. The point corresponding to the graft copolymer lies on the curve for the mechanical mixtures.

Pyrolytic gas chromatography is sensitive to such structural characteristics of the polymer chain as the relative arrangement of the substituents. Groten[34] obtained different pyrograms for polypropylenes with different stereoregularity—atactic and isotactic; this emphasises the extensive possibilities provided by the method.

It has been shown possible[76], in the case of double copolymers of α-alkenes, to use pyrolytic hydrogenation to determine the composition of a copolymer, and also the order of arrangement of the monomer units and the nature of their attachment ("head to head" and "head to tail").

* RPA ratio of peak areas.

** RPH ratio of peak heights.

*** AP area of the peak due to the component indicated in parentheses.

**** HP height of the peak due to the component indicated in parentheses.

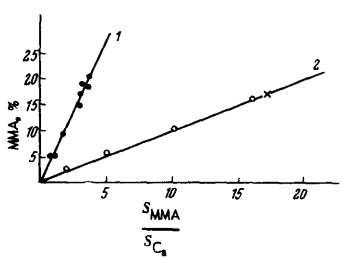

Fig. 9. Dependence of the relative area of two characteristic peaks on the pyrograms of random copolymers (1) and mixtures of polymethyl methacrylate and polyethylene homopolymers (2) on the methyl methacrylate concentration. The point × corresponds to the graft copolymer.

The yield of monomers in the pyrolysis of copolymers which decompose chiefly to the monomer depends on the distribution of the monomer molecules in the copolymer. This is due to the fact that if a polymer decomposes by a radical mechanism with removal of monomer units from the ends of the polymer molecules, the probability of removal of the next monomer unit depends on its immediate neighbour. A method has been developed for calculating the structures of copolymers from the quantity of monomers formed on pyrolysis[77]. The corresponding probabilities can be determined by pyrolysis of copolymers with known composition. The method was tested using styrene–acrylonitrile and styrene–methyl methacrylate copolymers.

In all the above applications of the method, the determination of the individual compositions of the products is not necessary. The study of the mechanism of degradation is a much more complex problem, since it is necessary to obtain as far as possible the complete spectrum of pyrolysis products and to determine their qualitative composition. In these instances it is desirable to carry out the pyrolysis in thin films, to use capillary columns with temperature programming[48], and to use specific, for example chemical, methods of peak identification[78]. Chromatography combined with mass spectroscopy will obviously be of considerable assistance in the interpretation of the chromatographic peaks.

Berton[79], for the example of a number of polymeric materials, proposed the use of selective galvanic detection of the pyrolysis products, based on the reaction of the pyrolysis products with the electrolyte of the detector. This reaction leads to a change in the polarisation of the electrode and the electric current. The nature of the electrolyte determines the classes of compounds detected. The use of a saturated solution of chromium(VI) oxide in nitric acid as electrolyte makes it possible to detect alcohols, aldehydes, and various unsaturated substances, with a high sensitivity[79]. The use of galvanic detection with the above electrolyte appears particularly promising for the analysis of the products of oxidative pyrolysis.

In some instances the identification of pyrolysis products can be carried out gas-chromatographically from their molecular weights, using a density detector and carrier gases with different molecular weights[80] or two katharometers, one of which operates as a density detector[81]. In the latter instance, when certain conditions are satisfied, the ratio of the signals from these detectors is directly proportional to the molecular weight of the substance. The study of processes which take place in polymers at elevated temperatures and are accompanied by the liberation of products volatile at the temperature of the experiment is also of interest.

Garzó and Székely[82] studied the thermal processes involved in the curing, decomposition, and depolymerisation of silicone polymers, by using a carrier gas to carry the volatile reaction products, at measured time intervals, from the micro-reactor into the chromatograph.

Finally, it may be noted that the published experimental material makes it possible to recommend the pyrolytic method for research purposes, and in some instances for technological control. A necessary condition for the extensive introduction of this method, however, is the development of standard apparatus and standardisation of the pyrolysis conditions (the size of sample, temperature of pyrolysis, conditions of chromatographic separation, etc.).

Future Prospects for the Development of Degradative Chromatographic Methods

In the study of the composition and structure of polymers, it is undoubtedly desirable, in addition to pyrolysis, to apply to polymers other, possibly more structurally sensitive, degradation methods, and also various combinations of these methods. Thus pyrolytic gas chromatography can be regarded as one version of degradative gas chromatography.

Scholz and coworkers[83] proposed the characterisation of polymers from the spectra of the products of their oxidative degradation. The polymer being studied is deposited on a solid inert carrier and placed in a short additional column placed between the device used to introduce the sample and the chromatographic separating column. The temperature of the additional steel column containing the polymer being studied can be controlled by means of a thermostat in the range 100–600°C. Oxidation of the polymer takes place on contact with oxygen (1 cm^3 of oxygen is introduced into the stream of inert carrier gas). The volatile oxidation products are carried by the stream of carrier gas into the chromatographic column for separation. The spectrum of volatile products from the oxidative degradation is characteristic for each polymer.

As noted above, a combination of thermal degradation and thermal oxidation has been used to identify pyrolysis products and to study the mechanism of pyrolysis[49]. It has been proposed[84] that the degradation of the polymer be carried out in a current of carrier gas under the conditions of the electric discharge (300 V, 1 mA). It has been shown for several polymers that the composition of the degradation products corresponds to the products formed under the conditions of pyrolysis at 600°C.

Kolbanovskii and coworkers[85], in the Institute of Petrochemical Synthesis, developed a new method of degradative gas chromatography—radiochemical chromatography.

In radiochemical chromatography, the polymer is characterised by the spectrum of volatile radiolysis products. After γ-irradiation (dose ~ 100 Mrad) of a specimen of the polymer at room temperature in an evacuated glass ampoule, the gaseous radiolysis products were analysed. About 50 specimens of different polymers were studied, and a characteristic spectrum of radiolysis products was obtained for each polymer. The method is sensitive to the structure of the polymer and the composition of the copolymer. Different line diagrams were obtained for natural rubber, gutta percha, SKD synthetic rubber, and *trans*-polybutadiene. All four specimens, which taken in pairs differ only in their spatial configuration, gave different spectra. In a study of the radiolysis of copolymers, a linear relationship was observed between the relative yield of ethylene and the concentration of acrylonitrile in its copolymer with butadiene. The method is very sensitive to branching of the carbon chain. High-pressure and low-pressure polyethylenes also give different spectra of products from radiochemical degradation.

In addition to purely analytical applications, the use of degradation methods to study the thermal stability of polymers and non-volatile compounds in various gaseous media (and also under the influence of radiation), for the rapid determination of the efficiency of various inhibitors, etc., is of particular interest. The possibility of carrying out the studies with very small quantities of substance, the simplicity of the method, and its high resolving power are opening up extensive possibilities for the application of gas chromatography for the estimation and study of non-volatile polymeric materials.

The development of new versions of degradative gas-chromatographic methods will undoubtedly open up new horizons in the study of polymeric materials.

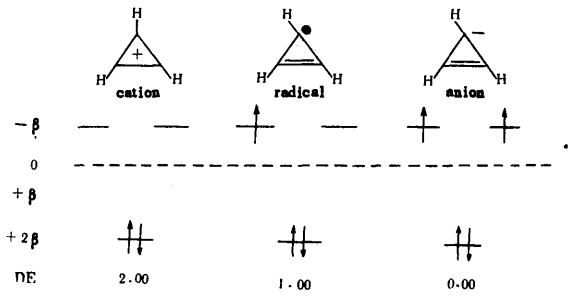
THE CYCLOPROPENYL CATION

I. A. D'yakonov and R. R. Kostikov

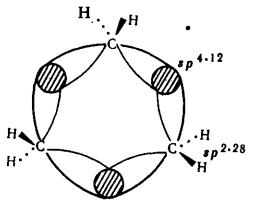


CONTENTS

1. The cyclopropenyl cation 557
2. Cyclopropenyl cations containing aryl and alkyl substituents 558
3. Reactions of cyclopropenyl cations with water, alcohols, and other nucleophilic reagents 558
4. Aromatic substitutions involving the cations 560
5. Reactions of cyclopropenyl cations with compounds containing an active methylene group 561
6. Methods of preparing cyclopropenyl cations 561

1. THE CYCLOPROPENYL CATION

A considerable amount of work has now been published on the three-membered analogue of the tropylium cation—the aromatic cyclopropenyl cation—and the present paper gives a brief survey of the literature on the preparation and the electrophilic character of this cation. A recent review[1] of the reactions of the cyclopropenyl cation and allied compounds paid very little attention to this question.



According to Hückel's rule, a planar monocyclic system having trigonal hybridisation of the carbon atoms and containing $4n + 2$ π-electrons possesses a filled electronic configuration and enhanced stability[2]. The simplest system satisfying Hückel's aromaticity conditions with $n = 0$ is the cyclopropenyl cation.

The accompanying diagram shows the molecular levels and the delocalisation energies (DE) for the cyclopropenyl cation, radical, and anion calculated by the LCAO-MO method[3]. The above scheme shows that the cation possesses the maximum delocalisation energy, while the anion has DE = 0 and is in a triplet state. Consequently these species can be arranged in the sequence—cation > radical > anion—of diminishing stability. For the cyclopropenyl cation DE = 2β, which is somewhat lower than the delocalisation energy of the tropylium cation (2.99β),[3] but considerably exceeds that for the allyl cation (0.8β).[4] Nevertheless, in spite of the considerable delocalisation energy, the cyclopropenyl cation itself has not yet been obtained, and several authors[1] cast doubt on the possibility of its existence. The strongest destabilising influence on the cation is exerted by the angular strain of the three-carbon ring. It is usually considered that the energy of the angular strain in cyclopropane is 27.6 kcal mole^{-1},[5] and for cyclopropene an estimate of 55 kcal mole^{-1} has been made[6]. This energy would increase still more in the cation, probably to 74 kcal mole^{-1} [1,7] as a consequence of the change in the valency state of the carbon atoms on formation of the cation from cyclopropene.

Baeyer's theory of angular strain has been discussed by Walsh[8] and also by Coulson and Moffit[9]. They reached

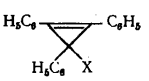
the conclusion that a satisfactory description of the state of the bonds in cyclopropane can be obtained only on the assumption that the type of hybridisation of the atomic orbitals of the ring carbon atoms is other than sp^3:

Coulson and Moffit calculated that the atomic orbitals involved in the formation of C–H bonds have $sp^{2.28}$ hybridisation.

It must be noted here that, in calculating the energies of strain in cyclopropane and cyclopropene from their heats of combustion or heats of hydrogenation compared with those of unstrained cycloalkanes, these workers took no account of the change in valency state of the carbon atoms on passing from unstrained to strained rings. Actually, however, such transfer of a carbon atom is accompanied by a change in its valency state from the first to the second in cyclopropane, and to the second and the third in cyclopropene. We have attempted to allow for these changes [10] by using in the calculation values of the C–H bond energies in ethylene and acetylene [11], and have thus obtained higher values for the energies of strain in cyclopropane and cyclopropene than had been accepted hitherto (48.6 and 87 compared with 27.6 and 55 kcal mole^{-1} respectively). It is quite obvious that the energy of strain for the cyclopropenyl cation, too, will be greater than the value calculated previously (102.5 instead of 74 kcal). Results obtained by Wiberg et al. on the heats of dissociation of propene and cyclopropene into a hydride ion and the corresponding carbonium ions are consistent with these calculations. They show [6] that the cyclopropenyl cation is only 10 kcal more stable than the allyl cation. Such a small difference can be explained by the presence of a high energy of strain in the cyclopropenyl cation, which brings its delocalisation energy close to that for the allyl cation.

Another cause of the instability of the cyclopropenyl cation may be electrostatic repulsion between positively charged carbon atoms of the three-membered ring. It must be regarded as proved that, in this cation just as in the tropylium cation, the positive charge is uniformly distributed among all the ring carbon atoms. X-Ray examination of triphenylcyclopropenyl perchlorate [12] has shown that the interatomic distances in the C–C bonds of the three-membered ring all have the same value of 1.37 Å. Hence it follows that the charge in this compound is uniformly distributed among the three carbon atoms forming the ring.

2. CYCLOPROPENYL CATIONS CONTAINING ARYL AND ALKYL SUBSTITUENTS



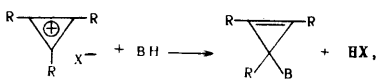
Manatt and Roberts [13] calculated the delocalisation energies of the mono-, di-, and tri-phenylcyclopropenyl cations by the simple Hückel molecular-orbital method. Table 1 gives the values calculated by these [13] and other authors [3,7,14,15] for the total and excess delocalisation energies of these cations. The latter parameter represents the difference between the total delocalisation energy of a given cation DE and the delocalisation energy of the cyclopropenyl cation itself ($DE_0 = 2.00$) together with the sum of the delocalisation energies of the phenyl groups (ΣDE_{ph}): $\Delta DE = DE - DE_0 - \Sigma DE_{ph}$.

TABLE 1. Total and excess delocalisation energies (in β-units) of phenylated cyclopropenyl cations.

No. of C_6H_5	DE	ΔDE	Ref.
0	2.00	—	3
1	4.39	0.39	13
	4.40	0.40	14
2	6.70	0.70	13
	6.78	0.78	7,14
3	9.19	1.19	13
	9.16	1.16	15

Table 1 shows that replacing a hydrogen atom in the cyclopropenyl cation by a phenyl radical increases both the total and the excess delocalisation energy of the ion. Breslow and his coworkers studied the influence of the number and nature of substituents on the ease of formation of cyclopropenyl cations [7,16,17], and found that their stability increases primarily with increasing degree of substitution. From this it followed that the cyclopropenyl cation itself will be the most unstable. It was further found that, with the same degree of substitution of the ring, electron-donor substituents have a more favourable effect than have electron-acceptor substituents on the formation of the cation. Dialkoxycyclopropenyl cations proved to be more stable than diaryloxycyclopropenyl cations [18–20].

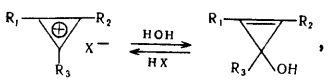
The ease of formation of a cyclopropenyl cation from a cyclopropene derivative depends both on the ring substituents and on the nature of the anion which is eliminated. Thus in triphenylcyclopropenyl bromide, for example, the bromine is present as an anion, whereas in tetrabromocyclopropene all the bromine atoms are combined covalently [21]. A series of cyclopropene derivatives is now known in which a definite relationship can be observed between the nature of the atom of group X and the character of the C–X bond in compounds of the type



where X = H, OCH_3, CN, 2,4,5-$(NO_2)_3C_6H_2O^-$, Br^-, BF_4^-. In the first three of these compounds the C–X bond is found to be covalent, and in the latter three it was ionic. A similar series is known also for derivatives of the tropylium cation [22]. Vol'pin et al. [23] showed that the weakest acid whose anion forms an ionic compound with the tropylium cation is isocyanic acid HNCO ($K_a = 1.2 \times 10^{-4}$), while the strongest acid with which the same cation will give a covalent compound is benzoic acid ($K_a = 6.3 \times 10^{-5}$).

3. REACTIONS OF CYCLOPROPENYL CATIONS WITH WATER, ALCOHOLS, AND OTHER NUCLEOPHILIC REAGENTS

As follows from the preceding Section, a greater or smaller concentration of cationic charge on the carbon atoms of the three-membered ring is determined by the number and nature of the substituent groups. The more delocalised is the cationic charge on the substituent groups,

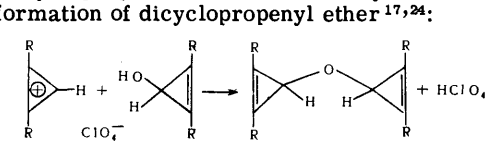


the greater its stability and the smaller the electrophilic activity. With less delocalisation of the charge, the electrophilic properties of the cation will be more strongly developed.

Just like the aromatic tropylium cation, the cyclopropenyl cation can take part in electrophilic substitution reactions, represented by the general equation

where R = Alk, Ar, or Hal; BH is a nucleophilic reagent, e.g. HOH, CH_3OH; and X = Br, BF_4, ClO_4.

The simplest reaction of this type is the hydrolysis of cyclopropenyl salts to the corresponding cyclopropenols. In this case the electrophilic cation attacks the nucleophilic water molecule. Breslow et al. have shown[7] that this can be regarded as an equilibrium:



where HX is the conjugate acid. The equilibrium constant K_{R^+} is given by the equation

$$K_{R^+} = \frac{[C_3H_3OH]\cdot[H^+]}{[C_3H_3^+]}$$

where $[C_3H_3OH]$ and $[C_3H_3^+]$ are the concentrations of cyclopropenol and cyclopropenyl cation respectively. This constant can be more conveniently expressed in the form $pK_{R^+} = -\lg K_{R^+}$, which is numerically equal to the pH at which the cyclopropenyl salt is 50% converted into the cyclopropenol.

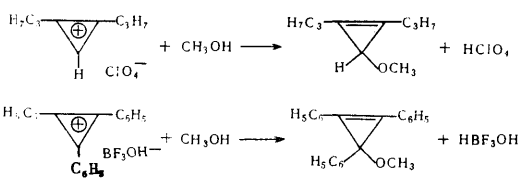


Table 2 lists experimental values of pK_{R^+} obtained by Breslow and his collaborators, and of ΔDE for the cyclopropenyl cations calculated by the LCAO-MO method. The latter represent the difference in delocalisation energy between the cation and the corresponding cyclopropenol. Table 2 clearly shows that ΔDE and pK_{R^+} are directly related. It is noteworthy also that, while the triphenylcyclopropenyl cation is stable at pH 3, the tripropylcyclopropenyl cation is stable even at pH 7. Hence it may be concluded that alkyl groups stabilise the cyclopropenyl cation better than do aromatic groups.

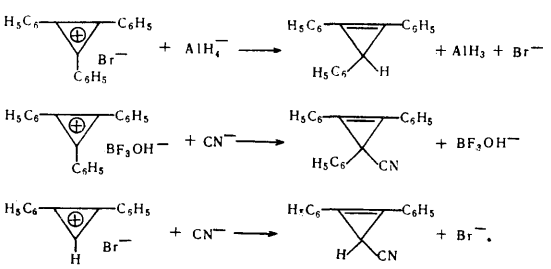
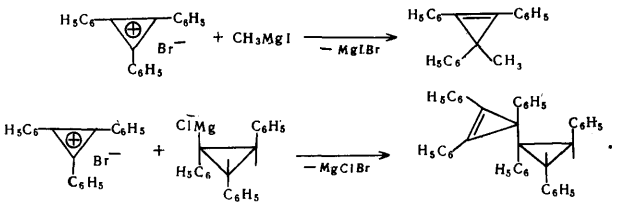
In the case of the above equilibrium hydrolysis of disubstituted cyclopropenyl salts, account must be taken of the possibility that the cation will undergo another, irreversible reaction, involving its hydrolysis product, dipropyl(or diphenyl)cyclopropenol. This secondary reaction results in the formation of dicyclopropenyl ether[17,24]:



where R = C_3H_7, C_6H_5. Since the rate of the equilibrium reaction far exceeds that of the secondary reaction, the occurrence of the latter does not complicate study of the former: equilibrium is established before appreciable quantities of the dicyclopropenyl ether are able to accumulate in the reaction products.

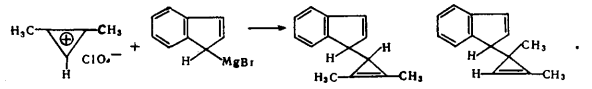
Substitutions in which the cyclopropenyl cation acts as an electrophilic reagent take place also with alcohols. For example, dipropyl- and triphenyl-cyclopropenyl cations react with methanol to form respectively methoxydipropylcyclopropene[17] and methoxytriphenylcyclopropene[25]:

Like the tropylium cation the cyclopropenyl cation reacts also with lithium tetrahydroaluminate[26] and with potassium cyanide[16,25,27], the tetrahydroaluminate and cyanide anions acting as nucleophiles. The reaction products are in both cases covalently bound compounds. Examples of these reactions given below involve the tri- and di-phenylcyclopropenyl cations



The electrophilic character of the cyclopropenyl ion is exhibited also in its ability to react with other typical nucleophilic reagents, such as organomagnesium and organolithium compounds. The triphenylcyclopropenyl cation reacts with methylmagnesium iodide and with *trans*-1,2,3-triphenylcyclopropylmagnesium chloride, to yield

TABLE 2. Influence of substituents on the position of the cation–cyclopropenol equilibrium.



Substituted cyclopropenyl cation	ΔDE[a]	ΔDE[b]	pK_{R^+} ±0.05	Ref.
Unsubstituted	2.00	—	>0[c]	16

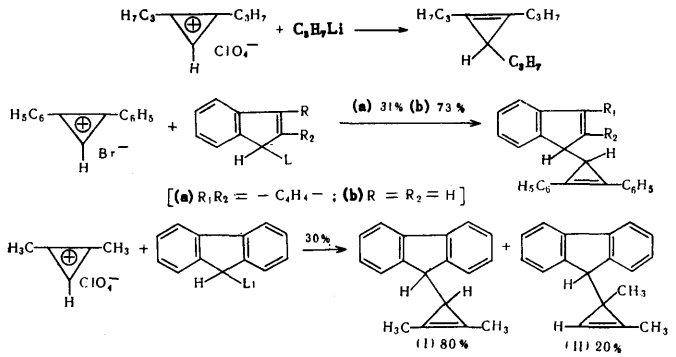
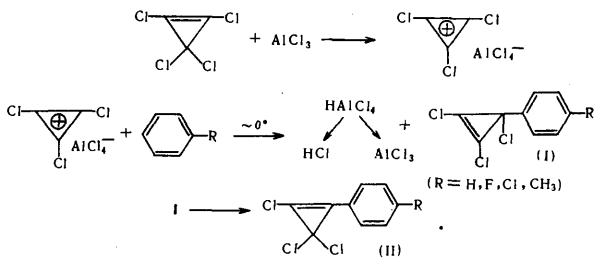
respectively methyl-1,2,3-triphenylcyclopropene and 1,2,3-triphenyl-(*trans*-1,2,3-triphenylcyclopropyl)cyclopropene [28]:

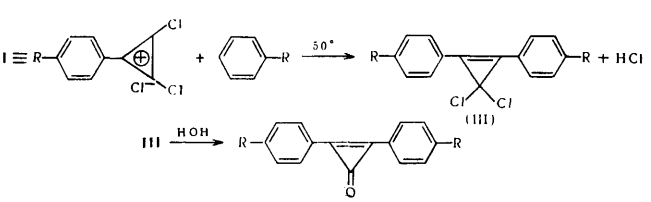


Interaction of the dimethylcyclopropenyl cation with indenylmagnesium bromide gives a mixture of two isomeric indenyldimethylcyclopropenes [28]:

The appearance of two isomers in the reaction product indicates that the positive charge in the cyclopropenylium cation is distributed among its three ring carbon atoms, and is not fixed on one of them. Since two of the three positions of the charge in the ring are equivalent, two—not three—isomers are formed.



In all the reactions of organolithium compounds with cyclopropenyl cations, the electrophilic cation displaces the metal in the form of a cation from the organolithium compound [17,29,30]:

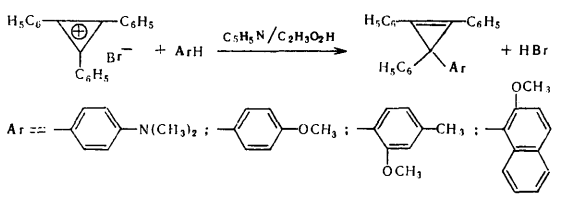


In conformity with the result observed for the reaction of dimethylcyclopropenyl with indenylmagnesium bromide, two isomeric cyclopropene hydrocarbons might have been expected to result also from the interaction of diphenyl- and dimethyl-cyclopropenyl cations with organolithium compounds. This has been confirmed, however, only for the reaction of the dimethylcyclopropenyl cation with fluorenyl-lithium. In other cases the expected isomers could not be isolated. The fourfold yield of the isomer (I) relative to that of (II) is probably to be explained not only by the not entirely uniform distribution of the cationic charge inside the cyclopropenyl ring but also by the unexpected magnitude of the steric hindrance accompanying the attack of the nucleophilic reagent on the electrophilic centres of the cation—ring carbon atoms 1 (or 2) and 3.

4. AROMATIC SUBSTITUTIONS INVOLVING THE CATIONS

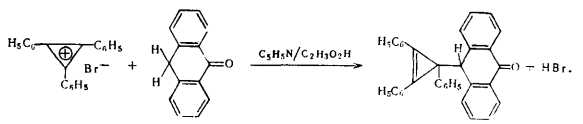
The cyclopropenyl cation can take part in the electrophilic substitution of an aromatic nucleus, just like other carbonium ions. An example is the interaction of the trichlorocyclopropenylium cation with benzene, toluene, chlorobenzene, and fluorobenzene, studied by Tobey and West [31,32]. The reaction proceeds under the conditions of the Friedel–Crafts reaction. The aluminium chloride employed as catalyst is necessary to convert the tetrachlorocyclopropene into a trichlorocyclopropenyl salt. If the reaction is conducted at 0°C, it can be represented by the equations

The trichloro-derivative (I), which is the normal product of reaction between the cation and an aromatic hydrocarbon or its halogeno-derivative, cannot be isolated, since under the conditions of the reaction it undergoes allylic rearrangement into the isomer (II), which is more stable as a consequence of conjugation of the endocyclic double bond with the aromatic ring. This isomer is the final product of the Friedel–Crafts reaction. However, the conversion of the cyclopropene (I) into (II) is not a simple allylic isomerisation. It must probably be interpreted as reaction of the aryldichlorocyclopropenyl cation, already present in (I), with its own chloride anion, which attacks the sterically least hindered site in this cation. This is consistent with the fact that, when the reaction with the trichlorocyclopropenyl cation is conducted at a higher temperature (50°C), the reaction products are found to contain diphenyl-*gem*-dichlorocyclopropenes (III), formed by secondary interaction of (I) with the initial aromatic derivative. The compounds (III) are readily converted by water into the corresponding cyclopropenones [31]:



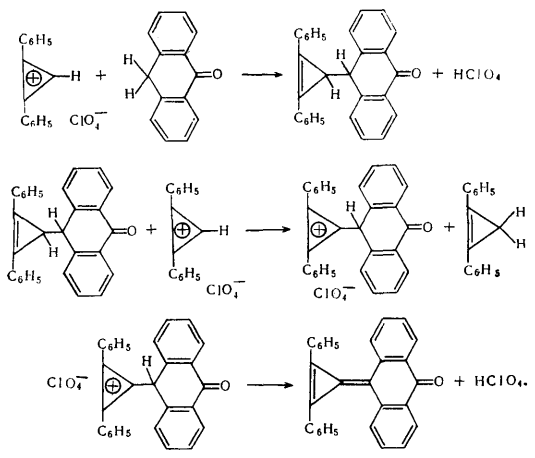
where R = H, F, Cl, CH_3.

This reaction can thus be regarded as a kind of "capture", by the aromatic hydrocarbon or its halogeno-derivative, of the saltlike compound (I), which exists only at a relatively low temperature. Attempts to obtain in this way triarylcyclopropenyl cations or tetra-arylcyclopropenes by the more prolonged and severe heating of trichlorocyclopropenyl tetrachloroaluminate with the same benzene derivatives proved unsuccessful [32].



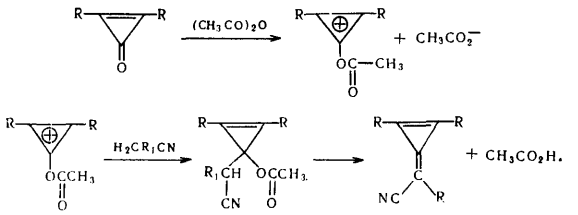
In contrast to tetrachlorocyclopropene, a cyclopropenyl cation is already present in triphenylcyclopropenyl bromide. In this case, therefore, cyclopropenylation of the aromatic ring can be carried out even in the absence of aluminium chloride [33]. No other cycloalkenyl or alkyl

halide alkylates an aromatic ring in the absence of a catalyst. This can be regarded as some indication of a cationic mechanism for the Friedel–Crafts reaction.

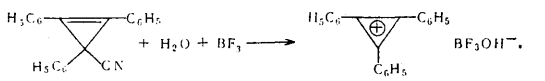


5. REACTIONS OF CYCLOPROPENYL CATIONS WITH COMPOUNDS CONTAINING AN ACTIVE METHYLENE GROUP

The literature contains a large number of examples of the reactions of tropylium cations with compounds containing a reactive methylene group. Little work has been done on such reactions with cyclopropenyl cations. It is known, however, that heating triphenylcyclopropenyl bromide with anthrone in the presence of pyridine and acetic acid yields 10-(1,2,3-triphenylcycloprop-2-enyl)anthrone[33]:

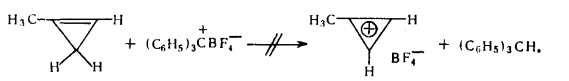


Another example is the reaction between anthrone and diphenylcyclopropenyl perchlorate. This gave a new compound of the triafulvene (methylenecyclopropene) series[33], 10-(2,3-diphenylcycloprop-2-enylidene)anthrone. The formation of this ketone can be represented by the following sequence of reactions



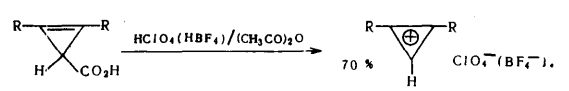
The first stage in the process is electrophilic substitution of a methylene proton in anthrone by the diphenylcyclopropenyl cation with formation of 10-(2,3-diphenylcycloprop-2-enyl)anthrone. In the second stage the cyclopropenyl cation reacts with the reaction product of the first stage, the latter losing a hydride ion and anthronyldiphenylcyclopropenyl perchlorate being formed. In the third (and last) stage of the reaction, perchloric acid is eliminated, and the final product—10-diphenylcyclopropenylideneanthrone—is obtained.

Compounds of the triafulvene series are formed also when dipropyl- and diphenyl-cyclopropenones are heated with malononitrile or cyanoacetic ester in the presence of acetic anhydride[20,34–38]. Available data on the mechanism of this reaction indicate that the primary product is the acetoxydipropyl(or diphenyl)cyclopropenyl cation, formed by the action of acetic anhydride on the dipropyl(or diphenyl)cyclopropenone[37]. The resulting cation then undergoes a substitution reaction with the labile hydrogen atoms of the methylene group in the malononitrile (or cyanoacetic ester). Subsequent elimination of acetic acid from the cyclopropenyl acetate formed as an intermediate stage leads to the triafulvene:

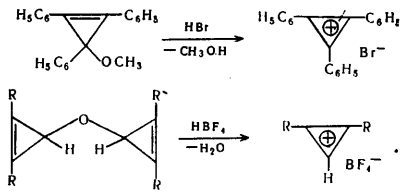


6. METHODS OF PREPARING CYCLOPROPENYL CATIONS

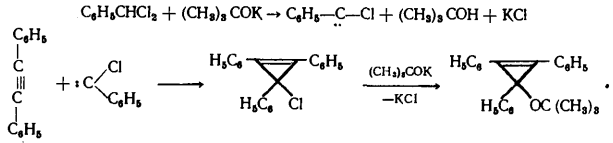
The first experimental confirmation of the existence of the two-π-electron aromatic cyclopropenyl system was obtained by Breslow, who treated cyano-1,2,3-triphenylcyclopropene with a moist ethereal solution of boron trifluoride and isolated triphenylcyclopropenyl hydroxotrifluoroborate[27]:



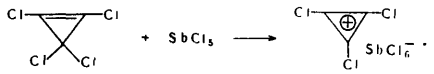
The unsubstituted cyclopropenyl cation has not yet been obtained[6]. Several investigators consider, however, that the ion $C_3H_3^+$ (M = 39), which is frequently met in the mass spectra of various organic compounds, has the cyclopropenyl cation structure rather than that of a prop-2-ynyl or allenyl cation[6,39–41]. Nor has it proved possible to obtain the methylcyclopropenyl cation[42] by abstracting a hydride ion from the hydrocarbon by means of the triphenylmethyl cation:



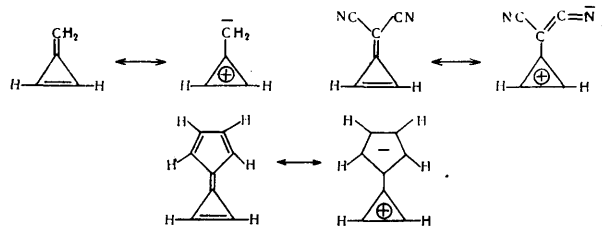
Formation of certain mono- and di-substituted cyclopropenyl cations has been observed mass-spectrometrically in the fragmentation of monocyclic 2-pyrones[43].



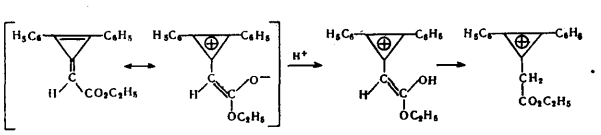
The simplest stable cation known at the present time is the dimethylcyclopropenyl ion[28]. To obtain this ion, and also several of its disubstituted homologues, wide use is made of a method proposed for preparing the tropylium cation from cycloheptatrienecarboxylic acid[44]. This method consists essentially in converting the cyclopropene(or cycloheptatriene)carboxylic acid, by means of a solution of perchloric or fluoroboric acid in acetic anhydride, into the cyclopropenyl (or tropylium) perchlorate or fluoroborate[17,26,28,45]:



Good yields of cyclopropenyl cations are obtained also by the cleavage of cyclopropenyl ethers [7,16,17,19,25,46] with mineral acids:

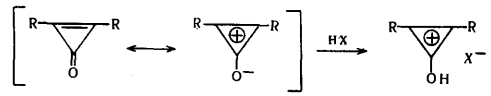


Ethers of cyclopropenols can be obtained by the interaction of arylchlorocarbenes with mono- or di-arylacetylenes in the presence of excess of an alkali-metal alkoxide: e.g.



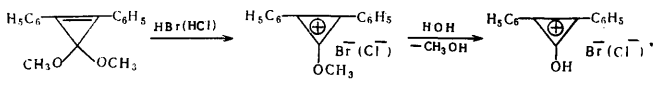
As already mentioned above, tetrachloro- and tetrabromo-cyclopropenes react with Lewis acids ($AlCl_3$, $SbCl_5$) to give stable trihalogenocyclopropenyl cations [21]:

Vigorous attempts have recently been made to synthesise methylenecyclopropene (triafulvene) and its derivatives [47-49]. Success has been achieved with derivatives containing electronegative substituents (CN, $COOC_2H_5$) in the methylene group of triafulvene [34-36,38,50,51] and with compounds having this group in a pentadiene ring (calicenes) [20,28-30,37,52,53]. Calculations made by the simple Hückel method indicate that triafulvene should be relatively stable (DE = 0.96β [3,13]). This result and also the calculated dipole moment of triafulvene (μ = 5.26 [2], 5.00 [54], 1.21 [55] D) are consistent with the view [34] that a considerable contribution to its ground state is made by a dipolar structure.



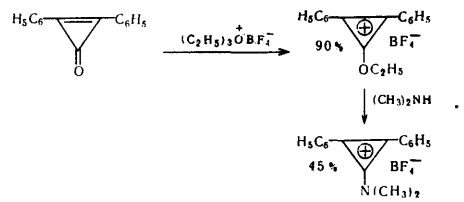
This contribution can be strengthened by introducing electronegative substituents into the methylene group of the triafulvene. The presence of a dipolar structure in the ground state of the molecule is indicated by the tendency of certain triafulvene derivatives to form salts of the corresponding cyclopropenyl derivatives by the action of strong mineral acids: e.g. [51]

This reaction has quite often been used to confirm the structure of triafulvenes [20,28,46,50].



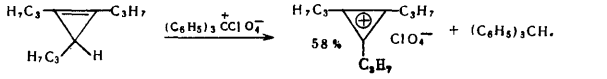
Quantum-mechanical calculation by the LCAO-MO method indicates [3] that cyclopropenylidenecyclopentadiene (calicene) should possess a delocalisation energy of 2.94β (almost 50% greater than that of benzene) and exhibit a dipole moment, as a consequence of its tendency to form a dipolar structure [53] in which the three-carbon ring is positively charged, while the five-carbon ring is negatively charged.

The oxygen analogue of methylenecyclopropene—cyclopropenone—is unknown, like methylenecyclopropene itself. However, several disubstituted cyclopropenones are now known [18,19,56-60]. In agreement with theoretical predictions, the physical and chemical properties of these compounds indicate a considerable contribution by a dipolar structure to the ground state. As a result, cyclopropenones are able to yield salts with strong mineral acids:



where R = C_3H_7, C_6H_5 and X = Cl, Br.

This reaction involves the formation of hydroxycyclopropenyl cations. The hydroxydiphenylcyclopropenyl cation can be obtained also by dealkylating 3,4-dimethoxydiphenylcyclopropene with a hydrohalic acid [56], and then hydrolysing [19,57,58] the methoxydiphenylcyclopropenyl cation formed as intermediate:



Several new derivatives of the cyclopropenyl cation have recently been prepared from diphenylcyclopropenone [19]:

On treatment with triethyloxonium fluoroborate, diphenylcyclopropenone is converted into ethoxydiphenylcyclopropenyl fluoroborate, which with dimethylamine yields *NN*-dimethylaminodiphenylcyclopropenylium fluoroborate. This last compound is so difficult to hydrolyse with water that it can be recrystallised from it.

At the present time the most widely used method for obtaining cyclopropenyl cations is abstraction of a hydride ion from derivatives of cyclopropene [17,28-30,61,62]: e.g.

INTRODUCTION

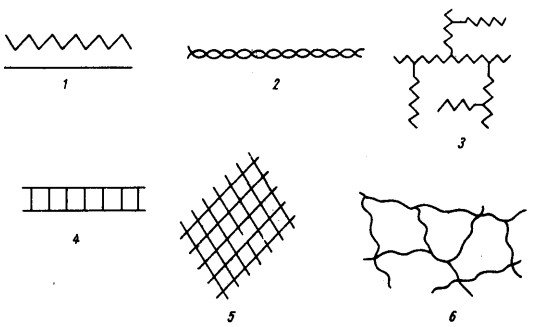
The accompanying diagram illustrates schematically the molecular structures of all polymers known at the present time.

Polymers of types *1*, *3*, and *6* have been studied for many years. Research workers have recently been paying increasing attention to polymers whose molecules correspond to the remaining three types (*2*, *4*, *5*). This is not accidental, since regularly arranged cyclic units confer on the polymer exceptionally high resistance to the action of temperature, radiation, and corrosive media. This applies especially to aromatic systems.

Structures of types *4* and *5* are distinguished from the others by the presence of regularly fused cyclic systems. The structure of these cyclic systems resembles either a rope ladder, whence the name "ladder polymers", or a parquet, when an ideal network structure is formed ("parquet polymers"). These two types of macromolecular structures will be briefly discussed in the present review.

I. LADDER POLYMERS

The rings in ladder polymers comprise either carbon atoms alone (carbocyclic ladder polymers), carbon together with various heteroatoms, such as oxygen, nitrogen, phosphorus, etc. (heterocyclic ladder polymers), or no carbon at all. The last type include inorganic and organoelementary polymers, the rings of which contain oxygen atoms alternating with silicon, titanium, etc. atoms to which are attached organic or inorganic substituents.



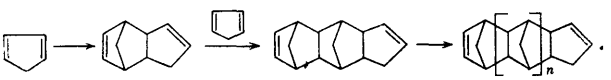


Diagram of structure of various polymers:
1) linear polymers; 2) spiran polymer; 3) branched polymer; 4) ladder polymer; 5) parquet polymer; 6) three-dimensional network polymer.

A. CARBOCYCLIC LADDER POLYMERS

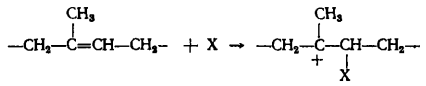
This fairly considerable group of ladder polymers may contain rings of two types—(1) alicyclic or hydroaromatic and (2) aromatic—which show fundamental differences in modes of preparation and in properties, so that the two groups will be considered separately.

1. Alicyclic Ladder Polymers

A representative of ladder polymers having five-membered carbon rings, which has been known for a long time, is polycyclopentadiene. At room temperature cyclopentadiene readily forms a dimer, and by prolonged heating Staudinger[1] was able to obtain tri-, tetra-, and pentacyclopentadienes and products of higher molecular weight. Polymerisation proceeds by the Diels–Alder reaction[2–4] as follows:

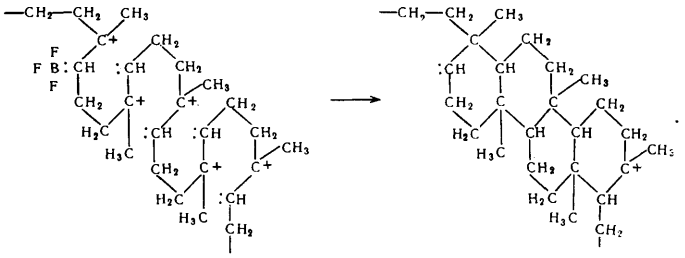
The melting point increases sharply with increase in molecular weight. Thus the di-, tri-, tetra-, and pentamers have melting points of 32°, 60°, 190°, and 270°C respectively, while polymers of higher molecular weight soften with decomposition at 373°C. Tetracyclopentadiene is readily soluble in benzene, whereas pentacyclopentadiene is very sparingly soluble, and the products of higher molecular weight are completely insoluble in benzene[1].

Cyclic polymers of butadiene, isoprene, and their derivatives are of great theoretical and practical interest. A good review of cyclised rubber has been given by van Veersen[5,6] who has made a valuable contribution to the study of the structure, properties, and methods of preparation of this polymer.



Harries[7] first reported that he had obtained an insoluble cyclisation product of natural rubber by treating a benzene solution of the latter with sulphuric acid. Later Kirchhof[8] and Staudinger[9] observed that the physical and chemical properties of rubber were greatly changed by the action of sulphuric acid. Staudinger[9] obtained a brittle solid having the same empirical formula as the original rubber. Fisher[10] developed the technical production of cyclised rubber: a mixture of rubber, sulphuric acid, and kieselguhr (or titanium oxide) was heated and stirred at 130°C. Besides sulphuric acid, aromatic sulphonic acids could be used successfully.

Bruson et al.[11] cyclised rubber in solution, using such Friedel–Crafts catalysts as $SnCl_4$, $TiCl_4$, and $FeCl_3$ for this purpose.

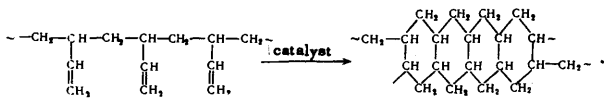


Cyclisation was found to take place under the influence of electrophilic reagents[12] or on heating[13]. Staudinger showed[14] that cyclised rubber can be obtained from hydrochlorinated rubber by the prolonged heating of a solution of

the latter in toluene in the presence of zinc chloride. Hydrobrominated or hydriodinated rubber can also be used for this purpose.

A mechanism of chain initiation and growth in the cyclisation of rubber was suggested by van Veersen[5], according to which a double bond first interacts with an electron acceptor X;

where X = H^+, $AlCl_3$, BF_3. The resulting carbonium ion, in its turn, reacts as an acceptor for the next double bond:



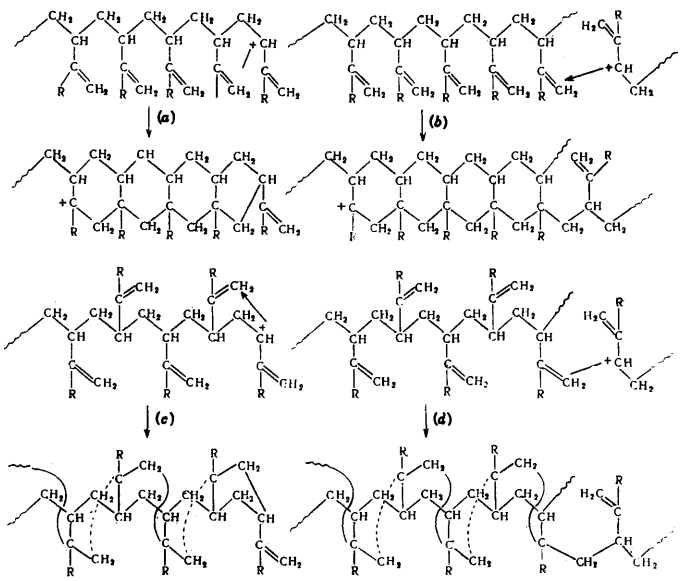
In this way macromolecules containing fused six-membered rings are formed. In van Veersen's view[5] the probability of interaction between different macromolecules is very small, and cyclised rubber represents an aggregate of fused six-membered rings separated by shorter or longer polyisoprene sections.

With increasing degree of cyclisation the material becomes harder and harder, and when the content of cyclic groups is sufficiently large, brittleness ensues. Polymers in which 60–80% of the double bonds have disappeared by cyclisation have softening points of 50–80°C.[6] The cyclised polymer is stable to the action of 10% H_2SO_4 and 50% NaOH at room temperature, but it is rapidly oxidised by oxygen owing to the presence of a tertiary hydrogen atom.

Considerable progress has been made during recent years in the synthesis of polymers using catalysts of ionic type. Attention has been paid also to diene monomers. It was found that the chemical nature, composition, and quantity of the ionic catalyst has a fundamental effect on the structure, properties, and yield of polymers obtained from conjugated dienes. It was established that insoluble products can be formed by the polymerisation of dienes in the presence of titanium tetrachloride and organometallic compounds[15–19].

When isoprene is polymerised in the presence of triethylaluminium and titanium tetrachloride with the molar ratio of the components of the catalyst below 0.8 (especially at 0.3), a large amount of gel is formed[17]. A similar effect has been observed in the case of the triisobutylaluminium–titanium tetrachloride catalytic system[17,18]. When the molar ratio of these components is 1.25 or less, the polymerisation of butadiene in a solvent also results in products which are insoluble in hot xylene[19].

Kropacheva et al.[16] obtained two types of polymers—an elastomer soluble in petroleum ether and an insoluble amorphous powder—in an investigation of the polymerisation of isoprene in petroleum ether solution at room temperature in the presence of equimolecular proportions of isopentylsodium and titanium tetrachloride. Analogous products are formed in the polymerisation of butadiene. The yield of the insoluble solid polymer increases with increase in the quantity of titanium tetrachloride, and it is the sole product when the ratio of isopentylsodium to titanium tetrachloride is 1 : 3. Solid polybutadiene softens and begins to decompose at about 400°C. Such a high softening point is due to the cyclic structure of the polymer, which is formed according to the scheme

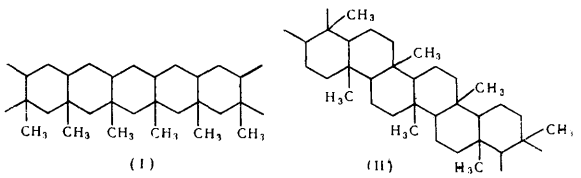


In an investigation of the isomerisation of natural rubber, Dolgoplosk and his collaborators have shown[15,16,20–22] that diethylaluminium chloride, triethylaluminium, ethylbis-2-phenylbutylaluminium, tri-isobutylaluminium, ethylaluminium dichloride, and also titanium tetrachloride and hydrogen chloride cause chemical changes in the polymers accompanied by a diminution in the unsaturation as a result of intramolecular cyclisation. A similar phenomenon is observed in the action of alkylmagnesium halides on a solution of 1,4-polybutadiene[21].

Cyclic polymers of butadiene and isoprene, obtained by direct polymerisation of the monomers in the presence of an alkylaluminium dichloride or titanium tetrachloride[21], have softening points of 420° and 370°C respectively. The cyclopolymerisation of isoprene in the presence of ethylaluminium dichloride has been subjected to a detailed investigation by Kössler et al.[23]

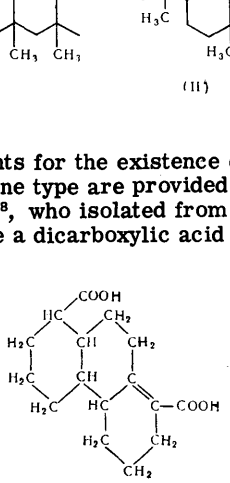
Gaylord and a number of Czechoslovak investigators have published interesting work on the polycyclisation of diene monomers with conjugated double bonds, and also on the cyclisation of stereoregular polymers of dienes[24–27]. Thus by the polymerisation of butadienes, isoprene, and chloroprene with the aid of a Grignard reagent and titanium tetrachloride at molar ratios of Mg/Ti < 2 (especially with Mg/Ti = 0.5–1), and also by the polymerisation of butadiene and chloroprene with triethylaluminium and titanium tetrachloride at molar ratios of Al/Ti ≤ 0.5, Gaylord, Kössler, et al.[24,25] obtained insoluble polymeric powders, whose spectra resembled the infrared spectra of cyclised *trans*-1,4-, *cis*-1,4-, and 3,4-polyisoprenes. These investigators suppose that cyclic structures are formed in the course of polymerisation from 1,2-polymers, not as a result of action by the catalyst on initially formed linear chains. The products obtained, still containing a definite proportion of linear structures, were completely cyclised by the action of sulphuric acid on a suspension of the polymers in toluene.

The following mechanism has been suggested for the cyclopolymerisation of conjugated dienes. Since the metal halide is present in considerable quantity, the polymerisation can be regarded as cationic. The first stage involves 1,2-isotactic or 1,2-syndiotactic polymerisation (3,4-isotactic or 3,4-syndiotactic in the case of isoprene or chloroprene). Initiation of polycyclisation can take place in two ways: (1) the end of a growing chain may interact with a double bond in the penultimate monomeric



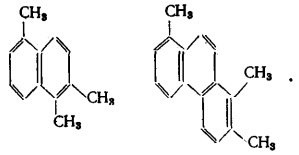
unit (*a*, *c*); or (2) the growing chain may interact with a double bond in another chain (*b*, *d*):

Thus an isotactic polymer yields a planar ladder structure, whereas a syndiotactic polymer gives a spiral structure, one chain being curled around another and joined to the latter at every third carbon atom.



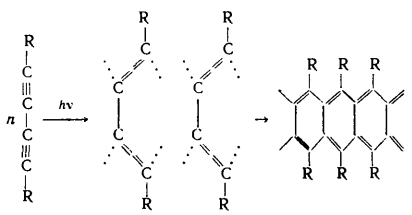
A characteristic feature of cyclopolymers is their high thermal stability. The decomposition temperatures of cyclopolyisoprene, cyclopolybutadiene, and cyclopolychloroprene are respectively[24,25] 370°, 405°, and 422°C.

Kössler et al. concluded[27] from their investigations, which involved mainly a study of the infrared spectra of cyclopolymers of isoprene and cyclised steroregular polymers of isoprene, that polycyclic ladder systems may be of two types—perhydroanthracene (I) and perhydrophenanthrene (II).



(I) (II)

Definite arguments for the existence of polymers of perhydrophenanthrene type are provided by results obtained by Shelton and Lee[28], who isolated from the oxidation of cyclic polybutadiene a dicarboxylic acid having the structure



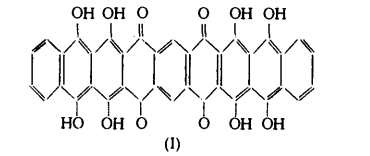
and also by Wallenberger[29], who by the aromatisation of the polymer of isoprene obtained 1,2,5-trimethylnaphthalene and probably 1,2,8-trimethylphenanthrene.

The technical application of cyclised rubber is extremely promising. It can be successfully used as a filler for natural and synthetic rubbers[6,30-32], the properties of the resulting products being improved and the processing technology facilitated. Cyclised rubber is employed for the production of paints[6,32], coatings for paper[6,32] and textiles[32], etc.

2. Aromatic Ladder Polymers

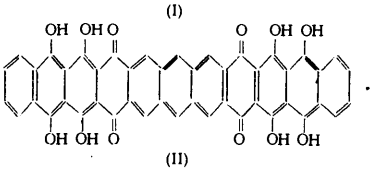
The aromatic ladder polymers obtained by Bohlmann[33,34] by the photopolymerisation of polyacetylenes are of great interest. Thus irradiation of deca-4,6-diyne-1,10-diol $HO[CH_2]_3[C{:}C]_2[CH_2]_3OH$ and also of its diurethane yields insoluble red polymers. If the diurethane is heated below the melting point, a red polymeric product is formed, but on rapid heating above the melting point the compound melts without change in colour and does not polymerise at 250°C. In Bohlmann's opinion this indicates that, for polymerisation to occur, the molecular chains of the polyyne should be arranged in parallel. The polymerisation of a conjugated diyne can then be represented by the scheme

Under the influence of light energy the π-electron pairs of the triple bonds break down, and polymerisation takes place by a Diels–Alder type of synthesis. Reaction takes place only in the crystalline monomer, but not in solution or in the melt.



The infrared spectrum of the polymers shows broad peaks in the region of absorption by aromatic hydrocarbons, but neither triple nor isolated double bonds have been detected in the spectrum. X-Ray examination of the polymers indicates that they are amorphous substances[33].

In an attempt to prepare 1,6-dicyanohexa-2,4-diyne, Lee[35] obtained chemically inert polymeric products of high melting point (above 600°C), resembling "brick dust". His starting materials were a dihalogeno-, ditoluene-*p*-sulphonyl-, or dihydroxy-hexadiyne and sodium or copper(I) cyanide. Polymerisation proceeds as follows

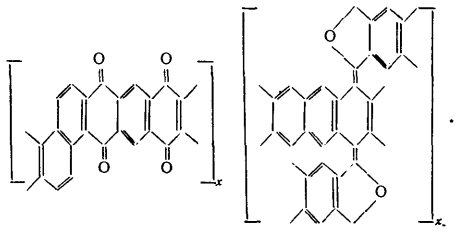


$$X{-}CH_2{-}C{\equiv}C{-}C{\equiv}C{-}CH_2{-}X \xrightarrow[\text{salt}]{\text{cyanide}} [X{-}CH_2{-}C{\equiv}C{-}C{\equiv}C{-}CH_2{-}CN]^{-} \rightarrow \text{polymer.}$$

Although Lee does not attribute a definite structure to this polymer, nevertheless in his view it may contain fused aromatic rings, recalling in this respect the structures of heat-treated polyacrylonitrile or of graphite.

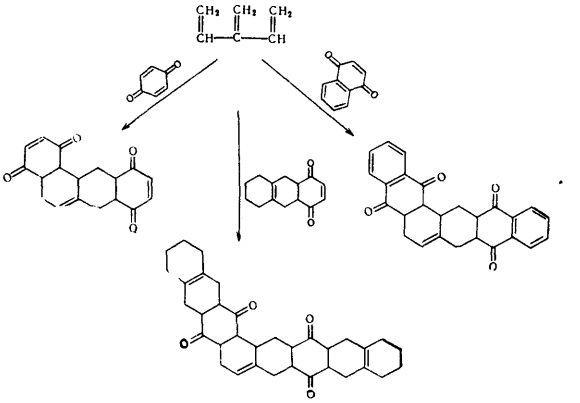
By the interaction of the dianhydrides of aromatic tetracarboxylic acids (pyromellitic and anthracenetetracarboxylic acids) with 1,4-dihydroxyanthraquinol in the presence of aluminium chloride, Marschalk obtained[36] fused polycyclic aromatic systems, to which he ascribed the structures

(I)



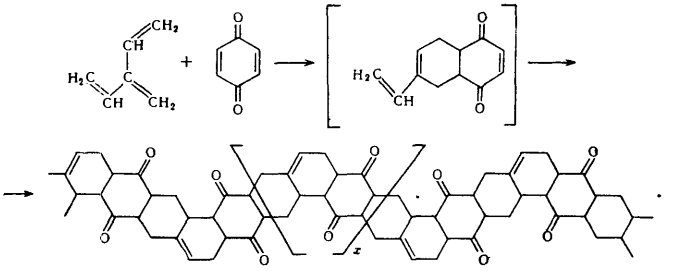
(II)

These compounds were synthesised by heating 1 mole of the dianhydride with 2 moles of the anthraquinol in the presence of a Friedel–Crafts catalyst to 310–320°C. The product (I) is a brown–violet substance, insoluble in alkalis and organic solvents, which can be crystallised from slightly fuming sulphuric acid on gradual dilution. The product (II) likewise does not dissolve in alkalis or organic solvents, and is crystallised in a similar manner to (I).



In order to study the mechanism of conduction in semiconductor materials, Pohl and Engelhardt[37] synthesised polymers from various acenes (naphthalene, anthracene, phenanthrene, pyrene, chrysene, perylene, dibenzopyrene, and picene) and aromatic acid anhydrides (phthalic and pyromellitic) in the presence of zinc chloride or aluminium chloride. (Polyacenes were also prepared by the Wurtz–Fittig method from 1,2,4,5-tetrabromobenzene by its interaction with a sodium–potassium alloy.) Pyromellitic dianhydride or phthalic anhydride was carefully mixed with zinc chloride and the various acenes, and heated at 256° or 306°C for 24 h. The resulting polymers were insoluble, infusible black products. Yields were 5–50% based on the mixture of dianhydride and acene. Elementary analysis indicated that the polymers contained approximately 2 molecules of acene for each molecule of pyromellitic dianhydride after allowing for a loss of 2 molecules of water. Polymers containing up to 14 aromatic nuclei could be prepared. It was found that the resistance diminished with increase in the proportion of the initial acene.

In the opinion of Pohl and Engelhardt[37], two reaction mechanisms are possible, one resulting in the formation of keto-groups or quinone groups, whereas the second yields lactone structures—

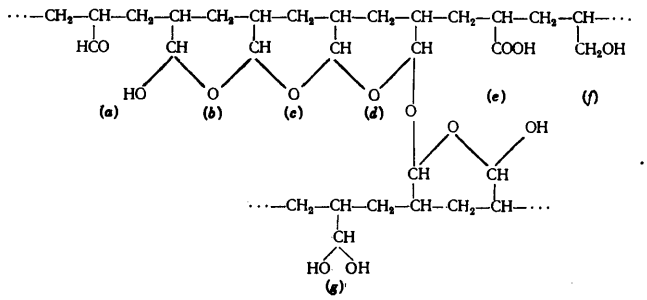


By analogy with the work of many other investigators, however, they consider that the former types of structures are mainly produced, rather than lactone structures, although secondary reactions of the quinone groups are not excluded.

An extremely interesting method for obtaining quinones of hydrogenated acenes has been worked out by Bailey and Economy[38], using 3-methylenepenta-1,4-diene and mono-, di-, and tri-cyclic quinones. Toluene solutions of the hydrocarbon and the quinone are mixed, left at room temperature for 24 h, and then boiled for 24 or 48 h. On cooling, crystalline products separate. The reactions underlying the synthesis of these compounds are

This original variety of diene synthesis has been used somewhat later for the preparation of ladder polymers[39] from 3-methylenepenta-1,4-diene and benzoquinone in equimolecular proportions: a chloroform solution of the mixture was kept at room temperature for 4 days, and then boiled for 24 h, after which most of the solvent was distilled off and boiling continued in the presence of tetrachloroethane for 48 h, until a brown deposit was formed. Two products—a polymer softening at 340–400°C, practically insoluble in all solvents in the cold, but soluble in hot solvents, and probably having a molecular weight of ~ 2000; and a soluble polymer, softening at 170–200°C, and of molecular weight 440—were obtained, the first of these polymers being assigned the following ladder structure[39]

B. HETEROCYCLIC LADDER POLYMERS

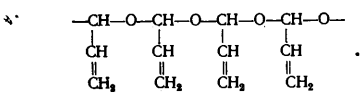


Heterocyclic ladder polymers constitute a group of numerous compounds of high molecular weight. Their macromolecules contain heterocycles comprising carbon atoms together with one, two, or more atoms of other elements, e.g. oxygen and nitrogen. Many organoelementary and inorganic polymers, either containing no carbon at all or containing it only in side-chains, are of the same type.

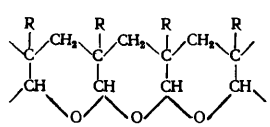
1. Ladder Polymers Consisting of Oxygen Heterocycles

Polyacrylaldehyde, obtained by the spontaneous polymerisation of acrylaldehyde, was first described by

Redtenbacher[40] in 1843. The polymer was termed "disacryl". The "disacryls" are colourless substances, either flocculent or powdery, having no definite melting point and decomposing at temperatures above 220°C.[42]



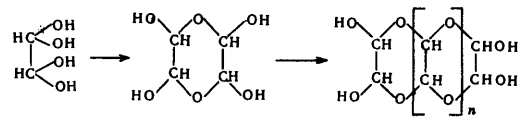
A systematic investigation of the polymers formed by acrylaldehyde was made by Schulz[41]. The polyacrylaldehydes which he obtained by a radical mechanism, as well as those formed by spontaneous polymerisation (also proceeding by a radical mechanism), were polymers of vinyl type, with a "head-to-tail" structure. However, the formyl groups in the polymers can interact to form rings. From the chemical properties and the infrared spectra Schulz attributes to such polymers the structure[41]



The formyl groups may be present either in the free state (*a*), hydrated (*g*), in ethereal form (*c*), or in an intermediate form (*b*). The hydroxyls of the hydrated formyl groups are able to form cross-links (*d*). Under certain conditions they break down, the polymers acquiring solubility and reacting as polyals.

In the presence of metallic sodium, the polymerisation of acrylaldehyde in boiling benzene takes place in the 1,4-positions, as Andreeva and Koton[43] have shown.

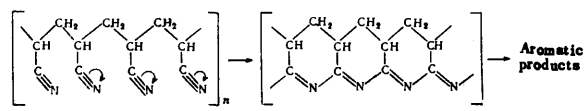
According to Schulz[44] the polymerisation of acrylaldehyde in the presence of various anionic catalysts and the boron trifluoride–ether complex results in a polymer having the structure



Andreeva et al.[45] polymerised acrylaldehyde and methacrylaldehyde in the presence of respectively ~ 1.5 and 2.5–3 mole % of boron trifluoride at temperatures from −20° to −40°C. The vitreous polyacrylaldehyde obtained under these conditions contained no detectable free formyl groups. It was insoluble in organic solvents, it dissolved in sulphurous acid, and it decomposed at about 270°C. The polymethacrylaldehyde had rather greater thermal stability than the acrylaldehyde polymer, and differed from the latter in being insoluble in most organic solvents and only swelling in sulphurous acid. In view of their properties, these polymers were assigned[45] the polycyclic structure

where R = H or CH_3.

The polymerisation of glyoxal yields a white solid, aqueous solutions of which comprise a mixture of hydrated forms capable of changing from one into another[46,47]:



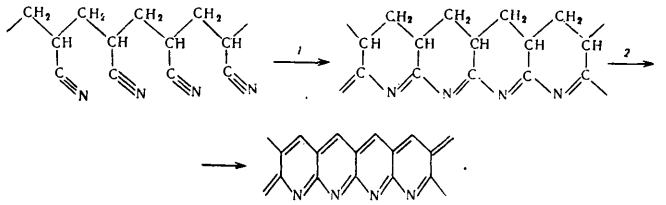
where n = 3 or 4. Okamura et al.[48] investigated the polymerisation of glyoxal under the influence of γ-rays at −196°, −78°, and 0°C, obtaining degrees of conversion of 23.9%, 42.2%, and 60.6% respectively after irradiation for 65 h. The infrared spectra of the polymer showed absorption corresponding to C–O–C and C–H bonds, but no absorption due to the carbonyl group. The polymers were distinguished by infusibility and insolubility. At 222°C some 45% of the polymer had decomposed after 10 min.

2. Ladder Polymers Consisting of Nitrogen Heterocycles

Most investigators consider that a ladder type of polymer is formed by the heat-treatment of polyacrylonitrile. A fair number of papers have been published on the thermal transformation of polyacrylonitrile and the properties of the products, and only a proportion of these will be briefly discussed in the present review.

Houtz[49] heat-treated polyacrylonitrile fibre, and obtained a thermostable material which withstood brief heating in the burner flame. He was the first to ascribe a polycyclic structure to it.

Burlant and Parsons[50] heated samples of polyacrylonitrile in an atmosphere of nitrogen over a range of temperatures from 200° to 320°C, and investigated their infrared spectra. The process of polycyclisation was represented as follows:

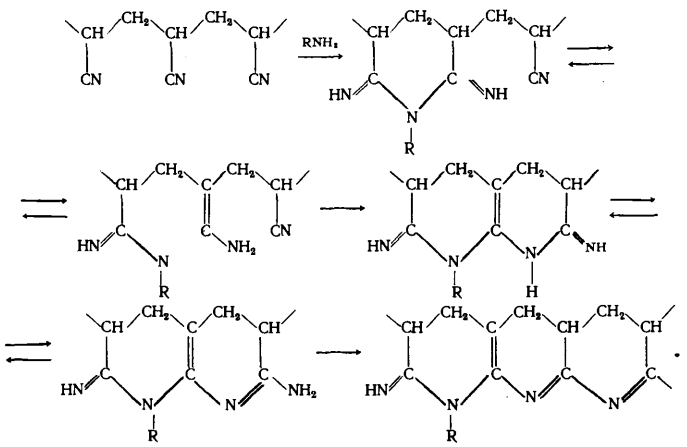


This scheme explains the high nitrogen content of the heated polymer and the gradual, almost complete disappearance of nitrile groups, with the simultaneous appearance of conjugated C=N bonds. Aromatisation occurs slowly below 300°C, whereas at higher temperatures aromatic products are readily formed.

Topchiev et al.[51] showed that heat-treatment of polyacrylonitrile fibre or powder may yield materials possessing semiconductor properties and electronic conduction. The number of electrons having unpaired spins in the substance is 10^{18}–10^{19} g^{-1}. After heat-treatment the semiconductor material can be used at far higher temperatures than, for example, germanium, since the polymer does not decompose even at 300°C. Preliminary exposure of polyacrylonitrile to γ-rays followed by heat-treatment leads to a sharp increase in the concentration of electrons with unpaired spins in comparison with the unirradiated polymer.

From a study of the infrared absorption spectra Topchiev and his collaborators[52] consider that the thermal

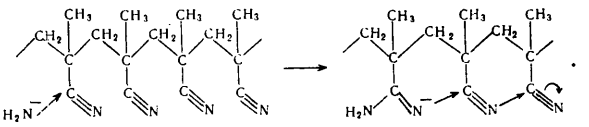
transformation of polyacrylonitrile takes place in two stages:



Intramolecular cyclisation, resulting from conversion of a C≡N into a C=N bond, is mainly completed by 270°C. At higher temperatures dehydrogenation takes place, with the formation of C=C bonds. The conditions of heat-treatment have a great effect on the electrical properties of the semiconductors. Thus heat-treatment of polyacrylonitrile in ammonia under pressure increases its conductance by factors of the order of 10^2 in comparison with specimens which have been subject to the same heat-treatment but in an atmosphere of an inert gas.

Vosburgh[58] made a detailed study of the conditions required for the production of non-flammable cyclised polyacrylonitrile fibres and fabrics. He heated the polymer in air above 160°C, and established that the logarithm of the reaction time is inversely proportional to the temperature. The most important parameters in this process are the duration of heating, the temperature, the fabric construction, and the atmosphere in which reaction occurs. The optimum concentration of oxygen is 15–20%. The cloth obtained in this way considerably surpasses all others in thermal stability. At 900°C the material is completely destroyed in 3 h.

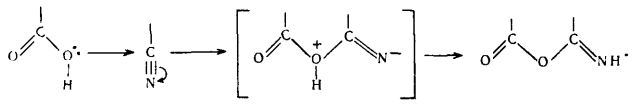
Drabkin et al.[54] investigated the processes occurring in polyacrylonitrile on heating. They studied the absorption spectra after heating in a vacuum of 10^{-5}–10^{-6} mmHg.



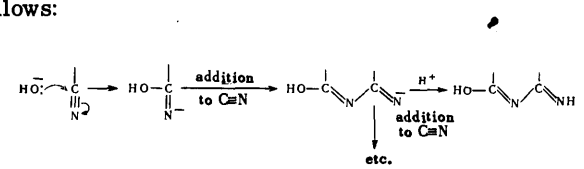
Airapetyants et al.[55] investigated the temperature dependence of the electrical properties of polyacrylonitrile (in a vacuum of 5×10^{-6} mmHg) for specimens of the polymer which had been heat-treated from 520° to 730°C.

Many authors[56-61] consider that the coloration of polyacrylonitrile and polymethacrylonitrile is caused by the formation of fused polycyclic systems. This process is accelerated by the presence of bases or organic acids. Thus La Combe[56] found that heating polyacrylonitrile in the presence of a small quantity of a base at 100°C for 1 h results in the appearance of a yellow colour in the polymer. He explains this phenomenon by means of the suggested scheme

Dilute mineral acids hydrolyse the fused rings, with almost complete disappearance of the colour[56].

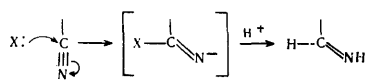


Overberger et al.[57] investigated the polymerisation of methacrylonitrile in the presence of lithium and ammonia at −75°C. The appearance of a colour in the polymer was, in their view, due to the reactions



Chain growth occurs by interaction of an imino-anion with a nitrile group.

Lipatnikov[58] also explains the coloration of polymethacrylonitrile, when the monomer is polymerised in the presence of benzoyl peroxide under pressure (6000 kgf cm^{-2}) at or above 100°C, by the formation of fused pyridine rings.



From an investigation of the appearance of a colour in polymethacrylonitrile[59-62] and polyacrylonitrile[62], Grassie concluded that this process is in considerable measure bound up with the presence of carboxy-groups, which initiate polymerisation:

Carboxyls are usually present in the polymer, since the monomer contains methacrylic acid as impurity. However, other compounds, not necessarily located in the polymer chain, can also initiate cyclisation[60]. The efficiency of initiation by acids of the type RCOOH is then strongly dependent on the nature of R: the more strongly developed the electron-acceptor properties of R, the more difficult is initiation[61]. An analogous relationship is observed with phenols. Initiation by alkalis occurs as follows:

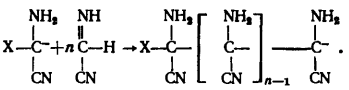
In summarising the results of observations on the change in colour in polymethacrylonitrile and polyacrylonitrile, Grassie[61] gives the general mechanism

for the initiation of polycyclisation. Thus the start of the reaction is reduced to attack on a nitrile group by a nucleophilic reagent. Here OH, NH_2, etc. are stronger nucleophilic reagents, and carboxylic acids and phenols less strong. All these compounds are in essence Lewis bases.

While noting much in common in the behaviour of polyacrylonitrile and polymethacrylonitrile on heat-treatment, Grassie[62] nevertheless points out two fundamental differences. Firstly, in the absence of nucleophilic reagents polymethacrylonitrile does not change colour below 200°C,

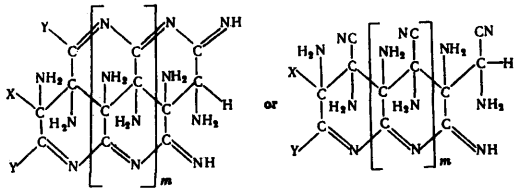
whereas pure polyacrylonitrile becomes coloured at a definite rate, which does not decrease after careful purification of the monomer. This fact is explained by the presence in the polyacrylonitrile molecules of hydrogen atoms attached to tertiary carbon atoms, which are capable of initiating polycyclisation. Polymethacrylonitrile molecules, however, do not contain the $\geq$C–H group. Secondly, even intensely coloured polymethacrylonitrile does not lose its solubility, whereas polyacrylonitrile rapidly becomes insoluble. The explanation given for this is that in the latter polymer the process of chain growth takes place by the cross-linking of the latter (propagation cross-linking) owing to the denser packing of the macromolecules [62].

Kennedy [63] considers that, besides the ionic reactions which accompany the heat-treatment of polyacrylonitrile, radical processes must also be considered.



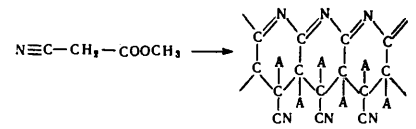
Nizova et al. [64] have synthesised a polyacetylenenitrile whose structure does not essentially differ from that attributed to heat-treated polyacrylonitrile. The polymer obtained is a dark coloured powder, insoluble in the usual organic solvents and readily soluble in concentrated acids. It neither melts nor decomposes up to 450°C, and is distinguished by a narrow electron spin resonance (e.s.r.) signal, which is characteristic of polyconjugated systems. The number of unpaired electrons is 10^{18}–10^{19} g^{-1}. The infrared spectra support the structure proposed for the polymer, and contain an absorption band characteristic of polyconjugated C=N bonds. They indicate that prolonged heating in a vacuum up to 300°C has practically no effect on the chemical structure of the polymer.

The literature on the polymer of hydrocyanic acid was reviewed by Völker [65], who synthesised this polymer by anionic polymerisation in aqueous solution. Polymeric hydrocyanic acid consists of dark brown amorphous flakes, which do not dissolve in any solvent without chemical change. Ammonia is eliminated by the action of aqueous alkali, and gaseous compounds of nitrogen are formed by concentrated nitric acid. The polymer possesses limited solubility in other dilute mineral acids. It is thermally stable up to 200°C, but at higher temperatures hydrogen cyanide, ammonia, carbon dioxide, and an amine are split off.



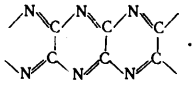
Polymerisation is initiated by interaction of an anion with the dimer of hydrocyanic acid:

$$X^- + HN{=}CH{-}CN \rightarrow H_2N{-}\overline{C}(X){-}CN.$$



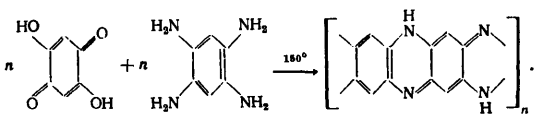
Chain growth proceeds by interaction of the dimeric acid with the resulting anion:

Chain termination results from addition of a cation (usually a proton) to the polymeric molecule. Völker [65] considers that, owing to steric hindrance, the nitrile groups occupy *trans*-positions in the course of polymerisation, which leads to formation of the polycyclic structures



Korshak and Sosin [66] prepared a polymer from methyl cyanoacetate by polyrecombination:

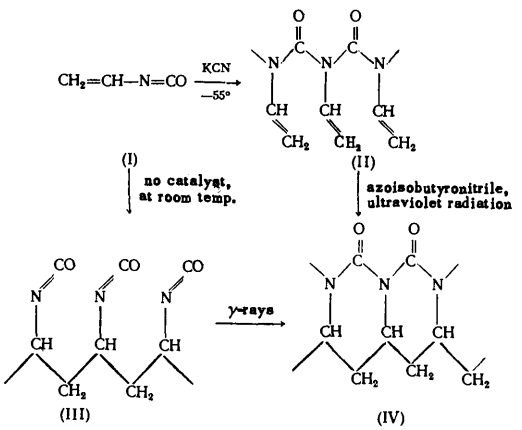
where A = $COOCH_3$. Polyrecombination is accompanied by polymerisation of the nitrile groups with formation of a system of conjugated C=N bonds in fused six-membered rings. The infrared spectra of the polymer exhibit absorption characteristic of C=N bonds, and also of nitrile and ester groups. The molecular weight of the polymer is 7200, and its softening point 500°C. The product possesses semiconductor properties. A signal is observed in the e.s.r. spectra (7 oersteds), and the number of electrons having unpaired spins is 10^{18} g^{-1}. An analogous structure (with fused nitrogen heterocycles) is possessed also by polymers based on malononitrile [67], adiponitrile [67,68], and benzyl cyanide [67], as well as copolymers of methyl cyanoacetate and benzyl cyanide [69].



Bircumshaw [70] published a survey of work on polymers of cyanogen $(CN)_2$ obtained in various ways, and reported the synthesis and a study of the properties of a polymer, paracyanogen, formed by the polycondensation of oxamide in the solid phase under pressure at 250–300°C. Paracyanogen contains conjugated double bonds and no free nitrile groups. The polymer molecules consist of fused pyrazine rings

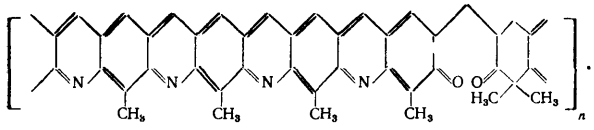
Paracyanogen is insoluble in water and most organic solvents, but soluble in inorganic acids. The polymer withstands being heated in a vacuum at 450°C. Strong heating in air leads to decomposition with the formation of carbon dioxide. Davydov et al. [71] investigated the temperature dependence of the semiconductor properties of paracyanogen.

Several polymers containing a conjugated system of C=N groups have been obtained by Paushkin et al. [72] from amides and ammonium salts of mono- and di-carboxylic acids heated in the presence of zinc chloride in an autoclave (at 400°C). The polymers were insoluble, infusible powders, from dark brown to black in colour. They possessed very high thermal stability: the losses in weight on heating to 800°C were only 7–12%. The infrared spectra of these products are identical with those of polymers obtained by polymerisation of the corresponding nitriles. The electrical properties of the polymers were examined over the range 20–300°C.



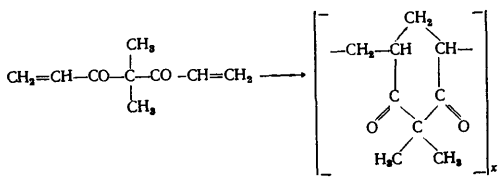
By heating equivalent amounts of 2,5-dihydroxy-*p*-benzoquinone and benzene-1,2,4,5-tetra-amine in dimethylacetamide, hexamethylphosphoramide, or polyphosphoric acid at 150°C, Stille and Mainen [73] have quite recently obtained ladderlike polyquinoxalines:

With dimethylacetamide the polymers form extremely stable compounds, which decompose only on prolonged



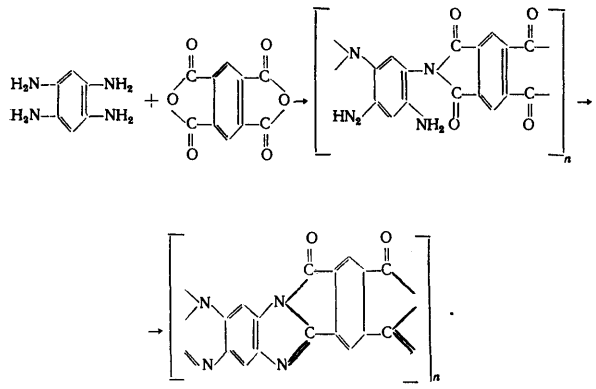
heating in a vacuum. Removal of solvent from the association complex results in an insoluble polymer. Thermogravimetric tests showed that the structure of the polymer is evidently not completely ladderlike.

Overberger et al.[74] obtained a ladder polymer of vinyl isocyanate by the series of reactions

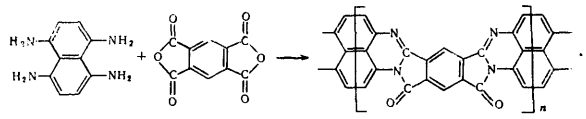


The polymer (IV) is soluble in solvents of high dielectric constant. The intrinsic viscosity of its solution in pyridine is 0.45. The polymer decomposes at 385–390°C. The structures of the intermediate products (II) and (III) and of the polymer (IV) have been demonstrated by means of the infrared spectra.

De Winter and Marvel[75] synthesised a ladder polymer whose molecules were made up of fused alternating aromatic pyridine and toluene rings:



Polymerisation in a solution of 4,4-dimethylhepta-1,6-diene-3,5-dione in the presence of azoisobutyronitrile at 65°C first yielded a polymer containing six-membered rings in the chain:

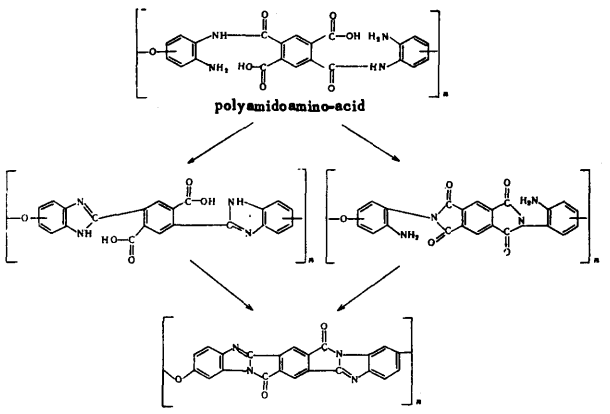


Then hydroxyimino-groups (approximately one group for each ring) were introduced into it in strongly alkaline medium. Careful dehydration of the polyoxime yielded a ladder polymer (whose structure has been given above), soluble in hot quinoline, dimethyl sulphoxide, and dimethylacetamide. Thermogravimetric tests showed that the loss in weight of the polymer on being heated from 300° to 500°C was ~ 20%, after which only a slight change in weight was observed right up to 900°C.

Novel thermostable ladder polymers have recently been obtained based on aromatic tetra-amines and aromatic tetracarboxylic acids or their dianhydrides[76–80]. Dawans and Marvel[76] have synthesised such polymers from benzene-1,2,4,5-tetra-amine and pyromellitic dianhydride:

They also replaced the benzenetetra-amine by naphthalene-1,4,5,8-tetra-amine for the polycondensation:

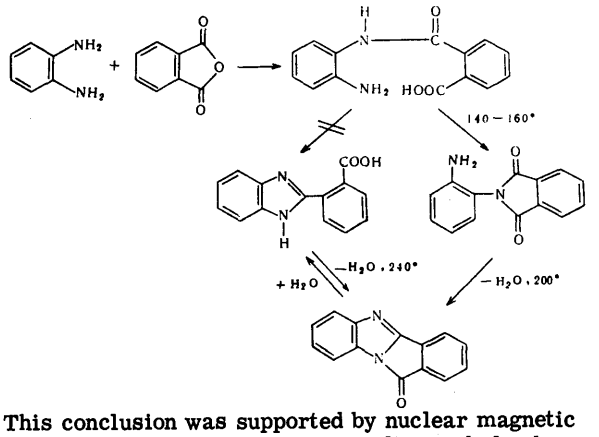
These workers observed with model compounds that the nature of the intermediate products depends on the conditions of the condensation, and concluded that, in order to obtain the above ladder structures, the process must be carried out with a slow rise in temperature (2 deg min^{-1}). The polycondensation was conducted in a melt or a solution in a stream of nitrogen[76]. Reactions begins in the melt at 105–110°C, but intramolecular cyclisation takes place only at 140–150°C. Polymers of maximum molecular weight are obtained with the starting materials in equimolecular proportions: when the molar ratio of anhydride to amine exceeded unity, the yield of the polymer was higher, but its molecular weight lower.



The polymer based on benzene-1,2,4,5-tetra-amine was prepared by gradually heating a mixture of the amine with the dianhydride to 220°C, and then heating in a vacuum at 300°C for 3 h. The yield was 86%. The reduced viscosity of a 0.25% solution in concentrated sulphuric acid was 0.3. Use of polyphosphoric acid as solvent for the synthesis of this polymer[76] makes it possible to employ the stable tetra-amine tetrahydrochloride instead of the readily oxidisable amine, and also gives the same yield (86%) of polymers of high molecular weight. The intrinsic viscosity of the polymer based on benzene-1,2,4,5-tetra-amine, measured in concentrated sulphuric acid, was 1.10.

The polymer based on naphthalene-1,4,5,8-tetra-amine was obtained in 60% yield in 2,5,8-trioxanonane solution. The reduced viscosity of a 0.25% solution in concentrated sulphuric acid was 0.41.

It was established that in a solvent the reaction between tetra-amine and dianhydride occurs essentially at room

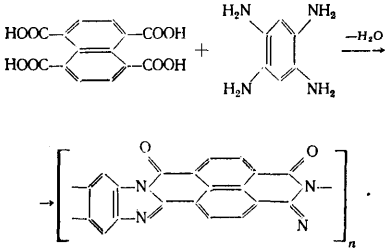


temperature and is weakly exothermic. A polyamido-amino-acid is formed as intermediate product [77,78].

Scheme 1

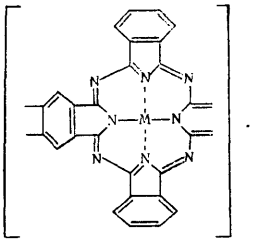
On the basis of infrared spectroscopic data Bell [78] suggests Scheme 1 for ring formation in the interaction of pyromellitic dianhydride with bis-3,4-diaminophenyl ether. According to this both imide and benzimidazole rings are formed in the cyclisation of the polymeric amido-amino-acid. In a study of the condensation of *o*-phenylenediamine with phthalic anhydride when they were heated at 160°C for 30 min, Colson et al.[79] found that only a phthalimide ring is formed, and no benzimidazole ring formation is observed (see Scheme 2).

Scheme 2



This conclusion was supported by nuclear magnetic resonance and infrared spectral results, and also by a comparison of the melting point of *N*-*o*-aminophenylphthalimide with published values. The imide obtained is converted, when heated to 200–210°C, into benzoylbenzimidazole (see Scheme 2). This last product cannot be formed from *o*-benzimidazol-2-ylbenzoic acid below 240–250°C, which provides additional evidence for the scheme of cyclisation given by Colson et al.[79]

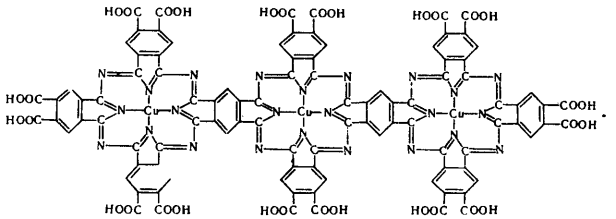
Ladder polymers of this type, termed "pyrrones" [77], are coloured substances, which do not melt below 400°C. They are not soluble in the usual organic solvents, but dissolve in concentrated sulphuric acid [76]. Thermogravimetric tests have shown that in an inert atmosphere (nitrogen) pyrrones are thermostable up to 450–500°C. In air they oxidise fairly rapidly at 350–400°C, [76] but they are non-flammable. Pyrrones are extremely resistant to the action of radiation [78].



The possibility of obtaining soluble intermediate products in the synthesis of pyrrones facilitates the technical production of thermostable films, coatings, adhesives, filaments, and plastics based on them [77,78].

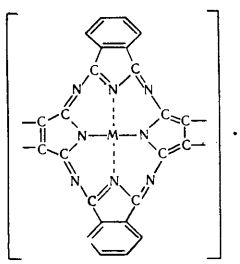
By the polycondensation of naphthalene-1,4,5,8-tetracarboxylic acid with benzene-1,2,4,5-tetra-amine in polyphosphoric acid, the system being heated in an atmosphere of nitrogen at 220°C, van Deusen [80] obtained novel thermostable polymers, closely resembling pyrrones in structure:

In contrast to pyrrones, however, the imide ring of these polymers is six-membered. They are dark coloured products, partly soluble in sulphuric, polyphosphoric, and sulphonic acids, and also in aqueous alkalis. The polymer obtained at ~ 100°C has a reduced viscosity of 0.3. Polymers obtained at higher temperatures are very sparingly soluble, but have analogous infrared spectra. These products are distinguished by very great thermal stability: on heating in air, loss in weight does not begin below 400°C, and in nitrogen at about 600°C.



Phthalocyanine polymers have now been synthesised which are characterised by the presence of complicated polycyclic structures containing nitrogen. Individual members of this group are able to form ladder systems. Thus Marvel [81] heated pyromellitic acid, phthalic anhydride, urea, and copper(II) chloride to 200°C, and obtained polymers which may have the structure

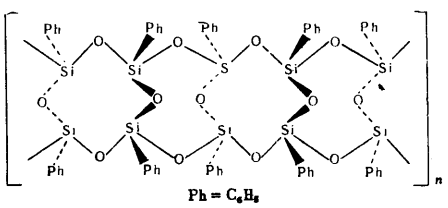
The polymers vary in colour from bluish green to greenish black. They are soluble in dimethylformamide, they are stable when heated in air to 350°C, and they burn with great difficulty.



Soluble phthalocyanine polymers were prepared by Felmayer and Wolf [82] and also by Berlin et al.[83] by the polycondensation of pyromellitic acid with urea and copper(I) chloride. Felmayer investigated the electrical properties of these black products, and found that the activation energy for conduction diminished with increase in the number of fused rings in the polymers. Berlin's polymers were blue-green powders, with molecular weights of 3000–4000, and were insoluble in dimethylformamide but soluble in concentrated sulphuric acid. The magnetic and electrical properties of these polymers were examined, as well as their thermal stability. The number of paramagnetic particles was 5×10^{21} g^{-1}. The polymers were stable in air up to 350°C.

Drinkard and Baylar[84] prepared phthalocyanine polymers from pyromellitic dianhydride, urea, copper(II) chloride, and a catalyst (ammonium molybdate or $ZrOCl_2 \cdot 8H_2O$) at 180°C, and attributed to them the structure

The maximum molecular weight of the polymers obtained was 4000, corresponding to six phthalocyanine units.

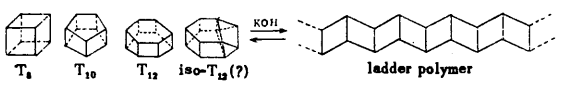


Berlin et al.[85] showed that the interaction of an equimolecular mixture of copper acetylacetonate, tetracyano ethylene, and phthalonitrile yields a chelate copolymer, which probably has the structure

3. Organoelementary Ladder Polymers

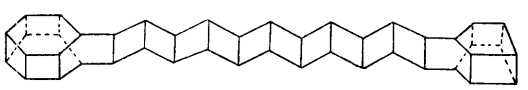
In 1939 Koton[86] reported the preparation of organosilicon polymers by the polycondensation of phenyl-, benzyl-, and also 1-naphthyl-silanetriol. These polymers were recommended for use as heat-resistant materials for electrical insulation.

By the equilibrium alkaline polycondensation of phenylsilanetriol, in toluene, xylene, or 2,5,8-trioxanonane, Brown et al.[87] have fairly recently obtained ladder polymers, to which they assign the structure



Ph = C_6H_5

The polymer obtained by the hydrolysis of phenyltrichlorosilane followed by polycondensation in toluene had $\overline{M}_n = 14\,000$ and $\overline{M}_w = 26\,000$, with a "most probable" molecular-weight distribution. A steep linear relationship ($a = 0.92$) exists between values of $\lg[\eta]$ and $\lg\overline{M}_w$ for fractions of this polymer, this being characteristic of a rigid elongated polymer. By using small amounts (e.g. 5–30%) of solvent, a polymer can be obtained having a molecular weight of the order of several millions. With $\overline{M}_w > 2 \times 10^5$, however, chain branching is observed[87]. Analogous products were synthesised by Sprung and Guenther[88] by the hydrolysis of phenyltriethoxysilane. These products had a somewhat higher molecular weight and a narrower molecular-weight distribution than the polymer synthesised by Brown.

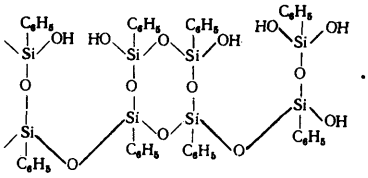


Brown considers[89] that the trifunctional product forms initially a syndiotactic Si–O–Si chain having phenyl side-groups attached to each silicon atom. This chain then reacts with another chain, to form the "unidimensional" ladder structure shown above.

From a detailed study of the influence exerted by the equilibrium conditions on the nature of the products, Brown[90] showed for the polycondensation of phenylsilanetriol that in dilute (5%) solutions oligomers of cagelike structure are formed, in 5–70% solutions a linear ladder polymer of low molecular weight, at 85–95% a ladder polymer of high molecular weight, and at 100% a ladder gel. All these products are interconvertible by varying the concentration in the solution.

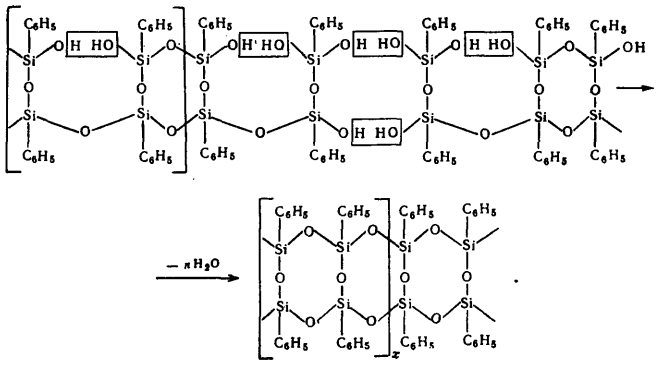
The equilibrium between the oligomers and the polymer can be represented in general as follows:

where $T = RSiO_{1.5}$. The phenyl derivatives T_8, T_{10}, and T_{12} have been isolated as pure crystals. Since the product of low molecular weight contains no unchanged silanolic groups, while the spectra confirm the presence of rings similar to T_{10} or T_{12} at the ends of the chains, the polymer was given the structure



Raising the equilibrium temperature results in an increase in the proportion of cagelike compounds. At 250°C and a polymer concentration exceeding 80%, branchings appear in the macromolecules, accompanied by a decrease in the concentration of cagelike compounds.

From a study of the properties of the solutions, X-ray examination of oriented specimens, determination of the infrared and ultraviolet spectra, and calculations of bond angles, Brown[87,90] concluded that the product of the polycondensation of phenylsilanetriol is a ladder polymer having a *cis*-syndiotactic structure of the double bond.



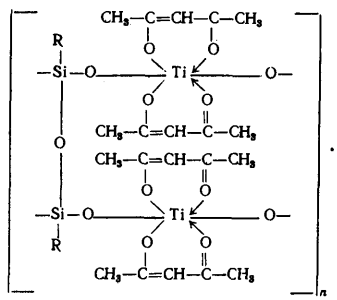
The above organosilicon ladder polymers have been investigated also by Pavlova et al.,[91,92] who used benzene, toluene, xylene, and succinonitrile as solvents for the synthesis. All the polymers obtained, having high glass points (~ 300°C), were divided into 6–10 fractions. The closely similar glass points for all four polyphenylsiloxanes indicate that the conditions of preparation have no fundamental effect on their structure. These conditions likewise have little influence on the degree of polydispersity of the polyphenylsiloxanes: thus in the series—benzene, toluene, xylene, and succinonitrile—the ratio M_w/M_n has the values 1.82, 2.15, 2.50, and 2.70 respectively.

The suggested mechanism[91] for the formation of ladder polyphenylsiloxanes involves the initial production, by the

hydrolysis of phenyltrichlorosilane, of polymers of low molecular weight, containing free hydroxyls:

followed by further intramolecular and intermolecular condensation:

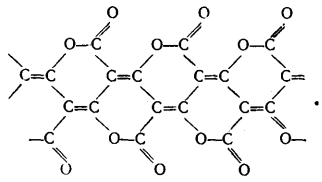
Polyphenylsilsesquioxanes have been obtained also by Andrianov et al.[93] by polymerising the crystalline octamer $(C_6H_5SiO_{1.5})_8$ in a solvent (diphenyl oxide, nitrobenzene, etc.) in the presence of 0.05% of an alkali, and then removing the solvent and heating at 250–270°C. The polymers have glass points above 300°C.



Study of the properties of dilute benzene solutions of polyphenylsilsesquioxanes has shown[92] that at molecular weights of 10 000–50 000 the polymers are present in the form of short rods, whereas over the range 50 000–2 700 000 they exist as tangles of thread. The relation between the intrinsic viscosity and the molecular weight of the polymers is given by

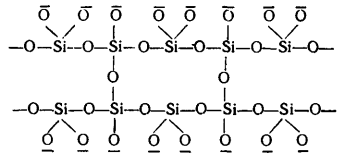
$$[\eta] = 1.305\times10^{-7}M^{1.29} \quad (M = 10\,000 - 50\,000);$$
$$[\eta] = 1.93\times10^{-4}M^{0.634} \quad (M = 50\,000 - 2\,700\,000).$$

The mean square distances between the ends of the macromolecular chains and the flexibility of the chains have also been calculated.

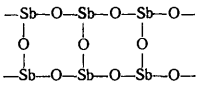


Ladder polyphenylsiloxanes are infusible products, which can dissolve, however, in benzene, tetrahydrofuran, chloroform, and dichloromethane[87,89]. Films can be obtained from the solutions, and these can be oriented in the swollen state. The polymers are more stable towards hydrolysis than are ordinary silicones, and they have a higher tensile strength than have silicones of iregular structure (281–422 kgf cm^{-2}). They possess very good dielectric properties and high thermal stability. Losses in weight are observed at temperatures above 525°C. The polymer withstands brief (1–2 min) heating at 650°C, and several months at 300°C.[90]

Hydrolysis of compounds of type $RSiCl_3$ together with bisacetylacetonatotitanium dichloride yields[94] ladder polymers containing cyclic titanium atoms.



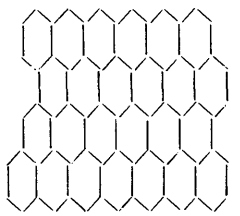
4. Inorganic Ladder Polymers



Smith et al.[95] obtained variously coloured—from yellow to violet—polymers of carbon suboxide C_3O_2. The polymers of low molecular weight dissolved in water and aqueous alkali to give red solutions; those of high molecular weight were insoluble. The polymers decomposed above 300°C, and at 500°C were converted into carbon. In Smith's opinion, these products have the structure

Inorganic polymers having molecules or ladderlike structure are quite often encountered in Nature. For example, the mineral tremolite, of which asbestos is a variety, contains amphibole chains[96]:

One form of antimony oxide, valentinite, also has a ladder structure[97]:



Arsenic sesquioxide[98] and bismuth sesquioxide[99] have similar structures.

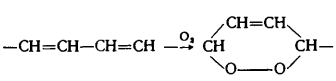
II. PARQUET POLYMERS

A typical representative of polymers having a parquet type of structure is graphite. It consists of fused six-membered carbon rings, the distance between the carbon

atoms in them being 1.42 Å, close to the corresponding length in the benzene molecule[100,101]:

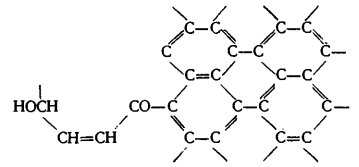
The planar networks of carbon atoms form parallel layers, 3.38 Å apart. Graphite is formed in Nature by reducing processes at high temperatures[102]. The graphite layers readily separate from one another, so that this polymer is used in the manufacture of pencils and antifriction materials. The refractoriness and ability to conduct an electric current make it possible to employ graphite for the manufacture of crucibles and electrodes and in foundry work[103].

Graphite can be prepared artificially. Thus flexible fibres and fabrics containing up to 99.9% of graphite have been obtained[104,105] by heating viscose rayon fibre in conformity with the following scheme:



$$\underset{\text{viscose rayon fibre}}{(C_6H_{10}O_5)_x} \xrightarrow{800^\circ} \underset{\text{carbon fibre}}{(C_{36}H_5O)_x} \xrightarrow{3000^\circ} \underset{\text{graphite fibre}}{(C_{28}H)_x}$$

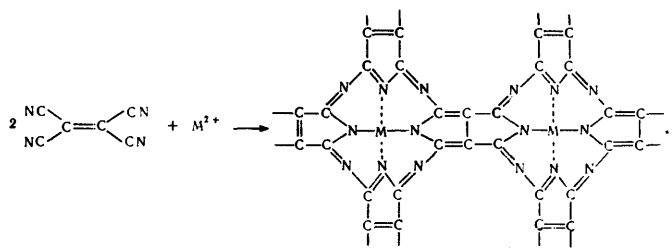
A carbonised fibre containing 90–91% of carbon is first formed, then on further heating a carbon fibre (91–98% of carbon), and at ~ 3000°C the graphite fibre (> 98% of carbon). Carbonisation and graphitisation are complicated processes, which occur when various carbonaceous materials are gradually heated without access of air (up to 3000°C). Practically any textile material can be converted into graphite.



Graphitised fibres are used for reinforcing thermostable plastics, and for manufacturing corrosion-resistant equipment and thermal insulation. Phenolic plastics reinforced with graphite fabric and silicon dioxide fabric can be used for the manufacture of rocket nozzles[104,106].

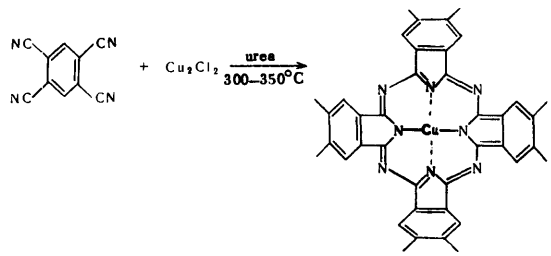
Winslow et al.[107] investigated the pyrolysis of a 48% divinylbenzene–ethylvinylbenzene copolymer. On heating to 960°C the yield of carbon product was only 6% on the weight of the initial copolymer. Preliminary oxidation (to a content of 18% of oxygen in the polymer), however, leads to a sharp increase in the yield of carbonaceous product (47% calculated on the oxidised copolymer). The pyrolysis of the chlorinated polymer (45% of chlorine) up to 1000°C gives a 55% yield of carbonaceous residue. In Winslow's opinion graphitelike structures are ultimately formed as a result of the thermal changes undergone by the copolymer.

By oxidising conjugated polyenes Berlin and his collaborators[108,109] obtained polymeric peroxides:



which on being heated over the range 200–300°C underwent complicated chemical reactions resulting in the elimination of water, carbon dioxide, alcohols, ketones, unsaturated hydrocarbons, and benzene with the formation of fused aromatic systems containing up to 15% of oxygen

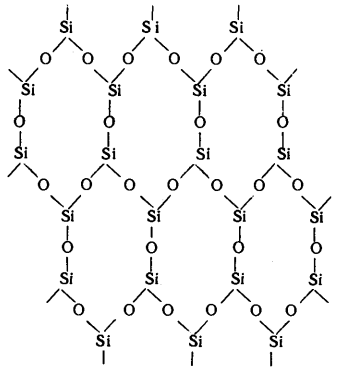
This polymeric product possessed paramagnetic and semiconductor properties.



A parquet polymer was obtained by Berlin et al.[85] in the reaction of copper acetylacetonate with two molecules of tetracyanoethylene under vacuum at temperatures from 160° to 300°C:

The polymer was an infusible black product, insoluble in organic solvents, alkalis, and dilute acids. The polymeric chelate complexes of tetracyanoethylene are crystalline and chemically stable; they do not burn, and withstand prolonged heating at 500°C without degradation[110,111]. These products possess semiconductor properties. Analogous polymeric compounds have been obtained using iron and magnesium[112].

Berlin and Matveeva[113] synthesised polymers of tetracyanoethylene also in the absence of metals or their salts. These polymers were regarded as close to the polymeric metal complexes in structure (azaporphyrin rings). When heated in a vacuum (1–2 mm) at 200°C for 200 h, the polymer is probably stabilised, and losses in weight produced by raising the temperature to 350°C reach only 9.6%. Further rise in temperature causes appreciable degradation. The electrical properties of polytetracyanoethylenes and of polychelates of tetracyanoethylene are analogous.



Epstein and Wildi[114] examined the electrical properties of the polymer of copper phthalocyanine obtained by heating the tetranitrile of pyromellitic acid with copper(I) chloride and urea:

The polymer is a purple-black powder. When it is heated in a vacuum (0.25 mm) at 410°C for 18 h, the loss in weight is 10.8%.

A considerable number of parquet polymers are found among the silicates. All silicates are based on the tetrahedral silicon atom combined with four oxygen atoms

located at the vertices of the tetrahedron. Coupling such tetrahedra together may yield the layer structure

in which each silicon atom is attached to an oxygen atom (not shown in the diagram) located either above or below the silicon atom on the normal to the plane of the diagram.

An example of the layer silicates of magnesium is talc, whose composition corresponds to the formula $Si_8O_{20}Mg_6(OH)_4$ or $Mg_3(Si_4O_{10})(OH)_2$. The structure of this mineral can be represented schematically as

$$\begin{matrix} 6\,O \\ 4\,Si \\ 4\,O+2\,(OH) \\ 6\,Mg \\ 4\,O+2\,(OH) \\ 4\,Si \\ 6\,O \end{matrix}.$$

In this polymer two layers of silicon–oxygen tetrahedra are linked together by a "brucite" layer, which consists of $Mg(OH)_2$ and is located between them. The vertices of the tetrahedra in the two silicon–oxygen layers point towards one another[115]. These three layers are firmly bound into packs, between which very weak attactive forces operate, which explains the low hardness, easy cleavage, and absence of elasticity in talc.

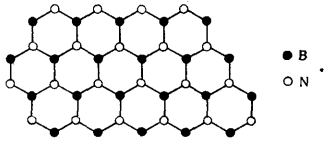
Talc is a poor conductor of heat and electricity. It does not melt below 1300–1400°C, and does not dissolve in acids even on heating[116]. Talc is widely used in the manufacture of rubber (as a filler), in perfumery, in the paint and ceramic industries (insulators, etc.), and in other fields[117].

A layer structure is possessed also by crystals of chrysotile asbestos, which forms fine fibres[118] sometimes reaching 160 mm in length. It is stable to the action of fire and alkali, but is broken down by hydrochloric acid. This material is of great practical value as a consequence of its stability at high temperatures.

The chief component of most clays is the mineral kaolinite $Al_4(Si_4O_{10})(OH)_8$, which is a variety of aluminium hydrosilicate. The crystals of kaolinite form two-layer packs, comprising a layer of silicon–oxygen tetrahedra and a "hydrargillite" layer. The structure of kaolinite crystals can be written

$$\begin{matrix} 6\,O \\ 4\,Si \\ 4\,O+2\,(OH) \\ 4\,Al \\ 6\,(OH) \end{matrix}.$$

They are easily cleaved into thin plates. The mineral is stable towards hydrochloric and nitric acids, but is readily decomposed by sulphuric acid, especially on heating. Kaolin is used in the ceramic industry (for the manufacture of china and pottery, firebricks, etc.), in building, and in other fields[119].

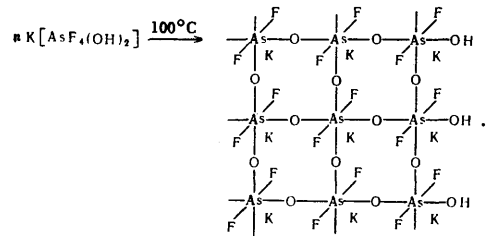


A layer structure is possessed also by montmorillonite. In contrast to kaolinite, it forms a three-layer structure comprising two layers of silicon–oxygen tetrahedra, between which is located a "hydrargillite" layer[120].

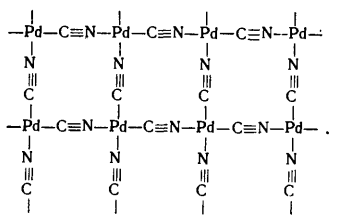
Micas are aluminosilicates which occur quite widely in Nature. Their composition can be expressed by the formulae[121] $M^+M_3^{2+}(AlSi_3O_{10})(OH)_2$ or $M^+M_2^{3+}(AlSi_3O_{10})(OH)_2$, where M^+, M^{2+}, and M^{3+} are uni-, bi-, and ter-valent cations. The hydroxyls may be replaced by fluorine. Micas are minerals having a crystal lattice of typical layered structure, in which 25% of the silicon–oxygen tetrahedra have been replaced by aluminium–oxygen tetrahedra.

A typical representative of the micas is muscovite $KAl_2(AlSiO_{10})(OH)_2$. As with many micas, the crystalline leaflets of this mineral are elastic on flexure[122]. It is stable towards acids. Muscovite possesses excellent electrically insulating properties, and is widely used for the manufacture of electrically insulating materials.

The manufacture of synthetic mica has now been organised[123–127]. It is produced in electric furnaces, by fusing together at 1370°C a stoichiometric mixture of magnesium oxide, aluminium oxide, silicon dioxide, potassium fluorosilicate, and orthoclase, and then slowly cooling the molten mass. The resulting mica has the same structure as the natural variety, but contains fluoride instead of hydroxyl groups, which confers on it a higher thermal stability (800°C) than natural mica (500–600°C).



A layer structure resembling graphite is exhibited also by a variety of boron nitride BN:[128–130]



The distance between nitrogen and boron atoms is 1.45 Å, while that between the layers is 3.35 Å, as in graphite. Boron nitride can be prepared by heating boron and nitrogen above 1200°C or by heating boron or boron sesquioxide in an atmosphere of ammonia[131]. Boron nitride is a powder similar to talc, melting at ~ 3000°C (under pressure). It is stable towards acids and alkalis.

Crystals of the mineral molybdenite MoS_2 have a hexagonal structure of layer type[132,133], in which the molybdenum atom is surrounded by six sulphur atoms forming a trigonal prism. The unit cell of the crystal contains three lattices of molbdenum atoms, two layers of sulphur atoms being arranged between two of these lattices. Like graphite, molybdenum disulphide is easily cleaved, and is therefore used as a lubricant[134]. When rapidly heated in an inert atmosphere, it melts with decomposition at 1700–1800°C. At atmospheric pressure thermal dissociation of the polymer begins above 1300°C. In air molybdenum disulphide is stable up to 300–350°C; it is practically insoluble in water and dilute sulphuric and hydrochloric acids, but it dissolves in aqua regia and hot concentrated nitric and sulphuric acids[133].

Polymers of parquet type can be obtained by heating fluoroarsenates[135]:

According to Pauling[136] complex palladium cyanides have the structure

I. INTRODUCTION

The production of polymeric products on solid surfaces, by the action of electron bombardment or ultraviolet radiation on organic compounds of low molecular weight, or in the glow discharge, is of interest both from the theoretical point of view and in connection with the practical utilisation of this effect. Under these conditions films can be obtained from practically any organic compound, whereas with ordinary methods of polymerisation or polycondensation the presence of unsaturated bonds, rings, or certain functional groups in the molecules is essential. It is an extremely complicated task to establish the mechanism of the chemical reactions caused by the action of active particles on an adsorbed layer and leading to the formation of polymer films on the surface. It must be borne in mind that the resulting polymer is also subject to the action of ions and electrons, which may produce free macroradicals and cause degradation and cross-linking reactions. In view of the complexity and diversity of the reactions occurring under these conditions and leading to the formation of polymer films, only qualitative assessments can at present be made of their mechanism.

The method under discussion has already found practical application for the production of insulating and anticorrosive coatings. The thin polymeric films obtained in this way on a solid surface are distinguished by high thermal stability, chemical stability towards acids, alkalis, and organic solvents, good adhesion, and also homogeneity and the absence of pores. These properties of films, their superior dielectric characteristics, and the possibility of obtaining films of semiconductor type under special conditions indicate the wide opportunities for applying the method in various technical fields, and especially in microelectronics.

The present review will examine successively the possibilities and conditions for obtaining polymer films on solid surfaces by electron bombardment, in the flow discharge, and under the influence of ultraviolet radiation. Problems connected with possible practical uses of this method will be discussed separately.

II. PRODUCTION OF POLYMER FILMS ON IRRADIATION OF A SOLID SURFACE WITH ELECTRONS

Formation of polymeric films on solid surfaces under the influence of electrons occurs even with low concentrations of the organic substance in the gas phase, corresponding to pressures of 10^{-4} mmHg or lower. Consequently the processes governing film growth take place mainly in an adsorbed layer, since the probability of interaction between electrons and molecules in the gas phase is extremely small at such low pressures. Interaction between electrons and sorbed molecules may lead to a diminution in the concentration of molecules in the adsorbed layer or to the formation of polymeric deposits on sites which have been subjected to electron bombardment.

The qualitative view held at present on the mechanism of these processes is that desorption of molecules into the gas phase can take place only by inelastic collisions of electrons with the molecules: otherwise, the transfer of kinetic energy is too small to detach the molecules from the surface. In inelastic collisions, electronic states in the sorbed molecules can be excited, which may lead to dissociation of the molecules into fragments (ions and radicals). The fragments, which possess sufficient kinetic energy to overcome the bonding to the surface, are desorbed. Those fragments which have not acquired sufficient kinetic energy on dissociation remain on the surface, and may react either with one another or with molecules of the starting material, which will lead to the formation of solid polymeric deposits on the surface. Hence it follows that the interaction of electrons with sorbed organic molecules may lead simultaneously to the desorption of particles into the gas phase and to the formation of polymeric deposits on the surface. Henceforward we shall examine only one aspect of this process—the deposition of polymer films.

It must be mentioned, however, that very intensive research is now being undertaken into processes of the desorption of molecules under the influence of electrons. This is of definite interest for an understanding of the processes occurring in heterogeneous catalysis, and for radiation-chemical reactions on a solid surface. The investigations have shown (1) that the probability of desorption of molecules under the action of electrons is small[1]—from 10^{-3} to 10^{-5}—while the desorption of positive ions is still less probable[2], whereas the probability that molecules will be desorbed by ions approaches unity[3]. (2) The appearance potentials of ions from adsorbed molecules are lower than those of the same ions from molecules in the gas phase. This suggests that adsorption considerably changes the energy state of the adsorbed molecules in comparison with their state in the gas phase[1,4]. (3) Curves for desorption plotted against the energy of the electrons pass through maxima, whose positions agree well in most cases with the excitation functions of the molecules in the gas phase[5]. These results confirm that desorption is caused by dissociation of excited molecules and ions into neutral and charged species. (4) With electrons of low energy ($E < 6$ eV) the desorbed molecules do not differ in character from the initial molecules, which probably indicates that in this case

desorption is due to simple dissociation of complexes formed by the sorbed molecules with atoms of the support[6].

It is possible[7-9] to prepare graft polymer layers on various inorganic surfaces by exposing the latter to fast electrons (700 kV and more) in the presence of gaseous monomers. However, the conditions under which polymerisation takes place in this case (highly penetrating radiation, high vapour pressure of the monomer) are fundamentally different from those adopted in work on the action of electron bombardment, and therefore these results will not be discussed here.

1. Influence of Various Factors on Rate of Formation of Polymer Films by Electron Bombardment

The deposition of polymeric coatings on surfaces exposed to electrons in a vacuum was discovered as long ago as the 1930s. Stewart[10] observed the formation of insulating deposits when metallic substrates were bombarded with electron and ion beams. The electrical resistance of the films was measured as well as the breakdown voltage, and the films were also shown to be thermostable up to 450°C.

Further development of work on these lines resulted mainly from observations made when various specimens were examined in the electron microscope. It was found that, under the conditions of exposure in such an instrument, the specimens in time became covered with a brown coating and changed in size. This phenomenon was noted by many workers[11-14]. König and Winkler[15,16] observed the formation of carbon when specimens of organic origin were examined in the electron microscope. Cosslett[17] observed the formation of polymeric deposits on specimens of the oxides of nickel, molybdenum, and magnesium.

One of the first to make a special investigation of this phenomenon was Watson[18], who measured the size of carbon black particles in an electron microscope. He discovered that the particles increase in size with time owing to the formation on them of a light brown film. He suggested that the film resulted from the action of the electron beam on the vapours of organic substances.

Hillier[19] investigated the chemical properties of the film and the kinetics of its growth as a function of various factors. He showed that the film was insoluble in the usual organic solvents, strong acids, and alkalis, has an amorphous structure, and always contained carbon. The rate of film growth was proportional to the first power of the intensity of irradiation, did not depend on the material of the substrate, and fell with time. If, however, irradiation was terminated after a certain time, and was then begun again, the rate of growth reached its original value. This was explained[19] by a low rate at which the surface layer was filled with molecules. Hillier concluded that film formation occurs only when three factors—a vapour capable of yielding a polymer, a surface on which it can be formed, and a beam of electrons—are present. It was assumed that the surface was activated by the irradiation, and behaved as a catalyst. The organic molecules could reach the gas phase in two possible ways—by spontaneous diffusion from metal gaskets, the walls, and grease, and by degassing of metal parts of the instrument under the influence of electron bombardment. To prevent film formation this author recommends first eliminating the access of organic substances to the gas phase.

Ennos[20] used a specially designed apparatus to investigate the cause of the deposition of films on solid surfaces and methods for their elimination. Direct measurements of film thickness established that the films grow at a rate of 1 Å s^{-1} with a current density of 0.5 mA cm^{-2}, electrons of energy 40–75 keV, and a pressure of 10^{-5} mmHg. He showed[20] that the rate of growth of the film is independent of the duration of exposure or the energy of the electrons within the above range, although it is strongly dependent on the temperature of the substrate. Discussing the mechanism of film formation, this author concluded that the deposits were formed by the interaction of organic molecules with the electron beam on the surface of the substrate, where a considerable concentration of hydrocarbon molecules is produced by adsorption. This same view on the mechanism of the formation of polymeric deposits was held also by Poole[21], who emphasised that, even with the organic substances at pressures of 10^{-4} mmHg and above, all processes responsible for film formation take place on the surface, not in the gas phase.

Several suggestions had been made even earlier to explain this phenomenon. Watson[18] assumed that film formation was due to ions produced in the residual atmosphere and deposited on the support near the electrically conducting surface. However, an estimate of the deposition due to ions formed in residual gases gives values for the reaction velocity which are smaller by several powers of ten than those observed experimentally.

Cosslett[17] supposed that film formation was due to ejection of adsorbed substance, perhaps of metal itself from the grid of the specimen-holder, on electron bombardment.

Haefer[22] noted that deposition of a substance on a substrate may result not only from the reactions of electrons and ions with adsorbed molecules but also from cathode sputtering. Ellis[23], like most workers, considered that a film was formed as a result of resinification of organic substances under the influence of the electron beam, but differed in ascribing replenishment of the number of adsorbed molecules mainly to the migration of molecules on the surface, while replenishment from the gas phase was of considerably less importance. However, Ennos[20], on the basis of the experimental results, reached the opposite conclusion—that replenishment of the number of adsorbed molecules by surface migration played an insignificant part in comparison with that from the gas phase.

Thus study of the reasons for contamination of specimens in an electron microscope and elucidation of the conditions under which it would be minimised have led to establishment of the important fact that the formation of polymeric deposits results from interaction of electrons with molecules in the surface layer.

In later work, where experiments have been made both in specially designed apparatus and in electron microscopes, the kinetics of film formation and the factors influencing the rate of growth have been studied quantitatively and in greater detail. The experimental techniques have been described in detail in the original papers, so that they will merely be mentioned here. Film thickness has been determined interferometrically[24,25], by means of a piezoelectric crystal[26], and by weighing[27]. Films of a sputtered metal[28,29] and of a dielectric[25] (quartz, glass) were employed as substrates. Experiments were made mainly in an atmosphere of the vapours of certain organic substances, but in some work use was made of an atmosphere of the residual gases in vacuum equipment, which always contain hydrocarbons.

The relative abilities of various organic substances to contaminate vacuum equipment was studied[30] by introducing them into a clean vacuum system, and then determining the characteristics of the polymeric deposits formed on surfaces bombarded by electrons. The tendency to film formation diminished in the sequence—hydrocarbon oil of diffusion pumps, vacuum greases, various types of rubber gaskets, silicone oil, and vacuum wax. Experiments carried out at the same time on the temperature dependence of the rate of deposition showed that raising the temperature to 200°C reduced the rate of film growth to 10% of its previous value. A cold trap at −15°C has a similar effect.

The influence of the temperature of the substrate on the rate of film formation on the surface has been investigated for various organic compounds[20,24,26,30-34]. Leisegang and Schott[32] studied the effect of temperature on the rate of contamination of a specimen in an electron microscope, and found the rate to diminish with rise in temperature. Christy[25] studied the rate of formation of films from the silicone oil DS 704 as a function of the current density of electrons with the substrate at various temperatures, and confirmed that rise in temperature diminishes the rate of film growth. Haller and White[26] studied the dependence of the rate of polymerisation of butadiene on its pressure in the gas phase (over the range 10^{-6}–3×10^{-4} mmHg), and established that the rate diminishes with rise in temperature throughout the pressure range investigated.

Several investigations have been made of the influence of the nature of the substrate on the rate of formation of polymeric deposits[19,21,35]. Experiments with silver, steel, copper, nickel, and copper–nickel alloy substrates revealed no dependence of rate of film growth on substrate material[21]. This is confirmed by the results of other work[19]. A study of film formation on nickel, copper, platinum, silver, iron, glass, and crystalline sodium chloride substrates in an electron microscope[35] yielded no definite conclusions on the influence of the substrate on the rate of film formation. The fact that no such relationship was observed in the above work is probably due to a phenomenon subsequently discovered by Mann[36], who studied the secondary electron emission from polymeric films under the influence of an electron beam. He found that, up to a film thickness of 25 Å, secondary emission occurs simultaneously from the growing film and from the substrate, whereas with thicker films secondary emission is observed only from the growing films themselves. It was shown that, with the substrate at a positive potential relative to the electrode accelerating the electron beam (which is usually the case in all experiments), secondary electrons also play a definite part in film formation. It may be concluded from this work that the material of the substrate can influence the rate of film growth only in the early stages of the process.

The influence of the vapour pressure of organic substances has been investigated[25-27,37]. Haller and White[26] determined the dependence of the rate of film growth on the pressure of butadiene over the range 1.3×10^{-6}–3.2×10^{-4} mmHg, and found the rate to increase with rise in pressure only to a certain limit, this saturation occurring at higher pressures with greater electron currents (Fig. 1). Similar pressure effects have been observed[27] in an investigation of the behaviour of silicone oil, and also in other work[19,25]. In another piece of work[37] the rate of film growth was found to be independent of the pressure of butadiene. This was probably because these experiments were conducted at high pressures, at which the rate had ceased to depend on pressure.

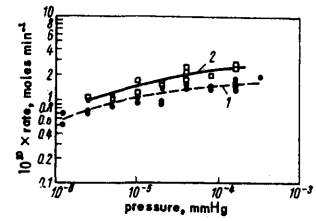

Fig. 1. Pressure dependence of rate of polymerisation of butadiene at: 1) 400 μA; 2) 800 μA.

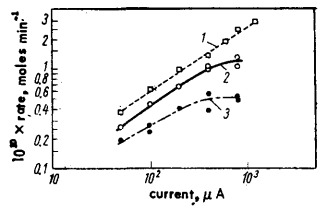

Fig. 2. Dependence of rate of polymerisation of butadiene on the current at pressures of (mmHg): 1) 1.6×10^{-4}; 2) 4.0×10^{-5}; 3) 1.3×10^{-5}.

The influence of the current density of the electron beam on the rate of film formation has been investigated[19,24-26,32]. Christy[24] found that, with a silicone oil, the relation is non-linear, the rate reaching saturation at definite values of the current. Haller and White[26] showed the rate of film formation from butadiene to be proportional to the square root of the current density. At higher currents the curves tend to form a plateau, this occurring at higher current densities the higher the pressure (Fig. 2). Similar results for the influence of current density on rate of film formation were obtained by other workers[32], and also more recently[38,39].

No detailed study has yet been made of the dependence of the rate of film growth on the electron energy. Only isolated experiments have been made, and in these the relationship was investigated only over a narrow energy range. Thus the rate at constant current density and pressure has been found[20] not to depend on the energy of the electrons over the range 40–75 keV. Nor does variation over the range 200–600 eV influence the rate of film formation from silicone oil[27]. Mayer[38] made experiments in a reflecting electron microscope, and found the rate to increase with low electron energies over the range 6–25 eV.

The influence of the duration of irradiation on the rate of formation of films has been examined[20,24,26,27,38]. Over the times investigated the rate was found to be independent of duration. A constant rate of growth is maintained[24,27] for film thicknesses of several thousand Ångström units.

It has been shown[24,40] that films of either semiconductor or metallic type can be obtained by irradiating solid surfaces with electrons in an atmosphere of the vapour of an organometallic compound [or of an inorganic salt of the tin(II) chloride type]. Baker and Morris[40] have demonstrated that, under more severe experimental conditions

(electrons of energy up to 1 keV, current density of ~ 5 mA cm^{-2}), the decomposition of the vapours of organometallic compounds (tetrabutyltin, tetramethyltin, tetraethyl-lead) proceeds as far as formation of a film of the pure metal on the surface of the substrate. Decomposition of tetrabutyltin $(C_4H_9)_4Sn$ on a quartz surface yields [25] films not of pure tin but of polybutyltin, possessing semiconductor properties. Both the rate of growth and the composition of the films depend on the pressure of tetrabutyltin vapour in the gas phase, the current density, and the temperature of the substrate. The same work included an examination of the formation of tin films by the decomposition of tin(II) chloride molecules by electrons on a quartz substrate.

2. Mechanism of Formation of Polymer Films

Most research workers consider that film formation is due to processes occurring in the surface layer as a result of interaction between sorbed molecules and electrons. The mechanism of film formation has been discussed in greater detail [24,26,37,41]. The process is supposed to occur in two stages: (1) active centres (radicals and ions) are formed on the surface by interaction of electrons with sorbed molecules; and (2) sorbed molecules react with these active centres. The surface formation of polybutadiene films, in particular, has been interpreted in this way [26,37,41]. These authors consider that the polymerisation of butadiene proceeds initially on the surface of the substrate, and continues as the film grows by interaction of adsorbed gas molecules with active centres of the polymer surface.

There is no generally accepted view in the literature as to whether ions or radicals play the main part in the process. Several workers assume a radical mechanism. This conclusion was reached by Christy [24], who examined the behaviour of silicone oil, and found that polymer formation results from the recombination of free radicals produced by the action of electrons on adsorbed molecules. Haller and White [26] supply evidence that the surface polymerisation of butadiene proceeds by an ionic mechanism. It is most likely that both mechanisms of polymerisation may play a part in film formation, with one or the other predominating depending on the experimental conditions and the nature of the molecules of the starting material. Schemes have been discussed [26] for both mechanisms applied to the polymerisation of butadiene on the surface of an already formed film.

The radical mechanism of polymerisation can be represented by the equations

$$P + e \rightarrow P^{\cdot} + H^{\cdot} + e \quad k_1 I \tag{1}$$

$$P^{\cdot}_M + Bu_a \rightarrow P^{\cdot}_{M+1} \quad k_2 [P^{\cdot}]\ [Bu_a] \tag{2}$$

$$P^{\cdot}_M + P^{\cdot}_N \rightarrow P_{M+N} \quad k_3 [P^{\cdot}]^2 \tag{3}$$

where P is a polymer molecule, Bu_a is an adsorbed butadiene molecule, P_M and P_N are polymer molecules on the surface containing respectively M and N monomer units, and k_1, k_2, and k_3 are the rate constants of reactions (1)–(3) respectively. On the assumption that the size of a radical does not affect its chemical properties and that the concentration of adsorbed monomer is constant, the rate of polymerisation can be written

$$r = -\frac{d[Bu_a]}{dt} = k_2 \sqrt{\frac{k_1}{k_3}} I [Bu_a]. \tag{A}$$

The relation between the pressure of butadiene in the gas phase and the surface concentration of its molecules $[Bu_a]$ is determined by the adsorption isotherm.

The ionic mechanism of polymerisation is described by the equations [26]

$$P + e \rightarrow P^{+} + H^{\cdot} + 2e \quad k_4 I \tag{4}$$

$$P^{+}_M + Bu_a \rightarrow P^{+}_{M+1} \quad k_5 [P^{+}] [Bu_a] \tag{5}$$

$$P^{+} + e \rightarrow P \quad k_6 [P^{+}] I \tag{6}$$

$$P^{+} + e_c \rightarrow P \quad k_7 [P^{+}] [e_c] \tag{7}$$

$$e_c + s \rightarrow e_s \quad k_8 [e_c] \frac{dv}{dx} \tag{8}$$

$$e_c + L \rightleftarrows e_L \quad [e_c] = [e_L] \exp(-E_L/kT) \tag{9}$$

where P is a polymer molecule, P^{+} a polymer molecule with a positive charge localised on one of the surface carbon atoms, e an incident electron, e_C an electron in the conduction band, e_L an electron in a trap of energy level L lying below the conduction band of energy E, and k_4–k_8 are the rate constants of the corresponding reactions. Equation (8) implies the transfer of a conduction electron into the metallic substrate s under the influence of the potential gradient dv/dx. If we consider that stage (8) is rapid, i.e. that there will be no great accumulation of charge in the polymer, we have

$$[P^{+}] = [e_c] + [e_L] \simeq [e_L]. \tag{10}$$

On the assumption that concentrations are constant, and that stage (7) is much more rapid than stage (6), the rate of polymerisation can be expressed in the form

$$r = k_5 \sqrt{\frac{k_4 I}{k_7 \exp(-E_L/kT)}} [Bu_a]. \tag{11}$$

In the deduction of this equation and of Eqn. (A), reactions such as the formation of cross-links and unsaturated bonds, etc. have been disregarded, since they do not affect the rate of polymerisation.

It is seen from Eqns. (A) and (11) that in both cases the rate of polymerisation is proportional to the concentration of sorbed butadiene molecules and to the square root of the electron current: i.e. the type of dependence of r on $[Bu_a]$ and I provides no opportunity of assessing the mechanism of polymerisation. Hence it follows that additional data are necessary in order to elucidate the mechanism of polymerisation.

Experimental results are now available which indicate unambiguously that in several cases the radical mechanism of polymerisation may play a considerable part. Mayer [38] has shown that films can be obtained with electrons of energy below 6 eV, i.e. under conditions such that ions cannot be formed. This mechanism of polymerisation is supported also by the fact that the resulting films contain considerable concentrations of free radicals [28,29] (up to 10^{18} spins cm^{-3}). Christy [24] has given a theoretical expression for the rate of formation of films by a radical mechanism, which shows good agreement with his experimental data obtained with the vapour of silicone oil. Other authors [20,21,27] consider that in the cases which they have investigated films are formed also predominantly by a radical mechanism.

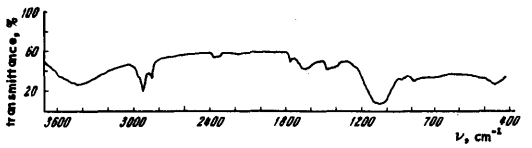
On the other hand, Haller and White [26], in a paper on the polymerisation of butadiene on a surface, give experimental data supporting an ionic mechanism. To determine the mechanism of polymerisation they used mixtures of butadiene with oxygen (4 : 1) and with hydrogen (1 : 4). If a

radical mechanism of polymerisation is assumed, the presence of oxygen should result either in complete suppression or to a slowing down of polymerisation; hydrogen should have a similar effect, and its presence should lead to an increase in the rate of migration of free radicals in the polymer and an increase in k_3 in Eqn. (3). It was found, however, that, within the limits of experimental error, the rates of polymerisation of pure butadiene and of its mixtures were the same when the partial pressures of butadiene in the mixtures were equal to its pressure in the experiments on the polymerisation of the pure monomer. This was regarded as indicating that butadiene polymerises by an ionic mechanism. This view is supported also by the fact that the life of positive ions in the polymer, determined [26,27] by means of a pulsed electron beam, is very long (around 1–3 min).

The preceding arguments have applied to the polymerisation of organic molecules on the surface of already formed polymer. However, formation of the first layer of polymer film directly on the pure metal surface has been found to involve far more rapid polymerisation than in the formation of subsequent layers. Hirsch [42], comparing his experimental results on the production of polymer films of monolayer thickness with those obtained by Ennos [20] on the formation of films several thousand Ångström units thick under roughly similar conditions, found that the rate of film growth was higher in the former case by factors of the order of 10^2. White [39] established that one incident electron causes the polymerisation of 30 butadiene molecules in the case of a pure metal surface, whereas on a previously formed film the polymerisation of one butadiene molecule requires 100 electrons. Such a difference in the rates of formation of the first layer of a film compared with that of subsequent layers is explained by the author in terms of the energy state of molecules adsorbed on the clean metal surface being such that only slight action by electrons is required for the chain reaction of polymerisation to begin. It must also be borne in mind that a high rate of formation of the initial layers of a film may be considerably affected also by secondary electrons dislodged from the substrate metal [36].

3. Structure and Properties of Films

Little work has been done on the structure of polymer films obtained on a surface by electron bombardment. This method probably does not allow films of ordered structure to be produced [38]. X-Ray examination has shown the films to be amorphous [19,33,43-45]. Infrared spectroscopy has been used in several cases to investigate the structure of the films. The infrared spectra [27] of films obtained, in an atmosphere of a silicone oil, on the surfaces of stainless steel and of an optically polished sodium chloride crystal contained in both cases a broad absorption band in the region of 1050 cm^{-1}, corresponding to stretching vibrations of the Si–O–Si group, together with absorption bands corresponding to vibrations of the $Si–CH_3$ bond, deformation vibrations of the Si–O bond, and oscillations of a hydrogen atom in CH_2 and CH_3 groups. The absorption spectrum of the film obtained on the metallic substrate also included a band in the region of 1750 cm^{-1}, indicating the presence of carbonyl groups in the film, and a broad band near 3400 cm^{-1}, corresponding to the hydroxy-group. The appearance of carbonyl and hydroxyl groups in the film is probably due to oxidising processes, as in the irradiation of ordinary polymer films with electrons [46,47]. The



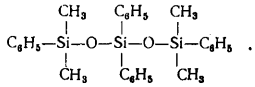


Fig. 3. Infrared spectrum of film obtained from silicone oil.

absorption band in the region of 1620 cm^{-1} for the film obtained on sodium chloride, and 1645 cm^{-1} for the film obtained on the metal, is especially interesting, for it indicates the presence of double bonds in the films. The infrared spectrum of the polymer film obtained on a stainless steel substrate is reproduced in Fig. 3.

The possible structure of films obtained from the silicone oil DS 704 is discussed by Holland and Laurenson [34]. The chemical formula of the oil (M = 484) is

The action of a discharge and of γ-rays on this compound in the gas phase gave large quantities of hydrogen and methane with little benzene. From this it is concluded that the phenyl group remains in the polymer molecule, the monomer units being linked by CH_2 and $CH_2.CH_2$ groups.

Several workers have examined the physical and chemical properties of the films [19,24,42-44]. Films obtained from organic compounds always contain carbon and hydrogen [19], sometimes also oxygen [11], and can be removed from the surface by heating in air to redness [10,19]. The films are insoluble in water, the usual organic solvents, and also strong acids and alkalis. They possess high thermal stability [10,43,44], especially those obtained from silicone oils [43]. The present method also enables especially thin films to be obtained, possessing good homogeneity [37], continuity [24,42], adhesion to the substrate surface [27,44], and superior dielectric properties [24,27].

Many studies have been made [10,24,27-29,34] of the electrical properties of films obtained in atmospheres of organic and silicone compounds. The film possess high values of the bulk resistivity R_v and the breakdown voltage [24,27]. Table 1 gives estimated values of R_v, the dielectric constant ϵ, the tangent of the loss angle tan δ, and the breakdown voltage v_{br} for films from silicone oil [27].

The electrical conductivity of the films varies between wide limits depending on the energy of the electrons, the temperature, and the material of the substrate. Poole [21] showed that films having a high resistance are obtained with electrons of energy below 300 eV, whereas films of low resistance are obtained above this value. Zinn [33] has investigated the influence of the substrate material on the insulating properties of the films: films obtained on

TABLE 1.

$1 \cdot 10^{-14}$	3—4	<0.01	$>10^6$

aluminium and tin possess good insulation, those on lead have moderate insulation, and those on gold and silver possess no insulating properties. He suggests[33] that the good properties on aluminium and tin are due to thin oxide films at the metal–dielectric interface. Experiments on the influence of the substrate temperature on the electrical conductivity of the film show[34] that those obtained at 240°C have a resistance of 6.5×10^9 ohms cm^{-2}, while those produced at room temperature have a value of 10^{13} ohms cm^{-2}. Nevertheless, films obtained at +50°C and −196°C have identical insulating properties. The absence of variation in electrical conductivity with temperature over this range is attributed[34] to similar coefficients of adhesion of the silicone oil molecules at these temperatures.

Holland and Laurenson[34] have investigated the effect, on the dielectric properties of films obtained from silicone oil, of adding various gases (oxygen, nitrogen, hydrogen, carbon dioxide, and water vapour) during their preparation. It was found that addition of oxygen and water vapour to the silicone oil vapour resulted in films showing higher resistance in air than in a vacuum, whereas films obtained with additions of nitrogen, hydrogen, and carbon dioxide show a higher resistance in a vacuum. The latter result was explained by adsorption of water vapour on the surface of the film in air. The dielectric constant ϵ of the films was 2.3 and 4.0 with additions of carbon dioxide and hydrogen respectively.

A considerable growth of interest has recently occurred in the mechanism of the passage of current through thin insulating films, including polymer films; the main reason for this interest is the need to use them for controllable sources of current, such as cold-cathode emission devices and tunnel triodes. The principle on which such devices operate has been discussed[48]. Two main mechanisms by which electrons can be transmitted through thin insulating films—passage of current by the tunnel emission of electrons and by Schottky emission—have been considered in the literature, and can be distinguished by the dependence of current on voltage and temperature (Table 2). Transport of current by the tunnel effect is independent of temperature, and is observed in extremely thin films (~ 100 Å), where the mean free path of the electrons in the film is comparable with its thickness. Transport of current by the Schottky mechanism occurs with thicker films, and is strongly dependent on temperature.

Studies have been made of the mechanism by which current passes through thin polymer films and of their electrical properties[28,29,49]. Mann[28] has examined the electrical properties of films obtained in the vapour of the silicone oil DS 704. Measurements were made of the current in the M–P–M system, over the range of film thicknesses 500–2500 Å, as a function of voltage and temperature (the system comprised a polymer film P enclosed between two sputtered metal electrodes M). At voltages up to 5 V the current density varies exponentially with the electric field strength, and is independent of film thickness. When the voltage is increased above 5 V, the current decreases, to disappear completely at ~ 6 V. A typical curve showing the variation in current density I with voltage is shown in Fig. 4.

The electrical conductivity of the films is strongly dependent on temperature at high voltages, but at low voltages, in the region of the negative resistance effect, the conductivity is independent of temperature. Christy[29] has investigated the electrical properties of analogous films over the thickness range 50–150 Å, and found that at low voltages (< 1 V) the current increases linearly with voltage, whereas at higher voltages it obeys the law $\ln I \propto V^{1/2}$. An investigation[49] of the conductivity of a polymer film 100 Å thick showed that $\lg I \propto V^{1/2}$ for voltages from 0.04 to 1 V. The temperature dependence of current for this film is reproduced in Fig. 5. The departure of this curve from a straight line is explained by a mixed mechanism for the transmission of electrons: a current due to tunnel emission is superimposed on the current due to Schottky emission, and makes a particularly large contribution at low temperatures.

The effect of ageing the film in air on its electrical properties has been investigated[28,29]. The volt–ampere characteristics gradually move to the right as the films remain in the air, and at the same time the capacitance of

the M–P–M system increases (Fig. 6). Placing the system in a desiccator resulted in a change in its electrical conductivity analogous to that occurring in the air, while the capacitance remained unchanged with time under these conditions. When, however, the system was placed in a vacuum or in an atmosphere of dry nitrogen, neither the conductivity nor the capacitance changed with time. It is concluded [28,29] that the change in conduction of the M–P–M system in air is associated with the adsorption and diffusion of oxygen molecules into the film through the electrodes, while the change in capacitance of the system is caused by the adsorption of water vapour. It has also been observed that the variation in the conductivity of films in air parallels the variation in the concentration of free radicals formed in the film during its preparation (the films contain high concentrations of free radicals, ~ 10^{18} spins cm^{-3}). This indicates that the mechanism of electrical conduction in the films is connected with free radicals, and that in this case the radicals are probably acting as electron-traps.

III. PRODUCTION OF POLYMER FILMS IN THE GLOW DISCHARGE

The chemical reactions leading to the formation of polymer films in the glow discharge are considerably more complicated and diverse than those occurring under the influence of a beam of electrons. This is due both to the high pressures and current densities (~ 1 mmHg and 0.1–1 mA cm^{-2}) and to the energy distribution of electrons in the discharge zone. A consequence of this distribution is that various electronic states in complicated organic molecules are already excited at the primary interaction step, so that a variety of dissociation fragments are formed. Furthermore, the breakdown of organic molecules may be caused by the action of free radicals and hydrogen atoms formed as a result of the primary reactions, since high pressures in the discharge zone favour the occurrence of secondary processes in the gas phase. It follows from this that the great diversity of chemical changes which organic molecules usually undergo under the influence of a glow discharge is not always due to the discharge itself, but is often a consequence of secondary processes caused by various neutral species. Hydrogen atoms can probably exert an especially large influence on chemical reactions in the discharge, since it has recently been established that they can possess high energies, close to the ionisation potential of the hydrogen atom, and the reaction cross-section for such excited particles far exceeds the usual gas-kinetic cross-section [50].

It follows from the above that film formation on a surface in a glow discharge may be caused not only by charged species, as occurs under the influence of electrons and ions, but also by active neutral species formed in the discharge zone, their concentration in the plasma far exceeding the concentration of charged species. It is also possible that ultraviolet radiation, produced by spontaneous loss of excitation by particles, may play some part in initiating the surface process.

As early as 1874 Thénard [51] and Wilde [52] noted that the action of an electric discharge on hydrocarbon vapours resulted in the formation of solid deposits on the walls of the apparatus. A later study (in the 1930s) of the chemical action of a glow discharge on methane showed [53] that, in a negative discharge at the temperature of liquid air, methane underwent dissociation followed by condensation. At room temperature dull yellow deposits were formed on the walls, which were unaffected by the usual solvents.

Austin and Black [54,55] studied the chemical behaviour of several cyclic hydrocarbons in a Tesla discharge. They found that a coating similar to shellac was formed on the walls of the reaction vessels, and solid reaction products condensed in a liquid nitrogen trap. With cyclohexane, benzene, toluene, and *p*-xylene the thin films resembling shellac were sometimes reddish brown or black in colour, and sometimes almost colourless. The freshly prepared films had good adhesion to the surface, but on standing they peeled off and cracked. The films did not dissolve in alcohol, acetone, ether, turpentine, benzene, toluene, xylene, or water, and were unaffected by the usual acids and alkalis. Elementary analysis of the films showed them to contain oxygen as well as carbon and hydrogen. From the results the formulae $(C_9H_7O_2)_x$, $(C_{21}H_{19}O_3)_x$, and $(C_{19}H_{19}O_3)_x$ were proposed for the solids present in the films formed from benzene, toluene, and xylene respectively.

Linder and Davis [56] investigated the behaviour of 57 different hydrocarbons in the discharge. In almost all cases they observed the formation of solid products on the cathode, the anode, and the walls of the discharge tube. These products were dark brown or black, mostly waxlike, but sometimes brittle. They evidently contained much carbon, although they did not burn completely on analysis.

Stewart [10], working with a discharge in a vacuum of around 10^{-5} mmHg, obtained insulating films which were insoluble in the usual solvents. He concluded that the films were of hydrocarbon origin, probably formed from residual gases and also from the vapour of the vacuum grease.

At the present time polymer films are obtained in a discharge usually under a vacuum bell jar at pressures of the order of 0.001–0.1 mmHg. [57-69] As an example let us consider the equipment for the production of thin polymer films patented by the [American] General Electric Co. [68] (Fig. 7). The pressure under the bell jar is ~ 0.02 mmHg, the electrodes are 16 mm apart, and the voltage between them is 1000 V. The optimum pressure range in the system is 0.01–0.1 mmHg. Polymer films less than 5 μm thick, possessing good dielectric characteristics, have

been obtained by this technique. The substrates on which the films are deposited have usually been of synthetic rubber metallised with aluminium, but films can be deposited on other materials—glass to which a surface layer of metal has been applied, metallic and siliceous plates, etc.

Coleman[61] uses as substrates moving tapes, which are gradually removed from the discharge zone, to obtain films of constant thickness undamaged by the heat evolved in the process.

König and Helwig[70] and Brockes and König[71] studied polymer films obtained from benzene vapour. In the former case[70] the discharge current was 7–9 mA and the voltage ~ 1000 V. The elementary composition of the film was determined ($C_{1.00}H_{0.83}$), its mass (by weighing on a quartz balance), its thickness with a Zener interferometer, and its density. These films proved to be less dense than carbon or graphite. The electrical conductivity of the films was ~ 10^{-9} ohm^{-1} cm^{-1}. The properties of the films were considerably changed by vacuum heat-treatment above 100°C. The optical transmission of the films was substantially diminished, and at 400°C they became first brown and then black. Heating the films produced an especially marked change in their electrical conductivity, which had increased by factors of 10^{10} after heating to 600°C.

Infrared spectroscopy was used[71] to establish the structure of the films. The infrared spectra of films obtained from benzene contained absorption bands characteristic of aromatic groups, whereas these bands were absent from the spectra of films obtained from methane (Fig. 8). It is interesting that the infrared spectra of a polymer film obtained from benzene and of a polystyrene film which had been irradiated with electrons had much in common with respect to both the character and the intensity of the bands. On storage in air the films underwent oxidation, and the infrared spectra contained bands corresponding to C=O and O–H bonds. Similar bands were observed also after irradiation of the film with electrons. Infrared spectroscopy was used also to investigate the oxidation of films from benzene as a function of their storage time in air (Fig. 9).

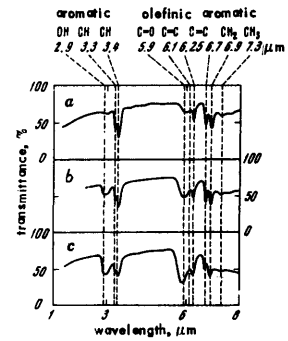

Fig. 9. Variation in infrared spectrum of polymer films obtained from benzene with time of storage in air:
a) 2 h; *b*) 5 days; *c*) 1 month.

If the films were heated in a vacuum immediately after preparation, they underwent no subsequent oxidation in air.

The influence of the conditions and parameters of the discharge on the properties of the resulting films was also investigated. An appreciable decrease in the hydrogen content of the films was observed, together with a diminished rate of film growth, when the discharge voltage was increased to 3000 V. Increase in the voltage also produced an increase in the quantity of degradation products of low molecular weight and the number of conjugated double bonds formed.

Pagnia[62,72] showed that the properties of films obtained in benzene vapour in a glow discharge depend to a considerable extent on the conditions of the discharge. With the same ignition voltage the films differ in electrical conductivity depending on whether the substrate is cooler or heated: it has the values 0.1 and 100 ohm^{-1} cm^{-1} respectively. Pagnia put forward the hypothesis that, with high ignition voltages and "hot" substrates, the films consist of

carbon alone, which may explain their relatively high conductance and great stability. This hypothesis was confirmed by the infrared spectra: the carbon content of films obtained with a "hot" substrate was very high, while the hydrogen content was insignificant. Nevertheless, the vacuum annealing of films obtained at low ignition voltages leads to a considerable loss in weight. The dependence of the resistivity on the ignition voltage, taking into account the temperature of the substrate, is illustrated in Fig. 10. Pagnia showed also that the resistance of the films remains constant on storage in a vacuum, but increases on storage in air, reaching a constant value only after several days (Fig. 11). Furthermore, all types of films obtained showed an increase in conductance with temperature.

Vastola and Wightman[73] also studied the behaviour of several hydrocarbons—ethane, methane, and ethylene (Group A) and acetylene, benzene, and naphthalene (Group B)—in a high-frequency discharge. The main product with both groups of hydrocarbons was a film a few Ångström units thick having a definite H/C ratio, and almost all the films absorbed a further quantity of hydrogen from the discharge, the ratio reaching a limiting value of 1.6. The films were insoluble in organic solvents. They were shown to be amorphous by X-ray and electron diffraction. The infrared spectra showed films of Group B to possess greater unsaturation than those of Group A, and the latter contained no aromatic groups. A high concentration of free radicals was found in films of Group B. According to the authors these results were consistent only with a mechanism of film formation which was independent of the type of bond in the initial hydrocarbon.

The electrical properties of films obtained in the glow discharge from 40 different substances have been investigated by Bradley and Hammes[57,74] and by Bradley[75]. The films were prepared at a pressure of ~ 1 mmHg, a current density of 1–3 mA cm^{-2}, and a voltage of 300–400 V, the thickness of the films being controlled by the discharge current and the time. These authors assume that the

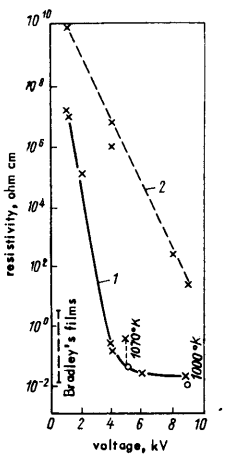

Fig. 10. Dependence of resistivity of film on ignition voltage of discharge with the temperature of the substrate taken into account:

2) substrate cooled.

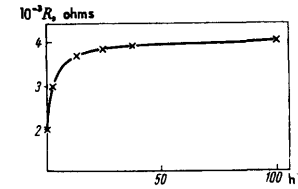

Fig. 11. Variation in resistance of film with duration of exposure to the air.

mechanism of conduction in the films studied in the same to a first approximation, although differences are observed in the structure, appearance, and stability of the films. The absorption of oxygen has no fundamental effect on the conductance (which is approximately doubled on the absorption of ~ 10 wt.% of oxygen). It was suggested that the magnitude and temperature dependence of the conductance are explained by the predominance of C–C bonds in the film structure. The same workers[74] investigated the photoconduction of films obtained in the glow discharge and containing nitrogen, sulphur, selenium, and several metals. They showed that the photoconductance varies by several orders of magnitude depending on the composition of the films, and a considerable increase in the photocurrent is observed with rise in temperature from −77°C to 185°C. The principal factor associated with photoconduction is probably the concentration of unsaturated groups in the films.

Bradley[75] has investigated the dark conductance and the photoconductance of polymer films obtained in a discharge, as functions of the temperature and the voltage during measurement. With most of the specimens examined the current was proportional to the voltage raised to a power exceeding unity: $I \propto V^{\Delta}$ ($\Delta > 1$). With many specimens the exponent Δ remains constant over a wide range of temperatures, although some highly conducting films show a sharp increase on heating above 180°C, after which Δ remains unchanged on cooling to room temperature. Films obtained from several sulphur, selenium, and nitrogen compounds gave values of the exponent Δ = 1–1.3, with the exception of films prepared from malononitrile. Such films and also those obtained from ferrocene exhibit a considerable increase in Δ on heating to 180°C. The activation energy of conduction was also determined, and for most of the films proved to be 0.4 ± 0.1 eV. It drops appreciably below 0°C, and may reach 0.1–0.2 eV. The author remarks that no theory is yet available to explain the temperature variation of Δ and of the activation energy.

Several papers have discussed a suggested mechanism for film formation in the glow discharge[57,60,76–78]. Goodman[60] assumes that ionised species form a polymeric substance on the electrode surfaces. Since the resulting polymer is again bombarded by ions, the same consequences—degradation and cross-linking—can be expected as with high-energy irradiation. Bradley and Hammes[57] proposed a mechanism consisting in the formation of ionic and radical-ion fragments by the intense electron bombardment, with recombination of these fragments on the electrodes. Haefer[76,77] assumes that molecules are ionised in the gas space of the glow discharge, forming intermediate products—free radical-ions—which exhibit a great tendency to recombine, and on striking the electrode surfaces form solid polymers.

CHEMICAL SOCIETY REFERENCE LIBRARY BURLINGTON HOUSE, W.1.

Thus investigators have reached essentially the same view of the possible mechanism of film formation in a discharge. On the basis of this type of mechanism, Haefer has calculated $p_1 = dp/dt$, the number of molecules entering a layer of the film of area 1 cm² in 1 s. If N molecules are adsorbed on 1 cm² of the electrode, we have

$$p_1 = \sigma \cdot j \cdot N \qquad (1)$$

where j is the number of charged particles on 1 cm² after 1 s, and σ the ionisation cross-section of a sorbed molecule on electron or ion impact. Let us consider two extreme cases, in which (1) the vapour pressure ensures a complete monolayer, or (2) the monolayer is incomplete.

In the former case the partial pressure of the starting material is quite high. The number of molecules F of the gas phase incident on unit surface in 1 s is then large compared with the rate of film formation p_1. During the first few moments the surface becomes covered with a monolayer: $N = 1/a$, where a is the surface necessary for the adsorption of one molecule. In this case the rate of growth of the polymer film is

$$p_1 = \frac{\sigma}{a} \cdot j. \qquad (2)$$

Experimental support for this conclusion has been given by Haefer and Mohamed [77].

If the number of adsorbed molecules is even less than a monolayer, i.e. if $N < 1/a$, we have

$$\frac{dN}{dt} = F - \frac{N}{\tau} - p_1 = F - \frac{N}{t} - \sigma j N = 0 \qquad (3)$$

where τ is the life of an adsorbed molecule. From Eqn. (3) we find that

$$N = \frac{F}{\sigma j + \frac{1}{\tau}} \qquad (4)$$

and from Eqns. (1) and (4) we obtain

$$p_1 = \frac{\sigma j F}{\sigma j + \frac{1}{\tau}} = \frac{F}{1 + \frac{1}{\sigma \tau j}}. \qquad (5)$$

Two cases can be distinguished:

$$1) \quad \sigma\tau j \ll 1, \text{ then } p_1 = \sigma\tau j \cdot F \qquad (5a)$$

i.e. at low current densities and with small interaction cross-sections the rate of growth of the polymer film is proportional to the current density and the vapour pressure.

$$2) \quad \sigma\tau j \gg 1 \text{ then } p_1 = F \qquad (5b)$$

i.e. at high current densities and with a large interaction cross-section the rate of growth reaches a limiting value: every molecule striking the electrode enters the polymer. This theory is supported by measurements made with oil molecules under conditions of electron impact [24,30,32,45].

A somewhat different mechanism for the formation of coating films in the glow discharge is suggested by Haisen [78], who assumes that the layers are formed from fragments produced, not in the gas space, but directly on the surface of the object. Particles incident on the surface, and carrying excess energy, split up the adsorbed hydrocarbon molecules, and the resulting fragments recombine to form a solid deposit. However, the author does not give sufficiently convincing experimental evidence in support of this view.

Film formation in a discharge has been studied not only with hydrocarbons which are incapable of ordinary chain polymerisation but also with typical monomers. Rubanovskii [79] studied the kinetics of the polymerisation of butadiene in the glow discharge, and observed the deposition of a solid polymer on the walls of the discharge tube and on the electrodes. He showed also that polymerisation is excited not only by the impact of electrons but also by that of hydrogen atoms. The process of polymerisation exhibits a clearly marked induction period.

The discharge polymerisation of one of the most widely investigated monomers, styrene, has been studied by Stuart [58], who obtained polystyrene films insoluble both in water and inorganic solvents. Electron spin resonance measurements, made in a vacuum at room temperature, showed the presence of free radicals, which most probably underwent oxidation to peroxide in air.

The production of solid polymers from several typical monomers in a discharge has been referred to in other papers [56,57,60,73]. However, it is only recently that the behaviour of typical monomers and polymers in a discharge has begun to be studied more thoroughly.

DaSilva and Miller [63] studied the rates of formation of polymer films from butadiene and vinyl chloride. They showed that, after the discharge has operated for 3 min, butadiene gives a film 400 Å thick at a gas pressure of 100 mmHg, whereas with vinyl chloride the rate of deposition is 30 Å s^{-1} (if the discharge current is 70–90 mA, and the voltage 100–150 V). The electrical properties of polybutadiene films obtained in a discharge (pressure 0.3–0.55 mmHg, voltage 350–400 V, and current 6–8 mA) have been studied by Bashara and Doty [66], who assume the films to consist of poly-1,4-butadiene and to be extremely strongly cross-linked. They found the resistivity of such films to be $\sim 10^{11}$ ohm cm.

Holland [80] studied the behaviour of several polymeric materials—polyethylene, polystyrene, epichlorohydrin resin, cross-linked melamine—in a discharge of voltage 5 kV and current density 0.13 mA cm^{-2} with cooled specimens in an atmosphere of air or argon. He showed that the cathodic samples became brown and non-transparent 50 min after the start of an experiment. Under the action of electrons the specimens underwent surface pitting, and ions sometimes caused "erosion" of the surface.

The action of a discharge on the surface of polymer films led to the idea that a polymer might be activated in a discharge with the aim of subsequent grafting. Korshak et al. [65] used the activation of polytetrafluoroethylene in a discharge in order to initiate on its surface the graft polymerisation of vinyl monomers with the object of improving the adhesive properties of the material. Special apparatus was used for a discharge of frequency 50 c/s and voltage 22–30 kV. The film obtained from tetrafluoroethylene was placed in the discharge zone for 10–30 min, then immersed in a vessel containing the vinyl monomer, and copolymerised at 85–90°C. Such grafting considerably improved the adhesion of the polytetrafluoroethylene to steel and other materials.

The production of films in a glow discharge is of very considerable value for the recently started wide application of silica and organosilicon films as surface passivators and diffusion coatings in microelectronics.

Leslie et al. [81] studied the low-temperature deposition of silica films, for which purpose an organic silicone (an

alkoxysilane) was decomposed in an argon plasma. Breakdown of the silicone molecules on collision with ionised and excited argon atoms took place on the electrode surface, where a stable Si–O–Si lattice was formed. The rate of deposition was studied as function of the flux of ions, the power of the discharge, the temperature, and the geometry of the substrate. The resulting silica films were studied by various methods: electron diffraction confirmed their amorphous structure, and the infrared spectra showed the absence of C–H bonds. Ing and Davern[82] also prepared silica films for coating semiconductors. Deposition was conducted in tetraethylsilane vapour in a glow discharge. The resulting film was homogeneous, and possessed good adhesion to a gallium arsenide surface. Such a film was 1800–2000 Å thick. These workers have subsequently investigated[83] thin silica films obtained from tetraethoxysilane in a discharge. These films can be successfully used as dielectrics in thin-film capacitors.

IV. PRODUCTION OF POLYMER FILMS ON EXPOSURE TO ULTRAVIOLET RADIATION

The chemical processes occurring under the influence of ultraviolet radiation, and leading to the formation of polymeric deposits on solid surfaces, resemble in many respects the analogous processes occurring on electron bombardment. It must be noted, however, that photochemical investigations in this field, which were begun in 1910 and continue at the present time, have mainly been purely descriptive and qualitative in character.

In 1910 Berthelot and Gaudechon[84] observed the formation of polymeric solid deposits on the walls of the reaction vessel when acetylene was exposed to ultraviolet radiation. The yellow film obtained was similar in appearance to that formed by the action of a discharge on acetylene. Even certain kinetic aspects of the formation of films of this kind were noted: the rate of deposition of films slowed down in the course of growth owing to absorption by them of ultraviolet radiation, and the rate of conversion of acetylene into solid polymer was approximately doubled in the presence of an inert gas.

Lind and Livingston[85], while studying the photochemical polymerisation of acetylene, observed the deposition of a solid polymer on the window through which the ultraviolet irradiation occurred, this resulting in diminished transparency of the window and a fall in the rate of polymerisation.

Bates and Taylor[86] and also Reinicke[87], while investigating the photoexcitation of ethylene and acetylene, also noted the formation of a solid polymer, insoluble in organic solvents.

Olson and Meyers[88] obtained polymeric solid deposits on the walls of a reaction chamber in which ethylene had been subjected to ultraviolet irradiation. The deposits were detected from the interference colours and also from the effect on the rates of subsequent reactions. Kemula and Mrazek[89] studied the mechanism of the photopolymerisation of acetylene, and found among the many polymerisation products a yellowish solid deposited on the walls of the reaction vessel. This substance absorbed the active part of the radiation very strongly, and diminished the reaction velocity. Livingston and Schiflett[90], who studied the photopolymerisation of methylene at high temperatures, detected two non-volatile solid products, one of them resembling cuprene, while the other formed a film recalling a dark yellow dried lacquer film. On heating the film charred, but it burned in air only with difficulty, forming a compact coating which adhered well to the surface. This film was partly soluble in ether, which was coloured a dark yellow. Melville[91] showed that the maximum permissible gas pressure in the vessel during the photochemical polymerisation of ethylene and acetylene was 10 mmHg, since at higher pressures deposits of a solid polymer were formed on the walls of the reaction vessel. The formation of solid films during the photopolymerisation of acetylene was noted also by Le Roy and Steacie[92]. The films could be removed by burning them off after an experiment. Numerous studies of the photopolymerisation of acetylene and ethylene were collated in Steacie's book[93], but in nearly all of these the authors had merely noted the formation of solid polymer films and described their properties sketchily. Nevertheless, even in the more recent work of the 1950s and 1960s the preparation of polymer films by ultraviolet irradiation has not been a subject of independent study. Zelikoff and Aschenbrand[94], while investigating the photochemistry of the vacuum ultraviolet, noted the formation of a solid polymer on the walls of an acetylene reaction vessel, and the consequent diminution in its transparency. The coating which had absorbed the ultraviolet radiation was formed in about 3 min. The resulting film was decomposed by nitric acid. DeCarlo et al.[95] also noted the formation of solid polymers by the ultraviolet irradiation of acetylene.

Although the polymer films formed on a solid surface by the action of ultraviolet radiation have not become a subject of independent study, several authors have nevertheless suggested possible mechanisms for their formation. Whereas in the early papers of the 1930s preference was given to a mechanism involving excited molecules, Steacie[93] was inclined to adhere to a free-radical mechanism.

All workers who have observed films of this type on ultraviolet irradiation have noted their good adhesion to the surface on which they had been deposited, their high thermal stability, and their resistance to many solvents.

V. APPLICATION OF FILMS

It has been shown above that polymer films obtained by the action of electrons and in a glow discharge possess good dielectric properties. They possess also great strength, good surface adhesion, high thermal stability, and a lack of pores. The method permits very thin films to be obtained. All this suggests that the use of such films as dielectric layers in capacitors is very promising. Several patents[61,68,69] have proposed the use for this purpose of polymer films obtained in a discharge. Use of polymer films of this type permits a considerable increase in the capacitance per unit volume of the condenser and a substantial decrease in the size of the latter. Other methods of obtaining thin (around 1–2 μm) dielectric films have been tried[68], but none has given good results, mainly because the capacitors rapidly became defective owing to breakdown of the dielectric layer. The poor quality of the films—presence of pores, and also various types of impurities—proved to be the cause of the breakdowns. These defects are absent in polymer films obtained in a discharge, since the dielectric layer is then obtained directly on the surface on which it is to be used. A great advantage of capacitors made with films obtained in this way is also their excellent temperature stability, for they

can work at temperatures from −55° to +200°C.[68] A British patent[68] proposes the use as dielectric layers of polymer films 0.01–1 μm thick obtained from unsaturated aromatic or aliphatic compounds in a glow discharge. To obtain organic films of specified thickness in this case, a synthetic, e.g. polyethylene, film, which has first been coated with a thin layer of aluminium, is drawn through the discharge zone at a constant speed, which determines the thickness of the newly formed film if the discharge parameters are kept constant. A second layer of metal is applied to the resulting film by sputtering. The conditions of the discharge comprised an optimum pressure of the organic substance in the discharge zone of 10–100 μm, and an ignition voltage of the discharge of 300–2000 V. Either direct or alternating current can be used to obtain the dielectric films. A necessary condition for the production of homogeneous films is the presence of a steady visible discharge in the region between the electrodes.

Various methods of obtaining dielectric films in capacitors, including use of a glow discharge, have been surveyed[96], and use of polytetrafluoroethylene films obtained in a glow discharge as dielectric layers is claimed to yield excellent thin-film capacitors[97]. Coleman[61] and the Radiation Research Corporation[67] have suggested designs for special apparatus for the production of homogeneous and especially thin polymer films in a discharge, which can be used for the manufacture of capacitors. Hopf[98] states that polymerisation in a discharge is one of the cheapest methods for obtaining capacitor layers and protective coatings.

It has been suggested[99,100] that polymer films, formed on a surface under the influence of a glow discharge, might be used as anticorrosive protective coatings. Production of the coatings involves preparing the film itself, hardening it, and drying it at a definite temperature. Styrene and other monomers of the vinyl series have been used as film-forming material. The metal to be coated with a protective film was used as electrodes in the discharge chamber at a voltage of 300–1000 V. Coatings 0.1–0.5 mm thick were obtained. A typical consumption of electrical energy is 1 kW h for the production of 50 g of film. Sandford[99] has compared the properties of metallic and non-metallic protective coatings on metals, including polymer films applied in a discharge, and has reached the conclusion that the polymer coatings fully replace the former and, moreover, are cheaper.

Buck and Shoulders[101] proposed the use of films, obtained from organic substances by the action of electrons, as dielectrics in microelectronic circuits. These films can probably be utilised both for the manufacture of microcapacitors and to protect the final circuit from the atmosphere. An analogous application of polymer films has been mentioned elsewhere[37]. The semiconductor films obtained by Christy[25] point to the possibility of producing film diodes, and study of the mechanism by which current flows through very thin polymer films[48,49] shows that it is possible in principle to make thin-film tunnel triodes.

The method of applying polymer coatings in a glow discharge has been used for a long time to obtain replicas from small objects in electron-microscopic investigations[64,70]. The method consists essentially in coating the surface of the object which is to be examined in the electron microscope with an organic film, using benzene vapour in a glow discharge. The object is then heated in a high vacuum to 400°C, when the organic film is converted into a carbon film. After this the material of the object itself is decomposed chemically, so that only the carbon sheath remains, which is penetrated strongly by the electron beam. This method enables the finest surface details of particles to be observed.

The production of polymer films by the action of electrons has been proposed[102,103] for the manufacture of diffraction gratings, and also[45] for the production of optical interference filters.

Hirsch[42] suggested using this phenomenon, of the deposition of a polymer film on a surface bombarded with electrons, for focussing beams in the design of electronic apparatus. At points bombarded by electrons images are obtained, invisible to the eyes, caused by the formation of very thin polymer films. This latent image can be made visible by developing it by electrodeposition in copper sulphate solution. This method of obtaining the focal characteristics of an electron beam makes it possible to obtain images even with electrons of very low energies (up to 5 eV).

Bradley[75] has shown that polymer films obtained in a discharge possess great photosensitivity. This had again been pointed out by Mayer[38], who had investigated films obtained under the influence of an electron beam, and found them to possess photosensitivity in the visible and near infrared region. These properties of the films can be utilised in photosensitive high-temperature detectors[74].

Woodman[43] has proposed the use of silica films as diffusion masks for protecting a germanium surface from the diffusion of indium and antimony into it, which may be of value in the production of germanium diodes and triodes. In this work the silica films were obtained by electron bombardment of a germanium surface on which a thin film of phenylsilanol had first been condensed from the vapour. The resulting polymer film was oxidised in air at 500°C until pure silicon dioxide was obtained. It was found that a silica film on the germanium surface was completely impermeable to antimony, but permeable to indium.

---o0o---

In the present paper we have summarised published information on the formation of polymeric organic films on solid surfaces by the action of active particles. A survey of the information given here shows that researches in this field have been quite widely developed in several countries, and even have already found practical application in the production of protective coatings and thin-film condensers, which possess high specific capacitance. The method discussed in this paper appears to us to open up several novel and interesting technical possibilities, and merits the attention of research workers in our own country.

THE USE OF RADIOACTIVE INERT GASES IN THE STUDY OF SOLIDS

G. M. Zhabrova and M. D. Shibanova

CONTENTS

1. Introduction 592

2. Theoretical principles of emanation methods. Methods of introducing and measuring radioactive inert gases 592

3. Emanating power as a function of the specific surface of solids 595

4. The use of radioactive inert gases to study phase transitions, changes in crystal structure, and the mobility and dimensions of particles 597

5. Study of the thermal decomposition and reactions of solids by emanation methods 598

6. The liberation of radioactive inert gases during chemisorption and catalytic processes on solid surfaces 600

1. INTRODUCTION

The development of work on the study of solids requires the use of sensitive methods of various types for the study of phase transitions, chemical changes, the production of imperfections and defects in the crystal lattice, changes in the properties of a surface, etc.

In addition to physical methods of study, the use of radiochemical methods is of interest; in these methods, the liberation of radioactive inert gases makes it possible to follow continuously various types of change taking place during processes in a solid at the temperature of the experiment. The general term "emanation" is often used to denote the radioactive inert gases formed in nuclear reactions, and the methods of study based on the introduction of a radioactive inert gas into a solid and subsequent measurement of the fraction of emanation liberated or the emanating power of the substance are usually described as emanation methods.

The classical emanation method, using natural radioactive inert gases, was suggested by Kolovrat-Chervinskii[1] and subsequently developed and improved by Hahn[2], Zimens and Flügge[3,4], and Starik[5]. Various modifications of this method are now known[6-8], based on the use of radioactive isotopes of the inert gases.

Work on the theory and application of the emanation method in the study of reactions in solids has been reviewed in papers by Hahn[2,9] and in a monograph by Wahl and Bonner[10].

In recent years, in connection with the development of work on the peaceful uses of atomic energy and new problems in the physical chemistry of solids, a large number of papers have been published on the use of different versions of the emanation method in the study of solids. At the same time there has been a marked increase in the range of problems studied by emanation methods, and in many cases these methods are combined with X-ray diffraction, thermographic, dilatometric, and sorption methods; this makes possible a more unambiguous interpretation of the results obtained[11-13].

2. THEORETICAL PRINCIPLES OF EMANATION METHODS. METHODS OF INTRODUCING AND MEASURING RADIOACTIVE INERT GASES

The emanation method is fundamentally different from other radiochemical methods; the classical version of the method is based on the properties of various radioactive elements, such as radium, thorium-X, and actinium-X, which disintegrate with the liberation of radioactive noble gases or emanations, which may be quantitatively determined with a high accuracy from their α-radiation. Less frequently, the β-radiation of the active residue from the emanation is measured[2]:

$$^{228}\mathrm{Th\,(RdTh)} \xrightarrow[5.4\ \mathrm{MeV}]{\alpha} \mathrm{ThX} \xrightarrow[5.7\ \mathrm{MeV}]{\alpha} {}^{220}\mathrm{Em\,(Th)} \xrightarrow{\alpha} {}^{216}\mathrm{ThA} \xrightarrow{\beta} \ldots$$

The method involves the introduction, into the solid being studied, of a mother isotope (Ra, RdTh, AcX), which generates emanation continuously by radioactive disintegration, followed by the measurement of the proportion of radioactive noble gas capable of being liberated from the specimen under certain conditions[4,10]. This liberated fraction of the emanation or the emanating power of the given substance is in general a function of the temperature, surface area, and state of the crystal lattice of the solid. The term emanation coefficient is generally used to denote the ratio of the fraction of the emanation liberated to the total quantity of emanation formed in the test specimen when a steady state is established. Since the radioactive gas liberated is inert and does not react with the solid, the results obtained are not complicated by any side chemical reactions.

The classical emanation method was developed chiefly by the work of Kolovrat-Chervinskii, Hahn, Zimens, Flügge, Starik, and others. The most complete theory of emanation was first given in papers by Flügge and Zimens[3,14,15], who emphasised the existence of two fundamentally different mechanisms for liberation of atoms of the emanation. The first involves that fraction of the atoms which is liberated directly as a result of the recoil energy on radioactive disintegration of the radioactive mother element, and the second involves the atoms of emanation formed within the solid and liberated by diffusion through the vacant sites, capillaries, and cracks in the solid. The values of the emanating power due to the processes of radioactive recoil and diffusion are denoted by the symbols E_0 and Ed respectively. Thus the total emanating power of a specimen determined experimentally, which is usually denoted by the symbol EV, consists of two parts: $EV = E_0 + Ed$. Zimens examined the liberation of emanation both from a single particle[15] and from an aggregate of particles[14]. A recoil atom from a particle will be liberated only when the mother element is situated at a distance x which does not exceed the recoil free path R. The average fraction of atoms formed in the range R from the surface will then be given by the ratio of the volume in which the atom of emanation is formed to the total volume.

The average fraction of atoms formed at a distance $x < R$ from the surface and ejected from the particle is

$$\frac{\int_0^R \frac{2\pi R(R-x)}{4\pi R^2}\,dx}{R} = \frac{\int_0^R \frac{R-x}{2R}\,dx}{R} = {}^1/_4 . \quad (1)$$

Thus

$$E_0 = {}^1/_4 \cdot \frac{R \cdot S}{v},$$

where S is the surface area, and v the volume of the particle, or

$$E_0 = \frac{R}{4} \cdot \rho \cdot \frac{S}{m}, \quad (2)$$

where ρ is the density and m the mass of the particle.

This is applicable to particles with dimensions $\geq 10^{-4}$ cm. The diffusion component of the emanation will in general depend on the diffusion coefficient D for the inert gas through the solid and the radioactive decay constant λ for the emanation.

Zimens[15] put forward the equation

$$E_d = \sqrt{\frac{D}{\lambda}}\,\rho\,\frac{S}{m} . \quad (3)$$

Thus

$$EV = E_0 + E_d = \left(\frac{R}{4} + \sqrt{\frac{D}{\lambda}}\right)\rho\,\frac{S}{m} . \quad (4)$$

When the process of emanation for an aggregate of particles is considered, it is also necessary to make allowance for the indirect effect of the recoil produced when the recoil atom collides with a neighbouring particle in the solid. For particles smaller than 1 μm, the distances between the particles generally do not exceed the recoil free path, and the atoms of emanation are liberated chiefly as a result of the indirect effect of the recoil. The proportion of these atoms is a sensitive function of the composition of the solid and of the presence of various impurities. A paper by Götte[16], for example, reports an increase in the emanation of thoron from zinc hydroxide from 22% to 60% when inactive iron hydroxide is added. The development of a theory of the process of emanation for an aggregate of particles is complicated by the need to make allowance for the length and diameter of the pores, the ratio of the volume of the pores and the volume of an individual particle, and the possible adsorption of emanation on the surface of the particles.

The practical utilisation of Eqns. (1)–(4) requires a knowledge of the magnitude of the recoil free path R, for which Flügge and Zimens[3] put forward the equation

$$R = g\,\frac{1}{\rho}\left(\frac{\overline{AB}}{s}\right) \quad (5)$$

where g is a proportionality factor, ρ the density, and $\overline{AB}/s$ the mean ratio of the atomic weight to the stopping power of the solid, which Flügge and Zimens[3] assumed, without sufficient justification, to be equal to the stopping power of the solid with respect to α-particles[17]. Flügge and Zimens also assumed that the recoil free path R was proportional to the square of the recoil energy ϵ_0:

$$R \propto C\epsilon_0^2. \quad (6)$$

To calculate the proportionality factor g in Eqn. (5), it is necessary to determine the emanating power due entirely to recoil. This can be done, for example, by measuring the coefficient of emanation for the liberation of two forms of emanation with different half-lives, or by measuring the temperature coefficient of emanation[10]. For radon and thoron the constant g can be found directly by measuring the emanating power of glass rods with known dimensions[18]. The values of the factor g are 57×10^{-8} for radon and 74×10^{-8} for thoron.

If it is assumed that all the recoil atoms are liberated immediately after formation and that their rate of liberation is independent of the quantity of inert gas in the specimen, the measured emanating power for a freshly prepared specimen will be due almost entirely to recoil. The diffusion component, however, will be a function of the total concentration of gas and the age and temperature of the specimen. Since the recoil energy for α-radiation is of the order of 100 000 eV, whereas the thermal energy amounts to ~ 0.1 eV, the recoil emanation is almost independent of temperature, and the temperature coefficient of the evolution of emanation is determined by the diffusion component[10]:

$$E_d = Ae^{-\epsilon_{EV}/RT} \quad (7)$$

where ϵ_{EV} is the activation energy of the emanation process. It should be noted that the applicability of Eqns. (2)–(6) is limited, since they make no allowance for side processes such as adsorption, the indirect effect of the recoil, and possible changes in the specimen itself.

Baulch and Duncan[19] compare calculated and experimental values of the recoil free path for atoms of emanation, obtained from the equation of Flügge and Zimens[15] and from their own formulae[19]. They consider that both of Zimens' equations—formulae (5) and (6)—which give the relationship between the length of the free path and the energy of the recoil atoms, are unsatisfactory. From Bohr's classical equation[20] for the adiabatic collision of a recoil atom with an atom of the retarding gas

$$R_0 = \frac{m_e\,\epsilon}{\pi N \hbar^2 Z_1^{2/3} Z_2} \quad (8)$$

(where m_e is the mass of the electron, N is the number of atoms of the stopping material in 1 cm^3, Z_1 and Z_2 are the nuclear charges of the recoil atom and the colliding atom respectively, R_0 is the mean free path of the recoil atom, and ϵ is the energy of the recoil atom), Baulch and Duncan put forward an equation for calculating the number of recoil atoms with free path length R.

These workers[19] determined the free path and the energy of the recoil atoms for ThC″ and RaA. The recoil atoms moved a known distance from the source to a metal collector plate through a gaseous stopping medium, whose pressure was measured with high accuracy. The activity of the collector plate was then measured with a Geiger counter. In the treatment of the results, allowance was made both for the geometric factor (i.e. the dependence of the number of recoil atoms reaching the plate on the geometry of the apparatus used) and for the degree of straggling (i.e. the deviation of the free path from its mean value). Allowance for these factors in the comparison of theoretical and experimental results leads, in their opinion[19], to satisfactory agreement with experiment. Thus for thoron with a recoil energy of 103 keV, the calculated mean free path in air at atmospheric pressure is 0.059 cm, while the value found experimentally[3] is 0.083 cm; in barium stearate the calculated free path is 960 Å, while that determined experimentally is 940 Å.[21]

The recoil energy ϵ_R was calculated from the equation

$$\epsilon_R = 4\epsilon_\alpha/M \quad (9)$$

where ϵ_α is the energy of α-decay, and M the mass of the recoil atom.

In conclusion, Baulch and Duncan[19] point out that formula (8) gives better agreement with experiment than do Eqns. (4)–(6), proposed by Flügge and Zimens, since the mean free path of the recoil atoms is proportional to the recoil energy to the first power—rather than to the square—of the recoil energy. Moreover, Eqn. (5) was derived without allowance for the degree of straggling, which depends on the stopping medium, and on the unjustified assumption that the stopping power of a substance is the same with respect to α-particles and to recoil atoms. It should be noted that there are a large number of systems for which the theoretical calculation of R_0 does not give satisfactory agreement with experiment, and further fairly complicated experiments are required, so that most authors dealing with the emanation method restrict themselves to a qualitative treatment of the results obtained.

The choice of method for the introduction of the emanating radioactive mother element and the nature of its distribution in the solid being studied are very important in the emanation method. This problem was examined in some detail by Zimens[4], who demonstrated the possibility of a uniform distribution of the radioactive element for most precipitates with an extensively developed surface, even when there is no isomorphism. He also described various types of emanation–temperature curves, which have generally figured in all subsequent studies using the emanation method. These curves are of the following types—(1) temperature curves (LT) obtained by measuring the emanating power EV with continuous rise in the temperature of the specimen; (2) temperature curves (RT) obtained by measuring EV after the heating has been interrupted at a given point and the specimen cooled; (3) isotherms, representing the dependence of EV on time or specimen weight at constant temperature; (4) cooling curves characterising EV directly during the cooling of a specimen previously heated to a high temperature; and (5) duplicate curves obtained by measuring the emanation of a specimen during repeated continuous increase in temperature at a given rate.

Later work using the classical emanation method demonstrated that the temperature variation of EV was almost completely unaffected by two methods of introducing the original mother isotope into the test solid (coprecipitation and impregnation). The introduction of radiothorium by the impregnation of a previously prepared precipitate of the test solid generally leads to higher absolute values of the emanating power compared with specimens labelled with radiothorium during precipitation, but does not alter the nature of the variation in EV with temperature. This has been shown by Zhabrova and Shibanova[22,23], who impregnated magnesium and zirconium hydroxides with aqueous solutions of radiothorium, and also by Zaborenko and Tetner[24], who impregnated inorganic salts with alcoholic radiothorium solutions.

In addition to the classical version of the emanation method, various modifications of the method are now used, distinguished chiefly by a fundamentally different method for introducing the radioactive inert gas into the solid being studied. Characteristic features common to all these methods are that the radioactive inert gas is liberated only by diffusion and is not replenished on liberation, so that allowance must be made for its decay with time.

One of these modifications of the classical emanation method is the method of surface radioactive gas labelling, developed by Jech in Czechoslovakia[6,25,26]. In this method, the radioactive inert gas—radon, xenon (^{131}Xe), or krypton (^{85}Kr)—is introduced into thin surface layers by ion bombardment of the surface of the solid in a high-frequency discharge[6]. The depth of penetration into the solid amounts to 10–30 Å. Both the quantity of radioactive gas introduced into the surface of the specimen, and the rate of its liberation, depend on the structure and the state of the surface. This was first used to study the thermal decomposition of nickel oxalate and to examine the surface of glasses subjected to different treatments[25]. Unlike the emanation method, which is based on the continuous formation of radioactive inert gas inside the solid, the method of surface gas labelling is based on the introduction of a definite limited quantity of radioactive gas; as already noted, the radioactive atoms penetrate to a very shallow depth, and can be liberated only by diffusion. This labelled-surface method can be used to determine the topography of various surface structures, and also to observe the course of surface chemical reactions, which alter the rate of evolution of the surface gas label.

Another method for introducing the emanation was proposed by Lindner[8]. It is based on the introduction of atoms of radium emanation (radon) into the surface of the solid being studied, by recoil when the specimen is placed in $^{226}RaCl_2$ solution. The radon penetrates to a depth of 100–150 Å, and the remaining radium chloride is removed by washing. With a sufficiently small particle size ($\sim$ 0.5 μm) the atoms of the emanation are distributed uniformly throughout the substance. The need to bring the test specimens into contact with solution and water undoubtedly restricts the possible applications of this method for introducing a radioactive noble gas into a solid surface.

The principle for utilisation of the emanation method proposed by Yajima and others[7,27] is closely related to those described above. Radioactive isotopes (xenon, krypton, etc.) were used, but they were introduced into the solid by mixing it with uranium dioxide and then irradiating the mixture with thermal neutrons. Thus, as a result of the recoil energy, the radioactive inert gases, which are fission products, are trapped by the surrounding powder[28], and their rate of liberation is determined by the state of the crystal lattice of the solid. A correlation was established[27] between the evolution of gaseous fission products and changes in the crystal structure of various specimens of haematite. Yajima et al.[27] prefer this method of introducing the radioactive gas, since it eliminates chemical treatment and can be applied to many solids, including metals. It should be noted that the specimens may exhibit induced activity, and this may introduce difficulties into subsequent work.

In all these varieties of the emanation method, the radioactive gas is present in the solid as a result of radiation effects. In the classical version, when the radioactive isotope of thorium ^{228}Th is introduced into the test solids, the ThX and then the thoron, formed by successive radioactive disintegration, penetrate into the lattice of the solid as a result of the recoil energy.

The radioactive gas label (Rn, ^{85}Kr) is introduced into the lattice of the solid by ion bombardment in an electrical discharge, etc. Thus the principle of the introduction of the radioactive gases is essentially radiative. Until recently, however, no work had been done making use

of different versions of the emanation method to study the same materials. Thus comparison of results obtained on the thermal decomposition of hydroxides[23] and oxalates[29], obtained by the classical emanation method and by surface gas labelling, are of undoubted interest; this comparison has shown that, for the simple topochemical processes of the conversion of hydroxide into oxide, the extremal points for the liberation of the emanation and the radioactive gas label generally coincide. There obviously should not be a sharp difference between these methods, since, as noted above, the radioactive gas is in all instances present in the lattice of the solid as a result of radiation effects. In the former case, however, the radioactive gas produced is present—according to calculations based on the formula of Flügge and Zimens[3]—at a depth of 300–400 Å and is generated continuously. In the latter case the radioactive gas is present at a depth of several dozen Ångström units, and is not replenished on liberation. Thus in some instances the fixation of high-temperature processes by the method of surface gas labelling is difficult, so that the thermally activated liberation of the radioactive gas, due to diffusion, and the state of the surface of the specimen before the deliberate introduction of the radioactive gas label, acquire considerable importance. Moreover, the surface layer may be broken down on the introduction of radioactive atoms of radon or krypton, and some of the radioactive gas is liberated during the annealing of the defects at 50–100°C, Thus the fairly broad low-temperature peaks for the liberation of ^{85}Kr, observed e.g. in the decomposition of oxalates[29], can be assumed to be due to thermal diffusion with simultaneous partial dehydration. These characteristic features of the methods possibly explain the differences observed[29] in the study of more complicated multistage processes, e.g. the decomposition of oxalates. Further deeper and more detailed comparison of different versions of the emanation method with different treatments of the solids being studied is of interest: it may give new information on fine changes in their structures and surfaces.

The use of the emanation method in most instances requires continuous recording of the α-activity of the inert gases (radon, thoron, and actinon) with time.

The flow method for measuring the quantity of emanation liberated has been described in detail[9,30,31]. The basic scheme used in the measurements is shown in Fig. 1: the inert carrier gas is passed at a definite rate from the purification and drying system into a reaction vessel, which is placed in a furnace and contains a known weight of the test substance, after which it passes together with the liberated fraction of the emanation through a system of traps and driers into the measuring chamber of the recording instrument. The procedure used in the measurements has remained basically unchanged. The changes introduced have been concerned with improving the design of the measuring chambers and of the counting and recording apparatus.

Many authors[30,32-34] have used ionisation chambers of volume 200–600 cm^3 as detectors for measuring α-activity. The conditions for measuring thoron and actinon by means of an ionisation chamber have been examined in most detail by Voltz and Adloff[35], who give equations relating the rate of flow of carrier gas with the distance from the chamber to the emanation source and with the geometry of the apparatus used, and also discuss in detail the influence of traces of moisture and organic substances on the conditions of ionisation in the chamber. Traces of

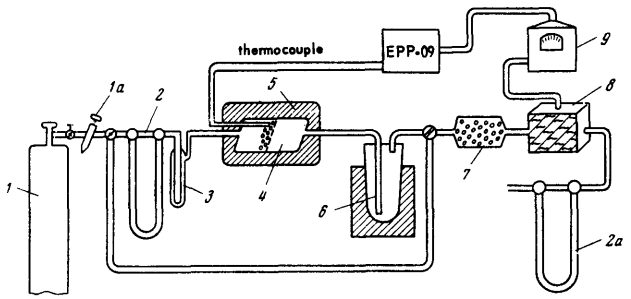

Fig. 1. Basic scheme for measuring the emanation of solids in a current of inert carrier gas:
1) cylinder containing inert carrier gas; 1a) fine control valve; 2, 2a) flowmeters to measure rate of flow of carrier gas; 3, 6, 7) system of traps for purifying and drying the gas being passed through; 4) reaction vessel containing test substance; 5) electric furnace; 8, 9) measuring chamber and recording instrument for determining and automatically recording the quantity of radioactive inert gas liberated.

organic substances generally influence the rate of collection of the ions formed, as a result of changes in their mobilities. This has been demonstrated by Roginskii and his coworkers[36]. Only hydrogen had almost no influence on the degree of ionisation, acetone vapour increased it, and isopropyl alcohol and propene decreased it by 20–40%. The use of ionisation chambers ensures high efficiency and high sensitivity (10^{-11}–10^{-13} c) in the measuring instruments used. A complicating feature in this instance is the need for fairly complicated electronic apparatus to measure the small ionisation current. Because of the high sensitivity of the electronic recording assemblies, thorough elimination of mechanical, electrical, and magnetic interference is necessary. Thus in recent years most workers[12,13,25] have begun to use scintillation counters with measuring chambers of different designs for measuring the α-activity of the emanation. This apparatus is more simple and stable in operation, and is almost unaffected by impurities in the carrier gas, but it requires slightly greater activities, since the efficiency of the assemblies used generally does not exceed 20%. At the same time, certain difficulties are encountered in the elimination of the "radioactive memory" of the scintillation measuring chambers.

Ordinary paired end-face counters are used to measure the β- and γ-activities of krypton, xenon, and other radioactive inert gases[26,37].

3. EMANATING POWER AS A FUNCTION OF THE SPECIFIC SURFACE OF SOLIDS

Although Kolovrat-Chervinskii[1] was the first to examine in detail only the conditions of liberation of emanation, Hahn[2,9,38] pointed out various possible promising applications of the emanation method to the study of physicochemical changes taking place in solids. Hahn first used the emanation method to study the surface of metal hydroxide gels and the changes in it during aging and dehydration[39]. Hahn[40] subsequently studied the change on heating occurring in the surface of $Fe_2O_3 \cdot xH_2O$ labelled with RdTh,

and noted the high emanating power of the original hydroxide due to the presence of an extensively developed internal surface in $Fe(OH)_3$ (Fig. 2). The initial decrease in the emanation, measured at the temperature of the experiment or at room temperature, was attributed to "aging", which masks the increase in emanating power due to the removal of water vapour, which entrains thoron. With careful heating or preliminary drying, the relationship between these processes can apparently be reversed. Above 400°C rapid crystallisation of the highly disperse gel takes place, with the evolution of a large quantity of heat, and this naturally leads to a decrease in surface area and to a more rapid decrease in the emanation. The subsequent increase in emanating power at 800°C was attributed[40] to the liberation of traces of water trapped inside the crystal lattice during precipitation of the gel from the colloidal solution. At 1000°C secondary ordering of the lattice is observed, leading to smoothing of the surface and an increase in the size of the particles of iron oxide formed. The temperature of the start of these processes, which can be determined accurately by the emanation method, was called the break temperature (*Knietemperatur*) by Hedvall[41]. The marked increase in the emanation above 1080°C is due to the increase in the mobility of the atoms or ions forming the crystal lattice. As pointed out by Tammann[42], for many powdered crystalline substances the temperature of the start of appreciable displacement of the atoms or ions in the lattice and increase in the rate of diffusion of the atoms between the crystalline solids in the case of a mixture of powders is close to 50–60% of the absolute melting point of the given substance, provided that no phase changes occur above this temperature (termed the Tammann temperature). Thus by studying the variation in the emanation with temperature it is possible to determine the Tammann temperature, above which reactions in the solid state become possible. The emanation method was used also[40] to study the behaviour of iron(III) oxide subjected to different treatments, and the temperature variation in the emanation of thorium oxalate and hydroxide was given for comparison. The emanation was not measured continuously, however, and the specific surface of the materials studied was not determined; these are unsatisfactory features of the work cited.

Hahn[2] also made an extensive study of the dependence of the emanation of various glasses on the state of their surfaces. Strassmann[43,44] observed an increase in the emanation coefficient for the barium salts of monobasic aliphatic acids with increase in the length of the carbon chain; for barium palmitate the emanation coefficient amounted to 100%. These substances, like various metal hydroxides with an extensively developed internal surface and hence a high emanation coefficient, found application in nuclear physics for the separation of short-lived decay products[45]. More detailed studies of the dependence of the emanation of inorganic salts and minerals on the state and "preservation" of their salts were made by Khlopin[46] and by Starik and Melikova[47]. These studies showed that the dependence of the emanation coefficient on the specific surface for various radon isotopes could give information on the form in which the radioactive mother substances were present in the solid; this in itself is very important for radiochemistry. An attempt to measure the surface area of cubic crystals by measuring the free path of emanation recoil atoms was made by Kurbatov[48] and later by Flügge and Zimens[49] on the basis of Eqns. (2)–(5) given above.

If radium isotopes yielding radon and thoron on radioactive decay are introduced into the specimen being studied, we have, from Eqn. (3),

$$\left.\begin{aligned} EV_{Rn} &= \left(\frac{R_{Rn}}{4} + \sqrt{\frac{D}{\lambda_{Rn}}}\right)\rho\frac{S}{m} \\ EV_{Tn} &= \left(\frac{R_{Tn}}{4} + \sqrt{\frac{D}{\lambda_{Tn}}}\right)\rho\frac{S}{m} \end{aligned}\right\} . \qquad (10)$$

The experimental values of EV and the recoil free paths R calculated from Eqn. (5) can be used to find the diffusion coefficient D and the specific surface S from the set of equations (10). Thus Strassmann[44], from the observed emanating power due to recoil E_0 and the length of the free path R, determined the specific surfaces for various specimens of barium salts, and Heckter[18] made the same determinations on powdered glass specimens. The use of the emanation method to determine the absolute value of the surface area and the diffusion coefficient for the atoms of the inert gas in the solid is restricted, however, by the inaccuracy of the equations used, as noted above.

Zhabrova, Shibanova (Sinitsyna), Roginskii, and Gordeeva compared the dependence of the specific surface and emanation coefficient on the temperature conditions and degree of dehydration of magnesium, thorium, and zirconium hydroxides[11,50]. The change in the same sense in these two characteristics of a solid (Fig. 3) leads to a linear relationship between them; this may also be true for a number of other metal oxides.

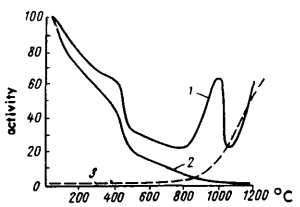

Fig. 2. Typical curves showing the change in emanation as iron hydroxide gel is heated: 1) activity during heating; 2) activity after heating; 3) activity on repeated heating.

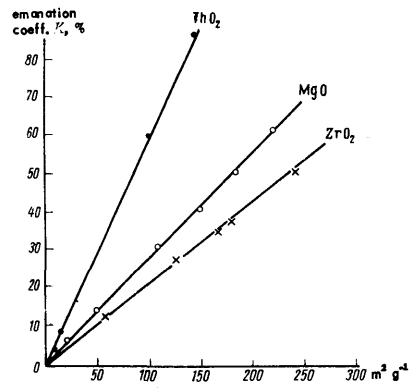

Fig. 3. Dependence of the emanation coefficient with respect to thoron on the specific surface for the oxides of thorium, magnesium, and zirconium.

4. THE USE OF RADIOACTIVE INERT GASES TO STUDY PHASE TRANSITIONS, CHANGES IN CRYSTAL STRUCTURE, AND THE MOBILITY AND DIMENSIONS OF PARTICLES

It can be seen from the work already cited that the emanation method makes it possible to follow changes in crystal structure and phase transitions occurring in salts and oxides when heated to high temperatures. Strassmann[44] observed a sharp increase in the emanation of barium sulphate between 700° and 800°C, when almost quantitative liberation of the emanation takes place in a short time interval. This temperature range corresponds to the Tammann temperature, at which breakdown and sintering of the salt begin. A more detailed study of barium sulphate and carbonate was made by Zaborenko and Babeshkin[32], who recorded the α-activity continuously. They confirmed the breakdown of the barium sulphate lattice in the range 650–800°C, but they also observed an increase in the emanation accompanying the polymorphic transformation of the salt above 1100°C. The emanation method was also used to determine the temperature of the two phase changes for barium carbonate. The enantiotropic transitions in barium carbonate were reported even earlier by Zimens[51,52], who used the emanation method to study the thermal behaviour of the alkaline-earth metals. The heating curves obtained in a current of carbon dioxide for calcium carbonate labelled with ThX showed changes in EV corresponding to the phase change from aragonite to calcite, the subsequent dissociation of the carbonate, and the breakdown of the structure of the calcium oxide formed.

Zaborenko and coworkers[12] showed, for the example of $KCl-CaCl_2$ and $CaO-Fe_2O_3$ (Fig. 4), that it is possible in principle to study equilibrium diagrams by the emanation method. The melting points of the eutectics on the emanation curves were determined from the temperatures of the maximal rates of decrease in emanating power. The observed temperature ranges corresponding to the phase transitions showed good agreement with published data.

In a study of phase changes in quartz, Sizmann and Rupp[53] made use of the absorption of radioactive krypton when the specimen was heated in a current of ^{85}Kr. It was observed that there was a marked increase in absorption of the gas at the point corresponding to the irreversible conversion of β-quartz into β-cristobalite (930° ± 15°C), whereas no such increase was observed for the reversible conversion of α-quartz into β-cristobalite (270°C) or of α-quartz into β-quartz (575°C). This difference was attributed to the difference in the phase transitions: in the first instance, a new crystal lattice was formed; whereas in the second, only rearrangement took place.

As noted above, the emanation method makes it possible to determine the temperature at which breakdown of the crystal lattice of a solid takes place. Schröder and Fricke[54] studied this problem, and also established the influence of preliminary aging of aluminium, iron, titanium, and tin oxides on the Tammann temperature and the shape of the emanation curves. They noted[54] that a sharp increase in the emanating power of the specimen always occurred at the temperature corresponding to the increase in mobility of the crystal lattice. For oxides previously heated at high temperatures, the start of the rising section on the heating curves is indistinct, and generally corresponds to a temperature which is higher than half the absolute melting point of the given oxide. For oxides which have not been subjected beforehand to treatment at high temperatures, the Tammann temperature corresponding to breakdown of the solid can be determined accurately from the inflection or minimum on the emanation curve, above which there is a prolonged increase in the liberation of emanation with rise in temperature (Fig. 5). An exception is aluminium oxide, for which the breakdown of the lattice does not give a sufficiently marked change in emanation; this was attributed to the low degree of ordering of its primary and secondary structures. When the emanation method is used to study processes taking place at high temperatures (1100–1200°C), allowance must be made, in accordance with Anderson's data[55], for the possibility of diffusion of ThX to the surface of the solid; this may lead to an increase in emanation which is not associated with a change in the specimen itself.

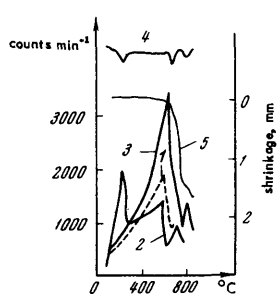

Fig. 4. Heating curves for mixtures of potassium chloride and calcium chloride activated with radiothorium. Emanation polythermals (mole % of $CaCl_2$): 1) 25; 2) 40; 3) 60; 4) differential thermal analysis curve (60); 5) shrinkage curve (60).

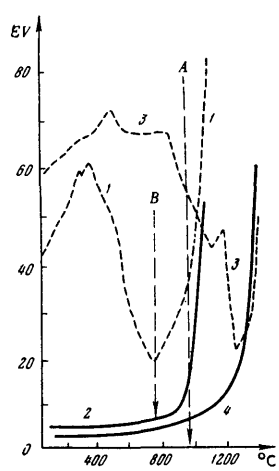

Fig. 5. Emanating power of: 1) γ-FeOOH; 2) α-Fe_2O_3 previously heated at 1000°C; 3) γ-AlOOH; 4) α-Al_2O_3 previously heated at 1000°C. A = 939°C (0.5 × m.p. of Al_2O_3); B = 685°C (0.52 × m.p. of α-Fe_2O_3).

A very interesting series of papers by Gregory and Moorbath[56,57] describe a study of the diffusion of thoron in barium stearate, and also during the dehydration and phase transitions of aluminium oxide. Unlike many other workers, these authors carried out a theoretical treatment of their results, and observed good agreement between experimental and calculated values. On the basis of the theory of emanation put forward by Flügge and Zimens[14,15], Gregory and Moorbath calculated the diffusion coefficient, activation energy, and mean particle size for aluminium oxide heated at various temperatures. From a study of the dependence of the emanating power of α-Al_2O_3 on the partial pressure of oxygen, they concluded[56,57] that a relationship exists between the degree of non-stoichiometry (defectiveness) of the aluminium oxide lattice and the rate of diffusion of thoron. The dependence of the emanating power on the defect nature of and quantity of non-stoichiometric oxygen in nickel oxide and zinc oxide containing added lithium and gallium oxides was studied by Shibanova and Zhabrova[58]. Thus, for example, a marked increase in the emanation (Fig. 6), evidently due to breakdown of the crystal lattice, begins with the original ZnO specimen (curve *1*) close to Tammann temperature (850–900°C). When lithium oxide is added, the increase in the quantity of emanation liberated from zinc oxide with rise in temperature is more clearly defined, and the temperature at which the ions of the crystal lattice begin to become mobile (the Tammann temperature) is lowered (curve *2*). The addition of the oxide of a metal with higher valency, in particular gallium oxide, leads to a marked decrease in the rate at which the emanating power of zinc oxide increases with rise in temperature (curve *3*). The effects observed are reversible, since repeated heating of the zinc oxide specimens containing the added oxides gives analogous results, with a slight decrease in the absolute magnitude of the emanation.

Thus the data obtained by the emanation method agree with the ideas regarding the defect nature of ZnO as due to the presence of interstitial Zn^+ ions, formed on the introduction of Li_2O into zinc oxide[59]. When Ga_2O_3 is added, the defect nature of the ZnO crystal lattice should diminish, leading to a decrease in emanating power. The same investigation showed that increase in the lithium concentration above 1 at.% does not lead to further increase in the emanation. This is probably due to the limited solubility of the added oxide in the zinc oxide being studied.

Yajima and coworkers[60], in a study of the diffusion of ^{133}Xe in natural and synthetic graphite specimens, mixed with uranium oxide and irradiated with neutrons, also observed a relationship between the rate of liberation of the radioactive inert gas and the density of dislocations in the specimens. The use of radiochemical emanation methods for the comparative study of defects produced during the irradiation of solids by various forms of ionising radiation evidently deserves attention. The few papers devoted to this problem, by Jech, Zhabrova, and Shibanova[29,61] and by Mundt and Richter[62], however, are purely qualitative.

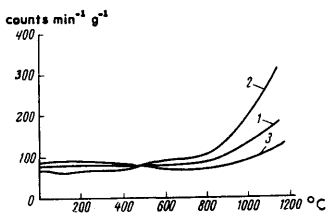

Fig. 6. Temperature dependence of emanating power for:
1) original zinc oxide; and zinc oxide modified with:
2) lithium oxide; 3) gallium oxide.

One of the narrower fields of application of this method is the use of emanation to study the physicochemical properties of metals and alloys[63]. In particular, Werner[64] followed the change in the internal deformation stress of zinc–barium alloys from the liberation of emanation.

5. STUDY OF THE THERMAL DECOMPOSITION AND REACTIONS OF SOLIDS BY EMANATION METHODS

The possibility of using the emanation method to observe phase transitions, the start of breakdown, and increase in the mobility of the atoms of the crystal lattice of solids led, as expected, to the extensive application of this method to study reactions in the solid state; interest in these reactions has increased considerably in the last ten years. This problem has formed the subject of several papers by Schröder and his coworkers[65–69], who studied the changes in the surface and the state of the crystal lattice of individual components of the reaction, and also the formation of chemical compounds, chiefly of the spinel type. They investigated the reactions involved in the preparation of iron–zinc and iron–cadmium spinels[66]. The indicator element was radiothorium, which was introduced into the specimens during the precipitation of highly disperse gels of basic zinc carbonate or zinc hydroxide and iron hydroxide. It was shown that basic zinc carbonate retains radiothorium much more strongly than does zinc hydroxide. The temperature curves for the emanation were used to find the decomposition temperature of basic zinc carbonate (~ 120°C) and the temperature corresponding to the start of appreciable displacement of the ions or atoms of the crystal lattice, ~ 800°C for zinc oxide. Study of the liberation of emanation as a mixture of zinc and iron oxides was heated established that spinel formation takes place in the range 700–800°C, the result being independent of the reactant containing the indicator element. Similarly, the increase in the liberation of emanation was used to determine the temperatures of dissociation, breakdown of the crystal lattice of the components, and spinel formation for mixtures of iron and cadmium oxides.

Later, Schröder[67,68] used the emanation method to study the thermal decomposition of aluminium and beryllium hydroxides. It was again confirmed that the emanation temperature curves obtained directly by heating (the *LT* curve) or by measuring the emanating power of rapidly cooled specimens (the *RT* curve) could be used to detect both chemical changes and allotropic transformations, and also changes in the active states, particularly in the specific surface. The opposite directions followed by the *LT* and *RT* curves at the start of heating (up to 150–160°C) were attributed to a combination of two processes: the liberation of adsorbed water led to an increase in the emanation, and recrystallisation of the hydroxide led to a decrease in the emanation. An interesting result was the detection[68] of an unstable state of beryllium oxide above 600°C, also observed with zinc oxide[65] at a temperature of ~ 25% of the absolute melting point. Hüttig[70]

considered that this temperature corresponded to the start of movement of the ions or atoms on the surface of the solid. The increase in emanation observed with γ-AlOOH, at 1150°C was attributed to the effect described by Hedvall [71], who predicted an increase in the mobility of the ions and the relative maximum of both physical and chemical activities in the transition state, in particular in the transition from γ-Al_2O_3 to α-Al_2O_3.

Schröder and Fricke [69] gave data on the thermal behaviour of a stoichiometric mixture of γ-AlOOH and $Be(OH)_2$, with coprecipitation of both aluminium hydroxide and beryllium hydroxide with radiothorium nitrate. With mechanical mixing of the hydroxides, the emanation curves obtained on heating the mixture differed little from the curves obtained for the starting materials. With jointly precipitated aluminium and beryllium hydroxides, however, the behaviour of the mixture on heating was quite different. When γ-AlOOH and $Be(OH)_2$ were heated separately, a decrease in emanation—due to recrystallisation—was observed at 900° and 800°C respectively whereas with the coprecipitated specimens the liberation of emanation increased sharply above 850°C, corresponding to the formation of beryllium aluminate, and the decrease in EV due to recrystallisation began only at 1150°C. All these results obtained by Schröder and his coworkers were confirmed by X-ray diffraction and analytical data, but unfortunately automatic continuous recording of the α-activity of the emanation liberated was not used, so that rapid processes might have been missed. The method used in the work cited was also used to study the processes involved in the transformation of copper hydroxide [72] $Cu(OH)_2 \rightarrow CuO \rightarrow Cu \rightarrow CuO$; an unambiguous interpretation of both reduction and oxidation processes was made possible by measurement of the quantity of emanation liberated.

The formation of zinc aluminate [73] and magnesium aluminate [74] was studied by the emanation method at a higher methodological level. It was suggested that it is possible to obtain a chemical compound by reaction in the powdered state, even when the lattice parameters of the components are dissimilar, if the mixture is heated sufficiently slowly [73]. In this instance, several intermediate states are observed, when the more mobile component envelops the granules of the passive component and subsequently diffuses into its lattice, with formation of the chemical compound [75]. The theories developed were verified for the example of zinc aluminate formation; the variation in emanation with temperature was recorded both for the individual oxides and for a mixture of zinc oxide and aluminium oxide (Fig. 7). The increase dEV/dt, where EV is the emanating power and t the temperature, is much more marked with zinc oxide than with alumina, owing to the greater mobility of the ions in the zinc oxide lattice. From a comparison of the emanation curves obtained by heating a mixture of inactive zinc oxide and aluminium oxide labelled with radiothorium (curve *6* in Fig. 7) and a mixture of inactive aluminium oxide and zinc oxide containing radiothorium (curve *5*), it was concluded that spinel formation took place above 850°C. [73] An unsatisfactory feature of this work [73] is the lack of data on the specific surfaces of the oxides and their mixtures, although, as shown by Schwab [76], the change in surface area during reactions of powdered components in the solid state may give additional information on the existence of various intermediate stages.

Curves giving the change in emanation when a mixture of barium and calcium carbonates labelled with ThX is heated, and also when Fe_3O_4 labelled with radiothorium is

1) ground ZnO; 2) unground ZnO; 3) ground Al_2O_3; 4) unground Al_2O_3; 5) mixture of activated ZnO with inactive Al_2O_3; 6) mixture of activated Al_2O_3 with inactive ZnO.

heated in an atmosphere of oxygen, were given by Zimens [30], who also described one of the first assemblies for the automatic recording of rapid changes in the quantity of emanation being liberated. The change in the structure of iron oxides was studied in more detail by the emanation method in subsequent work by the same author [14]. The influence of the addition of SiO_2 on the thermal decomposition of iron hydroxide was studied by Götte [77], using the emanation method. Unfortunately, Götte did not give a sufficiently unambiguous interpretation of the results obtained.

Cook [78] used the emanation method to study the processes involved in the dehydration of iron and chromium hydroxides at various temperatures. A most interesting feature is the proposed separation of the emanating power into its components by determining its temperature dependence for specimens subjected to preliminary heating and treatment at a given temperature until a constant value of the emanation was established. This makes possible an indirect determination of the influence of temperature and pretreatment of the specimen on the recoil component of the emanation. Cook [78] correctly pointed out that reliable interpretation of the results is impossible without a detailed study of the changes in the individual components of the emanating power at various temperatures, and allowance for possible errors in the determination of the apparent emanating power; this was also pointed out by Zimens [14].

The decomposition of the hydroxides of zinc, nickel, magnesium, aluminium, zirconium, and thorium over a wide temperature range has been studied simultaneously by the emanation, thermographic, and surface gas labelling methods [11,23]. With all the systems studied, the maximum emanating power coincided almost exactly with the onset temperature of the endothermic effect due to dehydration, determined thermographically. In the zirconium hydroxide–oxide system (Fig. 8), as in the system formed by heating thorium hydroxide, a second emanating power maximum is observed at 400°C. The thermogram for zirconium hydroxide shows a marked exothermic effect at the same temperature. This maximum is due to the crystallisation of previously formed amorphous zirconium dioxide, as has been confirmed by X-ray diffraction studies. The characteristic analogy between thermographic analysis and the emanation method has also been demonstrated in a study of the phase changes in manganese dioxide [79]. The unamibiguous nature of the results obtained

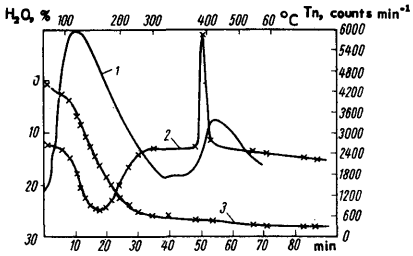

Fig. 8. Curves for zirconium hydroxide: 1) emanation curve; 2) thermogram; 3) change in weight of specimen.

on studying the dehydration of a wide range of metal hydroxides by several methods indicated[79] that the emanation method is applicable also to systems whose oxides do not form true substitutional solid solutions with the added radioactive isotope. The regular distribution of the indicating element was undoubtedly due to the penetration of recoil atoms formed by the disintegration of the radioactive mother element added, and to the high degree of dispersion of the materials studied (5×10^{-6}–5×10^{-5} cm).

Combined investigations of the thermal decomposition of thorium nitrate, thorium oxalate, and barium chloride by emanation, thermogravimetric, and dilatometric methods have been made also by Bussière[13] and by Zaborenko[12]. Particular attention was paid to the methodological aspects of the problem and to the design of assemblies which made possible simultaneous measurement of all the characteristics being studied (the emanation, change in weight of the specimen, and temperature); this eliminated the possibility of errors associated with differences in experimental conditions.

In the study of processes taking place in solids, a knowledge of their kinetics is extremely important. The emanation method is one of the few methods which make it possible to follow changes in structure and surface directly during a topochemical process at a given temperature. The first attempt to use the emanation method to study the kinetics of the formation of calcium silicate from silicon dioxide and calcium oxide was made as early as 1937. Jagitsch[80] published curves giving the time dependence of the liberation of emanation at a given temperature, and put forward a kinetic equation for the change in emanation with time. An unsatisfactory feature of the work was that direct measurement of the emanation was not carried out continuously during the reaction, and only one of the reactants—the silicon dioxide—contained the indicator element. Characteristic "kinetic" curves, giving the change in emanating power with time during dehydration of the hydroxides of magnesium, zinc, thorium, zirconium, and aluminium over the range 100–1000°C, were studied by Roginskii, Zhabrova, and Shibanova (Sinitsyna)[11,81]. The specimens were heated at a definite temperature for a time sufficient to ensure almost complete conversion of the hydroxide into the oxide. The percentage decomposition of the original hydroxide was determined in parallel by weighing at measured time intervals. It was established that the kinetic curves pass through a maximum corresponding in almost all instances to a fairly high percentage decomposition (~ 75–80%). With increase in the temperature of decomposition, the maximum was displaced towards the ordinate axis and at the same time a sharper decrease in activity with increase in the duration of heating was observed. This characteristic form of the kinetic curves giving the time dependence of the emanating power at the temperature of the experiment can be attributed to the combined effects of dehydration, leading to an increase in the specific surface and hence in the emanation of the specimen, and thermal sintering, leading to a decrease in emanation.

6. THE LIBERATION OF RADIOACTIVE INERT GASES DURING CHEMISORPTION AND CATALYTIC PROCESSES ON SOLID SURFACES

Chemisorption and catalytic processes are accompanied by changes in the surface of the catalysts, the formation of surface compounds, blocking of the surface by the reaction products, etc. The use of the emanation method, which is extremely sensitive to all forms of surface and structural changes in solids, to the study of the state of the surface of a catalyst during chemisorption and catalysis is of interest in this connection. Unfortunately, this problem has as yet formed the subject of only a few studies, and these are purely qualitative in character.

Thus Fricke and his coworkers[82,83], in a study of the dependence of the emanating power of magnesium, aluminium, and zinc oxides and γ-Fe_3O_4 on the conditions (temperature, duration of heating, and gaseous medium) of preparation, density, and particle size, observed an increase in the emanation of active magnesium and aluminium oxides as a result of the adsorption of water vapour and carbon dioxide; this was attributed to breakdown of the secondary structure of the oxide. However, these workers did not compare the changes in emanating power with the sorption properties of the magnesium oxide.

Using the method of surface gas labelling described above, Jech[84] established that about half of the radon introduced is liberated from the surface of a platinum catalyst when a hydrogen–oxygen mixture is passed over the catalyst. It was also found that removal of the gas marker takes place chiefly as a result of the reaction of hydrogen with chemisorbed oxygen. An analogous phenomenon is observed in the adsorption of water vapour on platinum at room temperature[84]. It is suggested that this method might be used to detect the location and distribution of active sites on a catalyst surface.

Zhabrova et al.[36] have studied the emanating power of various oxide catalysts (ThO_2, ZrO_2, MgO, and ZnO containing added Na_2O and $ZnSO_4$), labelled with radiothorium, during the chemisorption of the gases and vapours formed in the decomposition of isopropyl alochol. The results obtained show that the physical sorption of gases and vapours of various types has almost no influence on the emanating power of thorium and zirconium oxides. The chemisorption of acetone, water, isopropyl alcohol, and carbon monoxide on the oxides of thorium, zirconium, nickel, and magnesium leads to marked changes in the emanation of these oxides. The original values of the emanating power are generally restored only by regenerating the catalyst in a current of air at 400–500°C. It was suggested that the change in the emanating power of oxide catalysts during chemisorption and catalytic processes may provide a unique criterion indicating the formation of surface chemical compounds and, as can be seen from data on the change in the emanation of modified zinc oxide

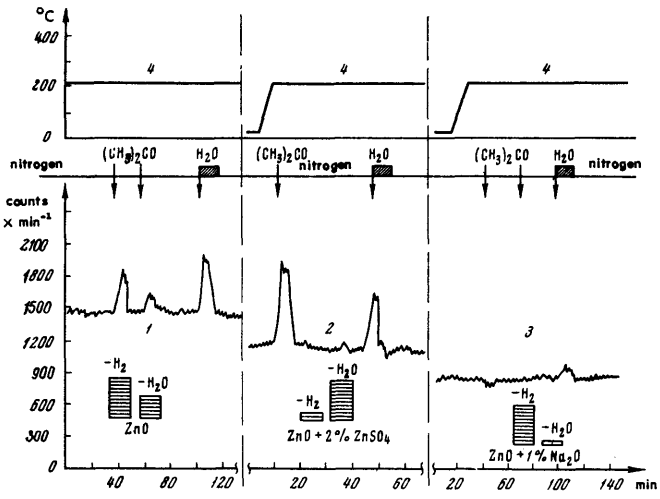

Fig. 9. Emanating power during the chemisorption of acetone and water for:

specimens during the chemisorption of acetone (Fig. 9), characterising to some extent the strength of the bond formed by the chemisorbed substances with the surface. The results obtained by the emanation method must naturally be subsequently combined with kinetic data on the chemisorption and the characteristics of the catalytic activity of the catalysts studied.

The above results obtained by a large number of workers show the promising possibilities offered by the use of emanation methods in the study of solid-phase topochemical reactions, changes in specific surface, breakdown and thermal sintering, and crystallisation and phase transitions in solids.

It is fairly difficult to obtain radioactive materials with a high specific activity and a minimum concentration of impurities, and also to develop methods of introducing the original radioactive materials, for example in the study of almost insoluble polymers. It is also necessary to make allowance for the characteristic features of each version of the emanation method, described above.

The high sensitivity of the emanation method makes it possible to detect fine differences in the crystal structures of solids, for which X-ray diffraction does not always give sufficient information. At the same time the emanation method is a sensitive analogue of differential thermal analysis, and makes it possible to detect crystallisation and phase changes accompanied by extremely small thermal effects, which are almost undetectable by the latter method.

The method of ion bombardment has recently begun to be used in the study of the mechanism of the diffusion of inert gases in oxides and metals [85-87]. This new approach, making it possible to determine the activation energy of diffusion [86,88] and to study the low-temperature diffusion of radioactive inert gases, which depends on the previous treatment of the surface [87], undoubtedly deserves further development.

It is also of interest to use both the emanation method and the introduction of radioactive inert gases by ion bombardment for the solution of a number of problems related to the state of the active surface of catalysts at various stages in their preparation and application. In most instances, emanation methods must be combined with other methods—sorption, kinetic, X-ray diffraction, thermographic, etc. —and may then give new data in the study of surfaces, structures, and chemical reactions taking place in the solid phase.

9. Maximum yield in the decomposition of water 614

INTRODUCTION

It is well known that radiolytic transformations in dilute aqueous solutions result from reactions of the solutes with products of the radiolysis of water†. Until recently, research workers considered that these products were the H atom, the OH and HO_2 radicals, molecular hydrogen, and hydrogen peroxide. The latest stage in the development of the radiation chemistry of water and aqueous solutions has been marked by the discovery of yet another primary product of the radiolysis of water—the hydrated electron e^-_{aq}.

In recent years, considerable progress has also been made in the study of the kinetics of radiation reactions in aqueous solutions. The absolute values of the rate constants of many reactions involving intermediate products

† The radiolysis of water and aqueous solutions has been examined in detail by a number of authors [1-4].

of the radiolysis of water have now been determined. It is thus possible to compare their properties, and also (which is particularly important) their reactivities towards various dissolved substances‡.

1. THE FREE-RADICAL THEORY OF THE RADIOLYSIS OF WATER

In 1944 Weiss[5] put forward the hypothesis that the action of ionising radiation on water produces H and OH free radicals. Subsequently, this hypothesis was confirmed in many studies and was developed further.

The free radicals appear as a result of a number of physical and chemical processes, taking place after the passage of the ionising particle through the water. These processes can be characterised briefly by the following time parameters[6]. Transfer of the energy of the ionising radiation to the water takes place in 10^{-16}–10^{-18} s, with the production of excited water molecules, H_2O^* ions, and secondary electrons. The last of these have considerable energy, and ionise and excite more water molecules. Ultimately, with γ-radiation, X-rays, or electron irradiation, individual isolated groups of ionised and excited molecules ("spurs") are formed, where the primary stages of the chemical action of the ionising radiation develop. With heavy charged particles, these spurs lie close to one another, and immediately after their appearance they merge to form a continuous cylindrical column.

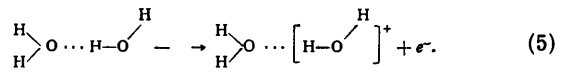
After about 10^{-13}–10^{-14} s, dissociation of the positive ion takes place:

$$H_2O^+ + H_2O \rightarrow H_3O^+ + OH. \qquad (1)$$

Reaction (1) in the gas phase has a rate constant[7] of 5×10^{11} litres mole^{-1} s^{-1}.

Opinions differ regarding the fate of the secondary electron. Most authors, following Lea[8], Gray[9], and Platzman[10-12], consider that the electron, before undergoing thermalisation, moves a considerable distance from its point of origin. At this distance, it is almost uninfluenced by the coulombic field of the mother ion (more accurately, the H_3O^+ ion), so that this electron becomes, as it were, free. It polarises the medium and as a result is "trapped" by the latter, i.e. it becomes hydrated, and in this form takes part in the radiolytic transformations of dissolved substances. The process of "self-capture" of the electron is complete in about 10^{-10}–10^{-11} s. It should be emphasised that the concepts of polarisation "self-capture" of the electron by the medium were first developed by Landau[13] and by Pekar[14] in the physics of solids, where such an electron is called a polaron. This theory was modified and applied to liquids by Davydov[15] and by Deigen[16]. It was extended by Platzman[10-12], with some limitations, to the radiation chemistry of water and aqueous solutions. The suggestion that an important part in the radiolytic transformations of dissolved substances is played by e^-_{aq} was first put forward by Stein[17,18] and by Weiss[19].

Another hypothesis has recently been developed by Magee[20] and by Sworski[21]. At the instant of formation of the H_3O^+ ion [reaction (1)], the dielectric relaxation of the water is not complete, so that this ion is not the ordinary solvated ion. In the opinion of these authors, the electron is attracted to this ion:



$$H_3O^+ + e^- \rightarrow H_3O. \qquad (2)$$

The H_3O particle may undergo thermal dissociation in two ways:

$$H_3O \rightarrow H + H_2O \qquad (3)$$

$$H_3O \rightarrow e^-_{aq} + H_3O^+. \qquad (4)$$

According to Sworski[21], the formation of OH and H_3O particles takes place as a result of the ionisation of one of two water molecules joined by a hydrogen bond:

(5)

This is followed by transfer of a proton:

and neutralisation of the charges:

The main difference between these two hypotheses lies in the initial distribution of the e^-_{aq} and OH radicals. According to the first hypothesis, the hydrated electrons are distributed more diffusely than the OH radicals. According to the Magee–Sworski hypothesis, the two types of radicals have identical initial distributions§. It is difficult to give preference to either of these hypotheses. In order to settle this question, it is necessary to carry out accurate diffusion-kinetic calculations¶ of the initial dimensions of the spurs for the OH radicals and reducing-agent radicals, using up-to-date values for the rate constants of the reactions of H atoms, e^-_{aq}, and OH radicals.

Thus about 10^{-10}–10^{-11} s after passage of the ionising particle, the track contains OH radicals, e^-_{aq}, H_3O^+ ions, and excited water molecules. Their concentration is fairly high (~ 0.1–1.0 M), so that, with the track becoming broader as a result of diffusion, they react extremely rapidly with one another:

$$e^-_{aq} + OH \rightarrow OH^- \qquad (7)$$

$$e^-_{aq} + H_3O^+ \rightarrow H + H_2O \qquad (8)$$

$$e^-_{aq} + e^-_{aq} + H_2O \rightarrow H_2 + 2OH^- \qquad (9)$$

$$e^-_{aq} + H + H_2O \rightarrow H_2 + OH^- \qquad (10)$$

$$OH + OH \rightarrow H_2O_2 \qquad (11)$$

$$H + H \rightarrow H_2 \qquad (12)$$

$$H + OH \rightarrow H_2O \qquad (13)$$

$$H_3O^+ + OH^- \rightarrow 2H_2O. \qquad (14)$$

‡ Except where otherwise stated, the present review deals with radiolysis under the influence of X-rays, γ-radiation, and fast electrons.

§ Recently, Peers and Cottin[22] have studied the production of H_3O^+ ions on electron collision (energy of the electrons 11–20 eV) in water vapour. They find that these ions are formed chiefly from H_2O^+. Some of the ions, however, appear at a rate which is independent of the field intensity in the ion source. These workers conclude that the precursor of this fraction of the H_3O^+ is "excited water":

$$H_2O^* + H_2O \rightarrow H_3O^+ + (OH + e^-). \qquad (6)$$

It may therefore be assumed that in liquid water some of the hydrated electrons may be produced by the breakdown of H_2O^*.

¶ The problems of diffusion kinetics in the radiolysis of water have been examined in various reviews[23-26].

The above processes have high rate constants (5×10^9–10^{11} litres mole^{-1} s^{-1} [27-52]). Reactions (9)–(12) lead to formation of the so-called molecular products of the radiolysis of water (H_2 and H_2O_2), and reaction (8) leads to the production of H atoms. Kuppermann[53] made appropriate diffusion-kinetic calculations and found that the value of G_H, determined on the assumption that the H atoms are formed in the "spurs" by reaction (8), is close to the experimental value.

The reactions in the tracks take place in an interval 10^{-8}–10^{-10} s after passage of the ionising particle. When the time interval exceeds 10^{-8} s, the "spurs" have become so broad, and the concentration of particles in them has decreased to such an extent, that some of their reactions with dissolved substances in the bulk of the solution become significant.

2. THE HYDRATED ELECTRON

The formation of e^-_{aq} during the radiolysis of water has been proved many times. The proofs can be divided into the following categories.

1. Proof by the method of competing acceptors[54-102]. This method has revealed that the reducing radicals can exist in two forms.

2. Proof using the kinetic salt effect[27,55,103-111]. It is found for a number of reactions that the chief reducing species in the radiolysis of water has a charge of –1.

3. Proof by the pulse radiolysis method[31,42,112-117]. This method has revealed short-lived optical absorption with a maximum at 720 nm for H_2O [31,42,116,117] and 690 nm for D_2O [117] in irradiated liquid water†. This absorption does not appear in acid medium and disappears in the presence of electron acceptors.

4. Proof by electron spin resonance (e.s.r.)[126-127]. Trapped electrons have been identified by this method in alkaline[126-135] and neutral[136,137] vitreous frozen aqueous solutions subjected to the action of radiation at 77°K.

5. Proof by measurement of the electrical conductivity of irradiated water[138-140]. This method has shown, in particular, that the electrical conductivity of water "induced" by radiation disappears in a time interval which is approximately the same as that for the corresponding optical absorption.

Thanks to efforts in many laboratories, the properties of e^-_{aq} have been studied in considerable detail‡. The first point to be noted is that this species is a powerful reducing agent. It reacts with ions of the type M^{2+}, where M represents a metal, to give ions M^+ having an anomalous valency[162-164]. This has been demonstrated for Zn^{2+}, Mn^{2+}, Ni^{2+}, Co^{2+}, Cd^{2+}, etc.

When the water does not contain e^-_{aq} acceptors, the hydrated electron, at low dose rates, reacts with water with the production of an H atom[31,42,44,115,154,165,166]:

$$e^-_{aq} + H_2O \rightleftarrows H + OH^-. \quad (15)$$

Reaction (15) is slow. According to the latest data[166], $k_{15} = 16$ litres mole^{-1} s^{-1}. The reaction is reversible, and the value of pK for the equilibrium is 9.6.[166] The conversion of the H atom into e^-_{aq} in alkaline medium was demonstrated by Matheson and Rabani[44], who measured the optical density of e^-_{aq} in neutral medium and in a solution of alkali (pH 13) saturated with hydrogen at pressures up to 100 atm, for equal radiation doses per pulse, and found that the optical density of e^-_{aq} is greater by a factor of about 2.2 in the second system than in the first. In alkaline solution reactions (15) (the reverse reaction) and (16) take place:

$$H_2 + OH \rightarrow H + H_2O. \quad (16)$$

Thus $G(e^-_{aq}) = Ge^-_{aq} + G_H + G_{OH} \simeq 2.2Ge^-_{aq}$.

In acid medium, e^-_{aq} is effectively converted into the H atom [reaction (8)]. The rate constant for this reaction is 2×10^{10} litres mole^{-1} s^{-1}.[27-31,42]. This transformation also takes place in the reactions of e^-_{aq} with ions which are proton donors (e.g. $H_2PO_4^-$, HPO_4^{2-}, etc.)[89,154,165].

The reactions of the hydrated electron can be divided into three groups[160]. The first group corresponds to simple addition, e.g.

$$e^-_{aq} + O_2 \rightarrow O_2^- \quad (17)$$

$$e^-_{aq} + C_{10}H_8 \rightarrow C_{10}H_8^-. \quad (18)$$

The second group corresponds to simple reduction, of the type

$$e^-_{aq} + Cu^{2+} \rightarrow Cu^+. \quad (19)$$

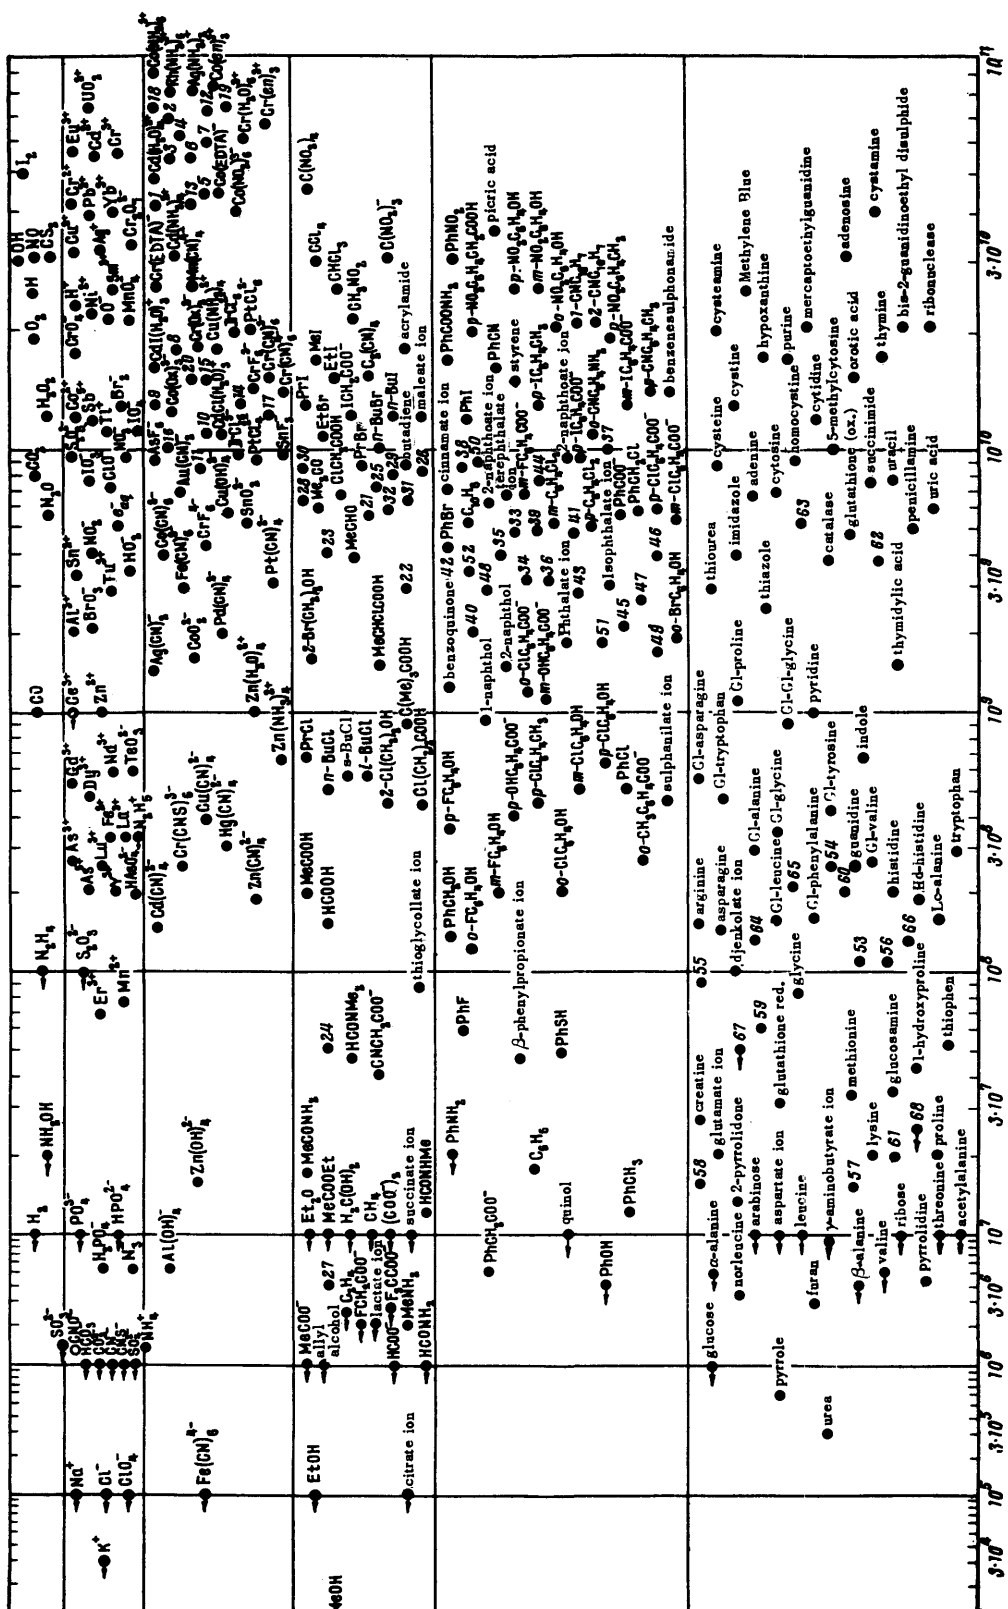
The third group corresponds to dissociative addition:

$$e^-_{aq} + ClCH_2COOH \rightarrow [ClCH_2COOH]^- \rightarrow Cl^- + CH_2COOH. \quad (20)$$

The pulse radiolysis method has identified many-short-lived species which are products of the reactions of e^-_{aq} with dissolved substances. The characteristics of the optical spectra of these species are given in Table 1.

The rate constants for the reactions of e^-_{aq} with about 400 compounds have now been determined, chiefly by the pulse radiolysis method. Scheme 1, prepared from published data[27-32,42,44,50,92,106,114,117-153,165,166,171,176-180,183-205] characterises the reactivity of e^-_{aq} with respect to various substances§. Most of these constants have been found from the rate of disappearance of the optical absorption of e^-_{aq} in the presence of the given compound.

On the basis of published data, some general conclusions may be reached regarding the reactivity of this reducing species.



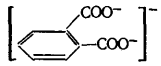
1. The hydrated electron is highly reactive towards molecules which have unpaired electrons, e.g. H, OH, and NO.

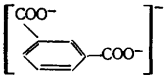
2. In the reactions of e^-_{aq} with cations, the rate constants are generally greater the greater the charge and dimensions of the cation.

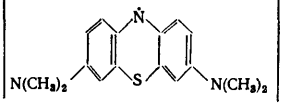
† An identical absorption band has been observed in the flash photolysis of aqueous solutions of various inorganic ions (Cl^-, Br^-, I^-, CNS^-, $Fe(CN)_6^{4-}$, and OH^-) and organic compounds (phenol, alanine, etc.)[118-123]. In these examples, e^-_{aq} is produced by excitation of the solute by light. Similar phenomena are observed with solutions in ethanol[124,125].

‡ The properties of e^-_{aq} have been examined in a book by Pikaev[4] and in various reviews[141-161].

§ A large number of absolute values of the rate constants for the reactions of e^-_{aq} are given in Pikaev's book[4] and in various reviews[141-143,152,204,205].







Scheme 1. Rate constants for the reactions of e^-_{aq} in aqueous solution at room temperature:
1) $[CoCl_2en_2]^+$; 2) *cis*-$[Co(CNS)_2en_2]^+$; 3) *trans*-$[Co(CNS)_2en_2]^+$; 4) $[Co(H_2O)(NH_3)_5]^{3+}$; 5) $[Co(H_2O)_4(NH_3)_2]^{3+}$; 6) $[CoCl(NH_3)_5]^{2+}$; 7) $[Co(NH_3)_6$ (teraphthalate)$]^{+*}$; 8) $[CoCl(CN)_5]^{2-}$; 9) $[Co_2N_3(CN)_8]^{4-}$; 10) $[Co(OH)(CN)_5]^{2-}$; 11) $[Co(NO_2)(CN)_5]^{3-}$; 12) $[Cr(CNS)_2en_2]^+$; 13) $[Cr(CNS)_4en_2]^-$; 14) *cis*-$[CrOx_2(H_2O)_2]^-$; 15) *trans*-$[CrOx_2(H_2O)_2]^-$; 16) PbO_2^-; 17) $[PdCl_4]^{2-}$; 18) $[Os(NH_3)_6]^{3+}$; 19) $[Ru(NH_3)_6]^{3+}$; 20) $[Ir(NH_3)_6]^{3+}$; 21) bromopropionate ion; 22) β-bromopropionate ion; 23) $ClCH_2COO^-$; 24) β-phenylpropionate ion; 25) β-iodopropionate ion; 26) CCl_3COO^-; 27) nitrilotriacetate ion; 28) $BrCH_2COO^-$; 29) fumarate ion; 30) methacrylate ion; 31) pyruvate ion; 32) CF_3Cl; 33) *o*-iodobenzoate ion; 34) *o*-hydroxybenzoate ion; 35) *p*-fluorobenzoate ion; 36) *o*-fluorobenzoate ion; 37) *p*-cyanobenzoate ion; 38) *o*-hydroxybenzonitrile; 39) *m*-hydroxybenzonitrile; 40) *p*-hydroxybenzonitrile; 41) *o*-dichlorobenzene; 42) *p*-bromophenol; 43) *o*-bromophenol; 44) *p*-bromobenzoate ion; 45) *p*-aminobenzoate ion; 46) benzenesulphonate ion; 47) *m*-toluate ion; 48) *p*-toluate ion; 49) toluene-*p*-sulphonate ion; 50) α-trichlorotoluene; 51) α-trichlorotoluene; 52) trimesate ion; 53) leucylglycine; 54) leucyl-leucine; 56) phenylalanine; 57) sarcosine; 58) serine; 59) thiobarbiturate ion; 60) tyrosine; 61) acetylglycine; 62) acemosine-5-phosphate**; 63) adenylic acid; 64) alanylalanine; 65) alanylglycine; 66) alanyl-leucine; 67) *d*-sorbitol; 68) *d*-xylose; Me= CH_3; Et = C_2H_5; Pr = C_3H_7; Bu = C_4H_9; Ph = C_6H_5; Gl = glycyl; Hd = histidyl; Lc = leucyl; en = ethylenediamine; EDTA = ethylenediaminetetra-acetate ion; Ox = oxalate; ⟵ = upper limiting value of constant; ⟵• = lower limiting value of constant.

Notes. (1) In those instances where the published values of the constants were given for various pH-values, the Scheme gives the value at pH 6 ÷ 8. (2) The rate constants for the reactions of e^-_{aq} with H_2O and D_2O are 16 and 200 litres mole^{-1} s^{-1} respectively.

$G_{e^-_{aq}}$ (pH 7.0)	2.6 (±10%)	179
$G_{e^-_{aq}}$ (pH 13.0)	3.6—3.8	55,91,117

* In this and subsequent tables, ϵ, E^0, and $\tau_{1/2}$ denote respectively the molecular extinction coefficient, standard redox potential, and half-life.

3. The reactivity of e^-_{aq} with respect to anions decreases with increase in the charge on the anion. The hydrated electron reacts slowly with the anions of elements in higher oxidation states, and with anions whose central atom has no vacant orbital accessible to the electron.

4. The reactivity of complex compounds towards e^-_{aq} is parallel to their reactivity in outer-sphere redox processes. Here, however, the hydrated electron is a much more powerful reductant than most ordinary chemical reducing agents.

5. The hydrated electron reacts with organic substances as the strongest nucleophilic reagent, and it generally reacts at the positive centre of the molecule.

The chief properties of the hydrated electron are summarised in Table 2.

The question of the magnitude of $G_{e^-_{aq}}$ has been the subject of lively discussion for a number of years. For a neutral medium, various authors[55,60,72—75,77,81,82,89—91,97,101,107,110,211—236] have given values for the yield of e^-_{aq} of 2.2–2.9. These contradictory values are evidently due to the fact that the yields were not determined under comparable conditions. This might have led to differences in the values of $G_{e^-_{aq}}$ as a result of the suppression of reaction (7) in the spurs to different extents[217,237], or to differences in the contribution made by "excited water" to the reaction with the acceptor[54,55,107,108,218], depending on the concentration of the latter and its reactivity. Moreover, it is not excluded that oxygen atoms, which, as postulated by Allen[238], may be produced as a primary product of the radiolysis of water, may react with some substances and be inactive towards others¶. It has recently been found by the pulse radiolysis method that in neutral medium $G_{e^-_{aq}} = 2.6$ (accuracy ±10%)[179]. In these examples the yield was found directly from the measured values of $\epsilon G_{e^-_{aq}}$ and ϵ.

Published data[55,107,108,221,224,233,234,240—250] on the magnitude of $G_{e^-_{aq}}$ in alkaline medium are also contradictory. Most authors consider, however, that the yield of e^-_{aq} is greater in alkaline than in neutral medium. This is confirmed by direct measurement of $G_{e^-_{aq}}$ at various pH-values, using the pulse radiolysis method[117,251]. There may be several reasons for the increase in $G_{e^-_{aq}}$ in alkaline medium. Firstly, the H atom (if it is formed as a primary product of the radiolysis of water) is converted in alkaline solution into e^-_{aq}. This process alone, however, can increase $G_{e^-_{aq}}$ to only 3.2–3.4. Secondly, it is possible that hydrated electrons are produced by the reaction of OH^- ions with excited water molecules or radical pairs (H + OH) in the cell[54,55]:

$$OH^- + H_2O^* \rightarrow e^-_{aq} + OH + H_2O \quad (21)$$

$$OH^- + (H + OH) \rightarrow e^-_{aq} + OH + H_2O. \quad (22)$$

Thirdly, $G_{e^-_{aq}}$ may increase as a result of the partial suppression of reaction (7) in the spurs by OH^- ions[224]. Fourthly, it is not excluded that $G_{e^-_{aq}}$ under these conditions may increase partly as a result of the excitation of

¶ The problem of the value of $G_{e^-_{aq}}$ in various media has been discussed in detail by Haïssinsky[239].

OH^- ions by radiation, followed by breakdown of the $(OH^-)^*$ formed:

$$(OH^-)^* \rightarrow OH + e^-_{aq}. \quad (23)$$

In the theory of the self-capture of an electron by a polar medium, use is often made of a model in which the solvent is regarded as a continuous dielectric medium, characterised by macroscopic properties (static and optical dielectric constants, D_{st} and D_{opt}). The additional electron interacts with the polarisation field of the medium. The equation for the energy of bonding of the electron to the medium contains the term $1/D_{opt} - 1/D_{st}$. Since D_{opt} is generally close to unity, capture of the electron by the medium requires that $D_{st} \gg 1$. Calculations based on this model can be made in two ways—(1) by using the electronic-adiabatic theory, and (2) by using the self-consistent field theory—in the first of which it is assumed that the mean velocity of an electron which is weakly bound to the medium is low compared with the velocity of the valency and inner electrons of the solvent molecules. This method has been used by Weiss [61,252], who finds that the mean radius of e^-_{aq} is about 5 Å. A sphere with this radius can contain ~ 10 water molecules. The second theory considers the influence of the mean charge distribution of the additional electron on the electrons of the medium. Jortner [210] considers that this theory is more applicable than the first theory to this problem. The chief results of his calculations are as follows: (1) the radius R_0 of the cavity containing the electron is much smaller for water than for ammonia (it is possible that for water $R_0 = 0$); (2) the mean radius of the distribution of the charge of the electron in the energy ground state is 2.5–3.0 Å; and (3) the optical absorption maximum of e^-_{aq} is due to a $1s \rightarrow 2p$ transition. Since according to the Franck–Condon principle the water molecules retain their orientation during the transition, the excited $2p$-state is not an equilibrium state, and λ_{max} for e^-_{aq} corresponds almost exactly to the hydration energy of this radiolysis product (720 nm = 1.72 eV).

A number of experimental data, however, provide evidence in support of the so-called "cavity" theory [185,253-259], which has often been used to explain the characteristic features of the optical absorption spectra of halide ions in solution [253-258]. According to this theory, the halide ion (in our case e^-_{aq}) is present in a spherical "cavity" (i.e. in a certain volume accessible to the ion in solution), whose radius depends on the nature of the ion and the solvent. The absorption maximum is determined chiefly by the energy required to remove the ion from the cavity into the bulk of the solvent. Contraction of the cavity leads to displacement of λ_{max} towards shorter wavelengths. Decrease in the dimensions of the cavity takes place with fall in temperature and with the addition, to the solution, of anions which bind firmly the protons of water molecules. The optical absorption maximum of e^-_{aq} for concentrated electrolyte solutions is displaced towards shorter wavelengths compared with pure water [185]. Decrease in temperature also displaces λ_{max} for this species towards shorter wavelengths [160]; this effect is observed not only for water, but also for alcohols [260]. Similar relationships are observed in the radiolysis of vitreous aqueous solutions at 77°K. [137,261]

Natori and Watanabe [262] have recently developed a structural theory for e^-_{aq}. On the assumption that the electron is trapped in a quasi-tetrahedron of the icelike structure of water and interacts with the nearest four oxygen atoms and eight hydrogen atoms, they calculated the energy of the optical transition at the absorption maximum and the oscillator strength as 0.8 and 0.26 eV respectively (compared with experimental values of 1.72 and 0.6–0.7 eV).

3. THE HYDROGEN ATOM

In 1954 Livingston and his coworkers [263,264], using the e.s.r. method, detected the formation of H atoms in the radiolysis of aqueous solutions of the acids $HClO_4$, H_2SO_4, and H_3PO_4 at 77°K. Later the production of H atoms in frozen aqueous solutions of acids was observed by many workers [265-277]. The spectrum of atomic hydrogen consists of a doublet with a splitting of 500 oersteds and a g-factor close to that of the free electron. The spectrum of the D atom for a solution of an acid in D_2O consists of a triplet with a separation between the components of ~ 78 oersteds. The yield of H atoms depends on the nature of the anion and the concentration of the acid, and also on the state (crystalline or vitreous) in which the frozen solution is irradiated.

Atomic hydrogen is not detected in pure ice irradiated at 77°K. Its spectrum has been recorded at 4.2°K. [273-276] The initial yield of H atoms amounts in this instance to 0.5–0.9 [273,274]. Rexroad and Gordy [275] consider that the H atoms in ice irradiated at 4.2°K are produced as a result of the capture of electrons ejected from water molecules by H_3O^+ ions present in the matrix. The probability of such capture is obviously increased considerably in acid solutions. This probably explains the increase in the yield of H atoms in frozen solutions of inorganic acids, to 2.0–2.2 in perchloric acid solution at 77°K. [270,277]

The e.s.r. spectrum of H atoms has also been observed in solutions of alkalis and various inorganic salts, irradiated at 77°K. [126,127,129,137,272] In this instance, however, the yield of H is low; it is higher in crystalline alkaline ice than in the vitreous material [129].

At present there is no direct proof of the formation of H atoms in the radiolysis of liquid aqueous solutions. There is only indirect evidence for the production of this species. It has been shown [62-65] that the kinetic characteristics of the reducing species in the radiolysis of acid solutions are identical to those of atomic hydrogen prepared by non-radiative methods.

The part played by H atoms is most significant in the radiolysis of acid solutions. This is due to the fact that, since k_8 is high, e^-_{aq} is converted into H even in dilute acid solutions.

In neutral medium the greater part of the reducing radicals consist of hydrated electrons. The yield of H atoms is 0.5–0.6. This value has been found for G_H by many workers [82,83,86,88,90,97,100,213,278].

When neutral solutions do not contain acceptors of hydrated electrons, the latter, at low dose rates, are transformed by reaction (15) into H atoms, which can evidently take part in corresponding processes. This phenomenon is observed, for example, in neutral solutions of methanol. In this system $G(H_2)$ is almost equal [213] to the sum $G_{H_2} + G_H + Ge^-_{aq}$.

According to Baxendale [279] the reactions of H atoms can be divided into three main groups. The first group corresponds to simple reduction, e.g.

$$H + Cu^{2+} \rightarrow H^+ + Cu^+. \quad (24)$$

The second group comprises the addition of H to unsaturated bonds, e.g.

$$C_6H_6 + H \rightarrow C_6H_7. \quad (25)$$

The third group involves the detachment of H with the formation of H_2. Reactions of this group are extremely characteristic of saturated organic compounds, e.g.

$$CH_3OH + H \rightarrow CH_2OH + H_2. \quad (26)$$

The H atom is characterised by strong reducing properties. Its reactivity is indicated in Table 3, which includes data obtained using pulse radiation. The H atom is generally a weaker reducing agent than e^-_{aq}. This is true for the reactions with NO_3^-, NO_2^-, H_2O_2, N_2O, Ag^+, Cu^{2+}, Zn^{2+}, Cd^{2+}, Mn^{2+}, Ni^{2+}, Co^{2+}, etc.[56,62,64,66,94,95,146,212,278,285-390] The reactivities of H and e^-_{aq} towards O_2 and OH are almost identical. These reactions involve simple addition of H and e^-_{aq}. The H atom is more reactive than e^-_{aq} towards certain organic compounds, e.g. alcohols. The redox potential of H is 2.1 V.[208]

The rate constants for the reactions of H atoms in aqueous solution are greater (by not more than one order of magnitude) than the constants for the analogous gas-phase reactions. This is in accordance with the theory of chemical kinetics[301].

Hydrogen atoms and e^-_{aq} often give the same reaction products. There is one characteristic property of H atoms, however, by means of which they can be distinguished on the basis of an analysis of the final products. Unlike e^-_{aq}, they exhibit a dehydrogenating action in reactions with saturated organic compounds.

The yield of H atoms is 3.65[1] in acid medium (pH < 2) and 0.5–0.6 in neutral medium[238]. In alkaline medium this species is effectively transformed into e^-_{aq} [reverse reaction (15)].

In 1950 Weiss[302] postulated the formation of H_2^+ radical-ions in acid medium:

$$H + H^+ \rightarrow H_2^+. \quad (27)$$

Later various characteristic features of the radiolysis of acid solutions were also attributed to the production of this radical-ion[71,72]. As shown subsequently, however, the rate constant for reaction (27) is comparatively low, 10^2–2.6×10^3 litres mole^{-1} s^{-1}.[37,296] It has been shown[303] that $G(Fe^{3+})$ in aqueous Fe^{2+} solutions is independent of the acid concentration, indicating that H_2^+ plays little part, even in strongly acid solutions. According to certain authors[62,303,304], the oxidation of Fe^{2+} by atomic hydrogen involves the intermediate formation of hydride complexes:

$$Fe^{3+} + H \rightleftarrows FeH^{3+} \quad (28)$$

$$FeH^{3+} + H^+ \rightarrow Fe^{3+} + H_2. \quad (29)$$

The H_2^+ radical-ion apparently does not oxidise methanol in sulphuric-acid solutions[305].

There are two hypotheses regarding the mechanism of formation of H atoms as a primary product of the radiolysis of water. According to the first, these particles are produced by reaction (8), taking place in the spurs[53,79,80,306]. The second hypothesis[76-78,307-309] suggests that H atoms are produced from highly excited water molecules. According to Anbar and Meyerstein[308] substances which are efficient excitation-quenching agents (in particular ions of variable valency) can apparently react directly with the possible precursors—H_2O^* molecules—of the H atoms. These authors regard[309] the second hypothesis as confirmed by the results of a study of H/D isotope effects in the radiolysis of water. They find[309] that the isotope effect in the formation of H atoms is much greater in acid medium than in neutral medium. At present, however, there are no direct experimental data in support of either hypothesis.

TABLE 3. Rate constants for the reactions of H atoms with dissolved substances at 20–25°C.

Solute	k, litres mole^{-1} s^{-1}	Ref.	Solute	k, litres mole^{-1} s^{-1}	Ref.

* Rate constant for the recombination of H_2^+ radical-ions.

4. THE OH RADICAL

The formation of OH radicals by the action of radiation on water has been observed repeatedly. Dainton and Collinson[310], in a study of the radiation polymerisation of acrylonitrile in water, observed in the infrared absorption spectrum of the polymer a broad band due to OH groups. A large number of products of the reactions of OH radicals with dissolved substances have now been identified by the pulse radiolysis method. A list of these products and some characteristics of their optical spectra are given in Table 4.

Recently, Hart, Matheson, et al.[51], using the pulse radiolysis method, have recorded the optical absorption spectrum of the OH radical in irradiated liquid water. It is found that λ_{max} for this radical lies at $\leqslant$ 230 nm.

One of the most important pieces of evidence for the formation of OH radicals in the radiolysis of water is provided by data obtained from the e.s.r. spectra of irradiated ice. The e.s.r. spectrum of OH radicals radicals in ice irradiated at 77°K was first observed by Matheson and Smaller[265,267]. The e.s.r. spectrum due to OH radicals (in H_2O) and OD radicals (in D_2O) has since been observed by many workers[126,127,137,271-277,328-338]. The e.s.r. spectrum of the OH radical consists of a doublet with a separation of ~ 40 oersteds between the components and a g-factor of 2.01, and that of the OD radical consists of a triplet with a separation of ~ 6 oersteds between the components.

The chief source of OH radicals is H_2O^+ ions (reaction 1). Weiss[252] suggested that H_2O^+ (or, in his terminology, the positive polaron) in liquid water has a lifetime which is sufficient to enable it to take part directly in the radiolytic transformation of various substances. Later, Weiss and Moorthy[339,340] have reported that they were able to record the e.s.r. signal of this ion in a study of the radiolysis of frozen solutions of various acids. Hummel and Allen[341] found, however, that the ionic strength does not influence the rate of the reaction between the oxidising

TABLE 4. Characteristics of the optical spectra of short-lived species which are products of the reactions of OH and O^- radicals with dissolved substances.

species in the radiolysis of water and bromide ion. Hochanadel[298] found that in the pH range 2–7 the oxidising species in the radiolysis and the OH radical obtained photochemically have the same reactivity towards hydrogen and hydrogen peroxide. From this it follows that the species being considered is not charged. Moreover, the e.s.r. signal observed by Weiss and Moorthy[339,340] has later been shown[137,277] to be due most probably to the OH radical. Nevertheless, it is not excluded that H_2O^+ ions may take part in radiolytic transformations in strongly acidic or highly concentrated solutions, when the reactions of the substances with this species may take place at a greater rate than reaction (1).

The OH radical is a strong one-electron oxidant. On reaction with a solute it oxidises one equivalent of the latter. It can sometimes act as a reducing agent, e.g. in the radiolysis of potassium permanganate solutions[342].

The most characteristic reactions of OH radicals can be divided into three groups. The first group corresponds to ordinary oxidation, e.g.

$$Ce^{3+} + OH \rightarrow Ce^{4+} + OH^-. \qquad (30)$$

The second group comprises the addition of OH to unsaturated bonds. The third group involves the abstraction of H with the formation of H_2O.

In alkaline medium the OH radical dissociates[343]:

$$OH \rightleftarrows O^- + H^+. \qquad (31)$$

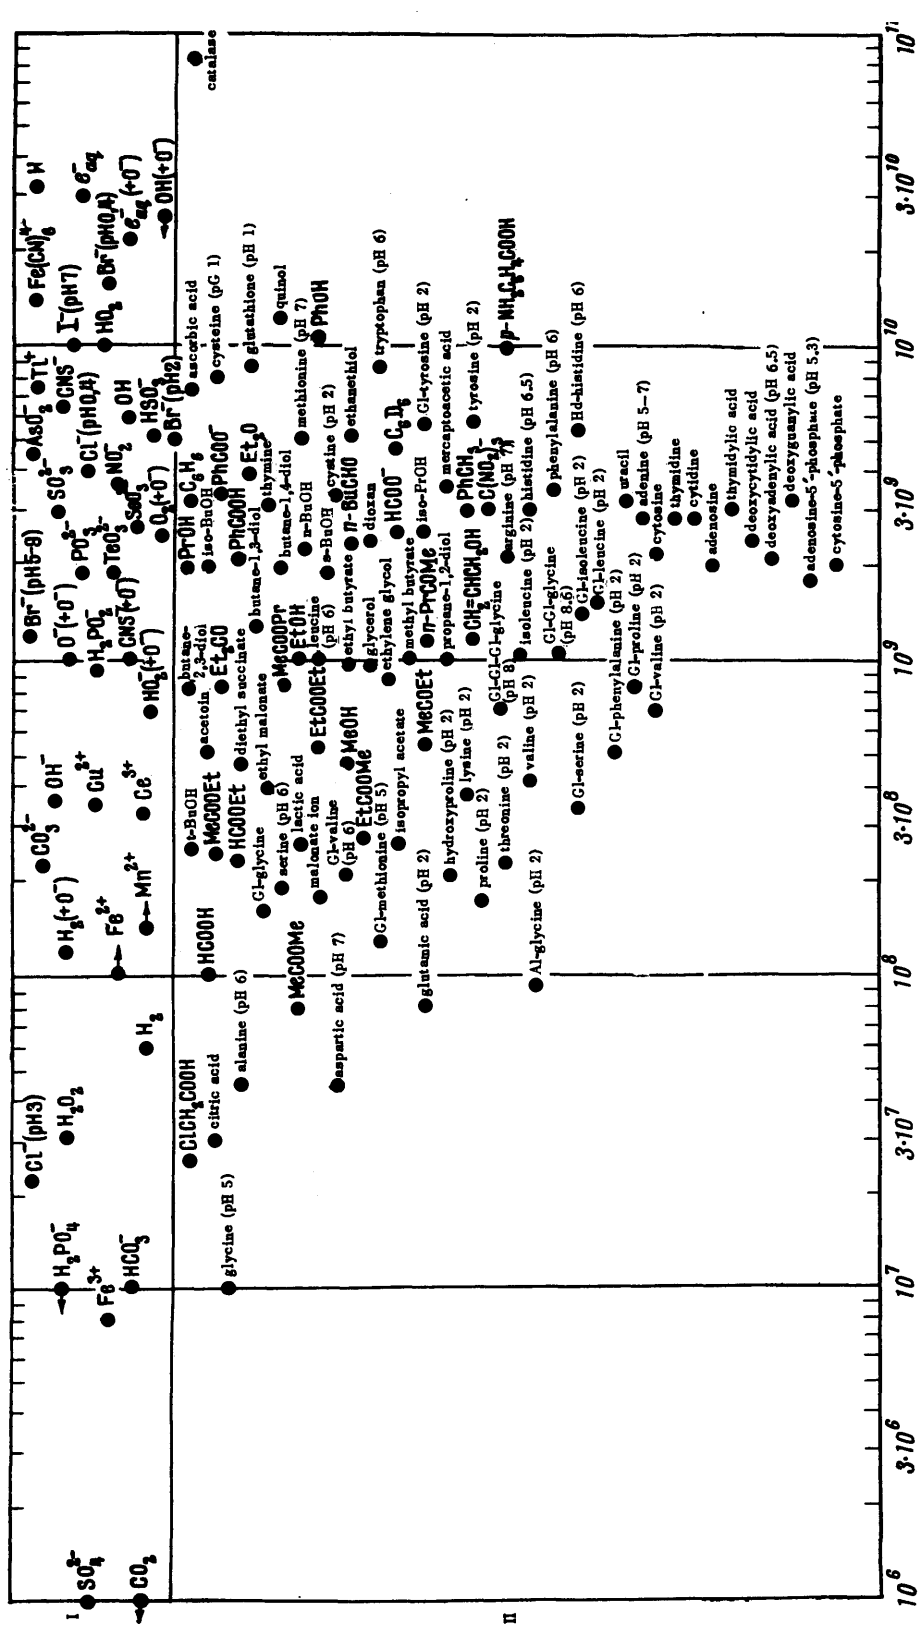
The value of pK for this dissociation[39] is 11.9 ± 0.2. Like the OH radical, the O^- radical-ion absorbs in the wavelength range below 300 nm.[39] The ozonide ion O_3^- has been observed during the pulse radiolysis of alkaline solutions of oxygen[167,311] (see Table 4). This ion may be formed by the reaction

$$O^- + O_2 \rightarrow O_3^- \qquad (32)$$

which provides evidence for the existence of O^- in alkaline medium. The dissociation of the OH radical according to Eqn. (31) is also confirmed by measurements of the e.s.r. spectra of irradiated frozen alkaline solutions[126–135,344].

The O^- radical-ion is a weaker oxidising agent than the OH radical. In alkaline medium the yields of a number of oxidation processes—$G(AsO_4^{3-})$ for the oxidation of arsenite[345,346], $G(CO_2)$ for the radiolysis of oxalic acid solutions[347–351], $G(I_2)$ for the radiolysis[221] and photolysis[296] of KI solutions in the presence of N_2O, etc. —show a decrease. On the other hand, there is an increase in the yields for reductions, when the product undergoes reconversion into the starting material as a result of reaction with OH. For example, $G(NO_2^-)$ for $NaNO_3$ solutions increases sharply in alkaline medium[91]. Sometimes it is even necessary to assume that the O^- radical-ion has a reducing action[221,296].

Scheme 2, which indicates the reactivities of OH and O^- radicals, uses data[30–34,36,38,39,44,47,49,51,52,117,147,167–170,177,179,181,182,189,194,200,202,311–327,352–354] obtained in studies in which the reaction rate constants for these radicals were determined by means of pulsed radiation. In addition, a large number of relative rate constants for the reactions of OH and O^- have been determined by the method of competing acceptors[38,205,238,293,341,355–369].



An important feature of the kinetics of reactions involving OH radicals is that the rate constants for reactions of type (13) have much larger values in aqueous solution than in the gaseous phase. Thus $k_{OH + H_2}$ for the gaseous phase is[370,371] about 10^4 litres mole^{-1} s^{-1}; for aqueous solutions, this constant has the value[38] $(4–6)\times10^7$ litres mole^{-1} s^{-1}. There are as yet, however, insufficient experimental data for a rigorous explanation of this effect.

The yields of OH radicals are greater in acid and alkaline media than in neutral medium. Since the processes of

G_{OH} (pH 7)	2.6 (±10%) *	
G_{O^-} (pH 13)	3.0—3.1	54, 55, 79

* Mean value from results given in a large number of papers.

Scheme 2. Rate constants for the reactions of OH and O$^-$ radicals in aqueous solution at room temperature. The constants for O$^-$ are denoted (+O$^-$); Al = alanyl; the other symbols are the same as those used in Scheme 1.

OH and e^-_{aq} formation are interrelated, the reasons for the increase in G_{OH} in alkaline medium are for the most part the same as those for the increase in Ge^-_{aq}.

The chief properties of OH radicals in water are summarised in Table 5.

5. THE HO_2 RADICAL

A study of the radiolysis of the Fe^{2+}–Cu^{2+} system by Hart in 1956 showed[373-375] that the perhydroxyl radical HO_2 is formed as a primary product. It is produced in the spurs as a result of reaction between H_2O_2 and OH. The yield of HO_2 for $^{60}Co\gamma$-radiation is extremely low (~ 0.02)[373]. For heavy particles, however, G_{HO_2} is much greater. For ^{210}Po α-particles, $G_{HO_2} = 0.23$.

The HO_2 radical is formed very efficiently in solutions containing oxygen, by reaction between O_2 and H or e^-_{aq}. Since k_{H+O_2} and $ke^-_{aq}+O_2$ have extremely high values, it may be concluded that the HO_2 radical plays an important part in these solutions.

Formation of the perhydroxyl radical has been demonstrated by many methods. Schmidt[377,378] observed an increase in electrical conductivity due to the presence of O_2^-—a product of the dissociation of HO_2—in irradiated water containing oxygen. The pulse radiolysis method has been used[167,177,311,313] to record the optical absorption spectra of HO_2 and O_2^- radicals. The absorption maximum of the HO_2 radical lies at 230 nm, and that of the O_2^- radical-ion at 240 nm. Proof of the formation of HO_2 radicals was also obtained in a study of the e.s.r. spectra of irradiated frozen water and various aqueous solutions[126,127,328,329,333].

The HO_2 radical is amphoteric. In neutral and alkaline media it dissociates according to the equation

$$HO_2 \rightleftarrows H^+ + O_2^-. \qquad (33)$$

The pK value for this dissociation is 4.4–4.5.[167,179,379] According to Bielski and Allen[380], the perhydroxyl radical is present in strongly acidic medium in the form $H_2O_2^+$:

$$HO_2 + H^+ \leftrightharpoons H_2O_2^+ \qquad (34)$$

the pK value for this equilibrium being 1.0 ± 0.4.[380]

The perhydroxyl radical may act as either an oxidising agent or a reducing agent, depending on the conditions and the nature of the dissolved substance. Under ordinary conditions, the oxidising power of HO_2[208] is close to that of Ce^{4+}. In oxidations HO_2 is converted into H_2O_2, and in reductions it is converted into H_3O^+ and O_2.

The reactions of HO_2 with the OH radical require special mention. Until recently it was assumed that this reaction takes place as follows:

$$HO_2 + OH \rightarrow H_2O + O_2. \qquad (35)$$

Kinetic proof has been obtained[379], however, of the formation of H_2O_3 by the combination of HO_2 and OH. The yield of H_2O_3 at pH 2–3 is 1.7. The pK value for the dissociation

$$H_2O_3 \rightleftarrows H^+ + HO_3^- \qquad (36)$$

is 9–10. The disappearance of H_2O_3 depends on the acidity of the medium. Its half-life is ~ 2 s in 0.02 M acid, and less than 0.1 s in 1 M and 10^{-4} M acid. This substance does not react with Ce^{4+}, tetranitromethane, or KI in neutral solution, but it oxidises Fe^{2+}. The formation and the stabilisation of compounds of the type H_2O_3 are observed[381] in various free-radical reactions on cooled surfaces.

TABLE 6. Rate constants for the reactions of perhydroxyl radicals in aqueous solution at 20–25°C.

Reaction	Medium	k, litres mole^{-1} s^{-1}	Ref.

Table 6 gives absolute reaction rate constants for HO_2, O_2^-, and $H_2O_2^+$ radicals in aqueous solution, determined by various authors. The chief properties of perhydroxyl radicals in water are summarised in Table 7.

6. THE OXYGEN ATOM

The possible formation of atomic oxygen as a primary product of radiolysis has been postulated by a number of workers[238,385]. Allen[238] gives some indirect evidence for the production of O atoms in the decomposition of neutral water under the influence of radiation. He argues that, if it is assumed that H atoms are produced in yield 0.55 in neutral medium, $G(-H_2O)$ becomes 4.3. In this case, however, the oxidising products do not balance. To preserve the balance, it is necessary to assume the formation of another oxidising radiolysis product, which, from results for radiolytic transformations in a number of systems, should not react with hydrogen or ethanol, but is reactive towards hydrogen peroxide. Since in neutral medium $G_{OH} = 2.2$ and $G_{H_2O_2} = 0.7$, the yield of this product should be 0.7 equiv. eV^{-1}. If this product is atomic

oxygen, $G_O = 0.35$. Allen uses this hypothesis to explain various features of the radiolysis of a number of systems—H_2O_2–O_2 [57], NO [226], formate solutions [386], and H_2O_2 in H_2O. [18,387]

Allen [238] suggests the OH^+ ion as a possible source of atomic oxygen. Mass-spectroscopic data [388] in fact show that H_2O^+ and OH^+ ions (ratio 100 : 23.2 [289]) are formed in largest quantities in water vapour as a result of electron collisions (energy of electrons 100 eV). Baxendale and Gilbert [390] consider that OH^+ ions react in the gaseous phase with H_2O to give OH radicals:

$$OH^+ + H_2O \rightarrow H_2O^+ + OH \qquad (37)$$

but it has recently been shown experimentally [391] that this reaction produces H_3O^+ ions:

$$OH^+ + H_2O \rightarrow H_3O^+ + O. \qquad (38)$$

According to the data of Thynne and Harrison [391], in the gaseous phase $k_{38} = 2.9 \times 10^{11}$ litres mole^{-1} s^{-1}.

It is of course difficult to suppose that the relative proportions of H_2O^+ and OH^+ should be the same in the gaseous phase and in the liquid, but it may be assumed that the OH^+ ion is also produced by the action of radiation on liquid water. It may evidently then be a precursor of atomic oxygen. It is probable that in neutral medium OH^+ dissociates with the formation of O and H_3O^+ [reaction (38)]. In this connection it is interesting to note that the proposed ratio G_{OH}/G_O is close to the ratio of the quantities of H_2O^+ and OH^+ in the gaseous phase. It should be emphasised that the production of O by this mechanism should be accompanied by the formation of the same quantity of H:

$$H_2O \rightsquigarrow OH^+ + H + e^-. \qquad (39)$$

In acid medium, because of the presence of H_3O^+ ions, different routes for the disappearance of OH^+ are possible.

Another source of O atoms may be the recombination of OH radicals [392]:

$$OH + OH \rightarrow H_2O + O. \qquad (40)$$

Experiments [393,394] on the radiolysis of acidic and neutral water at high absorbed dose rates—i.e. under conditions where the recombination of radicals is highly probable—show, however, a significant increase in $G(H_2O_2)$ compared with low dose rates. It is thus unlikely that atomic oxygen is formed by the recombination of OH radicals.

There are at present no quantitative data on the properties of atomic oxygen in aqueous solutions. Taube [395], in a study of the reactions of excited O atoms (in the ^1D-state), showed that these atoms react readily with water to form hydrogen peroxide. In the ground state O atoms do not react with water. Katakis and Allen [396], studying the radiolysis of concentrated perchloric acid solutions, have observed not an increase but a decrease in $G_{H_2O_2}$ with increase in the $HClO_4$ concentration. In these solutions the direct action of radiation on perchloric acid produces excited perchlorate ions, which decompose to ClO_3^- and O. From the observed dependence of the yield of H_2O_2 on $[HClO_4]$, these workers conclude that the O atoms produced are in the ground state. Formation of O atoms is possible in the radiolysis of concentrated solutions of various other oxygen-containing anions (NO_3^-, $KMnO_4$, etc.).

7. EXCITED WATER

As already noted, the passage of ionising radiation through water leads to ionisation and excitation of H_2O molecules. The fate of the "excited water" and the part it plays have not yet been elucidated, however.

Excited water molecules may be formed [397] in two ways—(1) by capture of the ejected electron by the H_2O^+ ion (Samuel–Magee hypothesis), and (2) by collision of slow electrons with water molecules—and Magee [398] considers that water molecules in the singlet and triplet states may be produced in a spur, in the ratio 1 : 3, as a result of the first process.

Platzman [399] suggests that, in the gaseous phase, irradiation produces both ionised and excited molecules in equal yields. In the condensed phase "superexcited" molecules (their energy exceeding the ionisation potential) use up the excess of energy, not only for ionisation but also for other processes. For example, breakdown of the molecule into two radical fragments is possible. In Allen's opinion [1], however, excitation of H_2O to an upper electronic level in liquid water may lead to ionisation. According to Voevodskii [400,401] the excitation in liquid water may be transferred through hydrogen bonds and be localised at impurities, leading to the formation of H, OH, H_2, and H_2O_2. If the excitation of water does not lead to ionisation, the H and OH radicals formed by the breakdown of H_2O^* will be produced close to one another and will possibly, as a result of the "cage effect" [402], recombine for the most part, to re-form water. It is of course not excluded that a certain proportion of the H atoms, because of their very small dimensions, will escape from the "cages" into the bulk of the liquid, through the cavities in the quasi-crystalline water lattice. If, however, excitation of the water leads to ionisation (see footnote on p. 603), the H (or e^-) and the OH formed from the H_2O^* produced as a result of the capture of the ejected electron by H_2O^+ will be in the same small spur as the H_3O^+ and OH (from the H_2O^+), as is assumed by Matheson [403]. This also facilitates the H + OH reaction. These considerations lead to the conclusion that, in dilute solutions of ordinary substances, the part played by excited molecules is small. The radiolysis of concentrated solutions is quite different. As first postulated by Proskurnin [404–407], at high concentrations a solute can penetrate into the "cage", as a result of which its reaction with radicals becomes possible. Later, Bakh and his coworkers [408], Pikaev [409], Kabakchi [410,411], Sowden [412,413], and Katakis and Allen [396] attributed various features of the radiolysis of concentrated solutions to reactions in which H_2O^* takes part. Dainton and his coworkers [54,55] put forward similar explanations for the increase in the yields of radical products of the radiolysis of water in acid and alkaline media, and also in relatively concentrated N_2O solutions. Shubin and Dolin [414,415] observed a considerable increase in yields in a number of systems when these were saturated with inert gases under very high pressures. It was suggested that in these experiments ordering of the water structure takes place. This creates favourable possibilities for the transmission of excitation along a chain of hydrogen bonds. In the opinion of these authors, the excitation here appears in the form of exciton-like formations (electron–positive-hole pairs).

Recently, the idea that "excited water" takes part in radiation reactions has been introduced into the interpretation of certain features of the radiolysis of dilute aqueous

solutions of a number of substances. Hayon[78] considers that, in the radiolysis of neutral solutions, certain substances (e.g. O_2) may react directly with H_2O^*. Shinohara and his coworkers[416,417], in a study of the radiolysis of neutral or weakly acidic HgX_2–NaN_3 and HgX_2–$NaNO_2$ solutions, conclude that under the most favourable conditions about five excited water molecules per 100 eV absorbed energy may take part in radiolytic transformations. Anbar and Meyerstein[307,308,418], in an investigation of the influence of ions of the type Zn^{2+}, Cd^{2+}, Co^{2+}, Ni^{2+}, and Mn^{2+} on the magnitude of G(HD) in irradiated solutions of 2-deuteriopropan-2-ol and methanol (0.01–0.1 M), have been forced to postulate the possibility of reactions between H_2O^* and these ions and alcohols. Shagisultanova et al.[419] attribute the hydrolytic decomposition of oxalato-complexes of Co^{III} in aqueous solution under the influence of ^{60}Co γ-radiation to the penetration of excited water molecules into the coordination sphere of these compounds. Getoff[420] assumes that the carboxylation of amines in aqueous solution is due partly to reactions involving H_2O^*. Kabakchi et al.[421,422] attribute the characteristic features of the radiolysis of the H_2O_2–O_2–H_2 system to the reactions of the dissolved substances with exciton-like formations.

There is at present no direct experimental proof of the formation of excited water molecules. Niira[423] has predicted theoretically that water has a triplet excited state, and Kuppermann[424], in a study of the scattering of electrons with energies of 25–100 eV in the gaseous phase, has detected an excited state of H_2O with an energy 4.2 ± 0.2 eV higher than the energy of the ground electronic state. Sitharamarao and Duncan[425], in an examination of the emission of light from water during γ-irradiation, conclude that H_2O^* and OH^* are formed in appreciable yield during the radiolysis of water. More recently, however, a similar investigation by Czapski and Katakis[426], carried out at a higher experimental level, has shown that the radiation yield of light emission is negligible ($\leq 10^{-5}$).

In the liquid phase an excited molecule in the triplet state has a lifetime of 10^{-4} s or more[427]. The possibility that this also applies to water cannot be excluded. It is evident that, as a result, these H_2O^* molecules may also take part in radiation reactions in comparatively dilute solutions. Chemically, however, H_2O^* molecules are generally equivalent to (H + OH), so that they should "develop" only with certain solutes[54,55]. This effect can be observed particularly clearly when the solution contains "conjugated acceptors"[404–407,428–431], i.e. when, as it were, both an acceptor for H atoms and an acceptor for OH radicals are present. At the same time it is necessary that a given acceptor be an effective excitation "quencher".

There are no experimental or theoretical data on the possibility of the existence of excitons in liquid water. According to Protopopov[432,433], free and local excitons may exist in aromatic liquids and solutions. In addition to the local exciton, the liquid also contains a state of local ordering, which is termed an orienton. The lifetime of these formations is short ($\leq 10^{-9}$ s), however. Davydov[434] considers that in some instances excitons of the Wannier–Mott type (an electron–positive-hole pair) may be produced in the liquid phase. Jortner[435] has recently carried out quantum-mechanical calculations and demonstrated the possibility of the existence of excitons in media of the liquefied inert gas type. For water, it is apparently necessary to make allowance for its high polarity. It follows from theory that the bond energy of the exciton decreases in proportion to the square of the dielectric constant of the medium[436]. Moreover, with marked polarisation, the bound electron and positive hole can in principle form a polaron pair[437]. Finally, it must be emphasised that water is characterised by a high reactivity towards H_2O^+ ions. It can therefore probably be concluded that, although water has a crystal structure with short-range order, excitons in it, if they are produced, have an extremely short lifetime, and in dilute aqueous solutions they break down (possibly to OH and e^-_{aq}) without being able to spread. These discussions are of course qualitative, and it would be extremely desirable for the appropriate quantum-mechanical calculations to be carried out.

In connection with the foregoing, considerable interest attaches to work[438–440] using the pulse radiolysis method, which has established the formation of triplet-excited molecules of naphthalene and other aromatic substances during irradiation of their solutions in benzene and cyclohexane. In aqueous solutions, however, the yields are negligible[439].

Thus excitation of water can be observed only under strictly specific conditions. In dilute aqueous solutions of ordinary substances, the part played by this process is small.

8. THE MOLECULAR PRODUCTS H_2 AND H_2O_2

Hydrogen and hydrogen peroxide are the primary molecular products of the radiolysis of water. Many workers[268,272,273,286–301,356,361,408,412,413,441–455] have shown that the yields of H_2 or H_2O_2 decrease with increase in the concentration of dissolved substances which are acceptors of H atoms (e^-_{aq}) or OH radicals respectively. The following relationship is observed

$$G_{R_2} = G^0_{R_2} - A[S]^{1/2}$$

where G_{R_2} is the yield of H_2 or H_2O_2 at a given concentration of the acceptor S, $G^0_{R_2}$ the yield of molecular product at zero concentration of the acceptor, [S] the molar concentration of the acceptor, and A a parameter defining the probability of interaction between the acceptor and the corresponding radical.

Byakov and his coworkers[456,457] have carried out a theoretical treatment of the dependence of G_{R_2} on [S] on the basis of a simplified diffusion–radical model for the radiolysis of water. They have shown that this dependence is given by the equation

$$G_{R_2} = G^0_{R_2} - G^0_{R_2}\left(\frac{k_{R+S}}{k_{R+R}}\frac{v_0}{n_0}\right)^{1/2}[S]^{1/2}$$

where n_0 is the initial number of radicals in the spur, v_0 is the initial volume of the spur, and k_{R+S} and k_{R+R} are the rate constants for the corresponding reactions. Byakov and Bugaenko[458] use this equation and the experimental dependence of G_{R_2} on [S] to calculate a large number of relative rate constants for radiation reactions. The calculated values are close to the experimental values. The agreement between the constants provides evidence in support of the hypothesis that at least the greater part of the H_2 and H_2O_2 is formed as a result of the recombination of radicals in the spurs [reactions (9–12)].

Weiss and Hayon[59], Hayon[459], and Rabani and Stein[212] postulated that a large proportion of the molecular hydrogen is formed as a result of the recombination of e^-_{aq} in

the spurs or at a short distance from the latter. Proof for the possibility of formation of H_2 from e^-_{aq} was obtained by Dorfman and Taub[30], who measured the yields of HD and D_2 in alkaline and acidic solutions of C_2H_5OD in D_2O. Production of H_2 occurs also[28,29] by the reaction of e^-_{aq} with H at sites of high radical concentration. The mechanisms of these two interesting reactions are still unknown, however. The recombination of e^-_{aq} possibly passes through a stage involving the formation of $(e^-_{aq})_2$. The production of such "bipolarons" was postulated in one of the theories of metal-ammonia solutions[460]. Anbar and Meyerstein[461,462] have studied the isotopic effect in the formation of hydrogen by the recombination of e^-_{aq}, and found that this effect is much greater than would be expected on the basis of the hypothesis that the H_2 is produced by the diffusion-controlled process $e^-_{aq} + e^-_{aq}$. They therefore conclude that the recombination of e^-_{aq} involves the formation of $(e^-_{aq})_2$, and that decomposition of the latter (into $H_2 + 2OH^-$) with rupture of the H–O bond takes place much more readily than the corresponding decomposition with rupture of the D–O bond. In the second reaction, the H^- ion is probably produced as an intermediate product.

There are other theories regarding the ways in which the molecular products of the radiolysis of water are produced. Many authors[245,388,459,461-465] suggest that H_2 and H_2O_2 may be produced by the decomposition of "excited water". Stein and his coworkers[387,463] have studied the radiolysis of H_2O_8 in $H_2{}^{18}O$. According to their data, one fraction of the H_2O_2 precursors is readily captured by acceptors of OH radicals, whereas the other fraction does not exhibit this property. These authors conclude that the yield of H_2O_2 corresponding to the second type of precursor (possibly H_2O^*) is about 0.4. Similar results[245] have been obtained in a study of the dependence of $G_{H_2O_2}$ on the concentration of $[Fe(CN)_6]^{3-}$. Here the yield of H_2O_2 corresponding to H_2O^* amounts to 0.3. It should be emphasised, however, that these values of the H_2O_2 yield, which are independent of the concentration of acceptors of OH radicals, are apparently too high. Czapski[466] has represented the results of published work[245,388,463] graphically by plotting $G_{H_2O_2}$ against $[S]^{1/3}$, and obtained an almost linear relationship. Some of these authors have subsequently[467] agreed with this conclusion. Anbar and Meyerstein[388,463,461,462] find that the isotopic effect in the formation of H_2 as a result of the radiolysis of water is much smaller than that for the recombination of e^-_{aq} obtained photochemically. On this basis they conclude that, in the irradiation of water, a large proportion of the H_2 is produced, not by the reaction $e^-_{aq} + e^-_{aq}$ in the spurs, but as a result of various other processes (e.g. the decomposition of "excited water"). It is undoubtedly extremely desirable to confirm this very interesting observation for a number of other materials, and to establish the fraction of H_2 and H_2O_2 produced from "excited water".

In Platzman's opinion[468], a certain proportion of the H_2 is formed by the reaction of underexcited electrons (of energy ≤ 6.5 eV) with water, with the intermediate formation of H^- ions. The calculations show that the yield of H_2 as a result of this reaction may reach 0.2 ± 0.1.

Molecular hydrogen generally does not react with dissolved substances. When the solution contains large quantities of H_2, however, or when no other acceptors of hydroxyl radicals are present, the hydrogen reacts with OH radicals, converting them into H atoms in acidic and neutral media, and into e^-_{aq} in alkaline medium.

Hydrogen peroxide may exhibit reducing properties or oxidising properties, depending on the nature of the dissolved substance and the pH of the medium†. Hydrogen peroxide undergoes electrolytic dissociation:

$$H_2O_2 \rightleftarrows HO^-_2 + H^+ \qquad (41)$$

the pK value for this reaction being 11.75.

9. MAXIMUM YIELD IN THE DECOMPOSITION OF WATER

The magnitude of $G(-H_2O)$ is determined by the ionisation of the water, without allowance for the reactions $H + OH$ and $e^-_{aq} + OH$ in the spurs. If we assume that in neutral water H is produced in addition to e^-_{aq}, we reach the conclusion that $G(-H_2O)$ depends little on pH. The values found for this yield are 4.55, 4.3, and 4.6–4.8 in acidic, neutral, and alkaline media respectively. It is difficult to make accurate allowance for the contribution of the reactions $H + OH$ and $e^-_{aq} + OH$, taking place in the spurs. According to Hochanadel[397], the yield for the decomposition of water $G'(-H_2O)$ with allowance for these reactions amounts to ~ 6. Diffusion-kinetic calculations carried out by Byakov et al.[457] show, however, that this yield may reach ~8. Various data provide evidence in support of this last value. Proskurnin and his coworkers[407,428,429] found that $G(NO_2^-)$ in concentrated (1 M and above) alkaline solutions of $NaNO_3$ saturated with nitrogen is 4.0–4.5 ions per 100 eV. If it is assumed that two reducing particles are used up in the formation of one nitrite ion, $G(-H_2O) \simeq 8$–9. Baxendale and Gilbert[390] studied the radiolysis of mixtures of the vapours of H_2O and methanol, ethanol, ether, or cyclohexane, and concluded that $G'(-H_2O) = 8.0 \pm 0.7$. According to Anderson et al.[470,471] in the gaseous phase in the presence of cyclohexane or ammonia $G(-H_2O)$ has the values 7.0 (over the range 125–250°C) and 10.6 (above 300°C).

Firestone[472] studied the formation of HD in mixtures of gaseous D_2 and water vapour containing tritium, and found that $G(HD) = 11.7 \pm 0.6$. If it is assumed that the HD is produced as a result of the reaction $H + D_2$, it is obvious that $G(HD) = G(-H_2O)$. Baxendale and Gilbert[390], discussing these results, have suggested that, in the D_2–H_2O system, isotopic exchange by deuterium involves both ionised and excited water molecules. If this is so, the difference between the yields for the decomposition of water, observed in these experiments, gives the yield of excited molecules. This difference is ~4. The same value for the H_2O^* yield can be obtained by examining the results of work by Proskurnin and his coworkers[407,428,429]. These authors found that $G(NO_2^-)$ in concentrated alkaline solutions of $NaNO_3$ increases to ~6 ions per 100 eV when a "conjugated acceptor"—glycerol or glucose—is added. Finally, it has been shown[414,415] that under certain conditions the yield for the decomposition of water may reach ~14.

Thus definite data have now been obtained, indicating that the maximum yield for the decomposition of water amounts to 12–14 molecules per 100 eV. The maximum yield due to ionisation is 6–8 molecules per 100 eV. It is evident that in dilute solutions these yields can be achieved only in exceptional instances, if at all.

† The properties of hydrogen peroxide have been described in detail in a monograph[469].

VIBRATIONAL AND ELECTRONIC SPECTRA OF AROMATIC SIX-MEMBERED AZACYCLIC COMPOUNDS

M. A. Kovner and S. K. Potapov

CONTENTS

Introduction 621

I. Vibrational spectra 621

1. Geometrical structure of azines and classification of vibrations 621

2. Experimental data on vibrational spectra and their interpretation 622

3. General characteristics of the force field in azine molecules 624
4. General features of vibrational spectra of azines 625
II. Electronic spectra 625
A. Experimental work on absorption and emission spectra 625
1. Pyridine 625
2. Diazines 625
3. 1,3,5-Triazine 627
4. 1,2,4,5-Tetrazine 627
B. Theoretical work on absorption and emission spectra 627
1. Comparative characteristics of $\pi-\pi^*$ and $n-\pi^*$ transitions 627
2. Calculation of excited electronic states and main parameters of electronic transitions 628
C. Principles of the classification of electronic states and the interpretation of electronic spectra 630

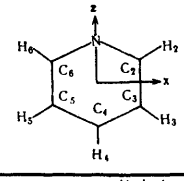
INTRODUCTION

Six-membered aromatic azacyclic compounds occur as structural units in a large number of more complicated compounds having important and diverse applications. These molecules are present in biologically active substances[1,2]. For example, thymine and cytosine, component parts of deoxyribonucleic acids (DNA)[3-5], are pyrimidine derivatives. Pyrazine derivatives are widely used in the synthesis of medicinal preparations and dyes[6]. Although pyridine and the diazines have been known for a long time, free symmetrical triazine was discovered only in 1953, by Grundmann and Kreutzberger[7]; its physical and chemical properties were soon studied in detail, and have been described in a review by Finkel'shtein and Boitsov[8]. Apart from their varied practical applications, these substances are of great interest also for the further development of the theory of chemical structure.

One of the chief physical methods for studying molecular structure is the application of spectroscopy, and during recent years a large amount of theoretical and experimental research has been done on the vibrational and electronic spectra of six-membered aromatic nitrogen heterocycles. The present review is devoted to their interpretation and systematisation. It consists of two parts: the first discusses the vibrational spectra of pyridine, and three diazines, triazine, and tetrazine; and the second part gives an analysis of the absorption and luminescence spectra of the same compounds. The review covers all the important experimental papers and calculations completed up to 1966.

I. VIBRATIONAL SPECTRA

1. Geometrical Structure of Azines and Classification of Vibrations

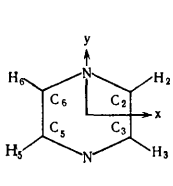


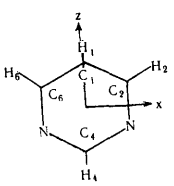
The replacement of one or more carbon atoms in the benzene ring by nitrogen atoms results in a change in the force field and distortion of the ring from the regular hexagon form. All azine molecules are planar. The bond lengths and valency angles have been determined by various physical methods—X-ray examination, electron diffraction, microwave spectroscopy, study of the rotational structure of the electronic spectra—and a complete list of all the geometrical parameters of the azines has been compiled by Berezin[9] (Tables 1 and 2). Experimental data on the geometrical structure of pyridazine are lacking.

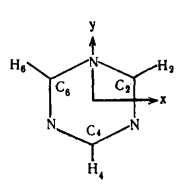
The coordinate axes indicated in Tables 1 and 2 have been used in the classification of the normal vibrations of azines according to symmetry types. The symmetry group and the types of vibration are given below for each of the molecules.

Pyridine C_{2v}, $10A_1 + 3A_2 + 9B_1 + 5B_2$.
Pyrimidine C_{2v}, $9A_1 + 2A_2 + 8B_1 + 5B_2$.
Pyridazine C_{2v}, $9A_1 + 4A_2 + 8B_1 + 3B_2$.
Pyrazine D_{2h}, $5A_g + 2A_u + 4B_{1g} + 2B_{1u} + B_{2g} + 4B_{2u} + 2B_{3g} + 4B_{3u}$.
1,3,5-Triazine D_{3h}, $3A_1' + 2A_2' + 2A_2'' + 5E' + 2E''$.
1,2,4,5-Tetrazine D_{2h}, $4A_g + A_u + 3B_{1g} + 2B_{1u} + 3B_{2u} + 2B_{2g} + 3B_{3u}$.

Vibrations of the symmetry types A_1, B_1, A_g, B_{1g}, B_{2u}, B_{3u}, A_1', A_2', and E' are planar, whereas the remaining vibrations are non-planar. The vibrations E' and E'' are doubly degenerate. All vibrations of molecules with symmetry C_{2v}, vibrations having the subscript g, and the vibrations A_1, E', and E'' are active in the Raman spectra. The vibrations A_1, B_1, and B_2, vibrations having the subscript u, and the vibrations A_2'' and E' are active in the infrared spectra. Vibrations of types A_u and A_2' are forbidden by the selection rules, and are inactive in vibrational spectra of both types.







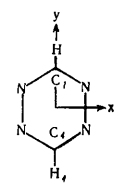


TABLE 1. Bond lengths (Å) and valency angles in the pyridine molecule according to various authors*.

Bonds and angles	Method					
	electron diffraction (Ref. 10)	microwave spectrum (Ref. 12)	microwave spectrum (Ref. 14)	microwave spectrum (Ref. 12)	electron diffraction (Ref. 14)	calc. (Ref. 15)

2. Experimental Data on Vibrational Spectra and Their Interpretation

(*a*) Pyridine. Many investigations have been made of the Raman spectrum of pyridine [23-30], in all of which the intensity was merely estimated qualitatively or on a denary scale. Depolarisation measurements were made [23,24] only for a very few lines, and the results did not give the true depolarisations. Only one paper [31] has given quantitative data for standard intensities and true depolarisation measurements, together with the Raman line widths.

Determinations have been made of the infrared spectra of pyridine vapour [32,27] and liquid pyridine [24,27,33-35]. Interpretation of the vibrational spectra became considerably more reliable after examination of the Raman and infrared spectra of pentadeuteriopyridine [24], and of 4-mono- and 2,6- and 3,5-di-deuteriopyridines in liquid and vapour states [29]. The infrared spectrum of pyridine vapour itself was also obtained in the latter work [29]. The infrared spectra of the above two dideuteriopyridines in both states have subsequently been examined in detail [36]. In another case the infrared spectra of the three monodeuteriopyridines were obtained [37].

Before the problem of the normal vibrations of pyridine and its deuterio-derivatives was solved, the interpretation of the vibrational spectra had been based on the product rule for the frequencies of isotopic molecules, selection rules, comparing the spectra of pyridine and deuteriopyridines with thoes of benzene and deuteriobenzenes, and comparing the infrared and Raman spectra of pyridines in liquid and vapour states [24,29]. A theoretical calculation [36] of the vibration frequencies of pyridine and pentadeuteriopyridine using the force constants of benzene did not give satisfactory results. A complete calculation of all the vibration frequencies of pyridine and the deuteriopyridines has been reported for the first time [38]. A solution has been obtained [39] to the problem of the non-planar vibrations of pyridine and the deuteriopyridines, with a determination of the system of force constants, and also for the planar vibrations [40]. A fresh calculation has been made [41] of the planar vibration frequencies of pyridine and pentadeuteriopyridine using the force constants of benzene. The frequencies and modes of vibration of 4-deuteriopyridine and of 2,6- and 3,5-dideuteriopyridines, together with the atomic displacements in all 27 vibrations of pyridine itself, these three deuterio-derivatives, and pentadeuteriopyridine, have been calculated [42] using the force constants of benzene. The Urey–Bradley potential function has been applied [43] to the calculation of the frequencies of the same molecules. An advantage of such a function is the smaller number of force constants involved, compared with the complete quadratic potential function in the valency–force system of vibrational coordinates. However, as discussions during recent years have shown, this advantage is ineffective, since the Urey–Bradley force constants have no real physical meaning. It is not suprising, therefore, that sufficiently good agreement was not achieved [43] between calculated and experimental frequency values.

The most complete interpretation of the vibrational spectra of pyridine and the deuteriopyridines has been given by Berezin [39,40,9]. Its reliability is based on a complete solution of the converse vibrational problem—calculation of the vibrational modes and the atomic displacements during vibration—and is confirmed by good adherence to the product rules and Sverdlov's addition rules for the squares of frequencies [44] and the frequencies themselves [45] for isotopic molecules and Brodersen and Langseth's complete isotopic rule [46].

(*b*) Pyrimidine. The experimental data are far more limited than in the case of pyridine. The Raman spectra of liquid pyrimidine have been obtained[47,48], and an interpretation has been suggested[48] for the spectra. The absorption curve has been given[49] over the range 750–2000 cm^{-1}. Separate narrow portions of the infrared spectrum have been studied[50–53], and a more detailed investigation of the infrared spectrum has been made[47]. Several vibration frequencies have been obtained from the phosphorescence spectrum recorded at a low temperature[54]. The frequencies and vibrational modes have been calculated, and the vibrational spectra interpreted[55]. The frequencies and band intensities of the non-planar vibrations of pyridine, pyrimidine, and their methyl derivatives have been compared[56] with the corresponding frequencies and intensities for benzene and its substituted derivatives. This comparison introduced certain changes into the previously accepted interpretation of individual bands, but we are unable to go into these details.

(*c*) Pyridazine. The Raman and infrared spectra of liquid pyridazine have been obtained[47,48]. In the first of these papers[47] only five frequencies were found in the Raman spectrum, while the infrared spectrum was examined only in the range $\nu > 650$ cm^{-1}. The second paper[48] reported a more detailed study of both spectra, the infrared spectrum beginning at 370 cm^{-1}, and an assignment of frequencies to symmetry types was suggested. The whole system of fundamental frequencies has been calculated[57].

(*d*) Pyrazine. The Raman and infrared spectra have been obtained[47]. Another paper[48] reports both infrared and Raman spectra of liquid pyrazine, together with the infrared spectrum of its vapour. Several vibration frequencies have been determined from the low-temperature phosphorescence spectrum[58,59]. None of these investigations gives a complete system of fundamental frequencies, but they mutually complete the vibrational spectrum.

The first theoretical interpretation was based[48] on selection rules (rule of mutual exclusion), intensities and depolarisations, and comparison with the spectra of benzene and pyridine. This approach does not solve the problem, but it serves as an important prerequisite for a theoretical calculation. The first such calculation[60] used the force constants of benzene, and did not give satisfactory agreement between calculated and experimental frequencies. New calculations have been made[61,62] of the frequencies of non-planar and planar vibrations. The most complete solution of the problem of non-planar and planar vibrations with the full quadratic potential function has been accomplished[63,64] by calculation of the derivatives of the frequencies with respect to the force constants. Nevertheless, the interpretation given in these papers cannot be regarded as definitive, since the number of force constants to be determined exceeded the number of frequencies. In this case neither the force constants themselves nor the frequency assignments were determined unambiguously.

New opportunities for theoretical calculations were opened up by the determination of the vibrational spectra of the deuteriopyrazines. The Raman spectra[65] of pyrazine and tetradeuteriopyrazine in the liquid state and the infrared spectra of the latter compound in both liquid and vapour states permitted a detailed discussion of the various ways in which individual frequencies could be assigned taking into account the product rule and the assignment of combination frequencies. In an investigation[66] of the infrared spectra of pyrazine, *cis*-di-, and tetra-deuteriopyrazines in vapour and solid states, over the wide range 400–4000 cm^{-1}, frequency assignment was partly based on such new data as measurements of the dichroism of oriented crystals, analyses of rotational band envelopes, and polarisation measurements. These characteristics enabled pyrazine frequencies of symmetry types B_{1g}, B_{2g}, and B_{3g}, which were inactive in the infrared spectrum, to be determined. Finally, some additional information on the vibrational frequencies of pyrazine could be obtained from an analysis of the vibrational structure of its ultraviolet absorption spectrum[67,68] and a comparison of the frequencies of the ground and excited electronic states. In spite of such diverse approaches to the problem, a final solution was not achieved, since the interpretations of different authors did not agree among themselves.

A fresh theoretical calculation of the planar vibration frequencies of pyrazine, *cis*-di-, and tetra-deuteriopyrazine has been made[69] both with a valence-force potential function and with the Urey–Bradley potential function. The fact that both methods yielded the same frequency assignments is reassuring. Nevertheless, in many cases this assignment contradicts the results of other authors. It is obviously an urgent task to obtain the Raman spectrum of dideuteriopyrazine and to make fresh theoretical calculations in which all the isotopic rules are taken into account.

(*e*) 1,3,5-Triazine. The first determination of the Raman and infrared spectra was accompanied[70] by the first suggested assignment of the frequencies. Other analyses of these spectra were made[71,72], but in the most complete investigation of both spectra for both the triazine and the corresponding trideuteriotriazine[73] the infrared spectra were obtained for both liquid and gaseous states, and an approximate calculation was also made of the vibration frequencies. The planar vibration frequencies for both compounds have been calculated[74] by means of the Urey–Bradley potential function, but the resulting frequency assignments showed poor agreement with the addition rule for the frequencies of isotopic molecules. An attempt has been made[75] to solve the converse vibrational problem by determining 19 force constant, but such a solution cannot be regarded as complete. Solutions of the problems concerning the non-planar and planar vibrations have been obtained for both molecules[63,64] with the force constants of pyridine as zero-approximation constants.

(*f*) 1,2,4,5-Tetrazine. Infrared spectra have been investigated[76] for the symmetrical tetrazine and its mono- and di-deuterio-derivatives. Those of tetrazine itself in the range 700–3070 cm^{-1} were recorded for three states—the frozen solid phase, a solution in carbon tetrachloride, and the vapour—but those of the deuterio-derivatives were obtained not for the isotopically pure substances but for mixtures containing various percentages of tetrazine and mono- and di-deuterio-tetrazines, which made interpretation extremely difficult. As far as we are aware, the Raman spectrum of 1,2,4,5-tetrazine has not been obtained, but several frequencies, which should be active in the Raman spectrum, appear as weak lines in the infrared spectrum, thus infringing the rule of mutual exclusion. Some additional results for the assignment of frequencies have been obtained from analysis of the vibrational structure of the ultraviolet absorption bands[77,78] of symmetrical tetrazine and dideuteriotetrazine. The above limited spectroscopic data, together with the product rule and a solution of the problem of the normal vibrations of 1,2,4,5-tetrazine[64], has enabled an interpretation of its

vibrational spectrum to be obtained which must be regarded as tentative. To refine this, the Raman spectrum must be obtained, and fresh calculations made.

We have been able to deal only briefly with the evolution of our knowledge of the vibrational spectra of the azines, without discussing individual frequencies. The results of comparing all the spectra and calculations of the frequencies and modes of the vibrations together with the atomic displacements during vibrations are listed in Table 3, which contains 27 fundamental frequencies for pyridine, 24 for each of the diazines, and 21 and 18 for symmetrical triazine and tetrazine. In Table 3 the frequencies of all the azines are compared among themselves and with those of benzene, for which the generally accepted Wilson numbers[79] are indicated. The symmetry types are given for each molecule. Table 3 permits the variation in frequencies to be traced in a series of azines. Unfortunately, owing to lack of space, we have not included the frequencies of the deuterioaxines in Table 3.

3. General Characteristics of the Force Field in Azine Molecules

It has now been established that vibrational spectra provide a great deal of information about the force fields in molecules. Indeed, the complete solution of the vibrational problem, with the establishment of a set of force constants and weighting coefficients [sic], permits conclusions to be drawn concerning the distribution of forces in a molecule and the variations in the force field occurring in series of compounds. Thus it follows from a comparison of these characteristics for benzene and pyridine that replacement of a carbon by a nitrogen atom leads to a breakdown in the equivalence of the bonds forming the ring. The carbon–nitrogen bond is more elastic than the remaining cyclic bonds or the carbon–carbon bond in benzene. The angles also become more elastic. The carbon–nitrogen bond exerts a greater resistance to displacement out of the plane of the ring than does the carbon–carbon bond. At the same time the interactions of non-adjacent structural units

of the ring are weakened in comparison with the corresponding interactions in benzene, which can be explained qualitatively by the greater degree of localisation of the π-electrons in pyridine. The CNC angle is, like the carbon–nitrogen bond, exceptional in its properties, which is obviously connected with the role of the lone pair of electrons on the nitrogen atom. The result is that the interaction of adjacent bonds in the ring is weaker if their common atom is nitrogen. The interaction of non-adjacent internal angles among themselves and with the external angles becomes weaker as the number of nitrogen atoms in the ring increases. These conclusions have been reached predominantly on the basis of an analysis of systems of weighting coefficients[9]. Comparison of them with other characteristics of the molecules (bond lengths and energies, atomic charges, bond orders) indicates a correlation with these parameters. It is especially interesting that a correlation has been established between the properties of the weighting coefficient of each nitrogen ring and its aromaticity, as well as with the Hammett σ-constants[9].

4. General Features of Vibrational Spectra of Azines

A comparative analysis of the vibrational spectra of benzene and the azines, together with calculations of the vibrational modes and the atomic displacements, enable the following generalisations to be made

(*a*) On passing from benzene to the nitrogen rings, the degeneracy is eliminated from ten degenerate vibrations of benzene. Each doubly degenerate frequency is split into two components (with the exception of 1,3,5-triazine). The magnitude of the splitting is small, but depends on the number and positions of the nitrogen atoms.

(*b*) Many vibrations of the nitrogen rings and the benzene ring are similar in mode and atomic displacements. The actual frequencies are also close to one another, and can be subdivided into the following groups (cm^{-1}).

1600–1500.	Planar stretching–deformation vibrations with varying participation of the bonds forming the ring, and of its external and internal angles. These lines are intense in both Raman and infrared spectra.
1500–1400.	Planar deformation–stretching vibrations with CCH angles predominantly involved. They are characterised by high intensity in the infrared spectrum.
1200–1060.	Planar stretching–deformation vibrations of the carbon–nitrogen skeleton.
1010–960.	Planar stretching vibrations of the ring bonds. They are distinguished by high intensity in the Raman and infrared spectra.
740–600.	Planar vibrations of the internal angles of the ring. The intensities vary in the series of nitrogen rings.
760–670. 420–320.	Non-planar vibrations of the carbon–carbon, carbon–nitrogen, and nitrogen–nitrogen bonds. They relate partly also to non-planar vibrations of carbon–hydrogen bonds. Frequencies in the first of these ranges are usually distinguished by high intensity in the infrared spectra

Besides the classification of frequencies according to vibrations of bonds and angles individual azines can be identified[80–88] from sets of frequencies However, discussion of this analytical problem lies outside the scope of the present paper.

II. ELECTRONIC SPECTRA

A. EXPERIMENTAL WORK ON ABSORPTION AND EMISSION SPECTRA

1. Pyridine

(*a*) Spectra of vapour. The early investigators[89–92] of the spectra of the vapour encountered difficulties in the range 3000–2400 Å in arranging the large number of lines observed in electronic–vibrational progressions having a common origin. Vibrational analysis of the bands showed[93] that two electronic transitions are apparent in this range, with frequencies of the 0–0 bands at 34 769 and about 38 350 cm^{-1}. Two band systems correspond to them—a very weak system, masked by a stronger diffuse system in the short-wavelength part of the spectrum—the first of which has no analogue in the spectrum of benzene, whereas the second system is analogous to the absorption of benzene in the region of 2600 Å. The similarity between the spectrum of pyridine in the region of 2500 Å and the absorption of benzene at 2600 Å was noted by another worker[94]. Extension of the spectral range to 1500 Å revealed[95] two new ranges of absorption, at 47 800–54 500 and 54 500–64 000 cm^{-1}. Estimates were made in this paper also of the oscillator strengths. Subsequent analysis[96] over the range 1800–1600 Å showed the presence of at least three band systems—sharp, diffuse, and continuous—so that the absorption spectrum contains five band systems—two sharp systems at 34 769 and 54 000 and three diffuse systems at 39 000, 49 769, and 56 405 cm^{-1}—and comparison of this spectrum with those of other aromatic compounds[97] indicates the possibility of using it for analytical purposes.

(*b*) Spectra of solutions. To determine the nature of the absorption spectrum and of the individual bands, it was important to investigate solvent effects on the spectrum. The spectrum of a solution in heptane was first studied[98], and subsequently that of an aqueous solution[99]. The spectra in many solvents showed[92,95,100,101] that the absorption maxima shift little, while the intensities increase in the sequence—hydrocarbons, water, alcohols, acids—a generalisation which has been used[102] to determine the acid–base properties of various substances with respect to pyridine. The absorption at 34 769 cm^{-1} disappears in polar solvents[100].

2. Diazines

(a) Spectra of vapours. The early investigations of the near ultraviolet absorption of pyrimidine[103], pyridazine, and pyrazine[104] showed the presence of two band systems—diffuse and sharp—in each case. The former corresponds to the absorption of benzene at 2600 Å, while the latter occurs at longer wavelengths. Analyses have been made of the vibrational structure of the sharp (3200 Å)[19,105–107] and diffuse[108] band systems of pyrazine.

TABLE 4. Interpretation of the electronic spectra of the azines.

Compound	Band characteristics	B_a and B_b bands (Refs. 68, 72)		Rydberg series, vapour Ref. 68	L_a bands (Refs. 68, 172)			L_b bands for solutions in (Refs. 68,101,127,138,172)					Solutions and vapour (Refs. 107, 127, 134, 138, 174)

The rotational structure has been investigated[107], together with the vibrational structure, of the bands of all three diazines. It is important to note that the 0–0 bands proved to be polarised at right angles to the plane of the azine molecule. Apart from the above bands, a study has been made[108] of weak absorption by pyrazine in the region of 3700 Å.

Studies have been made of absorption at shorter wavelengths of 2000–1500 Å by pyrimidine and pyrazine[96] and by all three diazines[68]. The spectra of pyrimidine, pyridazine, and pyrazine have been found to contain respectively four, two, and three bands—at wavelengths of 1932, 1911, 1777, and 1705; 1940 and 1745; and 1960, 1800, and 1650 Å—while a further band at 2000 Å has been suggested in the case of pyridazine. The absorption spectra of the completely deuteriated diazines have also been investigated[68].

(*b*) Spectra of solutions. Absorption spectra in various polar solvents and in hydrocarbons have been obtained for pyrimidine[103,109], pyridazine[110–112], pyrazine[104], and all three diazines[113,114]. This work relates to the sharp bands in the spectra of the vapours, and the following generalisations can be made. Increase in the concentration of a hydroxylated solvent mixed with a hydrocarbon is accompanied by displacement to shorter wavelengths with the intensity practically unchanged, while the vibrational structure becomes diffuse and the absorption continuous. As the acid concentration increases the absorption of all the diazines gradually disappears.

The bands corresponding to the diffuse bands of the vapours exhibit different properties in solvents: a slight hyperchromic effect is observed, while the positions of the maxima remain practically unchanged (in water and hydroxylated solvents). In acidic solvents there is a strong

hyperchromic effect, a bathochromic effect in the case of pyrazine and a hypsochromic effect with the other diazines. A two-step pH variation in ϵ_{max} has been found[115-117] (for all the diazines).

(*c*) Absorption and phosphorescence at low temperatures. The luminescence of pyrazine was first observed[58] in EPA mixture† at 77°K and the corresponding absorption in isopentane at 293°K in the region of 26 000 cm^{-1} with the one progression $\Delta\nu = 606$ cm^{-1}. A more detailed study of the phosphorescence of pyrazine has been made[59] at 90°K in many solvents. From their effect on the spectrum these can be divided into two groups: in EPA, ethanol, and petroleum ether the bands are diffuse in character, whereas in crystalline matrices of carbon tetrachloride, cyclohexane, dioxan, and benzene the bands possess a sharply defined line structure. Analogous investigations have been made[54] on pyrimidine. Other studies have been made[118,119] of the phosphorescence of pyrazine and pyrimidine. An investigation of the phosphorescence of all three diazines showed[120] that pyridazine does not phosphoresce at all.

Polarisation measurements made by the photoselection method[121] have established[122-124] that the phosphorescence of pyrimidine and pyrazine is polarised along the x and y axes respectively (Table 2).

It has been found[125,126] that transitions forbidden by the selection rules are intensified in the absorption of all three diazines in crystals of hydrogen, neon, argon, krypton, and xenon at 4.2°K.

3. 1,3,5-Triazine

Two band systems—sharp and diffuse, with maxima at 36 780 and 45 000 cm^{-1}—have been observed[127] in the absorption spectrum of 1,3,5-triazine vapour. Dissolution in acetonitrile, methanol, and water displaces the maximum of the first band by 520, 670, and 1670 cm^{-1} respectively to shorter wavelengths compared with the solution in cyclohexane, while the maximum of the second band does not move. The vibrational structure of the first band has been analysed[128]. It was established from the rotational structure that the permitted electronic transition corresponds to polarisation perpendicular to the plane of the molecule. Besides absorption, phosphorescence has been observed[129] in EPA solution at 77°K, as a band with its origin at 26 400 cm^{-1}. This work also revealed absorption in the range 13 000–31 000 cm^{-1}, which had not been noted in the earlier work[127].

4. 1,2,4,5-Tetrazine

Symmetrical tetrazine is characterised by absorption in the visible region with a pink colour[130-133]. A detailed investigation of the absorption spectrum over a wide range, 15 000–45 000 cm^{-1} (6000–2200 Å), has shown[134] the presence of strong absorption with a maximum at 2520 Å and a shoulder at 3200 Å, together with a sharp band system in the region of 18 000 cm^{-1}. In aqueous solution the shoulder and the visible absorption are displaced to shorter wavelengths. Studies have been made[76,77] of the vibrational structure at high resolution in the visible absorption of symmetrical tetrazine and its deuterium analogue (in the vapour state and in solutions). An important result of the rotational analysis[135] of the 0–0 band at 5515 Å was the finding that the molecule has a planar structure in the excited electronic state and that polarisation of the electronic transition is perpendicular to the plane of the molecule. Examination of the fluorescence in various solvents at 77°K and comparison with the absorption spectrum showed a mirror-image relationship between the emission and absorption spectra[136,137]. The vibrational structure becomes blurred on passing to solvents in which hydrogen bonding occurs, and the fluorescence undergoes an anomalous shift to longer wavelengths, in contrast to the opposite shift in the absorption.

Combined data will be found[114,138] on frequencies and wavelengths of the 0–0 bands, the band maxima, oscillator strengths, and molar absorption coefficients in the spectra of all azines and many of their derivatives in various solvents. All the most important experimental spectral data for the azines are given in Table 4.

B. THEORETICAL WORK ON ABSORPTION AND EMISSION SPECTRA

1. Comparative Characteristics of $\pi-\pi^*$ and $n-\pi^*$ Transitions

The old problem of the interrelationship between the absorption spectra of molecules and their structure is soluble in principle by quantum mechanics. The subdivision of electrons in a molecule into σ- and π-electrons has enabled regions corresponding to optical transitions of these electrons ($\sigma-\sigma^*$ and $\pi-\pi^*$ transitions, both denoted $N\rightarrow V$) to be delineated in the absorption spectra of hydrocarbons. In the case of aromatic systems containing heteroatoms, transitions of the lone-pair electrons to vacant σ^*- and π^*-orbitals ($n-\sigma^*$ and $n-\pi^*$ transitions, both denoted $N\rightarrow Q$) must also be taken into account. Since transitions of types $\pi-\pi^*$ and $n-\pi^*$ correspond to the same spectral region, the problem arises of establishing criteria by which they can be distinguished. The comparative characteristics of transitions of the two types are listed in Table 5, which is based on Refs. 139–142 and an analysis of experimental results. We will briefly clarify the main generalisations in this table.

Since an $n-\pi^*$ transition involves passage of the electron from a non-bonding orbital to an antibonding π^*-orbital, and a $\pi-\pi^*$ transition occurs from a bonding orbital to the same antibonding orbital, the former transitions will correspond to longer wavelengths. The low intensities of $n-\pi^*$ transitions are explained by the fact that only the $2s$-function of the hybrid orbital of the n-electron, which weakly overlaps the p-function of the upper state, makes a contribution to the transition dipole moment[140]. The polarisation properties are determined by the symmetry of the orbitals in the lower states of transitions of both types: n-orbitals are symmetric, while π-orbitals are antisymmetric, with respect to the plane of the molecule.

In a hydroxylated solvent conditions are created for the formation of hydrogen bonds of the type N...H–O, which stabilise the lone pair of electrons and therefore produce a

† A solvent comprising 5 parts of diethyl ether, 5 parts of isopentane, and 2 parts of ethanol by volume—cf. G.H.Lewis and D.Lipkin, J. Amer. Chem. Soc., 64, 2801 (1942) (Ed. of Translation).

TABLE 5. Comparison of chief characteristics of $n-\pi^*$ and $\pi-\pi^*$ transitions in the spectra of azines.

Band characteristics	$n-\pi^*$ Transitions	$\pi-\pi^*$ Transitions
Wavelength (for the first transitions)	2700–5500 Å	2500 Å
Molar extinction coefficient	300–1000	1000–6000 (except for 1,3,5-triazine)
Polarisation of absorption for singlet–singlet transitions	Allowed transitions polarised perpendicular to the plane of the molecule	Allowed transitions polarised in the plane of the molecule
Effect of a polar solvent (compared with the spectrum in a hydrocarbon) (*a*) alcohols and water	Hypsochromic shifts without substantial change in intensities; position of maximum depends on concentration of hydroxyl-containing solvent	Effect insignificant
(*b*) acid	Gradual weakening of absorption, until it disappears as the acid concentration increases	Always a hyperchromic effect, the intensity depending on the acid concentration; the magnitude and direction of the shift depend on the compound
Vibrational structure	Very sharp in vapour and crystals, less sharp in hydrocarbon, and becomes indiscernible in polar solvents	Diffuse
Vibrational progressions	The main frequencies forming progressions are those of totally symmetric deformation vibrations of the ring	Frequencies of totally symmetric stretching vibrations are involved
Envelopes of electronic–vibrational bands	They possess atomic sharpness; rotational structure resolved	Diffuse
Shift on conjugating substitution	Hypsochromic	Bathochromic

hypsochromic effect. This view is supported by measurements [112,143] indicating that the energy represented by the displacement of the absorption band for pyridazine and the energy of the hydrogen bond are equal. The band maximum shifts with increasing concentration of the solvent, and this has been used to investigate complex formation. Hydrogen bonding is concerned in the explanation of the hypsochromic shift based on the Franck–Condon principle [118,119].

In acid solution protonation occurs, accompanied by a strong hypsochromic shift in the $n-\pi^*$ transition. With increasing acid concentration, therefore, the gradual "disappearance" of the band is observed in the region examined. Calculation shows [144,145] that protonation changes the field of the skeleton and increases the oscillator strength of $\pi-\pi^*$ transitions, whereas the direction of displacement of the band depends on the nature of the solute and differs for the various azines. Hydrogen bonding or protonation leads to a broadening of the vibrational bands and a diffuse character of the vibrational structure of the transition.

Doubt has been cast [146] on the method of differentiating between $n-\pi^*$ and $\pi-\pi^*$ transitions based on the comparative characteristics described above. It is stated that the observed changes in the spectra produced by a solvent can be explained not only by local interactions between the two molecules but also by the general influence of the internal field in a liquid. A rather more conclusive method is therefore proposed for detecting $n-\pi^*$ transitions, based on hydrogen-bond formation in a non-polar solvent. For this purpose a small amount (0.01 M) of a feebly dissociated acid is added to a solution of the azine in a hydrocarbon. The $n-\pi^*$ transitions in the spectra of azines dissolved in hexane were investigated [146] in the presence of acetic acid, methanol, and phenol. A solution containing no proton-donor was taken as zero for the readings. An advantage of the method is that the concentration of the chromophore is not limited, and the investigation is made in the range of validity of the Lambert–Beer law.

After the bands observed experimentally in the spectra of azines have been assigned, the problem arises of a quantitative theoretical determination of the frequencies and intensities of transitions, with their classification on the basis of the symmetry properties of the molecules. This problem is solved by the three main methods of quantum chemistry—valence pairs, molecular orbital, and free electron methods—using group theory.

2. Calculation of Excited Electronic States and Main Parameters of Electronic Transitions

(*a*) $\pi-\pi^*$ Transitions. Present-day calculations can be subdivided into simplified calculations, in which the transition energy is determined as the energy of excitation of one electron, and more exact calculations, in which the wave function of a molecule is built up as an antisymmetrised product of molecular-orbital and spin functions, the interaction of the electrons and their configurations being taken into account.

The first type includes calculations by the sample Hückel method, which have been made for pyridine [95,147] and for all the azines [148,149]. In the last of these [149] second-order perturbation theory was included within the framework of the simple molecular-orbital method. The calculation has been made also for symmetrical tetrazine [150]. All such calculations are semi-empirical in character, and enable only the position of the absorption band of longest wavelength to be predicted. Only one paper [149] has compared the positions of such bands in a series of azines. Another variant of the same one-electron approximation is the free-electron model, in which the role of the heteroatom is allowed for by introducing an additional potential well near it. A particularly large number of such calculations have been made for pyridine [151–155]. The last of these papers includes a calculation of the energy of the first transition in pyrimidine. In another case [156] σ-potentials were introduced for the nitrogen atom in pyridine, pyrazine, and 1,3,5-triazine. A somewhat modified form of the method has been applied to pyridine and pyrazine [157]. The possibilities of all such calculations are confined to computation of the wavelength of the first band, while greater errors are involved in determination of oscillator strengths, and singlet and triplet states are not distinguished with respect to energy.

A far more complete description of the spectra is obtained by more exact methods. In the first, widely known attempt of this type [158] the various integrals were estimated by a semi-empirical method, and calculations made of the positions of singlet and triplet levels, oscillator strengths, and also bond orders in pyridine, pyrimidine, pyrazine, and 1,3,5-triazine. A detailed analysis has been made [159] of Pariser and Parr's method [158]. An analogous calculation for 1,2,4,5-tetrazine allowed for configuration interaction [160,161]. These last calculations, however, gave an unsatisfactory result owing to an unfortunate choice of orbitals for the initial approximation, although the resonance integral of the nitrogen–nitrogen bond calculated in this work (−2.35 eV) became generally accepted.

At a further stage calculations were made by the self-consistent field (Pariser–Parr–Pople) method[162], using the Pople approximation[163] for the Hartree–Fock Hamiltonian, together with a semi-empirical estimate of various integrals[158]. These calculations were made[164-166] with the separation of a term common to all the azines, and representing the electron affinity of the nitrogen atom, in the coulombic integral at the atom. With a single choice for this parameter it was possible to predict satisfactorily four excited singlet states for all the azines other than symmetrical tetrazine. The best results in calculating the energies of excited states are achieved[167] by using self-consistent orbitals including a limited number of configuration interactions. Calculations of the same type, but with a somewhat different estimate of the electronic interaction integrals, were made for pyridine, pyrazine, and 1,3,5-triazine[168,169] and for 1,2,4,5-tetrazine[170]. The same method has been used[171] in calculations for all the azines other than symmetrical tetrazine. However, agreement with experimental values for the transition frequencies proved unsatisfactory. The best results for all the azines (singlet and triplet states, oscillator strengths) were obtained[172] by taking into account the dependence of the resonance integrals on the bond lengths in the series of azines (these results are given in Table 4).

Analysis of all the calculations listed above leads to the conclusions that the electronic configurations between which significant interaction occurs are of the same type in benzene and in the azines. A parallel classification of electronic transitions in the spectra of these molecules is therefore possible.

Calculation by the self-consistent field method, with interaction of the electrons taken into account, does not ensure a sufficiently exact description of excited states. Such a description is considerably improved by allowing for configuration interactions, the most important of which are those corresponding to transitions from two filled upper orbitals to two vacant lower orbitals. A good interpretation of the electronic spectra is then achieved.

With regard to the vibrational structure of $\pi-\pi^*$ transitions, the angles retain their equilibrium values on excitation of a π-electron, while the bonds become only slightly longer. In conformity with the Franck–Condon principle, therefore, the frequencies of totally symmetric stretching vibrations in the excited state should be the most intense[173]. Experiment confirms this conclusion: progressions with the frequencies of totally symmetric stretching vibrations are observed in the absorption spectra of pyridine[93] and the diazines[68,106] in the region of 1550–2000 and 2500 Å.[68]

(*b*) $n-\pi^*$ Transitions. A more fundamental rearrangement of the whole electron shell of the molecule is produced by this transition. The nitrogen atom acquires a positive charge, while a seventh electron appears in the π-electron system. In the excited state, therefore, the properties of the hybridised functions[174] of the nitrogen atom are changed, while the change in the skeleton affects also the π^*-electron functions. These changes complicate the calculations, which are less satisfactory in the case of $n-\pi^*$ transitions.

A simplified model, in which the interaction between a pentadienyl radical and a nitrogen atom having two *p*-electrons is considered, has been used[175] to calculate the energy of the first $n-\pi^*$ transition in pyridine. Since delocalisation of the seventh electron was ignored, the calculation proved unsatisfactory.

An extended form of the Pariser–Parr method, in which the n-electrons were explicitly allowed for in calculating the atomic integrals, was used in a series of papers[176-179]. The energies of the singlet and triplet states of pyrimidine and pyrazine were calculated. However, a satisfactory result was obtained only on the assumption that the 2*s*-function participated to a small extent in hybridisation, in both ground and excited states. But this hypothesis leads to difficulties in explaining the valency angles in the ground state and the intensities of the transitions[174]. The hybridisation parameter was not calculated theoretically, but merely estimated from spectroscopic data.

This defect is absent in calculations[180], without variation of the hybridisation parameter, of the singlet and singlet–triplet transition energies in pyridine, pyridazine, and pyrimidine. The energy of the ground state was determined as the sum of the energies of six π-electrons in the field of the nuclei and the energy of one electron in a doubly occupied orbital, whereas the energy of the excited state was regarded as the energy of seven electrons in the field of the skeleton with a double positive charge on the nitrogen atom. Various integrals on which the difference between these energies depends were computed[180]. But the calculation made it possible to find only mean values of singlet and triplet states. These states could then be separated by application of a method[181] taking into account exchange interactions.

Nevertheless, the most complete description of the spectra of all the azines was accomplished by means of semi-empirical calculations to the one-electron approximation[114,174,182]. These papers showed that the energy of $n-\pi^*$ transitions was determined by two factors—the fall in the energy of the molecular orbitals of the π^*-electrons on introduction of the heteroatom, and the interaction between n-electrons in different atoms—the first factor being due to the enhanced electronegativity of the nitrogen atom relative to carbon, and the second being most significant in the presence of adjacent nitrogen atoms. When these factors were taken into account, the shifts in the $n-\pi$ bands relative to pyridine could be explained throughout the series of azines.

1,3,5-Triazine is especially interesting, since in this molecule the highest filled n-orbitals and the lowest vacant π^*-orbitals are degenerate. Allowance for the configurational interaction eliminates this degeneracy. Calculation of the removal of degeneracy revealed[183] that the resolution is small (around 1 eV) with various sets of semi-empirical values for the integrals, while all transitions between sublevels lie within the same band at 3200 Å.

The oscillator strengths f vary in the series of azines (see Table 4). These changes have been explained[174] by changes in the degree of delocalisation of the π-orbitals and differences in configuration interactions, which play an important part in the calculation of f. Accompanying calculations[174] of differences in energy between singlet and triplet states yielded reasonable values only on the assumption of a small participation of 2*s*-functions in the hybrid functions of the excited states. The above calculations determine the positions of excited singlet and triplet energy levels in azines, which are required in order to explain both absorption and emission spectra. However, the latter exhibit specific regularities. Among all the azines[137] only 1,2,4,5-tetrazine fluoresces, whereas pyrimidine and pyrazine exhibit intense phosphorescence. Pyridine and pyridazine do not luminesce at all. The reasons for these phenomena have been cleared up[184]. The lowest excited

singlet state in azines is an $S(n,\pi^*)$ state. The probability of a transition from it to the ground state is very small. But this is not the main reason for the absence of fluorescence. The main competing process suppressing it is a radiationless transition from the $S(n,\pi^*)$ state to a triplet state $T(\pi,\pi^*)$, located below the former state. This follows from a calculation of the probability of such a transition, which becomes possible as a result of spin–orbital interaction. Such a transition does not occur in symmetrical tetrazine, since the $T(\pi,\pi^*)$ level is located above the $S(n,\pi)$ level, and this compound therefore fluoresces. Phosphorescence is due to an intersystem transition from the $T(n,\pi^*)$ state to the ground state. Such a transition, however, may be radiationless. It is supposed [184] that in pyridine and pyridazine the probability of this process is high. But this explanation does not settle the problem, since this probability has not been determined, and the reason for the phosphorescence of pyrimidine and pyrazine remains obscure.

C. PRINCIPLES OF THE CLASSIFICATION OF ELECTRONIC STATES AND THE INTERPRETATION OF ELECTRONIC SPECTRA

Group theory provides the most general method for classifying electronic energy levels. The symmetry type of each electronic configuration is determined as the direct product of the symmetry types of molecular orbitals filled with one or two electrons. The ground state of the molecule is totally symmetric. When configuration interaction is taken into account, two cases must be distinguished: if the interacting configurations are not degenerate, the resultant state possesses the symmetry of the individual configuration (only configurations of the same symmetry type interact); if, however, one or more interacting configurations are degenerate, several states of different symmetry types arise. The notation for the excited states and transitions is identical with that of the symmetry types.

The second method is applied especially to cyclic systems containing conjugated bonds [185]: the one-electron energy levels are classified according to the values of the projection m_q of the angular momentum on an axis perpendicular to the plane of the molecule. If the sum of the m_q over all electrons in the molecule is 0, ±1, ±2, ±3, the states are denoted for monocyclic systems by A, B, C, L. A state having $\Sigma m_q \neq 0$ is doubly degenerate. The presence of a heteroatom eliminates the degeneracy, and the components of the splitting are denoted by Ba, Bb, Ca, Cb, La, Lb. A one-to-one correspondence is stated [186] to exist between the notations of the two methods, which are indicated in Table 4. Finally, the purely empirical notation—α, p, β, β'—was introduced [187] for transitions from the ground state to the states ^1L_b, ^1L_a, ^1B_b, and ^1B_a. The applicability of this notation to azines has been justified [164,167] by comparing the energy levels and the spectra of the azines and benzene. All these symbols are applicable only to $\pi-\pi^*$ transitions. Only the symbols of group theory are to be used for $n-\pi^*$ transitions, since the properties of n-electrons are not in general represented by the model of free electrons on which the notation of Ref. 185 was based.

The symbols of the transitions are closely linked with their polarisation properties. For singlet–singlet transitions the polarisation is unambiguously defined by the symbol of the upper state and the symmetry types of Cartesian coordinates. To establish the polarisation of a singlet–triplet transition it is necessary to know the symmetry of the sublevels into which the triplet level splits as a result of spin–orbit interaction. Such determinations have been made for the azines [188].

Interpretation of Electronic Spectra

Analysis of the above experimental and theoretical work enables a complete interpretation to be given for the absorption and luminescence spectra of the azines. The absorption spectra are set out in Table 4, in which columns 3–13 give the main characteristics of the $\pi-\pi^*$ transitions, and columns 14–18 those of the $n-\pi^*$ transitions. Assignment of the former transitions was based on the correspondence between the spectra of the azines and that of benzene. Theory predicts for pyridine and the diazines two transitions each in the range 1600–1700 Å. Only one maximum is observed experimentally in this range, which is consistent with the small degree of resolution of the benzene band at 1790 Å. The La-bands correspond to the benzene band at 2050 Å. They show a marked discrepancy between calculated and measured oscillator strengths, which may be tentatively explained by superimposition of a $\sigma-\pi^*$ transition in the same region. The Lb-bands correspond to the benzene band at 2600 Å, and are less intense than the B-bands.

As early as 1954 [127] all the long-wavelength sharp band systems were assigned to $n-\pi^*$ transitions on the basis of a study of solvent effects. Analysis of the rotational structure of corresponding 0–0 bands of diazines [107], 1,3,5-triazine [128], and 1,2,4,5-tetrazine [135] showed them to be polarised perpendicularly to the plane of the molecule. This fact finally confirms the assignment of the transitions to the $n-\pi^*$ type. Table 4 shows very clearly the effects of solvents on transitions of both types.

It follows from the scheme of energy levels [174] that a second permitted $n-\pi^*$ transition occurs in pyrimidine, pyridazine, and symmetrical tetrazine. To such transitions have been assigned the bands at 1932 and 1942 Å in pyrimidine and pyridazine [68] and at 3200 Å in 1,2,4,5-tetrazine [134]. The positions of the bands agree with theoretical predictions [174], but their assignment is tentative, and they are not included in Table 4.

While Table 4 indicates only singlet–singlet transitions, the singlet–triplet transitions are given in Table 6. [174] The latter are assigned to intersystem transitions in view of the long life-time of the excited states and the small oscillator strengths [174,188]. The important part played by radiationless transitions from excited states of the molecules was already pointed out in the early work [139,140]. In most cases, therefore, the nature of the radiating transition ($\pi-\pi^*$ or $n-\pi^*$) is determined by the type of the lower excited state, and the type of phosphorescence depends on the relative positions of the $T(\pi,\pi^*)$ and $T(n,\pi^*)$ levels [189]. Theoretical calculation is not a reliable criterion, since these states may be very close together, and the distinguishing features listed in Table 5 are used to assign the $S-T$ transitions.

The symmetry types indicated in Table 6 have been established from the correspondence with absorption bands and the law of mirror symmetry. Symmetrical triazine forms an exception. The long life-time indicates that the transition is forbidden not only with respect to spin but also with respect to symmetry. The transition is therefore assigned not to $^3A_2''$ but tentatively [174] to $^3E''$. Table 6

TABLE 6. Intersystem transitions in azines.

Compound	Position of 0–0 band, Å: absorption	Position of 0–0 band, Å: phosphorescence	Life, s	Assignment and polarisation
Pyridine	3381	—	—	$^3A_1(\pi, \pi^*)$
Pyrimidine	—	3534		$^3B_2(n, \pi^*)$, x
Pyrazine	3765	3769	$2\cdot10^{-3}$	$^3B_{1u}(n, \pi^*)$, y
1,3,5-Triazine	(3846)	(3788)	0.46	$^3E''(n, \pi^*)$

does not include the luminescence of symmetrical tetrazine, since the band at 5571 Å is assigned, in view of the short life-time and on the basis of the law of mirror symmetry, to the singlet–singlet transition $^1B_{1u}$: i.e. it is fluorescent.

GAS CHROMATOGRAPHY WITH TEMPERATURE PROGRAMMING

G.Ya.Myakishev

1. INTRODUCTION

The gas-chromatographic analysis of complicated mixtures of organic compounds, differing markedly in partition coefficients, almost always requires the application of a variable temperature. In fact, it is impossible to choose a constant temperature such that light and heavy components can be separated satisfactorily in the same analysis. If a low temperature is chosen, light components will be separated satisfactorily, but a long time will be required to analyse the heavy components. Furthermore, because of the considerable spreading of the peaks, the sensitivity of the chromatograph will be too low for the heavy components. At a high temperature the heavy components readily show up, but the retention time of the light components is so short that they cannot be separated even on a highly efficient column.

The problem has been solved by applying to the mixture to be separated either a moving temperature profile with a constant temperature gradient in the direction of flow of the carrier gas, or by varying the temperature simultaneously along the whole column.

The former method was proposed and developed by Zhukhovitskii and Turkel'taub together with their collaborators [1-5], and is termed stationary chromathermography. In this method the components of the mixture are distributed inside the column in such a way that the less volatile substances are located near the inlet, where the temperature is higher, and the more volatile substances near the outlet. The components remain practically stationary relative to the furnace producing the temperature gradient, and move towards the outlet from the column at the same speed as the furnace gradient. In the course of time the bands shrink and the mixture becomes enriched.

The other method, which has been called the programmed temperature method, was proposed by Griffiths et al. [6] Temperature programming permits the light components to escape at low temperatures, and the heavy components at high temperatures. In this way an acceptable retention time is obtained, together with quite narrow peaks for both light and heavy components.

At the present time the temperature programming method, which is simpler in practice, is predominantly used, and most of the papers have been devoted to it. Undoubtedly the stationary chromathermography method also shows promise, and will be developed in the future. The present paper discusses only the temperature programming method. A detailed description of stationary chromathermography can be found in two monographs [7,8].

The practice of temperature programming has developed greatly. A theory has been constructed which enables results for isothermal chromatography to be used to determine the retention temperature, ascertain the degree of component separation as a function of the operating conditions, and identify the components of a complex mixture.

Temperature programming is employed in the quantitative analysis of hydrocarbons, alcohols, ethers and esters, aliphatic acids, aromatic compounds, synthetic oils, etc.[9-16] Both packed and capillary columns are used. Several firms market instruments for chromatography with temperature programming.

Temperature programming in gas chromatography usually involves the use of linear programmes of the type

$$T = T_0 + rt \tag{1}$$

where T_0 is the initial temperature, r a parameter characterising the rate of change of temperature, and t the time. The choice of linear programmes is dictated primarily by the simplicity of producing them. But the most important reason is that linear programming enables reliable results to be obtained in the quantitative analysis of multicomponent mixtures. The peaks of components belonging to the same homologous series emerge at approximately equal intervals of time in a linear programme, while the resolution of the components is almost the same as under isothermal conditions. However, special forms of nonlinear programmes have several advantages, which will be discussed at the end of this paper.

2. DETERMINATION OF RETENTION TEMPERATURE AND TIME IN LINEAR PROGRAMMING

Underlying the theory of programmed-temperature gas chromatography is a simple equation obtained by several workers[17-20]. If a chromatographic peak traverses a path dl at a speed v in time dt, we have the differential equation

$$dl = v\,dt. \tag{2}$$

At constant temperature Eqn. (2) can be integrated to give

$$L = vt_R \tag{3}$$

where L is the length of the column and t_R the retention time of the peak. On the other hand, the retention time can be expressed in terms of the retention volume V_R and the speed of the carrier gas u:

$$t_R = \frac{V_R}{u}. \tag{4}$$

At any temperature the speed v of the peak at a given instant is

$$v = \frac{uL}{V_R} \tag{5}$$

(if u and V_R are measured at the same mean pressure in the column or at the pressure at the outlet). Substituting from Eqn. (5) in (2), we obtain

$$dl = \frac{uL}{V_R}\,dt. \tag{6}$$

Integration of Eqn. (6) yields

$$\int_0^{t_R} \frac{u\,dt}{V_R} = 1. \tag{7}$$

If the temperature is assumed to vary linearly with time as in Eqn. (1), we find that Eqn. (7) becomes

$$\int_{T_0}^{T} \frac{u}{r}\,\frac{dT}{V_R} = 1. \tag{8}$$

If there is a controlled rate of flow, and this rate is independent of temperature, it follows from Eqn. (8) that

$$\int_{T_0}^{T} \frac{dT}{V_R} = \frac{r}{u}. \tag{9}$$

Eqn. (9) is the starting point for further analysis. It is interesting in that the integral on the left-hand side is the same for all components and columns: it is determined solely by the rate r at which the temperature rises and the speed u of the carrier gas.

The retention volume V_R should be corrected for expansion of the carrier gas. Correction factors, which depend on the pressure gradient in the column, have been given in Ref. 21.

The corrected retention volume can be written

$$V_R = V_m + V_R' \tag{10}$$

where V_m is the retention volume of the gas peak, and

$$V_R' = Ae^{\frac{\Delta H}{R_0 T}}. \tag{11}$$

Eqn. (11) gives the temperature dependence of the retention volume. Here ΔH is the heat of dissolution, R_0 the universal gas constant, T the absolute temperature, and A a constant independent of temperature.

Eqn. (9) can be generalised by making it independent of column length for a column of a given type[22]. On multiplying both sides of this equation by m, the quantity of liquid phase present in the column, we obtain

$$\int_{T_0}^{T} \frac{dT}{V_{Rg}} = \frac{r}{F} \tag{12}$$

where $V_{Rg} = V_g + V_m/m$ is the retention volume per unit mass of the liquid phase, and $F = u/m$ is the speed of the carrier gas per unit mass of the liquid phase.

If, in particular, the length of the column is doubled, while the speed u of the carrier gas remains unchanged, F will be halved, and the retention temperature, i.e. the temperature at which a peak appears, will be given by

$$\int_{T_0}^{T} \frac{dT}{V_{Rg}} = \frac{2r}{F}. \tag{13}$$

But if, at the same time as the column length is doubled, r is halved or u is doubled, the retention temperature will be unchanged.

Eqn. (7) and hence Eqn. (9) can be simplified by postulating that the speed of a peak due to a component is small at $T \simeq T_0$, and that heating is started at the instant of appearance of the carrier-gas peak. We then have

$$\int_{t_a}^{t_R} \frac{u}{V_R'}\,dt = 1 \tag{14}$$

and

$$\int_{T_a}^{T_R} \frac{dT}{V_R'} = \frac{r}{u}, \tag{15}$$

in which t_a is the retention time for the carrier-gas peak, T_a is its retention temperature, and V_R' is defined by Eqn. (11). Rowan considers[20] that Eqn. (15) is accurate, but actually this is not so. If the retention volume of the carrier-gas peak is large (e.g. in a capillary column), the error will be considerable.

Eqn. (9) has several times been tested experimentally. For example, Rowan[20] made a careful comparison of theoretical values of the retention temperature with experimental results. From Eqns. (15) and (11) he obtains for the elution temperature of the components the expression

$$\frac{rAR_0}{u\Delta H}=\int_{\Phi_1}^{\Phi_2}-\frac{e^{-\Phi}}{\Phi^2}d\Phi \qquad (16)$$

where

$$\Phi=\frac{\Delta H}{R_0T},\ \Phi_1=\frac{\Delta H}{R_0T_a},\ \text{and}\ \Phi_2=\frac{\Delta H}{R_0T_R}. \qquad (17)$$

Integration by parts yields

$$\frac{rAR_0}{u\Delta H}=\left[\frac{e^{-\Phi_2}}{\Phi_2}-\frac{e^{-\Phi_1}}{\Phi_1}+\int_{\Phi_1}^{\Phi_2}\frac{e^{-\Phi}}{\Phi}d\Phi\right]=f(\Phi_1-\Phi_2;\Phi_1) \qquad (18)$$

in which all quantities other than Φ_2 and hence T_R are known (A and ΔH are determined from isothermal data). The paper contains tables, compiled by the author, of values of the function f for various values of $\Phi_1-\Phi_2$ and Φ_1. By plotting graphs of this function $f(\Phi_1-\Phi_2,\Phi_1)$, it is easy to determine Φ_2 and T_R for known values of A, ΔH, r, and u. The good agreement with experiment justifies the use of Eqn. (15) as starting point for further calculations.

Measurements have been made[22] of retention volumes in a capillary column for 2,3,3- and 2,3,4-trimethylpentane as a function of temperature in isothermal processes. From these data, the integral

$$\int_{T_0}^{T}\frac{dT}{V_{Rg}} \qquad (19)$$

was evaluated as a function of T_R by numerical integration, and hence the retention temperature was calculated for various values of r/F (from 0 to 0.07 g cm^{-3}). Here, too, agreement between theoretical values and experimental results was good.

In both these[20,22] and other papers the calculated retention temperature was lower by several degrees than the experimental values, and this difference increases with increase in the rate of heating r of the column. Giddings has shown[23] that these errors are caused by a temperature gradient between the walls and the centre of the column. This gradient is due to thermal inertia, and the column therefore operates at lower temperatures than are assumed in the calculations. At the same time the temperature gradient inside the column causes additional spreading of the peaks, which somewhat impairs the separation of the mixture. Temperature distribution profiles in the column have been calculated[24] for various rates of heating.

Dal Nogare and Langlois[18] and Giddings[19] have attempted to calculate the velocity of the peak due to a component by means of the refined formula (11) for the retention volume, with the coefficient A evaluated as a function of the column parameters. The formulae obtained were extremely complicated. In particular, the linear relation between retention time and number of carbon atoms in molecules of a homologous series was shown only by numerical integration on a computer[18]. In order to obtain retention times or temperatures in these papers, the chief constants had to be determined empirically from isothermal chromatographic data, as in other papers[17,20,22]. A detailed account of this work[18,19] has been given in a review by Vigdergauz and Gol'bert[25]. Therefore we shall not discuss it further, especially as application of the simple formula (11) has been shown by several workers to yield good results.

Another paper by Rowan[26] mentions a method for determining the elution temperature of a component when the pressure remains constant at the outlet and the inlet of the column. The speed of the carrier gas then varies according to the law

$$u=\frac{M}{T}+N \qquad (20)$$

where M and N are constants. This paper contains tables and graphs for calculating the retention temperature T_R. In programmed-temperature gas chromatography, however, a constant flow of the carrier gas is usually established, not a constant pressure. It is not necessary, therefore, to discuss the paper[26] in detail.

3. THE EQUIVALENT TEMPERATURE

The so-called equivalent temperature T_r —the constant temperature at which a peak is eluted in the same time as with the programmed temperature—is of considerable interest. It obviously lies between the limits $T_0<T_r<T_R$. The concept of "equivalent temperature" was introduced by Giddings[27,28].

The time t for elution of a peak at a constant temperature T_r is

$$t=\frac{V_{T_r}}{u} \qquad (21)$$

where V_{T_r} is the retention volume at this temperature. On the other hand, the elution time of a peak with a programmed temperature is

$$t=\frac{T_R-T_0}{r}. \qquad (22)$$

Equating (21) and (22), we obtain

$$r=\frac{u(T_R-T_0)}{V_{T_r}}. \qquad (23)$$

Substitution for r in Eqn. (9), with the speed of the carrier gas assumed constant, yields the equation

$$\int_{T_0}^{T_R}\frac{dT}{V_R}=\frac{T_R-T_0}{V_{T_r}}, \qquad (24)$$

which relates T_R with T_r, since V_{T_r} depends on the latter temperature.

To find the approximate dependence of T_r on T_R we shall neglect the retention volume of the gas peak, i.e. assume that $V_R\simeq V_R'$ and $V_{T_r}\simeq V_{T_r}'$. On then differentiating both sides of Eqn. (24) with respect to T_R, and making certain straightforward rearrangements, we obtain the differential equation

$$\exp\left\{-\frac{\Delta H}{R_0T_R}\left(1-\frac{T_R}{T_r}\right)\right\}=(T_R-T_0)\frac{\Delta H}{R_0T_r^2}\frac{dT_r}{dT_R}+1. \qquad (25)$$

An approximate solution of this equation with $T_0\simeq 300°K$ is

$$T_r\simeq\frac{T_R}{1+0.85\frac{R_0T_R}{\Delta H}}. \qquad (26)$$

With temperature programming the peak usually appears at $T_R\simeq T_k$, the boiling point of the component[29]. The value of the universal gas constant is $R_0\simeq 2$ cal deg^{-1}

mole^{-1}, and we also have the approximate value $\Delta H/T_k \simeq$ 23 cal deg^{-1} mole^{-1}. On the assumption that the boiling point of the component is $T_k \simeq 500°K$, we obtain

$$T_r \simeq 0.9T_R \tag{27}$$

whence

$$T_R \simeq T_r + 50. \tag{28}$$

The mean speed of a sample in a column with temperature programming approximately equals the speed of the sample at a constant temperature 50 deg lower than the temperature at which the peak appears with temperature programming.

4. SHARPNESS OF SEPARATION (RESOLUTION) OF COMPONENTS

The quality of the separation of two neighbouring peaks is usually represented by the expression

$$R = \frac{2(t_{R_2} - t_{R_1})}{W_1 + W_2} \tag{29}$$

where W_1 and W_2 are the widths of the peaks at the base, expressed in terms of time, while t_{R_2} and t_{R_1} are the retention times of the two peaks[22]. The formula (29) is used both in isothermal chromatography and with a programmed temperature. In the case of linear programming we have

$$t_{R_2} - t_{R_1} = \frac{T_{R_2} - T_{R_1}}{r}. \tag{30}$$

According to Habgood and Harris[17] the retention volume V_{T_γ} for a peak at a constant temperature T_γ and the peak width ΔV (retention volume of the peak) with a programmed temperature are linked by the relation

$$n = 16\left(\frac{V_{T_r}}{\Delta V}\right)^2, \tag{31}$$

in which n is the number of theoretical plates in the column, which defines its separating power[30]. The equivalent temperature defined by Eqn. (26) is to be taken[29] as T_γ, not the elution temperature T_R of the peak with temperature programming.

With high rates of heating, when $T_R \gg T_0$, the peak widths remain practically constant at the programmed temperature. It has been shown[31] that the width of a peak is independent of the "previous history" of the warming up of the column.

Since

$$W_1 + W_2 = \frac{\Delta V_1 + \Delta V_2}{F} \tag{32}$$

we obtain from Eqn. (31) the formula†

$$W_1 + W_2 = \frac{4}{F\sqrt{n}}(V_{T_{r_1}} + V_{T_{r_2}}). \tag{33}$$

It is assumed here that the column has the same separating power for the two components.

It follows from Eqns. (29), (30), and (33) that

$$R = 2\frac{F}{r}\frac{T_{R_2} - T_{R_1}}{V_{T_{r_1}} + V_{T_{r_2}}} = R_i\frac{\sqrt{n}}{4}. \tag{34}$$

† Here and subsequently we are dealing with specific retention volumes, i.e. volumes per unit mass of the liquid phase.

The quantity R_i is termed the intrinsic resolution. It is that part of the resolution which is independent of the separating power of the column and is determined by the thermodynamic properties of the components. In most cases R_i is a maximum at values of r/F lying within the range 0.001–0.1 g deg cm^{-3}.[32,33]

Experiment shows[15] that the intrinsic resolution R_i varies very little with F if the ratio r/F is maintained constant. This is not consistent with theoretical views, most likely because an isothermal retention volume is substituted in Eqn. (31). It is interesting that in general the intrinsic resolution varies little with r/F.

If we increase the column length L, while leaving the ratio r/F constant, the retention temperature remains unchanged. The resolution, however, increases as $L^{\frac{1}{2}}$, because $n^{\frac{1}{2}} \propto L^{\frac{1}{2}}$. When the input pressure far exceeds the output pressure, the former must be increased as $L^{\frac{1}{2}}$ for the ratio r/F to remain constant when the speed of the carrier gas is unchanged, while r should decrease as $L^{-\frac{3}{2}}$.[22] Consequently the emergence time of the peak (22) increases with $L^{\frac{3}{2}}$ under the above conditions, as in isothermal chromatography.

Since the intrinsic separation is almost independent of F for identical values of the ratio r/F, it is advisable to operate with values of F for which R_i is a maximum with the given r.

The effect of r on the retention time resembles the effect of temperature in isothermal chromatography. The time for elution of the peak decreases with increase in r, approaching a limiting value. Correspondingly, the resolution diminishes somewhat with increase in r, as is immediately evident from the formula (34).

The number of theoretical plates defined by Eqn. (31) may differ markedly from the corresponding number for a constant temperature. Attempts[17,34] to calculate the number of theoretical plates as a function of the column parameters with temperature programming did not yield results showing good agreement with experiment.

It is found experimentally that, with a programmed temperature, the number of theoretical plates varies with r at a fixed rate of flow, diminishing with increase in r. In the case of temperature programming the resolving power is more difficult to predict than in an isothermal process, where it is proportional to $n^{\frac{1}{2}}$. The resolution of components varies both with the number of plates and with R_i, which depends on r/F.

In conclusion it must be emphasised that experiment shows[22] that the resolution which can be achieved with temperature programming is almost the same as, and sometimes even better than, in isothermal chromatography. If, however, the time available for the analysis has been specified, programming the temperature ensures a sharper separation than does the isothermal process, as Zhukhovitskii and Turkel'taub have shown (Ref. 7, p. 150). Furthermore, the enrichment of the components of the mixture, which is associated with the narrowing of the chromatographic peaks in temperature programming, enhances the sensitivity of the instrument, which is extremely important in the analysis of microsamples[31].

5. RETENTION INDEX

The retention index was introduced by Kováts[35,36] as a measure of the retention of a component which would vary

little with the operating conditions of a separating column or its packing. Consequently the retention index can conveniently be used for the identification of the components of a complicated mixture.

In the case of isothermal chromatography the introduction of the retention index is based on a linear variation in the logarithm of the retention volume V_R' with the number of carbon atoms in unbranched-chain hydrocarbons. The retention index varies very slightly—and linearly—with temperature.

In the case of a programmed temperature, introduction of the retention index is based on an approximately linear dependence of the retention temperature on the number of carbon atoms. The retention index is then by definition

$$I = 100\,\frac{T_R(x) - T_R(z)}{T_R(z+1) - T_R(z)} + 100\,z \qquad (35)$$

where $T_R(x)$, $T_R(z)$, and $T_R(z+1)$ are the retention temperatures of the test compound and of hydrocarbon components containing z and $z+1$ carbon atoms. If the relation between the retention temperature and the number of carbon atoms in the molecules were strictly linear, the retention index would simply equal the number of carbon atoms multiplied by 100. Since, however, this relation will not be exactly linear, the index will not coincide with this product, although in several cases it will be close to the latter. The formula (35) for the retention index is convenient, as it can be evaluated directly from a chromatogram without any preliminary calculations.

The retention index (35) is usually equal to the index for the isothermal process conducted at the equivalent temperature[37].

It is significant that, as experiment shows with a programmed temperature, the retention index varies little over quite a wide range—variation in the initial temperature T_0 and in the rate r of rise in temperature—of operating conditions. If, therefore, a component has once been reliably identified, and its retention index is known, unknown components in a complicated mixture can be identified by measuring their retention indices by means of the chromatogram. A detailed examination has been made[38] of the temperature dependence of the retention index both with temperature programming and in isothermal chromatography.

It is difficult to use the retention temperature T_R directly for purposes of identification, since Eqn. (9) cannot be solved explicitly for constant ΔH, which characterises the component. Values of T_R, however, vary markedly with the operating conditions of the chromatographic column.

6. NON-LINEAR TEMPERATURE PROGRAMMING

The application of linear temperature programming, which has been discussed in the preceding paragraphs, involves certain difficulties. The chief of these is the impossibility of obtaining the retention time (or, what amounts to the same, the retention temperature) in a simple analytical form[8]. Recourse must be had either to numerical integration or even to the use of tables of special functions. Further, the coefficient r, representing the rate of change of temperature, cannot, for technical reasons, be varied continuously. Consequently, in order to obtain different rates of change of temperature, a set of programmes must be used.

These disadvantages (mainly the first) can be eliminated by using a special type of non-linear programme[39]. By this means it is possible to obtain practically the same results as with the linear programme, but with a simple analytical expression for the elution time of various components of the mixture. Furthermore, the choice of different initial points on the programme is roughly equivalent to varying the rate of temperature rise in a linear programme.

If the temperature of the column varies with time according to the law

$$T = \frac{T_0}{1 - \beta t} \qquad (36)$$

where β is a constant defining the rate of temperature rise, we obtain from Eqns. (14) and (11) for the retention time t_R the simple expression

$$e^{\varepsilon t_R} = \varepsilon t_{0R} + e^{\varepsilon t_a} \qquad (37)$$

in which

$$\varepsilon = \frac{\Delta H \beta}{R_0 T_0} \qquad (38)$$

and

$$t_{0R} = \frac{A}{u}\, e^{\frac{\Delta H}{R_0 T_0}} \qquad (39)$$

is the retention time of the peak on chromatographing at a constant temperature. If the elution time t_a of the carrier-gas peak is short, taking logarithms in Eqn. (37) yields the following simple formula for the retention time

$$t_R = \frac{1}{\varepsilon} \ln(\varepsilon t_{0R} + 1). \qquad (40)$$

From Eqn. (40) it is easy to show that the condition of equal distances on the chromatogram between peaks due to successive members of a homologous series is approximately satisfied with the temperature programme (36), provided that the number of carbon atoms in the molecules is sufficiently large. This conclusion is supported by experiment. Retention times measured experimentally for normal alkanes agree well with Eqn. (40).

The above non-linear programme (36) is equivalent to a series of successive linear programmes having increasing values of r. But, since the resolution R is only slightly dependent on r, the resolution obtained with the non-linear programme will differ little from that obtained with a linear programme having $r \simeq \beta T_0$. Of course, the peaks due to heavy components will be rather less well resolved, since they appear at high effective values of r.

With non-linear programming it is possible to introduce a retention index just as with linear programming, but the retention temperature must be replaced by the retention time, since it is the latter which depends approximately linearly on the number of carbon atoms. The retention index can be defined

$$I = 100\,\frac{t_R(x) - t_R(z)}{t_R(z+1) - t_R(z)} + 100\,z \qquad (41)$$

where $t_R(x)$, $t_R(z)$, and $t_R(z+1)$ are the retention times of the test compound and of hydrocarbon components containing z and $z+1$ carbon atoms.

Nevertheless, the relation between the retention time and the parameter ϵ characterising the component is so simple that components can be identified directly from the retention time by means of Eqn. (40).

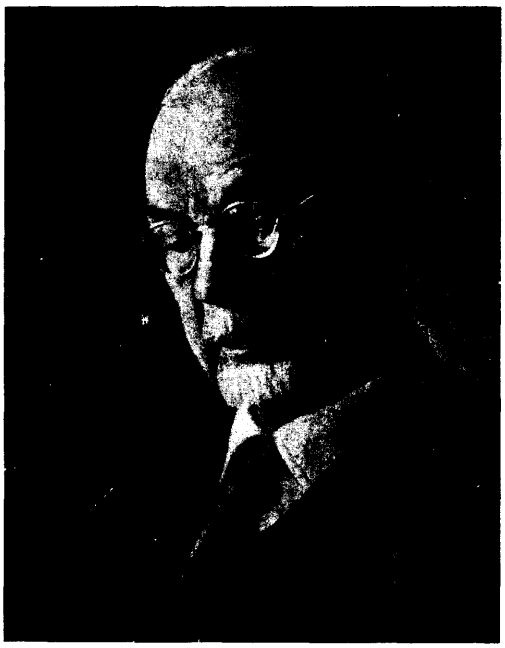
However, it is not always easy to carry out the isothermal experiment (e.g. with mixtures having a wide range of boiling points). A new method was therefore proposed for determining heats of dissolution ΔH and identifying components, based on the use of two non-linear programmes of the type (36) with different rates of temperature rise[40].

If two chromatograms are obtained with rates of temperature rise defined by the parameters β and $\beta' = \alpha\beta$ (where α is a number), the isothermal retention time t_{0R} of the component can be eliminated, and two equations of the type (40) used to obtain the simple expression

$$e^{\epsilon t_R} = \frac{1}{\alpha} e^{\alpha\epsilon t'_R} + e^{\epsilon t_a} - \frac{1}{\alpha} e^{\alpha\epsilon t'_a} \qquad (42)$$

for determining ϵ and hence ΔH, where t_R and t'_R are the retention times of the component for the different programmes, and t_a and t'_a those of the gas peak. It is easy to evaluate ϵ by the graphical solution of Eqn. (42).

Good results have been obtained in a test of this method of determining heats of dissolution using a mixture of primary alcohols, methyl ketones, and hydrocarbons. The heats of dissolution fitted satisfactorily on straight lines representing the homologous series, which permitted reliable identification of the components.



This method of identifying components has the advantage, in comparison with the method based on the retention index, that it does not in principle require a linear dependence of retention temperature on number of carbon atoms. Furthermore, from it an important physical quantity—the heat of dissolution—can be determined.

RUSSIAN CHEMICAL REVIEWS
Uspekhi Khimii

September 1967

ALEKSANDR ERMININGEL'DOVICH ARBUZOV

Dear Aleksandr Erminingel'dovich!

The Editorial Board of the journal "Uspekhi Khimii" convey to You their heartfelt greetings on the occasion of Your ninetieth birthday and the completion of 65 years of scientific, pedagogical, and public activity.

You are one of the eminent organic chemists of our country, a worthy continuer of the tradition of the great Russian chemists—Zinin, Butlerov, Markovnikov. Your remarkable investigations in the field of theoretical and synthetic organic chemistry and especially the chemistry of organophosphorus compounds have received worldwide recognition. You have created in Kazan' one of the largest schools for studying the chemistry of organophosphorus compounds.

We wish You, dear Aleksandr Erminingel'dovich, good health for many years and new creative successes.

The Editorial Board of the journal "Uspekhi Khimii"

U. D. C. 547.241

DEVELOPMENT OF THE CHEMISTRY OF ORGANOPHOSPHORUS COMPOUNDS IN THE WORK OF THE KAZAN' SCHOOL OF ORGANOPHOSPHORUS CHEMISTS†

A. N. Pudovik and I. M. Aladzheva

Organophosphorus compounds occupy an important place among the various types of organoelemental compounds in which chemists are now interested. Whilst being extremely interesting theoretically, organophosphorus compounds are also of considerable practical interest. They have found wide application in the various regions of

† Difficulties with nomenclature have arisen in the translation, particularly in the use of the terms phosphinic/phosphonic and phosphinous/phosphonous. These pairs of terms are sometimes used synonymously in the Russian: "phosphonic" can mean phosphinic, phosphonic, or even phosphinic and/or phosphonic. Adjustments have been made where possible to bring the nomenclature in line with current Western practice (Ed. of Translation).

the national economy as pharmaceutical preparations, insecticides and fungicides, plasticisers and stabilisers, surface-active compounds, extractants, catalysts, monomers for the preparation of organo phosphorus fire-resistant polymeric materials, lubricating oil additives, and additives conferring flame-resistance on fabrics, synthetic resins, etc.

The great practical possibilities led to the rapid development of the chemistry of organophosphorus compounds in the last two decades. A large number of new organic derivatives of phosphorus was obtained with the aid of known or new synthetic methods, the problems of the reactivity of the various classes of organo phosphorus compounds were widely studied, and interesting results were obtained appertaining to the structure of these compounds and the mechanism of their reactions.

The Kazan' school of organophosphorus chemists, created and already headed for over half a century by Aleksandr Ermingel'dovich Arbuzov, has played an important part in the development of the chemistry of organophosphorus compounds. In the present review we did not aim at describing all the investigations carried out by the Kazan' chemists in the field of organophosphorus compounds (these studies number more than 700), but have tried to trace the development of the principal scientific directions of the Kazan' school, touching on the study of the conversions of esters and some other derivatives of phosphorus(III) into phosphorus(V) compounds, the addition of organophosphorus compounds with a labile hydrogen atom to compounds with multiple bonds, investigations of the fine structure of organophosphorus compounds by physical and physicochemical methods, the preparation of phosphorus-containing insecticides and physiologically active compounds, the production of phosphorus-containing monomers and polymers based upon them. To give a more complete picture of the contemporary state of these fields of organophosphorus chemistry we also mention some of the most important and interesting investigations carried out outside the Kazan' school by Soviet and foreign scientists.

In 1903–05 A. E. Arbuzov, who was studying the structure of phosphorous acid and its organic derivatives, first isolated in a pure form the neutral esters of phosphorous acid and demonstrated the possibility of converting them into the corresponding esters of alkylphosphonic acids by the action of alkyl halides[1]. This remarkable reaction, which received the name of the Arbuzov rearrangement, subsequently became an important method of synthesising various esters of phosphonic acids and oxides of tertiary phosphines; it was studied in detail by A. E. Arbuzov and his students and by several other investigators. A. E. Arbuzov regarded the rearrangement of phosphite esters under the action of alkyl halides as a two-stage process. In the first stage an unstable product is formed, which then decomposes with the liberation of an alkyl halide and the ester of an alkylphosphonic acid:

$$(RO)_3P + R'X \rightarrow (RO)_3P\begin{matrix}R'\\X\end{matrix} \longrightarrow (RO)_2\overset{O}{\overset{\|}{P}}R' + RX.$$

It was shown later[2] that in addition to esters of phosphorous acid the esters of phenylphosphonous and diphenylphosphinous acids are capable of undergoing the reaction. The rate of isomerisation is considerably increased as alkoxyl groups in the phosphite ester are replaced by phenyl radicals. The rate of isomerisation of the phosphite esters falls in the order: $CH_3O > C_2H_5O > C_3H_7O >$ iso-C_4H_9O.

The Arbuzov rearrangement proceeds most readily with alkyl iodides and least well with alkyl chlorides.

The above studies, which were described in A. E. Arbuzov's Master's and Doctoral Theses formed the basis for a further extension of the investigations into the field of the rearrangement of esters of phosphorus(III) acids into phosphorus(V) compounds. One of the interesting and important problems is the effect of the structure of the phosphorus-containing components and of the alkyl halide on the rate and nature of the Arbuzov reactions that take place.

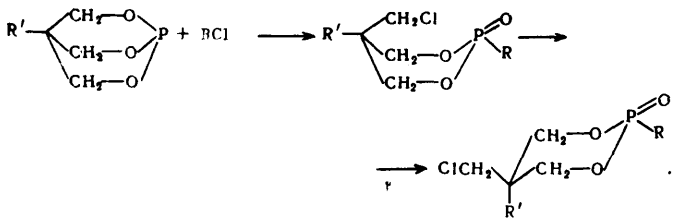
The success of B. A. Arbuzov and Rizpolozhenskii[3] and of Razumov[4] in synthesising esters of alkylphosphonous and dialkylphosphinous acids allowed their rearrangement into the corresponding esters of dialkylphosphinic acids and oxides of tertiary phosphines to be studied. The considerable increase in the rate of rearrangement on replacing an alkoxy-group by alkyl can be explained in terms of the positive inductive effect of alkyl groups[4].

A. E. Arbuzov was the first to describe the rearrangement of thioesters of phosphorus(III) acids, with the example of the thioesters of diphenylphosphinous acid:

$$PSR + R'Hal \longrightarrow P\begin{matrix}S\\R'\end{matrix} + RHal,$$

which is partly complicated by the formation of side-products[2,5,6]. With thiophosphites, substitution occurs instead of the Arbuzov rearrangement. The rearrangement of amido-esters of phosphorous acid [phosphoramidite esters] has been effected[7]:

$$RO\!\!>\!\!PNR'_2 + R''Hal \longrightarrow \left[RO\!\!>\!\!\overset{+}{P}\!\!<\!\!\begin{matrix}NR'_2\\R''\end{matrix}\right]Hal^- \longrightarrow RO\!\!>\!\!\overset{O}{P}\!\!<\!\!\begin{matrix}R''\\NR'_2\end{matrix} + RHal.$$



Interesting substances for studying the Arbuzov reaction were the cyclic esters of phosphorous acid, synthesised by A. E. Arbuzov, Rizpolozhenskii, Zoroastrova, and Razumova. The structure of the final products of the rearrangement depend on the size of the ring and the number and nature of the substituents in it[5,8]. Ethyleneglycol hydrogen phosphite and propylene glycol hydrogen phosphite, which contain five-membered rings, undergo the Arbuzov rearrangement with ring opening. The alicyclic product of the rearrangement can be cyclised by further heating:

$$R{-}CHO\!\!>\!\!POR' + R''Hal \rightarrow HalCH_2CHROP\begin{matrix}OR'\\\|O\\R''\end{matrix} \longrightarrow R{-}CHO\!\!>\!\!P\begin{matrix}R''\\\|O\end{matrix} + R'Hal.$$

Tetramethylethylene glycol hydrogen phosphite and methoxymethylethylene glycol hydrogen phosphite and esters with six-membered rings rearrange without rupture of the ring. These results have been confirmed by thermographic studies[9].

The rearrangement of hydrogen phosphite esters of pyrocatechol and of salicylic acid[10] and of spiro-diphosphites[11] under the action of alkyl halides takes place with retention of the cyclic structure. For bicyclic phosphites the Arbuzov reaction takes place with breaking of the ring

and replacement of the boat conformation by the energetically more stable chair conformation.

The Arbuzov rearrangement has been studied for diphosphites, esters of pyrophosphorous acid, and mixed anhydrides of phosphorous and carboxylic acids. In the last instance the reaction leads mainly to esters of ketophosphonic acids[12]:

$$(RO)_2POCOCH_3 + R'Hal \rightarrow (RO)_2P(O)R' + CH_3COHal$$

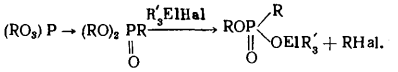
$$(RO)_2POCOCH_3 + CH_3COHal \rightarrow (RO)_2P(O)COCH_3 + CH_3COHal.$$

Kamai, Kuznetsov, and Valetdinov found that cyano-substituted esters of phosphorous acid do not undergo the Arbuzov rearrangement[13]. This is evidently because of the considerable negative inductive effect of the cyano-group, which lowers the electron density at the phosphorus(III) atom. Abramov and Khairullin[14] showed that the Arbuzov rearrangement proceeds normally for several mixed esters with one or two tertiary chloro-substituted radicals.

Study of the influence of the structure of the halogeno-derivatives on the course of the Arbuzov reaction showed that in addition to primary alkyl halides the rearrangement proceeds normally with primary arylalkyl halides, triarylmethyl halides, and acetylenic derivatives with a halogen atom at the triple bond[7]. As a result of the reaction of neutral esters of phosphorous acid with primary halides containing various heterocyclic radicals, B. A. Arbuzov and coworkers obtained esters of phosphorous acids with an α-oxide ring, thiazole, isoxazole, quinoxazole, furyl, phenthiazine, and various other radicals[15].

With secondary alkyl halides the rearrangement is more difficult and is often accompanied by the formation of alkenes. As Pudovik showed, the reaction of secondary halogenoallyl compounds and tertiary halogenoacetylenic compounds with phosphites is accompanied by allyl or acetylene–allyl rearrangement[16]:

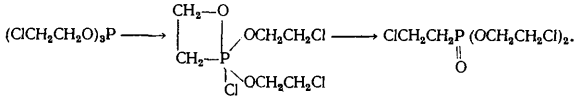
$$R'CHHal{-}CH{=}CH_2 + (RO)_3P \rightarrow R'CH{=}CH{-}CH_2P(O)(OR)_2 + RHal$$



$$(CH_3)_2CCl{-}C{\equiv}CH + (RO)_3P \rightarrow (CH_3)_2C{=}C{=}CH{-}P(O)(OR)_2 + RCl.$$

When esters of phosphorous acid react with dihalogeno-derivatives with the halogens at primary carbon atoms either one or both halogen atoms react, depending on the conditions. With halogeno-derivatives having the halogens at secondary or tertiary carbon atoms as well as primary, molecules of hydrogen halide or halogen are lost and unsaturated compounds are formed[8].

In 1945 Kamai and Egorova observed that trialkyl phosphites readily undergo the Arbuzov rearrangement with carbon tetrachloride to form esters of trichloromethylphosphonic acid. Subsequently[17] this reaction was extended to a series of other alkyl esters of phosphorous, pyrophosphorous, and phosphinic acids.



Derivatives of phosphonic acids are obtained by the Arbuzov rearrangement when various functional groups are present in the molecule of the halogen-containing compound. A. E. Arbuzov and Dunina obtained esters of phosphonocarboxylic acids by the reaction of phosphites and esters of α-halogenocarboxylic acids. With α-halogeno-substituted ethers and acetals, alkoxy- and dialkoxy-alkylphosphonates are formed; with acyl halides, the esters of ketophosphonic acids[8].

The Arbuzov rearrangement with alkylsilicon and alkyltin halides, first studied by B. A. Arbuzov, Pudovik, and Grechkin, proceeds anomalously and leads to the formation of compounds with a P–O–El bond. Malatesta[182] proposed a reaction mechanism including in the first stage the preliminary isomerisation of the phosphite esters into the corresponding esters of alkylphosphonic acids, which then react with the silicon and tin halides:

Later Pudovik and Muratova[18] confirmed and developed the Malatesta scheme, by showing that esters of phosphorus(III) acids are capable of forming unstable intermediate complexes with alkyltin and alkylsilicon halides; under mild conditions there is a rearrangement of these phosphite and phosphonite esters into phosphinate esters and tertiary phosphine oxides. These authors also studied in detail the reaction of alkylphosphonate esters with various halogen-containing compounds.

An anomalous course of the Arbuzov rearrangement was observed by B. A. Arbuzov and coworkers for α-bromonitrohydrocarbons, nitrosyl chloride, cyanogen chloride, dibenzoylbromomethane, tribenzoylbromomethane, and the halogeno-derivatives of some β-disulphones[15]. Phosphite esters with halogen atoms in the ester radicals at the α- or β-carbon atom were shown by Kabachnik and Rossiiskaya to undergo intramolecular isomerisation when heated or distilled[8]:

It was found subsequently that γ-, δ-, and ϵ-halogen-substituted phosphites isomerise in a similar manner. Pudovik and Faizullin synthesised a large number of β-chloro-substituted esters of phosphorus acids by the addition of acid chlorides of phosphorus(III) and phosphorus(V) acids to unsymmetrical α-oxides of alkenes[19]. It has been shown that all these reactions take place with participation of hydrogen chloride. The dependence of the order of breaking of the oxide ring on the structure of the original alkene oxide has been established. Nuretdinova[20] obtained a series of products of the addition of phosphorus(III) chloride and halogenophosphines to ethylene sulphide [thiairan] and propylene sulphide [1,2-epithiopropane].

The considerable experimental material which has accumulated in studying the Arbuzov rearrangement has allowed a more profound development of ideas on the mechanism of this interesting reaction. The two-stage scheme for the course of the reaction in the Arbuzov rearrangement, proposed by A. E. Arbuzov in 1905, was subsequently confirmed by him and by other investigators.

A. E. Arbuzov and Nesterov[21] obtained a whole series of new products of the addition of alkyl halides to triphenyl phosphite and studied their thermal decomposition. For a long time intermediate products of the rearrangement could not be isolated for aliphatic esters of phosphorus(III) acids. In 1954 Abramov and Karp[22] observed indirectly the formation of intermediate products in the reaction of trialkyl phosphites with various $\alpha\beta$-dihalogenoalkyl esters. Viscous non-crystalline substances were obtained, which on heating decomposed in accordance with the second stage of the Arbuzov reaction.

The formation of intermediate products was confirmed by the methods of physicochemical analysis[23] and by thermographic investigations[24], successfully applied by B. A. Arbuzov and coworkers to trialkyl phosphite–alkyl halide systems. For most of the reactions studied the thermograms had two exothermic effects, corresponding to the two stages of the rearrangement. Razumov and Bankovskaya[25] first succeeded in isolating in a pure state and studying the properties of the intermediate products of the Arbuzov rearrangement, which formed in the reaction of esters of diethylphosphinic acid with alkyl halides. The decomposition of the intermediate products takes place at room temperature or on slight heating:

$$(C_2H_5)_2POR + R'X \rightarrow (C_2H_5)_2\overset{R'}{\underset{X}{P}}{-}OR \rightarrow (C_2H_5)_2\overset{O}{\underset{R'}{P}} + RX.$$

On the basis of published data and the results of their own investigations, Razumov and Bankovskaya concluded that, depending on the nature of the phosphorus-containing components, the alkyl halide, and the solvent, the intermediate products can be a whole range of structures with various degrees of polarity—from ionic to covalent.

Important problems in studying the mechanism of the Arbuzov reaction are those concerning the nature of the first and second stages of the rearrangement and about the ratio of their rates. Kinetic investigations of the rearrangement, made by A. E. Arbusov and Nesterov[21], Zawidzki and Staronka[183], and Kosolapoff[184] showed that the process is complex. The reactions were usually carried out in the absence of a solvent, which brought about the appearance of an autocatalytic effect and complicated the interpretation of the results obtained[5]. Despite the absence of strict kinetic proofs the nature of the first stage of the Arbuzov rearrangement—the addition of alkyl halides to the esters of the phosphorus(III) acids—is not in dispute. Most authors regard it as a second-order S_N2 reaction. There are various views about the nature of the second stage of the rearrangement—the decomposition of the intermediate addition product. Gerrard and Green[185] consider it as an S_N2 reaction, on the basis of stereochemical investigations. Later the stereospecific S_N2 mechanism of the second stage of the rearrangement was supported and investigated by Berlin and coworkers[26]. Pudovik, in studying the rearrangement of phosphite esters containing unsymmetrical allyl radicals, concluded that the second stage of the rearrangement of trialkyl phosphites with primary saturated or unsaturated radicals is brought about on the basis of an S_N2 mechanism. With phosphites which contain secondary radicals the reaction proceeds by a mixed mechanism predominantly of the S_N1 type[27]. On the basis of a study of the kinetics of the decomposition of the addition products of alkyl halides to esters of diethylphosphinous acid, Razumov and Bankovskaya consider that the second stage of the Arbuzov reaction is a first-order unimolecular reaction[25]:

$$(C_2H_5)_2\overset{R'}{\underset{OR}{P}} \xrightarrow{\text{slow}} (C_2H_5)_2\overset{R'}{\underset{O}{P}} + R^+$$

$$R^+ + X^- \xrightarrow{\text{fast}} RX$$

Buck and Yoke[28] came to analogous conclusions in a conductimetric study of the reaction of tributyl phosphite with ethyl iodide in acetonitrile. Nesterov[29] later made some interesting investigations of the reactivity of quasi-phosphonium compounds.

Opinion is also divided over the relation between the rates of the first and second stages of the Arbuzov rearrangement. Buck and Yoke, and Razumov and Bankovskaya consider the second stage of the rearrangement to be the slower stage, which determines the rate of the overall reaction. According to the results of the Aksnes[30], who made a kinetic study of the reaction of ethyl iodide with several phosphites, phosphonites, and phosphinites [and triphenylphosphines] by quantitative infrared spectroscopy, the ethyl iodide concentration remains almost constant throughout the rearrangement. This suggests the absence of a significant accumulation of intermediate product indicating that the first stage of the Arbuzov rearrangement is rate-determining. Fainshtein and Gonikberg, who studied the reaction of triethyl phosphite with ethyl iodide at high pressures, also did not observe the accumulation of an intermediate product during the rearrangement[31].

The above mechanism of the Arbuzov rearrangement is evidently not the only one possible for all types of reaction[32]. As is well known, Rumpf earlier proposed an ion-chain mechanism for the Arbuzov rearrangement. To explain the reaction of phosphorus(III) esters with carbon tetrachloride, Kamai and Kharrasova introduced a radical-chain mechanism, which was subsequently confirmed experimentally by these authors and various other investigators[17]:

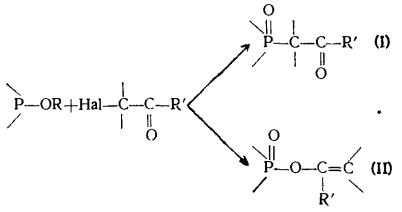
$$CCl_4 + h\nu \rightarrow \dot{C}Cl_3 + Cl^\cdot,$$

$$(RO)_3P + \dot{C}Cl_3 \rightarrow (RO)_3\dot{P}CCl_3 \xrightarrow{CCl_4} (RO)_3\overset{+}{P}CCl_3\overline{Cl} + \dot{C}Cl_3$$

$$\downarrow$$

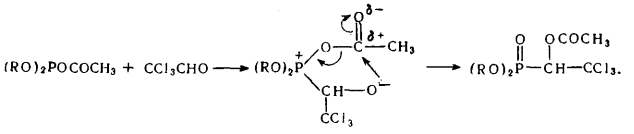
$$(RO)_2PCCl_3 + RCl$$

$$\parallel$$



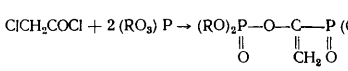
$$O$$

Recently Cadogan and Sharp[33] found that in the absence of ultraviolet radiation or radical initiators the reaction of triethylphosphite with carbon tetrachloride is apparently heterolytic.



In concluding the discussion of the mechanism of the Arbuzov rearrangement it should be noted that despite the considerable number of investigations that have been made, its mechanism is still not fully explained: further kinetic and stereochemical investigations are needed to obtain a more complete picture of the course of this interesting reaction.

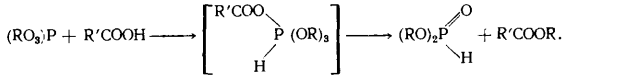
In recent years there has been great interest in studying the reactions of trialkyl phosphites with α-halogeno-carbonyl compounds. It was suggested initially that all reactions of this type proceed according to the scheme of the Arbuzov rearrangement with the formation of esters of keto- and aldehydo-phosphonic acids[32]. It was subsequently shown that although in several instances these products are actually formed to a certain extent, most of



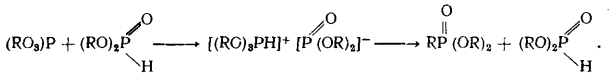
the reactions of trialkyl phosphites with α-halogenocarbonyl compounds proceed "anomalously" with the formation of unsaturated esters of phosphoric acid. Perkow[188] first stated the "anomalous" course of the reaction for α-halogenoaldehydes: it was proposed for α-halogenoketones somewhat later by one of us in Kazan'[34] and by the American chemists Allen and Johnson[187]:

Esters of phosphorus(III) acids react with α-halogenoaldehydes, usually with the formation of unsaturated esters of phosphoric acid (II). However, the reaction of mixed anhydrides of dialkyl phosphites and acetic acid with chloral proceeds without liberation of alkyl halide, with the formation of the acetates of the dialkyl esters of 2,2,2-trichloro-α-hydroxyethylphosphonic acids[35]:

With α-halogenoketones the formation of (I), (II), or mixtures of the two products depends on the structure of the α-halogenoketone, the number and nature of the halogen atoms, the reaction temperature, and the solvent. Pudovik has shown[36] that in the reactions of trialkyl phosphites with chloro-, bromo-, and iodo-acetones, and ω-chloro-, ω-bromo-, and ω-iodo-acetophenones, a mixture of (I) and (II) is formed, the relative amount of (II) rising in the series I < Br < Cl, and decreasing with increase in the reaction temperature. Going from primary to secondary α-halogenoketones leads to a relative increase in the concentration of unsaturated esters of phosphoric acid in the reaction products. As B. A. Arbuzov and coworkers showed[37], α-halogenoketones with the halogen atom at a tertiary carbon atom react with trialkyl phosphites exclusively with the formation of (II). The reaction of trialkyl phosphites with cyclic α-halogeno-ketones[36,38], with di- and tri-halogenocarbonyl compounds containing halogen atoms in the α position to the carbonyl group, with 2-halogeno-1,3-diketones, with α-chlorophosphonoacetone[36], and with esters of α-halogeno-β-keto-acids[34,36] also proceed analogously. Evidently the presence of electronegative groups at a carbon atom connected with a halogen causes a stronger polarisation of the molecule of the α-halogenocarbonyl compound and facilitates the formation of an unsaturated phosphate[32]. The reaction of α-halogenocarbonyl compounds with phosphonite esters usually proceeds in the same direction as with trialkyl phosphites[36,39,40]. As regards the acid chlorides of α-halogenocarboxylic acids, several authors have shown that both halogen atoms are involved in the reaction with a trialkyl phosphite[34]:

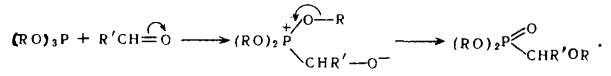


Reactions with α-halogenocarbonyl compounds have now been studied for an extremely wide circle of ester-amides of phosphorus(III) acids. As Abramov and Il'ina showed[41], the reaction of α-halogenoaldehydes and α-halogenoketones with the monoamides and diamides of phosphorous acid takes place preferentially with the formation of unsaturated esters of phosphoramidic and phosphorodiamidic acids.

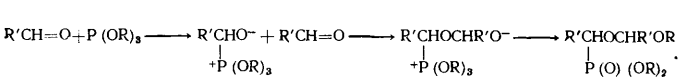


Several other scientists were concerned with studying the Perkov reaction and extending its field of use. A considerable number of investigations have been devoted to finding the mechanism of this interesting reaction. Theories have been developed about initial attack by the nucleophilic phosphorus atom of the trialkyl phosphite at the oxygen or carbon atom of the carbonyl group, halogen atom, or α-carbon atom[34].

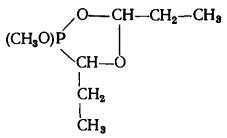
The numerous investigations of the Kazan' school of organophosphorus chemists and of a whole series of other Soviet and foreign scientists have shown that the esters of the phosphorus(III) acids readily react not only with organic halogen derivatives, but also with a wide circle of electrophilic reagents which do not contain a halogen atom. Reactions of this type are quite diverse and of great theoretical interest. In most instances they are considered as proceeding according to the Arbuzov rearrangement scheme[32].



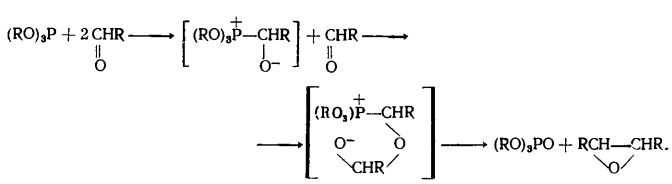
In 1951, A. E. Arbuzov and Alimov studied the reaction of some inorganic acids with trialkyl phosphites, leading to the formation of dialkyl hydrogen phosphites. Trialkyl phosphites react analogously with certain organic acids and their anhydrides[32]:



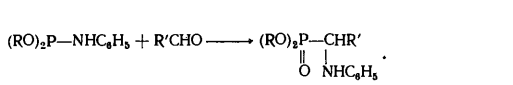
As Pudovik and Rakov showed recently[42], the reaction of trialkyl phosphites with acid esters of phosphorous and phosphonous acids leads to the formation of esters of phosphonic acids:



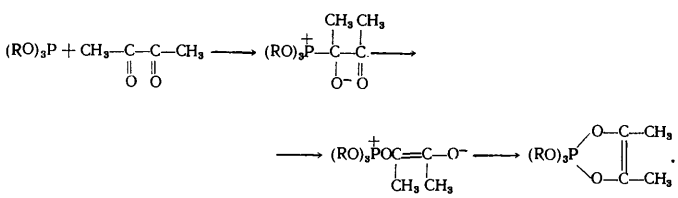
The reactions of α-ester-amides with triethyl phosphite leads, according to the results of Ivanov and coworkers, to the formation of esters of dialkylaminomethylphosphonic acids (in the presence of acetic or hydrochloric acids) or esters of alkoxymethylphosphonic acids (in the presence of ethyl iodide)[43]. Quite an interesting reaction is that of phosphites with carbonyl compounds. In 1954, when heating trialkyl phosphites with aldehydes Abramov isolated esters of α-alkoxyalkylphosphonic acids. The following scheme was proposed for this reaction[32]:



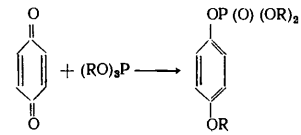
Alimov obtained similar results in studying the reaction of aldehydes with tetraethyl pyrophosphite and a diethyl acyl phosphite. Later Yakubovich and Ginsburg showed[44] that only aromatic aldehydes react with alkyl phosphites according to the Abramov scheme. Saturated aliphatic aldehydes form products of the addition of two molecules of aldehyde to one molecule of phosphite.



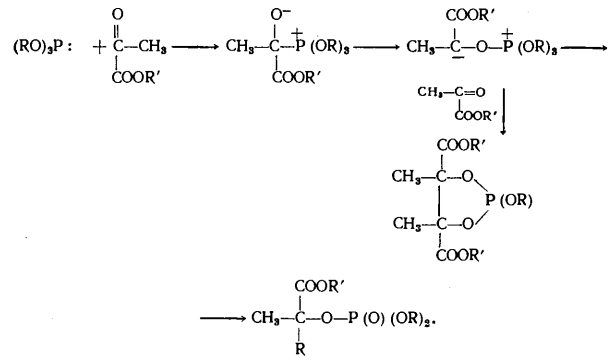
As Ramirez has shown[45], prolonged reaction of three moles of propionaldehyde with one mole of trimethyl phosphite at room temperature leads to a cyclic tetra-alkoxy-alkylphosphorane [sic; the compound shown is 2,5-dimethyl-4-methoxy-1,3,5-dioxaphospholan (Ed. of Translation)]:



On heating trialkyl phosphites with furfural and benaldehyde B. A. Arbuzov and Zoroastrova observed the oxidation of phosphites to phosphates and the formation of difurylethylene oxide and stilbene oxide respectively[7]:

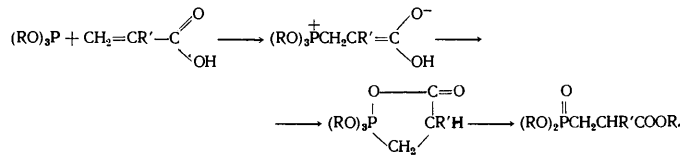


The alkene oxide which is formed in converted further by a second trialkyl phosphite molecule into the alkene. The reaction with triamidophosphites proceeds similarly[5]. Abramov and Il'ina assumed in studying the reactions of a series of *N*-phenylphosphoroamidites with aldehydes and ketones that they proceed by a scheme similar to that for trialkyl phosphites[41]. More detailed study of the structure of products formed in these and analogous reactions by Evdakov and coworkers[46], by Pudovik, and by Hudson and coworkers[47], showed that they are aminophosphinic esters [esters of aminoalkylphosphonic acids]:

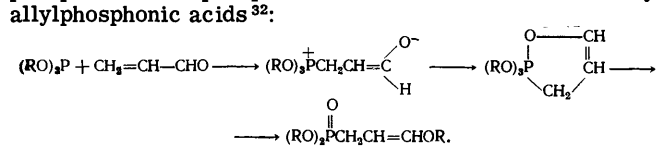


Ramirez and coworkers[45], Kukhtin and Kirillova[48,49], and Birum and Dever[188] studied the reaction of trialkyl phosphites with α-diketones. It was found[48,49] that the reaction of phosphites and phosphoroamidites with biacetyl at room temperature gives stable 1 : 1 addition compounds—the cyclic 1,3,2-dioxaphospholes:

By carrying out the reaction at a higher temperature, Kukhtin and coworkers isolated—in addition to the 1,3,2-dioxaphospholes—products which they regarded as α-alkoxy-β-keto-phosphonates. The reaction of trialkyl phosphites with 1,2-cyclohexadione proceeds in two directions, as for biacetyl[50]. In the reaction of phosphites with methylphenylglyoxal and *o*-quinones, Kukhtin and Kirillov obtained, irrespective of the reaction conditions, compounds with a 1,3,2-dioxaphosphole structure[51,52]. The addition of trialkyl phosphites to *p*-quinones takes place in the 1,6-position and leads to the formation of the corresponding phosphates[45]:

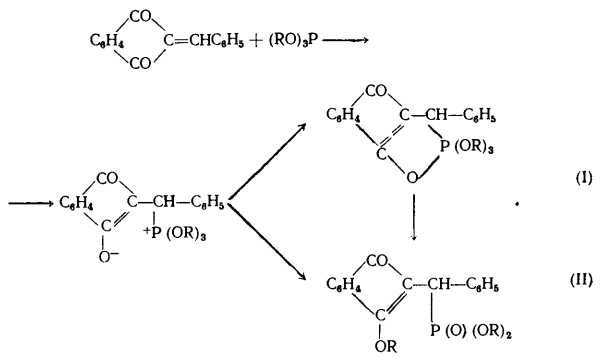


The reaction of esters of α-ketocarboxylic acids with trialkyl phosphites was studied by Pudovik and Konovalova and by Ramirez and coworkers. It was found[45,53] that under mild conditions (0–10°C) the phosphites react with two molecules of pyruvic ester to form the corresponding 1,3,2-dioxaphospholanes. At a higher temperature (80–100°C) in addition to the latter, dialkyl-α-alkyl-α-alkoxycarbonylethyl phosphates are formed, as Pudovik and Konovalova showed. They proposed the following reaction scheme:



In the reaction of trialkyl phosphites with ethyl mesoxalate only the corresponding dialkyl-$\alpha\alpha$-di(ethoxycarbonyl)-alkyl phosphates were isolated, irrespective of the reaction conditions[54].

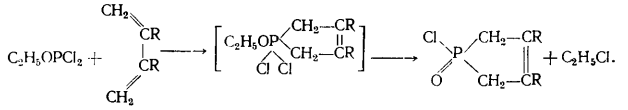
Kamai and Kukhtin investigated the reactions of esters of phosphorus(III) acids with $\alpha\beta$-unsaturated acids and aldehydes. It was shown[32] that trialkyl phosphites are readily added to $\alpha\beta$-unsaturated acids to form the esters of β-phosphonocarboxylic acids:



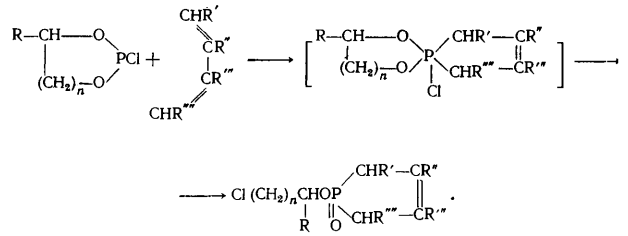
The intermediate cyclic products could not be isolated although several experimental facts show that they are formed. The reaction of trialkyl phosphites with alkynylcarboxylic acids leads to esters of β-phosphonocarboxylic acids[55]. With $\alpha\beta$-unsaturated aldehydes neutral esters of phosphorous and phosphonous acids form esters of alkoxyallylphosphonic acids[32]:

According to Ramirez' results, the reaction of $\alpha\beta$-unsaturated ketones is considerably affected by the structure of the original ketone and by the conditions[56]. B. A. Arbuzov and coworkers showed that the reaction of benzylideneindandione with trialkyl phosphites leads to the formation of either cyclic unsaturated phosphoranes [1,2-oxaphospholes (Ed. of Translation)] (I) or esters of the enolic

forms of indan-1,3-dion-2-ylbenzylphosphonic acids (II), depending on the temperature[57]:

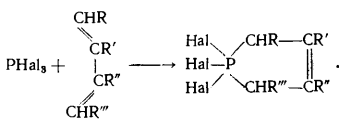


(I)

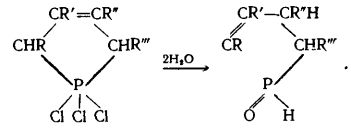


(II)

The reactions of acid chlorides of phosphorus(III) acids with diene hydrocarbons, $\alpha\beta$-unsaturated aldehydes, ketones, and acids, which have been widely studied in recent years, can also be considered as a variety of the Arbuzov rearrangement.

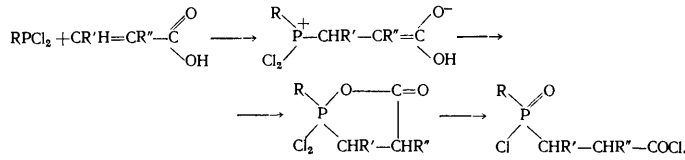


In 1953 a patent of McCormack reported the production of phosphorus-containing heterocyclic compounds in the reaction of diene hydrocarbons with aryl- and alkyl-dichlorophosphines. With the acid chlorides of esters of phosphorous acid, the 1,4-addition is accompanied by a simultaneous Arbuzov rearrangement, as B. A. Arbuzov and Shapshinskaya showed[7]:



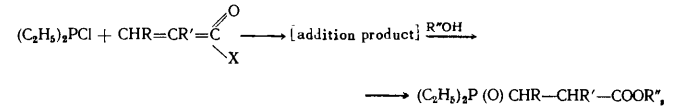
Similar reactions of this type were studied by B. A. Arbuzov and Shapshinskaya and by Petrov and Razumova using the acid chlorides of alkylene glycol esters of phosphorous acid and various diene hydrocarbons[58,59]. The reaction products are always five-membered heterocyclic compounds—derivatives of 1-oxa-1-phospha-3-cyclopentene:

B. A. Arbuzov and Vizel'[60] and Korte and coworkers[61] independently showed that trihalogeno-compounds of phosphorus are capable of adding to diene hydrocarbons to form derivatives of 1,1,1-trihalogeno-1-phosphacyclopent-3-ene. They were first isolated in a pure form by B. A. Arbuzov and Vizel':

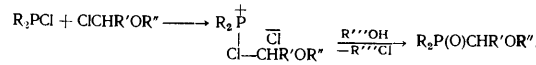


The reactions of derivatives of 1,1,1-trichloro-1-phosphacyclopent-3-ene are usually accompanied by migration of the double bond in the ring from the 3, 4 to the 2, 3 position:

1,1,1-tribromophosphacyclopent-3-enes have no tendency for migration of the double bond. Such unusual behaviour of the trihalogenophosphacyclopentenes allowed a large number of phosphacyclopentene derivatives with various locations of the double bond in the ring to be synthesised[62].

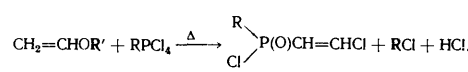


As Khairullin and Pudovik and their coworkers showed, the reaction of alkyl- and aryl-dichlorophosphines with $\alpha\beta$-unsaturated acids leads to the formation of the acid chlorides of alkyl- and aryl-(β-chloroformyl)alkylphosphinic acids[63]:



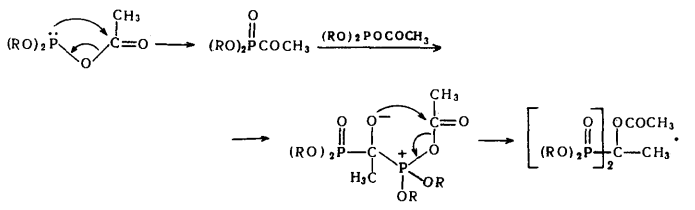
Nitriles of dialkylphosphinylcarboxylic acids were obtained by an analogous reaction with the amides of unsaturated acids:

$$R_2PCl + CH_2{=}CHCONH_2 \rightarrow R_2P(O)CH_2CH_2CN + HCl.$$



Kamai and Tsivunin studied the condensation of chlorodiethylphosphine with $\alpha\beta$-unsaturated acids and their acid chlorides. When the resulting addition products were treated with alcohol, esters of diethylphosphinylcarboxylic acids were obtained[64]:

where X = Cl or OH. The same authors investigated the reaction of secondary chlorophosphines with various halogen-containing organic compounds: α-halogeno-substituted ethers and sulphides, certain mono- and di-halogeno-derivatives of hydrocarbons, and α-halogenoaldehydes. The corresponding addition products are always formed: when these are decomposed with water, alcohols, or hydrogen sulphide, the oxides or sulphides of tertiary phosphines are liberated[65]:

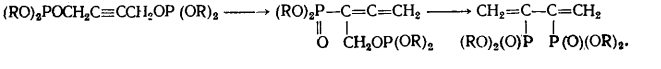


The reaction of various phosphorus(V) halides with vinyl ethers was also studied[66,67]. The thermal decomposition of the complexes of ethyl- and phenyl-tetrachlorophosphorus with vinyl ethers gave ethyl- or phenyl-β-chlorovinylphosphinic chloride:

To conclude the review of the investigations of the Kazan' school of organophosphorus chemists in the field of conversions of phosphorus(III) derivatives into phosphorus(V) compounds we will discuss the thermal rearrangements of unsaturated esters of phosphorous and phosphonous acids. Pudovik and Rakov showed[42] that neutral esters of phosphorous acid with saturated lower

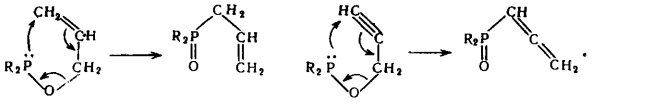
radicals are rather stable on heating, contrary to the results of Simon and Schulze[189]. Mixed anhydrides of phosphorous and acetic acid isomerise at elevated temperatures into ketophosphonate esters, which are subsequently converted into the acetates of methylbis(dialkyl phosphono)-carbinols[68]:

As A. E. Arbuzov and Nikonorov first showed[69], allyl and benzyl diphenylphosphinates readily undergo thermal rearrangement, with the formation of the corresponding phosphine oxides. Later the authors of the present review found that the rate of thermal isomerisation increases considerably on going from the allyl esters of phosphorous acid to the esters of phosphonous and especially phosphinous acids. When the allyl radical has a substituent at the α and γ carbon atoms, the rearrangement is accompanied by inversion of the unsaturated radical[70,71]:



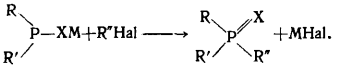
$$R_2POCHR'CH{=}CHR'' \xrightarrow{\Delta} R_2P(O)CHR''CH{=}CHR'.$$

The thermal isomerisation of the prop-2-ynyl esters of phosphorus(III) acids takes place especially readily at temperatures close to room temperature[70]. The products are esters of allenylphosphinic acids or allenylphosphine oxides, in many instances capable of undergoing a further prototropic conversion into prop-1-ynyl phosphonates and prop-1-ynylphosphine oxides, that is, an acetylene–allene–acetylene rearrangement takes place:



$$R_2POCH_2C{\equiv}CH \rightarrow R_2P(O)CH{=}C{=}CH_2 \rightarrow R_2P(O)C{\equiv}C{-}CH_3.$$

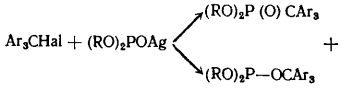
The American scientists Boisselle and Meinhardt[190] and Mark[191] observed the acetylene–allene rearrangement of esters of phosphorus(III) acids simultaneously with the authors of the present review, but isolated only esters of allenylphosphinic acids and allenylphosphine oxides.



Pudovik and Aladzheva carried out the acetylene–allene–diene rearrangement of tetra-alkylbutyn-1,4-diol diphosphites and obtained 2,3-bis(dialkylphosphono)buta-1,3-dienes[70,72]:

On the basis of the above investigations the authors concluded that the thermal isomerisations of $\beta\gamma$-unsaturated esters of phosphorus(III) acids are intramolecular S_Ni rearrangements, proceeding through a five-centre cyclic transition state:

In addition to the Arbuzov rearrangement, the most important method of preparing organophosphorus compounds is the Mikhaelis–Bekker reaction—the reaction of salts of phosphorous or phosphinous acids and their thioanalogues with various halogen derivatives:



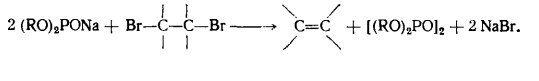
A large number of esters of phosphinic and thiophosphinic acids and their derivatives have been synthesised by this method[73]. Several studies in this direction were completed by the Kazan' organophosphorus chemists, but in their investigations they paid much attention to studying reactions which departed from the usual Mikhaelis–Bekker scheme. These investigations led to the discovery of new, interesting, and important reactions.

In 1929 A. E. and B. A. Arbuzov found[74] that in the reaction of sodium diethyl phosphite with bromotriphenylmethane the product is not diethyl triphenylmethylphosphonate (as for chlorotriphenylmethane) but the triphenyl free radical:

$$(C_2H_5O)_2PONa + (C_6H_5)_3CCl \rightarrow (C_6H_5)_3CP(O)(OC_2H_5)_2 + NaCl$$

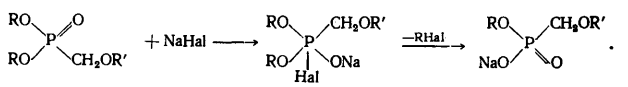
$$2(C_2H_5O)_2PONa + 2(C_6H_5)_3CBr \rightarrow 2(C_6H_5)_3C^{\cdot} + [(C_2H_5O)_2PO]_2 + 2NaBr.$$

This investigation led to the discovery of a new, quite simple, and elegant method of obtaining free radicals of the triarylmethyl series. A. E. Arbuzov and Valitova later showed what happens to the phosphorus-containing part of the reaction: ethyl hypophosphate was identified in the products[75]. Electron paramagnetic resonance was used recently to confirm the formation of free radicals in this reaction[76]. Free radicals were also obtained in the reaction of sodium diethyl phosphite with certain other triarylbromomethanes and in the reaction of lithium, potassium, rubidium, and caesium diethyl phosphites with bromotriphenylmethane[77]. The silver dialkyl phosphites are an exception; they react with the triarylhalogenomethanes to form triarylmethylphosphonates or mixed esters of phosphorous acid:



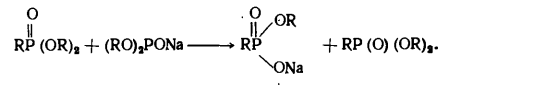
The halogenodiphenylmethanes react like the triarylhalogenomethanes with sodium diethyl phosphite[78]. Tetraphenylethane was isolated in the reaction of sodium diethyl phosphite with bromodiphenylmethane.

According to Pudovik and Tarasova, the reaction of triarylhalogenomethanes with the salts of ethylphosphonic acid or dialkyl hydrogen thiophosphites are much more complex than those with the salts of dialkyl hydrogen phosphites[79].



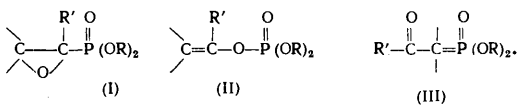
B. A. Arbuzov and Bogonostseva showed that in the reaction of sodium diethyl phosphite with dibenzoyl- and tribenzoyl-bromomethane, dibromobis(ethylsulphonyl)- and dichlorobis(ethylsulphonyl)-methane, the halogen derivatives are reduced to dibenzoyl- and tribenzoyl-methane and di(ethylsulphonyl)methane[80].

The reactions of salts of dialkyl hydrogen phosphites with 1,2-dihalogen derivatives—dibromostyrene, $\alpha\beta$-dibromopropionitrile, 9,10-dibromophenanthrene, tetramethylethylene dibromide, 1,2-dibromomethane, 1,2-dibromocyclohexane, and various other compounds[73,78,81]—proceeds by a similar scheme, with the formation of unsaturated compounds:

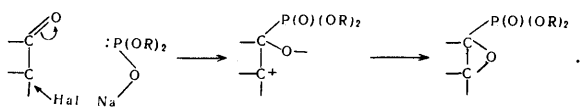


The reaction of salts of dialkyl hydrogen phosphites with α-halogeno-substituted ethers leads to esters of alkoxymethylphosphonic acids, according to the results of Abramov and coworkers[82]. It is interesting that in the distillation of the reaction mixture without separation of

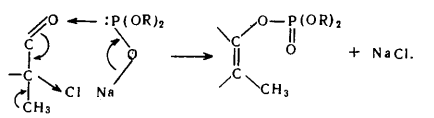
the precipitate of metal halide, ester-salts (not distilling) of an alkoxymethylphosphonic acid are obtained:



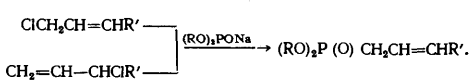
Petrov and coworkers explain the behaviour of ester-salts in these reactions by the alkylation of sodium dialkyl phosphite, formed in the first stage by the alkylphosphonates[83]:



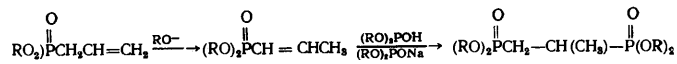
Pudovik and Tarasova showed recently that the formation of ester-salts is possible as the result of the isomerisation of sodium dialkyl phosphite in inert solvents at a temperature above 100°C.[84]



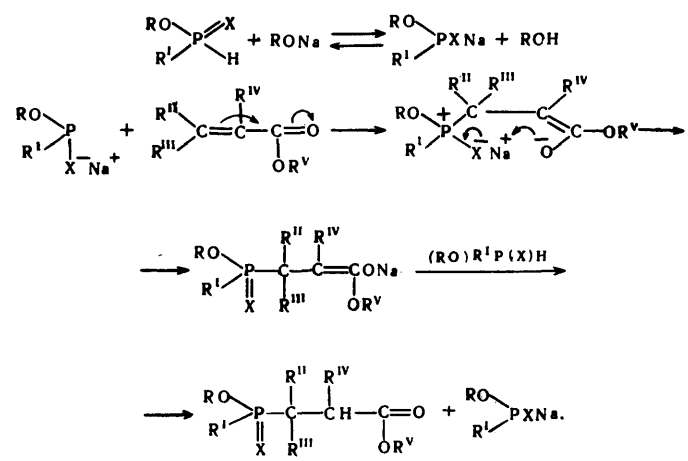
According to the results of B. A. Arbuzov and coworkers, reactions of sodium diethyl phosphite with α-halogenoketones takes place in a complex manner and, depending on the nature of the halogen, the reaction conditions, and the presence of substituents in the α-halogenoketone, lead to the formation of esters of epoxyphosphonic acids(I), unsaturated esters of phosphoric acid (II), or esters of β-ketophosphonic acids (III)[37,38,85]:



To explain the formation of (I), B. A. Arbuzov proposed a scheme including the initial addition of sodium diethyl phosphite at the carbonyl bond, with subsequent stabilisation of the bipolar ion formed:



(II) is formed by addition to the oxygen atom of the carboxyl group:



Interesting results were obtained by Pudovik in 1947 in studying the reactions of salts of dialkyl hydrogen phosphites and of thiophosphorous acids with α-halogenoallyl compounds[86,87]. In the reaction of sodium diethyl phosphite with allyl bromide, isomeric chlorobutenes, and chloro(methoxy)pentenes, esters of allyl- and substituted allyl-phosphonic acids were obtained. The reaction of secondary halogeno allyl compounds proceeds with an allyl rearrangement:

Subsequently, addition of sodium dialkyl phosphite takes place at the double bond of the unsaturated phosphonate esters formed in the first stage of the reaction and bis-(dialkyl phosphono)-derivatives are obtained:

The results obtained form a basis for a new method of synthesis of esters of phosphonic [and phosphinic] and thiophosphinic [and thiophosphonic] acids developed by Pudovik and consisting in the addition of acid esters of phosphorous, thiophosphorous, and phosphonous [and phosphinous] acids to unsaturated compounds of the electrophilic type. A large number of esters of phosphonocarboxylic, phosphonodicarboxylic, bisphosphonocarboxylic, and phosphonoketocarboxylic acids was obtained as a result of the addition of unsaturated esters of phosphorus acids to esters of monobasic and dibasic unsaturated carboxylic acids of the ethylene and acetylene series and to esters of unsaturated keto-acids[87-89]:

Acid esters of phosphorus acids react similarly with nitriles and amides of unsaturated acids[87,89]. The additions to αβ-unsaturated ketones usually take place at the carbon–carbon double bond with the formation of esters of ketophosphonic and ketothiophosphonic [and ketophosphonic and ketothiophosphinic] acids[87,89,90]. With acetylenic ketones the addition takes place primarily at the carbonyl group with formation of esters of acetylenic α-hydroxyphosphonic [and α-hydroxyphosphinic] acids[91]. Exceptionally, acid esters of phosphorus acids are added at the carbonyl group of unsaturated aldehydes containing ethylenic and acetylenic bonds[87,91]. With α-unsaturated nitro-compounds and sulphones the addition occurs at the carbon–carbon double bond[92].

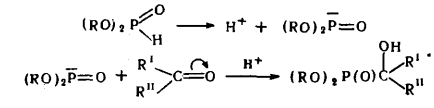
Pudovik found an important method of synthesising various derivatives of phosphonic and thiophosphonic acids—the addition of nucleophilic reagents to esters of unsaturated phosphonic acids. The simplest reaction of this type is "phosphonoethylation"—the addition of nucleophilic reagents to diethyl vinylphosphonate[87,93]:

where A = RO, RS, RNH, R_2N, $CH(CO_2C_2H_5)$, $(RO)_2PO$, $(RO)_2PS$, (RO)R'PO, etc. Pudovik and coworkers studied the addition of nucleophilic reagents to certain derivatives of vinylphosphonic esters: the esters of α- and β-cyano-vinylphosphonic acids[94], α- and β-alkoxycarbonylvinylphosphonic acids[88]. With the esters of β-alkoxycarbonyl- and β-cyano-vinylphosphonic acids the more electronegative

alkoxycarbonyl and nitrile groups determine the direction of the addition. Nucleophilic reagents add to esters of butadienylphosphonic and butadienylthiophosphonic acids in the 1,4 position[95]:

$$CH_2{=}CR{-}CH{=}CH{-}P(X)(OC_2H_5)_2 + AH \xrightarrow{RONa} ACH_2CR{=}CH{-}CH_2P(X)(OC_2H_5)_2$$

but to 2,3-bis(diethylphosphono)buta-1,3-diene in the 1,2 position[96]. In the esters of $\gamma\gamma$-dimethylallenylphosphonic acid the double bond in the $\alpha\beta$ position to the phosphono-group is the more active in nucleophilic addition[97]:

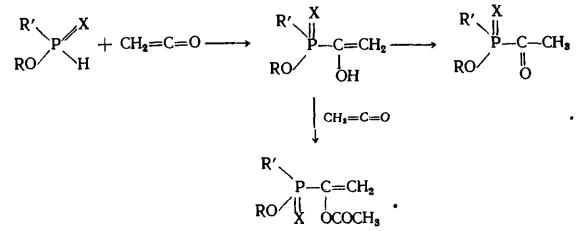


$$(CH_3)_2C{=}C{=}CH{-}P(O)(OR)_2 + HA \xrightarrow{RONa} (CH_3)_2C{=}CA{-}CH_2P(O)(OR)_2.$$

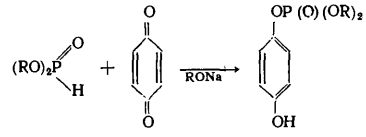
Depending on the ratio of the reactants in the reaction mixture, one or two molecules of nucleophilic reagent are added to esters of $\alpha\beta$-propynylphosphonic acid[98].

The addition of acid esters of phosphorus acids to unsaturated hydrocarbons of the ethylene and acetylene series, vinyl ethers, and halogenoalkenes does not take place under ionic catalysis conditions, according to Pudovik and Konovalova's results, but can be effected by a radical mechanism in the presence of peroxide compounds or by irradiating the reaction mixture with ultraviolet light[99]. Anti-Markovnikov addition occurs.

The addition of phosphorus-containing compounds with a labile hydrogen atom to a carbonyl group was first observed "by Marie and by Ville" with phosphorous and hypophosphorous acids[100]. A. E. Arbuzov and Azanovskaya put forward a scheme to explain the reaction of sodium diethyl phosphite with acetyl chloride; it was suggested that addition of the sodium salt at the carbonyl group initially gives an acetophosphonic ester[101].



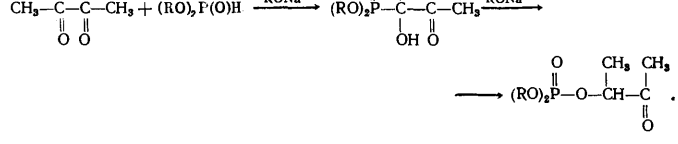
In 1950 Abramov proposed and subsequently developed extensively a method for the synthesis of esters of α-hydroxyalkylphosphonic acids, consisting in the addition of dialkylphosphoric acids and other acid esters of phosphorus acids to aldehydes and ketones[102]. The reactions of dialkyl phosphonates with aldehydes and ketones proceed with almost quantitative yields, usually in the absence of catalysts and solvents on holding the reaction mixtures at room or elevated temperatures[103]:



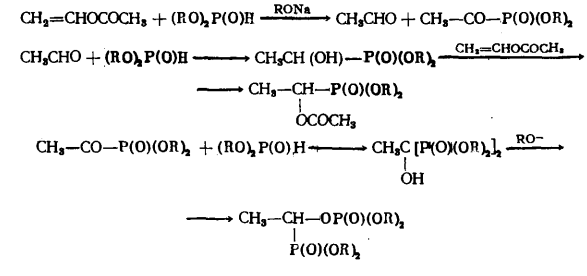
The possibility that the enol form of the dialkyl hydrogen phosphite takes part in the reactions is not ruled out[104].

Kabachnik and Tsvetkov[105] suggest the possibility of a termolecular reaction in the condensation of dialkyl hydrogen phosphites with aldehydes. In several instances the reactions are accelerated in the presence of alkali metal alkoxides which facilitate the formation of the dialkylphosphonium anion. Abramov and coworkers studied the addition of dialkyl hydrogen phosphites, dialkyl hydrogen thiophosphites, and acid esters of alkyl- and aryl-phosphonic acids to a large number of aldehydes and ketones of the aliphatic, aromatic, and heterocyclic series[103,104]. It was shown that the addition of acid esters of phosphorus acids is greatly facilitated with α-halogenocarbonyl compounds and certain other derivatives of aldehydes and ketones containing electro negative groups. The reactions with di-, tri-, and poly-chloro-substituted carbonyl compounds are particularly vigorous. Chloro-substituted dialkyl hydrogen phosphites, dialkyl hydrogen thiophosphites, and acid esters of phenylphosphonic acid add to aldehydes and ketones comparatively readily[106].

As Pudovik and Nikitina showed, acid esters of phosphorus acids react with ketens in the presence of pyridine or sulphuric acid, forming products by addition at the carbonyl group; under the conditions of the reaction the latter are partly or completely acetylated by a second molecule of the keten[107]:



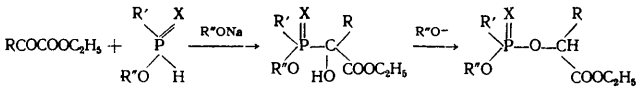
Mixed esters of dialkyl hydrogen phosphites and hydroquinone were obtained by the addition of dialkyl hydrogen phosphites to *p*-quinone in the presence of alkali metal alkoxides[108,109].



Rizpolozhenskii observed intramolecular addition at the carbonyl group in the reaction of alkyl dichlorophosphites [sic. presumably alkyl phosphorodichloridites] with diacetone alcohol in the presence of a base[110].

Interesting results were obtained in studying the reaction of the acid esters of phosphorus acids with carbonyl compounds containing electron-acceptor substituents in the α position to the carbonyl group. The addition here is accompanied by the rearrangement of the α-hydroxyalkylphosphonic esters formed initially into esters of phosphoric acid. Rearrangement was observed for esters of α-hydroxyalkylphosphonic acids with trichloromethyl[111] and cyano-[112] groups at the α-carbon atom.

Kukhtin and coworkers showed[113] that the reaction of dialkyl hydrogen phosphates with biacetyl at $> 100°C$ or on heating the reagents with sodium alkoxides also leads to esters of phosphoric acid:



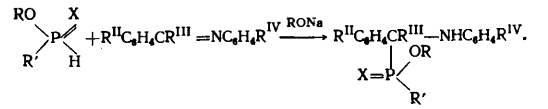
The phosphonate–phosphate rearrangement of bis(dialkylphosphono)carbinols was first observed by Pudovik and Konovalova in studying the reaction of dialkyl hydrogen phosphites with vinyl acetate[70]. The first stage of the reaction was the acetylation of the dialkyl hydrogen phosphite:

A special investigation of the reaction of acetophosphinic esters with dialkyl hydrogen phosphites showed that diphosphonocarbinols can be obtained only when the reaction is performed under mild conditions in the presence of diethylamine and at a temperature not exceeding 40–50°C. In the presence of alkaline catalysts they are rearranged into the esters of phosphoric acid. Somewhat later American scientists also observed the phosphonate–phosphate rearrangement[114]. The discovery of the phosphonate–phosphate rearrangement of diphosphonocarbinols enabled the mechanism of a series of other interesting reactions to be established[70]. For example, it was shown that the final products of the reaction of acetyl chloride and acetic anhydride with sodium diethyl phosphite are esters of phosphoric acid and not acetates of phosphonocarbinols, as had been suggested earlier:

$$CH_3COCl + (RO)_2PONa \rightarrow CH_3COP(O)(OR)_2 \xrightarrow{(RO)_2PONa} CH_3-C[P(O)(OR)_2]_2 \longrightarrow$$
$$\xrightarrow[(RO)_2P(O)H]{(RO)_2PONa} CH_3-CH(P(O)(OR)_2)-O-P(O)(OR)_2.$$

The mechanism of reaction of alcohols with esters of acetoxyvinylphosphinic acid has been demonstrated. A phosphonate–phosphate rearrangement was also observed in the reaction of acid esters of phoshorus acids with pyruvic[70] and mesoxalic[115] esters:

where R = CH_3, $CO_2C_2H_5$.



The esters of α-hydroxy-α-phenylalkylphosphonic acids obtained in the reaction of dialkyl hydrogen phosphites with acetophenone and its alkyl derivatives at elevated temperatures in the presence of sodium alkoxides also undergo rearrangement into the corresponding phosphates. As a result of the pyrolysis of the phosphates various derivatives of styrene were obtained in good yields[70]:

$$R''C_6H_4COCH_2R' + (RO)_2P(O)H \xrightarrow{RONa} R''C_6H_4CH(OP(O)(OR)_2)CH_2R' \xrightarrow{\Delta} R''C_6H_4CH=CHR' + (RO)_2P(O)OH.$$

On distilling the products of the addition of dialkyl hydrogen thiophosphites and acid esters of phenylphosphonic acid to acetophenone they were decomposed into the original reagents. Previously, Abramov and coworkers[116] had observed the analogous decomposition of esters of α-hydroxyalkylphosphonic acids obtained from the simplest aldehydes and ketones.

Pudovik and Konovalova think that under the conditions of alkaline catalysis decomposition into the initial reagents and the phosphonate–phosphate rearrangement are competing reactions for esters of α-hydroxyalkylphosphonic acids. The final result depends mainly on the environment of the α-carbon atom. The presence of electronegative substituents at the α carbon atom creates favourable conditions for the phosphonate–phosphate rearrangement to take place.

Pudovik studied the addition of acid esters of phosphorus acids at the C=N bond in the presence of alkaline catalysts, by the example of Schiff bases and the esters of isocyanic acid[87,89,117]:

Kuznetsov and Bakhitov obtained a series of products of the addition of dialkyl hydrogen phosphites to di-isocyanates[118].

Pudovik and Moshkina showed that the addition of dialkyl hydrogen phosphites and dialkyl hydrogen thiophosphites to diazophosphinic esters and tetra-alkyl esters of azodiphosphinic acid takes place at the nitrogen–nitrogen double bond[119].

Dialkyl hydrogen phosphites and dialkyl hydrogen dithiophosphite add to alkene α-oxides to form esters of β-hydroxyalkylphosphonic acids[87] and S-β-hydroxyalkyl esters of dithiophosphoric acids[120]

$$CH_2-CH_2 + (RO)_2P(O)H \longrightarrow HOCH_2CH_2P(O)(OR)_2.$$
$$\quad\ O$$

Opening of the epoxide ring has been established for a series of unsymmetrical α-oxides[121].

B. A. Arbuzov and Vinokurova synthesised a series of bifunctional organophosphorus compounds by the addition of phenylphosphine and butylphosphine to unsaturated compounds containing various functional groups[122]:

$$RPH_2 + 2CH_2=CHR' \rightarrow RP(CH_2CH_2R')_2,$$

where R = C_6H_5, C_4H_9; R′ = CO_2Alk, CH_2OH, CH_2NH_2, CN, etc.

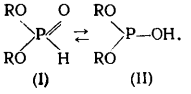
In 1952 Pudovik and Lebedeva effected the addition at the multiple bonds of various unsaturated compounds of the electrophilic type for a series of other phosphorus-containing compounds with a labile hydrogen atom: esters and the nitrile of phosphonoacetic acid, phosphonoacetone[87,123] and subsequently for esters of allylphosphonic acid[124]:

$$CH_2=CH-R + X-CH_2-P(O)(OR')_2 \rightarrow (R'O)_2P(O)CH(X)-CH_2CH_2R$$

where R = $CO_2C_2H_5$, CN, $COCH_3$; X = $CO_2C_2H_5$, $COCH_3$, CN.

Pudovik and coworkers were also the first to study the condensation of phosphonoacetic ester, phosphonoacetone, etc. with aromatic and aliphatic aldehydes, which led to the production of a series of phosphorus-containing alkene derivatives[125]:

$$RCHO + CH_2(X)P(O)(OR')_2 \rightarrow RCH=CX-P(O)(OR')_2 + H_2O,$$

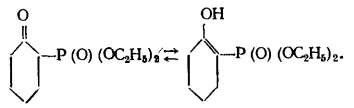


where X = $CO_2C_2H_5$, CH_3CO_2, or CN.

Unsubstituted amides of the dialkyl esters of phosphoric acid are also capable of addition at multiple bonds[126,127]:

$$(RO)_2P(O)NH_2 + CH_2=CHCN \xrightarrow{RONa} (RO)_2P(O)NHCH_2CH_2CN + (RO)_2P(O)N(CH_2CH_2CN)_2.$$

The addition of the anilide of diethyl hydrogen phosphite to the esters and nitriles of unsaturated acids takes place with transfer of the reaction centre and formation of N-phenylimidophosphonates[128].



In addition to the study of the reactivity of organophosphorus compounds problems of investigating their structure received considerable attention by the Kazan' scientists. In 1905 A. E. Arbuzov solved the problem of the structure of phosphorous acid and its organic derivatives, which is cardinal for the chemistry of phosphorus[1]. It was shown that all the neutral esters of phosphorous acid and derivatives of phosphorus (III) but that phosphorous acid itself and its acid esters are derivatives of phosphorus(V). On the basis of these investigations, A. E. Arbuzov concluded that compounds with hydroxyl at phosphorus(III) were unstable and similar to alcohols of the vinyl series. Even at that time he recognised the possibility of the existence of tautomeric forms for phosphorous acid itself and for some of its derivatives[77]. Subsequently this question was studied in detail in the example of the dialkyl hydrogen phosphites, the structure of which can be presented by two tautomeric forms:

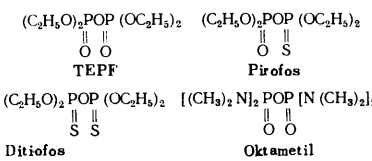
(I) (II)

The numerous investigations of A. E. Arbuzov and B. A. Arbuzov and their coworkers, and also of several other Soviet and foreign scientists showed that most of the chemical facts and the results of investigations of the dialkyl hydrogen phosphites by physical methods indicate their phosphonate structure although some reactions occur which are difficult to explain without accepting the existence of a tautomeric equilibrium[104]. At the present time it can be taken as proved that the tautomeric equilibrium of the dialkyl hydrogen phosphites is greatly displaced to the side of the phosphonate form (I). As B. A. Arbuzov and coworkers recently showed[129], dialkyl hydrogen phosphites with electronegative substituents at the ester radicals (the cyano-group, chlorine atoms), for which structure (II) can be postulated, are also represented by a structure with a phosphorus(V) atom. Esters of β-ketophosphinic acids formed an interesting subject for the study of tautomeric conversions in the series of organophosphorus compounds. More than once A. E. Arbuzov emphasised the deep analogy between the phosphono-group and the carboxyl group and stated the possibility of the existence of tautomeric forms in compounds of this type[130]. Later B. A. Arbuzov, Vinogradova, and Polezhaeva synthesised a large number of esters of β-ketophosphonic acids and made a systematic investigation with the aim of establishing the presence of tautomerism and of comparing the influence of carboxylic and phosphono-groups for the tendency to give enol forms.

With the aid of chemical and spectroscopic methods of investigation it was shown that phosphonoacetic and methylphosphonoacetic esters, like malonic, do not contain detectable amounts of enol. Phosphonoacetone and methylphosphonoacetone, in distinction from acetoacetic ester, exhibit considerable enolisation only in an alkaline medium[131]. With phosphonoacetophenone the results of the chemical and physical investigations suggest the presence of only insignificant amounts of the enol form[131,132]. Analogous results were obtained also for diphenylacetonylphosphine oxide and diphenylphenacylphosphine oxide[40]. The presence of a considerable amount of the enol form was observed in an ester of 2-oxocyclohexylphosphonic acid—the phosphorus analogue of the ester of 2-oxocyclohexylcarboxylic acid[133]. Titration with bromine in alcoholic medium showed the presence of 9% of the enol, and in hexane medium, of 60% enol:

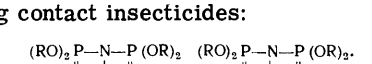
Only weak enolisation was observed for the diethyl ester of 2-oxocyclopentylphosphonic acid, which accords with the insignificant content of the enol form in the esters of 2-oxocyclopentylcarboxylic acid[134].

On the basis of these results B. A. Arbuzov and coworkers[134] concluded there was a definite analogy in the enolisation of the β-keto-acids and their phosphoric analogues. It was noted, however, that the β-ketophosphonic esters are enolised to a less extent. There is no complete parallel.



B. A. Arubuzov, Samitov, and Zykova obtained extremely interesting results in studying the structure of organophosphorus compounds by proton magnetic resonance. A large number of investigations in this direction was carried out on a high-resolution NMR spectrograph built in the Research Laboratory for the Structure of Organic Compounds of Kazan' University under the direction of Samitov in 1958–1960.[135] With the aid of the ^{1}H- and ^{31}P-NMR spectra the structure of a series of cyclic compounds of the phospholene type was established, the diastereoisomerism of the oxaphospholenes was studied, and interesting investigations were made into the structure of various types of acyclic esters of phosphoric and phosphonic acids of importance for establishing the mechanism of certain reactions[35,62,67].

In addition to spectroscopy and thermography, B. A. Arbuzov used several other physical methods to study the fine structure of organophosphorus compounds: the parachor method, dipole moments, viscometry, cryoscopy, and polarography[136]. With their aid he studied the problems of the association of molecules of organophosphorus compounds, their intramolecular and intermolecular interactions, and the nature of the arrangement of the alkyl groups and their mutual orientation in the esters of acids of phosphorus. The method of dipole moments was used to show the possibility of free rotation of non-regular groups in the molecules of organophosphorus compounds.



A series of investigations was concerned with compounds which contain an asymmetrical phosphorus atom[137]. In 1929, A. E. Arbuzov and coworkers synthesised certain phosphonic and thiophosphonic acids with an asymmetric phosphorus atom and attempted to resolve them into optical antipodes. Kamai and coworkers synthesised a large number of asymmetric phosphonium derivatives. They succeeded in obtaining two diastereomeric d-π-bromocamphorsulphonates for allylbenzylethylphenylphosphonium bromide. Later Kamai and Usacheva separated the dextrorotatory benzylethylmethyl-p-tolylphosphonium chloride, bromide, and iodide, which exhibit high optical stability. Somewhat earlier, Kumli and coworkers[192] had succeeded in separating into optical antipodes a heterocyclic asymmetric phosphonium salt.

The theoretical investigations in the field of organophosphorus compounds which are being carried out in the Kazan' school of organophosphorus chemistry are closely the Kazan' scientists in the field of the synthesis of physiologically active organophosphorus compounds. As is well known, as long ago as 1932, in studying the reaction of

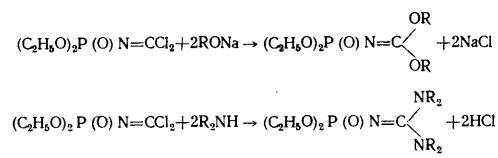
bromine with sodium diethyl phosphite, A. E. and B. A. Arbuzov were the first to obtain esters of pyrophosphorous and monothiopyrophosphorous acids and to isolate pure esters of hypophosphoric and pyrophosphoric acids[138]. Later Schrader observed that tetraethyl pyrophosphate, its thio-analogue, and several other organophosphorus compounds exhibit strong insecticidal action. From 1946 onwards systematic investigations were carried out in the Chemical Institute of the Kazan' Section of the Academy of Sciences of the USSR in the field of synthesis of new phosphorus-containing insecticides with contact and systematic action. During this period particular attention was paid to derivatives of pyrophosphoric and thiopyrophosphoric acids. In addition to the development of new, simple, and practicable methods of making such highly effective insecticides as TEPF, Pirofos, Ditiofos, Oktametil[139]

B. A. Arbuzov, Alimov, Nikonorov, Grechkin, Rizpolozhenskii, and others obtained a large number of new mixed esters, ester-amides, and amides of pyrophosphoric and thiopyrophosphoric acids[140]. Neklesova investigated their insecticidal activity and their action on warm-blooded creatures. Among the compounds obtained considerable interest attaches to the mixed ester amides of dithiopyrophosphoric acid, which exhibit pronounced insecticidal action and low toxicity. B. A. Arbuzov and Alimov synthesised a new type of organic derivative of phosphorus with the P–N–P bonding; some of these compounds are rather strong contact insecticides:

The dialkylphosphono-2,2,2-trichloroethyldialkyl phosphates obtained by B. A. Arbuzov and Nikonorov on the basis of chloral approach Pirofos, Ditiofos, and TEPF in their insecticidal action. B. A. Arbuzov and Alimov[140,141] synthesised a series of insecticides with three phosphorus atoms per molecule.

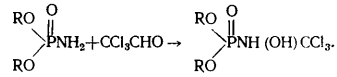
With the aim of obtaining physiologically active organophosphorus compounds the Kazan' chemists synthesised a large number of compounds not previously described in the literature with one phosphorus atom per molecule—esters and amides of phosphoric, thiophosphoric, dithiophosphoric, and [phosphonic] phosphinic acids and various derivatives of them. Strong insecticidal properties were shown by the esters of 1-acetoxy-2,2,2-trichloroethylphosphonic acid, obtained by Nikonorov[142,143]. The dimethyl ester of this acid, which exhibits low toxicity for warm-blooded creatures and good fungicidal properties, was recommended for clinical trials as a substance for the treatment of certain fungal illnesses.

The esters of thiophosphoric acid with alkoxycarbonylmethyl and cyanomethyl radicals acted as active insecticides[140]:

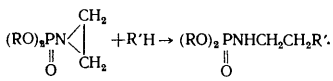


Yarmukhametova and Cheplanova synthesised phosphorus-containing derivatives of pentachlorophenol and pentachlorothiophenol[144].

An especially large number of investigations were made in the field of the synthesis of compounds with a phosphorus–nitrogen bond. Alimov and coworkers obtained many new mono- and di-*N*-substituted esters of phosphoramidic acid. Tests showed that dialkyl-*N*-alkoxycarbonylmethyl phosphoramidates are powerful insecticides but rather toxic for warm-blooded creatures[145]. As a result of the addition of secondary amines to the esters of mono- and di-isothiocyanatophosphoric acids Alimov and Levkova synthesised phosphorus-containing derivatives of thiourea[146]:



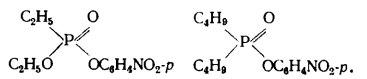
The dichloromethyleneamides of dialkyl hydrogen phosphates obtained by these authors by the action of chlorine on dialkylisothiocyanatophosphates [dialkyl phosphoro(isothiocyanatidates)] are extremely reactive compounds. They were used to synthesise a variety of derivatives of the methyleneamide of diethyl hydrogen phosphate [diethyl *N*-methylenephosphoramidate]: *N*-phosphorylated derivatives of iminocarbonic, iminothiocarbonic, and iminothiocarbamic acids, imidourea, formimine, etc.[147]:



Alimov and coworkers accomplished the *N*-phosphorylation of formamide[148] and of glycine and its derivatives[149]:

To obtain phosphorus-containing compounds with insecticidal or bactericidal activity, Alimov and Antokhina studied the condensation of a series of amides of phosphoric acid and some other organophosphorus compounds with chloral[150]:

Over several years Grechkin and coworkers made a systematic investigation of phosphorus-containing derivatives of ethyleneimine [aziridine], which as the literature indicates can exhibit anti-tumour activity and several other valuable properties. Mono-, di-, and tri-ethyleneamides of phosphoric, phosphorous, and thiophosphoric acids were synthesised[151–153] and it was shown that the ethyleneimine ring substituted at the nitrogen by a phosphono-group is much more stable to the action of various reagents than the free ethyleneimine ring. The addition of a series of compounds with a labile hydrogen atom and of halogens and alkyl halides to mono- and di-ethyleneimides of phosphoric acid was studied in detail, the reaction being given the name *N*-dialkylphosphonaminoethylation:



Grechkin and Khamitov obtained some organophosphorus derivatives of azetidine.

B. A. Arbuzov and coworkers synthesised a series of esters of phosphoric and thiophosphoric acids containing heterocyclic radicals. Among those which were powerful insecticides exhibiting comparatively low toxicity towards

warm-blooded creatures were derivatives of pyrimidine and imidouracil[154]. Dialkyl tetrahydrofurfuryl phosphates are rather active as insecticides and exhibit toxic properties[155]. Esters of phosphoric and thiophosphoric acids with pyrazole, α-aminopyridine, carbazole, and certain other radicals were also synthesised.

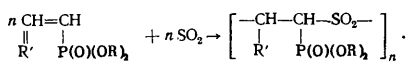
Razumov and coworkers prepared a large number of organophosphorus compounds with varying ranges of biological action[156,157]. In addition to compounds which exhibit anti-cholinesterase action, products were obtained with spasmolytic and cholinolytic activity. Among those compounds finding a wide use in medical practice and whose action is based on their anti-cholinesterase activity mention must be made of the ethyl *p*-nitrophenyl ester of ethylphosphonic acid (Armin). It is used as an antiglaucomatosic substance which is a hundred times more active than natural pilocarpine. Another strongly-acting antiglaucomatosic drug is *p*-nitrophenyl dibutylphosphinate (Nibufin). It simultaneously tones up smooth muscle, in consequence of which it is used in atonia of the gastrointestinal tract and of other smooth-muscle organs. It is also used with Armin as a parturifacient:

Armin Nibufin

Another antiglaucomatic drug is the tetraethyl monothiopyrophosphate (Fosarbin or Pirofos) first synthesised by A. E. and B. A. Arbuzov and mentioned above as a highly effective insecticide.

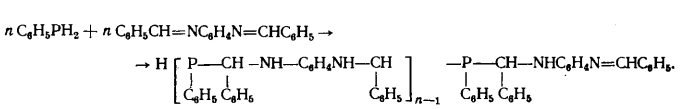
Razumov and coworkers also obtained a series of unsaturated esters of dialkylphosphinic acids and of polychlorinated esters of alkylphosphonic acids with antibacterial properties. It has been shown that certain phosphorylated acetals and aldehydes exhibit antivirus activity. Razumov synthesised some extremely interesting organophosphorus compounds with spasmolytic and also potentiating action based on the specific action on the central nervous system. The most active spasmolytics were the esters of diallylphosphinic acid, and of these the isopropyl diallylphosphinate, which is furthermore an antidote for powerful anticholinesterasis poisons—Armin and Nibufin.

B. A. Arbuzov and coworkers[158] synthesised a series of phosphacyclopentenes which exhibit anticholinesterase activity, low toxicity, and pronounced antispasmodic action.



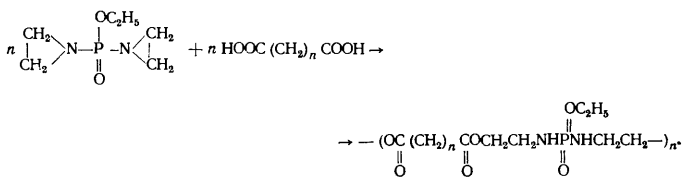
In recent years a new, interesting, and important direction in the chemistry of organophosphorus compounds has evolved—the synthesis of phosphorus-containing monomers and the production of polymers based upon them and exhibiting enhanced resistance to fire, thermal stability, inertness to many chemical reagents, good adhesion to various materials, and other valuable qualities. Several investigations in this field were carried out by the Kazan' scientists. A large number of derivatives of unsaturated phosphinic acids, unsaturated esters of phosphorus acids, various bi-, ter-, and multi-functional phosphorus-containing compounds were synthesised; their reactions were studied: polymerisation, copolymerisation, migration polymerisation, polycondensation, leading to the formation of polymeric products with a phosphorus atom in the principal or side chain. Derivatives of αβ-unsaturated phosphinic acids are of special interest for the synthesis of phosphorus-containing polymers. Kabachnik, Kolesnikov, and their coworkers and several other authors have studied the polymerisation and copolymerisation of esters of vinylphosphinic acids. Pudovik and Kuzovleva obtained solid transparent polymers based on the esters of α-acetoxyvinylphosphonic, α- and β-alkoxycarbonylvinyl- and cyanovinyl-phosphonic acids[159]. Kamai and Tsivunin investigated the ability to polymerise of a series of derivatives of ethylalkenylphosphonic acids[160]. Kuznetsov and coworkers[161] studied the copolymerisation of esters of vinylphosphonic, allylphosphonic, and but-2-en-1,4-bis(phosphonic) acid with acrylic and methacrylic acids. They obtained also a series of polymers of certain unsaturated phosphorus-containing compounds and their copolymers with alkenes, alkadienes, and other monomers on Ziegler-type catalysts[162]. Kamai and Kukhtin investigated the polymerisation of the allyl esters of phosphinic acids in the presence of peroxide initiators[163]. It was shown that the various groups at the phosphorus atom can be arranged in the following series according to the magnitude of their influence on the ability of allyl esters to polymerise:

Kennedy and coworkers[164] later added to this series.

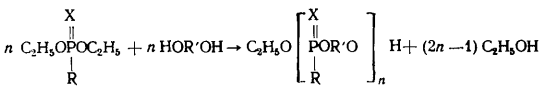


Pudovik and Kashevarova synthesised a large number of organophosphorus monomers which were derivatives of acrylic and methacrylic acids. They obtained phosphorus-containing esters and amides of acrylic and methacrylic acids, mixed anhydrides of acrylic and methacrylic acids, and acid esters of phosphoric, phosphonic, and phosphorous acids. Their polymerisation and copolymerisation gives solid vitreous product, insoluble in organic solvents and exhibiting reduced combustibility[165].

Kuznetsov and Faizullin synthesised a series of organophosphorus polysulphides by the copolymerisation of sulphur dioxide and certain unsaturated phosphorus-containing compounds[166]:



The possibility of hardening liquid organophosphorus polysulphides by reaction with mono- and di-isocyanates has been demonstrated.



A. N. Pudovik and M. A. Pudovik brought about the migration polymerisation in a series of phosphorus-containing compounds[167]. When acid diphosphites, diphosphinites, and phenylphosphine react with certain organic compounds with two double bonds, polymeric products are formed according to the scheme:

A series of phosphorus- and nitrogen-containing polymeric products was obtained by Grechkin on the basis of the reaction of *N*-phosphonaminoethylation[168]:

Pudovik and coworkers[169,170] used polyester interchange of esters of phosphorus acids with glycols to obtain a series of polymeric products with a phosphorus atom in the main chain—polyalkyleneglycolphosphonates, polyalkyleneglycolethyl(phenyl)phosphinites, polyalkyleneglycol-phosphorothiolates and -phosphorothiolothionates[169,170]:

where R = Alk, C_6H_5, SH; and X = O or S.

The products of the addition of polyalkyleneglycol-phosphorothiolothionates to certain unsaturated electrophilic reagents exhibit insecticidal properties and are distinguished by considerable duration of the action under natural conditions. Phosphorus-containing polyesters were also obtained by the homopolycondensation of esters of hydroxymethylphosphonic acid[171] and in the reaction of the di(acid chloride) of 4-chlorobut-2-enphosphonic acid with dihydroxy-compounds.

Kuznetsov and Shermergorn and their coworkers synthesised polyphosphites based on alkyl(or aryl) phosphorodichloridites and diphenols, and studied in detail the properties of the polymers formed[172]. On the basis of the polycondensation of tetra(hydroxymethyl)phosphonium chloride, tri(hydroxymethyl)phosphine, di(hydroxymethyl)-phosphonic acid, and bis-2-carboxyethylphosphinous acid with various bifunctional organic compounds, Kuznetsov and coworkers synthesised phosphorus-containing polyesters and polyamides which are incombustible resins and in several instances capable of hardening[173,174]. A series of organophosphorus polysulphonates has also been obtained[175]. Kuznetsov and Khairullin have developed methods for the synthesis of phosphorus-containing Thiokols [polysulphide rubbers (Ed. of Translation)].

The phosphorylation of organic high-molecular-weight compounds has been used increasingly in recent years for the production of phosphorus-containing materials. A. E. Arbuzov and Alimov were the first to phosphorylate cellulose. Pudovik and coworkers synthesised a series of phosphorus-containing polymers on the basis of the addition of acid esters of phosphorus acids to unsaturated polyesters and poly(Schiff bases).[176] A graft copolymer of cellulose and 1-(diethyl phosphono)ethyl methacrylate has been obtained.

Kuznetsov and Devitaeva have phosphorylated polyethylene with phosphorus acid chlorides[177].

Kirpichnikov and coworkers have completed important investigations on the use of organophosphorus compounds for improving the properties of polymeric materials[178]. It has been shown that alkylaryl esters of pyrocatechol-phosphorous acid are good stabilisers for several polymers. The variation of inhibiting action with structure of organophosphorus compounds has been studied. Certain di- and poly-phosphites have also been shown to exhibit high stabilising properties[172,178].

In several papers and patents the Kazan' scientists have described phosphorus-containing plasticisers for tri-acetate cinematographic film base[179] and catalysts for the synthesis of carbodi-imides[180], have carried out the synthesis of extractants, and have found that oxidative phosphorylation can be used to obtain certain products based on petroleum alkanes which are interesting practically[181].

As it is impossible to give a complete list of the works of the Kazan' scientists in the field of the chemistry of organophosphorus compounds, we list only references to the most important papers, review articles, and also the first and last works of individual series.

αβ-UNSATURATED ETHERS AND THEIR ANALOGUES IN REACTIONS OF DIENE SYNTHESIS

L. S. Povarov

CONTENTS

1. Introduction 656
2. Structure of the αβ-unsaturated ethers and their analogues 657
3. Mechanism of diene condensations 659
4. Reactions with hydrocarbon dienes 661
5. Reactions with substituted hydrocarbon dienes 662
6. Reactions with heterodienes 663
   A. Reactions with oxygen heterodienes 663
   B. Reactions with nitrogen heterodienes 665

1. INTRODUCTION

αβ-Unsaturated ethers, such as simple vinyl ethers, cyclic unsaturated ethers of the dihydrofuran and dihydropyran type, alkoxydienes, and alkoxyacetylenes, represent a special group of unsaturated compounds as regards their combination of chemical properties. Similar properties are possessed by their sulphur analogues, the αβ-unsaturated sulphides, and by ketens. The compounds of this group are distinguished by high reactivity in a variety of conversions which proceed by an ionic mechanism, mainly with electrophilic reagents. From the standpoint of chemical structure these compounds are distinguished by the presence at the double bond of an electron-donating substituent (–OR or –SR), which determines the special nature of the polarisation of the double bond.

The most characteristic representatives of this group of compounds are the vinyl ethers, in the properties of which appear most distinctly and uniquely the fundamental features of the chemical properties and structure possessed by the unsaturated ethers and their analogues.

Among the reactions of the vinyl ethers which take place by an ionic mechanism are hydrolysis, addition of alcohols and organic acids, hydrogen halides and halogens, polymerisation and copolymerisation. Most of the reactions of vinyl ethers are catalysed by mineral acids and by Lewis acids, that is, by electrophilic reagents. At the same time they are completely stable to the action of nucleophilic reagents—alkalis. Vinyl ethers do not react with alkali metals[1]. Many reactions which proceed by a radical mechanism are not characteric for alkyl vinyl ethers. In sharp contrast to the ease with which ionic (cationic) polymerisation of alkyl vinyl ethers takes place is their passivity in radical polymerisations[2–5]. Schildknecht and coworkers[4], who made a comparative study of the polymerisation of various unsaturated compounds, divided them into three groups according to the type of

TABLE 1. Classification of the alkene monomers by polarisability type.

First group	Second group	Third group
2-Methylprop-1-ene	styrene	ethylene
Methylbutene	butadiene	vinyl halides $CH_2=CHX$
α-Methylstyrene	divinyl ether	vinylidene dihalides $CH_2=CX_2$
2-Isopropenyltoluene	methyl vinyl ketone	vinyl esters $CH_2=CHOCOR$
Alkyl vinyl ethers	*N*-vinylpyrrolidone	acrylic esters
Methyl vinyloxyacetate $CH_2=CH-O-CH_2COOCH_3$	*N*-vinylcarbazole	methacrylic esters

polymerisation (Table 1): first group—compounds which polymerise by an ionic mechanism under the action of Friedel-Crafts catalysts at low temperatures but which do not give the usual high-molecular-weight polymers in free-radical or thermal polymerisation; second group—those which polymerise by both an ionic and a radical mechanism; third group—compounds which polymerise by a radical mechanism and give high-molecular-weight polymers in peroxide or thermal polymerisation.

Even by the above criterion alkyl vinyl ethers are sharply distinguished from unsaturated compounds which contain at the double bond such electron-acceptor substituents as carbonyl, carboxyl, an acyloxy-group, halogen, etc. which enter into the third group. In one group with the alkyl vinyl ethers are certain unsaturated compounds which contain electron-donor substituents at the double bond. The existence of an intermediate group of unsaturated compounds is natural. According to polymerisation type, the intermediate group includes not only divinyl ether but also aryl vinyl ethers and alkoxy-dienes, which are capable of both ionic and radical polymerisation[6,7], to which, however, all the ionic reactions of alkyl vinyl ethers are inherent. In addition to high reactivity in relation to various electrophilic reagents, in which they show complete similarity with alkyl vinyl ethers, acetylenic ethers also react with nucleophilic reagents, for example, with amines, by forming addition products at the triple bond[8,9]. Evidently this can be explained by a breakdown in the symmetry of the electron cloud of the carbon atom in the formation of a triple bond and by the exposure of a positive charge, which makes nucleophilic attack possible[10].

In vinyl sulphides, the properties of which are in many respects analogous to those of vinyl ethers, the presence of a sulphur atom brings about a series of peculiarities, which are expressed, in particular, in a duality in their properties, and in a greater variety of chemical conversions. In polymerisation type these compounds can evidently be assigned to the second group, since they readily polymerise by both an ionic and a radical mechanism[11]. Furthermore, the vinyl sulphides generally show considerable activity in radical reactions[12]. Many ionic reactions of keten are extremely close in nature to the reactions of alkyl vinyl ethers[13].

The reaction with acetals discovered by Müller-Cunradi and Pieroh[14] which proceeds by an ionic mechanism is especially specific for αβ-unsaturated ethers. This reaction has now been studied well[15,16] and it has been shown that a great variety of αβ-unsaturated ethers and sulphides, as well as keten, react with acetals[13]. Nevertheless unsaturated compounds with electron-withdrawing substituents, for example, the compounds of the third group in Table 1, which are generally distinguished by high reactivity, were completely incapable of condensing with acetals.

The behaviour of αβ-unsaturated ethers in the reactions of diene synthesis is highly specific. This appears most sharply in the diene condensations with Schiff bases[17-19]. These reactions serve as yet another criterion for the separation of αβ-unsaturated ethers and sulphides into a special group of compounds. Consideration of the behaviour of αβ-unsaturated ethers in diene condensations with a different type of dienophiles allows certain conclusions to be drawn concerning the mechanism of diene synthesis in general.

At the basis of the specifics of chemical properties of the αβ-unsaturated ethers lies a feature of their structure, the investigation of which has been investigated in a series of special physicochemical and spectroscopic studies. Especially interesting results were obtained recently in studying the infrared and NMR spectra of these compounds.

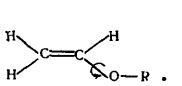
2. STRUCTURE OF THE αβ-UNSATURATED ETHERS AND THEIR ANALOGUES

A feature of the structure of the αβ-unsaturated ethers and their sulphur analogues is the presence of an –OR or –SR group at a double bond. According to the theory of electron displacement[20,21] the –OR and –SR groups exhibit a negative induction effect ($-I_S$), but less than, for example halogen atoms. This is shown clearly from Table 2, which gives the dissociation constants of substituted acetic acids[22]. In accordance with the lower electronegativity of the sulphur atom in comparison with the oxygen atom the –SR group has a smaller induction effect than the –OR group.

On the other hand, the –OR and –SR groups exhibit a positive mesomeric effect ($+M$), greater than the halogen atoms. The mesomeric effect of the –SR group is less than that of the –OR group, in accordance with the rule[20,21] by which within the limits of a given group of the Periodic System the higher the atomic number the less the tendency to form double bonds. The above two factors should evidently determine the static state of the electrons of the double bond of unsaturated ethers and sulphides. Finding the relation of these two effects is of considerable importance.

The orientation of ionic addition of various reagents to αβ-unsaturated ethers leads to the conclusion about the presence of an excess of negative charge at the β-carbon atom. On this basis it could be assumed that on the negative induction effect of the –OR group in these compounds is superposed a positive mesomeric effect and that as a whole this group is an electron donor:

TABLE 2. Dissociation constants of substituted acetic acids.



Acid	K
CH_3COOH	$1.855 \cdot 10^{-5}$
CH_3S-CH_2COOH	$1.92 \cdot 10^{-4}$
$C_2H_5O-CH_2COOH$	$2.50 \cdot 10^{-4}$
CH_3O-CH_2COOH	$2.94 \cdot 10^{-4}$
$Cl-CH_2COOH$	$1.55 \cdot 10^{-3}$

In recent years the investigation of the NMR spectra of a series of unsaturated ethers has allowed direct proof to be obtained of the existence of increased electron density at β-carbon atoms due to the mesomeric effect of the –OR group, which is expressed in the conjugation of the unshared electron pair of the oxygen atom with the π-electrons of the double bond. Analogous results were also obtained for unsaturated sulphides. Investigation of the ultraviolet and infrared spectra and heats of hydrogenation also suggest the presence of $p-\pi$-conjugation.

In the NMR spectra of alkyl vinyl ethers[23-25] an extremely large chemical shift has been observed for β-protons to the side of higher fields (75–85 Hz) in comparison with ethylene[26]. It has been shown[25] that this effect cannot be due to the anisotropy of the oxygen atom but is the consequence of conjugation of the unshared pair of the electrons of the oxygen atom with the unsaturated system. In methyl vinyl sulphide the shift for the β-protons is considerably less (14–28 Hz). Were the chemical shift of the protons due to the inductive effect of the oxygen and sulphur atoms the picture should be reversed. The observed difference in the chemical shift of the β-protons is explained by the difference in the degree of $p-\pi$-conjugation of the oxygen and sulphur atoms, which is more significant for oxygen. For α-protons the observable difference in the chemical shift corresponds to the order of electronegativity of the oxygen and sulphur atoms. The chemical shifts in methyl vinyl and butyl vinyl ethers are almost the same. Group R does not significantly affect the β shift and evidently does not change the degree of $p-\pi$-conjugation of the oxygen. The oxygen atom acts as a buffer between group R and the double bond. In isopropenyl methyl ether the methyl group decreases the total shift of the two β-protons by 16 Hz, which is considerably below the effect of the methyl group in propene, where there is a general shift of the β-protons by 30 Hz in comparison with ethylene.

Interesting results[27] were obtained in investigating the NMR spectra for the series of substituted ethylenes $CH_2=CHX$, where X = H, CH_3, Cl, OCH_3, CN, and C_6H_5. The existence of a linear relation between the chemical shift of the β-protons and the group dipole moments of substituents X was demonstrated. Parallel curves were obtained for *cis*- and *trans*-β-protons. The results for methyl vinyl ether (X = OCH_3) fit into this relation if it is assumed that the group OCH_3 as a whole is positive in relation to ethylene (dipole moment +1.16 D). This is analogous to *p*-chloroanisole, in which the group dipole moment of the chlorine atom and the OCH_3 group are added together.

Investigation of the vibrational spectra (infrared and microwave) of alkyl vinyl ethers showed that they have a series of features connected with the direct proximity of the ethereal oxygen to the double bond[28-31]. In the region of the C=C stretching vibrations in the spectra of alkyl vinyl ethers the presence of three absorption bands is noted, at 1642 cm^{-1}. On the basis of a consideration of the published data and additional experimental investigations it was shown[28,29] that the presence of these bands is connected with the realisation of rotation isomers:

On the basis of the microwave spectra the difference in the energies of the rotation isomers for butyl vinyl ether was determined. The vibrational spectrum of methyl vinyl ether was investigated in detail[29]. The results of the investigations suggest that the rotation isomers which arise differ in the degree of interaction of the π-electrons of the double bond with the unshared electron pair of the oxygen atom. The bathochromic shift of the absorption band of the double bond of alkyl vinyl ethers which is observable in their ultraviolet spectra[32] (absorption band in the region 1900–2000 Å) in comparison with the double bond of alkenes (absorption band at 1800 Å) can be explained by conjugation. The results of an investigation of the spectra of vinyl sulphides[33] also show the existence of interaction of the sulphur atom with the double bond.

Kistiakowsky and coworkers[34] determined the value of the heat of hydrogenation of certain unsaturated compounds including several vinyl ethers (Table 3). The results obtained show that there is considerable conjugation of CH=C–O–C. This conclusion follows from the heats of hydrogenation of the alkyl vinyl ethers having a mean value between the heats of hydrogenation of unconjugated double bonds, for example, in allyl alcohol, and the heats of hydrogenation of the double bond having an aromatic nature, for example, in furan.

The results of Doliver and coworkers[34] were recently confirmed by calculation of the heat of hydrogenation from measured heats of combustion[35]. The heats of combustion of ethyl vinyl and divinyl ethers compared with the heat of combustion of diethyl ether are:

$$\Delta H^\circ_c \text{ (diethyl ether, } g) = -657.52 \pm 0.18 \text{ kcal mole}^{-1},$$
$$\Delta H^\circ_c \text{ (ethyl vinyl ether, } g) = -615.98 \pm 0.22 \text{ kcal mole}^{-1},$$
$$\Delta H^\circ_c \text{ (divinyl ether, } g) = -578.14 \pm 0.19 \text{ kcal mole}^{-1}.$$

The authors state that conjugation in ethyl vinyl ether is slightly higher than in divinyl ether.

The dipole moments of vinyl ethers[36] (Table 4) differ little from those of the corresponding saturated ethers. Evidently, in the present instance they cannot give any information about the degree of polarisation of the double bond.

Ketens are analogues of the vinyl ethers in the sense that they also contain an oxygen atom at a double bond and in them, just as in the vinyl ethers, conjugation of the unshared electron pair of the oxygen atom with the π-electrons of the double bond is possible, as Ingold first stated[37]. Determination of the dipole moments of the transition in ketens showed that they are considerably (30–40%) lower

TABLE 3. Heats of hydrogenation of unsaturated compounds.

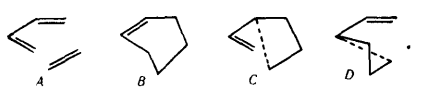
than in the corresponding ketones[38]. The authors gave the explanation that the effect normal for ketones

is weakened (but not extinguished) by the competing mesomeric effect

Spectrometric studies of keten[39] show the presence of an excess of negative charge at the β-carbon atom.

In the presence of an increased electron density at the β-carbon atom at the double bond, that is, the presence of a nucleophilic centre, $\alpha\beta$-unsaturated ethers and their analogues are distinguished from other types of unsaturated compounds in which the substituents at the double bond have an electron-withdrawing character. On comparing $\alpha\beta$-unsaturated ethers with vinyl halides in which p-π-conjugation is also possible, in the latter it evidently does not appear to the same extent and does not predominate over a more significant induction effect.

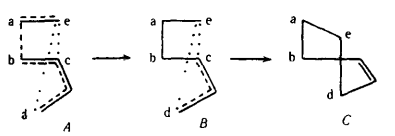
The nucleophilic nature of the double bond of $\alpha\beta$-unsaturated ethers explains their high reactivity in relation to electrophilic reagents and the inertness to the action of nucleophilic reagents.



3. MECHANISM OF DIENE CONDENSATIONS

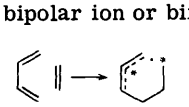
It has now become evident that many of the reactions of diene synthesis which unite the general scheme of addition of a dienophile in the 1,4 position to a diene system cannot be ascribed to any single mechanism both from the viewpoint of the order of combination of the reagents (single- or two-stage) and from the viewpoint of the type of transition of the electrons (homolytic or heterolytic)[40,41]. In support of the single-stage mechanism of a series of diene condensations there are the low values of the pre-exponential factors in the equations for the rate constants of the reactions, approximately 10^{-5}–10^{-6} times the usual rates of collision in gas reactions. In other words, the reactions are characterised by a high negative entropy of activation, which shows that to effect the reactions extremely specific orientation of the reacting molecules is necessary, for example, collision at two points.

In complete agreement with the single-stage mechanism are results[42] which show that acyclic dienes (butadiene) are capable of participating in a diene condensation only after isomerisation into a cisoid conformation. The observance in diene condensations of the principle of *cis*-addition of reagents is also more understandable in single-stage conversion. The mechanisms of the two-stage formation of addition products should provide for additional factors which exclude the possibility of rotation in the product of the first stage of addition[43].



At the same time there are individual instances of diene condensations in respect of which a two-stage mechanism has been established. For example, determination of the change in volume in the formation of a transition state ($\Delta v^{\neq}$) in the dimerisation of isoprene[44] and the diene condensation of 2,3-dimethylbutadiene with butyl acrylate[45] suggested that these reactions are two-stage. It appeared that the transition state is characterised by a significantly greater volume than the reaction products. A single-stage mechanism for the dimerisation of cyclopentadiene was confirmed by the same method[45,46].

According to contemporary views, diene condensations which are stereospecific proceed by the approach of the diene and dienophile molecules which are in parallel planes. The formation of new bonds starts with the overlap of the orbitals of the π-electrons. For a single-stage diene synthesis according to Wassermann[47] the transition state is expressed by a set of resonance structures. For example, structures *A*, *B*, *C*, and *D* represent the transition state for the reaction of butadiene with ethylene:



For more complex molecules which contain polar substituents structures which take into account the interaction of specified substituents with unsaturated systems also enter into the transition state.

According to Woodward and Katz[43] the transition state for a two-stage stereospecific diene synthesis can be represented as:

This scheme represents the two-stage mechanism when conversion $B \rightarrow C$ requires an energy of activation. Here the bonds *ed* and *ec* are formed by secondary forces—electrostatic, electrodynamic, and partly exchange forces. When the stage $B \rightarrow C$ of the conversion does not require an energy of activation the bonds *ed* and *ec* are partial and the mechanism stated becomes indistinguishable in practice from a four-centre mechanism.

For a non-stereospecific diene synthesis, transition states of the bipolar ion or biradical type are possible:

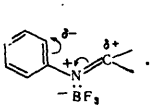
There are also contradictory information and opinions concerning the type of electron transition in reactions of diene synthesis. The reactions of the classical diene synthesis (with hydrocarbon diene systems and dienophiles) evidently cannot be related to the heterolytic in external characteristics, since it was shown that the values of the

rate constants and parameters in the Arrhenius equations are almost the same both in the gas phase and in non-polar solvents[40,41]. Moreover, the ideas about heterolytic processes do not agree in many instances with the structural directionality of these reactions[48]. However, it is impossible to classify them as radical reactions, as it was found that they are not catalysed by peroxides[40,41].

Wassermann[47] states that since electrons are indistinguishable there is no sense in speaking of a heterolytic or homolytic transfer of electrons in a four-centre mechanism.

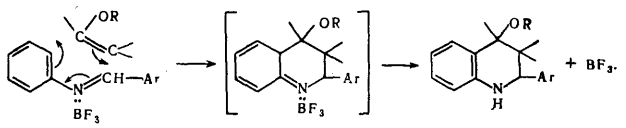
In the mechanism of Woodward and Katz[43] it was assumed that the spins of all the electrons included in the process remain paired all the time. The production of a triplet state under conditions of stereospecific diene synthesis is not very probable[49].

However, it must be noted that the available information on the mechanism of the diene synthesis relates almost exclusively to hydrocarbon dienes and dienophiles. Other types of conversions cannot be ruled out for heterodienes and heterodienophiles, in particular, conversions through bipolar or biradical transition states. Thus, Japanese investigators[50] propose a transition state in the form of a bipolar mesomeric ion for the reaction of octyl vinyl ether with substituted cinnamaldehydes. Henecka[51] states that the formation of ascaridol from α-terpinene and oxygen is a radical reaction. Some authors consider that diene condensations can be brought about by the transfer of electrons into a non-planar six-membered complex, both heterolytically[52,53] and homolytically[51]. We note that apropos of reactions of diene synthesis with hydrocarbon dienes and dienophiles Ingold writes[40] that they proceed predominantly homolytically.



Undoubtedly, for the stereospecific diene synthesis with participation of $\alpha\beta$-unsaturated ethers a tendency to heterolytic transfer of electrons should be more characteristic, considering the unequivocal structural directionality of these reactions and the general uncharacteristic nature of homolytic conversions for this type of dienophile. For example, the condensation of oxygen-containing heterodienes, such as $\alpha\beta$-unsaturated aldehydes, with vinyl ethers always takes place in the same way structurally in accordance with the polarity of the reagents[54,55]. These reactions, moreover, are characterised by the great ease with which they take place and the very high yields of addition products (up to 85%). Alkyl vinyl ethers react with great difficulty with dienes which tend to react preferably by a homolytic mechanism (such as cyclopentadiene)[56]. In their turn these oxygen-containing heterodienes form addition products in very low yields (3–9%) with dienophiles which contain electron-withdrawing substituents at the double bond and tend to radical conversions (such as vinyl acetate, methyl acrylate, methylallyl alcohol, etc.)[57]. Moreover, these condensations proceed structurally despite the polarity of the reagents. Thus the condensation of acrylaldehyde with methyl acrylate leads not to dihydro-3-methoxycarbonylpyran, as might have been expected from the polarity of the reagents, but to dihydro-2-methoxycarbonylpyran. This course of the reaction is explained by the principle of the conjugation of oxygen atoms in the formation of the transition state.

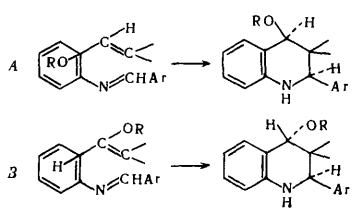
As is well-known, in those instances when the formation of stereoisomers is possible diene condensations proceed stereospecifically with the preferential formation of *endo*-addition products. This was shown by the example of the condensation of cyclopentadiene with maleic anhydride[58,59]. To explain the preferential formation of *endo*-addition products, the principle of the accumulation of multiple bonds in the orientation of reagents in the transition state was advanced. The essence of this principle, which was given quantitative expression in the works of Mousseron and coworkers[60], together with the principle of the conjugation of oxygen atoms (or in the more general form, the principle of the conjugation of unshared electron pairs) is that there are factors other than the polarity of the reagents which are capable of the formation of the transition state. Consideration of the many results on the diene condensation suggests that such a factor can be the general state of charge of the diene system and of the double bond of the dienophile. The action of this factor facilitates the approach of the reagents but does not determine the structural and steric orientation of the components.



Thus in many of the reactions of classical diene synthesis a diene which does not contain electron-withdrawing substituents is an electron-donor component in relation to the dienophile, whereas the dienophile serves as an acceptor of electrons. This has been confirmed recently by special investigations.

For example, Konovalov[61] studied the reactivity of a series of vinyl and isopropenyl dienophiles which contain electron-withdrawing substituents in reactions of diene synthesis with 2,3-dimethylbutadiene and cyclopentadiene. It was found that the reactivity of these dienophiles increased with decrease in the electron density at the double bond of the dienophile, which was determined as a function of the β-proton chemical shift in the NMR spectrum.

However, as was shown recently[62], there are diene condensations with a reversal of the electronic properties of the components, that is, when the diene serves as the electron-withdrawing component and the dienophile as the electron donor. From this viewpoint the behaviour of alkyl vinyl ethers in the diene synthesis is interesting. Since the double bond of vinyl ethers exhibits a clearly expressed nucleophilic nature, which appears especially sharply in alkyl vinyl ethers, their reactions with dienes should take place the easier the more electron-withdrawing the diene system, and contrariwise will be hindered in electron-donating diene systems. As will be clear from what follows, this position is observed for all the known examples of diene condensations with participation of alkyl vinyl ethers. In addition, such an approach makes it possible to understand the catalysis by Lewis acids of diene condensations of unsaturated ethers and their analogues with Schiff bases[17–19]. As was shown, in the absence of catalysts Schiff bases do not react with unsaturated ethers. And this is understandable, since the quasidiene system formed in this instance by the double bond of the benzene ring and the azomethine group is electron-donating, thanks to the presence of the nitrogen atom. At the same time there are results[63] showing that the diene systems C=C–N=C in oxazoles are capable of reacting with such electron-withdrawing dienophiles as maleic anhydride. In the presence of Lewis acids iminium salts are formed, as was shown[18] by the example of the complex of benzylideneaniline with BF_3. It can be assumed that in this there is strong polarisation of the double bonds:

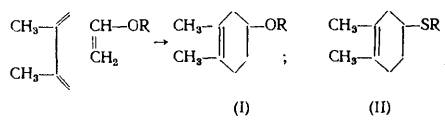


However, besides the above polarisation of the bonds which determine the structural orientation of the components an important factor is that the diene system mentioned acquires electrophilic properties to a high extent. Thanks to this the nucleophilically unsaturated ethers and their analogues react extremely readily with such systems. The reactions begin at room temperature and proceed with considerable evolution of heat giving high yields of addition products:

In addition to conferring electron-withdrawing properties on a diene system a catalyst plays yet another important part. It is already known that to carry out a diene condensation the diene system should have a planar configuration[36]. Moreover it was found[64,65] that in Schiff bases the amine ring is turned through an angle of ~ 60° relative to the plane of the rest of the molecule. This is explained by the competing interaction of the π-electrons of the azomethine group ($\pi-\pi$-conjugation) and the unshared pair of electrons of the nitrogen atom ($p-\pi$-conjugation) with the π-electrons of the aromatic amine ring. During quaternisation of the Schiff base the unshared electron pair is blocked as a result of which it becomes possible to realise the planar configuration of the molecule necessary for the reaction to take place.

Usually only one addition product, or predominantly one, is formed as a result of the condensation. This shows that the reaction is stereospecific.

The structural directionality of the reaction is always determined unambiguously by the polarity of the reagents. The possibility of stereoisomerism under the conditions of single-stage diene synthesis is connected with the different types of orientation of the reagents in the transition state (*A* or *B*):



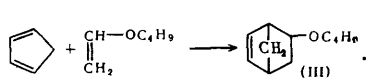
If it is assumed that orientation *A*, corresponding to the principle of the accumulation of unsaturation and unshared electron pairs, is pre-eminent, then the addition products formed predominantly must be considered to be the *cis*-isomers. This also agrees with the observed dependence of the ratio of the isomers on the reaction temperature[19].

Hence the reaction of unsaturated ethers with Schiff bases, which is a new type of diene condensation, is one of the extreme instances of the combination of the electron structures of the dienophile and a diene, namely, the instance when the dienophile exhibits clearly expressed nucleophilic properties and the diene system is electron-withdrawing to a high degree.

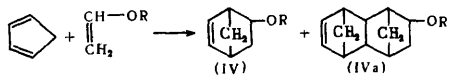
4. REACTIONS WITH HYDROCARBON DIENES

Diene systems which do not contain electron-withdrawing substituents exhibit increased electron-donating properties as has been shown by many examples of the reactions of diene synthesis, where they emerge as electron-donating components. Reactions with such dienes evidently have a predominantly homolytic character, which first and foremost relates to dienes not containing strongly polarised double bonds with substituents of electron-donating nature. Dienes such as butadiene, isoprene, 2,3-dimethylbutadiene, etc. easily form addition products with dienophiles containing electron-withdrawing substituents, the double bond in which has a diminished electron density. Thus butadiene and 2,3-dimethylbutadiene form addition products with maleic anhydride in quantitative yields even at room temperature[66].

There are very few examples of the reaction of vinyl ethers with the above hydrocarbon dienes. Apparently, alkyl vinyl ethers are generally incapable of giving addition products with many of these. This can be judged from the fact that in those instances when addition products were obtained, very severe conditions were used and the yields of the addition products were low. Thus, Shostakovskii and coworkers[67] carried out a diene synthesis of n-hexyl vinyl, cyclohexyl vinyl, and phenyl vinyl ethers with 2,3-dimethyl-1,3-butadiene. When the reagents were heated at 220–235°C for 10–12 h addition products were obtained—derivatives of 3,4-dimethylcyclohex-1-ene (I):



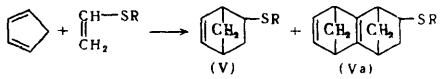
where (I) R = n-C_6H_{13}, C_6H_{11}, C_6H_5; (II) R = C_2H_5, C_6H_5.



With n-hexyl vinyl ether the yield of addition product was 33.3%. Cyclohexyl vinyl ether (yield of addition product 43.3%) and phenyl vinyl ether (yield of addition product 47%) are somewhat more active. n-Decyl vinyl ether did not give an addition product. Analogous products (II) were obtained with ethyl vinyl sulphide and phenyl vinyl sulphide under milder conditions (175°C, 12 h and 180–185°C, 15 h), the yields being 38.2 and 27.4% respectively.

One of the most active dienes in the reactions of classical diene synthesis is cyclopentadiene, the structure of the molecule of which favours the formation of the transition state. In reactions of diene synthesis cyclopentadiene acts as a donor of electrons. This can explain the extreme ease of reactions with dienophiles which exhibit an electron-withdrawing double bond. For example, methyl vinyl ketone condenses with cyclopentadiene with liberation of heat, by forming an addition product in quantitative yield[68]. On the other hand, alkyl vinyl ethers, as nucleophilic dienophiles, have very weak activity in relation to cyclopentadiene. Reactions take place under severe conditions and give insignificant yields of addition products; in several instances addition products are not formed in general.

Plate and Meerovich[68] first condensed butyl vinyl ether with cyclopentadiene by heating a mixture of the reagents at 200°C for 15 h. This gave 5-butoxybicyclo[2,2,1]hept-2-ene (III) in only 10% yield;



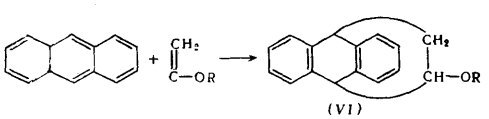
Subsequently Shostakovskii and coworkers[53,69-71] studied the condensation of a series of vinyl ethers with cyclopentadiene. As was shown, the reaction with alkyl vinyl ethers is more difficult and necessitates heating at 180–195°C for 15 h. Under these conditions ethyl vinyl ether did not give an addition product at all and addition products were obtained in low yield from butyl vinyl and cyclohexyl vinyl ethers. Aryl vinyl ethers form addition products in high yields under somewhat milder conditions (heating at 160–170°C for 13 h). It has been found that in the reaction in addition to mono-addition products—ethers of 5-hydroxybicyclo[2,2,1]hept-2-ene (IV)—an insignificant quantity of bis-addition products (IVa) is formed:

where R = C_4H_9, C_6H_{11}, $C_{10}H_{17}(\beta)$; C_6H_5, C_6H_4-t-C_4H_9.

For aryl vinyl ethers the total yield of the mono- and bis-addition products reached 95%. Vinyl sulphides also give addition products more readily than alkyl vinyl ethers[53,72], derivatives of 5-mercaptobicyclo[2,2,1]hept-2-ene (V) being formed, as well as bis-addition products (Va)

where R = C_2H_5, C_4H_9, C_6H_5.

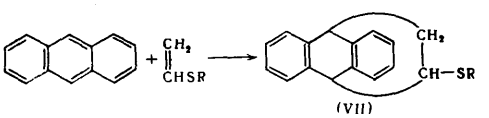
Heating at 160–165°C for 12 h leads to the formation of a mixture of mono- and bis-addition products with a total yield of 72–80%.



Earlier Alder and coworkers[73] obtained an addition product of cyclopentadiene with *p*-tolyl vinyl sulphide. Prilezhaeva and coworkers[74] state that ethyl vinyl sulphide did not give an addition product with cyclopentadiene at 110°C.

It has been reported[62] that the cyclic unsaturated ether 2,3-dihydrofuran does not form addition products with cyclopentadiene and 9,10-dimethylanthracene.

Shostakovskii and coworkers[71] showed that the reaction of vinyl ethers is stereospecific. In several instances they isolated two isomeric addition products, evidently corresponding to the *endo*- and *exo*-orientation of the reacting components, and showed that their ratio varied with the temperature.

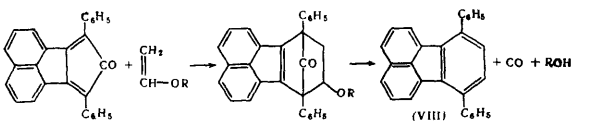


Anthracene, the central ring of which contains an active diene system, reacts rather readily with electron-withdrawing dienophiles. Thus, on boiling anthracene and maleic anhydride in benzene for 3 h, an addition product was obtained in 96% yield[66].

Shostakovskii and coworkers[75] studied the reaction of a series of vinyl ethers and sulphides with anthracene, at 220–240°C for 13–15 h. Phenyl vinyl ether was the most active. At higher temperatures the reaction products resinified, and at lower temperatures the reaction was retarded. Under these conditions addition products (VI) were obtained in yields from 66 to 90% on the anthracene participating in the reaction:

where R = C_4H_9, C_6H_{13}, C_6H_{11}, C_6H_5, *m*-$C_6H_4CH_3$, $C_{10}H_{21}$, $C_{10}H_{17}(\beta)$, and $C_{10}H_7(\beta)$.

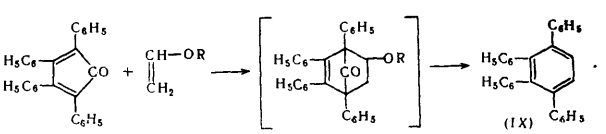
Condensation of anthracene with vinyl sulphides under analogous conditions at 180°C gave addition products (VII) in yields of ~ 65% on the anthracene undergoing reaction:



where R = C_2H_5, C_6H_5.

Hence here also the electron-donating properties of vinyl ethers and sulphides hinder the reaction of diene synthesis. Note that the authors give the yields of (VI) and (VII) on the anthracene entering into the reaction. Evidently the yields are considerably less than theoretical. For example, for n-hexyl vinyl ether the experimental results show that the yield of addition product is 46% of theoretical, whereas the yield on the anthracene entering into the reaction was 77.6%.

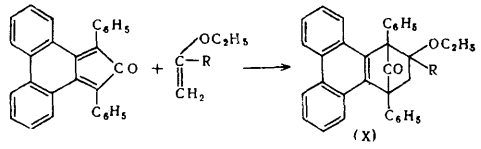
5. REACTIONS WITH SUBSTITUTED HYDROCARBON DIENES



Abramov and coworkers[76-78] studied the reaction of a series of vinyl ethers with various cyclones. These are dienes which contain an electron-withdrawing substituent (the C=O group). The presence of this group should diminish the nucleophilic nature of the diene system, possibly conferring on it to some extent an electrophilic nature. Actually, with electrophilic dienophiles such as maleic anhydride cyclones do not react as readily as cyclopentadiene. The reaction of cyclopentadiene with maleic anhydride starts at room temperature and is exothermic[79,80]. With a cyclone rather prolonged heating of the mixture of reagents is necessary[81]. On the other hand the reaction of cyclones with vinyl ethers takes place more readily than with cyclopentadiene, giving higher yields of addition products under analogous conditions. Thus, ethyl vinyl ether, which did not give an addition product with cyclopentadiene, gave addition product (VIII) in 77% yield with acecyclone[76]. Analogous addition products were obtained with butyl vinyl and phenyl vinyl ethers.

where R = C_2H_5, C_4H_9, C_6H_5.

The reactions take place on heating the reagents in sealed tubes at 180–200°C for 10–15 h, and are accompanied by loss of the *endo*-carbonyl bridge and the alcohol. It has been shown[76] that allyl derivatives and vinyl bromide react with acecyclone with great difficulty.

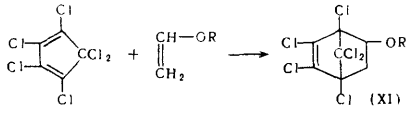


In the reaction with tetracyclone, carried out under analogous conditions[77] vinyl ethers were used: butyl vinyl, isopentyl vinyl, phenyl vinyl, and 1,2,3-trivinyloxypropane. These reactions take place by the equation:

In all the reactions 1,2,3,4-tetraphenylbenzene (IX) was obtained in good yield (74–86%).

Addition products of tetraphenylcyclone and acecyclone with ethyl 1-methylvinyl and ethyl 1-phenylvinyl ethers were obtained[78]. These condensations required more prolonged heating (up to 75 h).

Phencyclone reacts more readily than other cyclones with 1-substituted vinyl ethers[78], giving addition products with an *endo*-carbonyl bridge (X)



(X)

where R = CH_3, C_6H_5.

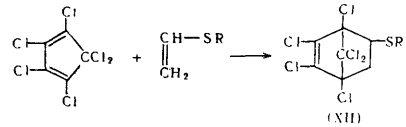
Of other dienes with electron-withdrawing substituents only the chloro-substituted dienes, mainly hexachloropentadiene, have been investigated in reactions with vinyl ethers and sulphides. Only one communication about the condensation of chloroprene with ethyl vinyl ether has been published[82], and in this the addition products could not be isolated from the reaction products.

Thanks to the presence of the electronegative chlorine atoms hexachlorocyclopentadiene has a diene system impoverished in electrons and therefore capable of showing electron-withdrawing properties. This can explain the much greater ease with which diene condensations proceed with nucleophilic dienophiles[62], including vinyl ethers. For example, with ethyl vinyl ether[83] hexachloropentadiene gave an addition product—1,2,3,4,7,7-hexachloro-5-ethoxybicyclo[2,2,1]hept-2-ene (XI)—in 36% yield on heating for 6 h at 80–90°C. Under analogous conditions an addition product is also obtained with isobutyl vinyl ether

(XI)

Analogous addition products were obtained with cyclohexenyl ethyl ether[84] on heating at 160°C for 8 h in a sealed tube.

By heating a mixture of phenyl vinyl ether and hexachlorocyclopentadiene at 120–130°C for 2 h, 1,2,3,4,7,7-hexachloro-5-phenoxybicyclo[2,2,1]hept-2-ene was obtained in 72% yield[69].



Addition products were also obtained with other aryl vinyl ethers, including naphth-2-yl vinyl and *p*-t-butylphenyl vinyl ethers[70].

Kalabina and coworkers[85] studied the reaction of vinyl ethers of *o*-, *m*-, and *p*-nitrophenols with hexachlorocyclopentadiene. These condensations proceed under more severe conditions in comparison with phenyl vinyl ether (in boiling xylene for 6.5 h) and give smaller yields of the addition products (11–15%).

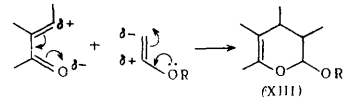
The condensation of divinyl ether with hexachlorocyclopentadiene takes place[86] at 120°C and leads to 1,2,3,4,7,7-hexachlorobicyclo[2,2,1]hept-2-en-5-yl vinyl ether.

2,3-dihydrofuran reacts with hexachlorocyclopentadiene at an appreciable rate[62], much more rapidly than maleic anhydride.

A series of addition products have been obtained from vinyl sulphides. Thus ethyl vinyl sulphide[74], which did not give an addition product with cyclopentadiene at 110°C, gave one with hexachlorocyclopentadiene at room temperature after 36 days—1,2,3,4,7,7-hexachloro-5-ethylmercaptobicyclo[2,2,1]hept-2-ene in 71% yield. In another study[72] this reaction was carried out at 100–105°C (3.5 h) and then addition product (XII) was obtained in 83% yield:

(XII)

where R = C_2H_5, C_6H_5.

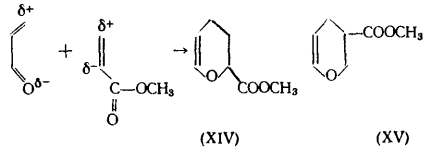


In the same work an addition product of hexachlorocyclopentadiene and phenyl vinyl sulphide was obtained (120°C, 3 h) in 71.5% yield.

In contrast to the electron-withdrawing substituents, electron-donating substituents of the diene system hinder the diene synthesis with vinyl ethers. Thus, furan and 2-methylfuran, which with maleic anhydride form addition products at room temperature in quantitative yields[86], did not give addition products with alkyl vinyl ethers even on heating at 280°C for many hours[87].

6. REACTIONS WITH HETERODIENES

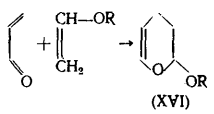
A. Reactions with Oxygen Heterodienes



In 1950 Longley and Emerson[88] found that acrylaldehyde and other $\alpha\beta$-unsaturated aldehydes and ketones, on reacting as dienes, readily add vinyl ethers in the 1,4-position, to form the addition products (XIII) in accordance with the polarity of the reagents. For example, with acrylaldehyde they obtained 2-alkoxy-derivatives of dihydropyran:

(XIII)

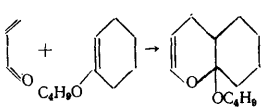
The reactions were carried out by heating mixtures of the components in a bomb in the presence of a little hydroquinone at 135–200°C for 12–30 h. The yields of addition products were 50–85%.



The diene systems of this type contain an electronegative oxygen atom, due to the polarisation of double bonds and imparting an electron-withdrawing character to the system as a whole. By this it was possible to explain the relative ease with which the condensation of such dienes with vinyl ethers is effected. These dienes also react with electron-withdrawing dienophiles, for example, with methyl acrylate[54]. As already stated above, here the reaction proceeds despite the polarity of the reagents and the addition product formed is 2-methoxycarbonyl-3,4-dihydro-2*H*-pyran (XIV) and not 3-methoxycarbonyl-3,4-dihydropyran (XV):

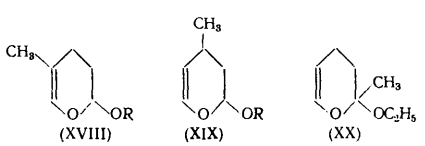
(XIV) (XV)

Hence although the presence of an oxygen atom also confers electron-withdrawing properties on the diene system, this system is capable of reacting also as electron-donating with dienes which exhibit strong electron-withdrawing properties.



Diene condensations between $\alpha\beta$-unsaturated aldehydes or ketones and vinyl ethers have been studied for many examples[88-91]. In the work mentioned[88] it was shown that acrylaldehyde, on reacting with various alkyl vinyl ethers, forms 2-alkoxy-3,4-dihydro-2*H*-pyran (XVI) in up to 84% yield:

(XVI)

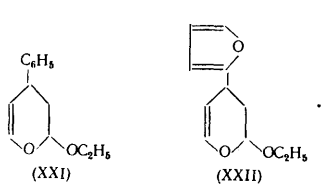


where R = CH_3, C_2H_5, C_4H_9, iso-C_4H_9.

In the reaction with butyl cyclohex-1-enyl ether the addition product obtained was 1-butoxy-2-oxabicyclo[4,4,0]dec-3-ene (XVII):

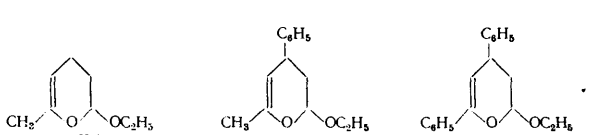
(XVII)

In the condensation of methylacrylaldehyde and crotonaldehyde with vinyl ethers 2-alkoxy-5-methyl- (XVIII) and 2-alkoxy-4-methyl- (XIX) 3,4-dihydro-2*H*-pyran are formed with yields of up to 87%:



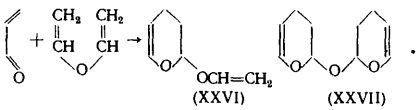
(XVIII) (XIX) (XX)

where R = CH_3, C_2H_5, C_4H_9, iso-C_4H_9.



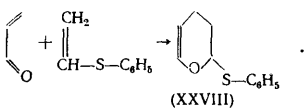
A low yield (25%) was obtained only in the condensation of methylacrylaldehyde with methyl vinyl ether. 2-Ethoxy-3,4-dihydro-2-methyl-2*H*-pyran (XX) was obtained in the condensation of acrylaldehyde with ethyl isopropenyl ether[88].

On condensation with ethyl vinyl ether, cinnamaldehyde and β(furfurylidene) acrylaldehyde give addition products (XXI) and (XXII) in 60–85% yield:



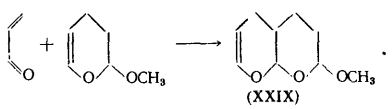
(XXI) (XXII)

On heating methyl vinyl ketone, benzalacetone, and benzalacetophenone with ethyl vinyl ether at 140–200°C for 13–16 h, derivatives of dihydropyran (XXIII), (XXIV), and (XXV) are obtained in yields of up to 75%:



(XXIII) (XXIV) (XXV)

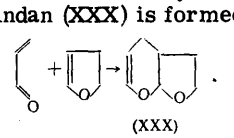
Independently of Longley and Emerson, Smith and coworkers[89] carried out a series of similar condensations, but under somewhat different conditions—they carried out the reaction at higher temperatures and for a shorter time, mainly by heating a mixture of the components without a solvent at 180°C for 1 h. The yields of addition products were as high. In addition, the authors studied the reaction of acrylaldehyde with divinyl ether and showed that here two addition products are formed—mono- (XXVI) and bis- (XXVII) addition products:



(XXVI) (XXVII)

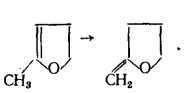
In addition, addition products of acrylaldehyde with phenyl vinyl ether and phenyl vinyl sulphide were obtained. The latter gave addition product (XXVIII) in 77% yield:

(XXVIII)



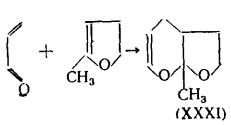
It was shown that the addition product of acrylaldehyde and methyl vinyl ether—3,4-dihydro-2-methoxy-2*H*-pyran—is capable of condensing with a second molecule of acrylaldehyde, giving (XXIX):

(XXIX)

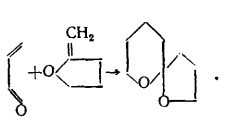


The structure of the addition products was shown by hydrolysis to the corresponding glutaraldehydes, and also by hydrogenation with subsequent hydrolysis of the tetrahydropyrans to 5-hydroxyvaleraldehyde and its derivatives.

Cyclic $\alpha\beta$-unsaturated ethers of the type of 4,5-dihydrofuran and 5,6-dihydropyran[92] under analogous conditions are readily condensed with $\alpha\beta$-unsaturated carbonyl compounds. Thus, on heating in an autoclave (140°C, 16 h) mixtures of 4,5-dihydrofuran and acrylaldehyde, 4,7,8,9-tetrahydro-1,7-dioxaindan (XXX) is formed:

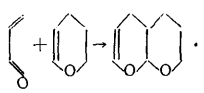


(XXX)



The condensation of 4,5-dihydro-2-methylfuran with acrylaldehyde under the same conditions is complicated by the isomerisation of the unsaturated ether into tetrahydro-2-methylenefuran:

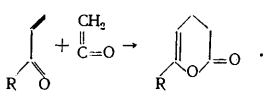
This leads to the formation of two addition products, (XXXI) and (XXXII), in the ratio 7 : 3, with a total yield of 39%:



(XXXI)

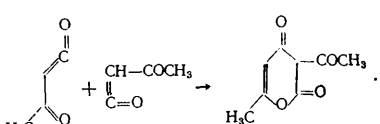
(XXXII)

Addition product (XXXII) is formed with a yield of 60% in the condensation of acrylaldehyde with pure tetrahydro--2-methylenefuran. The structure of the addition products was shown by hydrogenation and subsequent hydrolysis with a yield of the compounds described.



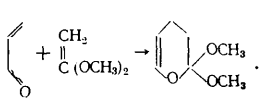
Dihydropyran was less active. On heating it with acrylaldehyde at 140°C for 15 h, Δ^2-octahydro-1,8-dioxanaphthalene (XXXIII) was obtained in only 15% yield:

(XXXIII)



Hydrolysis of (XXXIII) led to 2-(3-hydroxypropyl)glutaraldehyde.

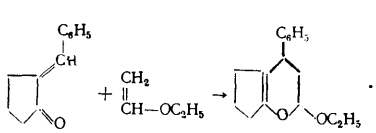
The condensation of a series of $\alpha\beta$-unsaturated carbonyl compounds with keten has been described[93]; these condensations proceed analogously to the reactions of alkyl vinyl ethers, leading to the δ-lactones (XXXIV):



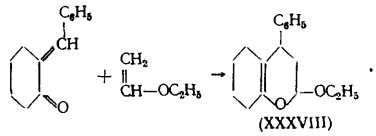
(XXXIV)

The dimerisation of diketen[94] proceeds by a diene synthesis scheme with formation of the addition product (XXXV):

(XXXV)



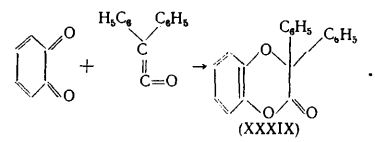
Condensations of a series of $\alpha\beta$-unsaturated aldehydes and ketones with keten dimethyl acetal [1,1-dimethoxyethylene] have been described[95]. With acrylaldehyde at 100°C, 5,6-dihydropyran-6-one dimethyl acetal (XXXVI) was obtained in 70% yield:



(XXXVI)

The condensation of cinnamaldehyde and benzalacetone with keten dimethyl acetal takes place at a higher temperature (150–200°C), giving the corresponding addition products with yields of 30–60%.

Heterodienes such as cyclic *o*-methyleneketones are also capable of the reactions of the diene synthesis with ethyl vinyl ether. It has been shown[96] that 2-benzylidenecyclopentanone and 2-benzylidenecyclohexanone with ethyl vinyl ether at 160–168°C form the corresponding addition products (XXXVII) and (XXXVIII) with yields of 38–52%:

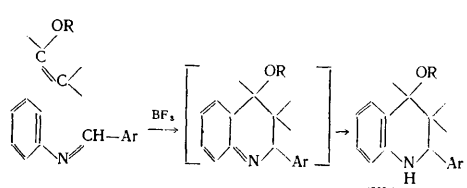


(XXXVII)

(XXXVIII)

The structure of these products was shown by conversion of (XXXVIII) into 4-phenylquinoline. 2-Arylideneindan-1,3-diones condense analogously with ethyl vinyl ether, forming addition products in yields of 43–49%.

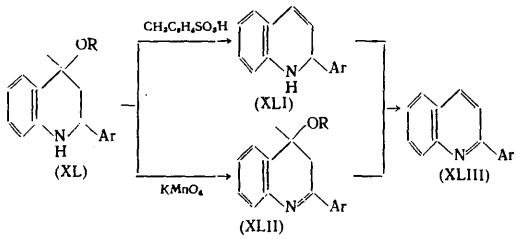
Diphenylketen was found capable[97] of being condensed with *o*-benzoquinone, the diene system of which contains two oxygen atoms:



(XXXIX)

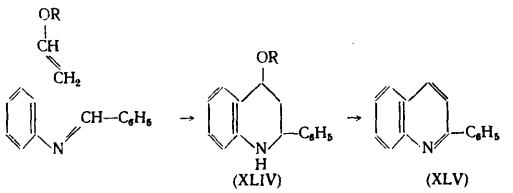
B. Reactions with Nitrogen Heterodienes

Almost the only known diene condensations of $\alpha\beta$-unsaturated ethers with nitrogen heterodienes are those with Schiff bases. In 1962 Povarov and Mikhailov [17,98] found that in the presence of boron trifluoride Schiff bases react readily with alkyl vinyl ethers to form addition products according to the diene synthesis scheme. It was shown subsequently that in the reaction with a Schiff base the dienophile can be ethoxyacetylene or keten [18], vinyl sulphide [18,99], the cyclic ethers 4,5-dihydro-2-methylfuran and dihydropyran [100,101], or cyclohexenyl ethyl ether [102]. A wide variety of Schiff bases with various substituents were used as dienes [101,103,104]. It was shown that the anils of non-aromatic aldehydes are also capable of participating in the reaction. For example, addition products were obtained with anils of cinnamaldehyde, citral, and cyclohexanone [101]. The anils of aliphatic aldehydes which are distinguished by a tendency to polymerisation are also capable of condensing with alkyl vinyl ethers at the moment of formation [105]. Apart from BF_3, $AlCl_3$ and $AlBr_3$ are also used as catalysts [19,101]. A diene synthesis between Schiff bases and alkyl vinyl ethers takes place in acetic acid which serves here as the catalyst [106]. The reactions were carried out in solvents such as ether, benzene, and ethyl acetate.



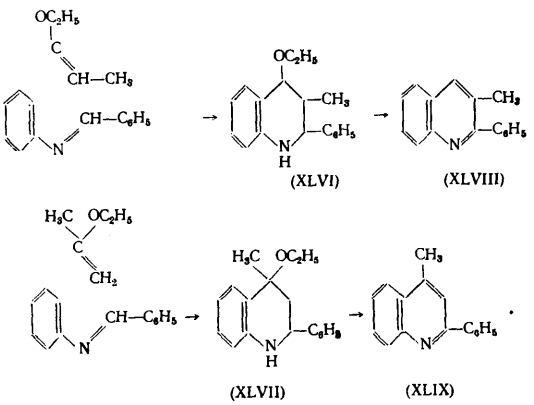
In the reaction of Schiff bases with alkyl vinyl ethers [17,107] derivatives of 4-alkoxy-2-aryl-1,2,3,4-tetrahydroquinoline (XL) are formed:

(XL)



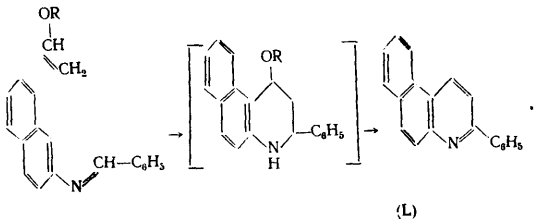
These compounds exhibit extremely weak basic properties; they do not give picrates and do not dissolve in dilute mineral acids. On heating with *p*-toluenesulphonic acid or under the action of oxidants they are converted into the corresponding derivatives of quinoline (XLIII). In the first instance alcohol is lost initially with the formation of 1,2-dihydroquinolines (XLI) and subsequently dehydrogenation takes place. In this part of the 1,2-dihydroquinoline molecule acts as an acceptor of hydrogen. Moreover, in

this example a polymer is formed as a result of the polymerisation of the 1,2-dihydroquinolines (XLI). The yields of quinolines here do not exceed 50%. Under the action of an oxidant ($KMnO_4$ in acetone), the hydrogen atoms in positions 1 and 2 are oxidised initially with the formation of 4-alkoxy-3,4-dihydroquinolines (XLII), then loss of an alcohol takes place readily, and the quinolines (XLIII) are formed with a yield of up to 90%:

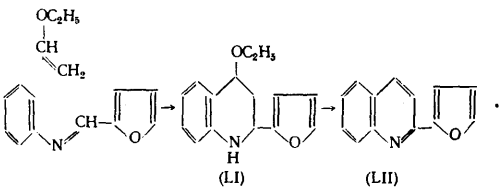


The partial loss of alcohol from addition products (XL) is observed during the reaction and during fractionation, which explains the formation in several instances of an appreciable polymeric residue and the drop in the yield of addition products.

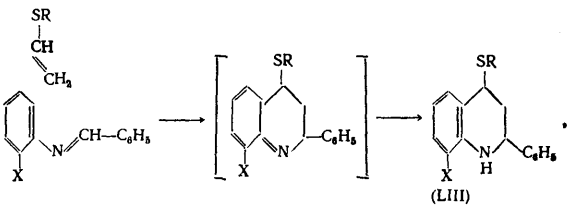
In the condensation of benzylidineaniline with ethyl vinyl, isopropyl vinyl, and butyl vinyl ethers, 4-alkoxy-2-phenyl-1,2,3,4-tetrahydroquinolines (XLIV) were obtained with yields of up to 60%. The structure of the addition products was shown by conversion into 2-phenylquinolines (XLV):



where R = C_2H_5, $CH(CH_3)_2$, C_4H_9.

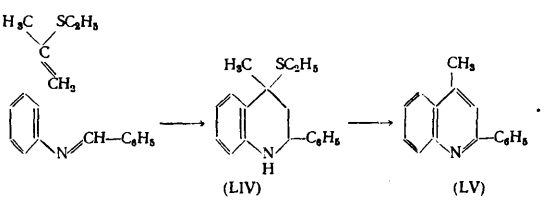


Ethyl prop-1-enyl and ethyl isopropenyl ethers gave respectively 3-methyl- (XLVI) and 4-methyl- (XLVII) 2-phenyltetrahydroquinolines, which were converted further into 3-methyl- (XLVIII) and 4-methyl- (XLIX) 2-phenylquinolines:

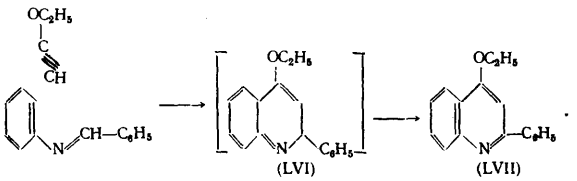


The yield of addition product (XLVII) was low because of the instability of the alkoxy-group at the tertiary carbon atom. The example of these condensations showed the structural directionality of the reaction. Addition products were obtained for alkyl vinyl ethers with a series of substituted benzylidene anils: salicylideneaniline, *o*-nitrobenzylideneaniline, benzylidene-*p*-bromoaniline, benzylidene-*p*-iodoaniline, benzylidene-*p*-anisidine, benzylidene-*p*-phenetidine, *N*-benzylideneanthranilic acid, etc. In several instances the intermediate tetrahydroquinolines (XL) were not isolated but the corresponding quinolines (XLIII) were obtained directly. For example, for benzylidene-2-naphthylamine 2-phenyl benzo[*f*]quinoline (L) is crystallised directly from the reaction mixture:

The condensation of furfurylideneaniline with ethyl vinyl ether led to 4-ethoxy-2-furyl-1,2,3,4-tetrahydroquinoline (LI) from which 2-furylquinoline (LII) was obtained in 36% yield:

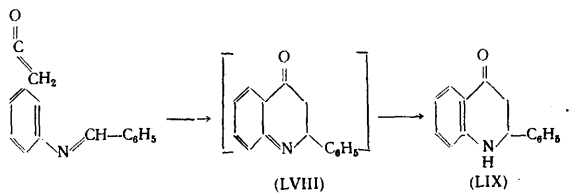


Alkyl vinyl sulphides react no less vigorously than alkyl vinyl ethers with Schiff bases [18,99]. Here the addition products formed are 4-alkylmercapto-1,2,3,4-tetrahydro-2-phenylquinolines (LIII) with yields of 40–60%:



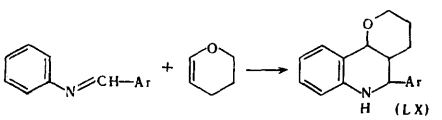
where R = C_2H_5, C_4H_9; X = H, CH_3, CO_2H.

The structure of the addition products was shown by converting them into the corresponding quinolines, which was brought about by heating with *p*-toluenesulphonic acid. This results in the loss of mercaptan and hydrogen. The structural directionality of the reaction was shown by the example of the condensation of benzylideneaniline with ethyl isopropenyl sulphide. The 4-ethylmercapto-1,2,3,4-tetrahydro-4-methyl-2-phenylquinolines (LIV) thus obtained gave, under the action of *p*-toluenesulphonic acid, 4-methyl-2-phenylquinoline (LV):



It was shown that the weaker the basicity of the Schiff bases the more readily they react with alkyl vinyl sulphides. Thus the condensation of benzylidene-*p*-anisidine and benzylidene-*p*-phenetidine, the basic properties of which are higher than those of benzylideneaniline, proceeded with difficulty. The only addition products isolated were 6-methoxy- and 6-ethoxy-2-phenylquinolines with yields of 6.6 and 34.7% respectively.

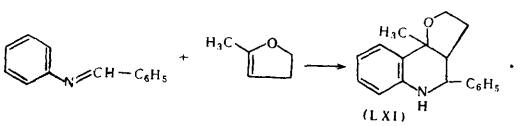
The reaction of ethoxyacetylene with benzylideneaniline[18] leads to 4-ethoxy-2-phenylquinoline (LVII). Addition product (LVI), which is produced initially in accordance with the diene synthesis scheme, is unstable and, on losing hydrogen, is converted into the stable compound (LVII):



(LVI) (LVII)

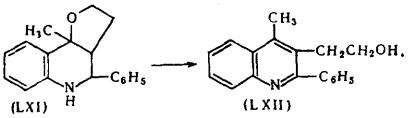
In the reaction of benzylideneaniline with keten[18] the addition product (LVIII) which is formed initially is isomerised into 2,3-dihydro-2-phenylquinol-4-one (LIX):

(LVIII) (LIX)



Cyclic ethers, such as dihydropyran and dihydrosylvan, are also capable of being condensed with Schiff bases. Dihydropyran[100] gave 2-aryl-3,4:3′,2′-tetrahydropyrano-1,2,3,4-tetrahydroquinolines (LX):

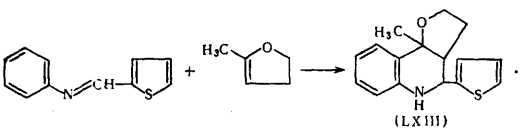
(LX)



where Ar = C_6H_5, 

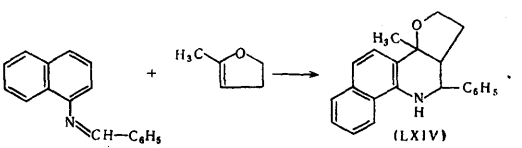
An especially active dienophile in relation to Schiff bases is dihydrosylvan, from which a large number of addition products was obtained, the yields reaching 70–80% in many instances. Usually the addition products are stable crystalline substances. Thus with benzylideneaniline[100], 4-methyl-2-phenyl-3,4:3′,2′-tetrahydrofurano-1,2,3,4-tetrahydroquinoline (LXI) was obtained in 81.3% yield:

(LXI)



By the action of $KMnO_4$ in acetone[108] on addition product (LXI) the hydrogen atoms in positions 1 and 2 are readily oxidised and the furan ring is opened to form 3-(2-hydroxyethyl)-4-methyl-2-phenylquinoline (LXII):

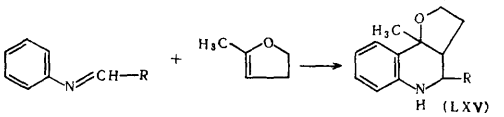
(LXI) (LXII)



Addition products of dihydrosylvan with various substituted Schiff bases have been obtained[100,101,103,104].

4-Methyl-2-(2-thienyl)-3,4:3′,2′-tetrahydrofurano-1,2,3,4-tetrahydroquinoline (LXIII) was obtained by the condensation of dihydrosylvan with thienylideneaniline[100]:

(LXIII)



With benzylidene-1-naphthylamine[100] addition product (LXIV) was obtained:

(LXIV)
