Phosphorus Fluorides

G.I.Drozd

Advances in the chemistry of compounds containing P–F bonds, published during the past three or four years, are surveyed. Methods of synthesising several novel and some previously known products containing phosphorus and fluorine are reported, together with their chemical properties and the results of structural investigations using optical spectroscopy, nuclear magnetic resonance spectroscopy, and electron diffraction. The Review covers recent investigations on the stereochemistry of fluorides of five-coordinated phosphorus, and also problems of the complexing power of P[III] and P[V] fluorides, which have been widely studied during recent years. Progress in the chemistry of the phosphorus fluorides will help to solve such important and continuing problems as the degree of hybridisation and the nature of the phosphorus-substituent bond in five-coordinated phosphorus compounds, the mechanism of chemical reactions involving phosphorus compounds of various coordination numbers, the possibility and the character of interference between substituents, etc. A list of 188 references is given.

CONTENTS

I. INTRODUCTION

In 1965 a review by Schmutzler appeared in the series "Advances in Fluorine Chemistry"[1], which surveyed the main results of investigations on the fluorides of phosphorus varying in coordination, made from the time of Moissan's discovery of phosphorus trifluoride to 1964 inclusive. The present Review is based on work published during 1965–1968, and reflects both the increasing intensity of research in this field and the shift in the centre of attention from fluorides of four-coordinated phosphorus P[IV] to compounds in which the coordination number of phosphorus is either three (P[III]) or five (P[V]). The latter feature depends upon the widespread possibilities of modern physicochemical methods for identifying and investigating structure. This has given the most significant results in the study of the stereochemistry of the molecules PF_5, CH_3PF_4, and $(CH_3)_2PF_3$, for which the previously suggested configuration of a trigonal bipyramid has been quite rigorously confirmed.

II. METHODS OF PREPARATION AND CHEMICAL PROPERTIES

1. Fluorides of Three-coordinated Phosphorus

Phosphorus trifluoride, mixed halides, and fluoride pseudohalides of P[III]. It has recently been proposed to prepare phosphorus trifluoride by double decomposition between the halides $PHal_3$ (Hal = Cl, Br) and salts of hexafluorosilicic acid[2], which are considerably more readily available than the fluorides of arsenic, antimony, lead, and calcium which are usually employed[1].

During this period, however, research workers have paid greater attention not to phosphorus trifluoride itself but to its derivatives XPF_2 (X = I, Br, Cl, CN, NCO, NCS), which open up possibilities for the preparation of interesting new compounds. In particular, immediately after Cavell's reported[3] preparation of phosphorus iodide difluoride by treating *NN*-dimethylphosphoramidous difluoride with hydrogen iodide, publications appeared[4-6] confirming his results and developing the chemistry of phosphorus iodide difluoride. Reaction of the latter with mercury yielded the previously unknown tetrafluorodiphosphine[6], attempts to prepare which from tetrachloro- or tetraiododiphosphine had been unsuccessful[7]. The preparation of tetrafluorodiphosphine was conducted in a vacuum (residual pressure ~50 mmHg), since at higher pressures the initial phosphorus iodide difluoride disproportionates into the trifluoride and the tri-iodide of phosphorus.

Analysis of the mass spectrum of tetrafluorodiphosphine led to the conclusion[6] that the product contained pyrophosphorous tetrafluoride as impurity, which might have been formed by the hydrolysis of tetrafluorodiphosphine:

$$2\,P_2F_4 + H_2O \rightarrow 2\,PHF_2 + F_2POPF_2\,.$$

This compound has been prepared from phosphorus iodide difluoride and copper(I) oxide[6,8]. It is unstable, and at room temperature it decomposes slowly in conformity with the equation

$$F_2POPF_2 \rightarrow PF_3 + (POF)_n\,.$$

Phosphorus iodide difluoride reacts with cuprous cyanide to form phosphorus cyanide difluoride[6]:

$$IPF_2 + CuCN \rightarrow PF_2CN + CuI\,.$$

This compound is stable only below 0°C. Above −20°C it probably undergoes exchange interactions with the more stable phosphorus trifluoride and phosphorus tricyanide.

The previously unknown phosphorus di-isothiocyanate fluoride has been obtained, together with the difluoride $P(NCS)F_2$, by exchange between the tri-isothiocyanate and antimony trifluoride[9]:

$$2\,P(NCS)_3 + SbF_3 \rightarrow F_2P(NCS) + FP(NCS)_2 + Sb(NCS)_3\,.$$

The quite substantial difference in the boiling points reported[9,10] for phosphorus isothiocyanate difluoride indicates that the earlier investigation[10] had dealt not with $P(NCS)F_2$ but with a phosphorus fluoride of greater coordination number—most probably $SP(NCS)F_2$.

Fluorides of the type XPF_2 (where X = Br, I, H) exhibit an interesting peculiarity on reaction with hexafluoroacetone. Unlike most other P[III] derivatives, which form 1 : 2 adducts, in which the coordination number of the phosphorus is five, these fluorides give with hexafluoroacetone 1 : 1 adducts having the structure of phosphorodifluoridous esters of the type $(CF_3)_2CX.OPF_2$.[11] Quite recently Lustig[12] has obtained $(CF_3)_2C(CN)OPF_2$ by the reaction between phosphorus bromide difluoride and hexafluoroacetone in the presence of sodium cyanide. This involves the initial formation of $(CF_3)_2C(CN)O^-Na^+$, which then reacts with $BrPF_2$ to yield the final product.

Phosphorofluoridous amides and esters. Synthetic work in this field is distinguished by a broader study of the chemical properties of derivatives of phosphorofluoridous acids, which previously had hardly been investigated.

An interesting result is obtained from the reaction of phosphorodifluoridous esters and amides with primary amines. In both cases hydrides of P[V] are among the main products[13,14]:

$$XPF_2 + H_2NR \rightarrow XF_2PH(NHR) \quad (X{=}OR,\ NR_2)\,.$$

Nevertheless, the phosphorus-31 nuclear magnetic resonance spectra indicate that no P[V] derivatives are formed in the reactions of amides R_2NPF_2 and esters $ROPF_2$ or $(RO)_2PF$ with alcohols. Only after prolonged heating of an alcohol and a phosphorofluoridous diester do signals from $(RO)_2POH$ appear in the spectra. Amides of phosphorodifluoridous acid react readily with alcohols even at room temperature, to form a series of P[III] derivatives, among which phosphorofluoridous diesters have been identified by their ^{31}P and ^{19}F n.m.r. spectra. When, however, the fluorides $ROPF_2$ are treated with secondary amines, at least three products—an amide R_2NPF_2, a phosphoramidous ester R_2NPFOR, and a diester $(RO)_2PF$—are formed. There are grounds for supposing that this reaction involves the initial formation of hydrides $RO(R_2N)PHF_2$, which at elevated temperatures may break down into R_2NPF_2 and $R_2N(RO)PF$, whereas the formation of diesters $(RO)_2PF$ may be a consequence of subsequent reactions in the phosphoramidous esters $R_2N(RO)PF$ in the multicomponent reaction mixture. The higher stability of hydrides containing an NHR group may be a consequence of intramolecular hydrogen bonding[13,14].

The addition of chlorine to phosphoramidous difluorides was first noted by Ivanova[15]. It has since been established[13,16,17] that chlorine and bromine form with these derivatives liquid 1 : 1 adducts, which in several cases can be distilled in a vacuum, their spectral characteristics indicating that they are P[V] derivatives. Furthermore, dimethylaminodichlorodifluorophosphorane has been obtained by treating the corresponding phosphoramidous difluoride with copper(II) chloride[16]:

$$(CH_3)_2NPF_2 + 2\,CuCl_2 \rightarrow \text{Complex} \rightarrow (CH_3)_2NPF_2Cl_2 + 2\,CuCl\,.$$

The formation of 1 : 1 adducts has been established also in the reactions of diamides $(R_2N)_2PF$ and amides $R(R_2N)PF$ with halogens, but the products are probably ionic, not pentacovalent structures[13,17]. It is obvious that 1 : 1 adducts are formed also in the initial stage of the interaction of P[III] fluorides with cyanogen bromide[13,18].

At temperatures up to 50−60°C amides and esters of phosphorofluoridous acids do not react with simple ketones. Nevertheless, the amides R_2NPF_2 and the diesters $(RO)_2PF$ react exothermally with hexafluoroacetone to form 1 : 2 adducts containing a five-coordinated phosphorus atom. Phosphorodifluoridous esters do not react with hexafluoroacetone under the same conditions[19]. As already mentioned, fluorides of the type XPF_2 (X = I, Br, H) form 1 : 1 adducts with hexafluoroacetone, which have been regarded as phosphorodifluoridous esters[11].

The condensation of cyclic phosphorofluoridous esters with diene hydrocarbons led to the isolation of four-coordinated phosphorus compounds[20], which are probably decomposition products of the initially formed P[V] fluorophospholens:

The first attempt to isolate difluorodihalogenophosphoranes of the type $ROPF_2X_2$ (X = Cl, Br) were unsuccessful[21], the reaction of phosphorodifluoridous esters with halogens yielding instead halide fluorides $XPOF_2$, which have since been proved[13] to be products of the rearrangement of the difluorodihalogenophosphoranes (P[V]):

$$ROPF_2 + Hal_2 \rightarrow ROPF_2Hal_2 \rightarrow HalPOF_2 + RHal \quad (Hal{=}Cl,\ Br).$$

More stable addition products are obtained from halogens and phosphorofluoridous esters containing ArO groups or the phosphorus atom in a five-membered phospholan ring.

Among work on the synthesis of phosphorofluoridous amides and esters themselves we must first note the development of a process for preparing the previously unknown amides $RN(PF_2)_2$, which have been obtained in good yield by the reaction of their chlorine-containing analogues with antimony trifluoride[22]. The same type of reaction has been used to synthesise several new dialkylamides of phosphorodifluoridous acid[15] and cyclic phosphorofluoridous esters[20]. A previously unknown phosphorodifluoridous ester has recently been obtained by Lustig[12] by means of the reaction

$$BrPF_2 + OC(CF_3)_2 + NaOCN \xrightarrow[-CO]{} (CF_3)_2C{=}NC(CF_3)_2{-}OPF_2\ .$$

Difluorophosphines and dialkylfluorophosphines. In 1965 Rudolph and Parry reported the synthesis of the first member HPF_2 of the series of difluorophosphines, by the reaction of phosphorus iodide difluoride with hydrogen iodide in the presence of mercury[23]:

$$F_2PI + Hg + IH \rightarrow HPF_2 + Hg_2I_2\ .$$

Later the same workers noted[6] that difluorophosphine is formed by the reaction of tetrafluorodiphosphine with water or with hydrogen iodide:

$$2\,P_2F_4 + H_2O \rightarrow 2\,HPF_2 + F_2POPF_2$$

$$P_2F_4 + HI \rightarrow HPF_2 + IPF_2\ .$$

Little work has yet been done on the chemical properties of difluorophosphine, although available information shows that they are unusual in the quite high lability of the P–H bond, as indicated both by the above reaction with hexafluoroacetone[11] and by the hydrolysis of difluorophosphine, the latter accompanied by the evolution of hydrogen[23]:

$$PHF_2 + H_2O \rightarrow HOPF_2 + H_2\ .$$

A theoretical yield of hydrogen is not obtained, this being attributed[23] to secondary processes accompanying the cleavage of P–F bonds.

Difluorophosphine is more basic than phosphine and phosphorus trifluoride towards borine. Its adduct $F_2PH.BH_3$ (b.p. 6.2°C) is stable to decomposition up to 25°C at a pressure of ~1 atm.[24] Under comparable conditions $F_3P.BH_3$ and $H_3P.BH_3$ will dissociate into the initial components.

The first alkyl(or aryl)difluorophosphines were described in 1959 by Kulakova and her coworkers[25]. However, owing to a misprint in this paper—the boiling point of $C_6H_5PF_2$ was printed 74–70°, whereas actually it is 74°C at 70 mmHg—the possibility of obtaining these compounds by reaction between their chloro-analogues and antimony trifluoride was open to doubt. A more detailed investigation of the reaction of alkyl(or aryl)dichlorophosphines with antimony trifluoride showed that, under certain conditions, it could be successfully used for the preparation of difluorophosphines. In particular, 80–85% yields of gaseous methyl- and ethyl-difluorophosphines are formed by the reaction of their chloro-analogues with the complex $SbF_3.2C_5H_5N$,[26,27] and high-boiling difluorophosphines can be obtained in 40–60% yield by exchange between the corresponding dichlorophosphines and antimony trifluoride in dialkylaniline in a vacuum[26,27].

The fluorophosphines CH_3PF_2 [29] and $(CH_3)_2PF$ [30] have been prepared by exchange between the chloro-analogues and the highly active potassium fluoride in a vacuum. Sodium fluoride has been successfully used in thiolan 1,1-dioxide medium for the preparation of $C_6H_5PF_2$.[31]

Fluorinated phosphines can be obtained also by the elimination of hydrogen fluoride from the hydrides $RPHF_3$ [26,32] and R_2PHF_2.[33] Better results are given by heating the monohydride aryltrifluorophosphoranes with potassium fluoride[26,32], whereas alkyldifluorophosphines could not be obtained in this way[26]. The elimination of hydrogen fluoride from unsubstituted alkyltrifluorophosphoranes and dialkyldifluorophosphoranes can be accomplished by means of tertiary amines[26,33], but the yields of the final compounds are low, since the reaction is accompanied by secondary processes.

In assessing existing methods for the preparation of fluorophosphines, we note that, in order to obtain gaseous compounds, it is advisable to use the reaction of chlorophosphines with the complex $SbF_3.2C_5H_5N$, which requires only simple apparatus and ensures high yields of the final products. For the preparation of high-boiling fluorophosphines it is more convenient to use the reaction between chlorophosphines and sodium fluoride in thiolan 1,1-dioxide, since in this case the purest fluorophosphines are obtained.

The study of the chemical properties of alkyldifluorophosphines has revealed that the reaction of three-coordinated phosphorus fluorides with reagents of the type H–X (where X = NHR, OR, F, Cl) may yield hydrides containing five-coordinated phosphorus[27,30,34-42]. The resulting hydrides $RPHF_2X$ vary greatly in thermal stability depending on the structure of the radical X. In particular, the hydrides $RPHF_2NHR$ [37,38], $RPHF_2OR$ [34-36], and $RPHF_3$ [39,40] can in several cases be distilled even at atmospheric pressure, whereas the hydrides in which X = NR_2, Cl [42] possess far lower thermal stability. Formation of the hydride $CH_3PHF_2SC_2H_5$ in a mixture of CH_3PF_2 and C_2H_5SH could not be detected at temperatures between −30° and +20°C by means of the ^{31}P n.m.r. spectra[41].

Both alkyl- and aryl-difluorophosphines add chlorine and bromine to form alkyl(or aryl)difluorodihalogenophosphoranes RPF_2Hal_2, which are extremely unstable even below 0°C, with a tendency to intermolecular exchange of ligands[13]. With rise in temperature the exchange processes become more intense, so that it is possible to isolate from the reaction mass alkyl(or aryl)tetrafluorophosphoranes and crystalline products approximating closely in composition to alkyl(or aryl)fluorotrihalogenophosphoranes[13,17].

Alkyl(or aryl)phosphonofluoridous amides and O- and S-esters. Compounds of this type have been described quite recently, and their chemical properties have not yet been adequately studied. The most detailed investigations have been made on alkyl(or aryl)phosphonofluoridous amides, rather less work has been done on O-alkyl alkylphosphonofluoridites, and the *S*-alkyl analogues of the latter have been the least studied.

It has been noted above that at low temperatures alkyldifluorophosphines form with secondary amines the hydrides $RPHF_2NR'_2$ [42], which, with rise in temperature to 50–60°C in the presence of excess of the amine, eliminate hydrogen fluoride to give 40–60% yields of *NN*-dialkylamides of alkylphosphonofluoridous acids. The same compounds can be obtained by treating the amides $RPClNR'_2$ [38,43] with antimony trifluoride or pentafluoride in an inert solvent (ether, benzene), but the results were more satisfactory when this exchange interaction was accomplished in a dialkylaniline, the products containing phosphorus and fluorine being distilled off under a vacuum[38]. Prolonged heating of the hydrides $RPHF_2NHR'$ with tributylamine gives 10–15% yields of monoalkylamides of alkylphosphonofluoridous acids[44]. The single example has also been reported of the synthesis of the *NN*-dibutylamide of methylphosphonofluoridous acid from methylchlorofluorophosphine and dibutylamine[38]. Most of the above reactions are suitable also for the synthesis of arylphosphonofluoridous amides. However, it has been noticed[28] that, although the products of the interaction of aryldifluorophosphines with secondary and even with primary amines contain signals from arylphosphonofluoridous amides in their ^{31}P n.m.r. spectra, vacuum distillation enables only their adducts with hydrogen fluoride to be isolated (the structure of the latter was not investigated).

Amides of alkyl(or aryl)phosphonofluoridous acids are relatively stable compounds: in sealed ampoules they can be kept for several months without any signs of change in structure. In air the substances are slowly oxidised to the corresponding alkyl(or aryl)phosphonofluoridic amides. Prolonged heating with antimony trifluoride oxidises them to alkyl(or aryl)trifluoroaminophosphoranes[38]. Like the phosphorofluoridous amides they form liquid 1 : 1 adducts with chlorine and bromine, which as a result of intermolecular exchange of ligands yield the trifluorophosphoranes $RPF_3NR'_2$, and on hydrolysis form the amides $RPOFNR'_2$ [17,45]. Hydrogen chloride causes rupture of the P–N bond in alkyl(or aryl)phosphonofluoridous amides with the formation of alkyl(or aryl)chlorofluorophosphines[27,38,46]. With α-diketones the alkylphosphonofluoridous amides form 1 : 1 products, which on the basis of spectral investigations are regarded as dioxophospholens containing a five-coordinated phosphorus atom[47].

O-Alkyl (or aryl) alkylphosphonofluoridites were first reported in 1968.[35,41] They can be obtained by—(1) treating the hydrides $RPHF_2OR'$ with ammonia or a tertiary amine[35,41], (2) the reaction of alkyldifluorophosphines with sodium alkoxides[48], or (3) exchange interaction between alkylphosphonochloridous esters and antimony trifluoride[48]—but in all cases the yields are low, since the reactions are accompanied by secondary reactions. The purest products are formed from difluorophosphines and sodium alkoxides[48].

Alkylphosphonofluoridous esters are oxidised comparatively easily by oxygen, and add sulphur to form the corresponding phosphonofluoridates[48]. In the presence of alkyl halides[49] or of halogens[50] they undergo a Michaelis–Arbuzov type of rearrangement, with the formation of dialkylphosphinic fluorides and alkylphosphonofluoridic halides respectively. Like other compounds containing a three-coordinated phosphorus atom, alkylphosphonofluoridous esters react with trifluoromethyl azide to form phosphazo-compounds $R(R'O)PF:NCF_3$.[51]

The only *S*-alkyl alkylphosphonofluoridite known at present has been obtained by the reaction of methyldifluorophosphine with butanethiol in the presence of triethylamine[52].

Complex compounds containing fluorides of three-coordinated phosphorus as ligands. In the general development of the chemistry of complex compounds comprehensive investigations have been made during recent years on a series of complexes containing fluorides of three-coordinated phosphorus as ligands. Methods of preparation, chemical and physical properties, structure, and spectroscopic results, as well as theoretical aspects of the problem of transition metal–PF_3 (ligand) complexes, have been discussed in a review by Kruck[53], who covered work published up to 1967 inclusive. Schmutzler's review[1] considers the same aspects of the chemistry of complex compounds containing other phosphorus-containing ligands as well as the trifluoride. We recommend that the reader, who wishes to be fully informed on this research, refer first to these two reviews[1,53], and the small amount of work not covered by them will be discussed below.

To estimate the electron-donor capacity of difluorophosphine Rudolph and Parry[24] studied its reaction with diborane to form the complex $HPF_2.BH_3$, which does not decompose below 25°C. The same complex can be obtained by substituting HPF_2 for the phosphorus-containing ligand in the complexes $F_3P.BH_3$ and $H_3P.BH_3$. Substitution of the PF_3 ligand takes place even between −78° and −45°C, whereas replacement of the PH_3 ligand requires considerably more severe conditions. From these results it was concluded[24] that HPF_2 is more basic than PF_3 and PH_3 towards the Lewis acid BH_3. This fact was explained on the hypothesis that difluorophosphine contains an intramolecular hydrogen bond (FHF interaction).

Tetrafluorodiphosphine reacts at 25°C with diborane to form the complex $P_2F_4.BH_3$. At room temperature this decomposes slowly in conformity with the equation[54]

$$F_2P{-}PF_2\cdot BH_3 \rightarrow F_3P\cdot BH_3 + (PF)_n,$$

Deewer and Ritter[55] have recently been able to obtain the relatively stable complex $B_2H_4(PF_3)_2$ by the reaction of B_3H_7 with PF_3. The reaction was conducted in dimethyl ether at −15°C under pressure (35 atm). The adduct $B_3H_7.O(CH_3)_2$, formed initially, then reacted with PF_3 to give diborane–bistrifluorophosphine. Hydrogenation of the latter yielded $BH_3.PF_3$.

Complexes of fluorides of three-coordinated phosphorus with zerovalent nickel NiL_4 are usually obtained from the corresponding phosphorus fluoride and tetracarbonylnickel[1,53,56]. A disadvantage of this method for obtaining NiL_4 complexes is the necessity of isolating them from a mixture of products of all degrees of substitution, which in several cases is a difficult task. A more convenient method in this respect is that proposed by Nixon, who prepared several such complexes by the reaction of π-dicyclopentadienylnickel with fluorides of three-coordinated phosphorus[57]:

$$\pi\text{-}(C_5H_5)_2\,Ni + 4\,X_n\,PF_{3-n} \rightarrow Ni\,(X_n\,PF_{3-n})_4 + (2\cdot C_5H_5)$$
$$X{=}F,\ CCl_3,\ (C_2H_5)_2\,N,\ C_5H_{10},\quad n = 1;\ X{=}CF_3,\ n = 1.\ 2$$

In order to prepare $Ni(PF_3)_4$ and $Pd(PF_3)_4$ Kruck et al.[58] used the direct reaction of the metals with phosphorus trifluoride in the presence of iodine as catalyst. Under the same conditions platinum gives only traces of $Pt(PF_3)_4$ with phosphorus trifluoride. When cobalt was treated under pressure with a mixture of phosphorus trifluoride and hydrogen, the hydride $HCO(PF_3)_4$ was obtained.

A large number of complexes of the type $Ni(CO)_nL_{4-n}$ (n = 0–3), $Mo(CO)_3L$ [$L = RPF_2$, $ROPF_2$, R_2NPF_2, $(RO)_2PF$, R_2PF, $R(R_2N)PF$, $(R_2N)_2PF$], and $Mn_2(CO)_n(PF_3)_{10-n}$ (n = 7–9) have been obtained by replacing carbonyl groups in the complexes $M(CO)_4$ (M = Ni, Mo) and $Mn_2(CO)_{10}$ by the appropriate phosphorus-containing ligands[56,57,59–61].

2. Fluorides of Four-coordinated Phosphorus

Phosphoryl fluoride, mixed halides and fluoride pseudohalide, phosphorofluoridic esters, and their derivatives. Fluorides of the type ZPF_nX_{3-n} (where Z = O, S; X = Cl, Br, NCO, NCS; n = 1–3) are usually obtained by double decomposition between ZPX_3 and the metal fluorides[1]. Phosphoryl and thiophosphoryl fluorides can also be obtained by the reaction of P_2O_5 and P_2S_5 with CaF_2, SF_4, HF, or IF_5.[1] These methods have been somewhat developed during recent years. In particular, the possibility has been reported of using fluorosilicates in the exchange reaction with the halides $ZPHal_3$ (Z = O, S) in order to obtain phosphoryl and thiophosphoryl fluorides. In view of the accessibility of the starting materials, this method can probably be used on an industrial scale. A 40% yield of phosphoryl fluoride has been obtained by heating a mixture of P_2O_5 and NF_3 (1 : 2) in a nickel autoclave to 480°C. However, the reaction is complicated by secondary processes leading to the formation of $NOPF_6$.[62]

Useful results have been obtained in the search for new methods of synthesising halide fluorides POF_2Hal (where Hal = Cl, Br), which will be convenient in laboratory practice. All three new reactions which can be used to obtain these compounds provide good yields and require only simple apparatus, so that the choice of method of synthesis in the laboratory may be governed merely by the availability of particular starting materials:

$$(1)\quad ROPF_2 \xrightarrow{Hal_2} OPF_2Hal + RHal\ ^{21}$$

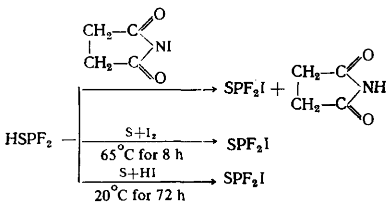
$$(2)\quad F_2POOOPF_2 \xrightarrow{PHal_5\ \text{или}\ MHal_3} OPF_2Hal\ ^{63}\quad (Hal{=}Cl,\ Br;\ \ M{=}Al)$$

$$(3)\quad HOPOF_2 \xrightarrow{PHal_5} OPF_2Hal + OPHal_3 + HHal\ ^{63}\ .$$

An attempt to prepare $OPIF_2$ by reaction (1) was unsuccessful. Nor was this product obtained on treating phosphorodifluoridic amides with hydrogen iodide. Although this compound is probably formed in the initial stages, only phosphorodifluoridous acid can be isolated, which, like $HSPF_2$ obtained in a similar manner, contains a four-coordinated phosphorus atom[64],[65]:

$$ZPF_2(NR_2) + 3\,HI \rightarrow ZPF_2H + R_2NH\cdot HI + I_2\quad (Z{=}O,S)\,.$$

Charlton and Cavell[66] have since reported that $SPIF_2$ can be obtained by treating phosphorodifluoridothious acid with the following reagents:



Thiophosphoryl iodide difluoride, unlike PIF_2, is thermally stable, and can be distilled at atmospheric pressure almost without decomposition. Only 5% of the substance had decomposed after the sample had been heated at 150°C for 4 days[66].

Treichell and his coworkers[67] reported that phosphorodifluoridous acid is formed also as a result of interaction between tetrafluorophosphorane and glass.

The chemistry of pseudohalide fluorides of P[IV] has been considerably extended during recent years. Roesky[63],[68-70] investigated the chemical properties of the tetrafluoride of pyrophosphoric acid, and found a convenient method of synthesising OPF_2NCS, $OPF(NCO)_2$, and OPF_2NCO, which consisted in reaction of the tetrafluoride with potassium isothiocyanate and isocyanate respectively. It was found that phosphoryl di-isothiocyanate fluoride is formed by disproportionation of the initially formed OPF_2NCS:

$$F_2POOOPF_2 \xrightarrow[25^\circ C\ \text{for}\ 12\ h]{KNCS} OPF_2(NCS)\quad (\text{yield } 50\%)$$

$$2\,OPF_2(NCS) \xrightarrow[65^\circ C\ \text{for}\ 1\ h]{} OPF(NCS)_2 + OPF_3.$$

Treatment of thiophosphoryl tri-isothiocyanate with antimony trifluoride at elevated temperatures yields thiophosphoryl fluoride isothiocyanates[9],[68]:

$$SP(NCS)_3 + SbF_3 \rightarrow SPF_2(NCS) + SPF(NCS)_2 + Sb(NCS)_3$$

and phosphoryl fluoride isocyanates have been obtained[71] by the reaction

$$OPCl(NCO)_2 \xrightarrow{SbF_3} OPF(NCO)_2 + OPF_2(NCO)\,.$$

An interesting method for obtaining OPF_2NCO, consisting in the reaction at elevated temperatures of silicon tetraisocyanate with phosphoryl trifluoride, has been proposed by Glemser and his coworkers[72], and a good yield of the di-isothiocyanate $SPF(NCS)_2$ is given by the reaction between $SPFCl_2$ and potassium isothiocyanate[73].

It should be noted that the boiling point given in Ref. 9 for SPF_2NCS is identical with that reported previously[10] for PF_2NCS, so that doubt is cast on the three-coordinated structure of the latter compound.

The new fluorides OPF_2OSO_2F and $OPF(OSO_2F)_2$, which are essentially mixed anhydrides of fluorosulphuric acid and the corresponding acids of phosphorus, have been obtained by heating $OP(OSO_2F)_3$ to 100°C for 2 h.[74]

Investigation of the chemical properties of P[IV] fluoride pseudohalides has shown that they react with alcohols and amines primarily at the NCO or NCS group[71],[73]:

$$OPF(NCO)_2 \;-\!\!\left[\begin{array}{l} \xrightarrow{ROH} OPF(NHCOOR)_2 \\ \xrightarrow{RNH_2} OPF(NHCONHR)_2 \end{array}\right.$$

$$RO(S)PF(NCS) \xrightarrow{RNH_2} RO(S)PF(NHCSNHR)\,.$$

NN'-Dialkoxy(or aroxy)carbonylphosphorodiamidic fluorides are able to react further with alcohols and phenols to give the corresponding phosphorodiamidate esters.

Phosphoryl difluoride isocyanate reacts similarly to the monofluoro-derivative with alcohols and amines. The resulting difluorides $OPF_2NHCONHAr$ on treatment with phosphorus pentachloride form *N*-difluorophosphonyl-*N'*-aryl-*C*-chloroformamidines. Similar treatment of OPFClNHCONHAr yields *N*-chlorofluorophosphonyl-*N'*-aryl-*C*-chloroformamidines[75]. These compounds are hydrolysed to phosphoric acid, although phosphorofluoridic acids may be formed at an intermediate stage:

$$ArNHC({=}NPOF_2)Cl + 5\,H_2O \rightarrow ArNH_2\cdot NF + NH_3\cdot NCl + HF + CO_2 + H_3PO_4.$$

Study of the chemical properties of phosphoryl and thiophosphoryl fluorides has shown that they react with alkali-metal fluorides to form salts containing the anions $[PO_2F_2]^-$ and $[PS_2F_2]^-$. The salt KPS_2F_2 can be obtained also, together with potassium hexafluorophosphate, by the reaction between thiophosphoryl chloride and potassium fluoride[76]:

$$2\,MF + 2\,ZPF_3 \rightarrow MPZ_2F_2 + MPF_6\quad (M{=}Cs,\ K;\ Z{=}O,\ S)$$

$$8\,KF + 2\,SPCl_3 \rightarrow KPS_2F_2 + KPF_6 + 8\,KCl\,.$$

The caesium salt $CsPS_2F_2$ has been used for the preparation of $(C_6H_5)_4AsPS_2F_2$ and $[(C_6H_5)_3P]_2NPS_2F_2$. Onium compounds of nitrogen, phosphorus, and arsenic containing the anion $[POSF_2]^-$ can be obtained by the reaction[77]

$$SPF_3 + (R_3R'Z)OH \rightarrow [R_3R'Z]^-[POSF_2)^-\quad (Z{=}N,\ P,\ As).$$

Ammonium salts containing the anions $[POSF_2]^-$ and $[PO_2SF]^{2-}$ have been obtained by treating with hydrogen fluoride salts containing the anions $[POSNH_2]^-$ and $[PO_2SNH_2]^{2-}$.[78] In water P_4S_{10} reacts with sodium fluoride[79] to form a salt containing the doubly charged anion $[S_2PF-S-PS_2F]^{2-}$.

An interesting reaction takes place between phosphoryl fluoride and difluorocarbene. The latter acts as both reducing and fluorinating agent, first adding to the P=O bond and then forming OCF_2 and PF_3 or F_4PCOF. It is assumed[80] that the latter compound is formed by migration of a fluorine atom from the carbonyl carbon to the phosphorus atom in the initially formed trifluorophosphorane

accompanied by cleavage of the P–O bond.

Among work on phosphorofluoridates the greatest interest attaches to the synthesis of the silyl esters and to the study of their chemical properties. Bistrialkyl(or aryl)-silyl phosphorofluoridates have been obtained by the reaction between silver phosphoromonofluoridate and the corresponding chlorosilanes[81]:

$$2\,R_2R'SiCl + Ag_2PO_3F \rightarrow (R_2R'SiO)_2POF + 2\,AgCl.$$

An analogous type of reaction has been used for the synthesis of silylene diphosphorodifluoridates[82]:

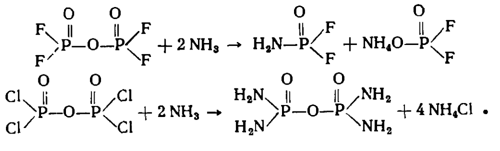
$$RR'SiCl_2 + 8\,NH_4PO_2F_2 \rightarrow RR'Si\,[OP(O)F_2]_2 + RR'Si\,[OP(O)F_2]\,F + RR'SiF_2.$$

It is interesting that with alkali-metal alkoxides silylene diphosphorodifluoridates yield salts of phosphorodifluoridic acid. The hydroloysis of silyl phosphorofluoridates is accompanied by the formation of fluorosilanes, disiloxanes, and $[PO_3F]^{2-}$ anions[81,82].

Several new phosphorofluoridates have been obtained by Roesky by the widely applied reaction of mixed halide fluorides of four-coordinated phosphorus with alcohols or thiols in the presence of tertiary amines[63].

Canadian workers[83] have described a new synthesis of dialkyl phosphorofluoridates based on cleavage of the P–N bond in phosphoroamidates by means of hydrogen fluoride. Phosphorofluoridates $(RO)_2PZF$ (where Z = O, S) can be obtained[84] by the reaction of salts of phosphorodithioic and the corresponding *SS'*-diethyl acids with aromatic and heterocyclic fluorides.

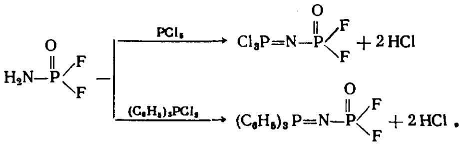
Heating the compound OPF_2OPOF_2 with ammonia leads to the formation of phosphoramidic difluoride and the salt $[NH_4]^+[PO_2F_2]^-$: i.e. the reaction involves cleavage of a P–O bond which has been weakened by the displacement of electrons towards the highly electronegative fluorine atoms[85]. This explanation for the rupture of a P–O bond in OPF_2OPOF_2 appears to be sound, since the compound $OPCl_2OPOCl_2$ reacts with ammonia without cleavage of such a bond[86,87]:



$$F_2P(O){-}O{-}P(O)F_2 + 2\,NH_3 \rightarrow H_2N{-}P(O)F_2 + NH_4O{-}P(O)F_2$$

$$Cl_2P(O){-}O{-}P(O)Cl_2 + 2\,NH_3 \rightarrow (H_2N)_2P(O){-}O{-}P(O)(NH_2)_2 + 4\,NH_4Cl\,.$$

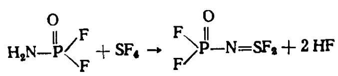
The compound H_2NPOF_2 obtained in this way has been used for the synthesis of phosphazophosphoryl fluorides[85]:



$$H_2N{-}P(O)F_2 \xrightarrow{PCl_5} Cl_3P{=}N{-}P(O)F_2 + 2\,HCl$$

$$H_2N{-}P(O)F_2 \xrightarrow{(C_6H_5)_3PCl_2} (C_6H_5)_3P{=}N{-}P(O)F_2 + 2\,HCl\,.$$

Glemser and his coworkers[88] obtained the compound $OPF_2N:SF_2$ from H_2NPOF_2 and sulphur tetrafluoride:



$$H_2N{-}P(O)F_2 + SF_4 \rightarrow F_2P(O){-}N{=}SF_2 + 2\,HF$$

The previously unknown aroxydifluorophosphazoiminoaryls[89] and alkoxydifluorophosphazosulphonylaryls[90] have been obtained by the reaction of phosphorodifluoridic esters with *N*-chloroarenamines and with dichloroamides of arenesulphonic acids respectively. The P–N bond in the first group of compounds is ruptured by the action of water, to give arenesulphonamides, and treatment with aqueous potassium carbonate yields the salts $ArSO_2NKPFOOR$, which can also be obtained by replacing a fluorine atom by an alkoxy-radical in potassium arenesulphonylamidophosphorodifluoridates[90].

Several new phosphorofluoridates of the type $(CF_3)_2CXOPZF_2$ (X = CN, N_3 and Z = O, S) have recently been obtained by Lustig[12] by the reactions

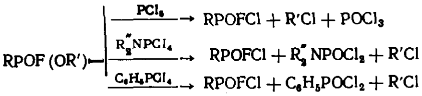
$$ZPF_2Br + [(CF_3)_2C(CN)O]^-\,Na^+ \rightarrow (CF_3)_2C(CN){-}O{-}P(Z)F_2 + NaBr$$
$$(Z{=}O,\ S;\ \text{yield } 60{-}87\%)$$

$$OPF_2Br + [(CF_3)_2CO + NaN_3] \rightarrow (CF_3)_2C(N_3){-}O{-}P(O)F_2 + NaBr\,.$$
$$(\text{yield } 64\%)$$

The above compounds have been characterised by nuclear magnetic resonance using the ^{31}P and ^{19}F nuclei, by their infrared spectra, and by their mass spectra; there is no doubt about their structure.

A recent paper by Shreeve[91] records the preparation of $SPIF_2$ by the addition of sulphur to PIF_2 at 80–90°C (duration of contact of reactants 1 h). The yield of the final product was ~50%, which is extremely surprising in view of the tendency of PIF_2 to disproportionate at elevated temperatures.

Fluorides of four-coordinated phosphorus containing a C–P bond. Here we must first note the development of new syntheses of mixed halides of alkylphosphonic acids and the investigation of their chemical properties. Good yields of CH_3POClF, C_6H_5POClF, and also several previously unknown chloride fluorides have been obtained by the reaction of alkylphosphonofluoridic esters with the chlorides $XPCl_4$ (X = Cl, R_2N, C_6H_5):[92]



$$RPOF(OR') \xrightarrow{PCl_5} RPOFCl + R'Cl + POCl_3$$

$$RPOF(OR') \xrightarrow{R''_2NPCl_4} RPOFCl + R''_2NPOCl_2 + R'Cl$$

$$RPOF(OR') \xrightarrow{C_6H_5PCl_4} RPOFCl + C_6H_5POCl_2 + R'Cl\,.$$

When phosphorus pentachloride is used, the temperature of the reaction mass must be kept between 30° and 40°C, since considerable quantities of the dichlorides $RPOCl_2$ are formed at higher temperatures. Under laboratory conditions the choice of a particular chloride $XPCl_4$ is governed not only by its accessibility but also by the relative boiling points of the phosphorus-containing products formed. In particular, it is inadvisable to use phosphorus pentachloride to obtain chloride fluorides $RPOClF$ whose boiling points are close to that of phosphoryl chloride, which would make it difficult to separate the final products by distillation.

The same workers[92] have used the reaction

$$RPSF(OR') + Cl_2 \rightarrow RPOFCl + SCl_2 + R'Cl$$

to obtain alkylphosphonic chloride fluorides. This probably involves the intermediate formation of the dichlorofluorophosphorane $RPCl_2FOR'$ (as is observed in the reaction of the amides R_2NPSF_2 with chlorine), which, being unstable, splits off R'Cl to form $RPOClF$.

Under the influence of thionyl chloride, phosphorus pentachloride, or phosphorus pentabromide alkylphosphonofluoridic acids, like phosphorodifluoridic acid[63], are able to replace their hydroxyl by Cl or Br, to form the corresponding mixed halides RPOHalF, among which the bromine-containing products can be obtained also by treating alkylphosphonofluoridous esters with bromine[50,92]:

$$\mathrm{RPOF(OH)} \xrightarrow{\mathrm{SOCl_2}} \mathrm{RPOFCl}$$
$$\mathrm{RPOF(OH)} + \mathrm{PBr_5} \rightarrow \mathrm{RPOFBr} + \mathrm{HBr} + \mathrm{OPBr_3}$$
$$\mathrm{RPF(OR')} + \mathrm{Br_2} \rightarrow [\mathrm{RPFBr_2(OR')}] \rightarrow \mathrm{RPOFBr} + \mathrm{R'Br}.$$

On hydrolysis all the fluorides RPOHalF (where Hal = F, Cl, Br) produce initially alkylphosphonofluoridic acids, these being followed by alkylphosphonic acids[50]. The differing activities of the halogen atoms in alkylphosphonic chloride fluorides have been used in the preparation of the previously unknown alkylphosphonisocyanatidic and alkylphosphon(isothiocyanatidic) fluorides[92]:

$$\mathrm{RPOFCl} - \begin{cases} \xrightarrow{\mathrm{NaOCN}} \mathrm{RPOF(NCO)} + \mathrm{NaCl} \\ \xrightarrow{\mathrm{KSCN}} \mathrm{RPOF(NCS)} + \mathrm{KCl}. \end{cases}$$

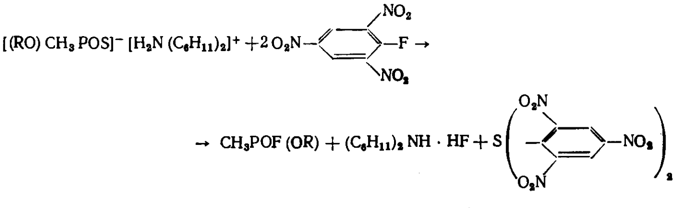
The yield of alkylphosphon(isothiocyanatidic) fluorides exceeds 50% in this reaction, whereas, among the considerably more unstable derivatives containing an isothiocyanato-group, only $\mathrm{CH_3PO(NCS)F}$ has been isolated, in 10% yield.

Trichloromethylphosphonisocyanatidic fluoride has been obtained by double decomposition between $\mathrm{CCl_3PO(NCO)Cl}$ and antimony trifluoride. The use of excess of the latter reagent makes it possible to conduct the reaction so that it yields exclusively trichloromethylphosphonic difluoride[93] (the latter is formed as a byproduct in the reaction of $\mathrm{Cl_3CPCl_4}$ with antimony trifluoride).

Investigation of the chemical properties of the alkylphosphonisocyanatidic and alkylphosphon(isothiocyanatidic) fluorides has shown that their reactions with primary amines and alcohols involve firstly the NCO and NCS groups[92,93]:

$$\mathrm{RPOF(NCO)} - \begin{cases} \xrightarrow{\mathrm{ArNH_2}} \mathrm{RPOF(NHCONHAr)} \\ \xrightarrow{\mathrm{R'OH}} \mathrm{RPOF(NHCOOR')} \end{cases}$$
$$\mathrm{RPOF(NCS)} \xrightarrow{\mathrm{ArNH_2}} \mathrm{RPOF(NHCSNHAr)}.$$

An interesting synthesis of alkyl methylphosphonofluoridates has been suggested recently by Boter and Berg[94], who used the reaction between the ammonium salts $[(\mathrm{C_6H_{11}})_2\mathrm{NH_2}]^+[\mathrm{CH_3PSOOR}]^-$ and fluorotrinitrobenzene:



This method has been successfully used[94] to prepare t-butyl methylphosphonofluoridate, which is difficult to obtain by other methods, since it decomposes appreciably even at room temperature.

Several new phosphonofluoridates containing P–O–El bonds (where El = Si, Ge, As) have been obtained by the reaction of methylphosphonic difluoride with oxides of the type $\mathrm{R_nEl{-}O{-}ElR_n}$.[95]

3. Fluorides of Five-coordinated Phosphorus

Phosphorus pentafluoride and the mixed halides $\mathrm{PHal_nF_{5-n}}$ ($n = 1-4$). Phosphorus pentafluoride is usually obtained[1] by double decomposition between the pentachloride and such fluorides as $\mathrm{AsF_3}$, HF, AgF, and $\mathrm{C_6H_5COF}$. In the laboratory it is convenient to use the reaction between phosphorus pentachloride and antimony pentafluoride, which guarantees a relatively high yield of the final product[13]. The recently patented[2] preparation by treating phosphorus pentachloride with salts of hexafluorosilicic acid is evidently a promising method for industrial application.

Phosphorus trifluoride is readily oxidised[1] to the pentafluoride by elementary fluorine, molybdenum hexafluoride, and $\mathrm{O_2F_2}$. Lustig showed[96] that difluorohydrazine also reacts under comparatively mild conditions (room temperature for 17 h) with phosphorus trifluoride to form the pentafluoride. It is interesting that phosphoryl fluoride can also be converted into phosphorus pentafluoride by the action of difluorohydrazine:

$$\mathrm{PF_3} + \mathrm{N_2F_2} \rightarrow \mathrm{PF_5} + \mathrm{N_2}$$
$$\mathrm{OPF_3} + \mathrm{N_2F_2} \rightarrow \mathrm{PF_5} + \mathrm{N_2} + \mathrm{O_2}.$$

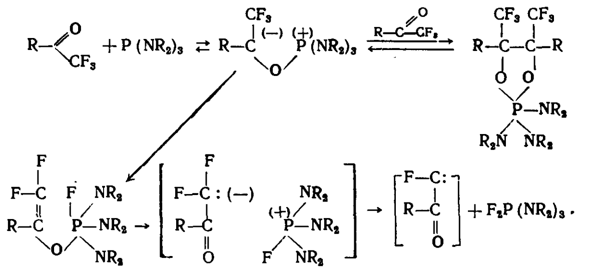
Among the mixed halides $\mathrm{PHal_nF_{5-n}}$ those in which n has the values 1 and 4 have been the least studied. Only in 1965 did Carter and Holmes[97] obtain $\mathrm{PClF_4}$ by the reaction of $\mathrm{PCl_2F_3}$ with antimony trifluoride. Phosphorus chloride tetrafluoride is a gas having an extrapolated boiling point of –43.4° and a melting point of –132°C. When kept at room temperature, it slowly decomposes to form a solid deposit on the walls of the vessel together with gaseous phosphorus pentafluoride and phosphorus dichloride trifluoride. It has since been shown[13,98] that $\mathrm{PClF_4}$ and $\mathrm{PBrF_4}$ can be obtained from dialkylaminotetrafluorophosphoranes and the corresponding hydrogen halides. It has not proved possible to obtain $\mathrm{PIF_4}$ by this method.

Phosphorus tetrachloride fluoride was first obtained by Kolditz[99] by the vacuum sublimation of $[\mathrm{PCl_4}]^+[\mathrm{PF_6}]^-$. The product exists in two forms—covalent and ionic $[\mathrm{PCl_4}]^+\mathrm{F}^-$—and the former can be converted into the latter merely when allowed to warm to room temperature from –40° to –50°C, at which the covalent form is preserved for quite a long time. The compound was obtained directly in the ionic form by Kesavadas and Payne[100] by the gas-phase reaction of phosphorus trichloride with fluorine in nitrogen. The structure $[\mathrm{PCl_4}]^+\mathrm{F}^-$ is supported by X-ray examination.

Many papers have appeared during recent years on the donor–acceptor properties of phosphorus pentafluoride and some of its derivatives. Investigation of the reaction of the pentafluoride with secondary amines has confirmed the initial formation of 1 : 1 adducts, which at high temperatures yield dialkylaminotetrafluorophosphoranes[101]. With excess of the secondary amine bisdialkylaminotrifluorophosphoranes can also be obtained[13,101]. The original conclusion reached by Brown and his coworkers[102], that only bisdimethylaminotrifluorophosphorane can be obtained in this way, is incorrect, since the corresponding bisdiethylamino-derivative has been obtained by heating a mixture (1 : 4) of phosphorus pentafluoride and diethylamine from –180° to 110–130°C.[13]

As a consequence of the sharp decrease in electron-acceptor power on passing from phosphorus pentafluoride to bisdialkylaminotrifluorophosphoranes, the latter do not react with secondary amines even at 100–120°C.[13,101] The triaminodifluorophosphoranes which might be expected in this reaction have been obtained in a different way—by treating the amides $(\mathrm{R_2N})_3\mathrm{P}$ with fluorinated ketones[103,104]—the initially formed 1 : 1 adducts being able below 0°C to add a further molecule of the ketone to form dioxophospholans containing a five-coordinated phosphorus atom.

Above 100°C the 1 : 1 adducts undergo reduction and defluorination to yield trisdialkylaminodifluorophosphoranes:



The adducts formed by phosphorus pentafluoride with trimethylamine and acetonitrile, as well as the adducts $AsF_5.CH_3CN$ and $SbF_5.CH_3CN$, are electrically conducting, this being explained[105] by self-ionisation:

$$2AF_5 \cdot L \rightleftarrows AF_4L_2^+ + AF_6^- \quad (A{=}P,\ Sb,\ As).$$

From a study of the ^{19}F nuclear magnetic resonance spectra, however, Tebbe and Muetterties concluded[106] that no appreciable self-ionisation occurs in these systems. Their results seem to be convincing, and the electrical conductivity of the complexes investigated by Kolditz and Rehak was probably due, not to self-ionisation, but to ionisation resulting from the initial formation of an F^- ion (this may be caused by partial hydrolysis of the complexes), which attacks the complexes by an S_N1 or S_N2 mechanism.

Phosphorus pentafluoride forms an adduct with thiolan. Determination of the molecular weight of the adduct has shown that ~ 50% of the pentafluoride is bound into a 1 : 1 complex. The ^{19}F n.m.r. spectrum indicates complete loss of P–F splitting in this complex, which may be due to partial ionisation of the pentafluoride with rapid exchange of ligands between ionised and non-ionised forms[107].

The adducts $(CH_3)_2O.PF_5$ and $(CH_3)_2S.PF_5$ both undergo rearrangement even at room temperature in conformity with the equation[108]

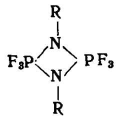
$$3(CH_3)_2O \cdot PF_5 \rightarrow 2[(CH_3)_3O]^+[PF_6]^- + POF_3$$
$$3(CH_3)_2S \cdot PF_5 \rightarrow [(CH_3)_3S]^+[PF_6]^- + [(CH_3)_2SSCH_3]^+[PF_6]^- + PF_3\,.$$

Several properties of the resulting saltlike compounds have been studied[108]. The oxonium compound $[(CH_3)_3O]^+[PF_6]^-$ reacts with acetone and dimethylformamide. It dissolves satisfactorily in acetonitrile, but in time reacts even with this solvent. It reacts with water with the evolution of hydrogen fluoride. The n.m.r. spectra of a rapidly cooled acetonitrile solution indicate the formation of a saltlike product $[(CH_3)_2CN]^+[PF_6]^-$.

Aminofluorophosphoranes and aminofluorohalogenophosphoranes. It has already been noted that dialkylaminotetra- and bisdialkylaminotri-fluorophosphoranes have been obtained by the reaction between phosphorus pentafluoride and secondary amines[101], and trisdialkylaminodifluorophosphoranes by interaction of the corresponding phosphorous amides with $(CF_3)_2CO$ or $CF_3COC_6H_5$.[103,104] Dialkylaminotetrafluorophosphoranes are formed also as a result of intermolecular exchange of ligands in the difluorodihalogenophosphoranes $R_2NPHal_2F_2$ (where Hal = Cl, Br).[13,45] Treatment of the latter with antimony pentafluoride in a solvent while the temperature is gradually raised from –30° to 20–25°C may give 30–70% yields of the dialkylaminotetrafluorophosphoranes[13]. The quite considerable fluctuations in the yield of the final products are probably associated with the thermal stability of the initial dialkylaminodifluorodihalogenophosphoranes, which increases appreciably on passing from the brominated to the chlorinated products, and reaches a maximum in the fluorophosphoranes

(the fluorophosphoranes $R_2NPF_2Cl_2$, where R = CH_3, C_2H_5, C_4H_9, are less stable at corresponding temperatures).

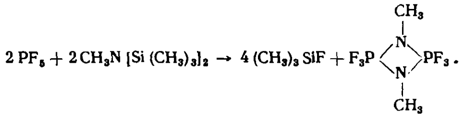
A more detailed investigation of the interaction between phosphorus pentafluoride and primary amines has recently been reported[109]. Compounds $RNHPF_4$ cannot be isolated or even detected here, cyclic derivatives of the type



and salts $[RNH_3]^+[PF_6]^-$ being formed. Dehydrofluorination of the adduct $NH_3.PF_5$ by means of triethylamine gives a low yield of phosphonitrile fluoride, the main product being a partly dehydrofluorinated oil.

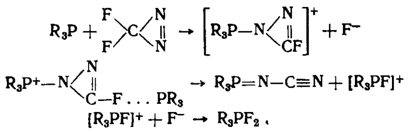
The reaction of dialkylaminodifluorodihalogenophosphoranes with secondary and primary amines gives the corresponding triaminodifluorophosphoranes[13]. The trifluorophosphoranes $(R_2N)_2PF_3$ or R_2NPF_3NHR' were also isolated, their formation evidently being a consequence of intermolecular exchange of ligands either in the final triaminodifluorophosphoranes during distillation or in the intermediate chlorodifluorophosphoranes $(R_2N)_2PClF_2$ or R_2NPClF_2NHR'. The trifluorophosphoranes R_2NPF_3NHR' can be obtained also by the reaction between dialkylaminotetrafluorophosphoranes and primary amines.

The reaction of phosphorus pentafluoride with silazanes can be successfully used to obtain aminofluorophosphoranes. Dimethyl- and diethyl-aminotetrafluorophosphoranes have been obtained in this way[110,111]. The reaction involves intermediate formation of a 1 : 1 adduct stable at –78°C. At room temperature the adduct breaks down into R_2NPF_4 and R_3SiF. 2,2,2,4,4,4-Hexafluoro-1,3-dimethyl-1,3-diazadiphosphetan can easily be obtained by a reaction of similar type[110]:



A large number of fluorophosphoranes, including some containing R_2N, RO, RS, and mixed functional groups attached to the phosphorus atom, have been obtained by reaction of the corresponding P[III] derivatives with difluorodiazirine[112]:

where R = Alk, Ar, RO, RS, R_2N. The amide $[(CH_3)_2N]_3P$ reacts the most easily with difluorodiazirine (at –78°C), with the formation of $[(CH_3)_2N]_3PF_2$ (the same worker[112] obtained the product by the reaction of $[(CH_3)_2N]_3P$ with tetrafluorohydrazine). Compounds containing more electronegative substituents react under more severe conditions with difluorodiazirine. The reaction is assumed to have an ionic mechanism, in conformity with the probable scheme



The fact that phosphorodifluoridous amides are able to add chlorine to form adducts, which can be converted by sulphur dioxide into phosphorodifluoridic amides, was first noted by Ivanova[15]. Later work has established that both chlorine and bromine, in a solvent at low temperatures, react with the amides R_2NPF_2 [13,16,17], $(R_2N)_2PF$ [13,17,45], and $RPFNR_2$ [13,17,45] to give 1 : 1 adducts, in most cases liquid and soluble in the usual organic solvents, among which the chlorinated adducts $(CH_3)_2NPCl_2F_2$, $(C_2H_5)_2NPCl_2F_2$, and

have been isolated in the pure state by distillation[13,17]. The phosphorus-31 n.m.r. spectra confirm the pentacovalent structure of the adducts $R_2NPHal_2F_2$ (Hal = Cl, Br), but saltlike structures of the type $[X_2PHalF]^+Hal^-$ are more probable in the case of the adducts $(R_2N)_2PHal_2F$ and $RPHal_2FNR_2$.

All the above addition products can be kept satisfactorily only below 0°C. At room temperature they undergo intermolecular exchange of ligands, with the formation of both mixed fluorohalogenophosphoranes and phosphoranes containing only one halogen. The fluorine-19 n.m.r. spectra have shown[45] that diethylaminodibromodifluorophosphorane forms the bromotrifluorophosphorane $(C_2H_5)_2NPBrF_3$ and the tetrafluorophosphorane $(C_2H_5)_2NPF_4$ as a result of exchange. The adducts $RPHal_2FNR_2$ gradually form trifluorophosphoranes RPF_3NR_2 and probably the halides $RPHal_3NR_2$ even below 0°C. Exchange processes are appreciably accelerated by raising the temperature to 40–60°C, and at 100–150°C phosphorus(III) halides in particular are formed, evidently as a result of redox reactions.

Emeléus and Onak have recently proposed[113] a new synthesis of aminofluorohalogenophosphoranes, consisting in the reaction of P[III] fluorides with compounds containing a nitrogen–chlorine bond. They have obtained the previously unknown fluorohalogenophosphoranes $(CF_3)_2NPClF_3$ and $(CF_3)_2NPCl_2F_2$ by the reaction of *N*-chlorobistrifluoromethylamine with phosphorus trifluoride and phosphorus chloride difluoride.

Several investigations have shown[13,16,17,113] that the hydrolysis of aminofluorodihalogenophosphoranes results in formation of the corresponding phosphorofluoridic amides. The same products result from the interaction of these phosphoranes with carboxylic anhydrides. The reaction of $(C_2H_5)_2NPClF_2$ with ethanethiol in the presence of triethylamine yields the difluorophosphorane $(C_2H_5)_2NPF_2(SC_2H_5)_2$, and interaction of the same difluorodihalogenophosphorane with alcohols in the presence of tertiary amines produces the fairly unstable fluorophosphoranes $R_2NPF_2(OR')_2$.[13] Monitoring both reactions by means of the n.m.r. spectra revealed also partial formation of the amides R_2NPXF_2 (X = O, S), which may be due to rearrangement of the products of the first stage of substitution:

$$R_2NPF_2Cl_2 \xrightarrow{HXR',\ NR'''_3} R_2NPF_2Cl(XR') \rightarrow R_2NP(X)F_2 + R'Cl \quad (X{=}O,\ S).$$

On treatment with antimony trifluoride, adducts of all types form either tetra- or tri-fluorophosphoranes[13]. The same type of interaction has been used[13] for the synthesis of $(C_2H_5)_2NPF_3CN$ from $(C_2H_5)_2NPBrF_2CN$, and Clune and Cohn[18] have isolated $(CH_3)_2NPF_3CN$, formed by the disproportionation of $(CH_3)_2NPBrF_2CN$.

Fluorophosphoranes containing a C – P bond. The most widely used syntheses of fluorophosphoranes containing a carbon–phosphorus bond have been described in Schmutzler's reviews[1,114]. However, immediately after publication of these reviews Treichel and Goodrich proposed[115] a new and extremely promising synthesis of alkyltetrafluorophosphoranes based on the reaction between phosphorus pentafluoride and tetra-alkyl stannates. Yields of 15–19% of methyltetrafluorophosphorane are obtained when the duration of the reaction is 1–2 days. Increasing the time of contact of the initial reactants increases the yield to 60–70%. This synthesis of alkyltetrafluorophosphoranes is attractive in that the initial phosphorus-containing compound used is the readily available phosphorus pentafluoride, not the alkyldichlorophosphines from which alkyltetrafluorophosphoranes are usually obtained.

The reaction of phosphonothionic and phosphinothionic halides with antimony trifluoride has been proposed[116] for the preparation of alkyl(or aryl)tetra- and dialkyltri-fluorophosphoranes. A reaction of similar type had previously[114] been used for the synthesis of trialkyldifluorophosphoranes. The possibility of converting thione derivatives of four-coordinated phosphorus into fluorophosphoranes is of the greatest value for the synthesis of dialkyltrifluorophosphoranes, which are mostly obtained by the reaction of antimony trifluoride with dialkylchlorophosphines, these being considerably less readily available substances than their thione derivatives.

Triphenyldifluorophosphorane has been obtained by the reaction of triphenylphosphine with dinitrogen tetrafluoride[117], perfluoropiperidine, and nitrogen trifluoride[118]. The reaction between diphenylphosphine and tetrafluorohydrazine might be expected to yield the hydride $(C_6H_5)_2PHF_2$, but diphenyltrifluorophosphorane is said[117] to be formed (though in a later patent[119] the same workers state that reaction of the appropriate phosphines with tetrafluorohydrazine yields the hydrides R_2PHF_2).

It has not proved possible to isolate alkyl(or aryl)difluorodihalogenophosphoranes in the pure state[13,45]. Thermally the compounds are considerably less stable than their analogues[1] containing perfluoroalkyl radicals, and their formation in the reaction of alkyl(or aryl)difluorophosphines with chlorine or bromine has been detected[13] by means of the low-temperature fluorine-19 n.m.r. spectra. Even below 0°C they form, as a result of intermolecular ligand exchange, fluorophosphoranes $RPHalF_3$, RPF_4, and solids, insoluble in most organic solvents, whose composition is close to that of alkyl(or aryl)fluorotrihalogenophosphoranes (on treatment with antimony trifluoride the latter also give RPF_4).[13] Trichlorofluorotrifluoromethylphosphorane CF_3PCl_3F has been obtained as the desired product by Griffiths[120] by the addition of chlorine fluoride to dichlorotrifluoromethylphosphine.

During the past three or four years a large amount of work has been done on alkyl(or aryl)mono(or di)alkylaminofluorophosphoranes, among which the trifluorophosphoranes $ArPF_3NR_2$ were reported originally[121], and then other members of the series of alkyl(or aryl)aminotrifluorophosphoranes[40,122–126]. Alkyldiaminodifluorophosphoranes have recently been obtained[127] by the reaction of trifluorophosphoranes RPF_3NR_2 or RPF_3NHR with primary or secondary amines. Alkyl(or aryl)mono(or di)alkylaminotrifluorophosphoranes have been synthesised by the following methods:

(1) $RPF_4 + 2\,H_2NR' \rightarrow RPF_3(NHR') + HF \cdot H_2NR'$[40,122–124]

(2) $2\,RPF_4 + 2\,HNR'_2 \rightarrow RPF_3(NR'_2) + [R_2NH_2]^+[RPF_5]^-$[122,123,125]

(3) $RPF_3Cl + 2\,HNR'_2 \rightarrow RPF_3(NR_2) + HCl \cdot HNR_2$[121,125]

(4) $RPHal(N{<}) \xrightarrow{SbF_3} RPF_3(N{<})$ (Hal=Cl, F)[40,122,123,125]

(5) $RPF_4 + (CH_3)_3Si{-}NR'_2 \rightarrow RPF_3(NR'_2) + (CH_3)_3SiF$[122,123,126]

Arylaminotrifluorophosphoranes are most conveniently obtained by reaction (3), since the initial arylchlorotrifluorophosphoranes can easily be prepared by treating aryltrifluorophosphoranes with chlorine, the latter being comparatively readily available compounds. Reaction (4) is advisable for the preparation of alkyldialkylaminotrifluorophosphoranes, and reaction (1) for their monoalkylamino-derivatives.

Study of the hydrolysis of alkyl(or aryl)aminotrifluorophosphoranes by means of the ^{19}F n.m.r. spectra has shown[13,128] that the addition even of catalytic quantities of water results in formation of the anion $[RPF_5]^-$, whose concentration initially increases as fresh portions of water are added, reaches a maximum at a ratio of the initial reactants of ~1 : 1, and then diminishes until signals due to $[RPF_5]^-$ have completely disappeared from the spectrum. Ultimately, as had been noted previously[121], hydrolysis yields the salts $[HN{<}]^+[RPO_2F]^-$, which can be obtained also by the direct reaction between alkylphosphonofluoridic acids and amines[13].

In a series of papers Schmutzler and Reddy have shown[129–131] that on storage the fluorophosphoranes $C_6H_5PF_3N(CH_3)_2$ and $CH_3PF_3N(CH_3)_2$ undergo rearrangement accompanied by formation of the ionic compound $[RPF(N(CH_3)_2)_2]^+[RPF_5]^-$. Other workers have found[13,128] that the anions $[RPF_5]^-$ are formed also on the storage of most fluorophosphoranes RPF_3NHR, although the formation of cations containing phosphorus has not been established in this case.

The first attempts to obtain the trifluorophosphoranes RPF_3OR' from tetrafluorophosphoranes and siloxanes did not give the results expected[1,114]: instead of compounds of five-coordinated phosphorus, the phosphonic fluorides $RPOF_2$ and $RPFOOR'$ were isolated, among which at least the former product might be formed by the rearrangement

$$RPF_3(OR') \rightarrow RPOF_2 + R'F.$$

Investigation of the reaction of methyl- and ethyl-tetrafluorophosphoranes with siloxanes by means of the low-temperature ^{19}F n.m.r. spectra has shown the actual formation in this case of the trifluorophosphoranes RPF_3OR', which are stable only at subzero temperatures. On warming up to room temperature the signals from the trifluorophosphoranes disappeared, and signals appeared from the phosphonic fluorides $RPOF_2$ and $RPFOOR'$. Formation of the latter compounds may be due either to reaction of the difluorides $RPOF_2$ with the siloxanes or to rearrangement of alkyldialkoxydifluorophosphoranes

$$RPF_2(OR')_2 \rightarrow RPOF(OR') + R'F,$$

which may be formed both by interaction of the trifluorophosphoranes RPF_3OR' with siloxanes and as a consequence of intermolecular exchange in the alkylalkoxytrifluorophosphoranes themselves

$$2\,RPF_3(OR') \rightarrow RPF_2(OR')_2 + RPF_4.$$

The relatively stable difluorophosphoranes $RPF_2(OC_6H_5)_2$ and $(C_6H_5)_2PF_3OC_6H_5$ have recently been obtained by reaction of the corresponding tetra- and tri-fluorophosphoranes with siloxanes[132]. Fluorophosphoranes containing alkylthio- or arylthio-groups attached to the phosphorus atom have been described[13,132,133].

The attention of research workers has long been attracted to the acceptor properties of fluorophosphoranes. Alkyl(or aryl)tetrafluorophosphoranes are weaker acceptors of electrons than is phosphorus pentafluoride, but nevertheless they exhibit this property quite distinctly. Thus phenyltetrafluorophosphorane forms relatively stable complexes with dimethylformamide and with pyridine. The temperature variation in the parameters of the ^{19}F n.m.r. spectra observed in solutions of these complexes may be due to the partial dissociation[134]

$$C_6H_5PF_4.\text{Donor} \rightleftharpoons C_6H_5PF_4 + \text{Donor}.$$

According to Muetterties and Mahler[134] donor–acceptor interaction is not observed in solutions of phenyltetrafluorophosphorane in acetonitrile and triethylamine. Alkyltetrafluorophosphoranes undergo an exothermic interaction with many organic bases, but at room temperature the resulting complexes are in considerable measure dissociated. According to their acceptor power the fluorides of five-coordinated phosphorus form the sequence[134]

$$PF_5 > ArPF_4 > AlkPF_4 \gg R_2PF_3 > R_3PF_2$$

which reflects the diminution in the relative positive charge on the phosphorus atom when the fluorine atom is replaced by less electronegative substituents. Steric factors probably play an important part also.

Phenyltetrafluorophosphorane forms with dimethyl sulphoxide a complex, which at 25°C dissociates with increase in the electrical conductivity of the solution. Spectroscopic investigation indicates that the reversible process

$$C_6H_5PF_4 \cdot OS(CH_3)_2 \rightleftarrows C_6H_5PF_4 + (CH_3)_2SO$$

is accompanied in the solution by another interaction involving formation of the anion $[RPF_5]^-$ and of $RPOF_2$ (the role and the fate of the dimethyl sulphoxide in this process have not been ascertained)[134].

Alkyltetrafluorophosphoranes react irreversibly with dimethyl sulphoxide. The products contain the anions $[RPF_5]^-$ and alkylphosphonic difluorides. The ^{19}F n.m.r. spectrum of these anions varies with temperature, this being attributed to exchange with F^- ions[134].

It has come to be accepted[1,114,134] that the donor properties of fluorides of five-coordinated phosphorus may be due either to ionisation $PX_5 \rightleftharpoons PX_4^+ + X^-$ or to the presence of lone pairs of electrons on the atoms attached to the phosphorus. All derivatives of phosphorus pentafluoride possess donor properties, although it is unknown which of the above causes is operative. Alkyl- and aryl-tetrafluorophosphoranes form colourless crystalline 1 : 1 complexes with strong acceptors such as boron trifluoride, antimony pentafluoride, and phosphorus pentafluoride. The complexes of dialkyltrifluorophosphoranes with the same acceptors are usually more stable than those of alkyltetrafluorophosphoranes [the dissociation pressure for the complex $PF_5.(CH_3)_2PF_3$ is less than 1 mm at 25°C, whereas for $CH_3PF_4.PF_5$ it is ~10 mm at –61°C].[134]

Hydrides of five-coordinated phosphorus. The first hydrides containing a five-coordinated phosphorus atom were described in 1961[135,136]: tetra- and tri-fluorophosphorane were obtained by the reaction of orthophosphorous and hypophosphorous acids with hydrogen fluoride, and treatment of aryldichlorophosphines with potassium hydrogen fluoride gave aryltrifluorophosphorus monohydrides. Treichell and his coworkers have since found[67] that the hydrides HPF_4 and H_2PF_3 can be obtained by the gas-phase reaction of phosphorus pentafluoride with trimethylstannane [the deuteriated derivatives DPF_4 and D_2PF_3 have been prepared by the use of $(CH_3)_3SnD$]. Available data indicate[67,137,138] that both compounds are monomeric in the vapour state, whereas in the liquid state the H_2PF_3 molecules are in considerable measure associated. The chemical properties of these compounds have not been studied. It is known only that HPF_4 reacts with glass or quartz to form the unstable phosphorodifluoridous acid[67].

The hydrides methyl- and ethyl-trifluorophosphorane were first described in the patent literature[39]. Their synthesis and also several chemical properties have since been reported[13,35,38,40,139-141]. Both alkyl- and aryltrifluorophosphoranes (monohydrides) can be obtained in 80–90% yield by the low-temperature reaction between the halides $RPHal_2$ (where Hal = Cl, Br, F) and hydrogen fluoride[13,39,40,140,141]. The reaction of methyl- and ethyltetrafluorophosphoranes with trimethylstannane has also been used to prepare the alkyl derivatives[139].

All the trifluorophosphorus monohydrides investigated are relatively low-boiling liquids, which distil satisfactorily in an atmosphere of nitrogen, are easily hydrolysed, and react with glass. The compounds can be stored for a long time in vessels of an inert material (quartz, polyethylene, polytetrafluoroethylene). With tertiary amines they form alkyl(or aryl)difluorophosphines and salts $[NHR_3]^+[R'PHF_4]^-$ [26,38,40,141]. By the action of sodium alkoxides on aryltrifluorophosphoranes (monohydrides) the fluorine atom can be replaced by an alkoxy-group[35,141,142], and the action of primary amines on the corresponding alkyl monohydrides yields the alkyl-alkylaminodifluorophosphoranes $RPHF_2NHR'$ [38,41,141]. The latter compounds, as well as the hydrides $AlkPHF_2OR$, can also be obtained by the reaction of alkyldifluorophosphines with alcohols and with primary amines respectively[13,34-38,141,143]. The hydrides $AlkPHF_2NR_2$ are formed also in the first stage of interaction between alkyldifluorophosphines and secondary amines[13,42]. However, these compounds break down at high temperatures to form alkylphosphonofluoridous amides, and it proved extremely difficult to isolate them in the pure state by distillation.

Somewhat obscure results have been obtained for the reaction of aryldifluorophosphines and aryltrifluorophosphoranes with primary and secondary amines[38]. The formation of amides $ArPFN\langle$ in these cases is established by the ^{31}P n.m.r. spectra, whereas on distillation only their adducts with hydrogen fluoride, corresponding formally in composition to the hydrides $ArPHF_2N\langle$, can be isolated.

The previously unknown hydrides $ROPHF_2NHR'$ and R_2NPHF_2NHR' have been obtained from the corresponding fluorides XPF_2 and primary amines[14]:

$$XPF_2 + H_2NR' \rightarrow XPHF_2(NHR') \quad (X{=}OR,\ NR_2)$$

and the hydrides R_2PHF_2 (R = Alk, Ar) by reaction of the halides R_2PCl and R_2PF with hydrogen fluoride[13,107].

The above cases of the formation of hydrides of five-coordinated phosphorus by the reaction of fluorides of three-coordinated phosphorus with alcohols, amines, and hydrogen halides have several common features, which suggest that the initial step in this process is the reaction of a weak n-base with an acid HX (where X = F, Cl, OR, NHR, NR_2). The driving force in this stage of the reaction should be the high electronegativity of X. Where the electronegativity of X is small, systems may be formed containing a hydrogen bond $\rangle$P:...H:X, the strength of which depends on the state of the lone pair of electrons of the base. When, however, X is strongly electronegative, and the phosphorus is combined with substituents of low electronegativity, the H–X bond may be ruptured with formation of the ion-pair $[\rangle PH]^+X^-$. The presence on the phosphorus atom of highly electronegative substituents, tending to lower the energy and localise the d-orbitals, is evidently a necessary condition for conversion of the initially formed system $\rangle$P:...H:X into a hydride of five-coordinated phosphorus.

It may be supposed then that the hydrides HPF_3X (where X = F, Cl, OR, NHR, etc.) will be fairly difficult to obtain by direct reaction of the compounds HX with phosphorus trifluoride, owing to the weak donor power of the latter. This conclusion is supported by the well known experimental fact that the hydride PHF_4 is not formed as a result of contact between phosphorus trifluoride and hydrogen fluoride. Replacement of one of the fluorine atoms in phosphorus trifluoride by a less electronegative substituent is sufficient for the compound to react exothermally with HX to form, as is shown experimentally, hydrides of five-coordinated phosphorus. On the whole it is obvious that, in the series PF_3, YPF_2, Y_2PF, and Y_3P (where Y is a substituent other than fluorine), the last compound will react most easily with the acid HX. However, if the reaction can produce a five-coordinated molecule thanks to the presence of highly electronegative substituents in the compounds YPF_2 and to a less extent Y_2PF, such possibilities should be limited in the latter compounds. This conclusion also is supported by the experimental results available at present. In particular, the fluorophosphines RPF_2 and R_2PF form with hydrogen fluoride hydrides of five-coordinated phosphorus, whereas the products of the interaction of hydrogen fluoride with trialkyl(or aryl)phosphines have a clearly ionic structure[144].

III. PHYSICOCHEMICAL INVESTIGATIONS

The wide use of modern physicochemical methods of investigation, primarily n.m.r. spectroscopy, has had an exceptionally fruitful influence on the development of the chemistry of the fluorides of phosphorus. The most significant result has been obtained from a combined study (by electron diffraction, and n.m.r. and vibrational spectroscopy) of the structure of P[V] compounds, which are in most cases found to have a trigonal–bipyramidal configuration.

Another important result of work done during recent years is the evaluation of the true parameters of the ^{31}P and ^{19}F n.m.r. spectra for the fluorides of three-coordinated phosphorus, and in particular for derivatives of alkylphosphonofluoridous acids, which exhibit abnormally small chemical shifts δ_P.

Particular attention will be paid here to the results of n.m.r. and vibrational spectroscopy, and also to the investigation of the structure of the fluorides of phosphorus by electron diffraction.

1. Phosphorus-31 and Fluorine-19 n.m.r. Spectra

^{31}P and ^{19}F n.m.r. spectra of the fluorides of three-coordinated phosphorus. The fluorides C_2H_5PFX (where X = F, Cl, iso-OC_3H_7) were among the first organophosphorus compounds to be investigated by means of the ^{31}P n.m.r. spectra. Unfortunately, the relevant paper[145] contained a mistake, these compounds being attributed the spectral characteristics of more highly coordinated fluorides of phosphorus. Only eight years later[146] was the error in the original results demonstrated, and subsequently the true parameters of the ^{31}P and ^{19}F n.m.r. spectra have been determined[26-29,33,41,49,52,147] for these types of compounds (see Table 1), which were found to possess abnormally low δ_P values, disproving the theory of "group shifts"[145].

Quite a large amount of experimental information has now accumulated providing knowledge of the values of δ_P, δ_F, and J_{P-F} for about a hundred phosphorus(III) fluorides. However, it has not yet proved possible to use this information in developing theoretical aspects of the problem of screening and spin–spin interaction in the series of compounds considered. Solution of these problems is complicated by the absence of any well-developed regularities in the variation of these parameters with the structure of the compounds. Only in narrow series of closely related derivatives, where the variation in structure seemingly does not involve substantial variation in angles and bond lengths, is it possible to detect a more or less well defined inverse relation (e.g. for compounds 15–19 in Table 1) and occasionally even a direct relation (compounds 8–10, 12, and 13) between the values of δ_P and the aggregate electronegativities of the substituents. However, when broader series of compounds are considered, e.g. fluorides of the type XPF_2 (compounds 1–13, Table 1) and XYPF (compounds 14–24), this relation breaks down, probably because of the considerable fluctuations in the valency angles within series of these compounds.

Not only δ_P but also the chemical shifts of the ^{19}F nuclei vary over a wide range. Thus for compounds of the type RPFX (Table 1, compounds 12–19) the range of variation in δ_P is ~90 ppm, while the chemical shifts δ_F vary over the range 522–626 ppm. The screening of the ^{31}P nuclei changes with the nature of X in the sequence $F < Cl < OR \simeq SR < R < NR_2$, which differs from the sequence of variation in δ_F in the same compounds (the screening of ^{19}F nuclei varies in the sequence $OR < F < NR_2 < SR < R$). The constants J_{P-F} increase in the sequence $R < NR_2 < SR < Cl < OR < F$, which differs from both δ_P and δ_F sequences.

It must be noted in conclusion that ^{31}P nuclei are usually considerably less screened in P[III] fluorides than in the corresponding derivatives containing P[IV] or P[V], whereas ^{19}F nuclei, on the other hand, are more screened in P[III] fluorides than in the P[IV] compounds. In virtue of these facts phosphorus(III) fluorides can often be easily identified by means of the ^{31}P and ^{19}F n.m.r. spectra not only in the pure state but also when mixed with more highly coordinated phosphorus compounds.

Phosphorus-31 and fluorine-19 n.m.r. spectra of complex compounds. An interesting paper appeared recently[60] on the investigation by means of the ^{31}P and ^{19}F n.m.r. spectra of complex compounds containing P[III] fluorides as ligands. It contains extensive experimental results, and makes an analysis of possible factors influencing the variation in the parameters of the n.m.r. spectra on passing from the free ligands to the complex compounds. In the complexes the ^{31}P nuclei are deshielded in comparison with the free ligands ($\Delta\delta_P$ = 6–55 ppm); the ^{19}F nuclei also become less well screened ($\Delta\delta_F$ = 17–46 ppm). The constants J_{P-F} are, with rare exceptions, smaller in the complexes than in the free ligands. It has also been noted that, the better screened are the ^{31}P nuclei in the free ligands and complexes, the smaller is $\Delta\delta_F$ accompanying complex formation.

Analysis of these results led to the conclusions[60] that complex formation is accompanied by an increase in the paramagnetic contribution to the screening constants of the ^{31}P and ^{19}F nuclei, and this contribution is greater in molybdenum complexes than in nickel complexes. Part of this contribution is due to $d_\pi - d_\pi$ bonding between the phosphorus atom and the metal. The change in hybridisation of the phosphorus atom accompanying complex formation should also play an important part. However, the absence of data on valency angles and bond lengths, both in the initial phosphorus-containing compounds and in the complexes, prevents serious discussion of this problem. It is clear only that a diminution in the *s*-character of the phosphorus–fluorine bond, which should be observed on complex formation, will lead to a decrease in the J_{P-F} constants in the complexes (and this is actually observed in the vast majority of compounds investigated). In the opinion of the authors, polarisation of the lone pair of electrons on the

central atom of the free ligand by the unsymmetrical field of the substituents should promote descreening of the ^{31}P nuclei in the compounds XPF_2 and X_2PF. This effect should be considerably weaker in the complexes, since the "lone" pair in them is already bound, and therefore less subject to polarisation.

Nuclear magnetic resonance of fluorides of four-coordinated phosphorus. Until recently data on the parameters of the ^{31}P and ^{19}F n.m.r. spectra of P[IV] fluorides were extremely limited (a 1965 review[1] gave the spectral characteristics of forty compounds). Shortly after this the characteristics of about eighty more compounds were recorded, including the thiophosphoryl derivatives SPF_nX_{3-n} ($n = 1-3$ and X = Cl, Br, NCS, H, NR_2, SR, OR) [12,64,68,150-152], isocyanates and isothiocyanates of phosphorofluoridic acids[68], phosphazofluorides[153,154], the mixed halides XPOHalF (X = R, NR_2, Hal and Hal = Cl, Br) [14,50,155], and also a large number of phosphorofluoridates[66,147,148] and phosphonofluoridates[156,157].

A paper[156] giving the spectral characteristics of about thirty compounds of the type XYPOF, some new and many which had been investigated previously, noted that all the compounds can be divided into three groups, within each of which the chemical shifts δ_P and δ_F increase linearly with the sum of the electronegativities of the substituents X and Y. The first group comprises molecules in which X and Y ≠ F, Cl, or OH (Table 2, compounds 1–18); in the second group X = F, Cl, OH (compounds 20–27); and in the third group X and Y = F, Cl, OH (compounds 28–30). In each group δ_P and δ_F vary in the same sense, the dialkylphosphinic fluorides constituting an exception. The occurrence of such groups may be due to a slight variation in valency angles within each series of compounds.

On the whole, methods at present available for the quantum-chemical calculation of the parameters of the ^{31}P and ^{19}F n.m.r. spectra do not provide quantitative estimates of δ_P and δ_F. Moreover, there is no generally accepted view on the main factors responsible for the variation in the chemical shifts in these compounds[158-161].

Nuclear magnetic resonance of fluorides of five-coordinated phosphorus. Among phosphorus compounds the P[V] fluorides are some of the most interesting subjects for investigation by n.m.r. spectroscopy on ^{31}P and ^{19}F nuclei. However, theoretical aspects of screening and spin–spin interaction are still less developed for these compounds than for P[III] and P[IV] fluorides, which makes it important to seek purely empirical rules for the variation in the parameters of the spectra for different groups of these compounds.

The number of P[V] fluorides which have been investigated by the n.m.r. method now exceeds a hundred. They include most of the structures from XPF_4 to X_4PF which are conceivable in practice, the spectral data for which, with rare exceptions, are satisfactorily interpreted on the basis of a trigonal–bipyramidal model. Such exceptions include in particular the spectral characteristics of certain adducts of P[III] fluorides with halogens (Table 3), which have been investigated quite recently[13,16,17,45,162].

In spite of the formal similarity in structure, these compounds (Table 3) give an extraordinarily wide range of variation in δ_P (from +110 to −80 ppm); the majority have very low values of δ_F, and the constants J_{P-F} are unusually large for axial fluorine atoms. However, the low-temperature ^{19}F n.m.r. spectra proved the trigonal–bypyramidal configuration (with an axial conformation of the two fluorine atoms) of compounds 1 and 2 [162] and 3–13 [13] (Table 3) (an axial arrangement of the fluorine atoms was confirmed for compounds of the type $R_2NPF_2Hal_2$ by examining the ^{19}F n.m.r. spectra of compounds 5 and 11 at various temperatures). In view of the closeness of the spectral characteristics, compounds 21–31 can also be assigned to the same molecular model. Compounds 14–20 most probably have an ionic structure, especially in view of their very low δ_P values.

Another unexpected result, which at first glance seems to contradict the trigonal–bipyramidal model of the molecules, has been obtained for the structure of the trifluorophosphoranes RPF_3NHR' [13,40,125,128,163]. As was first shown for methylisobutylaminotrifluorophosphorane[40], the

*Chemical shifts δ_P given relative to H_3PO_4, and δ_F relative to F_2. Data taken from Ref. 156.

^{19}F n.m.r. spectra of compounds of this type have a pattern indicating the magnetic non-equivalence of all three fluorine atoms in the molecule, whereas the fluorine resonance spectra of the trifluorophosphoranes X_2PF_3 investigated previously indicated interaction of phosphorus nuclei with two magnetically equivalent (axial) ^{19}F nuclei and one ^{19}F nucleus differing from them. A more detailed investigation of the ^{19}F and ^{31}P n.m.r. spectra of the trifluorophosphoranes RPF_3NHR' showed[13,125,128,163] that the signals from these compounds in the fluorine resonance spectra can also be divided into signals from an equatorial and two axial fluorine atoms, because of the fact that under normal conditions the ^{31}P nuclei do not "sense" the non-equivalence of the two less well screened (axial) fluorine atoms, and preserve the normal pattern of the ^{31}P n.m.r. spectrum.

* Values of δ_P given relative to H_3PO_4, and of δ_F relative to F_2.

** Axial fluorines are magnetically non-equivalent (recorded at −50°C).

*** Values of δ_F and J_{P-F} arbitrarily attributed to axial fluorine atoms.

Likewise the equatorial fluorine atoms do not "sense" the non-equivalence of the axial fluorine atoms.

It was subsequently established[13,164] that magnetically non-equivalent axial fluorine atoms are present not only in trifluorophosphoranes containing an NHR group attached to the phosphorus atom but also in fluorophosphoranes containing NR^1R^2 and SR groups. There are grounds for assuming that the cause of this phenomenon is the relatively high energy barrier to internal rotation about the P–N and P–S bonds[13,163,164].

* Chemical shifts δ_P given relative to H_3PO_4, and δ_F relative to F_2.

** At −50°C the axial fluorine atoms exhibit magnetic non-equivalence: $\delta'_{F_{ax}} = 450$ ppm and $\delta''_{F_{ax}} = 442$ ppm; $J'_{P-F_{ax}} = 940$ c/s and $J''_{P-F_{ax}} = 1030$ c/s [13,164]. A similar phenomenon cannot be observed in compounds containing RO-groups[13].

A large number of fluorophosphoranes containing alkoxy- and alkylthio-groups attached to the phosphorus atom have recently been investigated by means of the ^{19}F n.m.r. spectra (Table 4). Compounds of this type are in most cases unstable, and their spectral characteristics are therefore especially important for identifying newly prepared products. Table 4 makes it clear that these compounds are characterised by positive chemical shifts δ_P, spin–spin interaction constants $J_{P-F_{eq}}$ exceeding 1000 c/s, and large fluctuations in the values of $J_{P-F_{ax}}$ (from 690 to 970 c/s). An appreciable increase in screening of the axial fluorine atoms is noteworthy on passing from fluorophosphoranes containing a carbon–phosphorus bond (Table 4, compounds 2–6 and 9–15) to compounds containing more electronegative substituents (e.g. compounds 7, 8, and 16). The trigonal–bipyramidal configuration of compounds of this type is confirmed by the n.m.r. spectra of the trifluorophosphoranes (compounds 2, 3, and 10–12) containing signals from two (axial and equatorial) groups of fluorine atoms. In several cases, e.g. with the cyclic monofluorophosphoranes 20 and 21, whether the fluorine is located at the equator or in an axial position of the bipyramid remains an open question, since the values of δ_F remain unknown, while those of the constants J_{P-F} are nevertheless large for an axial position, usually occupied by the more electronegative substituents, to be assigned to the fluorine atoms solely on the basis of these data[165]. The spectral characteristics of the recently reported[166] compound CH_3OPF_4 demand special notice (Table 4, compound 1): the ^{31}P nuclei are considerably better screened than in CH_3PF_4 and PF_5, almost to the same extent as in $BrPF_4$ [98]; the quantity δ_F occupies an intermediate position between its values for CH_3PF_4 and PF_5 (but is closer to the latter); while the constant J_{P-F} is considerably smaller than in the above compounds.

The parameters of the n.m.r. spectra for all the phosphorus(V) hydrides other than the monohydride phenyltrifluorophosphorane[167] have been given in papers published since 1964. During this time n.m.r. spectroscopy has been used to examine about fifteen compounds having various types of structure, beginning from HPF_4 and H_2PF_3 and ending with the hydrides $XYPHF_2$ (where X and Y are substituents other than fluorine). The parameters (Table 5) and the character of the ^{31}P and ^{19}F n.m.r. spectra of the phosphorus hydrides investigated indicate that they have a five-coordinated structure, and are well interpreted on the basis of a trigonal–bipyramidal model. The compounds are characterised by positive values of the chemical shifts δ_P, reaching ±70 ppm for the hydrides $ROPHF_2NHR'$ (Table 5, compound 13) and extremely large numerical values of the constants J_{P-H}, exceeding by more than 100 c/s the constants $J_{P-F_{ax}}$. There is also a tendency for the constants J_{P-H} to increase with increase in the sum of the electronegativities of the substituents attached to the phosphorus atom.

2. Electron Diffraction

An examination of phosphorus pentafluoride, methylphosphorus tetrafluoride, and dimethyphosphorous trifluoride, made in 1965 by Bartell and Hansen[165], confirmed the trigonal–bipyramidal structure of the molecules and led to the following important conclusions: (1) the more electronegative substituents occupy the vertices of the bipyramid; (2) axial bonds are more polar and longer than equatorial bonds; and (3) the replacement of fluorine atoms by alkyl and other less electronegative substituents results in an increase in the difference $r_{ax} - r_{eq}$. The results can be satisfactorily explained both on the basis of Rundle's model[168–170], which postulates that axial bonds are three-centred and have a bond order of ~ 0.5, and by means of Gillespie's model[171–174], in which the stereochemistry of the molecule is determined by the repulsion of electron pairs. It is difficult to give preference to either model, for, as Bartell remarked[175], they both require additional postulates to explain all the details found for the five-coordinated structure.

3. Vibrational Spectra

Vibrational spectroscopy has also been fairly widely used for analysing the structure of the fluorides of phosphorus. The most significant results have been obtained when the vibrational spectra have been used to solve structural problems in the fluorides of five-coordinated phosphorus. The infrared and Raman spectra of HPF_4 [67,137], H_2PF_3 [67,137,138], and the fluorophosphoranes $(CH_3)_nPF_{5-n}$ (n = 1 – 3) [176] have been interpreted in terms of a trigonal–bipyramidal molecular model in which the less electronegative substituents occupy equatorial positions. In the vapours all the compounds are found to be monomeric,

*** Axial and equatorial fluorine atoms indistinguishable.

whereas in the liquid state the phosphorane PH_2F_3 is associated by means of hydrogen bonds. It is interesting that in the liquid state the hydride HPF_4 is either considerably less or not at all associated.

Investigation by means of the vibrational spectra of phosphorus hydrides of different degrees of coordination has shown that the P–H stretching frequencies appear over a wide range from 2233 cm^{-1} (in HPF_2)[23] to 2545 cm^{-1} (in H_2PF_3). The most significant are the frequencies ν_{P-H} and the constants J_{P-H}, which vary in parallel with the former on passing from the phosphorus(III) fluorides to the four- and five-coordinated compounds (for HPF_2 [23], $HPOF_2$ [64], and HPF_4 [67] we have 2233, 2500, and 2485 cm^{-1} for ν_{P-H}, and 182, 844, and > 1000 c/s for J_{P-H}). Within groups of four- and five-coordinated compounds there is a tendency for ν_{P-H} and J_{P-H} to increase with the electronegativity of the substituents attached to the phosphorus atom (e.g. on passing from $HPSF_2$ [20] to $HPOF_2$ [20] the frequencies ν_{P-H} and the constants J_{P-H} increase by 42 cm^{-1} and 119 c/s respectively, and on passing from HPF_4 [67] to $RPHF_3$ [40,139] by ~40 cm^{-1} and ~150 c/s).

Table 6. Spin–spin interaction constants $J_{P-F_{ax}}$ and P–F stretching frequencies compared with lengths of $P-F_{ax}$ bond for the fluorophosphoranes X_nPF_{5-n}.

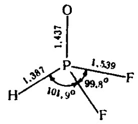
* Data taken from Ref. 176.

Increase in the sum of the electronegativities of the substituents in the series of fluorophosphoranes X_nPF_{5-n} ($n = 0-3$) has been shown[176] to be accompanied by contraction of the $P-F_{ax}$ bonds together with an increase in the frequencies of the symmetric and antisymmetric vibrations $\nu_{P-F_{ax}}$ (see Table 6). A similar relation between the sum of the electronegativities of the substituents and the frequencies ν_{P-F} is observed also for several series of compounds of four-coordinated phosphorus[148,149] [for the main results on the vibrational spectra of phosphorus(IV) fluorides see Refs. 148, 149, and 177–184].

Quite recently[185] the microwave spectrum has yielded for $HPOF_2$ the parameters



∠OPF = 116.5°
∠OPH = 117.9°
Dipole moment 2.65 ± 0.03 D

Vibrational and especially microwave spectroscopy has been used very rarely to solve structural problems in the phosphorus(III) fluorides, the number and significance of papers published during the period in which we are interested being fairly limited[186–188].

Cyclodiphosphazanes

A.F.Grapov, N.N.Mel'nikov, and L.V.Razvodovskaya

The chemistry of four-membered cyclic compounds containing both nitrogen and phosphorus, which may find application in the preparation of thermostable plastics and the synthesis of biologically active compounds, has been widely investigated in recent years. This review deals with problems concerning the determination of the structure, the investigation of the physical and chemical properties of cyclodiphosphazanes containing trivalent tetraco-ordinate and pentaco-ordinate phosphorus atoms, and the methods of their synthesis and chemical reactions.

20 The bibliography includes 103 references.

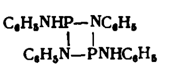
CONTENTS

I. INTRODUCTION

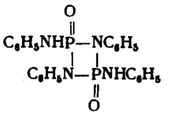
Towards the end of the 19th and the beginning of the 20th century, Michaelis[1,2] described for the first time compounds containing a four-membered ring with alternating phosphorus and nitrogen atoms. The work of Michaelis and his school led to the development of the simplest methods for the synthesis of such compounds. Then for a long time this class of organic phosphorus derivatives remained sidetracked from the mainstream of the development of organic chemistry. It was not until a few years ago that four-membered ring compounds containing both phosphorus and nitrogen atoms again attracted the attention of investigators. The year 1959 must be regarded as the start of the new period in the study of these compounds, when Kirsanov and Zhmurova published their investigation of dimeric trichlorophosphazoarenes[3]. In recent years new synthetic methods have been developed for these compounds, their reactivity has been investigated, and physicochemical studies have been made to determine their structure and to elucidate the mutual effects of the atoms.

Four-membered ring compounds containing both trivalent and tetraco-ordinate and pentaco-ordinate phosphorus atoms have now been obtained.

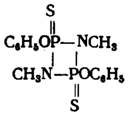
There is no agreement as regards the nomenclature of such cyclic systems. In Sasse's monograph[4] they are referred to as derivatives of imidophosphorous, imidophosphoric, imidophosphonic, imidothiophosphoric, and imidothiophosphonic acids. In chemical literature in English they are sometimes called 1,3,2,4-diazadiphosphetidines[5]. The term "dimeric phosphazo-compounds" is fairly frequently encountered. The name cyclodiphosphazanes proposed by Shaw et al[6] and also by Davydova and Voronkov[7] is the most apt. For example:



2,4-dianilino-1,3-diphenylcyclodiphospha(III)azane



2,4-dianilino-2,4-dioxo-1,3-diphenylcyclodiphosphazane



1,3-dimethyl-2,4-diphenoxy-2,4-dithionocyclodiphosphazane

2,2,2,4,4,4-hexachloro-1,3-diphenylcyclodiphosphazane

This nomenclature will in fact be adhered to in the present review.

II. THE STRUCTURE OF THE CYCLODIPHOSPHAZANE RING

To establish the structure of cyclodiphosphazanes, various physicochemical methods have been used: X-ray diffraction measurements of dipole moments, infrared and ultraviolet spectroscopy, Raman spectroscopy, and nuclear magnetic resonance (NMR). The data obtained made it possible not only to establish the relative positions of the atoms in the molecule but also to arrive at certain conclusions concerning the nature of the nitrogen–phosphorus bond.

Unfortunately almost all studies of this kind deal with compounds with tetra- and penta-co-ordinate phosphorus atoms. There are no physicochemical data in the literature for cyclodiphosphazanes with a trivalent phosphorus atom.

1. Vibration and Electronic Spectra

Most investigators attribute the intense absorption in the region 850–865 cm^{-1} in the infrared spectra of dialkyl- or diaryl-hexachlorocyclodiphosphazanes to P–N vibrations of the four-membered ring[8-10]. The intense band at 1160–1165 cm^{-1} may be assigned to N-alkyl vibrations[11] but not to P–N–P bridge vibrations or P–N stretching vibrations[8-12].

The vibration frequencies in the infrared and Raman spectra of hexafluorodimethylcyclodiphosphazane have been assigned (Table 1)[13] by analogy with the spectra of alkylfluorophosphoranes[14,15].

The spectra of dithionocyclodiphosphazanes have been investigated in greatest detail[11]. The intense absorption bands in the region 850–900 cm^{-1} in the infrared spectra 1,3-dialkyldithionocyclodiphosphazanes are due to antisymmetric vibrations of the four-membered ring. The replacement of the *N*-alkyl group by an *N*-aryl group leads to an increase of the vibration frequency by about 100 cm^{-1}. The symmetrical vibrations of the ring are revealed only in the Raman spectrum in the region 430–570 cm^{-1}. The infrared spectroscopic data for bis(diphenylthiophosphono)-*N*-alkylamines are satisfactorily consistent with these results. The P–N–P antisymmetric vibration band in their spectra lies in the region 912–928 cm^{-1}, while the band due to the P–N–P symmetrical vibrations is in the region[16] 528–583 cm^{-1}.

The absorption bands at 1150–1180 cm^{-1} in the infrared spectra of 1,3-dialkyl-2,4-dithionocyclodiphosphazanes have been assigned to N–C (alkyl) vibrations. In the spectra of the *N*-aryl analogues these bands occur at 1250–1270 cm^{-1}. 2,4-Dialkyl-2,4-dithionocyclodiphosphazanes absorb in the region 615–630 cm^{-1}, which may be attributed to P=S vibrations. In the spectrum of 2,4-diphenyl-2,4-dithionocyclodiphosphazane the absorption shifts to the region 650–670 cm^{-1}. Such as increase in the P=S vibration frequency as a function of the immediate environment of the phosphorus atom is consistent with the available data[17,18].

Table 1. Infrared and Raman spectra of hexafluorodimethylcyclodiphosphazane

Frequencies of band maxima, cm^{-1}		Assignment
i.r. (vapour)	Raman (liquid)	
1264	1202	C–N antisymmetric
~964	960	C–N symmetrical
934	904	$P-F_{eq}$ antisymmetric
858	839,5	$P-F_{eq}$ symmetrical
807	741,5	$P-F_{ax}$
614	626	$P-N_{eq}$
535	563	$P-N_{ax}$

The ultraviolet spectra 2,4-dialkyl-1,3-diaryl-2,4-dithionocyclodiphosphazanes are virtually identical with those of the dianilides of methylthiophosphonic [methylphosphonothioic? (Ed. of Translation)] acid[11] (Table 2).

Compared with the spectra of *NN'*-dialkyldiaminophenylphosphonothioates, those of 1,3-dialkyl-2,4-diphenyl-2,4-dithionocyclodiphosphazanes show a bathochromic shift of the nearest absorption band [band at the lowest frequency? (Ed. of Translation)] together with an increase in its intensity, and an additional maximum appears at 245 nm.

2. Nuclear Magnetic Resonance Spectra

The ^1H-NMR spectra of hexachlorodimethylcyclodiphosphazane show a 1 : 2 : 1 triplet at 3.00 p.p.m.† with a spin–spin interaction constant $J_{P-N-C-H} = 20$ Hz.[8,19]

The signal due to H–C–N–P protons in the homologues of this compound occurs in the region 3.29–3.58 p.p.m. with an interaction constant of 28–29 Hz. In the NMR spectra of the fluoro-analogues $[CH_3NPF_2X]_2$, where X = F, alkyl, or aryl, the chemical shift of the protons is 2.32–2.48 p.p.m. with an interaction constant J = 12.5–12.9 Hz {for $[CH_3NPF_3]_2$, $J_{P-N-C-H}$ = 14.5 Hz[19,20]}.

The ^{31}P chemical shifts in the spectra of $[RNPCl_3]_2$ and $[CH_3NPF_2C_6H_5]_2$ are +78.2–79.8 and +56.1 p.p.m. respectively (relative to 30% of phosphoric acid)[8,21], i.e. the phosphorus nucleus in chlorocyclodiphosphazanes is more screened than in the fluoro-derivatives. The marked shift indicates that the phosphorus atom in these compounds has a co-ordination number of 5 (for PCl_5, I = +80 p.p.m.).[22]

Table 2. Positions and intensities of the ultraviolet absorption bands of solutions in heptane

Compound		λ_{max}, nm	ϵ_{max}
$[CH_3P(S)NCH_3]_2$	(I)	220	10500
$[CH_3P(S)NC_2H_5]_2$	(II)	222	11000
$[CH_3P(S)NC_6H_5]_2$	(III)	236,280	29000,1500
$[CH_3P(S)NC_6H_4CH_3-4]_2$	(IV)	239,280	42000,1800
$[CH_3P(S)NC_6H_4Cl-4]_2$	(V)	243,285	42800,1900
$[CH_3P(S)NC_6H_4OCH_3-4]_2$	(VI)	238,282	40000,2700
$[CH_3P(S)NC_6H_4OC_2H_5-4]_2$	(VII)	238,282	47000,2500
$[C_6H_5P(S)NCH_3]_2$	(VIII)	220,242,283	20000,11500 s, 8500
$[C_6H_5P(S)NC_3H_7\text{-изо}]_2$	(IX)	220,245,292	25000,12800,9000
$[C_6H_5P(S)NC_6H_5]_2$	(X)	236,265,300	41700,9500, 3000 s
$[C_6H_5P(S)NC_6H_4OC_2H_5-4]_2$	(XI)	236,270,295	41200,9000,4000 s
$C_6H_5P(S)[NHC_3H_7\text{-изо}]_2$	(XII)	255	2500
$CH_3P(S)(NHC_6H_5)(NHC_2H_5)$	(XIII)	238,278	177000,1300
$CH_3P(S)(NHC_6N_5)_2^*$	(XIV)	238,278	28000,2300

*In alcohol. The letter s denotes a shoulder.

In the spectra of 1,3-dialkyl-2,4-dioxocyclodiphosphazanes the constant for the spin–spin interaction of the proton with the phosphorus nucleus via three H–C–N–P bonds is 13.0–16.3 Hz, the chemical shift of the proton signal amounting to 2.6–3.37 p.p.m.[19]

In the ^{31}P-NMR spectra there is a signal in the region between −7.0 and +5.7 p.p.m.,[10,19] which is characteristic of the P=O group[23].

In the ^1H-NMR spectrum of 1,3-dimethyl-2,4-diphenyl-2,4-dithionocyclodiphosphazane Trippett[24] observed a 1 : 2 : 1 triplet (δ = 2.32 p.p.m., J = 14 Hz) and a second triplet, 10 times less intense, at 2.56 p.p.m. (J = 15.5 Hz). According to Mel'nikov et al.[11], the NMR spectrum of a preparation obtained by a different method contains 1 triplet at 2.52 p.p.m. (J = 15 Hz). The ^1H-NMR spectrum of the 1,3-dibenzyl analogue of this compound was found to have two triplets of approximately equal intensity at 4.14 and 3.99 p.p.m. (J = 15.0 and 18.0 Hz). The two triplets are probably due to the presence in the specimens investigated of *cis*- and *trans*-isomers of 1,3-dimethyl- and 1,3-dibenzyl-2,4-diphenyl-2,4-dithionocyclodiphosphazanes. These data agree satisfactorily with the results of the measurements of the dipole moment of 1,3-dimethyl-2,4-diphenyl-2,4-dithionocyclodiphosphazane[25].

---

† In the ^1H-NMR spectra the chemical shifts are given in terms of the δ scale relative to tetramethylsilane as an internal standard.

The chemical shifts in the ^{31}P-NMR spectra of dithionocyclodiphosphazanes are in the range between −51.5 and −60 p.p.m.,[10] i.e. the screening of the phosphorus atom decreases in the sequence

$$>PCl_3 > \; >P\begin{smallmatrix}O\\R\end{smallmatrix} \; > \; >P\begin{smallmatrix}S\\R\end{smallmatrix}$$

3. Bond Lengths and Valence Angles

Hess and Forst[26] and also Hoard and Jacobson[27] determined by X-ray diffraction the angles and bond lengths in 2,2,2,4,4,4-hexachloro-1,3-dimethylcyclodiphosphazane. Cox and Corey[28] and Weiss and Hartmann[29] made similar measurements (Table 3) for 2,2,4,4-tetrafluoro-1,3-dimethyl-2,4-diphenylcyclodiphosphazane $[MeNPF_2Ph]_2$ and a compound which was isolated by Becke-Goehring et al.[10] (see p. 27).

Table 3. Bond lengths (in ångstroms) and angles (in degrees).

Bonds and angles	Ref.26	Ref.27	Ref.28	Ref.29
Bonds				
P—Cl axial	2.152	2.133	—	2,16
P—N axial	1.776	1.769	1.78	1,71
P—F axial			1.62	
P—Cl radial	2.022; 2.018	2.026		2.05
P—N radial	1.629	1.635	1.64	1.66
P—F radial			1.57	
P—C			1.79	
N—C	1.476	1.475	1.44	
Angles				
P—N—P	98.3	99.5	99.4	99.1
N—P—N	81.7	80.5	80.6	80.7

A centrosymmetric structure with a planar four-membered ring is characteristic of the molecules of cyclodiphosphazanes with a pentacovalent phosphorus atom (see Figure). Each phosphorus atom exhibits dsp^3 hybridisation and consists of a trigonal bipyramid. In such hybrid structures the axial orbitals are longer than the radial orbitals by a factor of 1.1–1.2. This ratio is 1.05–1.07 for P–Cl bonds, 1.085–1.09 for P–N bonds, and 1.08 for P–F bonds. The P–N–P and N–P–N angles are 98.3–99.5°C and 80.5–81.7°C respectively.

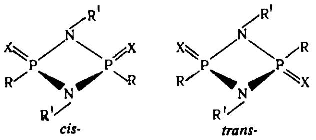
In 2,4-dichloro-1,3-dimethyl-2,4-dithionocyclodiphosphazane containing an sp^3-hybridised phosphorus atom, P–N bonds are of the same length (1.67 Å), i.e. they assume the average value for the radial and axial bond lengths[30]. The lengths of other bonds and the angles between them are given below.

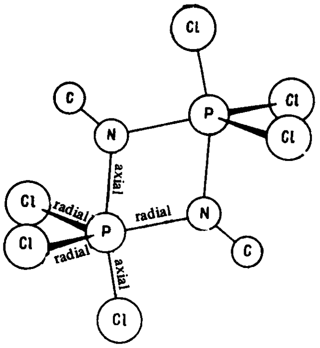
Bond length	P—S (Cl)*	1.93 A
	N—C	1.46 A
Angle	N—P—N	84.0°
	P—N—P	96.0°
	N—P—S (Cl)	114.7°
	S—P—Cl	111.5°

*Weiss and Hartmann do not distinguish S and Cl; usually the P–Cl bond length is 0.01 Å.[23]

4. Dipole Moments

Cyclodiphosphazanes with a tetraco-ordinate phosphorus atom can exist as *cis*- or *trans*-isomers[25]:





The occurrence of *cis*- and *trans*-isomerism in the series of 2,4-dithionocyclodiphosphazanes has been fairly convincingly confirmed by the measurements and calculations of their dipole moments (Table 4), although the calculations were based on a simplified scheme and the extrapolated results of a relatively small number of measurements by different investigators. The considerable deviation of experimental dipole moments of the *trans*-isomers from zero may be explained by their partial inversion in solution.

Table 4. Dipole moments of certain dithionocyclodiphosphazanes.

R	R′	μ_{exp}	$\mu_{cis.\,calc}$
CH_3	CH_3	6.11	7.18
C_6H_5	C_6H_5	5.84	6.70
CH_3	C_6H_5	1.82	7.18
C_6H_5	CH_3	0.7	6.70
Cl	C_6H_5	1.32	3.57

5. Bond Energies

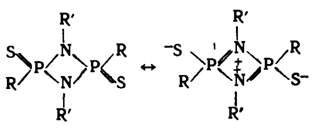
Only one study has been made on the thermochemistry of cyclodiphosphazanes, namely that of Fowell and Mortimer[31], who found that the average P–N bond energy in 2,2,2,4,4,4-hexachloro-1,3-dimethylcyclodiphosphazanes is 74.3 kcal mole^{-1} according to measurements of the heat of hydrolysis. This is close to the P–N bond energy in cyclotriphosphazenes (72.3 kcal mole^{-1}) and cyclotetraphosphazenes (72.5 kcal mole^{-1})[32] and greatly exceeds the energy of the same bond in tri(diethylamino)phosphine (66.8 kcal mole^{-1}).[33] The fact that the formation of the cyclodiphosphazane ring is favoured by thermodynamic factors is indicated also by chemical data. The reaction of tri(diethylamino)phosphine with aniline yields the corresponding cyclodiphospha(III) azane[34].

The P–Cl bond energy is 63.1 kcal mole^{-1},[31] i.e. is smaller by 13.1 kcal mole^{-1} than in PCl_5.[35]

6. The Nature of the Phosphorus–Nitrogen Bond

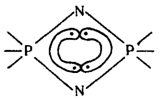
The available physicochemical data on the structure of cyclodiphosphazanes permit certain conclusions concerning the nature of the P–N bond. The shortening of the P–N bond, the planarity of the dimer, the location of the N atoms in the same plane (according to X-ray diffraction analysis), the thermochemical data, and the relatively high stability of the ring in cyclodiphosphazanes with tetra- and penta-co-ordinate phosphorus atoms (see sections IV and V) are evidence of an additional interaction between nitrogen and phosphorus atoms.

The idea that dithionocyclodiphosphazane molecules are stabilised by isomerisation, described by the resonance of the structures[24]



is not confirmed by physicochemical investigations.

It is most probable that the molecules of cyclodiphosphazanes are stabilised by the interaction of the unshared electron pairs of the nitrogen atoms with the *d* orbitals of the adjacent phosphorus atoms[26,36] via three-centre *π*-molecular orbitals[37,38]:



III. CYCLODIPHOSPHAZANES WITH TRICO-ORDINATE PHOSPHORUS ATOMS

The reaction of phosphorus trichloride with aromatic amines in a non-polar solvent yields 2,4-diaminocyclodiphospha(III) azanes[39,40]:

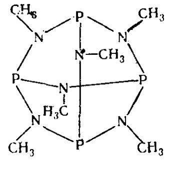
$$10\,C_6H_5NH_2 + 2\,PCl_3 \rightarrow \begin{array}{l} C_6H_5NHP{-}NC_6H_5 \\ \quad\;\; | \quad\; | \\ C_6H_5N{-}PNHC_6H_5 \end{array} + 6\,C_6H_5NH_2 \cdot HCl.$$

An excess of the amine introduced into the reaction or a tertiary amine may be used as the acceptor of hydrogen chloride[5]. Phenyldichlorophosphine reacts similarly[39].

The reaction of phosphorus trichloride with ammonia and primary aliphatic amines does not take place unambiguously. With ammonia, a number of products are formed, according to the following mechanism[41,42]:

$$PCl_3 + NH_3 \rightarrow P(NH_2)_3 \rightarrow [HNP(NH_2)]_n \rightarrow (PNH)_n \rightarrow PN.$$

The reaction of phosphorus trichloride with methylamine gives a compound with a urotropine-like structure[43,44]:



When straight-chain primary amines containing two and more carbon atoms are introduced into the reaction, the corresponding cyclodiphospha(III) azanes are formed[40].

The reaction of aniline hydrochloride with phosphorus trichloride yields 2,4-dichloro-1,3-diphenylcyclodiphospha(III) azane[45]. Its 1,3-dimethyl analogue has been obtained by the amination of phosphorus tetrachloride with heptamethyldisilazane[46]:

$$2\,C_6H_5NH_2 \cdot HCl + 2\,PCl_3 \rightarrow \begin{array}{l} \quad\;\; ClP{-}NC_6H_5 \\ \qquad\;\; | \quad\; | \\ C_6H_5N{-}PCl \end{array} + 6\,HCl,$$

$$2\,[(CH_3)_3Si]_2NCH_3 + 2\,PCl_3 \rightarrow \begin{array}{l} \quad\; ClP{-}NCH_3 \\ \qquad | \quad\; | \\ CH_3N{-}PCl \end{array} + 4\,(CH_3)_3SiCl.$$

It is noteworthy that the reaction of *N*-ethylhexamethyldisilazane with phosphorus trichloride yields a mixture containing 2,4,6-trichloro-1,3,5-triethylcyclotriphosphazane and 2,4,6,8-tetrachloro-1,3,5,7-tetraethylcyclotetraphosphazane[47].

The reaction of tri(triethylamino)phosphine with aniline or *p*-toluidine at 60–70°C leads to the formation of 2,4-dianilino-1,3-diarylcyclodiphospha(III) azanes[34]:

$$3\,ArNH_2 + [(C_2H_5)_2N]_3P \rightarrow \begin{array}{l} ArNHP{-}NAr \\ \quad\;\; | \quad\; | \\ \quad ArN{-}PNHAr \end{array}.$$

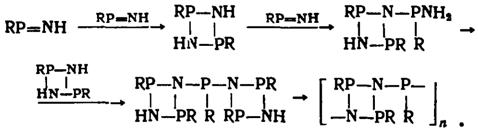
The synthesis of 1,3-dibenzyl-2,4-di(benzylamino)cyclodiphospha(III)azane by the thermal dissociation of the di(benzylamide) of pentafluorophenylphosphonus acid[48] is interesting:

$$2\,C_6F_5P(NHCH_2C_6H_5)_2 \xrightarrow{200^\circ} \begin{array}{l} C_6H_5CH_2NHP{-}NCH_2C_6H_5 \\ \qquad\qquad\quad | \quad\; | \\ \quad C_6H_5CH_2N{-}PNHCH_2C_6H_5 \end{array}$$

Cyclodiphosphazanes can form part of certain polymeric compounds. Thus the thermal decomposition of the amides of pentafluorodimethylphosphinous acid, obtained by the ammonolysis of di(trifluoromethyl)phosphine with liquid ammonia at −78°C, yields linear and cross-linked polymers:

$$(CF_3)_2PH + NH_3 \rightarrow CF_3\overset{\displaystyle NH_2 \atop |}{P}CHF_2 \xrightarrow{\Delta t} (CF_3P{-}NH)_n.$$

The mechanism of their formation is probably as follows[49]:

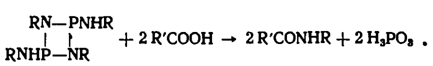


Cyclodiphosphazanes containing a trivalent phosphorus atom are present in solution with a corresponding phospha(III)azo-compounds. On raising the temperature and increasing the polarity of the solvent, the equilibrium shifts to the right[5,40]:

$$\begin{array}{c} {-}P{-}N{-} \\ |\quad\; | \\ {-}N{-}P{-} \end{array} \rightleftarrows {-}P{=}N{-}.$$

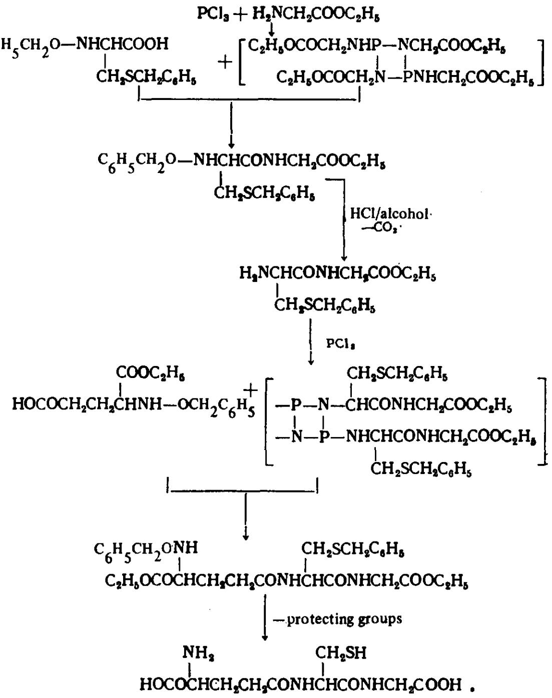
This equilibrium accounts to a large extent for the ease of the dissociation of the cyclodiphosphazane ring under the action of nucleophilic reagents.

When water reacts with diaminocyclodiphospha(III)azanes, diamides of phosphorous acid are formed. Inorganic acids decompose cyclodiphosphazanes to phosphorous acids and substituted ammonium salts. Organic acids react with formation of carboxylic acid amides[45,50,51]:

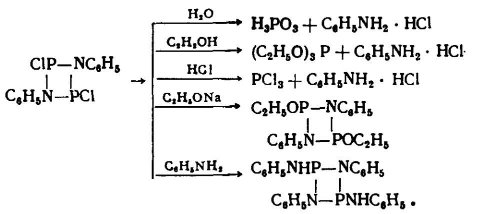


$$\begin{array}{l} \quad RN{-}PNHR \\ \qquad | \quad\; | \\ RNHP{-}NR \end{array} + 2\,R'COOH \rightarrow 2\,R'CONHR + 2\,H_3PO_3.$$

The salts of carboxylic acids do not react with cyclodiphosphazanes. Preparative methods for the synthesis of acid amides, substituted ureas, and di-, tri-, and tetrapeptides have been developed on the basis of these data[50-56]. In the synthesis of peptides, amino-acid derivatives are allowed to react with phosphorus trichloride, the reaction mass being subsequently treated with the amino-acid without isolating the cyclodiphospha(III)azane in a pure form. The following elegant synthesis of glutathione may be quoted as an example[51]:



2,4-Dichloro-1,3-diphenylcyclodiphospha(III)azane also readily reacts with nucleophilic reagents, undergoing ring rupture, under the conditions of acid catalysis. It undergoes substitution reactions with alkaline nucleophilic reagents (sodium alkoxides, piperidine, aniline)[45,56]:



Cyclodiphospha(III) azanes also enter into addition reactions with electrophilic reagents via the unshared electron pairs. Thus in the reaction with alkyl halides, arylalkyl halides, and halogenomethyl ethers, 1,3-dialkyl-2,4-di(alkylamino)cyclodiphosphazanes are converted into the corresponding salts[5]:

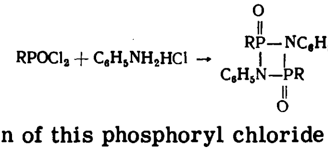
The charge distribution in this molecule has not been investigated.

N-Methylaniline has been isolated after the reaction of 2,4-dianilino-1,3-diphenylcyclodiphosphazane with methylmagnesium iodide and dimethyl sulphate[53].

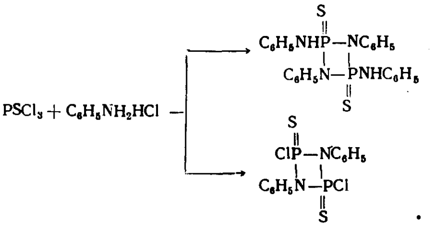
IV. CYCLODIPHOSPHAZANES WITH TETRACO-ORDINATE PHOSPHORUS ATOMS

Cyclodiphosphazanes with tetraco-ordinate phosphorus atoms are obtained both from linear molecules and from pre-formed cyclic structures.

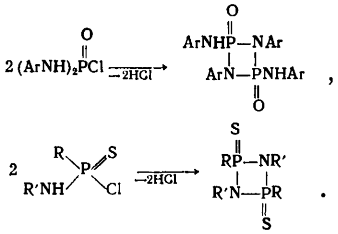
When the hydrochlorides of aromatic amines[2,57,58] or the free amines themselves[59] are heated for many hours with phosphorus oxychloride, phosphoramidic dichlorides, aryl phosphorodichloridates, or phenylphosphonic dichlorides in xylene, 2,4-dioxocyclodiphosphazanes are obtained:



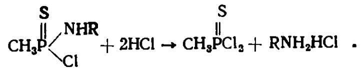
The reaction of this phosphoryl chloride with aniline hydrochloride leads to 2,4-dianilino-1,3-diphenyl or 2,4-dichloro-1,3-diphenyl-2,4-dithionocyclodiphosphazanes depending on the reactant ratio and the process conditions[60]:



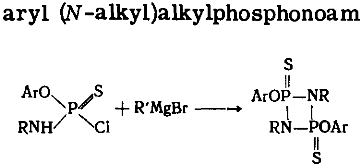
The thermal dehydrochlorination of the chlorides of pentavalent phosphorus acid amides containing a primary or a secondary nitrogen atom results in the formation of the corresponding 2,4-dioxo- or 2,4-dithionocyclodiphosphazanes[1,11,58]:



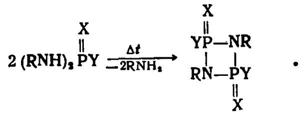
The last reaction is carried out at a reduced pressure of 100–200 mmHg and 120–150°C. Methylphosphonothionic dichloride and the hydrochloride of the corresponding amine were isolated as side products. Their formation may be explained by the following mechanism[11]:



The attempts to employ tertiary amines as acceptors for hydrogen chloride in this process were unsuccessful. However, quite unexpectedly, it was found that organomagnesium compounds may be used as dehydrochlorinating agents. Thus the reaction of butyl- or pentyl-magnesium bromide with aryl *N*-alkylphosphoramidochloridothionates led to the corresponding dithionocyclodiphosphazanes together with aryl (*N*-alkyl)alkylphosphonoamidothionates[61]:



The most general method for the synthesis of dioxo- and dithiono-cyclodiphosphazanes of different structures is thermal deamination of the amides of phosphorus acids containing at least two secondary amide groups[1,24,58,62-66]:

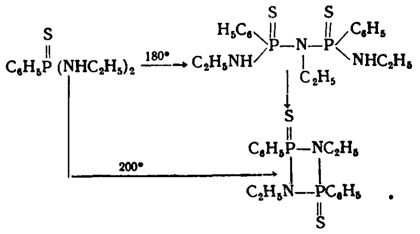


Compounds of the following types have been used as the starting materials:

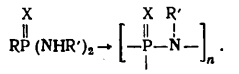
$(RNH)_3P{=}O,\ (RNH)_3P{=}S;\ (RNH)_2P({=}O)NR_2;\ (RNH)_2P({=}S)R'.$

The reaction is carried out in a stream of an inert gas at 200–300°C. The derivatives of thioic acids usually decompose at a lower temperature and give higher yields of the final products than oxygen analogues. When phosphorothionic tri(isobutylamide) was heated in the temperature range 260–280°C, the corresponding dithionocyclodiphosphazane was isolated in a 56% yield. The preparation of the oxygen analogue required a temperature of 280–295°C and the yield fell to 21%.[64]

Ibrahim and Shaw[65] obtained data demonstrating indirectly that thermal cyclisation of phosphorus acid amides takes place in steps. Thus on heating to 180°C phenylphosphonothionic di(ethylamide) is converted into di-*N*-ethylphenylphosphonamidothionylethylamine, while the reaction at 200°C leads to the formation of the corresponding dithionocyclodiphosphazane:

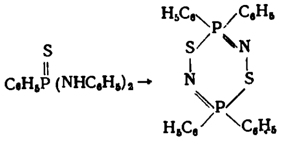


The synthesis of dioxo- and dithiono-cyclodiphosphazanes by the thermal deamination of the amides of phosphorus acid is accompanied by a side process—polycondensation involving the formation of polymers with phosphorus—nitrogen bonds[67-69]:

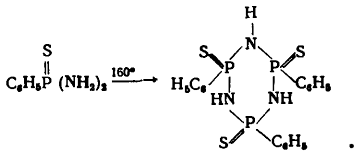


$RP(X)(NHR')_2 \rightarrow \left[-\overset{X}{\underset{|}{P}}-\overset{R'}{N}-\right]_n.$

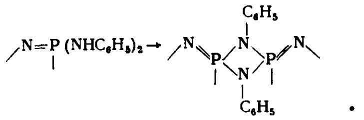
Cleavage of the dianilide of phenylphosphonothionic acid at 265°C leads to the formation of 1,1,4,4-tetraphenyl-2,5-diaza-3,6-dithia-1,4-diphosphacyclohexa-1,4-diene[65] and not tetraphenyldithionocyclodiphosphazane:



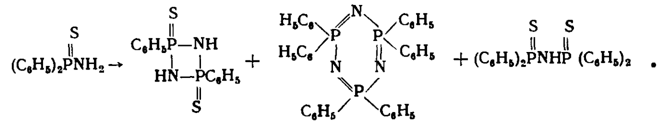
Thermal deamination of phenylphosphonothionic diamide at 160°C results in the formation of 2,4,6-triphenyl-2,4,6-trithionocyclotriphosphazane, while *N*-alkyl homologues yield under these conditions dithionocyclodiphosphazanes[65]:



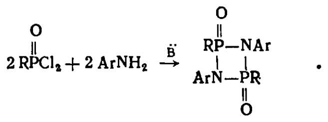
Probably the polymeric products formed in the thermal condensation of hexa-anilinocyclotriphosphazenes include cyclodiphosphazane structures[70]:



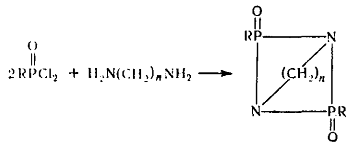
2,4-Diphenyl-2,4-dithionocyclodiphosphazane in a yield of 17% together with bisdiphenylphosphonothionic imide and 2,2,4,4,6,6-hexaphenylcyclotriphosphazene were isolated from a mixture obtained on thermal decomposition of diphenylphosphinothionic amide at 280°C for 30 min[71]:



The reaction of the dichlorides of alkyl(aryl)phosphonic acids with primary aliphatic or aromatic amines in the presence of bases (molar ratios of the reactants 1 : 1 : 2) in inert solvents constitutes a convenient method for the synthesis of 1,3-dialkyl(aryl)-2,4-dialkyl(aryl)-2,4-dioxocyclodiphosphazanes[66,72-76]:

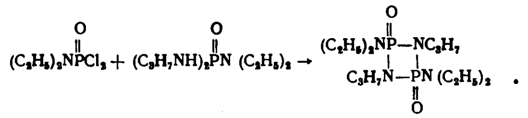


According to Binder and Heinle[72], the reaction of one mole of an alkylenediamine with two moles of a phosphonic acid dichloride can lead to the formation of dioxocyclodiphosphazanes with an alkylene bridge between the nitrogen atoms:

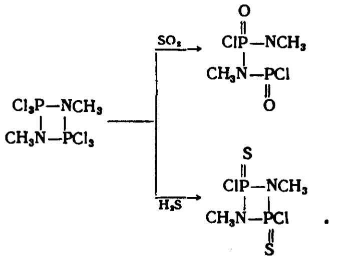


However, the structure of the compound obtained was not proved.

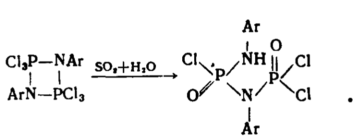
Bock and Wiegrabe[64] proposed an interesting method for the synthesis of dioxocyclodiphosphazanes with various substituents at the nitrogen atom. When the dichloride of *NN*-diethylphosphoramidic acid was heated with phosphoric *NN*-diethyldi(*N'*-propyl)triamide in benzene in the presence of triethylamine, the product was 1,3-dipropyl-2,4-di(diethylamino)-2,4-dioxocyclodiphosphazane:



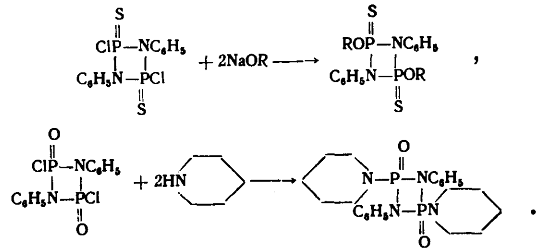
The conversion of 2,2,2,4,4,4-hexachlorocyclodiphosphazanes into 2,4-dichloro-2,4-dioxo- or 2,4-dichloro-2,4-dithiono-cyclodiphosphazanes takes place when the former compounds are treated with sulphur dioxide or hydrogen sulphide in the presence of pyridine[10,19].



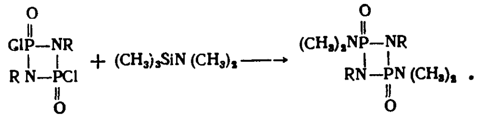
Treatment of hexachlorocyclotriphosphazanes with sulphur dioxide in the presence of moisture in phosphorus oxychloride results in ring rupture and the formation of *NN'*-diaryl-*N*-(dichlorophosphinyl)phosphorodiamidic chloride[77]:



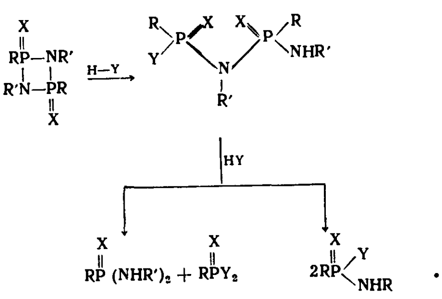
Substitution of a halogen in 2,4-dichloro-2,4-dioxo- or 2,4-dichloro-2,4-dithiono-cyclodiphosphazanes may be used for the introduction of various substituents into the molecule. Thus the reaction with sodium alkoxides or phenoxides under mild conditions leads to the formation of 2,4-dialkoxy-derivatives. The reactions with amines or anilines yield 2,4-diamino-derivatives of 2,4-dioxo- or 2,4-dithiono-cyclodiphosphazanes[2,60]:



Halogen substitution in 2,4-dichloro-2,4-dioxocyclodiphosphazanes by dialkylamino- and alkylthio-groups has also been achieved by reaction with dialkylamino- and alkylthio-trimethylsilanes respectively[19]:

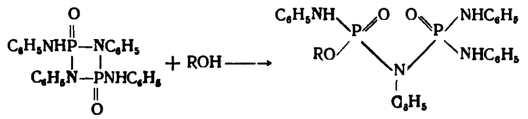


Cyclodiphosphazanes with tetraco-ordinate phosphorus atoms are fairly stable. However, nucleophilic reagents with a labile hydrogen atom, such as water, alcohols, phenols, amines, β-diketones, esters of β-keto-acids, etc. at a high temperature rupture the four-membered ring[1,2,8,62,63,78,79]. The process takes place in steps:

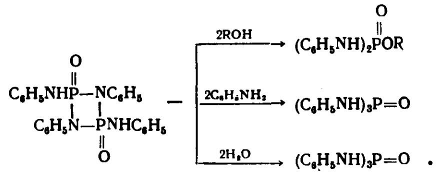


Initially one P–N bond dissociates and an unsymmetrical diphosphoric imide (or a diphosphonic imide or their thio-analogues) is formed and reacts with a molecule of the nucleophilic reagent with dissociation of the second P–N bond. This may result in the formation of both symmetrical and unsymmetrical compounds[63,79].

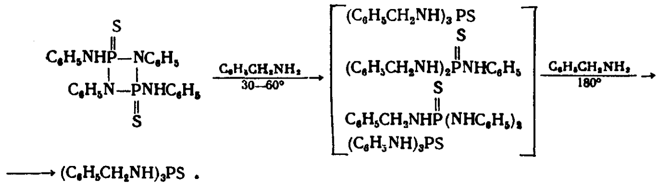
The cleavage reactions of 2,4-dioxocyclodiphosphazanes have been investigated in greater detail. Michaelis[1,2] showed that the process may also be stopped at the first stage. For example, when one mole of phenol, ethyl alcohol, or sodium alkoxide reacts with 2,4-dianilino-1,3-diphenyl-2,4-dioxocyclodiphosphazane, the corresponding diphosphoric imides are formed[2,58]:



Esters of *NN*-diphenylphosphorodiamidic acid have been isolated after reaction with two moles of phenol or alcohol. The reaction with two moles of water gives phosphoric trianilide. The latter was also isolated after the reaction with aniline:

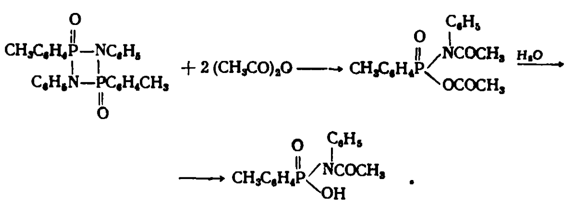


The reaction of 2,4-dianilino-1,3-diphenyl-2,4-dithionocyclodiphosphazane with benzylamine at 30–60°C leads to a mixture of phosphorothionic triamides, which could not be separated. If the mixture is heated with an excess of benzylamine at 180°C, transamination takes place and phosphorothionic tri(benzylamide) is formed[63]:

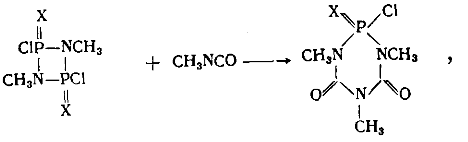


The reaction of 2,4-dimethyl-1,3-diphenyl-2,4-dithionocyclodiphosphazane with butylamine in a sealed tube at 160–170°C for several hours yielded a mixture of products containing the dianilide, *N*-butyl-*N'*-phenyl-diamide, and di-(n-butylamide) of methylphosphonothionic acid. The mixture could be separated by thin-layer and column chromatography[79].

The reaction of acetic anhydride with 1,3-diphenyl-2,4-ditolyl-2,4-dioxocyclodiphosphazane gave the *N*-acetylated mixed anhydride of phosphonic and acetic acids, which is readily hydrolysed by water and yields the corresponding phosphonoamidic acid[2]:



The reaction of 2,4-dichloro-1,3-dimethyl-2,4-dioxocyclodiphosphazane or its sulphur analogue with methyl isocyanate results in the formation of 1-chloro-2,4,6-trimethyl-1,2,4,6-phosphatriazane-1,3,5-trione. The process is carried out in a sealed tube in dry benzene at 100°C for several days[80]:



where X = O or S.

V. CYCLODIPHOSPHAZANES WITH PENTACO-ORDINATE PHOSPHORUS ATOMS

The simplest and most general method for the synthesis of 1,3-dialkyl- or 1,3-diaryl-2,2,2,4,4,4-hexachlorocyclodiphosphazanes consists in the reaction between phosphorus pentachloride and primary aliphatic amines and also the hydrochlorides of aliphatic and aromatic amines[3,8,81-87]:

$$2\,PCl_5 + 2\,RNH_2\cdot HCl \longrightarrow \begin{array}{c} Cl_3P-NR \\ |\quad\ \ | \\ RN-PCl_3 \end{array} + HCl\ .$$

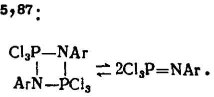
This reaction was discovered by Kirsanov and Zhmurova[3] in 1959. The reaction of phosphorus pentachloride with aniline hydrochloride was first investigated by Gilpin[88], but the latter was unable to establish the structure of the compound produced.

Whether or not the reaction occurs depends on the basicity of the initial amines. An empirical rule has been deduced from experimental data for substituted anilines, according to which hexachlorocyclodiphosphazanes are formed only if the basicity constant of the initial aniline is higher than 1×10^{-13}.

With less basic anilines, the reaction leads to the formation of trichlorophosphazoarenes[85,87]:

$$PCl_5 + RNH_2\cdot HCl \rightarrow Cl_3P{=}NR + 3\,HCl\ .$$

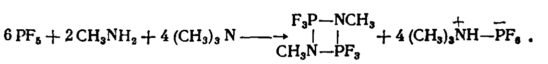
On heating in benzene solution or without solvent up to 150°C and above, hexachlorodiarylcyclodiphosphazanes are frequently converted into phosphazo-compounds, which on evaporation of the solution dimerise and are reconverted into cyclic products[85,87]:



$$\begin{array}{c} Cl_3P-NAr \\ |\quad\ \ | \\ ArN-PCl_3 \end{array} \rightleftarrows 2Cl_3P{=}NAr\,.$$

In the case of aliphatic amines, the structure of the aliphatic chain plays an important role rather than the basicity of the compound[8,82-84]. While amines with an unbranched chain and their hydrochlorides form hexachlorodialkylcyclodiphosphazanes in the reaction with phosphorus pentachloride, amines with substituents in α- and β-positions yield as a rule trichlorophosphazoalkanes. Substituents in the γ-position do not have a significant effect on the reaction.

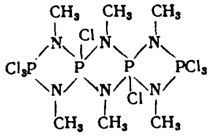
$C_6H_5PCl_4$ can react with aliphatic and aromatic amines[89,90] to form 1,3-dialkyl(diaryl)-2,2,4,4-tetrachloro-2,4-diphenylcyclodiphosphazanes. Amines react with phosphorus pentafluoride in the presence of tertiary amines:



$$6\,PF_5 + 2\,CH_3NH_2 + 4\,(CH_3)_3\,N \longrightarrow \begin{array}{c} F_3P-NCH_3 \\ |\quad\ \ | \\ CH_3N-PF_3 \end{array} + 4\,(CH_3)_3\overset{+}{N}H-\overset{-}{P}F_6\ .$$

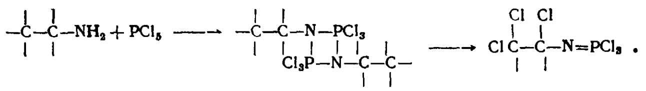
In many cases it is convenient to employ adducts of amines and phosphorus pentafluoride. Thus the 1 : 3 adduct of aniline with phosphorus pentafluoride yields hexafluoro-2,4-diphenylcyclodiphosphazane[91,92].

As regards side reactions, mention should be made of the formation of a tricyclic spirane when phosphorus pentachloride reacts with methylamine hydrochloride[10]:

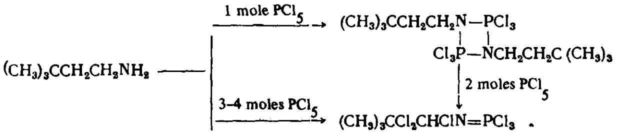


(I)

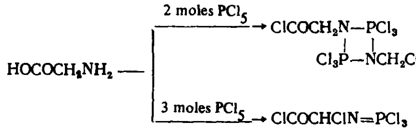
Another side process is the chlorination of the carbon chain of the amine by the excess phosphorus pentachloride. For example, aliphatic amines can be chlorinated simultaneously in the α- and β-positions, This process consists of many stages. A cyclodiphosphazane evidently forms initially and is then chlorinated in stages and converted into a trichlorophosphazochloroalkane[93]:



This mechanism is confirmed indirectly by experimental data. Thus the reaction of $\gamma\gamma$-dimethylbutylamine with one mole of phosphorus pentachloride leads to the formation of the corresponding cyclodiphosphazane and the reaction with 3–4 moles of phosphorus pentachloride yields $\alpha\beta\beta$-trichloro-trichlorophosphazo-$\gamma\gamma$-dimethylbutane. The latter has also been isolated as the product of the reaction between two moles of phosphorus pentachloride and 2,2,2,4,4,4-hexachloro-1,3-di-($\gamma\gamma$-dimethylbutyl) cyclodiphosphazane:



Similarly the reaction of glycine with two moles of phosphorus pentachloride leads to the formation of hexachloro-1,3-di(chlorocarbonylmethyl)cyclodiphosphazane. When the amount of phosphorus pentachloride is increased, the product is trichlorophosphazochlorocarbonylchloromethane[84,93].

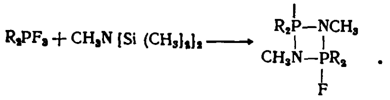


Hexafluorocyclodiphosphazanes can be synthesised in high yields by double decomposition of hexachlorocyclodiphosphazane with antimony trifluoride[94]:

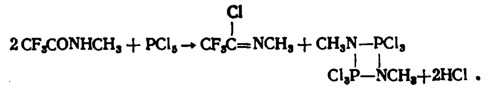
$$\begin{array}{c} CH_3N-PCl_3 \\ |\quad\ \ | \\ Cl_3P-NCH_3 \end{array} + SbF_3 \longrightarrow \begin{array}{c} CH_3N-PF_3 \\ |\quad\ \ | \\ F_3P-NCH_3 \end{array}.$$

Fluorination can be also achieved with KSO_2F in nitrobenzene but the yields are low[95].

An interesting method for the synthesis of fluorinated cyclodiphosphazanes is the reaction of heptamethyldisilazane with phosphorus pentafluoride, alkyl- and aryltetrafluorophosphoranes, or dialkyl- and diaryl-trifluorophosphoranes[96,97]:

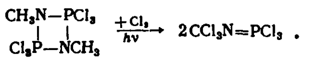


When the methylamide of trifluoroacetic acid was heated with phosphorus pentachloride, dimethylhexachlorocyclodiphosphazane and 1-chloro-2,2,2-trifluoro-*N*-methylethylideneimine were isolated[98]:

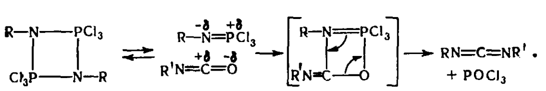


All hexachloro- or tetrachloro-diphenylcyclodiphosphazanes are white crystalline materials readily soluble in organic solvents and readily hydrolysed by atmospheric moisture.

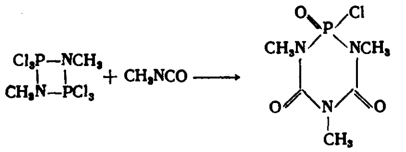
Photochemical chlorination converts hexachlorodimethylcyclodiphosphazane into monomeric trichlorophosphazotrichloromethane[94]:



Hexachlorocyclodiphosphazanes readily react with compounds having a polarised double bond[99]. The reaction takes place above 150°C. Under these conditions, cyclodiphosphazanes probably dissociate to phosphazo-compounds. For example, the reaction of hexachlorodimethylcyclodiphosphazane with phenyl isocyanate in *o*-dichlorobenzene at 175–180°C yields methylphenylcarbodi-imide. Similarly diphenylcarbodi-imide is obtained from hexachlorodiphenylcyclodiphosphazane. The corresponding isothiocyanates and isocyanates are formed analogously in the reaction with carbon disulphide and carbon dioxide. The reaction probably involves the formation of a four-membered cyclic intermediate:

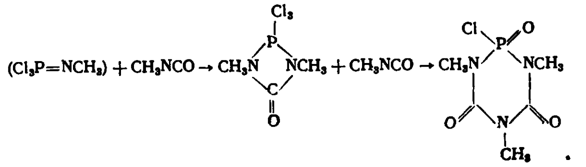


1-Chloro-2,4,6-trimethyl-1,2,4,6-phosphatriazane-1,3,5-trione was obtained on prolonged heating of hexachlorodimethylcyclodiphosphazane with methyl isocyanate in a sealed tube with dry benzene at 100°C:[80]

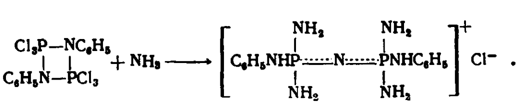


Phosphorus oxychloride and *N*-methyliminophosgene were formed as side products.

To account for the mechanism of this reaction, one may suppose that methyl isocyanate attacks the "intact" four-membered ring with formation of a cyclic system comprising a large number of units as the result of the addition of one or several methyl isocyanate molecules. Transannular double decomposition reaction with other methyl isocyanate molecules yields a six-membered cyclic system which is energetically more favoured. The dissociated bonds are reformed and the process can be repeated. On the other hand, one may suppose that monomeric trichlorophosphazomethane reacts with methyl isocyanate:

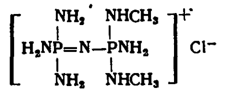


The reactions of hexachlorocyclodiphosphazanes with sulphur dioxide and hydrogen sulphide in the presence of bases were considered in the preceding section. The reaction of hexachlorodiphenylcyclophosphazane with liquid ammonia yields a phosphonium salt (II) in a yield of 41%:[100]



(II)

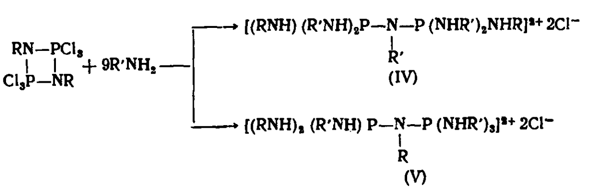
Hexachlorodimethylcyclodiphosphazane reacts similarly with ammonia: both chlorine atoms are substituted with simultaneous cleavage of the ring and the formation of the salt (III), the structure of which has been confirmed by X-ray diffraction analysis[102, 103]:



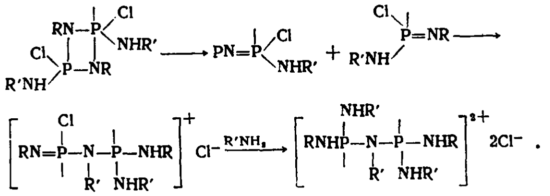
(III)

The reaction of methylamine and hexachlorodiphenylcyclodiphosphazane leads to a polymer with a molecular weight of 1450 and a melting point of 58°C; dimethylamine yields monomeric products[101] with the general formula $C_6H_5N{-}PCl_n[N(C_2H_5)_2]_{3-n}$.

Hexachlorodialkylcyclodiphosphazanes react with an excess of primary amines to form bisphosphonium salts, the structure of which has not, however, been demonstrated[104]:



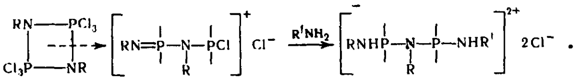
Two mechanisms have been proposed for the aminolysis of hexachlorocyclodiphosphazanes[104]. In the first of these the initial formation of a phosphazo-structure is postulated:



Compounds with the structure (IV) can also be formed by this mechanism if one takes into account the possibility of the tautomerism of the intermediate phosphazo-compound:

$$RN{=}P{-}NHR' \rightleftarrows RNHP{=}NR' .$$

The second mechanism involves the dissociation of one phosphorus–nitrogen bond at a definite stage in the substitution of chlorine atoms by alkylamino-groups:



The available experimental data are more consistent with this mechanism; it also agrees with the mechanism proposed for the reaction of cyclodiphosphazanes having tetraco-ordinate phosphorus atoms with nucleophilic reagents[79].

Interactions between Atoms and Radicals in the Liquid Phase

E.T.Denisov

CONTENTS

The review presents a compilation and an analysis of the results of quantitative kinetic studies on liquid-phase interactions between atoms and free radicals. Problems such as the diffusion mechanism for the recombination of atoms in solution, the competition between recombination and disproportionation reactions of alkyl radicals in the liquid phase, the mechanisms of the reactions of secondary and tertiary peroxy-radicals, the effect of the viscosity, internal pressure, and dielectric constant of the liquid on the rate constant for the interaction between the radicals, and also the role of radical hydrogen bonds are discussed. The rate constants for 142 interactions of atoms and radicals in different solvents are quoted.
The bibliography includes 165 references.

I. INTRODUCTION

The interactions of atoms and radicals play an important role in a wide variety of free-radical reations. In chain reactions such as polymerisation, oxidation, and halogenation the elementary steps involving interactions between free radicals are responsible for chain termination (in the absence of inhibitors). For this reason, the concentration of free radicals and hence the rate of the chain process depend on the rate constants for these reactions. Atoms and radicals arise in the liquid phase under the action of light and penetrating radiation. Very frequently in such cases the reactions between free radicals determine not only the rate of formation of products but also their composition.

Reactive free radicals and atoms interact with one another very rapidly; this retarded the quantitative study of these processes for a long time. The development and extension of the kinetic methods for the investigation of fast reactions constituted an important pre-condition for the vigorous development of studies on radical reactions in the last twenty years. A large amount of data has accumulated on the kinetics of recombination and disproportionation reactions of free radicals. The interest in these reactions is not fortuitous, since they constitute an example of the interaction of chemically highly reactive species and occupy an important place in chain processes. The aim of the present review is to examine the experimental data and theoretical concepts concerning the interactions of atoms and radicals in solution.

The rate constants for the reactions of atoms and radicals are measured by the following methods: electron spin resonance (ESR), method of the non-steady-state kinetics of chain reactions (NKR), the method of intermittent illumination—the rotating sector method (RSM), flash photolysis (FP), pulse radiolysis (PR), flow methods (FM), the method of photochemical space intermittency (PSI), and the method of competing reactions (MCR). These methods have been described in monographs and individual papers [1-8].

II. RECOMBINATION OF ATOMS IN SOLUTION

In the gas phase atoms recombine in triple collisions of two atoms with a third particle (molecule or atom) which partially deactivates the excited molecule formed from the atoms. In solution a third particle (solvent molecule) is always present. Therefore the rate of recombination of atoms in solution is limited solely by their diffusion. The rate constants for the recombination of hydrogen, bromine, and iodine atoms are similar (Table 1) and lie in the range $1 \times 10^{10}-3 \times 10^{10}$ litre mole^{-1} s^{-1}. Since in each elementary recombination step two atoms disappear and one molecule is formed, in the steady state $w_i = 2k[x]^2$, where w_i is the rate of initiation and k the recombination rate constant. Table 1 and other tables list the values of $\lg(2k)$, the dimensions of k being throughout litre mole^{-1} s^{-1}.

Table 1. Rate constants for the recombination of atoms in solution ($\theta = 4.57T/1000$).

The rate constant for diffusion is related to the diffusion coefficient by Smoluchowski's equation[19]: $k_D = 4\pi\sigma DN/1000$, where σ is the diameter of the diffusing species (cm), N the Avogadro number, and D the diffusion coefficient (cm^2 s^{-1}); k_D is expressed in litre mole^{-1} s^{-1}. The diameter of the iodine atom is 4.3 Å. Table 2 lists the diffusion coefficients of iodine atoms[14] calculated from the experimental values of k, and includes for comparison the experimental diffusion coefficients of iodine molecules[20,21].

Table 2. Diffusion coefficients of atomic[14] and molecular[20,21] iodine.

$CCl_2{=}CCl{-}CCl{=}CCl_2$	25	1.9	—
$CCl_2{=}CCl{-}CCl{=}CCl_2$	35	2.1	—

Using the Stokes–Einstein equation $D = kT/3\pi\eta\sigma$, it is possible to calculate k_D from the viscosity η: $k_D = 8RT/3000\eta$. According to this expression, the product $k_D\eta T^{-1}$ for different solvents should be constant. However, in fact $k_D\eta/T$ for iodine atoms varies from solvent to solvent[14]: at 25°C it is 1.29×10^5 in n-hexane, 2.22×10^5 in carbon tetrachloride, and 6.15×10^5 in hexachloroethane. Consequently the Stokes–Einstein equation does not hold rigorously for the diffusion of atoms in liquids. This can be explained by the fact that the viscosity depends on the dimensions of solvent molecules and the interaction forces between them, while the diffusion coefficient is determined by the interaction between the diffusing species and solvent molecules.

III. DISPROPORTIONATION AND RECOMBINATION OF ALKYL RADICALS

Alkyl radicals interact in two ways: they recombine with formation of a new C–C bond and disproportionate with the abstraction of a hydrogen atom by one radical from another with formation of an olefin and an alkane. The interaction between methyl and ethyl radicals may serve as an example:

$$CH_3^{\cdot} + C_2H_5^{\cdot} \rightarrow CH_3CH_2CH_3 + 80.5 \text{ kcal mole}^{-1}$$
$$CH_3^{\cdot} + C_2H_5^{\cdot} \rightarrow CH_4 + CH_2{=}CH_2 + 64 \text{ kcal mole}^{-1}$$

The heats of these reactions have been calculated from the heats of formation of the radicals quoted in Ref. 22. The ratio of the disproportionation and recombination rate constants of alkyl radicals has been measured experimentally in the following way. An azo-compound was decomposed photochemically in a solvent; this resulted in the following reactions:

$$R{-}N{=}N{-}CH_2CH_2R' \xrightarrow{h\nu} \overline{R' + R'CH_2CH_2^{\cdot}} + N_2 \,,$$
$$\overline{R^{\cdot} + CH_2CH_2R'} \xrightarrow{k_d} RH + CH_2{=}CHR' \,,$$
$$\overline{R^{\cdot} + \cdot CH_2CH_2R'} \xrightarrow{k_r} RCH_2CH_2R' \,.$$

The radicals disproportionated and recombined in a solvent cage. Since the olefin $CH_2{=}CHR'$ was obtained only by the disproportionation reaction and the hydrocarbon RCH_2CH_2R' by the recombination reaction, analysis of the products for the relative amounts of the olefin and the alkane yields the ratio of the rate constants: $k_d/k_r = [CH_2{=}CHR^{\cdot}]/[RCH_2CH_2R']$. Table 3 shows that this ratio depends on the structure of the reacting radicals and is in the range 0.1–1. The difference between the activation energies for recombination and disproportionation in the reactions between a methyl and an ethyl radical and between two ethyl radicals is $E_r - E_d = 0.4$ kcal mole^{-1}. In the solid state, in contrast to solution, $\lg(k_d/k_r)$ is independent of temperature[26].

Table 3. Relative contributions of the disproportionation and recombination of radicals with a free valence at a carbon atom ($\theta = 4.57T/1000$).

$2CH_3\dot{C}HOH$	H_2O	23	$\bar{1}.40$	30
	cyclo-$C_6H_{11}OH$	25	0.30	31
$2{\sim}CH_2\dot{C}(CH_3)COOCH_3^{-}$	$CH_2{=}C(CH_3)COOCH_3$	0–60	$1.99-2.26/\theta$	32

The recombination of hydroxyalkyl radicals results in the formation of a diol and their disproportionation yields an alcohol and a carbonyl compound. For example:

$$2\,CH_3\dot{C}HOH \begin{cases} \xrightarrow{k_r} CH_3CH(OH)CH(OH)CH_3 \\ \xrightarrow{k_d} CH_3CHO + CH_3CH_2OH \,. \end{cases}$$

The rate constant ratios k_d/k_r have been calculated from the composition of the products formed in the radiolysis of the corresponding alcohols. The relative contributions of the disproportionation and recombination of alkyl radicals vary from solvent to solvent owing to the effect of the internal pressure of the liquid on k_d and k_r. With increase of the internal pressure in the solvent, k_d/k_r for ethyl radicals increases from 0.13 in the gas phase to 0.26 in ethylene glycol at 0°C.[26] There is a satisfactory linear relation between $\lg(k_d/k_r)$ for ethyl radicals and $P_s^{1/2}$, where P_s is the internal pressure of the solvent[25]:

$$\lg(k_d/k_r) = -1.08 + 4.76 \times 10^{-3} P_s^{1/2} \,.$$

The explanation is that the volume of the activated complex in the disproportionation process is somewhat smaller than in recombination. For ethyl radicals, $V_r^{\ddagger} - V_d^{\ddagger} = 2.4$ cm^3 mole^{-1} at 0°C.[26]

Table 4. Overall rate constants for the interactions of radicals having a free valence at a carbon atom.

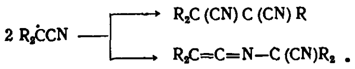
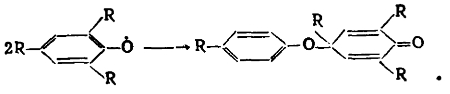
Kinetic methods make it possible to measure the overall rate constants for the interactions between alkyl radicals, which are listed in Table 4 [$k = k_d + k_r$, the values of lg(2k) are listed]. Table 4 shows that the radicals $C_2H_5^\bullet$,[33] $(CH_3)_3C^\bullet$,[44] $C_6H_5CH_2^\bullet$,[34] and $CH_3\dot{C}HOH$,[30,46,47] interact with very high rate constants in the range 1×10^9–5×10^9 litre mole^{-1} s^{-1}, which are equal [lg(2k)] or close to the rate constants for the diffusion of radicals. The radicals $R_2\dot{C}CN$ recombine with formation of a C–C or C–N bond[78]:



Tetralyl, cumenyl, and trichloromethyl radicals interact with rate constants which are significantly smaller than the diffusional rate constants. The problems associated with the interactions of macroradicals with one another in polymerisation processes have been examined in monographs[3,79] and in a review[80].

IV. REACTIONS OF HO$^\bullet$ AND RO$^\bullet$ RADICALS

The rate constant for the recombination of hydroxy-radicals is equal to the diffusion rate constant (Table 5). On the other hand, phenoxy-radicals substituted in the 2-, 4-, and 6-positions recombine very slowly. The recombination of substituted phenoxy-radicals is mainly of the "head to tail" type[81]:



V. REACTIONS BETWEEN PEROXY-RADICALS

1. The Hydroperoxy-radical

The $HO_2^\bullet$ radical has amphoteric properties and in aqueous solution can be present in the forms $HO_2^\bullet$, O_2^-, and $H_2O_2^{\bullet+}$ depending on the pH. At pH ⩾ 5 the equilibrium $HO_2^\bullet \rightleftharpoons H^+ + O_2^-$ is displaced to the right[92]: $pK_{HO_2^\bullet} = 4.4 \pm 0.4$ at 23°C.[92] The rate constant for the reaction $O_2^- + O_2^- \rightarrow O_2 + O_2^{2-}$ is 1.5×10^7 litre mole^{-1} s^{-1} at 23°C.[92] At pH ⩽ 2 the equilibrium is displaced to the left and under these conditions the disproportionation of the HO$^\bullet$ radicals takes place: $HO_2^\bullet + HO_2^\bullet \rightleftharpoons O_2 + H_2O_2$; $k = 2.2 \times 10^6$ litre mole^{-1} s^{-1} at 23°C.[92] It is interesting to note that the electron transfer process between two O_2^- radical-ions which bear the same charge is much faster than the adiabatic reaction with transfer of a hydrogen atom between two neutral $HO_2^\bullet$ radicals. In strongly acid media at pH < 1, $HO_2^\bullet$ is protonated: $HO_2^\bullet + H^+ \rightleftharpoons H_2O_2^{\bullet+}$; at 23°C $pK = 1.0 \pm 0.4$.[93] In this pH range the rate constant for the reaction of $HO_2^\bullet$ radicals depends on the ionic strength of the solution, which is characteristic of an ion–ion type of reaction. The rate constants[93] are $k = 3 \times 10^6$ litre mole^{-1} s^{-1} for the reaction between $HO_2^\bullet$ and $H_2O_2^{\bullet+}$ and $k = 0.5 \times 10^6$ litre mole^{-1} s^{-1} for the reaction between $2H_2O_2^{\bullet+}$ species.

In organic solvents the formation of hydroperoxy-radicals is postulated in the oxidation of cyclohexadiene, dihydronaphthalene, and 9,10-dihydrophenanthrene:

or

This is proved by the fact that in the oxidation of the above hydrocarbons hydrogen peroxide is formed and also by the similarity of the disproportionation rate constants for the peroxy-radicals derived from the hydrocarbons. For example, in chlorobenzene at 30°C $k = 6.3 \times 10^8$ litre mole^{-1} s^{-1} in the oxidation of cyclohexadiene and $k = 3.5 \times 10^8$ litre mole^{-1} s^{-1} in the oxidation of dihydronaphthalene. The sharp difference between the rate constants for the disproportionation of hydroperoxy-radicals in organic solvents and in water can be accounted for by the fact that in water $HO_2^\bullet$ radicals are linked by hydrogen bonds of the type $HO_2^\bullet \ldots HOH$ and $^\bullet O_2H \ldots O\langle^{H}_{H}$, which sharply reduces the rate of their interaction. In a hydrocarbon solvent the rate constant for the interaction of $HO_2^\bullet$ radicals is close to the diffusional rate constant (Table 7).

2. Tertiary Peroxy-radicals

The reaction between tertiary peroxy-radicals has been investigated in detail for cumenyl peroxy-radicals. Among the products of the initiated oxidation of cumene, Blanchard[94] detected a peroxide acetophenone and proposed the following reaction mechanism:

$$2RO_2^\bullet \rightarrow [ROOOOR] \rightarrow 2\overline{RO^\bullet} + O_2\,,$$
$$2\overline{RO^\bullet} \rightarrow ROOR\,,$$
$$RO^\bullet \rightarrow CH_3^\bullet + CH_3COC_6H_5\,.$$

The formation of oxygen in the reaction $RO_2^\bullet + RO^*O^{\bullet *} \rightarrow ROO^*R + OO^*$ was demonstrated by Bartlett and Traylor[95,96] in experiments with heavy oxygen (oxygen-18). Oxygen

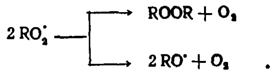
was passed through cumene undergoing oxidation and containing together with $^{16}O{=}^{16}O$ molecules also 1–6% of $^{18}O{=}^{18}O$. At the outlet from the reactor the oxygen was analysed mass-spectrometrically and the presence of $^{16}O{=}^{18}O$ molecules was established, thus demonstrating the occurrence of the reaction $R{-}^{16}O{-}^{16}O^{\bullet} + {}^{18\bullet}O{-}^{18}O{-}R \rightarrow R^{16}O^{\bullet} + {}^{16}O{=}^{18}O + R^{18}O^{\bullet}$. In experiments on the sensitised oxidation of cumene under conditions such that the chains are short it was established that the amount of oxygen evolved as a result of the reaction between two peroxy-radicals exceeds by a factor of 1.7–2.6 the number of elementary steps involving the disappearance of free radicals in this reaction[98]. Consequently the interaction of two tertiary peroxy-radicals has the following mechanism:



$$2\,RO_2^{\cdot} \rightarrow \begin{cases} ROOR + O_2 \\ 2\,RO^{\cdot} + O_2 \end{cases} .$$

The recombination of alkoxy-radicals and their liberation into the bulk phase has been investigated in the decomposition of di-t-butyl peroxyoxalate[97]:

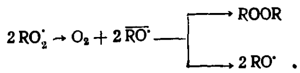
$$(CH_3)_3COOCOCOOOC\,(CH_3)_3 \rightarrow 2\,(CH_3)_3CO^{\cdot} + 2\,CO_2\ ,$$
$$\overline{2\,(CH_3)_3CO^{\cdot}} \longrightarrow (CH_3)_3COOC\,(CH_3)_3\ ,$$
$$\overline{2\,(CH_3)_3CO^{\cdot}} \longrightarrow 2\,(CH_3)_3CO^{\cdot},$$
$$(CH_3)_3CO^{\cdot} + RH \rightarrow (CH_3)_3COH + R^{\cdot},$$
$$(CH_3)_3CO^{\cdot} \rightarrow CH_3COCH_3 + CH_3^{\cdot}\ ,$$

The decomposition products are a peroxide and an alcohol. Table 6 shows that, with increase in the viscosity of the solvent, the yield of the peroxide increases at the expense of a reduced yield of the alcohol (temperature 45°C).[97]

Table 6. Products of decomposition of di-t-butyl peroxalate in various solvents.

Solvent	Viscosity, cP	Yield of ROOR, %	Yield of ROH, %
n-C_5H_{12}	2.20	3.9	94.6
C_6H_6	5.6	5.5	53
$(CH_3)_3COH$	46	10	...
Nujol	1000	76.8	23.2

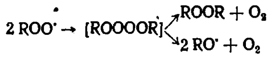
Evidently a similar situation arises in reactions between peroxy-radicals:



$$2\,RO_2^{\cdot} \rightarrow O_2 + \overline{2\,RO^{\cdot}} \rightarrow \begin{cases} ROOR \\ 2\,RO^{\cdot} \end{cases} .$$

This mechanism of the interaction between tertiary peroxy-radicals has been demonstrated for t-butylperoxy-radicals[98] in a study of the decomposition of t-butyl hydroperoxide initiated with azobisisobutyronitrile. It was established that the rate of decomposition of the hydroperoxide w, measured from the amount of oxygen evolved, is directly proportional to the rate of initiation w_i and the ratio w/w_i is significantly greater than unity: it is 9 at 65°C and 4 at 36°C. The rate constant for the reaction $2RO_2^{\cdot} \rightarrow 2RO^{\cdot} + O_2$ is 19.5×10^2 litre mole^{-1} s^{-1} at 22°C with $E = 15.5$ kcal mole^{-1}, while for the reaction $2RO_2^{\cdot} \rightarrow ROOR + O_2$, $k = 3.9 \times 10^2$ mole^{-1} s^{-1} (also at 22°C) with $E = 10.2$ kcal mole^{-1}.

The data for the isotope effect in the oxidation of cumene with deuterated methyl groups are somewhat inconsistent with the above mechanism[99]. The mechanism leads to the expectation that the replacement of a CH_3 group in cumene by CD_3 should not affect the rate of reaction between two $RO_2^{\cdot}$ radicals and consequently also the rate of oxidation. However, experiments have shown that [CD_3]cumene is oxidised somewhat faster owing to a lower rate of chain termination. This contradiction can be accounted for by postulating a more complex mechanism for chain termination in cumene undergoing oxidation, in particular by the participation in these processes of the radicals $CH_3OO^{\cdot}$ (and $CD_3OO^{\cdot}$). The overall mechanism of chain termination of cumene undergoing oxidation is as follows[100]



$$2\,R\dot{O}O^{\cdot} \rightarrow [ROOO\dot{O}R] \begin{cases} \nearrow ROOR + O_2 \\ \searrow 2\,RO^{\cdot} + O_2 \end{cases} ,$$
$$RO^{\cdot} + RH \rightarrow ROH + R^{\cdot}\ ,$$
$$RO^{\cdot} \rightarrow CH_3^{\cdot} + CH_3COC_6H_5\ ,$$
$$CH_3^{\cdot} + O_2 \rightarrow CH_3OO^{\cdot}\ ,$$
$$CH_3OO^{\cdot} + ROO^{\cdot} \rightarrow ROH + O_2 + CH_2O\ ,$$
$$RO^{\cdot} + ROOH \rightarrow ROH + ROO^{\cdot}\ .$$

The involvement of methylperoxy-radicals in chain termination can be avoided by introducing into cumene, cumenyl hydroperoxide at a concentration such that the following rapid transfer reaction takes place[101]:

$$CH_3OO^{\cdot} + ROOH \rightarrow CH_3OOH + RO_2^{\cdot}\ .$$

The rate constants for the reactions of tertiary peroxy-radicals are in the range 10^3–10^5 litre mole^{-1} s^{-1}.

The reaction of ozone with $KOOC(CH_3)_3$ at −78°C yielded a solid[102] soluble in pentane which decomposes at −30°C with formation of t-butyl peroxide and O_2. It is suggested that it is the tetroxide ROOOOR. The reaction of t-butyl hydroperoxide with lead tetra-acetate in dichloromethane at a low temperature[103] gives rise to a substance which decomposes reversibly to peroxy-radicals on raising the temperature from −110° to −85°C. At a higher temperature (in excess of −82°C) it decomposes with evolution of O_2 and irreversible destruction of free radicals. The results have been interpreted as follows[103]:

$$2\,RO_2^{\cdot} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} ROOOOR \xrightarrow{k_2} \overline{2\,RO^{\cdot} + O_2} \begin{cases} \nearrow ROOR + O_2 \\ \searrow 2\,RO^{\cdot} + O_2 \end{cases} ,$$
$$K = \frac{k_{-1}}{k_1},\ \lg K = 3.55 - 6.0/\theta,\ \lg k_2 = 9.27 - 11.0/\theta\ ,$$
$$\theta = 4.57\,T/1000.$$

3. Secondary Peroxy-radicals

The C–H bond is involved in the elementary reaction step between two secondary peroxy-radicals[104] as shown by the reaction products and the isotope effect. The interaction of two peroxy-radicals derived from ethylbenzene yields one molecule of acetophenone[104], while in the interaction of cyclohexylperoxy-radicals the principal products are cyclohexanol and cyclohexanone in equal amounts[31]. The isotope effect in the reaction between two $RO_2^{\cdot}$ radicals amounts to 1.9 (at 60°C) in the case of ethylbenzene[104], while for the peroxy-radicals derived from styrene and α-deuterostyrene $k_H/k_D = 3.9$ (30°C) with $E_D - E_H = 1.9$ kcal mole^{-1}.[105] These results agree well with the mechanism proposed by Russell[104]:

$$2R_2CHOO^{\cdot} \rightarrow R_2C{=}O + O_2 + HOCHR_2\ .$$

A reaction of this kind can take place in two ways: via a cyclic activated complex or via the intermediate formation of the tetroxide. Calculation shows[2] that the formation of a cyclic activated complex should involve a high negative entropy of activation, which leads to the calculated constant $k \simeq 1$. The pathway via the intermediate formation of the tetroxide should be faster:

$$2\,R_2CHOO^{\cdot} - R_2CHOOOOCHR_2 \rightarrow R_2C{=}O + R_2CHOH + O_2\ .$$

This mechanism was recently confirmed by Howard and Ingold[105] in the following way. According to this mechanism and the spin conservation rule, the reactions between two peroxy-radicals should result in the formation of singlet oxygen. Singlet oxygen is known to react rapidly with 9,10-diphenylanthracene with formation of an *endo*-peroxide. Secondary peroxy-radicals were obtained in benzene solutions by the reaction of s-butyl hydroperoxide with Ce^{4+} ions. The addition of 9,10-diphenylanthracene to this type of system leads to the formation of an *endo*-peroxide. This demonstrates the formation of singlet oxygen by the reaction

$$2\,R_2CHOO^{\cdot} \rightarrow R_2CHOOOOCHR_2 \rightarrow R_2C{=}O + R_2CHOH + {}^1O_2\,.$$

If instead of a secondary hydroperoxide, a tertiary hydroperoxide is introduced, an *endo*-peroxide does not form in agreement with the mechanism

$$2\,RO_2^{\cdot} \rightarrow ROOOOR \rightarrow 2\,\overline{RO^{\cdot}} + {}^3O_2\,.$$

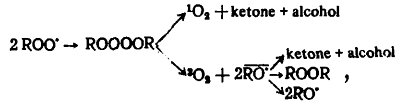
The rate constants for the reactions of secondary peroxy-radicals are of the order of 10^7–10^8 litre $mole^{-1}\,s^{-1}$. This mechanism can be revised slightly on the basis of data for the decomposition of peroxy-macroradicals derived from polyethylene[106]. It has been established that bond dissociation in the sensitised oxidation of linear polyethylene takes place in the peroxy-radical stage by the following reactions

$$RO_2^{\cdot} \rightarrow \text{dissociation of C-C bond}$$
$$2\,RO_2^{\cdot} \rightarrow \text{dissociation of C - C bond,}$$

The dissociation of the C–C bond following the reaction between two $RO_2^{\bullet}$ radicals can be accounted for by postulating the formation of alkoxy-macroradicals, which subsequently break down with dissociation of the C–C bond:

$$2\,RO_2^{\cdot} \rightarrow O_2 + 2RO^{\cdot}\,,$$
$$RO^{\cdot} \rightarrow \text{aldehyde} + R'^{\cdot}\,.$$

The linear polyethylene contained virtually no tertiary C–H bonds and therefore the alkoxy-radicals were obtained by the reaction between secondary peroxy-radicals, for which the following general mechanism may be proposed:



$$2\,ROO^{\cdot} \rightarrow ROOOOR \begin{cases} \nearrow {}^1O_2 + \text{ketone + alcohol} \\ \searrow {}^3O_2 + 2\overline{RO^{\cdot}} \begin{cases} \nearrow \text{ketone + alcohol} \\ \rightarrow ROOR \\ \searrow 2RO^{\cdot} \end{cases} \end{cases},$$

$$RO^{\cdot} + RH \rightarrow ROH + R^{\cdot}\,,$$
$$RO^{\cdot} \rightarrow \text{aldehyde} + R''\,.$$

Quantitative measurements show that in polyethylene undergoing oxidation in chlorobenzene at 115°C there are six C–C bond dissociation steps for each 100 elementary reaction steps between two $RO_2^{\bullet}$ radicals[106]. Thus for macroradicals also the reaction $2RO_2^{\bullet} \rightarrow$ alcohol + ketone + $^1O_2$ appears to predominate.

Among the reaction products from cyclohexylperoxy-radicals obtained by pulse radiolysis in cyclohexane at 25°C, cyclohexene and a hydroperoxide were detected, together with an alcohol and ketone, with radiation-chemical yields of 1.14 and 1.10 respectively[31]. Under these conditions (low temperature, high $RO_2^{\bullet}$ concentration), the hydroperoxide could not form in an appreciable amount by the reaction of the peroxy-radical with cyclohexane. One may postulate the formation of cyclohexene by disproportionation between two cyclohexyl radicals. Then dicyclohexyl, for which $k_d/k_r = 1$ (Table 7), should form with the same radiation-chemical yield. However, experiments have established that for dicyclohexyl $G = 0.3$, i.e. is 4 times smaller than for cyclohexene. This suggests a new disproportionation reaction of peroxy-radicals:

Table 7. Rate constants for the interactions of peroxy-radicals.

VI. REACTIONS OF MOLECULES WITH FREE VALENCES AT NITROGEN AND TIN ATOMS

Aromatic radicals with a free valence at a nitrogen atom interact very rapidly (Table 8). Very high rate constants have been obtained for the radicals R_3Sn.[44]

Table 8. Rate constants for the interactions of radicals having free valences at nitrogen and tin atoms.

VII. REACTIONS BETWEEN FREE RADICALS OF DIFFERENT TYPES

The reactions between $H^\cdot$ and $OH^\cdot$, between $H^\cdot$ and $HO_2^\cdot$, and between $HO^\cdot$ and $HO_2^\cdot$ radicals are very rapid and their rates are limited by diffusion (Table 8). The rate of recombination of alkyl radicals with peroxy-radicals is not limited by diffusion but the reaction takes place as a rule with higher rate constants than the reaction between two peroxy-radicals (Table 9). In particular this is the reason for the inhibiting effect of triphenylmethane when the latter is introduced, for example, into cumene undergoing oxidation. The $C-O_2^\cdot$ bond in the radical $(C_6H_5)_3COO^\cdot$ is weak, its energy amounting to only 9 kcal mole^{-1}, [148] and under oxidation conditions the following equilibrium obtains:

$$(C_6H_5)_3COO^\cdot \rightleftarrows (C_6H_5)_3C^\cdot + O_2 .$$

Therefore in a hydrocarbon undergoing oxidation there is always a fairly high concentration of triphenylmethyl radicals (the higher the temperature the higher the concentration) and there is rapid chain termination by the reaction

$$RO_2^\cdot + (C_6H_5)_3C^\cdot \rightarrow ROOC\,(C_6H_5)_3 .$$

VIII. EFFECT OF THE SOLVENT. VISCOSITY OF THE SOLVENT

If atoms or free radicals interact very rapidly so that $k > k_D$, diffusion limits the rate of the process and the diffusional rate constant k_D is measured experimentally. Then the viscosity of the solvent affects k_D: the higher the viscosity, the lower is the value of k_D. For low-molecular-weight radicals, $k_D \simeq 10^9-10^{10}$ litre mole^{-1} s^{-1}. Macroradicals diffuse much more slowly, so that even in not very viscous media diffusion may be rate-limiting for the reaction between two macroradicals. Since the viscosity of the solution increases as polymerisation proceeds, this entails a decrease of the rate constant for chain termination[79]. Data for the photopolymerisation of methyl methacrylate at 32 °C may be quoted as an example[59]:

% polymer.	0	15	25	35
$10^{-4}k$, litre mole^{-1} s^{-1}	570	140	35	8.8

*The significance of the Russian abbreviation (TsINR, not explained in the text) is obscure, but the authors quoted used a stop-flow technique (SFT) (Ed. of Translation).

1. Internal Pressure of the Liquid

Since recombination of two radicals to give one molecule is accompanied by a decrease of free volume, an increase of the rate constant for the reaction between two free radicals with increasing internal pressure of the liquid is to be expected. Unfortunately there have been no systematic studies on this problem. A distinct effect of the internal pressure of the liquid on the reaction between two radicals has been established for the process involving the competition between the disproportionation and recombination reactions of ethyl radicals[25], where a linear relation between $\lg(k_d/k_r)$ and $\Delta P_S^{1/2}$ has been demonstrated, P_S being the internal pressure of the solvent.

2. Non-specific Solvation

A free radical with a dipole moment is solvated in a polar solvent, i.e. it is surrounded by a "coating" of polar solvent molecules. If the solvent molecules do not form hydrogen bonds or π-complexes (specific solvation) with the free radical, then the solvation of a polar radical is due to electrostatic forces between its dipole and the polar medium. The rate constant for the reaction between polar species depends on the dielectric constant of the medium. If the dipole moment of the activated complex is higher than for the initial species, the reaction is faster in more polar media. The quantitative relation between the reaction rate constant and the dipole moments of the initial species and the activated complex on the one hand and the dielectric constant of the medium on the other is expressed by the following formula due to Kirkwood[157]:

$$\ln k = \ln k_0 - \frac{1}{\mathrm{k}\,T}\,\frac{\varepsilon-1}{2\varepsilon+1}\left(\frac{\mu_A^2}{r_A^3}+\frac{\mu_B^2}{r_B^3}-\frac{\mu_{\neq}^2}{r_{\neq}^3}\right),$$

where k is the Boltzmann constant, ϵ the dielectric constant of the medium, r_A, r_B, and $r_{\neq}$ are the radii of the initial species and of the activated complex, and μ_A, μ_B, and $\mu_{\neq}$ are their dipole moments. This formula was derived on the assumption that the medium surrounding the species is isotropic and the macroscopic dielectric constant ϵ holds also for the interaction between the species and the solvent molecules. Since strictly speaking this is not true, the above formula is approximate. The effect of non-specific solvation on the interaction between free radicals was investigated in detail by Zaikov, Maizus, and Emanuel' in the case of peroxy-radicals[116,158-160].

It was established that, when ethyl methyl ketone is diluted with various solvents (benzene, carbon tetrachloride, acetic acid, decane, and p-dichlorobenzene), the rate constant for the reaction between the peroxy-radicals derived from ethyl methyl ketone increases with ϵ and Kirkwood's formula holds satisfactorily:

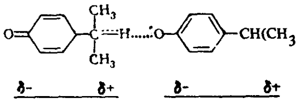
$$\lg k = A + B\,\frac{\varepsilon-1}{2\varepsilon+1}\ .$$

At 60°C $A = 3.36$ and $B = 6.0$. By extrapolation to $\epsilon = 0$ and $1/\epsilon \to 0$, the activation energies $E_{\epsilon\to 0} = 6.5$ kcal mole^{-1} and $E_{\epsilon\to\infty} = 1.2$ kcal mole^{-1} were obtained.

A linear relation between E and $(\epsilon - 1)/\epsilon$ holds for the disproportionation reaction of 2,6-di-t-butyl-4-isopropylphenoxy-radicals[89]:

$$E = E_0 + A\,\frac{\varepsilon-1}{\varepsilon}\ .$$

This relation is consistent with theoretical calculations. The reaction of two phenoxy-radicals constitutes, from the electrostatic standpoint, the interaction of two dipoles of the "head to tail" type:



When the dielectric constant changes from ϵ_1 to ϵ_2, the energy of this interaction is altered by an amount:

$$\Delta E = -\frac{28.9\,\mu_A\mu_B\Delta\varepsilon}{\varepsilon_1\varepsilon_2 r^3},$$

or on transition from $\epsilon = 1$ to $\epsilon = \epsilon$ with $\mu_A = \mu_B$, we obtain

$$\Delta E = \frac{28.9\,\mu^2(\varepsilon-1)}{\epsilon r^3}\ ,$$

which agrees with the experimental relation.

3. Specific Solvation

Radicals with a free valence at nitrogen and oxygen atoms can form a hydrogen bond of the type Y...H–X, which should be reflected in their reactivity. A hydrogen bond of the type ROO...H–X has been suggested[161] and its formation has been proved by Zaikov, Maisuz, and Emanuel'.[116,162-164]

According to Zaikov et al.[162], the equilibrium constant for the reaction

$$\mathrm{CH_3CO\overset{\overset{\displaystyle CH_3}{|}}{C}HOO^{\bullet} + H_2O \rightleftarrows CH_3CO\overset{\overset{\displaystyle CH_3}{|}}{C}H_2OO^{\bullet}\ldots HOH}$$

corresponds to $\lg K = 4.88 + 4.8/\theta$, where $\theta = 4.57T/1000$ (K is expressed in litre mole^{-1}).

The radical hydrogen bond appreciably retards the reaction between two peroxy-radicals[162,163]. However, for the peroxy-radical derived from ethyl methyl ketone[163], $2k(\mathrm{RO_2^{\bullet}} + \mathrm{RO_2^{\bullet}}) = 18\times10^5$ litre mole^{-1} s^{-1} and $2k(\mathrm{RO_2^{\bullet}}\ldots\mathrm{HOH} + \mathrm{RO_2^{\bullet}}\ldots\mathrm{HOH}) = 0.70\times10^5$ litre mole^{-1} s^{-1} at 60°C, $E_{\mathrm{RO_2^{\bullet}}} = 1.6$ kcal mole^{-1}, $E_{\mathrm{RO_2^{\bullet}}\ldots\mathrm{HOH}} = 4.6$ kcal mole^{-1}, $\lg 2A_{\mathrm{RO_2^{\bullet}}} = 7.30$, and $\lg 2A_{\mathrm{RO_2^{\bullet}}\ldots\mathrm{HOH}} = 7.86$. The existence of the hydrogen bond has been demonstrated kinetically for the cyclohexylperoxy-radical and t-butyl alcohol[116], the equilibrium constant corresponding to $\lg K = \bar{3}.69 + 3.5/\theta$ with $\theta = 4.57T/100$ (K expressed in litre mole^{-1}).

The rate constants for the interaction of cyclohexylperoxy-radicals do not differ greatly for solvated and unsolvated radicals[116]: $2k_{\mathrm{RO_2^{\bullet}}} = 5.0\times10^6$ and $2k_{\mathrm{RO_2^{\bullet}}\ldots\mathrm{MOR'}} = 1.6\times10^6$. Thus a hydrogen bond to a free radical lowers the rate of its destruction by reaction with other radicals and consequently increases the steady-state concentration of radicals in the system. However, the overall rate of the chain reaction usually falls in the presence of a solvent forming hydrogen bonds, since the hydrogen bond also retards the chain propagation reaction. Thus, as a result of the formation of hydrogen bonds in the system, free radicals become less active but their steady-state concentration increases. An interesting exception are the peroxy-radicals of 2-methylpent-2-ene[165], the rate constants for the interaction of which with one another and with the hydrocarbon increase as alcohol is added to the hydrocarbon. This has been explained by the formation of an intramolecular π-bond:

which in the presence of an alcohol dissociates as a result of the formation of the hydrogen bond; the hydrogen-bonded peroxy-radicals are apparently less active than the radicals with the intramolecular π-bond.

Vinyl Fluoride

V.A.Korin'ko, M.I.Levinskii, E.A.Chaika, and A.L.Englin

The review deals with the methods of preparation, physical and chemical properties, and polymerisation and copolymerisation of vinyl fluoride with various unsaturated compounds as well as the properties, stabilisation, processing, and applications of its polymers and copolymers based on the data published up to the end of 1968.
The bibliography includes 299 references.

CONTENTS

I. INTRODUCTION

Numerous studies dealing with the synthesis, polymerisation, and copolymerisation of vinyl fluoride have been published. Polymers and copolymers of vinyl fluoride are of great interest because they have many valuable properties: high thermal stability, resistance to the action of light, chemical reagents, and radiation, and exceptional resistance to weathering.

Certain results of studies dealing with vinyl fluoride were described in the 1951 review by Knunyants and Fokin[1] on the polymerisation of fluoro-olefins and in a later monograph by Vaculik[2] on the chemistry of monomers.

II. METHODS OF PREPARATION OF VINYL FLUORIDE

Vinyl fluoride (VF) was obtained for the first time by Swarts[3,4] in 1901:

$$BrCH_2{-}CHBr_2 \xrightarrow[100,180^\circ]{SbF_3,Br_2} \left[\begin{array}{l} BrCH_2{-}CHF_2 \\ BrCH_2{-}CHBrF \end{array}\right. \xrightarrow[C_2H_5OH]{Zn} H_2C{=}CHF$$

Later he synthesised it[5] in 98% yield from 1, 1-difluoro-2-iodoethane:

$$F_2CH{-}CH_2I \xrightarrow[\text{ether}]{C_2H_5MgBr} H_2C{=}CHF\ .$$

1. Preparation of Vinyl Fluoride by Hydrofluorination of Acetylene

Investigators have devoted most attention to the synthesis of vinyl fluoride by the hydrofluorination of acetylene. In the absence of a catalyst and high pressures vinyl fluoride is not formed at temperatures ranging from −70° to 0°C [6]. The possibility in principle of obtaining vinyl fluoride from acetylene and hydrogen fluoride under pressure was mentioned in patents as early as the 1920's[7], but the process itself was achieved much later by Grosse and Linn[6] with a conversion of acetylene of about 15%:

$$HC{\equiv}CH \xrightarrow[20^\circ,72\ h]{8-12\ atm} H_2C{=}CHF + CH_3{-}CHF_2\ .$$

The catalytic method is more effective. A number of catalysts have been proposed for the vapour-phase process, among which mercury compounds have become most widely known: HgO and $HgCl_2$ on activated charcoal[8], in the presence of hydrogen chloride[9] or hydrogen chloride and iron(III) chloride[10]. Newkirk[11], who used as catalyst mercury(II) chloride on activated charcoal promoted with barium chloride, obtained an 82% yield of vinyl fluoride at 97−104°C. Under the same conditions in the absence of barium chloride, the yield of vinyl fluoride fell to 51.5%. Dolgopol'skii et al.[12] used HgO in liquid paraffin as a catalyst. Acetylene was passed through a vessel with anhydrous hydrogen fluoride and then through a suspension of HgO in liquid paraffin. At 0°C, for a molar ratio $C_2H_2 : HF = 1 : 3.48$ and an acetylene flow rate of 6 litre h^{-1}, the yield of vinyl fluoride was 68.4%. Using mercury acetate on activated charcoal at 40°C and a molar ratio $C_2H_2 : HF = 1 : 1.5$, it proved possible to obtain vinyl fluoride in 86% yield[13]. Other mercury compounds on activated charcoal have also been used as catalysts, for example nitrates[14-17] (at temperatures between 0° and 100°C). Apart from activated charcoal, alumina, graphite[17], or solid organic polymers[16,17] can be used as carriers, which stabilise the catalyst and increase the duration of its activity. A method of preparation of vinyl fluoride in the presence of mercury salts on activated charcoal at 30−40°C in a polypropylene reactor has been described. The catalyst functioned for 240 h without loss of activity[18].

It has been noted that at an elevated temperature activated charcoal reduces mercury salts and deactivates them. The mercury thus produced evaporates and condenses in various parts of the apparatus. Loss of mercury also leads to a decrease of the activity of the catalyst and in addition results in the formation of mercury fluoride, which induces the polymerisation of vinyl fluoride. To prevent the reduction of mercury salts, iron(III) salts or other oxidants are added to the catalyst, which increases its activity and duration of its useful operational life[11].

Mercury nitrate deposited on alumina in an amount of 5−20 wt.% proved to be a long-lived catalyst for the synthesis of vinyl fluoride. After passing a mixture of 48% of acetylene, 50% of hydrogen fluoride, and 2% of nitrogen oxides through the catalyst at 65°C and neutralising the product, a mixture of 66% of vinyl fluoride and 34% of 1, 1-difluoroethane was obtained[17]. Zinc and mercury chromates[19] or mixtures of mercury, zinc, and nickel chromates[20] have also been used as catalysts at temperatures in the range 75–250°C. Boric acid was added to prevent the sintering of the catalyst[19].

The synthesis of vinyl fluoride at 20–100°C with catalysts consisting of mercury(II) oxide on activated charcoal or alumina and also TiO_2 or ZrO_2 on the same carriers, subjected to preliminary irradiation or irradiated during the reaction with γ-rays, has been described[21,22]. The yield of the monomer was 70%.

When activated alumina or aluminium trifluoride were used as catalysts at temperatures in the range 250–400°C, a mixture of vinyl fluoride and 1, 1-difluoroethane was obtained[23-28]. The same compounds were synthesised in the presence of aluminium sulphate[29] or a 3 : 1 mixture of Al_2O_3 and ZnF_2.[30]

Skiles proposed zinc[31] and chromium[32] catalysts. In the first case the catalyst was prepared by mixing zinc oxide with cane sugar in water and the resulting paste was dried and carbonised at 700°C.

Clark[33] obtained vinyl fluoride in the presence of copper cyanide deposited on activated charcoal or other porous carriers inert with respect to hydrogen fluoride. When copper chloride on activated charcoal was tested, the conversion of acetylene was only 0.3%.

The use of fluorosulphonic acid as a catalyst for the hydrofluorination of acetylene has been reported. At 0°C 1, 1-difluoroethane forms in 85% yield and at 80–90°C the product is a mixture of 50% of vinyl fluoride and 40% of 1, 1-difluoroethane[34]. Linn[35] obtained vinyl fluoride in the presence of boron trifluoride.

With cadmium sulphate, nitrate, or acetate on activated charcoal in a stationary or fluidised bed as catalysts, vinyl fluoride was obtained in 98% yield at 300°C. The catalysts functioned for 50 h without loss of activity. The vinyl fluoride contained traces of acetylene and 1, 1-difluoroethane[36].

When the catalyst was aluminium trifluoride with a small amount of BiF_3 or $Bi(OH)_3$, a mixture of 70.3% of vinyl fluoride and 29.6% of 1, 1-difluoroethane was obtained at 200–400°C; the conversion of acetylene was 96.7%[37]. Since vinyl fluoride and acetylene have similar boiling points, there are technical difficulties in the isolation of the pure monomer free from acetylene. McMillan[38] purified vinyl fluoride by azeotropic fractionation of the mixture using ethane, which forms an azeotrope with acetylene. Kalb et al.[39] separated vinyl fluoride from 1, 1-difluoroethane, hydrogen fluoride, and other impurities by distillation. Traces of hydrogen fluoride were removed by passing the monomer through columns filled with sodium carbonate and acetylene was removed by washing the monomer in a scrubber with an ammoniacal solution of copper(I) chloride. Oxygen was removed by repeated distillation at a pressure of 2.8–7 atm at temperatures ranging from −50° to −25°C.

For the removal of acetylene from vinyl fluoride, dimethyl sulphoxide and dimethylformamide or their mixtures[40] as well as *N*-methylpyrrolidinone[41] were proposed as selective solvents for acetylene. It has also been suggested that a mixture of vinyl fluoride, acetylene, and 1, 1-difluoroethane be brominated at 0°C with subsequent distillation of the bromination products; pure vinyl fluoride was obtained by treating 1, 2-dibromo-1-fluoroethane with zinc in alcohol[42]. The purification of vinyl fluoride by the hydrochlorination of the acetylene impurity with subsequent fractionation of the mixture is very promising[43]. Usmanov et al.[44] developed a method for a high degree of elimination of acetylene and difluoroethane from vinyl fluoride in a gas saturator with glass frit gas spreaders consisting of 5 saturators connected in series and two gas-absorption columns. Acetylene was absorbed in a solution of ammonium chloride and copper(I) chloride in aqueous ammonia. The gas flow rate was maintained in the range 10–15 litre h^{-1}. This method made it possible to reduce the acetylene content in the crude monomer to 4×10^{-5}%. Difluoroethane was removed from vinyl fluoride on a column for low-temperature fractionation. The purified monomer contained not more than 1×10^{-4}% of difluoroethane.

2. Preparation of Vinyl Fluoride by the Dehydrofluorination of 1, 1-Difluoroethane

Vinyl fluoride has been obtained[45-47] by the pyrolysis of 1, 1-difluoroethane at 350–1000°C and in the presence of activated charcoal at 300–600°C:

$$CH_3{-}CHF_2 \xrightarrow{-HF} H_2C{=}CHF \ .$$

Pyrolysis of 1, 1-difluoroethane in the presence of 2% of oxygen at 500°C gave a 61% yield of vinyl fluoride[48]. Calcium fluoride, charcoal, and steel filings were used as catalysts at 300–600°C, the yields of vinyl fluoride being 75, 84, and 88% respectively[49]. Vinyl fluoride forms in 32.7% yield at 400–850°C in the presence of a catalyst based on $CrF_3.H_2O$. Without the catalyst, the amount of acetylene increased and the conversion fell to 3.3%[50].

By dehydrofluorinating 1, 1-difluoroethane on activated charcoal at 350°C, a mixture containing 27.8% of vinyl fluoride and 62.7% of 1, 1-difluoroethane was obtained; at a reaction temperature of 400°C the amount of vinyl fluoride rose to 37.2%[51]. 1, 1-Difluoroethane has also been pyrolysed in a steel tube on charcoal or metals and their oxides and salts of Groups I, II, V, and VII,[52,53] at 300–800°C. The yield of vinyl fluoride reached 88%. When 4–6% of nickel oxide on alumina was used as a catalyst at 400°C, the yield of vinyl fluoride rose to 99%[54].

By passing a 1.7 : 1 mixture of 1, 1-difluoroethane and acetylene over aluminium trifluoride at 250–300°C, a mixture containing 64% of vinyl fluoride, 1.6% of acetylene, 0.3% of ethylene, and 1.1% of hydrogen fluoride was obtained. Unsaturated hydrocarbons were removed by catalytic hydrogenation (in the presence of palladium on charcoal) in the form of ethane and vinyl fluoride was isolated by fractional distillation[55].

3. Other Methods for the Preparation of Vinyl Fluoride

Henne and Midgley[56] synthesised vinyl fluoride by treating 1, 2-dichloro-1-fluoroethane with zinc in alcohol. Vinyl fluoride forms in 50% yield from 1, 1-difluoro-2-iodo- or 1, 2-dibromo-1-fluoro-ethane on treatment with magnesium, sodium, or potassium in ether[57]. Benning et al.[58] suggested acetone, pyridine, and dioxan, in addition to alcohol, as the medium for the elimination of halogen atoms with zinc.

Vinyl fluoride was synthesised in 58% yield from 1-chloro-2-fluoroethane by the elimination of hydrogen chloride with soda-lime at 400°C[59]. A high yield of vinyl fluoride in the pyrolysis of 1-chloro-1-fluoroethane at 500–800°C at a reduced pressure[47,60], in a chromenickel tube[61] and in the presence of copper or Cu_2Cl_2 powder[62], has been reported. In the last case the yield was 97.9%.

The fluorination of alkyl halides with hydrogen fluoride at an elevated temperature and pressure on activated charcoal[63] or alumina[64] is accompanied by the elimination of hydrogen halides and the formation of vinyl chloride and fluoride. The latter was also isolated in the pyrolysis of 1,2-difluoroethane on alumina, calcium sulphate, or activated charcoal at 200–400°C [65]. A mixture of ethyl and vinyl fluorides was obtained from ethane on oxidative fluorination in the presence of iron(III) oxide or lead oxide at 325–700°C [66]. The products of the fluorination of ethylene with mercury(II) fluoride at 150–180°C in an autoclave are hexafluoroethane and vinyl fluoride[67]. Vinyl fluoride has also been synthesised from ethylene, hydrogen fluoride, and oxygen, using as a catalyst a mixture of $PdCl_2$, $FeCl_3$, and $CuCl_2$ on activated charcoal[68]. The formation of vinyl fluoride by the reaction of ethylene and alkali metal fluorides in the presence of $PdCl_2$ in an autoclave at 160–190°C has been described; the reaction medium may be benzonitrile, nitrobenzene, dibutyl phthalate, or tetrahydrofuran (THF)[69,70]. After being passed over a Cr_2O_3 catalyst on alumina at 300–400°C, a mixture of 1,2-dichloroethane and hydrogen fluoride was found to contain about 20% of vinyl fluoride[71]. Vinyl fluoride forms in 70% yield when fluorine reacts with a complex of vinylmagnesium chloride and tetrahydrofuran[72].

By passing vinyl chloride through a vessel with anhydrous hydrogen fluoride in the presence of oleum at a temperature not exceeding 20°C, a mixture of vinyl chloride, 1-chloro-1-fluoroethane, 1,1-difluoroethane, and hydrogen chloride and fluoride was obtained; this was then pyrolysed at 400–800°C. The gas from the pyrolysis was passed through a fractionating column, where hydrogen chloride and vinyl fluoride were separated and a mixture of hydrogen fluoride, vinyl chloride, and fluoroethanes was returned to the hydrofluorination reactor. The vinyl fluoride did not contain acetylene as an impurity; the yield was 85%[73]. Vinyl fluoride forms when vinyl chloride reacts with a fluorinated anion-exchange resin in the presence of a palladium salt in acetic or propionic acid, tetrahydrofuran, or dimethylformamide at 0–200°C [74]. Vinyl fluoride has been isolated in the photolysis of 1,3-difluoroacetone[75].

III. PHYSICAL PROPERTIES OF VINYL FLUORIDE

At normal temperatures and pressures vinyl fluoride is a colourless gas with a boiling point of −72.2°C, a melting point of −160.5°C, and $d_4 = 0.853$ at −72.2°C. It is insoluble in water and is relatively sparingly soluble in alcohol and acetone[8]. It has not been found to have a narcotic effect[76]. The heat of formation ($-\Delta H$) of vinyl fluoride from the elements in the gaseous state at 25°C has been calculated as +28 kcal mole^{-1}.[7] The experimental dipole moment is $\mu = 1.42 \pm 0.01$ D.[78] The ionisation potential of vinyl fluoride, determined by photoionisation and electron impact methods, has been found to be 10.37 and 10.45 eV respectively[79-82].

In recent years spectroscopic methods have been widely used to study vinyl fluoride. The vibration spectra have been investigated by many workers[83-95], who used them largely to determine and describe the geometrical structure of the vinyl fluoride molecule. A full compilation of all the geometrical parameters is presented in Table 1. The infrared spectrum of vinyl fluoride was obtained for the first time by Torkington and Thompson[92]. Bak and Christensen[94] analysed the infrared spectra of vinyl fluoride and all seven of its deutero-derivatives and assigned the frequencies of the fundamental vibrations of the molecules. The isotopic compounds were isolated from the mixture and freed from non-isotopic admixtures on silica gel at 43°C, the purity of the compounds obtained being checked by infrared spectroscopy. Sverdlov et al.[91] achieved a complete interpretation of the vibration spectra of vinyl fluoride and its deutero-derivatives.

Table 1. Bond lengths (Å) and valence angles in the vinyl fluoride molecule

Bonds and angles	Method		
	microwave spectroscopy Ref.83	microwave spectroscopy, least squares method (Ref.84)	isotopic shift method (Ref.85)
C_1—F	1.348	1.344±0.002	1.347±0.009
C_1—H_1	1.073	1.080±0.005	1.082±0.004
C_2—H_3	1.080	1.075±0.005	1.077±0.003
C_1—C_2	1.333	1.337±0.002	1.329±0.006
C_2—H_2	—	—	1.087±0.003
FC_1H_1	115.4°	—	110.0±1°
$H_1C_1C_2$	123.7°	—	—
$H_2C_2C_1$	121.1°	—	120.9±0.3°
$H_3C_2C_1$	118.5°	—	119.0±0.3°
C_2C_1F	—	121±0.2°	120.8±0.3°

Quite recently the NMR spectra[96-103], electronic spectra[82], and mass spectra[81] of vinyl fluoride were reported. The values and relative signs of the spin–spin interaction constants and chemical shifts have been determined and it has been shown that the variation of the latter with the electronegativity of the atoms is close to linearity. Fogg and Lambert[104] studied the propagation of ultrasonic waves in vinyl fluoride at 100°C.

IV. ANALYSIS OF VINYL FLUORIDE

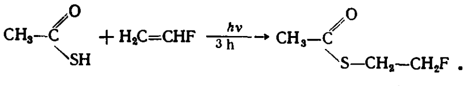
Newkirk[11] determined the density of gaseous vinyl fluoride on an Edwards balance and measured its amount by absorption in bromine water. Of the modern analytical methods, gas chromatography[44,105,106] and infrared spectroscopy[92] may be used. The analysis of the mixture consisting of 1-chloro-1-fluoroethane, 1-chloro-2-fluoroethane, and vinyl fluoride on a laboratory chromatograph of type KhL-3 has been described[105]. A mixture of trifluoromethane, chlorotrifluoromethane, 1,1-dichloro-2,2-difluoroethylene, vinyl fluoride, nitrogen, and oxygen has been separated[106]. Usmanov et al.[44] have proposed a method of analysis by gas–liquid chromatography with a flame-ionisation detector on a column with 25% of liquid paraffin on an INZ-600 carrier as the stationary liquid phase.

V. CHEMICAL PROPERTIES OF VINYL FLUORIDE

Reactions involving the double bond of vinyl fluoride have ionic and radical mechanisms. Reactions of the first type include the addition of halogens[3,42] and hydrogen halides, the latter following the Markovnikov rule with the exception of hydrogen bromide under the conditions of a radical process[107]. Hydrogen fluoride adds to vinyl fluoride with greater difficulty than to unsubstituted ethylenes, which can be accounted for by the effect of the highly electronegative fluorine atom. The addition of hydrogen fluoride to vinyl fluoride is catalysed by the halides of certain metals and also by fluorosulphonic acid[34]. Yakubovich et al.[108,109] showed that nitrosyl chloride adds to vinyl fluoride with formation of 1-chloro-1-fluoro-2-nitrosoethane, which is then oxidised to 1-chloro-1-fluoro-2-nitroethane:

$$H_2C{=}CHF + NOCl \rightarrow [FClCH{-}CH_2NO] \rightarrow FClCH{-}CH_2NO_2 \ .$$

The reaction of vinyl fluoride with thioacetic acid under irradiation with ultraviolet light and in the presence of benzoyl peroxide[110] gave a 75% yield of 2-fluoroethyl thioacetate:



$$CH_3{-}C(=O){-}SH + H_2C{=}CHF \xrightarrow[3\,h]{h\nu} CH_3{-}C(=O){-}S{-}CH_2{-}CH_2F \ .$$

Yarovenko and Vasil'eva[111] obtained a 30% yield of di(2-chloro-2-fluoroethyl) sulphide by irradiating with ultraviolet light a mixture of copper(I) chloride and vinyl fluoride under pressure in the presence of benzoyl peroxide for 200 h at 20°C [111]:

$$H_2C{=}CHF + S_2Cl_2 \xrightarrow{h\nu} S(CH_2{-}CHFCl)_2 + S \ .$$

A number of free-radical reactions involving the addition of perhalogenoalkanes to vinyl fluoride have been investigated. Haszeldine et al.[112] irradiated trifluoroiodomethane and vinyl fluoride with ultraviolet light for 14 days and obtained an 84% yield of 1,1,1,3-tetrafluoro-3-iodopropane as well as a small amount of 1,1,1,3,5-pentafluoro-5-iodopentane:

$$CF_3I + H_2C{=}CHF \xrightarrow{h\nu} F_3C{-}CH_2{-}CHFI + F_3C{-}CH_2{-}CHF{-}CH_2{-}CHFI \ .$$

The addition of dibromodifluoromethane[113] and 1,2-dibromo-2-chloro-1,1,2-trifluoroethane[114] to vinyl fluoride in an autoclave at 100°C in the presence of benzoyl peroxide has been described:

$$\begin{gathered} CBr_2F_2 + H_2C{=}CHF \rightarrow BrCF_2{-}CH_2{-}CHFBr + BrCF_2{-}CH_2{-}CHF{-}CH_2{-}CHFBr \ , \\ BrCF_2{-}CBrFCl + H_2C{=}CHF \rightarrow BrCF_2{-}CFCl{-}CH_2{-}CHFBr + BrCF_2{-}CFCl{-}CH_2{-} \\ {-}CHF{-}CH_2{-}CHFBr \ . \end{gathered}$$

Park et al.[115] showed that the free-radical addition of perfluorovinyl iodide to vinyl fluoride leads to the formation of 1,1,2,4-tetrafluoro-4-iodobut-1-ene:

$$H_2C{=}CHF + F_2C{=}CFI \rightarrow F_2C{=}CF{-}CH_2{-}CHFI \ .$$

The addition of trichloromethyl[116,117] and trifluoromethyl[118,119] radicals to vinyl fluoride has been reported. The free-radical addition of perfluoroacetonitrile to vinyl fluoride has been investigated[120]:

$$H_2C{=}CHF + F_3C{-}CN \rightarrow F_3C{-}CH_2{-}CHF{-}CN \ .$$

It has been shown[121] that the reaction of trichloro-, methyldichloro-, and trimethyl-silane with vinyl fluoride gives a high yield of the corresponding 2-fluoroethylsilanes:

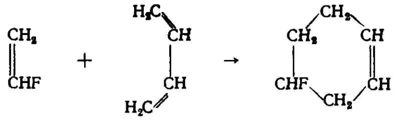
$$SiHCl_3 + H_2C{=}CHF \rightarrow CH_2F{-}CH_2{-}SiCl_3 \ .$$

The kinetics of the radical addition of tetrafluorohydrazine to vinyl fluoride have been studied[122]. It has been noted that the interaction of vinyl fluoride and ClF_3 in the gas phase at 70–125°C results, apart from substitution, in the addition of the decomposition products of chlorine trifluoride (Cl_2, F_2, ClF) to the double bond[123].

Haszeldine et al.[124] attempted to carry out the reaction of trifluoronitrosomethane with vinyl fluoride, but only the starting materials and the conversion products of trifluoronitrosomethane were isolated.

When tetramethyldiborane was allowed to react with vinyl fluoride, a mixture of ethyldimethyl-, diethylmethyl-, trimethyl-, fluorodimethyl-, and difluoromethyl-borane was obtained[125]. By allowing diborane to react with vinyl fluoride, Bartocha et al.[126] obtained a mixture of triethyl-, diethylfluoro-, and ethyldifluoro-borane with the last compound predominating; under these conditions, polymerisation of vinyl fluoride was not observed.

McQueen[127] showed that the reaction of vinyl fluoride with butadiene at 150–300°C and an elevated pressure, in the absence of polymerisation catalysts, gives a low yield of 4-fluorocyclohexene:



Soborovskii and coworkers[128,129] carried out the reaction of phosphorus trichloride with vinyl fluoride and obtained low yields of the chlorides of the isomeric 1-chloro-2-fluoro- and 2-chloro-2-fluoro-ethylphosphonic acids:

$$H_2C{=}CHF + 2PCl_3 + O_2 \rightarrow \begin{matrix} ClCH_2{-}CHF{-}P(O)Cl_2 \\ ClCHF{-}CH_2{-}P(O)Cl_2 \end{matrix}$$

Recently Jones[130] reported that butadiene is formed in high yield when vinyl fluoride is treated with tetraethylammonium trichlorostannate(II) in the presence of $PtCl_2$ and CsF in dimethylformamide, acetonitrile, or dimethyl sulphoxide:

$$CH_2{=}CHF + (C_2H_5)_4NSnCl_3 \xrightarrow[25°]{PtCl_2, CsF} H_2C{=}CH{-}CH{=}CH_2$$

Monofluorocyclopropane and its isomerisation products were obtained by the photolysis of keten in the presence of vinyl fluoride[131].

VI. POLYMERISATION OF VINYL FLUORIDE

The polymerisation of vinyl fluoride was observed for the first time by Starkweather in 1934[132]. Toluene was saturated with the monomer at −35°C, the solution was kept at 67°C and 6000 atm for 16 h, and the polymer was obtained in a low yield. Later, Newkirk[11] described the polymerisation of vinyl fluoride under ultraviolet irradiation in quartz capillaries in the presence of benzoyl, lauroyl, or acetyl peroxides as initiators.

Various methods have been described for the polymerisation of vinyl fluoride: emulsion, solution, suspension, and solid state. Emulsion polymerisation has found the widest application, since it takes place at a high rate at a relatively low temperature, which makes it possible to obtain a polymer with a high average molecular weight. Oxygen-free water or a mixture of water and organic solvents have been used as dispersion media[133–136].

Kalb et al.[39] studied the effect of impurities on the polymerisation of vinyl fluoride and found that, when the process is initiated with 0.2% of benzoyl peroxide at a pressure of 900 atm and a temperature of 80–100°C, 0.05% of oxygen in the monomer inhibits the polymerisation and 0.013% promotes it. Acetylene strongly inhibits the process, a brittle polymer of low molecular weight being formed in a yield of only 3%.

To improve the stability of the emulsions, emulsifying agents such as magnesium lauryl sulphate[137] or sodium bis(tridecyl)sulphosuccinate[138] are added to the system.

Redox systems, alkali metals, and substances which give rise to free radicals on heating have been investigated as initiators. Substances of the last type yielded polymers with the most successful combination of properties[39,139]. Of the peroxy-catalysts, benzoyl[39,136,140–142], dodecanoyl[134], diethyl, di-t-butyl[39] peroxides and t-butyl hydroperoxide[138] have been tested for the polymerisation of vinyl fluoride. When dialkyl percarbonates are used as initiators, the polymerisation takes place at a lower temperature and pressure[143]. Apart from peroxides, azo-compounds have been widely used as initiators: αα′-azo-bis-αγ-dimethylvaleronitrile, αα′-azobisisobutyronitrile[39,144], the hydrochloride of αα′-azobisisobutyramidine[39,145], azodisulphonates of alkali and alkaline earth metals[133], and the dihydrochloride of 2,2′-diamidino-2,2′-azopropane[146–149].

Tri-isobutylborane[134] and the products of the interaction of triethylborane with ammonia, hydrazine, hydroxylamine, and amines[150,151] have also been used for the polymerisation of vinyl fluoride.

The effect of various initiators on the polymerisation process has been studied[39]. Differences have been noted between initiators active at 125°C and above and those which activate polymerisation at 70–85°C. It was found that the polymers obtained at a high temperature had a lower molecular weight and more highly branched chains. The concentration of the initiator also affected the molecular weight of the polymer. With increase of the concentration of benzoyl peroxide in an aqueous medium at 80–90°C and a pressure of 250 atm, the effectiveness of the initiator and the characteristic viscosity of the polymer decreased. Analogous results were obtained when azo-compounds were employed as initiators.

The effect of temperature and pressure on the radical polymerisation of vinyl fluoride has been investigated. It has been established that, with increase of temperature, the effectiveness of the initiator reaches a maximum and then falls, the temperature corresponding to the maximum effectiveness being independent of pressure. As the reaction temperature rises, the viscosity of the poly(vinyl fluoride) (PVF) melt diminishes; an increase of pressure favours the formation of a polymer with a higher molecular weight[39].

Recently a number of continuous polymerisation processes have been developed for vinyl fluoride. Their essential feature consists of a continuous supply of vinyl fluoride, water, and the initiator into the reaction zone. The reaction is carried out in a homogeneous dispersion medium, the PVF formed being continuously removed. The required pressure and temperature are maintained in the reactor[145,146,149]. Processes with recycling of water, in which after the separation of the polymer water is deionised, freed from oxygen, and returned to the cycle, have been proposed[147–149].

In studies on the suspension polymerisation of vinyl fluoride much attention has been devoted to the search for new improved surface-active substances and stabilisers. Methylcellulose[137,152,153], glucose ethers[154], and the copolymers of ethylene[155], vinyl acetate, and allyl alcohol[156] with maleic acid or its anhydride have been suggested as dispersing agents for polymerisation in suspension. Using such compounds, it was possible to obtain highly porous PVF, which readily blends with plasticising agents, exhibits improved stability under illumination, and is a good electrical insulator. When lauroyl peroxide was used as an initiator, a polymer with a particle size of 0.05–2.5 μm was obtained[137]. The polymerisation of vinyl fluoride in the presence of titanium dioxide, yielding a product with a particle size of 0.3 μm, has been described[153].

PVF containing 14.4% of titanium dioxide and consisting largely of particles about 1 μm in diameter has been used in the form of dispersions in dimethylacetamide for coatings on metals.

In polymerisation in solution it is easier to control the reaction temperature, but, because of the lower concentration of the monomer, the polymers produced have a lower molecular weight. A number of organic solvents have been investigated as reaction media, using various polymerisation initiators: benzoyl, acetyl, lauroyl, diethyl, di-t-butyl[39,157,158], and perfluoroacyl[159–161] peroxides.

The search for new catalytic systems suitable for the polymerisation of vinyl fluoride has been vigorously prosecuted in recent years. The following systems have been tested: diethylaluminium bromide or triethyl aluminium–titanium tetrachloride[162,163], tri-isopropylaluminium–tetraisopropyloxytitanium[164], and cadmium and zinc alkyls[142]. Alkyl compounds of boron[165–168] and their coordination compounds with ammonia, hydrazine, hydroxylamine, and amines[150,151,169] have also been used as catalysts, which yielded PVF with a degree of crystallinity in excess of 30%. The polymerisation was carried out in solution, using methylene chloride, ethyl acetate, tetrahydrofuran, isobutyl alcohol, dimethylformamide, dimethyl sulphoxide, etc. as solvents[150]. A continuous process for the polymerisation of vinyl fluoride in carbon tetrachloride using peroxide initiators has been proposed[170]. It has been shown[39] that a common property of organic solvents is a tendency towards interaction (telomerisation) with vinyl fluoride, which leads to a sharp decrease of the molecular weight of the polymer obtained. Films produced from these polymers had a low impact strength.

Recently there has been a continuous increase in the number of experimental studies involving the use of radiation for the polymerisation of vinyl fluoride[171–177].

The use of radiation makes it possible to achieve polymerisation at low temperatures. Vinyl fluoride has been polymerised at a radiation dose rate ranging from 1×10^2 to 1×10^8 r h^{-1}.[73] The yield of PVF varied with the radiation dose and temperature, the maximum yield of the polymer being obtained at 0°C and a radiation dose rate of 10^4 r h^{-1}.[75] The polymerisation of vinyl fluoride at −78°C under γ-irradiation in the presence and absence of benzoyl peroxide has been studied[176].

VII. PROPERTIES OF POLY(VINYL FLUORIDE)

1. Physical Properties and Structure

A change in polymerisation conditions is reflected in the viscosity of the solutions and in the molecular weight of the resulting polymer. It has been shown[39] that the molecular weight is independent of the solvent used in the measurements. When benzoyl peroxide was employed, a decrease of the molecular weight of the polymer with increasing reaction temperature was observed. The molecular weight distribution of the polymer varies within wide limits as a function of the method of preparation, catalyst, and polymerisation temperature. Polymers synthesised using benzoyl peroxide as an initiator in the absence of a telogen melt at about 198°C.

Sapper[178] determined the heat of fusion per crystallising polymer unit, which amounted to 1800 cal.

The crystal structure of PVF has been studied by X-ray diffraction[167,179,180]. The NMR spectra of PVF have been recorded[181–183]. α-Particle absorption by PVF has been studied[184] at temperatures ranging from −59.7° to 42.7°C.

Ellison and Zisman[185] showed that the surface of PVF is readily wetted by solvents capable of forming hydrogen bonds.

2. Chemical Properties

Poly(vinyl fluoride) is resistant to the action of high temperatures, light, chemical reagents, and in particular hydrolysing agents. Characteristics such as tensile strength and modulus of elasticity do not change appreciably after exposure of the polymer to steam for 1500 h. After PVF specimens have been treated with 10% solutions of sodium hydroxide and hydrochloric acid for 7 days at 60°C, no changes in their mechanical properties were observed[186]. The treatment of PVF with nitrogen trifluoride and N_2F_2 at 80–100°C leads to formation of cross-links in the polymer and an improvement of its properties[187,188]. In the manufacture of laminate plastics adhesion between the carrier and the activated PVF layer can be achieved by the formation of OH, COOH, NH_2, etc. groups by treatment with boron trifluoride[189-191], concentrated sulphuric acid, hot alkali, or aluminium chloride[189].

Thermal decomposition of PVF in a vacuum at temperatures between 370°C and 500°C leads to the formation of hydrogen fluoride and fragments with different carbon chain lengths[192].

The telomerisation of vinyl fluoride by chloroformates at different temperatures in the presence of peroxides[193] and by trifluoromethyl iodide[194] has been investigated. The telomers obtained may be used as plasticisers for PVF. Telomers of chloroperfluoro-olefins and carbon tetrachloride have been recommended for the same purpose. Such plasticisers are not "sweated out" and do not cause turbidity of the specimen on bending[195]. Haszeldine et al.[196] carried out the telomerisation of vinyl fluoride with perhalogenoethanes under ultraviolet or X-ray irradiation or in the presence of peroxides at temperatures in the range 20–150°C.

The resistance of fluorine-containing polymers to ionising radiation has been investigated[197]. It has been found that polytetrafluoroethylene retains its structural properties only up to a dose rate of 2 Mrad, while PVF is stable up to 32 Mrad. After irradiation and simultaneous heat treatment the polymers become brittle.

Bro[198] studied the stability of various polymers in relation to amines and found that the PVF film is stable under the action of n-butylamine.

3. Stabilisation

Although PVF is distinguished by a comparatively high resistance to oxidative thermal and light-induced degradation, a number of stabilisers have been proposed for the preparation of compositions based on it which would be stable in various applications and under different processing conditions.

Monoalkyl esters of fumaric and maleic acids[199], glyceryl monolaurate[200], substituted 6-methyleneoctahydronaphthalenes[201], unsaturated terpenes and disulphides[202], alkali metal formates[203], and the copolymer of vinyl fluoride with bicyclo[2, 2, 1]hept-2-ene[204] have been proposed as thermostabilisers for PVF.

Benzophenone[205], *O*-hydroxybenzophenone[206], 2, 2′-dihydroxy-4, 4′-dimethoxybenzophenone[207,208], 2, 2′, 4, 4′-tetrahydroxybenzophenone[209], substituted triazoles[210], poly(2-hydroxy-4-methacryloyloxybenzophenone)[211], and a polyester obtained from the dichloride of adipic acid and 2, 4, 4′-trihydroxybenzophenone[212] proved to be effective photostabilisers under the action of ultraviolet light.

4. Processing and Applications

PVF is processed by the usual methods for thermoplastic materials: by extrusion, by pressing, by casting under pressure at temperatures in excess of 200°C, and also by deposition of coatings from dispersions[39,203,207-211,213-215].

PVF has found wide application in the form of films. Films are most often formed from solutions[39] or dispersions containing various substances which function as latent solvents for PVF[213,215-220]. Dimethylformamide[39], various lactones, for example γ-butyrolactone[213,217,219], tetramethylurea, dimethylacetamide, triethyl phosphate[216], 2-pyrrolidinone, *N*-isopropyl-*N*-methyl-, and 5-methyl-2-pyrrolidinone[218], *N*-formyl- and *N*-acetyl-piperidine[220], and dimethyl sulphoxide[214,215] have been used as solvents. A method has been described for the preparation of electroluminescent films from dispersions containing zinc sulphide[221]. To prepare opaque PVF films and dispersions, 1–35% of titanium dioxide, calcium carbonate, or their mixtures have been added. Pigments, stabilisers, and plasticisers have also been introduced into the films[222-227]. A method has been described[228] for the preparations of transparent films with low reflectivity by adding to PVF 1–5% of silica in the form of homogeneous spherical particles 2–10 μm in diameter. PVF films have been used in the manufacture of laminate plastics with high stability to wear and the effect of light[229-232].

Simril and Curry[186] made a detailed study of the physical, chemical, optical, and electrical properties of PVF films, and also of the effect of diaxial orientation of the films on some of their physical properties. PVF is transparent to visible and ultraviolet light but absorbs strongly in the infrared. PVF films have high tensile, bending, and impact strength, exhibit high resistance to wear, and undergo high relative elongation on stretching.

The principal distinctive feature of PVF is its high resistance to weathering. After exposure to sunlight for 7 years, a PVF film retained 50% of its initial tensile strength and remained flexible[39,233,234]. The permeability of PVF films to water and also to water vapour and various organic compounds and gases has been investigated[234-236]. A relation between the degree of orientation of the films and some of their mechanical properties has been demonstrated[39,237,238]. A highly oriented film shows a higher, tensile, impact, and bending strength and also exhibits a higher tear resistance.

To improve its adhesion to various materials, the film has been treated in a flame for periods ranging from 0.0025 to 0.5 s, with solutions of alkali metals in liquid ammonia, with organic derivatives of aluminium, zinc, and magnesium, and also with a solution of a diazo-compound in toluene, for example ethyl diazoacetate, 4, 4′-bis-(dimethylaminophenyl)diazomethane, etc. with subsequent irradiation of the treated surface by ultraviolet light[239-244].

The preparation of filaments from a dispersed paste containing 20–70% PVF has been described[245]. PVF in the form of films oriented to different extents has found a wide variety of applications in electrical insulation, packing, in the glazing of forcing frames, and in the protection of horticultural crops. Its exceptionally high resistance to the action of ultraviolet radiation makes PVF a very promising material for the protection of surfaces in apparatus designed for the collection of solar energy[246], in the building industry[233,247,248], and for protective coatings on metals[249-254]. The applications of PVF for internal coatings[255], for the preparation of diaphragms in electrolysers for the manufacture of chlorine[256], and also in chemical engineering[257] have been described.

VIII. COPOLYMERS OF VINYL FLUORIDE

Much work has been devoted[258-299] to the preparation, investigation of the properties, and applications of the copolymers of vinyl fluoride with various unsaturated compounds. The methods for the synthesis of vinyl fluoride copolymers are completely analogous to those for the synthesis of PVF. The copolymerisation has been carried out in suspension[155,156,164,268], in emulsion[138,150,152,261,263-265,272,288], in solution[166,167,170,259,262,263,266,288,295,296,299], or in the solid state[150,268,278,288,289]. A list of binary copolymers (comonomers) is given in Table 2.

Table 2. Binary copolymers of vinyl fluoride

Comonomer	References	Comonomer	References
Ethylene	138,150,262,277,279,299	Vinyl butyrate	156,274
Tetrafluoroethylene	142,150,167,168,263,266,279,299	Propene	278,290
Vinyl acetate	159,260,269,270,274,289, 297	Isobutene	152
Vinylidene fluoride	142,167,170,265,274,299	Bicycloheptene	138
Trifluoroethylene	170,268	Diethyl maleate	155,156
Vinyl chloride	150,164,166,168,271,275,276,280,283,289,299	Acrylate and methacrylate esters	159,299
Methylenemalononitrile	267	Vinyl benzoate	156
α-Acetamidoacrylamide	258	Dioctyl fumarate	156
Hydrogen cyanide	259	Vinyl carbonate	284
Chlorotrifluoroethylene	170,261,271,299	Acrylonitrile	156,296,299
Dichlorodifluoroethylene	264	Perfluoropropene	150,285,299
α-Cyanoacrylamide	267	Acrylamide	156
Methylenemalonamide	267	1,1,2,4-Tetrafluorobuta-1,3-diene	286
Fluoromethacrylate esters	273	1,1,2- and 1,1,3-trifluorobutadiene	287
Vinylidene chloride	299	1,1-Difluoroisobutene	288
Vinyl propionate	274,289	Perfluoronitrosomethane	291
		Styrene	299

The copolymers of vinyl fluoride are processed by the same methods as those used for PVF. The copolymers are widely used in the form of films[139,150,260,263,270,279,287,288] and coatings[271,286,287,298]. Coatings made from the copolymer of vinyl fluoride and vinyl chloride make various rubber articles resistant to light. Specimens with such coating remained unchanged after irradiation for 20 h with ultraviolet light, while ordinary rubber withstood only 7.5–25 min of such treatment[282]. The synthesis of foam plastics based on a copolymer of vinyl fluoride and vinyl chloride has been described.

Dimethyl sulphoxide, furfural, tetrahydrofuran, and dichlorobenzene have been used as solvents in the manufacture of fibre from the copolymers of vinyl fluoride and vinyl chloride; the fibre was spun by a wet method[150,270,280]. Copolymers of vinyl fluoride with isobutene and perfluoropropene proved to be resistant to heat, light, and chemical reagents. Extruded sheets of such copolymers are strong, flexible, and transparent, and, by virtue of their capacity for cold draining, can be used for the manufacture of various articles[150,152,155].

The synthesis of ternary copolymers has also been described. Thus the copolymer of vinyl fluoride, tetrafluoroethylene, and chlorotrifluoroethylene has been obtained in aqueous suspension at 80°C in the presence of benzoyl peroxide[292]. The copolymer of vinyl fluoride, tetrafluoroethylene, and vinyl chloride is incombustible and is readily soluble in acetone, ethyl methyl ketone, ethyl acetate, and halogeno-derivatives of hydrocarbons[293]. Copolymers melting without decomposition have been obtained from vinyl fluoride, dialkyl maleates, and vinylidene halides[294]. The copolymerisation of vinylidene fluoride, vinyl fluoride, and chlorotrifluoroethylene on γ-irradiation of the monomers has been described[274].

Detritylation and Transtritylation Reactions

P.Buckus

This review deals with various reactions involving the cleavage and certain interesting rearrangements of trityl compounds and the use of trityl protecting groups in the synthesis and reactions of glycerides, carbohydrates, nucleosides, nucleotides, and peptides. The lability of the bond between the trityl group and oxygen, sulphur, nitrogen, carbon, and other atoms has been demonstrated.
The bibliography includes 519 references.

INTRODUCTION

The tendency of compounds containing the labile trityl (triphenylmethyl) group to undergo detritylation and transtritylation reactions has been known for a long time. These reactions are of both theoretical and preparative interest. Various reactions involving the cleavage of trityl compounds and interesting rearrangements have been described. The ease of introduction and removal of the trityl group makes it possible to employ it as a protecting group. Trityl protecting groups have found particularly wide application in the synthesis and reactions of glycerides, carbohydrates, nucleosides, nucleotides, and peptides. They have assisted greatly in the development of the chemistry of natural compounds. The lability of the bond between the trityl group and the carbon atom led to the foundation and development of the chemistry of free radicals.

Until recently there have been no reviews dealing with detritylation and transtritylation reactions. The present review deals with data on the detritylation and transtritylation of oxygen, sulphur, nitrogen, carbon, and other tritylated compounds. The bonds between the trityl group and hydrogen and halogen atoms, the reactions of triphenylmethanol, triphenylmethanethiol, and triphenylmethylamine are not considered, since they are best treated as tritylation reactions.

In view of the enormous number of studies on the subject, the formation of triarylmethyl radicals must also be excluded from consideration. These problems may be the subject of separate reviews.

1. THE BOND BETWEEN THE TRITYL GROUP AND THE OXYGEN ATOM

The bond between the trityl group and the oxygen atom in alkyl trityl ethers dissociates when the latter are heated[1-5], acted upon by potassium[6], hydrogen halides[1,7-9], boron trifluoride[10], aluminium chloride[4], phosphorus pentachloride[9] and pentabromide[11], silica gel[12], formic acid, and acetyl chloride[1,13-15], and also when they are hydrolysed with alkali metal hydroxides[1] and inorganic acids[1,8,9,16]. The reaction products are triphenylmethane, triphenylmethanol, triphenylchloromethane, triphenylbromomethane, and triphenylmethylpotassium. When alkyl trityl ethers were allowed to react with magnesium and propyl iodide, the product was tritylmagnesium iodide[17,18], while the reaction with phenylmagnesium bromide yielded tetraphenylmethane[19]. The electrochemical elimination of a trityl protecting group has been demonstrated for *O*-trityl-*N*-palmitoylethanolamine[20].

When isopropyl trityl ether is allowed to stand with 0.1% solution of hydrogen chloride in methanol, transtritylation takes place[21]:

$$(CH_3)_2CHO{-}C(C_6H_5)_3 + CH_3OH \rightarrow CH_3O{-}C(C_6H_5)_3 + (CH_3)_2CHOH\ .$$

The reactions of alkyl trityl ethers with allyl alcohol, ethylene glycol, glycerol, and phenol yield respectively allyl trityl ether, the trityl ether of ethylene glycol, the *α*-trityl ether of glycerol, and *p*-hydroxytetraphenylmethane[22]. Methyl and ethyl trityl ethers were used for the tritylation of formamide[23]:

$$RO{-}C(C_6H_5)_3 + HCONH_2 \rightarrow HCONH{-}C(C_6H_5)_3 + ROH$$

Nesmeyanov et al.[24] showed that the reaction of the methyl ether of Crystal Violet with acetaldehyde, propionaldehyde, crotonaldehyde, and nitromethane takes place with formation of a new carbon–carbon bond. For example:

$$CH_3O{-}C[C_6H_4N(CH_3)_2]_3 + CH_3C{\overset{O}{\underset{H}{\lessgtr}}} \rightarrow [(CH_3)_2NC_6H_4]_3C{-}CH_2C{\overset{O}{\underset{H}{\lessgtr}}} + CH_3OH\ .$$

Cycloalkyl trityl ethers are cleaved by sulphuric[25] and acetic[26,27] acids. Benzyl and diphenylmethyl trityl ethers are hydrogenated catalytically on Raney nickel with dissociation of the bond between the trityl group and the oxygen atom[28]:

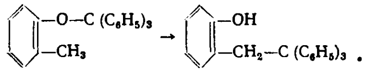
$$C_6H_5CH_2O{-}C(C_6H_5)_3 \rightarrow C_6H_5CH_2OH + (C_6H_5)_3CH\ .$$

Aryl trityl ethers are cleaved by water[29], alkali metals[6,30-32], hydrogen chloride[33], zinc chloride[34-36], and hydrochloric acid[5,35-37] with formation of the corresponding phenols and triphenylmethane or its derivatives. With acetyl chloride or hydrogen chloride in the presence of calcium chloride, ditrityl ether gives triphenylchloromethane[38,39].

When aryl trityl ethers are heated under different conditions, the corresponding tetraphenylmethane derivatives are obtained[22,30,32,35,40-48]. For example, when phenyl trityl ether is heated in ethylene glycol and glycerol[22,47,48] and also in a mixture of acetic and hydrochloric acids[41], *p*-hydroxytetraphenylmethane forms in 80–100% yield:

Tetraphenylmethane was also isolated in the reaction of phenyl trityl ether with phenylmagnesium bromide[19].

Shorygin[30,49], showed that the reaction of sodium (at 100°C) with *o*-tolyl trityl ether results, apart from the normal decomposition, in a rearrangement which leads to the migration of the trityl group to the side-chain of *o*-cresol:



A similar rearrangement takes place also under the action of zinc chloride[50].

The reaction of the ditrityl ether of catechol with methanol in the presence of hydrogen chloride yields methyl trityl ether[21]. When phenyl trityl ether reacts with monosubstituted benzenes containing *ortho*- and *para*-directing substituents, the initial ether undergoes rearrangement and the benzene derivative is tritylated[51]. For example:

$$C_6H_5O{-}C(C_6H_5)_3 + C_6H_5N(CH_3)_2 \rightarrow p\text{-}HOC_6H_4{-}C(C_6H_5)_3 + p\text{-}(CH_3)_2NC_6H_4{-}C(C_6H_5)_3\ .$$

On the basis of the relative amounts of the products, it was concluded that the migration of the trityl group to the *p*-position in both compounds takes place not only by an intermolecular mechanism but partially also by an intramolecular mechanism. The orienting power of the substituents follow the sequence $N(CH_3)_2 > NH_2 > OCH_3$.

Among trityl esters, trityl acetate[15,52-60], trityl benzoate[57,60-63], and others[52,54,60,63-66] have been decomposed. Their pyrolysis yields triphenylmethane[56,62,65]. They are decomposed by water, alcohols, and acetyl chloride with formation of triphenylmethanol, alkyl trityl ethers, and triphenylchloromethane respectively[15,52]. The interaction of trityl acetate with organomagnesium compounds yields, together with detritylation products, the corresponding hydrocarbons[58,59]:

$$CH_3COO{-}C(C_6H_5)_3 + RMgCl \rightarrow (C_6H_5)_3C - R + CH_3COOMgCl\ .$$

Other *O*-trityl compounds have also been decomposed[6,67-75], including peroxides containing one[69] and two[6,70-73] trityl groups and also *O*-trityl organometallic compounds[74].

Trityl protecting groups have been used for the synthesis of monoacyl derivatives of glycol[76]:

$$\begin{array}{l}CH_2OH\\|\\CH_2OH\end{array} \rightarrow \begin{array}{l}CH_2OH\\|\\CH_2O{-}C(C_6H_5)_3\end{array} \rightarrow \begin{array}{l}CH_2O{-}COR\\|\\CH_2O{-}C(C_6H_5)_3\end{array} \rightarrow \begin{array}{l}CH_2O{-}COR\\|\\CH_2OH\end{array}\ .$$

Such protection has also found wide application in the synthesis and investigation of the properties of glycerides[9,21,77-115] including lipoamino-acids[107,109,113-115].

It is interesting to note that the elimination of the trityl group from 1,2-diacyl- and 3-trityl-glycerol results in the migration of the acyl group from the 2-position to the 3-position[98,99,108]. However, detritylation with silicic acid avoids migration of acyl groups[93,106,108,110,111,113]. Optically active diglycerides, which are key intermediates in the synthesis of biologically important phospholipids, have been obtained in this way[104,108,111].

Quite recently in a study of the reaction of ethylene glycol and glycerol with their ditritylation products, the hitherto unknown disproportionation reaction of trityl groups leading to the formation of the corresponding monotritylation products, was observed[116]. For example:

$$HOCH_2CH_2OH + (C_6H_5)_3C{-}OCH_2CH_2O{-}C(C_6H_5)_3 \rightarrow 2\,(C_6H_5)_3C{-}OCH_2CH_2OH\ .$$

The reaction of the ditrityl ether of glycerol with methanol in the presence of hydrogen chloride yields methyl trityl ether[21].

Trityl protecting groups have found wide application in the synthesis of carbohydrates, in the study of the properties and structure of mono-, di-, and poly-saccharides and also their derivatives and analogues[8,9,12,101,102,117-198]. Their great importance in the chemistry of carbohydrates is due not only to the ease of elimination but also to the fact that they normally combine only with a primary hydroxy-group. The rate of tritylation of the primary alcoholic group in D-galactose is 225 times faster than the rate of tritylation of the hydroxy-group at the C_3 atom, evidently owing to the steric factors[168]. Although side reactions sometimes occur in detritylation[118], the trityl group gives ideal protection of the terminal hydroxy-group of the sugar chain in various syntheses.

Catalytic hydrogenation, refluxing with 80% acetic acid, and treatment at room temperature with hydrogen chloride in chloroform or hydrogen bromide in acetic acid are most often used to cleave the trityl ethers of carbohydrates. For example, when trityl ethers of cellulose and starch are shaken with a solution of hydrogen chloride in chloroform, the trityl residues are split off quantitatively as triphenylchloromethane (when aqueous hydrochloric acid is used, the product is triphenylmethanol)[137]. The methylation of the trityl ether of cellulose with dimethyl sulphate results in rapid elimination of the trityl group, while in the methylation with methyl iodide the elimination is slow[120]. It has been observed that the detritylation of tritylation and acylation products with acid reagents is frequently accompanied by the migration of the acyl groups[101,139-143]. The detritylation of (D-β-5′-*O*-trityl-2′,3′-di-*O*-acetylribofuranosyl)indole, yields, in addition to the normal product, also a small amount of the corresponding ribopyranose derivative—the product of the isomerisation of the carbohydrate ring[122].

Trityl[177,199-294] and also mono- and di-*p*-methoxytrityl[227,295-311] protecting groups have found wide application in the synthesis and the investigation of the properties and structure of nucleosides, nucleotides, and oligonucleotides. When triphenylchloromethane is allowed to react with nucleosides, the product is as a rule a 5′-*O*-trityl derivative, although this reagent, while reacting preferentially with a primary hydroxy-group, is nevertheless not entirely specific with respect to the latter[201,217,246,264,265]. In fact uridine forms a ditrityl derivative[217], shown to be 2′,5′-di-*O*-trityluridine[215]. A certain amount of 3′,5′-di-*O*-trityluridine also forms[201].

The differences between the conditions for the formation and cleavage of trityl and benzyl ethers constitute the basis of Todd's synthesis of uridine diphosphate-glucose[312]. Trityl protecting groups have been used in the synthesis and investigation of the properties and structures of the antibiotic nojirimycin[313], coenzyme A,[314,315], vitamin B_2,[316] lipids[317], and steroids[318-320]. It has been found that the detritylation of certain steroid derivatives is accompanied by the migration of the acetyl group[320]; in the absence of a trityl group such rearrangement does not occur.

2. THE BOND BETWEEN THE TRITYL GROUP AND THE SULPHUR ATOM

The bond between the trityl group and the sulphur atom is cleaved when aryl trityl sulphides are heated[321], refluxed in alcohol in the presence of Raney nickel[322], or acted upon by alkali metals[6], bromine[323], iodine[324], iron(II) chloride[325], aluminium bromide[324], silver nitrate[324], potassium permanganate[325], ruthenium tetroxide[326], chromic[325,327], nitric[325], and sulphuric[321] acids, a mixture of hydrochloric and acetic acids[41], and dichloro- and diacetoxy-iodobenzene[328]. The detritylation products are triphenylmethane, triphenylmethanol, triphenylchloromethane, triphenylbromomethane, and ditrityl peroxide. The yields of the peroxide reach 90%.

The interaction of phenyl trityl sulphide with *N*-bromosuccinimide gives a 97% yield of *N*-tritylsuccinimide[328]. The reaction of phenyl trityl sulphide with mercury(II) chloride in methanol takes place by the following mechanism[322]:

$$C_6H_5S{-}C(C_6H_5)_3 + HgCl_2 + CH_3OH \rightarrow CH_3O{-}C(C_6H_5)_3 + C_6H_5SHgCl + HCl\ .$$

The decomposition of ditrityl sulphide[329,330], ditrityl disulphide[329-331], trityl thioacetate[329], and trityl thiobenzoate[329,332] has been described. The dissociation of the bond between the trityl group and the sulphur atom in *p*-tolyl trityl sulphone by water has also been observed[3].

The trityl group has been used to protect the mercapto-group in the synthesis of sulphur-containing acids, amino-acids, peptides, and their derivatives[324,333-355]. These protecting groups have been used, for example, in the synthesis of glutathione[342], oxytocin[333], and cyclic cystine peptides[344,345,351]. Selective detritylation permits the elimination of the *S*-trityl protecting groups with retention of the *N*-trityl[334,342] and other protecting groups attached to the sulphur[354] and nitrogen[334,352,354,355] atoms. Thus in the reaction of the methyl ester of *SN*-ditritylcysteine with silver nitrate in methanol in the presence of pyridine, methanol is tritylated only by the *S*-trityl group[334]. On the other hand, the selective elimination of protecting groups attached to the nitrogen atom with retention of the *S*-trityl protecting group is also possible[353].

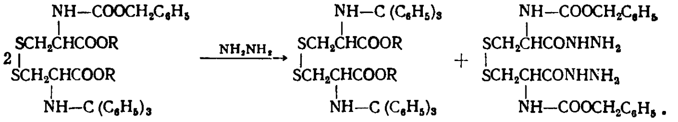
For the synthesis of asymmetric (with respect to the cysteine residues) cystine peptides, the mercapto-groups must be protected in various ways to permit their separate elimination[334,355]. *S*-Tritylcysteine and diphenylmethylcysteine have been proposed for this purpose. *S*-Trityl protecting groups are readily eliminated at room temperature by treatment with heavy metal salts. The *S*-diphenylmethyl group is then unaffected and can be removed separately with trifluoroacetic acid.

3. THE BOND BETWEEN THE TRITYL GROUP AND THE NITROGEN ATOM

As early as 1884, it was known that *N*-trityl groups are readily dissociated in an acid medium[356]. In 1925 trityl derivatives of amino-acids and even of a dipeptide were obtained[8]. However, the effectiveness of trityl protecting groups in the reactions of α-amino-acids and in the synthesis of peptides was not finally recognised until the second half of the present century[333,336,342,344,349-351,354,357-414]. For this reason, the honour and priority in the discovery of trityl protecting groups are attributed not only to Helfferich (1925) but also to Velluse (1955).[415]

N-Trityl protecting groups have been used in the study of the reactions of hydroxy-derivatives[357-359] and mercapto-derivatives[333,334,336,342,344,349-351,354,381,396] of α-amino-acids, diamino-acids[360-362,371,379,401], dicarboxylic[333,342,363-366,370,387,394,395,397-399] and heterocyclic[357,366,370,371,379] α-amino-acids, and also β-amino-acids[411] and cycloserine[369]. They have been also used in the synthesis and the study of the properties of cyclic peptides[344,351,372-378], including gramicidine C and its analogues[375-378]. It has been established that, when trityl protecting groups are employed, the most effective procedure for the synthesis of peptides is the carbodi-imide method.

The principal advantage of the trityl group consists in the ease of its elimination under mild conditions, although steric hindrance of the adjacent carboxy-group sometimes prevents the condensation of tritylamino-acids. With increase of the side chain length in the amino-acid residue, the steric hindrance becomes more pronounced, which is inconvenient from the preparative standpoint. The steric hindrance in $\alpha\omega$-diesters of *N*-trityl derivatives of dicarboxylic amino-acids makes it possible to hydrolyse the ω-ester group with retention of that in the α-position[365,387]. The tritylated acid esters obtained in this way have been successfully used for the synthesis of the peptides of asparagine, glutamine, and isoglutamine[365]. On the hypothesis that the bulky trityl group can suppress the reactivity of the adjacent ester group as a result of steric hindrance, an attempt was made to obtain the corresponding monohydrazide by the reaction of hydrazine with the diester of *N*-benzyloxycarbonyl-*N*-tritylcystine[396]. However, the reaction takes place according to the following mechanism:



$$2\begin{array}{l} \quad NH{-}COOCH_2C_6H_5 \\ \quad | \\ SCH_2CHCOOR \\ | \\ SCH_2CHCOOR \\ \quad | \\ \quad NH{-}C(C_6H_5)_3 \end{array} \xrightarrow{NH_2NH_2} \begin{array}{l} \quad NH{-}C(C_6H_5)_3 \\ \quad | \\ SCH_2CHCOOR \\ | \\ SCH_2CHCOOR \\ \quad | \\ \quad NH{-}C(C_6H_5)_3 \end{array} + \begin{array}{l} \quad NH{-}COOCH_2C_6H_5 \\ \quad | \\ SCH_2CHCONHNH_2 \\ | \\ SCH_2CHCONHNH_2 \\ \quad | \\ \quad NH{-}COOCH_2C_6H_5\ . \end{array}$$

Evidently, under the action of hydrazine there is a disulphide rearrangement involving two molecules of the asymmetric cystine derivative with formation of two symmetrical derivatives.

The high sensitivity of the *N*-trityl group to the action of acids makes possible its elimination under a wide variety of experimental conditions. *N*-Trityl peptides lose their protecting trityl groups when their solutions are refluxed in anhydrous and aqueous acetic acid for several minutes[357,371,379-382,410]. Aqueous trifluoroacetic acid eliminates the *N*-trityl group even at −5 °C.[375-377] It has been stated that the group is eliminated under the influence of lower alcohols[383]. Depending on the reagent used for its elimination, the trityl group is converted into triphenylmethane, triphenylchloromethane, triphenylbromomethane, triphenylmethanol, triphenylmethyl acetate and trifluoroacetate, alkyl trityl ethers, and also mixtures of these compounds[410].

Anhydrous hydrogen chloride in methanol eliminates *N*-trityl substituents from an α-amino group more readily than from an ω-amino group[361,410] and imidazole[366] and also *O*-trityl substituents from phenol[366]. Thus, when trityl groups of these two types are present in the molecule of the same compound, it is possible under certain conditions to eliminate selectively one *N*-trityl substituent attached to an α-amino group with retention of the *S*-trityl substituent[333,334,342,410] or an *N*-substituent attached to an ω-amino-group[360,410]. For example, when the hydrochloride of the methyl ester of *NS*-ditritylcysteine reacts with methanol in the presence of hydrochloric acid, methanol is tritylated by the *N*-trityl protecting group[334]. The selective detritylation of the trityl ester of *N*-tritylglycine allows the selective elimination of the trityl group from the nitrogen atom with retention of the ester group[384]. It is also possible to eliminate selectively the *N*-trityl protecting groups without affecting other protecting groups[375-377,385,386,410]. On the other hand, in catalytic hydrogenation the *N*-trityl group is eliminated more slowly than the *N*-benzyloxycarbonyl or *O*-benzyl groups[366,380].

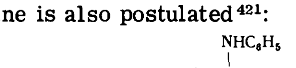
The condensation of amino-acids having amino-groups protected by *N*-substituents with tritylhydrazine yields the corresponding hydrazides[389,398,399,401]. A particular advantage of protecting groups of this type is that, after the elimination of the trityl group, the resulting derivative may be used directly in peptide synthesis by the azide method.

Under the conditions used to prepare certain oximes of *N*-trityl-α-amino-ketones and also on heating the latter in the presence of hydrogen chloride, ethanol is tritylated[416].

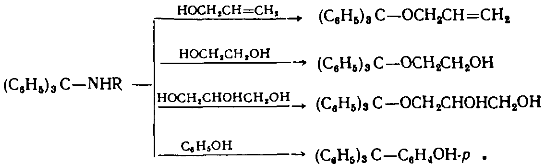
The cleavage of alkyl-[1,14,417], dialkyl-[48,417], alkylaryl-[418,419], aryl-[14,417,420-422], and diaryl-[8,423] tritylamines, trityl-[424,425] and ditrityl-[426,427] hydrazines, trityl azide[428,429], *N*-tritylurethanes[430], *N*-tritylacetamide[431], products of the *N*-tritylation of urea and thiourea[8], phenyl-[426,432-439] and benzoyl-[439] azotriphenylmethanes, quaternary ammonium bases containing the trityl group[440], and other *N*-tritylated compounds[441-445] has been described.

When *N*-tritylaniline[41,422], *N*-(β-cyanoethyl)-*N*-tritylaniline[419], *N*-trityldiphenylamine, and other *N*-tritylarylamines[422,446,447] are heated in an acid medium, in pyridine in the presence of its hydrochloride, or with zinc chloride, *C*-trityl compounds are obtained in yields up to 80%. For example:

The trityl group migrates to the *p*-position when *N*-trityl aniline reacts with monosubstituted benzenes having *ortho*- and *para*-directing substituents[51], as happened in the analogous reaction of phenyl trityl ether. The possibility of the conversion of *N*-trityl aniline into *o*-(phenylamino)-triphenylmethane is also postulated[421]:



When *N*-tritylalkylamines[47] and *N*-(β-cyanoethyl)-*N*-tritylalkylamines[48] react with allyl alcohol, ethylene glycol, glycerol, and phenol, transtritylation takes place according to the following mechanism:



$$(C_6H_5)_3C{-}NHR \xrightarrow{HOCH_2CH{=}CH_2} (C_6H_5)_3C{-}OCH_2CH{=}CH_2$$
$$(C_6H_5)_3C{-}NHR \xrightarrow{HOCH_2CH_2OH} (C_6H_5)_3C{-}OCH_2CH_2OH$$
$$(C_6H_5)_3C{-}NHR \xrightarrow{HOCH_2CHOHCH_2OH} (C_6H_5)_3C{-}OCH_2CHOHCH_2OH$$
$$(C_6H_5)_3C{-}NHR \xrightarrow{C_6H_5OH} (C_6H_5)_3C{-}C_6H_4OH\text{-}p\ .$$

The reaction of arylamines with *N*-(β-cyanoethyl)-*N*-tritylarylamines involves transtritylation by the mechanism[448]:

$$ArNH_2 + Ar'N\begin{matrix}CH_2CH_2CN\\ C(C_6H_5)_3\end{matrix} \rightarrow ArNH{-}C(C_6H_5)_3 + Ar'NH{-}CH_2CH_2CN\ .$$

1-Tritylimidazole and its 4,5-disubstituted derivatives are readily hydrolysed on refluxing with 10% acetic acid to imidazole and its derivatives and also triphenylmethanol[449]. It is suggested that, when 1-tritylimidazole is heated to its melting point, the trityl group may migrate from the nitrogen atom to a carbon atom[449]. The products of the addition of triphenylchloromethane to pyridine and quinoline are decomposed by water and alcohol to the heterocyclic base and triphenylmethanol or an alkyl trityl ether[3,9].

Together with *O*-trityl protecting groups, *N*-trityl protecting groups have found application in the chemistry of nucleosides and nucleotides[391-395].

4. THE BOND BETWEEN THE TRITYL GROUP AND THE CARBON ATOM

The study of the bond between the trityl group and the carbon atom began with the work of Gomberg[450], who obtained in 1900 a free radical of tervalent carbon (triphenylmethyl) in an attempt to synthesise hexaphenylethane by the action of silver on triphenylbromomethane. This quite unexpected discovery demonstrated for the first time the possibility of the existence of free radicals. The discovery, treated by the majority of chemists with considerable disbelief, was confirmed and developed further in the subsequent studies by Gomberg himself and also by Chichibabin, Markovnikov, Kerman, Flürscheim, Schmidlin, Cone, Walden, Wieland, Ullmann and Borsum, Heintschel, Schlenk, Ziegler, A. E. and B. A. Arbuzov, and others[451-453]. It was established that the crystalline colourless hexaphenylethane dissociates reversibly in solution, particularly at elevated temperatures, forming the yellow triphenylmethyl:

$$(C_6H_5)_3C{-}C(C_6H_5)_3 \rightleftarrows 2\,(C_6H_5)_3C.$$

Gomberg's discovery[450] gave rise to the chemistry of free radicals, which later developed very rapidly. From 1900 up to the present an enormous number of investigations have been carried out in this field. Apart from triphenylmethyl, many free radicals of the triphenylmethane series have been obtained and their properties investigated, including addition, disproportionation, and recombination reactions. These investigations have greatly influenced the development of theoretical concepts in organic chemistry, in particular the study of thermal and photochemical reactions involving chain mechanisms[451-453].

Tetraphenylmethane proved to be a perfectly stable hydrocarbon—its solutions are colourless and the compound itself distils without decomposition at atmospheric pressure at 431°C. However, under the action of a liquid potassium–sodium alloy, it dissociates even at room temperature with formation of triphenylmethane and other products[454]. On distillation[6] or under the action of oxidising agents[3,455] and potassium[6,456], asymmetric tetraphenylethane yields respectively triphenylmethane, triphenylmethanol, and triphenylmethylpotassium.

Chichibabin[457,458] showed that at an elevated temperature pentaphenylethane decomposes, like hexaphenylethane, at the C–C bond of ethane. The pentaphenylethane molecule then breaks down into radicals, which subsequently recombine in a different manner:

$$2\,(C_6H_5)_3C{-}CH(C_6H_5)_2 \rightarrow (C_6H_5)_3C{-}C(C_6H_5)_3 + (C_6H_5)_2CH{-}CH(C_6H_5)_2\ .$$

According to the observations of Cone and Robinson[459], the reaction of phosphorus pentachloride with this compound yields triphenylchloromethane. The instability of the central C–C bond in pentaphenylethane was later studied also by other chemists[6,460-466].

The thermal decomposition of ditritylmethane yields quantitatively a mixture of triphenylmethane and triphenylethylene[467]:

$$(C_6H_5)_3C{-}CH_2{-}C(C_6H_5)_3 \rightarrow (C_6H_5)_3CH + (C_6H_5)_2C{=}CHC_6H_5\ .$$

When two molecules of triphenylmethylsodium react with dichlorodiphenylmethane, the product is octaphenylpropane, which immediately breaks down into triphenylmethyl and pentaphenylethyl[468]:

$$(C_6H_5)_3C{-}C(C_6H_5)_2{-}C(C_6H_5)_3 \rightarrow (C_6H_5)_3C\cdot + (C_6H_5)_3C-(C_6H_5)_2C\cdot$$

The products of the *C*-tritylation of mono-, di-, and tri-hydric phenols, *o*-, *m*-, and *p*-cresols, and also their derivatives undergo slight detritylation on oxidation with chromium trioxide, on distillation with zinc dust and soda lime, and on heating with hydriodic, sulphuric, and acetic acids[6,446,447,469-471]. The dissociation of the carbon–carbon bond is influenced in this case by the position of the trityl group.

A number of studies have been made[466,472–483] on the dissociation of alkyl trityl and aryl trityl ketones. In a study of the possibility of using pyridine as a solvent for the reduction with lithium aluminium hydride of ketones which are sparingly soluble in ether and tetrahydrofuran, Lansbury[475–477] discovered an interesting reaction of phenyl trityl ketone. He found that in pyridine solution phenyl trityl ketone undergoes, with lithium aluminium hydride not normal reduction but reductive dissociation with formation of triphenylmethane and benzaldehyde or benzyl alcohol. Phenyltritylmethanol is an intermediate in this reaction[477]. Methyl trityl ketone is also reduced by the above reductant[476]. When organometallic compounds react with phenyl trityl[466,478] and 1-naphthyl trityl[479] ketones, the bond between the trityl group and the carbon atom is dissociated instead of the expected formation of tertiary alcohols. *C*-Tritylated compounds containing an oxo-group in the ring are known to undergo detritylation[484].

The decomposition of triphenylacetic acid and its derivatives has been extensively investigated[466,485–496]. The pyrolysis of ethyl α-tritylpropionate yields triphenylmethane and ethyl acrylate[497]. Methyl α-methyl-α-tritylpropionate decomposes similarly[497]:

$$(C_6H_5)_3C{-}C(CH_3)_2COOCH_3 \rightarrow (C_6H_5)_3CH + CH_2{=}C(CH_3)COOCH_3 \; .$$

The detritylation process takes place also in the hydrolysis and other reactions of diesters, diamides, and dinitriles of tritylmalonic acid[498–501]. The amide of tritylacetic acid undergoes an interesting transtritylation reaction on heating with sulphuric acid to 200°C:[501]

$$(C_6H_5)_3C{-}CH_2CONH_2 \rightarrow CH_3CONH{-}C(C_6H_5)_3 \; .$$

The self-condensation of methyl trityl ketone[502], the acyloin condensation of ethyl trityl acetate[503], the thermal decomposition of methylazotritylmethane[503], and the hydrolysis of the acid ester obtained from phenyltritylmethanol and phthalic acid[504] are accompanied by detritylation. For example:

$$(C_6H_5)_3C{-}COCH_3 + CH_3CO{-}C(C_6H_5)_3 \rightarrow (C_6H_5)_3C{-}COCH_2COCH_3 + (C_6H_5)_3CH \; .$$

The products of the condensation of triarylmethanols (including triphenylmethanol) with 3-methyl-1-phenyl-5-pyrazolone on dissolution in polar solvents dissociate into ions[505] and their reactions with diazo-compounds yield the corresponding diarylmethanol and an azo-dye[506, 507]. The reaction of carboxylic acids and magnesium bromide with the condensation products of the methyl ether of the base of Crystal Violet with acetaldehyde, propionaldehyde, crotonaldehyde, and nitromethane involves the dissociation of the carbon–carbon bond and the formation of Crystal Violet[24,508,509].

5. THE BOND BETWEEN THE TRITYL GROUP AND OTHER ATOMS

The dissociation of the bond between the trityl group and lithium[466], boron[510,511], magnesium[512], aluminium[511], silicon[513,514], phosphorus[515,516], nickel[517], zinc[518], and germanium[519] atoms has been investigated. For example, the reaction of tritylaluminium compounds with primary and secondary amines takes place as follows[511]:

$$(R)_2Al{-}C(C_6H_5)_3 + (R')_2NH \rightarrow (R)_2Al{-}N(R')_2 + (C_6H_5)_3CH \; .$$

When certain tritylated phosphorus compounds are heated with methanol, methyl trityl ether is formed in 88% yield[516]. Treatment of the trityl derivative of zinc with tributyltin bromide resulted in the isolation of tributyltrityltin[518].

Radical Degradation and Stabilisation Reactions of Solid Polymers

V.S.Pudov and A.L.Buchachenko

The thermal and oxidative thermal degradation of the majority of polymers occurs by radical mechanisms. Therefore the stabilisation of such polymers consists in the inhibition of the radical degradation processes. The aim of this review is to consider and analyse the kinetics and mechanisms of elementary radical degradation and stabilisation reactions in the solid phase, i.e. to examine the set of reactions which constitute the basis of the degradation and stabilisation processes. Before analysing and interpreting the experimental data, it is necessary, firstly, to note the characteristic features of solid-phase radical reactions which distinguish them from reactions in gases and liquids and, secondly, to consider the general theoretical postulates concerning the kinetics of solid-phase reactions.

The bibliography includes 83 references.

CONTENTS

I. KINETIC CHARACTERISTICS OF SOLID-PHASE RADICAL REACTIONS

The specific physical features of the solid state give rise to the definite kinetic characteristics of solid-phase reactions. The principal features of this type are as follows.

1. For reactions to occur, the reacting species must approach one another; however, in contrast to gas-phase reactions, the duration of contact, i.e. the lifetime of the pair of reacting species, is long, so that a static equilibrium involving all the degrees of freedom is established in the pair. This implies that such pairs must be regarded as kinetically independent species, which has a significant effect on the kinetics and frequently modifies the kinetic equations.

2. Since the pairs are comparatively long-lived, it is also necessary to consider the physical elementary steps involved in the motion of the reacting species (rotation, translation, orientation, etc.). It is then found that the kinetics of chemical reactions are related to the kinetics of molecular motion, i.e. the physical properties and the structure of the polymer.

3. The same chemical elementary steps in the solid phase can occur with a higher activation energy than in the gaseous or liquid phases. Indeed, in a gas or liquid the intrinsic chemical step (for example, the transfer of a hydrogen atom from the molecule to a radical) and steps involving a change in the structure of the reactants (for example, those occurring when the bond hybridisation is altered) take place simultaneously. In the solid phase these steps frequently occur at different times, since the rearrangement of the structure of the reactants after the reaction occurs much more slowly than the chemical reaction itself (during a period of the order of magnitude of the structural relaxation time). This applies to reactants in both the initial and the final states. In practice it implies that the potential surfaces of the elementary reactions in the solid phase may lie higher than for gas-phase or liquid-phase reactions.

The general theory of the kinetics of solid-phase reactions must reflect these features. In the most general case of a reaction between two reaction centres A and B, three kinetic stages may be distinguished: (a) the macrodiffusion stage when the reacting species A (or B) fill the specimen non-uniformly and diffuse as a result of an average concentration gradient; (b) the microdiffusion stage when there is no concentration gradient and the rate of reaction is determined by the frequency with which the species A and B, which are uniformly distributed throughout the specimen, approach one another (the mechanism involved in their mutual approach is unimportant at this stage); this stage results in the formation of the pair (A + B); (c) the intrinsic kinetic stage when the rate of the process is determined by the rate of the chemical interaction in the pair (A + B).

Here A and B may be understood as reaction centres in a group of macromolecules and macroradicals, molecules of reacting gases, low-molecular substances, inhibitors, etc.

We shall consider initially the case where there are only two stages—the microdiffusion and kinetic stages—i.e. where the reaction centres are uniformly distributed in the specimen. For this case, Lebedev proposed a simple cell reaction model and derived formal kinetic rate equations [1]. It is suggested that the chemical interactions of A and B begins only when A and B form a pair, i.e. enter a single "cage" with a volume v^* (of the order of $\frac{4}{3}\pi\lambda^3$, where λ is the effective length of the "monomer" unit). As a result of thermal or any other type of activation from outside, A and B can migrate in the specimen with a migration rate constant k_t and in the vapour phase they can also react with a rate constant k_p. In the steady-state case (with the rates of formation and destruction of the pairs are equal), it is easy to obtain a kinetic rate equation:

$$-\frac{d\,(\mathrm{A})}{dt} = -\frac{d\,(\mathrm{B})}{dt} = k_{\mathrm{eff}}(\mathrm{A})\,(\mathrm{B}), \tag{1}$$

where

$$k_{\mathrm{eff}} = \frac{k_t k_p}{k_t + k_p}\, v^*; \quad (k_t = k_t^{\mathrm{A}} + k_t^{\mathrm{B}}) \tag{2}$$

Thus the law of the additivity of the kinetic resistance in each component stage holds for the effective rate constant for the overall process:

$$1/k_{\mathrm{eff}} = 1/k_t v^* + 1/k_p v^* \tag{3}$$

When $k_t \gg k_p$, the kinetic stage is rate-limiting and $k_{\mathrm{eff}} = k_p v^*$; when $k_t \ll k_p$, the rate is limited by the microdiffusion stage and $k_{\mathrm{eff}} = k_t v^*$.

In the above equations k_t is the rate constant for physical or chemical diffusion of the species and k_p is the unimolecular rate constant for the destruction of the pair, which may be determined either by the frequency of rotation and steric factors for the species in the vapour phase or by the rate of the intrinsic chemical interaction. Since a wide variety of species may be involved in the reactions, the physical significance of k_t and k_p may be various; they can assume any relative values and therefore either of two types of kinetic regimes may be realised.

The cell model for bimolecular solid-phase reactions is confirmed also by non-steady-state kinetics, i.e. kinetics under conditions such that the steady-state concentration of the pairs has not yet been attained (an example is provided by the kinetics of the recombination of the radicals corresponding to the initial sections of the curves relating the rate of degradation of the radicals to time, which were analysed by Lebedev ^{1}).

The rates of bimolecular reactions in the solid phase were calculated by Waite ^{2} even earlier and more rigorously using the macroscopic diffusion equation (for the microdiffusion stage); the results of this calculation are virtually identical with those obtained on the basis of the cell model, but the latter has the advantage of simplicity of the interpretation of the experimental data and clear physical significance of the kinetic constants.

II. KINETICS OF RADICAL DEGRADATION AND STABILISATION REACTIONS OF POLYMERS

We shall now consider the experimental data on the mechanism and kinetics of radical degradation and stabilisation reactions of polymers taking into account the general kinetic considerations described in the preceding section. It will be more convenient to examine the individual reactions of macroradicals and low-molecular-weight radicals, which will henceforth be conventionally referred to as microradicals.

1. Oxidation of Macroradicals

The addition of oxygen to macroradicals is one of the fundamental kinetic chain propagation reactions in the oxidation of polymers. All the experimental data on the kinetics of this reaction were obtained in studies of the conversion of alkyl allyl macroradicals $\dot{R}$ in irradiated polymers into peroxy-macroradicals $\dot{R}O_2$. Such conversion takes place under the action of gaseous oxygen and therefore its rate may be determined by any of the three stages—macrodiffusion, microdiffusion, and kinetic.

The "recognition" of the rate-determining step in a complex multistage process of this kind is difficult. The system of kinetic equations for this case is of the form

$$-\frac{\partial n}{\partial t}=k_{\text{eff}}nc, \tag{4}$$

$$\frac{\partial c}{\partial t}=-k_{\text{eff}}nc+D\nabla^2 c, \tag{5}$$

where n is the concentration of radicals in the polymer (it is postulated that these are stationary) and c the concentration of oxygen. At zero time ($t=0$) we have $n=n_0$ and $c=0$ in the bulk phase and $c=c_0=K_S p$ on the surface of the polymer [K_S is the solubility (Henry's law) constant and p the pressure of oxygen]. The first of these equations corresponds in form to Eqn. (1); the constant k_{eff} is defined by Eqn. (2). Eqn. (5) describes the kinetics of the reaction and of the macrodiffusion of the gas into the polymer.

A rigorous analytical solution of Eqns. (4) and (5) is impossible. A solution was obtained numerically by Lebedev ^{3} using a computer and the results of the rigorous calculation were compared with approximate analytical solutions. Approximate solutions were obtained for limiting cases in which it was possible to neglect certain kinetic stages and to simplify Eqns. (4) and (5). In both cases (exact and approximate) the effective reaction time t_Σ, i.e. the time during which the initial concentration of the radicals $\dot{R}$ diminishes by the factor e, was calculated. Here t_Σ is used instead of $k_\Sigma = I/t_\Sigma$, where k_Σ is the effective rate constant for the overall diffusion-kinetic reaction $\dot{R} \rightarrow \dot{R}O_2$, which is described, as before, by the bimolecular equation $dn/dt = k_\Sigma nc$.

Comparison of the results of the exact and approximate calculations showed that it is possible to formulate several limiting regimes which are realised under various experimental conditions. The principal data are presented in Table 1. The fact that they were obtained for the case where the specimen is in an infinitely long cylinder of radius l does not diminish the generality of the results; for specimens of other shapes (spherical grains, films, etc.), the kinetic expressions remain unchanged except for constant coefficients [only the form of the diffusion term $D\nabla^2c$ in Eqn. (5) depends on the shape of the specimen].

We shall now consider briefly each regime—the conditions under which it occurs and the kinetic parameters. The quasi-steady-state regime is observed when the rate of reaction is high and the solubility of oxygen is low. Table 1 shows that the law of the additivity of the kinetic

Table 1. Kinetic regimes in the diffusion-kinetic process $\dot{R} + O_2 \rightarrow \dot{R}O_2$.

Regime	Experimental conditions	Criteria	Effective duration of reactions t_Σ	Characteristic kinetic features of the regime
Steady-state	high radical concns., low oxygen pressures	$\frac{n_0}{K_p p}>10$	$\frac{1}{k_{\text{эф}}K_p p}+\frac{0.63l^2 n_0}{aDK_p p}$	t_Σ decreases in proportion to p and depends on the dimensions of the specimen and the initial radical concn. n_0
Membrane	large specimen, n_0 large, p small	$\frac{k_{\text{эф}}n_0 l^2}{D}>100$ $n_0/K_p p>10$	$\frac{0,63l^2 n_0}{aDK_p p}$	t_Σ decreases in proportion to p and increases in proportion to n_0 and l^2
Kinetic	small size (l small), n_0 and p small	$\frac{k_{\text{эф}}K_p p l^2}{D}<0,1$ $k_{\text{эф}}n_0 l^2/D<1$	$\frac{1}{k_{\text{эф}}K_p p}$	t_Σ independent of the dimensions of the specimen and the initial radical concentration n_0
Quasi-diffusional	l large, p large, n_0 small	$\frac{k_{\text{эф}}K_p p l^2}{D}>10$ $n_0/K_p p<0,1$	$l\sqrt{\frac{4}{aDK_p p k_{\text{эф}}}}$ $a\simeq 8$	t_Σ independent of n_0, decreases in proportion to p and increases with l

resistances of all three stages holds for k_Σ; the effect of the diffusion constant is then given not by the term aD/l^2 (obtained from the usual Smoluchowski equation $l^2 = aDt$) but by the term $(aD/l^2)(c_0/n_0)$ (as already mentioned, $c_0 = K_s p$).

If the rate of reaction is very high compared with the rate of macrodiffusion, the conditions may be referred to as a membrane regime, since the rate of the process is limited by the rate of leakage of gas through the layer of the specimen (membrane) in which the reaction has already occurred. When the diffusion is rapid, a purely kinetic regime may be realised.

In an experimental study of the variation of t_Σ with oxygen pressure, the concentration of radicals, and the dimensions of the specimen, it is possible, using Table 1, to identify the regime and the rate-determining step of the reaction; by varying the experimental conditions, it is possible to pass from one regime to another.

In the limiting cases it is possible to calculate the following combinations of constants and their temperature variation:

$$\text{kinetic regime} - k_{\text{eff}}K_s = k^0_{\text{eff}}K^0_s\exp\left(-\frac{\epsilon_{\text{eff}} - \Delta H_s}{RT}\right)$$

$$\text{membrane regime} - DK_s = D^0K^0_s\exp\left(-\frac{\epsilon_D - \Delta H_s}{RT}\right)$$

$$\text{quasi-diffusion regime} - k_{\text{eff}}DK_s = k^0_{\text{eff}}D^0K^0_s\exp\left(-\frac{\epsilon_{\text{eff}} + \epsilon_D - \Delta H_s}{RT}\right),$$

and then it is easy to determine the complete set of kinetic constants, the activation energies, and the heats of solution.

On the other hand, if all the constants are already known, it is possible to calculate the rate of the diffusion-kinetic process and to predict the rate-limiting stage. An example of the use of the above theory for the determination of the rate constants for the reaction $\dot{R} + O_2 \rightarrow R\dot{O}_2$ is a study by Lebedev[3]. For alkyl radicals in Teflon,

$$k_{\text{eff}} = 5 \times 10^{-15}\exp(-10000/RT)\ \text{cm}^3\ \text{s}^{-1}$$
$$K_s = 2 \times 10^{12}\exp(10000/RT)\ (\text{cm}^3\ \text{mmHg})^{-1},$$
$$D_{O_2} = 2 \times 10^{-3}\exp(-9000/RT)\ \text{cm}^2\ \text{s}^{-1}.$$

From these relations, it is easy to find that $k_t \gg k_p$, i.e. $k_{\text{eff}} = k_p v^*$. If it is assumed that $v^* = 4 \times 10^{-21}$ cm^3 (for $\lambda = 10$ Å), it is easy to estimate $k^0_p \simeq 10^7\ \text{s}^{-1}$. On the other hand, $k^0_p = f_p \nu$ where ν is the normal pre-exponentional factor for the vapour-phase reaction of $\dot{R}$ and O_2 (of the order of magnitude of the vibration frequency $\nu \simeq 10^{12}\ \text{s}^{-1}$), whence the steric factor for the vapour-phase reaction between $\dot{R}$ and O_2 is $f_p \simeq 10^{-5}$.

Most of the kinetic data on the reactions between $\dot{R}$ and O_2 were obtained in studies on the mechanochemistry of polymers. Although the oxidation conditions (regimes) were not investigated, it may be assumed, since radicals are formed on the surface, that diffusion-dependent stages are absent and the constants determined are equal to $k_p v^*$, as for fluoroalkyl radicals. Table 2 summarises these results.

In the liquid and gaseous phases the reactions $\dot{R} + O_2 \rightarrow R\dot{O}_2$ usually have activation energies close to zero and pre-exponential factors in the range 10^{-11}–10^{-13} cm^3 s^{-1}.

The activation energies for solid-phase reactions are much higher and the pre-exponential factors are much lower. This very interesting feature of solid-phase reactions is probably due to the considerations related to potential surfaces of solid-phase reactions discussed above (see Section I). However, the stage reached in research on quantitative solid-phase reaction kinetics is not yet advanced enough for a serious discussion of any theoretical problems concerning the elementary reaction step.

In concluding our discussion of the kinetics of reactions between $\dot{R}$ and O_2, we may mention that Loy[7] has quoted 6 kcal mole^{-1} as the activation energy for this reaction in irradiated poly(vinyl chloride). However, the rate of reaction depended on the surface area of the powder, i.e. on the dimensions of the polymer grains; this implies that the above activation energy does not refer to the kinetic stage. However, Loy does not quote any other data which would make it possible to identify the regime governing the reaction and find the rate-determining step.

Table 2. Pre-exponential factors and activation energies for the reactions between $\dot{R}$ and O_2 in polymers.

Polymer	$k_p v^*$, cm^3 s^{-1}	ϵ_p, cal mole^{-1}	References

Ditto	—	~3800	5
Poly(vinyl acetate)	$1.6 \cdot 10^{-15}$	5900	4
Polystyrene	$4 \cdot 10^{-17}$	5300	4

Although the results presented in Table 1 refer to a particular reaction between gases and stationary radicals in the solid phase, their value is much wider and more fundamental. In particular, in the oxidation of solid polymers (where n should be replaced by the steady-state concentration of radicals, which depends on the rates of their initiation and destruction) these relations permit the determination of the limits of diffusion-dependent kinetics. For example, by studying the rate of sensitised oxidation of polymer film or powder under different experimental conditions (different film thickness, oxygen pressure, rate of initiation, etc.) and using the kinetic results for various regimes, it is possible to determine, in principle, all the constants for the elementary radical oxidation reactions. So far no experimental studies have been carried out on these lines.

The importance of kinetic regimes is not restricted to oxidation reactions. The kinetics of many degradation and stabilisation reactions may be modelled by Eqns. (4) and (5) and the regimes listed in Table 1. Among them, we may include the chain-termination reaction under conditions such that the inhibitor is non-uniformly distributed in the polymer and diffuses to the radical generation centres or reactions where the stabiliser, which inhibits degenerate branching, diffuses in the polymer towards the hydroperoxy-groups responsible for the branching.

2. Reactions with Low-Molecular Substances

The addition of macroradicals $\dot{R}$ to monomeric molecules M was investigated by Butyagin and coworkers in studies of the mechanical dispersion of polymer solutions in various monomers[8,9]. It was found for various combinations $\dot{R}_i + M_j$ that the activation energies (4–6 kcal mole^{-1}) and the pre-exponential factors (10^5–10^7 litre mole^{-1} s^{-1}) are close to the values of ϵ and k^0 in the liquid phase.

The same method was used to determine the rate constants for reactions with low-molecular hydrocarbons: $\dot{R} + rH \rightarrow RH + \dot{r}$. Since the macroradicals formed in the dispersion process are surrounded by solvent molecules, the reaction with them is determined by the true rate constants $k = k_p v^*$; it can be found from the rate of destruction of macroradicals and the rate of accumulation of low-molecular radicals $\dot{r}$ using the equation

$$\frac{(\dot{R})}{(\dot{R})+(\dot{r})} = \frac{1}{k\,(rH)\,t}\{1 - \exp[-k\,(rH)\,t]\}$$

The rate constants for the reactions of polystyrene radicals with toluene, ethylbenzene, and cumene (10^{-14}–10^{-15} $cm^3\,s^{-1}$) determined in this way at 77°K proved to be anomalously high compared with the "liquid phase" constants extrapolated to this temperature; it was suggested that these reactions take place under non-equilibrium conditions in the course of the dispersion of the polymer [8,9].

Activation energies of 38 and 36 kcal $mole^{-1}$ have been quoted [4] for the reaction with cumene of the macroradicals of poly(methyl methacrylate) and poly(vinyl acetate) (obtained mechanochemically) respectively (it should be noted that the maximum activation energy observed for reactions of similar type is only 15 kcal $mole^{-1}$–for the reaction $\dot{C}H_3 + CH_4 \rightarrow CH_4 + \dot{C}H_3$). [10] Since in the study quoted the formation of low-molecular radicals $\dot{r}$ was not observed, the validity of these data and their physical significance remain obscure.

Qualitative evidence for reactions of macroradicals $\dot{R}$ and $R\dot{O}_2$ with aldehydes, phenols, mercaptans, and thiophenols has been quoted in a number of studies [8,11,12], but quantitative data on the kinetics of such reactions are not available.

The above brief analysis shows that there are virtually no quantitative kinetic data for the reactions of macroradicals with low-molecular substances (including inhibitors) although these reactions are important in degradation and stabilisation processes. Firstly, low-molecular substances can serve as transfer-agents for oxidation chains, secondly, they take part in chain-termination reactions, and, thirdly, they function as catalysts for the recombination of macroradicals. In particular, the effectiveness of inhibitors is determined, apart from other conditions, by the relative efficiencies of the inhibitors in chain transfer and chain termination or their ability to catalyse the recombination of the macroradicals. The quantitative kinetic criteria governing such relative efficiencies are essential for practical purposes.

The extensive data on the rate constants for the reaction of radicals $R\dot{O}_2$ with inhibitors in the liquid phase can be hardly used for solid-phase reactions; this follows from general theoretical concepts (see Section I) and is confirmed by the reaction between $\dot{R}$ and O_2 considered above. We may note that, in order to determine the effectiveness of inhibitors in chain termination, it is necessary to know not only the rate constant for the interaction of $R\dot{O}_2$ with the inhibitor (which characterises the kinetic stage) but also the diffusion coefficient of the inhibitor in the polymer (the microdiffusion stage).

3. Reactions of Macroradicals with Macromolecules

These reactions play an important role in the transfer ($\dot{R} + R'H \rightarrow RH + \dot{R}'$) and propagation ($R\dot{O}_2 + RH \rightarrow RO_2H + \dot{R}$) of kinetic chains in polymer degradation. So far there have been no experimental studies designed to determine directly the rate constants for these reactions; here the only source of information is the kinetics of the recombination of alkyl and peroxy-macroradicals in irradiated polymers. Before discussing the kinetics, we shall first consider the recombination mechanism.

The destruction of macroradicals in irradiated polymers follows a bimolecular law. It is reasonable to suppose (as was in fact done in the early studies) that the recombination involves the mutual approach of macroradicals by diffusion. However, later it was found that many important facts are inconsistent with these hypotheses.

Firstly, data on the diffusion mobility of polymeric segments show that the idea of recombination via molecular collision is unsound. Thus even in low-molecular rubbers the diffusion coefficient is $D \simeq 10^{-14}$ $cm^2\,s^{-1}$; it has been estimated [13] that in polystyrene at temperatures close to the glass point $D \simeq 10^{-21}$ $cm^2\,s^{-1}$ and at 20°C $D \simeq 10^{-27}$ $cm^2\,s^{-1}$. This means that the recombination of radicals in such matrices would require an infinitely long period if it involved a diffusion mechanism; in fact the recombination is quite fast even in crystalline polymers, where physical diffusion of macromolecules is altogether without significance.

Secondly, in the same polymers, even in the same specimens, radicals of different chemical structures (alkyl, allyl, and peroxyradicals) recombine at different rates under the same conditions; the temperature ranges in which different radicals recombine are also markedly different. Thus peroxy-radicals usually recombine 10^2–10^3 times faster than alkyl radicals. If the rate of recombination of radicals were determined by the physical diffusion of macromolecules or their segments, the chemical structure of the radicals would have no effect on the rate of recombination.

Table 3. Number of oxygen molecules *n* for each recombined macroradical.

Polymer	T, °C	p_{O_2}, mmHg	n	References
Isotactic polypropylene	60	150	8±1	15.19
	75	150	4.5±1	15

Polyethylene			3	7
			5	16
Poly(methyl methacrylate)	25	~6; 525	1.5–2	17
Polyepoxyethylene	25		5–10	18

Thirdly, from the standpoint of the diffusion mechanism one cannot explain the finding that in a number of polymers [poly(vinyl chloride), polyformaldehyde] the interaction between oxygen and alkyl radicals does not result in the appearance of peroxy-radicals, although the destruction of alkyl radicals is greatly accelerated; the kinetics of their destruction remain bimolecular as before, and its rate is proportional to the pressure of oxygen [14] (for a more detailed discussion of the kinetics of such catalysis, see below).

Fourthly, the recombination of peroxy-radicals is accompanied by the formation of polymeric hydroperoxide and the absorption of oxygen. Table 3 presents data which show how many oxygen molecules are absorbed for each radical recombined.

Thus, as noted by Loy[7], a peroxy-radical migrating in the polymer leaves behind a trail—a chain of hydroperoxides—until it encounters another radical with which it recombines. It should be noted that the values of *n* in Table 3 are in fact too low, since no account was taken of the amount of oxygen involved in the $R\dot{O}_2$ recombination step; furthermore, during radiolysis radicals are frequently distributed non-uniformly in the specimen, forming groups, and therefore the path traversed by the radicals prior to their recombination is smaller than the path which would be traversed in the case of a uniform distribution. The low value of *n* for poly(methyl methacrylate) is due to the fact that the radicals were obtained by the mechanical degradation of the polymer and are probably localised on the surface.

Table 4. Activation energies and pre-exponential factors for the recombination of the radicals $\dot{R}$ in polymers.

All these features of the recombination can be explained by a "chemical" mechanism for the diffusion of radicals, i.e. the migration of free valence (relay mechanism) via the consecutive reactions $\dot{R} + RH \rightarrow RH + \dot{R}$ or $R\dot{O}_2 + RH \rightarrow RO_2H + \dot{R}$. This mechanism probably obtains in the majority of solid polymers; rubbers and amorphous polymers above the glass point probably constitute an exception. Thus in polybutadiene the activation energies for the recombination of allyl radicals are 1–4 kcal $mole^{-1}$,[20] which is close to the values observed for the recombination of radicals in liquids; the recombination rate constants in polybutadiene and amorphous polycapramide diminish markedly with increase in the number of cross-links, i.e. with the increase in the rigidity of the matrix[21,22]. The latter property constitutes a form of criterion for the recombination mechanism.

Eqn. (1) remains valid also for recombination; however, in contrast to the reaction between $\dot{R}$ and O_2 where $k_t \gg k_p$, here the rate-limiting stage is the relay process and not recombination in the vapour phase, i.e. $k_t \ll k_p$. Then $k_{rec} = k_t v^*$. This equation can also be obtained in another way. We introduce the valence diffusion coefficient $D = \frac{1}{6}\lambda^2 k_t$, where k_t is the frequency of "jumps", i.e. the frequency of the elementary steps in physical or chemical diffusion and λ the length of the diffusion path (of the order of dimensions of a monomer unit or the lattice constant). The recombination rate constant $k_{rec} = 8\pi\lambda D$; on substituting *D* in this expression, we have $k_{rec} = \frac{4}{3}\pi\lambda^3 k_t$ or $k_{rec} = k_t v^*$. Thus the recombination kinetics are determined by the kinetics of the valence transfer reactions and the recombination rate constants are the bimolecular rate constants for the relay process. This hypothesis was tested in a recent study[23]; the calculation of k_{rec} for the radicals $\dot{R}$ in polyethylene using the above equation for *D* and k_t for the reaction between $\dot{C}_2H_5$ and heptane in the liquid phase gave good agreement between the calculated and experimental values of k_{rec}. Tables 4 and 5 list the experimental results on the kinetics of the recombination of $\dot{R}$ and $R\dot{O}_2$ radicals in solid polymers.

Table 5. Activation energies and pre-exponential factors for the recombination of the radicals $R\dot{O}_2$ in polymers.

*Recalculated by Butyagin[17].

It is striking that the activation energies for recombination reach enormous values; in most cases the pre-exponential factors are anomalously high and are without physical significance; furthermore, there is a linear relation between the logarithm of the pre-exponential factor and the activation energy—the compensation effect (CEF)[24] (the nature of the compensation effect in these reactions is discussed below).

Clearly these results give no information about the kinetics of the valence transfer reactions. The reason for this is probable that the kinetics of reactions in polymers are related to the kinetics of molecular motion and in this sense the measured constants are not elementary. One can only suppose that the activation energies are about 13–17 kcal $mole^{-1}$ for reactions between $\dot{R}$ and RH and 10–15 kcal $mole^{-1}$ for reactions between $R\dot{O}_2$ and RH. In particular, the activation energy of the reaction between $R\dot{O}_2$ and RH in poly(methyl methacrylate), determined by a chemiluminescence method, is 11 kcal $mole^{-1}$.[17]

In certain polymers [polyformaldehyde, poly(vinyl chloride), polyamides] alkyl radicals are not fully converted into peroxy-radicals under the action of oxygen, as is usually the case, but the rate of their destruction is greatly increased. The rate of such catalytic recombination was calculated by Lebedev[25], who showed that catalysis is possible under conditions such that the diffusion of oxygen is hindered and the relay process $R\dot{O}_2 + RH \rightarrow RO_2H + \dot{R}$ is much faster than the reaction between $\dot{R}$ and RH. The rate of recombination is then $w_{rec} = k_{rec}(\dot{R})^2(O_2)$, where k_{rec}^{-1} may be calculated as the sum of the kinetic resistances in all the stages: macrodiffusion, microdiffusion, and kinetic; a linear relation between

w_{rec} and oxygen pressure has been observed experimentally[14].

The above analysis shows that at present there are no reliable data for the chain-propagation constants in solid polymers. Even the few studies available on the solid-phase oxidation of polymers, carried out in recent years, are open to a number of serious objections.

Recently an interesting study was carried out on the oxidation of polypropylene (degree of crystallinity 50%) at 110-140°C.[34]. The steady-state concentrations of the hydroperoxide and peroxy-radicals and the rate of absorption of oxygen were measured; these data are insufficient for the calculation of all the elementary constants. It was shown that the oxidation mechanism is almost the same as the mechanism of the oxidation of liquid hydrocarbons: the initiation takes place on decomposition of the hydroperoxide and the rate of reaction is proportional to $(ROOH)^{1/2}$, i.e. the chain termination is quadratic (recombination of $R\dot{O}_2$).

The chain propagation constant for reaction between $R\dot{O}_2$ and RH is of the form

$$k_{prop} = 5 \times 10^{-16} \exp(-9000/RT)\ cm^3\ s^{-1}.$$

The chain termination constant is $k_{ter} = 7.5 \times 10^{-15}$ cm^3 s^{-1} and the activation energy for chain termination is zero. From the standpoint of the above hypotheses concerning the migration of free valence by a relay mechanism, ϵ_{form} should be close to ϵ_{prop}. Even if one assumes that chain termination takes place via the physical diffusion of segments, the high chain termination rate constant and the zero activation energy are still quite incomprehensible (k_{ter} is higher almost by a power of ten than k_{ter} for 2,4,6-trimethylheptane, which may be regarded as a model of polypropylene[35]).

The results obtained by Chien and Boss[34] can be understood and can be seen to have physical significance if it is assumed that chain termination is effected by a product which readily reacts with the macroradicals $\dot{R}$ (with an activation energy close to zero) and readily diffuses in the polymer (also with an almost zero activation energy); this product then plays the role of a catalyst for the recombination reaction. This hypothesis has not of course been proved (although a method for experimental tests may be suggested), but, if found to be valid, it may be of fundamental importance. One cannot exclude the possibility that in the oxidation of solid polymers this mechanism of the termination of kinetic chains plays a leading role.

Denisov et al.[83] found for the sensitised oxidation of solid polyethylene (temperature range 13 deg)

$$k_{prop}/\sqrt{k_{ter}} = 7 \times 10^7 \exp(-21250/RT)\ mole^{-1/2}\ kg^{1/2}\ s^{-1/2}.$$

4. Decomposition of Hydroperoxides and Degenerate Branching in Polymers

Hydroperoxides are responsible for the degenerate branching in oxidative thermal degradation of polymers. Degenerate branching constitutes the principal stage in the oxidation process. Therefore the study of the kinetics of the decomposition of the hydroperoxides of polymers and of the probability of forming free radicals in the decomposition process constitutes a serious and important problem.

We shall consider initially the results obtained for the mechanism and kinetics of the decomposition of hydroperoxides in polymers and then the data on the formation of radicals and the probability of degenerate branching in polymers.

Decomposition of hydroperoxides. The following principal mechanisms for the decomposition of hydroperoxides (HP) have been considered in the literature;

$$ROOH \rightarrow R\dot{O} + \dot{O}H \qquad (I)$$

$$ROOH + RH \rightarrow R\dot{O} + H_2O + \dot{R} \qquad (II)$$

$$ROOH + ROOH \rightarrow R\dot{O} + H_2O + R\dot{O}_2 \qquad (III)$$

The unimolecular decomposition [reaction (I)] takes place with a high activation energy of about 35–40 kcal mole^{-1}.[36] It occurs only at low hydroperoxide concentrations in solvents without weakly bound hydrogen atoms. Reactions (III) and (II) are more probable; the heat of reaction (III) is approximately 9 kcal and that of reaction (II) varies within wide limits, depending on the R–H bond energy[37]. Reaction (III) predominates at high hydroperoxide concentrations, while at low concentrations and for enthalpy changes comparable with the heat of reaction (III) reaction (II) predominates. In solid polymers reaction (III), in the form in which it occurs in liquids, is even less probable. However, one cannot exclude another kinetic variant of this reaction, which is described by a first-order equation, while the stoichiometry of the reaction corresponds to Eqn. (III). The point is that, as already mentioned, hydroperoxides are obtained in the oxidation of polymers as a result of a sequence of two elementary reactions $R + O_2 \rightarrow R\dot{O}_2$ and $R\dot{O}_2 + RH \rightarrow RO_2H + \dot{R}$. Owing to the relay mechanism of the oxidation process, hydroperoxides are distributed in chains, each of which is in contact only with the nearest adjacent hydroperoxy-groups and the interaction with other peroxy-groups is unlikely. Then the decomposition of the hydroperoxide can occur in pairs and the decomposition kinetics are described by a first-order kinetic law.

In polymers containing weakly bound hydrogen atoms mechanism (II) will predominate; since usually $[ROOH] \ll [RH]$, it will also be described by a first-order kinetic equation. The only polymer for which the decomposition of hydroperoxides was studied in detail is polypropylene. However, even in this case there are contradictory views. A number of investigators[38,39] believe that the decomposition of the hydroperoxide is described by a second-order kinetic equation, in accordance with mechanism (III). This conclusion is based on the finding that the time variation of the concentration of the hydroperoxide derived from polypropylene is satisfactorily described by the equation

$$\frac{1}{[ROOH]} - \frac{1}{[ROOH]_0} = kt\ . \qquad (6)$$

The activation energy (27 kcal mole^{-1}) obtained by these investigators, which is typical for a process of this type, is also consistent with mechanism (II).

However, this is inconsistent with another observation by Dudorov et al.[38], who established that the degree of conversion of the initial peroxide is independent of the initial concentration of the hydroperoxide. Such a relation is typical for a first-order reaction. As a result, the rate constant for the decomposition of the hydroperoxide calculated from Eqn. (6) does not remain invariant when the initial hydroperoxide concentration is changed. Evidently the decomposition of hydroperoxides in atactic polypropylene cannot be described by mechanism (III). In fact recalculation of the results of Dudorov et al.[38] in terms of kinetic equations which are first-order in to the hydroperoxide concentration shows that, over a wide concentration range (7.4×10^{-3}–0.5 mole kg^{-1}), the constant remains satisfactorily invariant.

The above example confirms yet again the rule that, in order to determine the true order of the reaction, it is insufficient to investigate time dependences alone; a comprehensive kinetic study of the reaction is necessary. This is even more valid for polymers, since the hydroperoxide cannot be isolated from the latter in a pure form. For this reason the reaction is studied in a medium consisting of the oxidised polymer where the peroxide ROOH is present in addition to the hydroperoxide (incidentally, one usually obtains a set of different hydroperoxides, which may decompose at different rates); the peroxides are as a rule more stable than the hydroperoxides. When the mixture contains peroxides which decompose at different rates, the variation with time of their overall concentration is described by an equation which has nothing in common with the true reaction mechanism. Fig. 1 shows as an example the calculation of the time variation of the overall concentration of hydroperoxides in a 4 : 1 mixture assuming that the rate constants for their monomolecular breakdown are 4.6×10^{-2} min^{-1} and 4.6×10^{-3} min^{-1}.

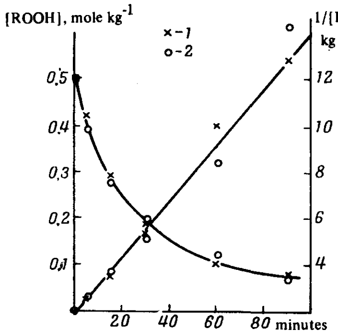

Figure 1. Decomposition of polypropylene hydroperoxide: 1) calculated points; 2) experimental values taken from Dudorov et al.[38]

Fig. 1 shows that the change in overall concentration up to 90% conversion is satisfactorily described by a second-order kinetic equation even though the hydroperoxides decompose [by a known unimolecular mechanism].

In a study[40] dealing with the decomposition of the hydroperoxides derived from isotactic polypropylene it was shown that the time variation of the concentration of the hydroperoxide is satisfactorily described by a second-order equation and the calculated rate constant remains invariant as the initial concentration of the hydroperoxide is varied.

However, the activation energies obtained[38-40] (25 to 27 kcal mole^{-1}) are inconsistent with the hypothesis of a purely unimolecular decomposition of the hydroperoxide (I). Furthermore, it has been established that the rate constant for the decomposition of hydroperoxides from isotactic polypropylene increases on introduction into the polymer of substances with labile hydrogen atoms[40] and diminishes when the polymer is diluted with substances in which all the hydrogen atoms are strongly bound[41]. Fig. 2 presents the decrease of the first-order rate constant when polypropylene is diluted with naphthalene or cetane. On the basis of these data, it is suggested[40,41] that the decomposition of hydroperoxides from isotactic polypropylene takes place according to mechanism (II). The hydrogen atoms attached to the tertiary carbon atoms evidently participate in the reaction. The experimental yield of water[41] amounts to 85% of theoretical.

The above mechanism is confirmed by the results obtained in a study of the kinetics of the absorption of oxygen and the assimilation of hydroperoxides in the oxidation of isotactic polypropylene[43]. On the basis of the mechanism proposed for the process, the authors calculated from these data the rate constant for the decomposition of the hydroperoxides by two independent procedures. The calculated constant agreed satisfactorily with the value obtained in the study of the thermal decomposition of polypropylene hydroperoxides.

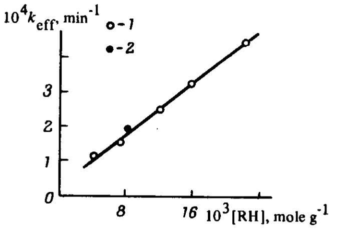

Figure 2. Variation of the effective rate constant for the decomposition of polypropylene hydroperoxide with polymer concentration: 1) dilution with naphthalene; 2) dilution with cetane.

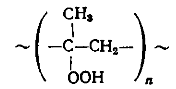
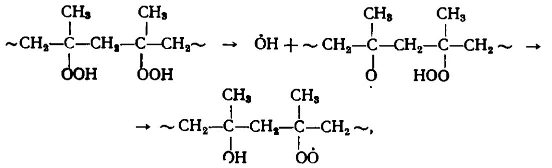
The study of the decomposition of the polypropylene hydroperoxides obtained in the sensitised oxidation of the polymer in a dilute solution is of considerable interest[43]. In this procedure hydroperoxy-groups distributed along the macromolecule at adjacent tertiary carbon atoms should form:



$$\sim\left(-\underset{\mathrm{OOH}}{\overset{\mathrm{CH_3}}{\mathrm{C}}}-\mathrm{CH_2}-\right)_n\sim$$

The authors demonstrated[44] that their hydroperoxides have precisely this structure; furthermore, they obtained the distribution of groups with respect to n, as shown in Fig. 3. It was found that 50% of the hydroperoxides are present in the form of pairs and only 7–9% in the form of single molecules.

The authors describe the breakdown of such hydroperoxides by the sum of two first-order kinetic equations with rate constants of 16×10^{-4} and 8×10^{-5} s^{-1} at 120°C. They suggest that the rapid reaction ($k = 16 \times 10^{-4}$ s^{-1}) is the chain decomposition of adjacent hydroperoxy-groups:



$$\sim\mathrm{CH_2}-\underset{\mathrm{OOH}}{\overset{\mathrm{CH_3}}{\mathrm{C}}}-\mathrm{CH_2}-\underset{\mathrm{OOH}}{\overset{\mathrm{CH_3}}{\mathrm{C}}}-\mathrm{CH_2}\sim \;\rightarrow\; \dot{\mathrm{O}}\mathrm{H} + \sim\mathrm{CH_2}-\underset{\dot{\mathrm{O}}}{\overset{\mathrm{CH_3}}{\mathrm{C}}}-\mathrm{CH_2}-\underset{\mathrm{HOO}}{\overset{\mathrm{CH_3}}{\mathrm{C}}}-\mathrm{CH_2}\sim \;\rightarrow$$

$$\rightarrow \sim\mathrm{CH_2}-\underset{\mathrm{OH}}{\overset{\mathrm{CH_3}}{\mathrm{C}}}-\mathrm{CH_2}-\underset{\mathrm{O\dot{O}}}{\overset{\mathrm{CH_3}}{\mathrm{C}}}-\mathrm{CH_2}\sim, \qquad \text{(IV)}$$

and the slow reaction is the chain decomposition of isolated groups:

$$\mathrm{ROOH} + \mathrm{R\dot{O}}\ (\dot{\mathrm{O}}\mathrm{H},\ \mathrm{R\dot{O}_2}) \rightarrow \mathrm{R\dot{O}_2}. \qquad \text{(V)}$$

The authors believe that this mechanism is confirmed by the fact that the contribution of the slow reaction is

10–15%, i.e. is close to the fraction of isolated hydroperoxy-groups and that the introduction of large amounts of an inhibitor (ionol) diminishes the contribution of the fast reaction and lowers the rate of the slow reaction to a limiting value, which can also be obtained by reducing the initial concentration of the hydroperoxide.

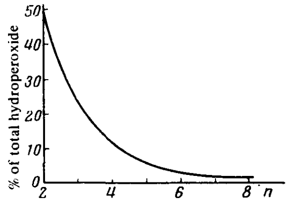


Figure 3. Distribution of adjacent hydroperoxy-groups with respect to *n* in polypropylene according to the data of Chien et al.[44]

However, the above study involves significant contradictions. In the first place the chain decomposition of the hydroperoxide cannot follow a first-order kinetic law. This is also shown by the variation of the rate constant for the slow reaction with the initial concentration of the hydroperoxide found by the authors themselves[43]. Furthermore, the contribution of the "slow" reaction must be much greater (30–40%). Indeed in the decomposition of two adjacent hydroperoxy-groups by mechanism (IV) two radicals, $\dot{O}H$ and $R\dot{O}_2$, are formed. Probably there is a high probability of the conversion of $R\dot{O}_2$ into the hydroperoxide, which will be formed as a separate molecule. Thus one half of the binary and one third of the ternary hydroperoxide sequences must ultimately decompose at the rate of the "slow" reaction.

Furthermore, in the chain decomposition of the hydroperoxide the yield of radicals per decomposition step should be much less than two, while Chien and Jabloner[43] found it to be 1.8. These findings show that the mechanism proposed[43] for the decomposition of the hydroperoxide derived from polypropylene is open to serious objections. It is difficult at present to interpret these results unambiguously.

In the decomposition of hydroperoxides in other polymers (other than polypropylene) the situation is even less satisfactory; data for such processes are virtually lacking. The results of Chien and coworkers[45] and Denisov and coworkers[46] for the decomposition of the hydroperoxides derived from polyethylene constitute an exception. However, the two sets of data show considerable discrepancies.

While Denisov and coworkers concluded that in polyethylene the hydroperoxides undergo a chain decomposition (an inhibitor retards the reaction), Chien and coworkers suggest that there is no chain decomposition in the breakdown of the polyethylene hydroperoxides, since inhibitors do not affect the decomposition process. According to these authors' findings[45], two unimolecular reactions take place in polyethylene: fast and slow reactions with activation energies of 25 and 27 kcal mole^{-1} respectively. According to Denisov[46], the activation energy for the inhibited decomposition of the hydroperoxides is 35 kcal mole^{-1}; it is suggested that the decomposition process is unimolecular and has mechanism (I). The authors of both investigations found that the rates of decompositions of the polyethylene hydroperoxides are the same in solution and in the solid phase.

Probability of radical formation in the decomposition of hydroperoxides. The available literature data on the probability of radical formation in the decomposition of hydroperoxides derived from polymers can be divided into two groups. The first group includes results obtained for the decomposition of the hydroperoxides in a vacuum or in an inert atmosphere[47] and the second group includes data obtained in an atmosphere of oxygen[42,43,45,46].

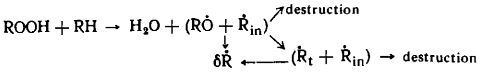
The inhibitor method in one form or another is used for the quantitative determination of the number of radicals formed in the breakdown of the hydroperoxide. The following difficulties must be overcome. As a rule, it is possible to obtain hydroperoxides derived from the polymers at concentrations of 10^{-5}–10^{-4} mole g^{-1}. In order to ensure the complete removal of the radicals by the inhibitor, the concentration of the latter in the polymer must be about 10^{-4} mole g^{-1}. When the probability of the formation of radicals is 10^{-2}–10^{-3}, about 1% of the inhibitor is consumed. Such a change in concentration is outside the error limits of the measurements.

In order to calculate the number of radicals formed in the decomposition of polypropylene hydroperoxides in a vacuum[47,48], a new version of the inhibitor method was developed. Phenoxy-radicals with t-butyl group in the *ortho*-positions can split off isobutene[49]. The amount of isobutene serves as a measure of the number of phenoxy-radicals formed in the interaction between phenol and radicals.

The mechanism of the radical processes can be represented by the following series of reactions:

$$ROOH \rightarrow \delta\dot{R} \xrightarrow{PhOH} \delta\,Ph\dot{O} \rightarrow \sigma\gamma\ (\text{iso-}C_4H_8)\ .$$

In order to find δ, it is necessary to determine, in addition to the amount of isobutene, also γ—the yield of isobutene in the decomposition of a phenoxy-radical. It was found that at 130°C in polypropylene 10% of phenoxy-radicals derived from ionol broke down with formation of isobutene, i.e. $\gamma = 10 \times 10^{-2}$.[47] The calculations showed that 17 radicals are formed for each thousand polypropylene hydroperoxide molecules decomposed in a vacuum. Such a low yield of radicals in the absence of a chain process can be explained either by postulating that the main bulk of the hydroperoxides break down without the formation of radicals or that most of the radicals formed are destroyed by recombination within the cage:



$$\begin{tikzcd} ROOH + RH \arrow[r] & H_2O + (R\dot{O} + \dot{R}_{in}) \arrow[d] \arrow[r] \arrow[rd] & \text{destruction} \\ & \delta\dot{R} & (\dot{R}_t + \dot{R}_{in}) \arrow[l] \arrow[r] & \text{destruction} \end{tikzcd}$$

A number of facts suggest that the latter explanation is correct. Thus, in a study dealing with the oxidation of isotactic polypropylene[42], it was shown, by comparing the rates of absorption of oxygen and of the decomposition of the hydroperoxide, that in the presence of O_2 the yield of radicals is much higher and approaches 2.

Table 6 shows the variation of δ with the pressure of O_2. The fact that in the presence of oxygen the mechanism of the decomposition of the hydroperoxide does not change is confirmed by the constancy of the rate of its decomposition both in a vacuum and in the presence of O_2.

Analogous calculation based on the data of Chien and Boss yields $\delta = 1.2$ for solid polypropylene at $p_{O_2} =$ 760 mmHg and 120°C.[34,43] For comparison, it should be noted that, using the inhibitor method, Chien obtained $\delta = 1.8$ for the decomposition of polypropylene hydroperoxides in solution at an O_2 pressure of 760 mmHg [43] and $\delta = 0.2$ for polyethylene hydroperoxides under the same conditions [45]. Denisov and coworkers [46] showed that the probability of the formation of radicals in the decomposition of polyethylene hydroperoxides is the same in solution and in the solid phase and is lower than the probability reported by Chien and coworkers [45] by a factor of 100. It is difficult to account for such a discrepancy between the results.

Table 6. Dependence of the yield of radicals δ in the decomposition of polypropylene hydroperoxide on the pressure of O_2 ($T = 130°C$).

p_{O_2}, mmHg	δ
0	$17 \cdot 10^{-3}$
50	0.25
100	0.5
200	0.8
400	1.2
600	1.5

The data for the variation of δ with oxygen pressure can probably be explained only on the basis of the cage effect hypothesis. The decomposition of hydroperoxides derived from polymers entails the formation of a pair of radicals which, in the absence of powerful radical acceptors, recombine with a high degree of probability. By adding to the radicals, oxygen can participate in the cage reactions and can alter the value of δ. However, it must be admitted that the mechanism of such participation remains obscure.

The participation of oxygen in the cage reactions makes it possible to estimate the lifetime of the cage τ. Evidently the order of magnitude of this time must not be less than that of the time during which the oxygen molecule migrates over the distance separating two nearest oxygen molecules (or half this distance). Using the available data on the solubility and diffusion of O_2 in polypropylene [50], we obtain τ for the amorphous polymer at 130°C of the order of 10^{-6}–10^{-8} s; in the crystalline polymer this quantity is probably somewhat larger. The value of τ obtained here agrees well with τ estimated from the probability of the breakdown of $R\dot{O}$ radicals (see below).

Shlyapnikova and Yasina [51] secured direct evidence that the yield of radicals in the breakdown of the hydroperoxides derived from solid propylene increases under the influence of oxygen; δ then varies linearly with oxygen pressure: $\delta = \delta_0 + \delta_i p_{O_2}$, where $\delta_i/\delta_0 \simeq 2 \times 10^{-3}\ \text{mmHg}^{-1}$ for the liberation of methane from the cage and $\delta_i/\delta_0 \simeq 1.3 \times 10^{-2}\ \text{mmHg}^{-1}$ for the liberation of propene.

From the standpoint of the stabilisation of polymers, it is significant that the yield of radicals in the decomposition of polymer hydroperoxides can also be increased by certain inhibitors. Thus in a study of the effect of ionol on the yield of hydrocarbons in the breakdown of polypropylene hydroperoxide [48], the results presented in Fig. 4 were obtained. Volatile hydrocarbons (methane, ethane, propane, propene, and isobutene) are produced in the breakdown of alkyl macroradicals generated from the hydroperoxide and isobutene is formed in addition also from phenoxy-radicals—the product of the interaction of ionol with macroradicals. Fig. 4 shows that the yields of all the hydrocarbons, with the exception of isobutene, decrease with increase in the concentration of the inhibitor; however, the decrease is not to zero but only to a limiting value. At the same time the amount of isobutene increases continuously. These results can be readily explained if it is supposed that the inhibitor can participate in an additional radical generation process. Then, starting with a certain inhibitor concentration, the concentration of radicals in the polymer becomes constant and independent of the concentration of the inhibitor, because the rates of formation and destruction of radicals are both proportional to the latter. This is why the rate of formation of hydrocarbons and consequently their yield cease to depend on the inhibitor concentration. At the same time the total amount of radicals and hence also the yield of isobutene increase continuously with increasing ionol concentration. Thus the inhibitor participates both in the destruction of radicals and in their formation.

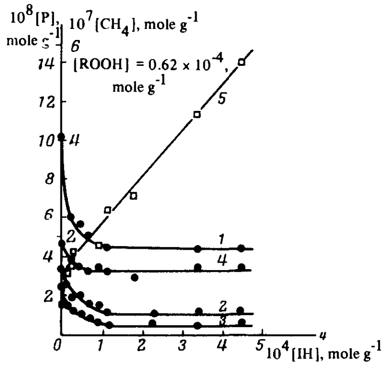


Figure 4. Dependence of the yield of polypropylene hydroperoxide decomposition products on the concentration of ionol: 1) methane; 2) ethane; 3) propane; 4) propene; 5) isobutene.

A kinetic analysis of the role of the inhibitor in the production of radicals and quantitative estimates of this participation have been made [48]. For example, in the breakdown of the polypropylene hydroperoxides in a vacuum at 130°C the yield of radicals in the presence of 5×10^{-4} M ionol increases by a factor of 5.

In principle, one can consider two mechanisms for the involvement of the inhibitor in radical generation. Firstly, the inhibitor may "enter" the cage ($R\dot{O} + \dot{R}_{in}$) destroying one of the radicals; the second radical is then capable of chain propagation. Secondly, the inhibitor can react with the polymer hydroperoxide; such a reaction is an additional source of radicals.

The branching function of the inhibitor can be shown only when the primary yield of radicals in the breakdown of the hydroperoxide (without the participation of the inhibitor) is very low.

In fact the inhibitor can successfully compete with the cage recombination of radicals only if the rate constant for its interaction with the radicals is not less than the rate constant for their recombination and the concentration of the inhibitor is also fairly high. At the usually employed inhibitor concentration (0.01–0.01 mole kg^{-1}) the probability of the interaction of the inhibitor with the cage is low (10^{-2}–10^{-4}). For this reason, such interaction can be important only when the spontaneous liberation of radicals from the cage is also low. In the direct interaction of the inhibitor with the hydroperoxide the following factors are evident. If the probability of the formation of radicals in the breakdown of the hydroperoxide is low, then even a slight interaction between the inhibitor and the hydroperoxide can have a significant effect on the yield of radicals. Otherwise even a high rate of interaction of the inhibitor with the peroxide cannot affect appreciably the efficiency of radical formation.

The above analysis of the data shows that no unambiguous results are yet available on the yield of radicals in the breakdown of polymer hydroperoxides in the presence of oxygen. In some studies the yield of radicals in the presence of oxygen has been determined as about 10^{-2} to 10^{-3}, while in others it is of the order of unity.

Nevertheless this finding is fairly important. The point is that the idea of the involvement of the inhibitor in degenerate branching in the oxidation of polymers and the associated theory of the effect of inhibitors (critical concentrations, classification of inhibitors into "strong" and "weak", etc.) are based on the hypothesis of a low value of δ; these hypotheses were put forward by Shlyapnikov and Neiman[52,53] and confirmed in studies of the high-temperature (180–220°C) inhibited oxidation of polypropylene.

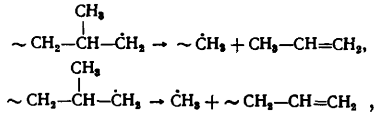
Thus there exists a definite contradiction concerning the value of δ. Possibly in solid polymers (at 100–130°C) δ is close to unity, while in melts at temperatures in the range 180–220°C δ is small (although from the physical point of view the opposite relation would be expected). Evidently the unambiguous solution to the problem of the probability of degenerate branching in the breakdown of hydroperoxides in polymers is very important for the theory of polymer stabilisation.

5. Decomposition of Macroradicals (Degradation of the Polymer Chain)

The kinetics of the decomposition of macroradicals of different types are of exceptional interest for the theory of degradation processes. Unfortunately there are virtually no quantitative data for the rates of decomposition in the solid phase. For this reason, only the qualitative aspects of this problem will be considered here.

In various forms of polymer degradation the following types of radicals play a leading role: alkyl macroradicals and peroxy- and alkoxy-macroradicals.

Decomposition of alkyl macroradicals. These reactions are usually investigated in thermal degradation processes of polymers at temperatures in excess of 300°C; this is because the rate of their decomposition is low. Thus it is known from the kinetics of gas-phase reactions[54] that low-molecular alkyl radicals break down with an activation energy exceeding 30 kcal mole^{-1}. Probably the activation energy for the decomposition of high-molecular radicals does not differ appreciably from this value. The breakdown of alkyl macroradicals leads to the rupture of the polymer chain and the formation of radicals with a free valence at the end of the macrochain (terminal macroradicals). These radicals give rise to volatile degradation products and in many cases alkyl macroradicals may isomerise, which leads to a wide range of degradation products. For example, in the thermal degradation of polypropylene the following reactions are postulated[55,56]:



$$\sim CH_2\text{—}\underset{}{\overset{CH_3}{\overset{|}{C}}}H\text{—}\dot{C}H_2 \rightarrow \sim\dot{C}H_2 + CH_3\text{—}CH\text{=}CH_2,$$

$$\sim CH_2\text{—}\overset{CH_3}{\overset{|}{C}}H\text{—}\dot{C}H_2 \rightarrow \dot{C}H_3 + \sim CH_2\text{—}CH\text{=}CH_2\ ,$$

etc.

Decomposition reactions of alkyl macroradicals have been observed in the inhibited oxidation of polypropylene at 200°C,[57] in the mechanical degradation of a number of polymers[58], and also in the breakdown of polypropylene hydroperoxide at 130°C.[59] In the last case a detailed study was made of the kinetics of the formation of volatile hydrocarbons—the degradation products of the terminal macroradicals. The yield was found to be extremely low. In the breakdown of 1.26×10^{-4} mole of hydroperoxide, at a concentration of 1.26×10^{-4} mole g^{-1} in the polymer, the amounts of products were 16.7×10^{-7} mole of methane, 0.85×10^{-7} mole of ethane, 0.89×10^{-7} mole of propane, 1.4×10^{-7} mole of propene, and 0.19×10^{-7} mole of isobutene. These data make it possible to estimate the probability of the decomposition of alkyl macroradicals at 130°C. In the same study it was shown that the terminal macroradicals are obtained mainly in the breakdown of alkoxy- and not alkyl radicals. For this reason, only half of the radicals liberated from the "cage" ($R\dot{O}$ + $\dot{R}_{in}$) are terminal. Since the yield of radicals is in this case 1.7×10^{-2},[47] it follows that 1.26×10^{-4} mole of hydroperoxide gives 10.7×10^{-7} mole of $\dot{R}_t$. Consequently only 8% of the $\dot{R}_t$ radicals decompose with formation of propene while the remaining 92% are converted into "inner" macroradicals by the reaction

$$\dot{R}_t + RH \rightarrow R_tH + \dot{R}_{in}$$

or isomerise and yield other hydrocarbons (propane, ethane, isobutene, etc.). Thus the rate of the chain-transfer reactions exceeds at least by a factor of ten the rate of decomposition of the terminal macroradicals.

In those cases where the activity of the alkyl macroradicals is low, the yield of the monomer is much higher; for example, in the degradation of poly(methyl methacrylate) (PMMA) almost pure monomer is found among the products. The rate constants for the depolymerisation of the terminal macroradicals have been measured in such processes: the rate constant for the breakdown of macroradicals in the photo-degradation of PMMA was measured by Cowley and Melville using the sector method at 167°C[60] and was found to be 5.8×10^{-2} s^{-1}. According to the same authors' estimate, the activation energy is 18.5 kcal mole^{-1}. These values agree well with data obtained in the measurements of the rate of decomposition of the radicals $\sim\dot{C}(CH_3)(COOCH_3)$ in PMMA at 20°C.[32] It was found that at a radical concentration of 10^{18} spins g^{-1} the rate of formation of methyl methacrylate is 0.56×10^{15} particles per cm^3 per second; hence the rate constant for the decomposition is 0.56×10^{-3} s^{-1}. According to the data of Cowley and Melville, it should be about 10^{-3} s^{-1} at 20°C. Thus depolymerisation in the solid phase takes place at the same rate as in the liquid phase[9].

Alkoxy-macroradicals. The activation energy for the decomposition of alkoxy-radicals in the gaseous and liquid phases does not exceed 10–12 kcal mole^{-1},[61] i.e. they are much more stable than alkyl radicals.

In the mechanism of the thermal oxidative degradation it is thought that alkoxy-radicals play a leading role in the dissociation of polymer chains. Thus Tobolsky, who studied the sensitised oxidation of polypropylene (in the absence of branching) at 80°C, established[62] that under these conditions at least one rupture of polymer chain occurs on the average for each oxidation chain. Hence it was concluded that the polymer chain ruptures in the recombination process of peroxy-radicals:

$$R\dot{O}_2 + R\dot{O}_2 \rightarrow 2R\dot{O} + O_2 \, .$$

The $R\dot{O}$ radicals formed break down with rupture of the polymer chain. Thus the probability of the decomposition of $R\dot{O}$ radicals is close to unity.

In oxidation processes with degenerate branching the principal source of $R\dot{O}$ radicals is the breakdown of hydroperoxide:

$$ROOH + RH \rightarrow (R\dot{O} + \dot{R}_c) + H_2O \, .$$

A quantitative study of the decomposition products of polypropylene hydroperoxides made it possible to estimate the probability of the breakdown of alkoxy-radicals[59]. It was established that in the decomposition of polypropylene hydroperoxide the amount of oxygen-containing products formed (formaldehyde, acetone, acetaldehyde, etc.), which may be obtained only from terminal hydroperoxides, is about 10–15% of the total amount hydroperoxides decomposed. Hence the yield of oxygen-containing products is equal to $\alpha\beta$, where α is the probability of the decomposition of $R\dot{O}$ radicals and β is the fraction of terminal hydroperoxides relative to the total amount of hydroperoxides; β may be determined as follows.

If it is assumed that in the breakdown of the hydroperoxide $\alpha\dot{R}_t$ and $(1 - \alpha)\,\dot{R}_{in}$ were formed, then these radicals would initiate new oxidation chains of length ν. Each chain, begun by the radical $\dot{R}_t$, contains one R_tOOH molecule and $(\nu - 1)R_{in}OOH$ molecules and the chain begun by $\dot{R}_{in}$ consists entirely of $R_{in}OOH$. Hence $\beta = \alpha/2\nu$ or $\alpha^2/2\nu = 0.10\text{–}0.15$. According to Pudov[63], ν at 130°C varies in the range 5–1.5; hence $0.5 \leqslant \alpha \leqslant 1$.

Thus the rate of dissociation of the polymer chain in the oxidation of polypropylene must not be less than the rate of decomposition of the hydroperoxides.

Bearing in mind that the probability of the breakdown of the radicals $R\dot{O}$ is high (about 1.0) and the yield of radicals liberated from the cage is low (about 1.7×10^{-2}), one must conclude that the decomposition of these radicals takes place during the lifetime of the cage. If 11 kcal mole^{-1} is adopted for the activation energy for the breakdown of $R\dot{O}$ radicals in polypropylene and about 10^{13} s^{-1} for the pre-exponential factor, it is possible to estimate the lower limit of the lifetime of the cage ($R\dot{O} + \dot{R}_{in}$); it proves to be 10^{-6}–10^{-7} s^{-1}.

A high probability of the dissociation of the chain in the breakdown of the peroxide was observed in the oxidation of polyoxymethylene copolymers at 160°C.[64] In the oxidative thermal degradation of rubbers it was also shown by a kinetic procedure that the probability of the breakdown of alkoxy-radicals is unity[65], i.e. even in rubbers the breakdown of $R\dot{O}$ at 100–130°C is much faster than the recombination in the vapour phase ($RO + \dot{R}_{in}$).

Thus alkoxy-radicals appear to be the principal species responsible for both the formation of volatile degradation products and the dissociation of polymer chains.

The kinetics of the decomposition of peroxy-radicals in Teflon according to the reaction

$$R\dot{O}_2 \rightarrow \dot{R} + O_2$$

were investigated by Voevodskii and coworkers[24]. The rate constant is $k = 10^8 \exp(-20\,000/RT)$ s^{-1}. The energy of the $R\text{–}O\dot{O}$ bond in this radical is about 10 kcal mole^{-1}.

We shall now consider the contribution of $R\dot{O}_2$ radicals to chain degradation. In 1959 Neiman and coworkers[66] compared the rates of decomposition of the hydroperoxide in the polymer and the rate of isomerisation of peroxy-radicals and concluded that they are of the same order of magnitude. Recently published data confirm this finding. Chien and Boss[34] showed that in the oxidation of polypropylene at 130°C the steady-state concentrations of the hydroperoxide and peroxy-radicals are 0.30×10^{-6} and 10.2×10^{-6} mole litre^{-1} respectively and the rate constant for the breakdown of the hydroperoxide is 16.5×10^{-4} s^{-1}. If it is assumed that the activation energy for the isomerisation of peroxy-radicals is about 20 kcal mole^{-1}†,[67] it is found that the rates of isomerisation of peroxy-radicals and of the decomposition of the hydroperoxide are comparable. This conclusion is confirmed by the data of Denisov and coworkers[68], according to which the contribution of the isomerisation of $R\dot{O}_2$ to the degradation of polymer chains is about 10%.

6. Cage Effects and Radical Pairs in Solid Polymers

Numerous studies on cage effects in the decomposition of initiators in the liquid phase showed that the probability of the liberation of radicals from the cage or from a radical pair is 0.3–0.7, i.e. 30–70% of the radicals avoid recombination in the cage. The principal mechanism of the liberation of radicals involves diffusion; this is confirmed by the finding that the yield of radicals depends on the viscosity, obeying the Debye–Stokes diffusion equation[69].

The data on the yields of radicals in highly viscous media (including polymers) are somewhat contradictory. In a number of studies yields of radicals close to those observed in the liquid phase are quoted. Haas[70] found that in the decomposition of benzoyl peroxide in polystyrene and poly(vinyl chloride) the probability of the liberation of radicals from the cell is 0.5–0.6. These data agree with the results of Denisov and coworkers[71], according to which about 70% of the radicals recombine in the cage in the breakdown of lauroyl peroxide in solid polystyrene (at 80°C) and about 95–96% in the breakdown of bisazoisobutyronitrile.

It may be expected that the yield of radicals liberated by the diffusion mechanism will be sharply reduced in solid polymers; this is clearly illustrated by the data in Table 7.

Evidently, the fraction of the products of recombination in the cage (t-butyl peroxide) increases with the viscosity of the medium and there is a parallel decrease of the fraction of the products derived from the radicals liberated from the cage (t-butyl alcohol).

In very viscous media relay mechanisms, including the interaction between an active species and the wall of the cage, play a significant role[70,73] supplementing to the diffusion mechanism of the liberation of radicals from the cage. It is useful to estimate the relative contributions of the mechanisms whereby radicals are released from the cage. The migration of low-molecular species by diffusion in polymers is characterised by diffusion coefficients in the range 10^{-7}–10^{-10} cm^2 s^{-1}. The liberation of radicals from the cage via interaction with the cage walls (for example, the abstraction of a hydrogen atom) can also be

---

†This value is fairly accurate. In fact for $R\dot{O}_2$ we have $\epsilon_{isomer} - \epsilon_{prod} \simeq 8.5$ kcal mole^{-1};[67] when $\epsilon_{prod} \simeq$ 12 kcal/mole^{-1}, $\epsilon_{isomer} \simeq 20$ kcal mole^{-1}.

characterised by a "chemical" diffusion constant, which is related to the rate constant for the abstraction of a hydrogen atom by the expression $D = \frac{1}{6}\lambda^2 k'$, where λ is a quantity of the order of magnitude of the intermolecular distance and k' is the frequency of the step involving the abstraction of a hydrogen atom, equal to the product of the rate constant for this reaction k and the polymer concentration (RH).

Table 7. Products of the decomposition of di-t-butyl peroxyoxalate at 35°C.[72]

Medium	Viscosity, cP	Yield of products as t-butoxy-radicals, %		
		t-butyl-peroxide	t-butyl alcohol	acetone
n-Pentane	0.22	4	95	1
Liquid silicone	74	46	46	0.5
Liquid paraffin	80	78	16	0
Polychlorotrifluoroethylene	560	88	2	7
Polyisobutylene	>1000	93	4.6	0

On substituting in this equation the usual values $\lambda \simeq 5$ Å and (RH) $\simeq 10^{22}$ cm^{-3}, we obtain $D \simeq 4 \times 10^{-6}\, k$. Thus, for the liberation of radicals from the cage by the relay mechanism to be comparable with the liberation by the diffusion mechanism, k must be of the order of 2.5×10^{-14}–10^{-17} cm^3 s^{-1}. Hence it is clear that for mobile species ($D \geqslant 10^{-7}$ cm^2 s^{-1}) the diffusion mechanism predominates; only in the case of the most reactive radicals can interaction with the cage wall play an appreciable role.

The liberation from the cage of less mobile species probably takes place by both mechanisms, their relative contributions being determined by the reactivity and mobility of the species. This is illustrated by the data of Smirnov et al.[74], who measured the effectiveness of various initiators in liquid and solid acrylate oligo-esters. The effectiveness of bisazoisobutyronitrile diminishes from 0.5 to 0.035 on transition from the liquid to the solid acrylate oligo-ester, while the decrease of the effectiveness of acyl peroxides is only from 0.5 to 0.3. The authors suggest that, for the relatively unreactive radicals $(CH_3)_2\dot{C}CN$, the extent of liberation from the cage is wholly determined by the diffusion of the radical and therefore depends markedly on the viscosity of the medium. On the other hand, for the radicals $RC\dot{O}O$ a relay mechanism plays an important role in the separation of the radical pair and the effectiveness of the initiation depends much less on the viscosity of the medium. It is possible to account for the results of Haas[70] quoted above and other data in a similar manner.

It has recently been shown that radical pairs in the cages can be detected by ESR. In such pairs dipole and exchange interactions take place between the unpaired electrons of the radicals and are reflected in the ESR spectra. The ESR spectra have been reviewed in relation to the theory of biradical systems (including radical pairs)[75]. In radical pairs trapped in crystals the distances between the radicals are rigidly fixed and therefore the energy of the dipole interaction between unpaired electrons is rigorously determined; this dipole splitting is a characteristic feature of the ESR spectra of radical pairs. The average distance between the unpaired electrons is found from the magnitude of the splitting.

In most cases the distance is 4–6 Å.[76] The kinetics of the reaction in pairs of azobutyronitrile radicals were investigated by Lebedev[77]. The probability of the liberation of radicals from the pair at 77°K in azobutyronitrile is about 2×10^{-3}. The rate constant for the "quenching" of the pair, i.e. for the recombination of the radicals in the pair, is given by an expression of the form[76]

$$k = 10^8 \exp(-3500/RT)\ \mathrm{s}^{-1}.$$

Thus in the solid phase even recombination in the pair requires an activation energy, i.e. the lifetime of the radical pair may be fairly long.

In glasses and polymers a fairly wide distribution of separations between radicals in each pair is to be expected. The ESR spectra in such cases are fairly broad and in general it is impossible to detect pairs in the region of the usual ESR transitions ($\Delta M_S = 1$). However, recently radical pairs have been detected in irradiated polymers (polyethylene, polyformaldehyde, polypropylene, etc.) by recording the "forbidden" $\Delta M_S = 2$ signal[78] (this signal corresponds to the simultaneous reorientation of both electron spins in the pair).

It is difficult to determine the concentrations of the pairs from such signals and to investigate the kinetics of their reactions, but the very fact of their detection in polymers is remarkable. The search for the broad signals due to radical pairs corresponding to $\Delta M_S = 1$ is more promising and these have also been observed[78,79].

III. RELATIONS BETWEEN THE KINETICS OF RADICAL REACTIONS AND THE KINETICS OF MOLECULAR MOTION IN POLYMERS

In the previous section convincing evidence was presented showing that in the majority of solid polymers radical recombination occurs by a relay mechanism. At first sight it would appear to follow from this that the kinetics of such reactions must be determined only by the chemical reactivity of the radicals and should not be sensitive to the physical state and the physical properties of the polymer matrix. However, a number of facts are inconsistent with this conclusion. Thus it is known that the temperature ranges in which molecular motion is "unfrozen" (for example, as measured by NMR) are the same as the temperature ranges in which radicals are destroyed. The kinetics of radical recombination in acrylate polyester glasses are qualitatively related to the rigidity of the matrix[29]. The rate of destruction of alkyl radicals in oriented polystyrene is much lower than in the non-oriented polymer[13]. The rate of recombination of PMMA peroxy-radicals in the stressed polymer is much higher than in the polymer subjected to preliminary annealing[5].

The relation between the reaction kinetics and the kinetics of molecular motion is not only qualitative but also quantitative. Thus in PMMA the effective activation energy for the destruction of alkyl radicals is 28 kcal mole^{-1},[26] while the activation energy for segmental motion, measured by NMR, is 27 ± 10 kcal mole^{-1}.[80] In polypropylene the destruction of the radicals in the low-temperature region takes place with an activation energy of 11 kcal mole^{-1}; the activation energy for molecular motion in the same temperature range is (100–250°K) is 13 kcal mole^{-1}. In the high-temperature region (> 250°K) the activation energies are respectively 48 and 58 kcal mole^{-1}.[30] The same behaviour is observed in polyethylene[31]. In the high-temperature region radicals with stereochemical conformations corresponding to a regular spiral are destroyed, while radicals with a distorted structure, markedly differing from the spiral structure, recombine at low temperatures (they are apparently localised in amorphous regions or structural defects).

Frequently such quantitative correspondance is regarded as proof of a diffusion mechanism for the recombination of radicals and the high activation energies for recombination are usually explained by the co-operative nature of the diffusion, requiring the simultaneous rearrangement of the structure and of the packing of a large number of segments and units of the polymer chains.

However, it should be noted that in the vast majority of such cases pre-exponential factors for the rate constant are anomalously high and are without physical significance. Furthermore, there is a linear relation between the logarithm of the pre-exponential factor (or the entropy of activation) and the energy (enthalpy) of activation, i.e. the compensation effect. Therefore it is clear that the above purely qualitative explanation of the correspondence between the reaction kinetics and the kinetics of molecular motion is inadequate.

Lebedev et al. were the first to draw attention to the compensation effect in the radical recombination reactions in polymers[24]. They proposed an explanation for this effect on the hypothesis that, over the temperature range of the recombination reactions, the activation energy decreases with increasing temperature as a result of changes in the structure of the polymer. The effective activation energy and the pre-exponential factor are then given by the following expressions:

$$\varepsilon_{\text{eff}} = \varepsilon(T) - T\,\partial\varepsilon/\partial T\ , \tag{7}$$

$$k^0_{\text{eff}} = k^0 \exp\left(-\frac{1}{R}\frac{\partial\varepsilon}{\partial T}\right) \tag{8}$$

and are linked by the reciprocal relation $\lg k^0_{\text{eff}} = A + B\epsilon_{\text{eff}}$.

However, this explanation of the compensation effect and the kinetic characteristics of the recombination is valid only within the framework of the hypothesis of a diffusion mechanism for the recombination process. In fact it is necessary to seek kinetic models which would yield the compensation effect within the framework of the relay recombination mechanism, i.e. the compensation effect associated with the rate constants k_t for the relay processes (see Tables 5 and 6).

The following model is the most natural. The reaction of $\dot{R}$ and RH (or $R\dot{O}_2$ and RH) requires that a definite orientation of the reactants—be achieved before the activated complex. Such a "preparatory" state i_p is attained via a series of thermodynamic equilibrium states $i_1, i_2, \ldots, i_{p-1}$, corresponding to different orientations of the reactants. The kinetic mechanism of the reaction can be represented as follows:

$$\dot{R} + RH \overset{K_1}{\rightleftarrows} i_1 \overset{K_2}{\rightleftarrows} \ldots \overset{K_p}{\rightleftarrows} i_p \xrightarrow{k_0} RH + \dot{R}\ , \tag{9}$$

where K_i are the constants governing the equilibria between the various states and k_0 is the rate constant for the reaction in the "preparatory" state.

It is easy to show that the measured effective rate constant is then $k_{\text{eff}} = k_0 \prod_p K_p$, where $\prod_p$ is the symbol representing the product of the constant K_p for all p states.

In the simplest case one may assume that all the states are of equal importance, i.e. for all the equilibrium constants one may write

$$K_p = e^{\Delta S_p/R} e^{-\Delta H_p/RT}.$$

Then

$$k_{\text{eff}} = k^0_0 \exp(p\,\Delta S_p/R) \exp\left(-\frac{\varepsilon + p\,\Delta H_p}{RT}\right) \tag{10}$$

where k^0_0 and ϵ are the pre-exponential factor and the activation energy for the reaction in state i_p.

Evidently the compensation effect is implied in this equation; furthermore, since the number of states p may depend upon temperature, this equation involves an additional cause of the compensation effect—by the mechanism of Lebedev et al.[24] It is noteworthy that an equation similar to Eqn. (10) can be obtained on the hypothesis that the "pre-start" state is attained by the "simultaneous" rearrangement of a large co-operative group, but within the framework of the model considered above this hypothesis is not essential.

Eqn. (10) also implies a relation between the reaction kinetics and the kinetics of molecular motion. In fact mechanism (9) is applicable to the motion of the polymer segment or a certain probe-species in the polymer matrix (for example a paramagnetic probe[81]) and all the considerations associated with this mechanism are valid. Then for the frequency of motion of the segment (or the probe), we have the equation $\nu_{\text{eff}} = \nu_0 \prod_p K_p$ or

$$\nu_{\text{eff}} = \nu^0_0 \exp(p\,\Delta S/R) \exp\left(-\frac{\varepsilon_r + p\,\Delta H_p}{RT}\right)$$

This equation is analogous to Eqn. (10); here ν^0_0 and ϵ_r are the true pre-exponential factor and the activation energy for the intrinsic motion of the segment or the probe. In particular, if it is found that ϵ and $\epsilon_r \ll p\Delta H_p$, then the effective activation energies for the reaction and molecular motion will be equal; examples of such agreement were quoted at the beginning of this section.

Thus the kinetic model represented by mechanism (9) gives a qualitatively satisfactory description of both the compensation effect and the relation linking the reaction kinetics to the structure of the polymer and the kinetics of molecular motion. It may be supposed that these considerations are in principle applicable to all radical reactions in solid polymers, including reactions in radical pairs.

Finally, the problem of the relation between the reaction kinetics and the structure, properties, and the molecular mobility of the polymers remains one of the most important and fundamental; in this respect hardly anything has been done and almost nothing is known apart from certain general hypotheses. A similar situation is typical also for liquid-phase radical reactions[82]; in both cases the solution of the general kinetic problem is necessary.

---o0o---

The above review has dealt with almost all the most important radical degradation and stabilisation reactions of polymers, their role in the overall process has been assessed, and their quantitative kinetic characteristics have been described. It is noteworthy that the level achieved in the quantitative kinetics of radical degradation and stabilisation reactions of polymers is fairly low. For the majority of elementary reactions, there are no quantitative data and one must be satisfied with only approximate estimates of the activation energies and rate constants. For many reactions, the available data are very contradictory; this frequently applies not only to the kinetic constants but even to the mechanisms. The most contradictory data concern the chain propagation and termination reactions, degenerate branching reactions, and the participation of inhibitors in these processes, despite the fact that these reactions are in fact the most important in oxidative thermal degradation.

However, the principal differences between the mechanism of degradation and stabilisation of solid polymers and the mechanism of liquid-phase oxidation are already clear; a kinetic theory for solid-phase reactions has been developed to a degree quite sufficient for the solution of problems associated with the degradation and stabilisation of solid polymers; the physical significance of the solid-phase rate constants and its difference from the physical significance of the "liquid-phase" and "gas-phase" constants are largely clear. Experimental difficulties in the study of elementary radical reactions in solid polymers are also not of fundamental importance in most cases.

Essentially, first steps have now been taken in this field and the principal kinetic problems associated with the specific features of the solid phase have been formulated. The solution of these problems constitutes an important component in the creation of a scientific basis for the stabilisation of polymers.

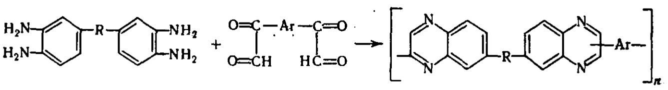
Polyquinoxalines

A.M.Berlin

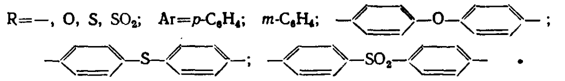
The present Review reports the most recent work on the synthesis, properties, and structure of a further class of thermostable heterocyclic polymers containing six-membered heterocyclic rings—the polyquinoxalines. A list of 24 references is given.

A considerable amount of research has been undertaken during recent years, both abroad and in the Soviet Union, on the production of thermostable polymeric materials. The fairly extensive class of macromolecular substances containing heterocyclic rings in the main chain is of undoubted interest, because several heterocycles, e.g. 1,3,5-triazine, oxadiazole, pyrazole, benzimidazole, benzoxazole, benzothiazole, etc., possess excellent stability to the action of heat, light, and oxidising agents, and are resistant to acids, bases, and various chemical reagents. The main investigations of the chemistry of macromolecular compounds containing five-membered heterocycles have been discussed in a number of reviews[1-4].

In view of the great thermal stability of the quinoxaline ring and its resistance to chemical reagents, several workers have synthesised polymers with chains containing these rings. They used the polycondensation of aromatic tetra-amines with bis-α-diketones:



where

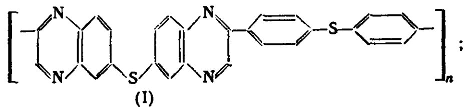


Two methods are at present used for the synthesis of polyquinoxalines: (1) stoichiometric quantities of the monomers are heated at 225–250°C for several hours[5], and the resulting polymer has an intermediate molecular weight which is then increased by further heating in a vacuum to 375°C; (2) the monomers first react in a solvent such as dioxan[5,6] or hexamethylphosphoramide (HMPA),[7] and the resulting solids of low molecular weight are again heated in a vacuum at 375°C. The polyquinoxaline obtained from *p*-phenylenediglyoxal and 3,3′-diaminobenzidine[5], which contains completely conjugated aromatic chains, possesses very high thermal stability when heated either in air or in nitrogen, its decomposition temperature being 500°C and above. It is insoluble in the usual organic solvents, and sparingly soluble in hexamethylphosphoramide; films obtained even from a polymer of high molecular weight are extremely brittle.

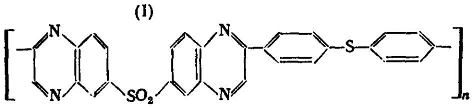
The introduction of an oxygen bridge into the polymer chain[8] increased the solubility of the polymers. Films cast from their solutions in hexamethylphosphoramide were also brittle initially, and showed various colours from pale yellow to red. After they had been heated in a vacuum in an atmosphere of nitrogen at 350–400°C, however, they were converted into tough, flexible, transparent films. Unfortunately, no information is given on the stability of these films. It is interesting that their infrared spectra have the same characteristic absorption bands before and after heating, which suggests the absence of cross-links in the polymer. On this basis the diminution in the solubility of the polymers after prolonged heating was explained by further increase in their molecular weight. This observation is common to all synthetic linear polyquinoxalines.

The presence of an oxygen bridge had no effect on the thermal stability of the polymers, the introduction of various sulphur-containing groups[9] produced only a slight decrease (the limit of thermal stability remained above 400°C even in air), and up to a considerable molecular weight these polymers retained their solubility not only in sulphuric acid but also in hexamethylphosphoramide (Table 1).

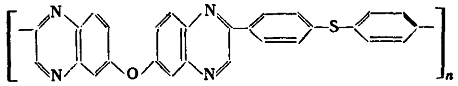
Polyquinoxalines[9] having the structures



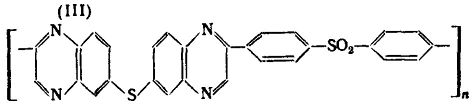
(I)



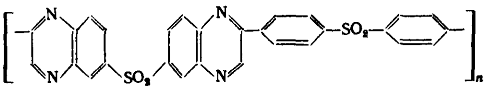
(II)



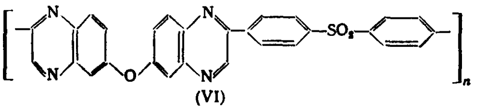
(III)



(IV)



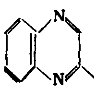
(V)



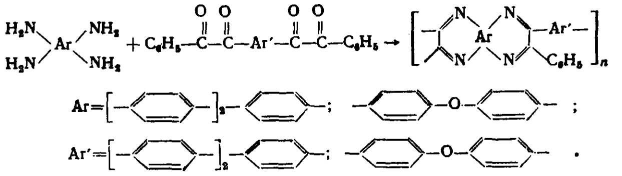
(VI)

have been obtained.

It had been shown previously that the pyrazine hydrogen in the quinoxaline ring



undergoes oxidation first[10]. An attempt was therefore made[10] to increase the stability of polyquinoxalines to oxidation by replacing the pyrazine hydrogen by a phenyl group. Four phenylated polyquinoxalines were obtained by the scheme



These polymers were synthesised in the melt and in solution.

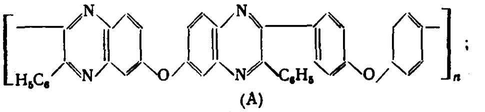
Condensation in the melt was performed at 180°, 200°, and 280°C and then at 380–400°C for 1 h. The resulting polymers exhibited extraordinarily good adhesion to glass. Various solvents—dimethylformamide, dimethylacetamide, *m*-cresol—were used for polycondensation in solution, between the temperature limits of −10° and 202°C. The initially formed polymer of intermediate molecular weight (η = 0.6–1.0) was then heated at 400°C until the final polymer (η = 1.5–2.2) was formed. Solutions of the polymers in *m*-cresol showed perfect stability for 30 days. Films from 10% *m*-cresol solutions of these polymers possessed a high tensile strength and excellent flexibility after being heated to 300°C.[10]

Table 1.

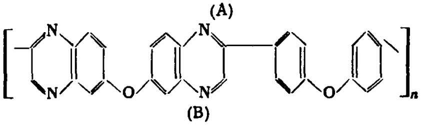
Polymer	Stage	Colour	Solubility, % in		[η]*	Wt. lost at, °C
			HMPA	H_2SO_4		
(I)	1st	brown	100	100	0.35	—
	2nd	black	70	100	2.40	500
(II)	1st	yellow	75	100	0.45	—
	2nd	brown	55	90	0.80	440
(III)	1st	yellow	100	100	0.35	—
	2nd	black	19	70	1.07	460
(IV)	1st	brown	100	100	0.41	—
	2nd	black	50	80	1.12	460
(V)	1st	brown	100	100	0.33	—
	2nd	brown	21	80	1.22	420
(VI)	1st	yellow	100	100	0.26	—
	2nd	black	14	60	1.11	420

*[η] = logarithmic viscosity in hexamethylphosphoramide, concentration 0.25 g/100 ml.

Phenylated polyquinoxalines, as expected, exhibited outstanding thermal stability and resistance to oxidation. The authors showed this by making a thermogravimetric analysis (Fig. 1), and also by the isothermal aging (Fig. 2) in air and in helium of two polyquinoxalines differing only in the presence of phenyl groups in one of them.



(A)



(B)

In helium the difference between the temperatures at which decomposition begins in phenylated and ordinary linear polyquinoxalines is about 40 deg, and in air it is still larger. Furthermore, the phenylated polyquinoxalines have considerably higher glass points, the value for the polymer (A) being 437°C. It is interesting that both polymers (A) and (B) are stable in air at 316°C (600°F), and 92–95% of the original weight remains after heating for 200 h. However, after 100 h at 371°C (700°F) the polymer (A) retains 93% of the original weight, and polymer (B) only 63%; the latter breaks down completely after being heated for 160 h, whereas polymer (A) retains 50% of its weight after heating for 200 h (Fig. 2).

Phenylated polyquinoxalines are stable to the action of 40% alkali. After boiling in 40% caustic potash for 6 h, polymer (A) was regained in quantitative yield, its viscosity, analysis, and infrared spectra being unchanged.

The characteristics of several polyquinoxalines are given in Table 2.

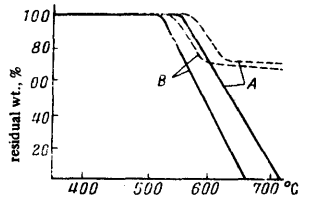


Figure 1. Thermogravimetric analysis of polyquinoxalines (A) and (B): full line in air; broken line in helium.

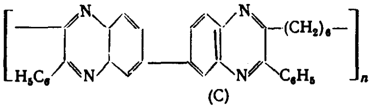
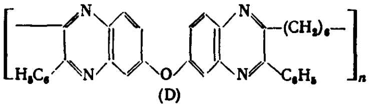
Aliphatic polyphenylquinoxalines have been obtained[11] by analogous methods to the above, by the reaction of 1,10-diphenyldecane-1,2,9,10-tetraone with 3,3′-diaminobenzidine or bis-3,4-diaminophenyl ether. As expected, the resulting polymers



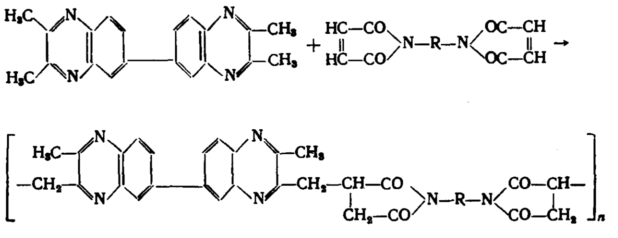
(C)



(D)

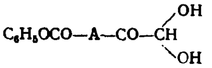
had a lower thermal stability than the aromatic polyphenylquinoxalines, their decomposition temperatures in air and in helium being about 450°C. The reduced viscosity (0.5% H_2SO_4 solution at 25°C) of such polymers was 1.16 and 1.04 for (C) and (D) respectively; they both possessed excellent adhesion to glass.

Quinoxalinimide polymers have been obtained[12] by the reaction of 2,2′,3,3′-tetramethylbiquinoxalinyl with *o*- and *m*-phenylenebismaleimides:



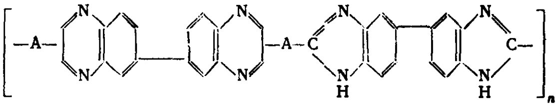
The reaction was conducted in anhydrous toluene, in xylene, or in dimethylformamide. The polymers are soluble in dimethylformamide, hexamethylphosphoramide, and sulphuric acid, do not melt, and lose 8% in weight when heated in air at 200°C for 2 h. No information is given on the molecular weight of the polymers.

New mixed polymers, polybenzimidazoquinoxalines, have been obtained[13] by the reaction of previously unreported phenoxycarbonylphenylglyoxals having the general formula



$$C_6H_5OCO{-}A{-}CO{-}CH(OH)_2$$

(where A represents *m*- or *p*-phenylene) with aromatic tetra-amines. In the opinion of the authors[13] quinoxaline rings are formed initially, and the structure of the resulting polymers corresponds to the formula



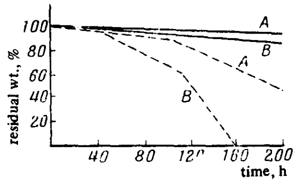


Figure 2. Kinetic curves for the loss in weight of polyquinoxalines (A) and (B) under isothermal conditions in air: full line at 316°C (600°F); broken line at 371°C (700°F).

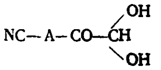
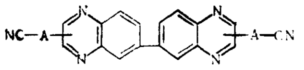
The reduced viscosity of the polymers varied between 0.28 and 0.42.

Nitriles of glyoxals with the general formula



$$NC{-}A{-}CO{-}CH(OH)_2$$

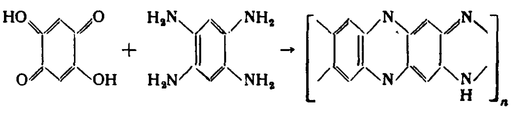
react with 3,3′-diaminobenzidine to give biscyanoarylbiquinoxalinyls



which in turn, on treatment with tetra-amine hydrochlorides in polyphosphoric acid, also formed polybenzimidazoquinoxalines.

Published information indicates that work on the polyquinoxalines is developing in two main directions—(1) the synthesis of linear polyquinoxalines discussed above, and (2) the synthesis of ladderlike polyquinoxalines—the second line of research being further divided into two subgroups as it were—(*a*) substances such as tetra-amines and tetracarbonyl compounds are used for the synthesis, and (*b*) compounds already containing a quinoxaline ring are used.

The interaction of stoichiometric quantities of 2,5-dihydroxy-*p*-benzoquinone with the tetrahydrochloride of benzene-1,2,4,5-tetra-amine in dimethylacetamide, hexamethylphosphoramide, or polyphosphoric acid leads to the formation of a polymer having a ladderlike structure[14]:



Polymers obtained in dimethylacetamide and hexamethylphosphoramide can be redissolved in these solvents after precipitation, and only after being heated at a low pressure do they lose their solubility. The occurrence of solubility in ladderlike polymers may be due to the formation of stable aggregates of polymer and solvent molecules, especially as ~ 20% of dimethylacetamide is removed from the polymer only by prolonged heating in a vacuum.

Table 2. Properties of polyquinoxalines[10].

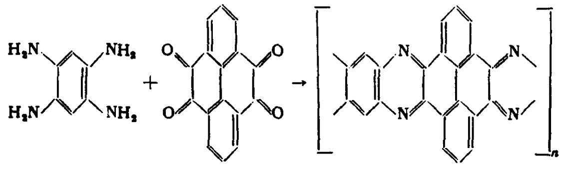
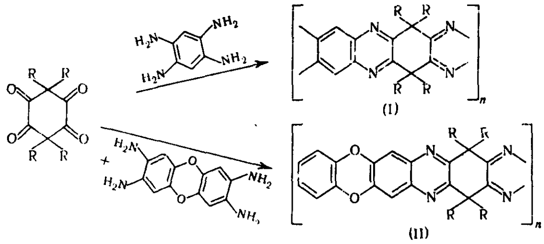
The thermal stability of these polymers in air was the same as that of the usual linear polyquinoxalines under similar conditions, probably owing to the presence in them of linear sections as well as the ladderlike structure. To test this hypothesis and obtain a completely aromatic ladderlike polyquinoxaline, pyrene-4,5,9,10-tetraone was used as the initial tetracarbonyl compound[15]:



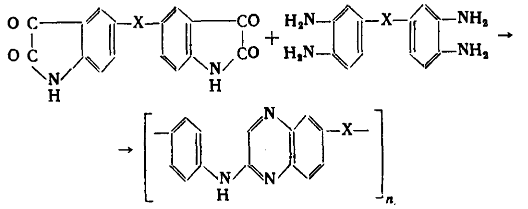
These polymers dissolved in hexamethylphosphoramide and in hexafluoropropan-2-ol, which was rather unexpected for ladderlike polymers. They began to decompose in air at 460°C, and in nitrogen at 683°C, the losses in weight by the onset of decomposition being less than 4% in both cases. Thus it can be accepted that in this case the authors were able to obtain a completely aromatic ladderlike polyquinoxaline, which in an inert atmosphere surpassed in thermal stability the known linear aromatic polyquinoxalines.

As was to be expected, ladderlike polyquinoxalines (η_{red} = 0.2–1.06) obtained from aliphatic tetracarbonyl monomers, e.g. 3,3,6,6-tetramethylcyclohexane-1,2,4,5-tetraone[16], are of no interest. Thermogravimetric analysis indicated that these polymers were considerably less stable than aromatic ladderlike polyquinoxalines: thus polymer (I) decomposes rapidly in air at 390°C, and (II) at 200°C.



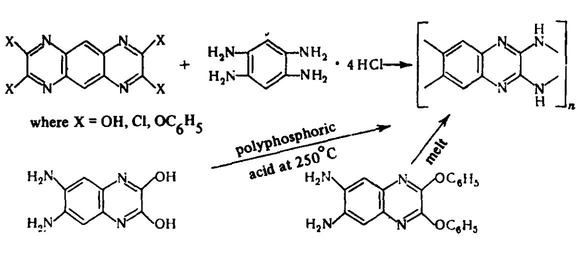
Both polymers begin to decompose slowly when heated in nitrogen at about 400°C.

Bulgarian scientists are investigating[17] the possibility of obtaining partly ladderlike polymers containing 6*H*-indolo[2,3-*b*]quinoxaline (indophenazine) as the main chain unit. Such polymers are prepared from the condensation of bisisatins with tetra-amines by heating in polyphosphoric acid:



They are powders, soluble in hexamethylphosphoramide, dimethylacetamide, dimethyl sulphoxide, and sulphuric acid. No data are given on their molecular weight or their thermal stability.

A ladderlike polymer has been obtained by condensing benzene-1,2,4,5-tetra-amine with a 2,3,6,7-tetrasubstituted 1,4,5,8-tetra-aza-anthracene[18,19] and by the self-condensation of 6,7-diamino-2,3-dihydroxy(or diphenoxy)quinoxaline:



Polycondensation was conducted in solution, in a melt, and in polyphosphoric acid; the reduced viscosity in methanesulphonic acid reached 2.5. Analogous polymers have been synthesised[19] also with 3,3′-diaminobenzidine. These polymers begin to lose weight when heated in air at about 350°C, and in nitrogen at 550°C, which is also explained by an imperfect ladderlike structure. This is evidently supplemented by too high a content of piperazine hydrogen atoms in the polymers, these being the first[10] to undergo thermo-oxidative degradation.

Thermally stable "ladderlike" or partly "ladderlike" polymers have recently been described which contain alternating quinoxaline and thiazine[20] or oxazine[21] units. They are obtained by condensing two diaminoarenedithiols—4,6-diaminobenzene-1,3-dithiol and 3,3′-dimercaptobenzidine—with three tetrachloro-derivatives of quinoxaline—2,3,6,7-tetrachloro-1,4,5,8-tetra-aza-anthracene, 2,2′,3,3′-tetrachloro-6,6′-biquinoxalinyl, and bis-2,3-dichloroquinoxalin-6-yl ether—in various combinations or by condensing diaminoarenediols, e.g. 2,5-diaminoquinol and 3,3′-dihydroxybenzidine, also with tetrasubstituted derivatives of quinoxaline. The solvents used for the reaction of aminoarenethiols are dimethylacetamide, hexamethylphosphoramide, and polyphosphoric acid. The resulting polymers are coloured powders, insoluble in the usual organic solvents and sparingly soluble in sulphuric and methanesulphonic acids. The reduced viscosity of a 0.2% solution of the polymers in methanesulphonic acid at 30°C varied from 0.22 to 1.55. A given polymer had a higher viscosity when dimethylacetamide was used as solvent in its preparation; polymers obtained in polyphosphoric acid had the lowest viscosities. No quinoxalinobenzoxazine was formed in dimethylacetamide; pyridine, naphthalene, and polyphosphoric acid were used as solvents to obtain the corresponding polymers.

Thermogravimetric analysis of polymers containing quinoxaline and thiazine units in the chain showed that in most cases they began to lose weight at about 500°C in nitrogen and at about 400°C in air. Data on thermal stability for the corresponding polymers containing oxazine rings are given only in an inert atmosphere, where they begin to lose weight at about 450°C.

The structure of polymers containing quinoxaline rings—both linear and "ladderlike"—was in all cases proved by a comparative study of the polymers and of model compounds, which included their ultraviolet spectra.

It is seen from the above survey that polyquinoxalines constitute an extremely promising class of thermostable polymers. Unfortunately, very little information is yet available on their practical application. It has been reported[22] that a plastic, which withstands heating to 480°C (900°F), has been developed on the basis of a polyquinoxaline of unstated composition. This material was tested at 590°C in an inert atmosphere, approaching the conditions of outer space. It is light, resembling graphite in structure, inelastic, and electrically non-conducting.

---o0o---

While this paper was being printed, further papers were published on the synthesis of ladderlike[23] and phenylated[24] polyquinoxalines.

Physicochemical and Spectroscopic Characteristics of Associated Compounds and Their Solutions

A.G.Kovaleva

In order to make the method of liquid-liquid extraction usable, it is necessary to have the complete characteristics of the liquid systems to be separated. The study and comparison of a range of physicochemical and spectroscopic properties of such systems makes it possible to discover factors affecting the miscibility of the liquids and to establish the presence of specific interactions between the components.

The study of specific interactions with the aim of determining their nature is complicated and requires in each case specific models which include the individual features of the interacting species. When such investigations are combined with the study of solutions by physicochemical techniques, the nature of the solutions and the mechanisms of the processes occurring in them are gradually elucidated.

The present review deals with solubility and the most important physicochemical methods for the investigation of the hydrogen bond in solutions. Certain problems in infrared spectra associated with the effects of general and specific intermolecular interactions and the effect of hydrogen bonds of the type OH...O=C in systems with ketones and aliphatic acids are discussed. The bibliography includes 146 references.

CONTENTS

1. INTRODUCTION

The technique involving the extraction of substances from their solutions by other solvents depends on a knowledge of the miscibilities of the components. A number of publications deal with miscibility in liquid systems. In some of these the results of experimental measurements of miscibilities are reported, while in others the variation of the binodal curve with temperature is discussed or the partition coefficients are quoted. However, experimental data on the effects of hydrogen bonds and of the molecular structures of the components on the miscibility are presented in only a few papers.

Physicochemical methods of analysis provide information about the nature of the processes occurring in these systems. On the other hand molecular spectroscopy is a direct method whereby it is possible to determine the interacting groups and the structure of the compounds formed. Indirect methods frequently fail to yield unambiguous information concerning this problem.

The elucidation of the mechanism of the interaction between the components of liquid systems requires the investigation and the comparison of a range of physicochemical and spectroscopic characteristics of the solutions.

2. SOLUBILITY AND CERTAIN PHYSICOCHEMICAL PROPERTIES

Solubility constitutes one of the most distinctive effects of intermolecular forces. Mendeleev believes that solutions are the best subjects for the investigation of the general phenomena of chemical interactions. He regarded dissolution as a chemical process leading to the formation of definite and indefinite compounds without a sharp boundary between them and the solutions as "liquid dissociation systems consisting of species of the solvent, the solute, and definite unstable but exothermic compounds formed by them, one or several, depending on the nature of the constituent elements"[1].

In solutions there is a very wide variety of chemical interactions leading to the formation of compounds of different stabilities and therefore solutions may play a significant role in the solution of the general problem of the nature of a chemical compound. Mendeleev wrote that "in the solution there must be association between species of different kinds, interacting chemically, combining, breaking down, or forming systems". This involves the operation of forces of different intensities which lead to the formation of compounds of different stabilities. According to Mendeleev[2], "it is futile to seek simplicities ranging over the entire scale of dissolution [phenomena]. It is futile to seek a function expressing the sum total of the observations". And further[3]: "...the formation of solutions may be regarded from two aspects: physical and chemical and in solutions it is more evident than elsewhere how close to one another are these two aspects of natural science". Mendeleev in fact chose solutions for the investigation of the problem of chemical compounds.

The aim of the modern studies on the problem of solubility is to establish special relations governing the dissolution of individual groups of substances in solvents of the same chemical type. Up to the present time, there has been no quantitative theoretical calculation of the solubility in the majority of cases. Theoretical advances are restricted mainly to the derivation of qualitative and semiquantitative relations. On the other hand, the creation of a quantitative theory of solubility would extend greatly the possibilities for the discovery of laws governing the intermolecular forces in concentrated solutions and for the investigation of the internal structure of solutions.

Attempts to set up a theory of solubility and to establish a physical and chemical standpoint concerning solutions were undertaken by Shreder[4], Semenchenko[7-9], who interpreted the solubility data in Seidel's handbook[10], and Shakhparonov[11-14].

The complex problem of intermolecular interactions has been solved only for rarefied gases, i.e. for the case where the intermolecular distances greatly exceed molecular dimensions. On the other hand, in the study of the liquid state we encounter distances close to equilibrium and the familiar expressions for orientation, polarisation, and dispersion forces cease to be valid; this makes it difficult to give a satisfactory description of intermolecular interactions in the liquid phase.

Furthermore, the liquid state of matter is characterised by a wide variety of types of interactions between the molecules. These include both different types of classical van der Waals interactions (orientation, inductive, and dispersion interactions) and physicochemical interactions of a wide variety of types (complex formation and hydrogen bonding).

Interactions of the first type (general intermolecular interactions) result, after averaging with respect to configuration and volume, in the effect of the solvent as a physical dielectric medium (volume dielectric effect).

Interactions of the second type, a characteristic feature of which is that they are directional, are physicochemical in nature and in fact lead to the formation of a fairly strong bond between molecules, the energy of which is nevertheless significantly lower than the energy of the chemical bond. Evidently this type of interaction is determined to a greater degree than the first by the individual properties and the nature of the solute and solvent molecules (specific intermolecular interactions).

The types of interaction discussed above are not of equal importance. Systems may exist in which specific interactions of one type or another are absent while van der Waals interactions are observed in all cases. The study of the specific interactions with the aim of elucidating their nature is undoubtedly very complex and requires definite models for each case which take into account the individual features of the interacting species.

The physical and chemical properties of water, alcohols, acids, proteins, and many other practically important substances depend significantly on the interaction of two functional groups of one or different molecules.

The formation of hydrogen bonds is a principal factor which determines the nature of the changes in the majority of physical and certain chemical properties in solution or in the pure substance. This is quite reasonable, since the formation of a hydrogen bond can alter not only the mass, dimensions, and the shape of the species and the distribution of individual atoms but also the electronic structures of the functional groups.

Hydrogen bonds were discovered for the first time by Il'inskii[15] in a study of solubility and were then found also by other classical methods in the study of vapour pressure and density, molecular weight, dielectric constant, distribution between different phases, molar volume, refractive index, electrical conductivity, and thermal conductivity.

Depending on molecular structure, intermolecular hydrogen bonds can lead to different types of association, complexes, structures with a multiplicity of bonds, chains, rings, and three-dimensional networks.

The differences in the types of association complexes formed via hydrogen bonding is one of the principal causes of the differences between the physicochemical properties of these substances in the liquid and solid states. As emphasised by Hildebrand[5], not all deviations should be attributed to one factor only. At the same time there is no doubt that in many cases a significant proportion of the deviations in the physicochemical properties of liquids and solutions are in fact determined by hydrogen bonds.

The capacity of various classes of organic compounds for the formation of hydrogen bonds was thoroughly investigated by Ewell et al.[16], who developed a simple classification, according to which different liquids were divided into five groups.

One must emphasise not only the quantitative but also the qualitative differences between three-dimensional association complexes (networks) and cyclic dimers and also between chain association complexes and cyclic dimers. Therefore Ewell is not quite correct in combining into a single class alcohols, acids, and amines. Acids, which form almost exclusively cyclic dimers, should constitute an entirely separate class. The system proposed provides a basis for qualitative predictions when only the dissociation or formation of hydrogen bonds takes place. In those cases where dissolution disturbs an existing equilibrium or sets up a new one, the classification is of less value.

The different amounts of molecules combined into association complexes and their continuous time variation make it difficult to apply the familiar thermodynamic postulates in the calculation of the dynamic equilibrium between such complexes. There is a complicated relation between the strength of a hydrogen bond of a given type, the average "lifetime" of association complexes with different numbers of molecules, and the capacity of molecules of different structures to form several hydrogen bonds simultaneously. All these problems become even more complicated when solvates are formed from different component molecules.

As pointed out by Landsberg[17], Malyshev[18], and Batuev[19-21], the solubility of water, methanol, and formic acid in acetone and dioxan is due to the dissociation of the hydrogen bonds of the pure substance and the formation of new bonds between solvent and solute molecules.

It has been established[22] that, in addition to hydrogen bonds of the type OH...O and N−H...O observed in water, alcohols, phenols, carboxylic acids, and ammonia, hydrogen bonds of the type C−H...O or C−H...N are formed on dissolution of chloroform, bromoform, or hydrogen chloride in solvents containing oxygen and nitrogen. This was confirmed by measurements of the viscosities[23], dielectric constants[24], and freezing points of these solutions[25].

The most important methods for the investigation of hydrogen bonds in solutions, are, apart from spectroscopic procedures, those based on the determination of dielectric properties of the liquids, the measurement of the vapour pressure, cryoscopy, and the study of solubility, partition between phases, viscosity, and density.

The theory of the dielectric constant may be regarded as a supplement to the modern theory of the liquid state. Dielectric properties arise as a statistical average result of many microprocesses. Hypotheses concerning the relation between dielectric properties and structure have been put forward by Girard[26]. He believes that monohydric alcohols can form two types of association complexes—polar and non-polar, the former predominating in primary and secondary alcohols and the latter in tertiary alcohols by virtue of the characteristics of their structure. Accordingly in the first case there is an anomalous increase in polarisation and in the second a decrease. The temperature variation of polarisation confirms that the breakdown of association complexes of the first type should make the decrease of the dielectric constant with temperature more rapid and the breakdown of association complexes of the second type should not only reduce the temperature-induced decrease of polarisation predicted by theory but should in fact result in an increase of the dielectric constant. This has been confirmed experimentally for certain isomers of higher alcohols[27] and also pyridine[28] and carboxylic acids[29,30]. The dielectric properties of acetic, propionic, butyric, and valeric acids are characterised by an increase of the dielectric constant with temperature[30-35]. The dielectric constants of caproic, oenanthic, and caprylic acids are almost invariant in the temperature range investigated[36]. These phenomena are usually explained by the formation of non-polar dimers in the liquid state.

The views on the mechanism of the effect of temperature on the dielectric constant are extremely varied. The most reasonable is the hypothesis that the formation of hydrogen bonds in the dimer may entail a significant change in the dipole moment of the molecule not only as a result of dipoles induced by long- and short-range forces but also in consequence of the super-position under these conditions of the electron clouds and the redistribution of electron density in the dimer. With increase of temperature, the hydrogen bonds in the dimer are deformed and their length changes, which leads to a change in the vibration frequencies of the molecule and the paramagnetic resonance signals[37-39]. Kerr's molecular constants calculated from measurements of the dielectric constants of dilute acetic acid solutions in benzene suggested[40] that a centrosymmetric planar conformation is most likely for carboxylic acid dimers. On the other hand, calculation of the same quantities for the dioxan–acetic acid complex showed that the latter has a non-planar structure and the angle φ between the molecular planes of the acid and dioxan is approximately 80°. Thus in the general case the effect of the hydrogen bond on the dielectric properties must be considered in two ways—as a factor responsible for the correlation between the relative orientations of molecules and as a factor leading to an additional change in the molecular dipole moment.

The cryoscopic method has been widely used for studies on the hydrogen bond, mainly for a qualitative assessment of the possible existence and type of association complexes and also for the determination of the equilibrium constant K_n in the association processes investigated. Cherkashin[41,42] determined cryoscopically the degree of association and the molecular composition of a number of organic substances dissolved in benzene, in particular[43,44] propionic and acetic acids. The average association constants K_n for acetic and propionic acids proved to be 0.5×10^5 and 1.5×10^3 respectively. According to Cherkashin's data, the straight line for the ideal dimer ($K_n = \infty$) and the calculated curve for acetic and propionic acids differ very appreciably from the experimental curves, which the author explains by an intermolecular field interaction and a weak chemical interaction with formation of readily dissociable association complexes. The author confirmed that acetic acid in benzene solution has the molecular composition $(CH_3COOH)_2$. The marked deviation from the ideal dimer curve in the case of formic acid is explained by chain association and a sharp change in the composition of the molecules as a function of the concentration of the acid.

Lutskii's studies[45,46] showed that density and viscosity data for solutions may be used to establish qualitatively the presence and nature of the association of the solute. The author showed that, when alcohol and benzene are used as solvents, the variation of the density and viscosity is the same despite the postulated difference in the nature of association in these different solvents, the variation being the same not only qualitatively but also quantitatively. The author explains this by postulating that in the comparatively concentrated solutions investigated, the species involved in association with the molecules of the solvent (alcohol, benzene) are not single molecules of the test substance but groups. The latter evidently do not break down on dissociation. It is interesting that the relations found for the densities and viscosities of aromatic acids in benzene and alcohol are similar to those observed for the pure substances in the liquid state; the author believes this makes it possible to draw inferences concerning the presence and nature of association of the solute based on the densities of the solutions.

The properties of aqueous acid solutions have been investigated by a number of workers. The viscosities, densities, and critical temperatures of the systems acetic acid–water and butyric acid–water have been studied by Solomko[47]. The viscosity and density isotherms for these systems have maxima, occurring at the same composition in the acetic acid–water system. For the system butyric acid–water, the density maximum is displaced towards higher water contents.

Golik et al.[48] investigated the kinematic viscosities of acetic and butyric acids in water at 30–90°C and established that the viscosity isotherms of aqueous acid solutions have maxima, which are more pronounced the higher the critical point of the acid and the greater the difference between the viscosities of the components. With increase of temperature, the maximum is somewhat reduced. The complex concentration variation of the viscosity is explained by the formation of structural entities due to the interaction between the carboxy-groups of the acids and the hydroxy-groups of water. Glagoleva studied the equilibrium in the system formic acid–water[49] and the viscosities and specific gravities[50,51] of the systems formic acid–water and acetic acid–water. These data established the formation of the compounds $HCOOH.H_2O$, $HCOOH.2H_2O$, $CH_3COOH.H_2O$, and $CH_3COOH.2H_2O$. In a study of the heats and integral heats of dilution of formic acid solutions, Glagoleva[52] established that these quantities are a maximum when the solution contains 1–2 moles of water per mole of acid. She assumes that, for aqueous solutions containing two moles of water for each two moles of acetic acid, a hydrate with a chain structure and a dimer with the composition $2CH_3COOH.2H_2O$ are formed, while in the presence of two moles of water per mole of acid the species produced is a hydrate with the composition $CH_3COOH.2H_2O$. These hypotheses were subsequently confirmed by Glagoleva herself[53] and other investigators[54-57] using Raman spectroscopy.

Spectroscopic investigations are particularly important in the study of the structure of liquids and solutions. The study of the molecular spectra of solutions reveals more clearly the role of individual groups of atoms in the molecule in the formation of intermolecular bonds.

3. INFRARED SPECTROSCOPIC EFFECTS OF UNIVERSAL AND SPECIFIC INTERMOLECULAR INTERACTIONS

Real systems can be adequately described only by taking into account the collective and individual effects of the molecules in the surrounding medium on the spectrum of the molecule in solution. However, at the present time there is no rigorous and logical theory of the effect of intermolecular interactions on the infrared spectra of solute molecules. Therefore the subdivision of interactions into general (collective) and specific (individual), which entails the introduction of model hypotheses in the study of specific interactions taking into account the individual features of the interacting species, is justified although it is in fact extremely arbitrary, and in real systems there is a continuous gradation from pair interactions to the overall effect of the surrounding species on the solute molecule[58].

The conditions under which the test molecule in solution interacts with a light wave differ from those for an isolated molecule. This is the reason why it is necessary to introduce generalised parameters such as the dielectric constant and the refractive index, which take into account the effect on the test molecule of the sum total of the surrounding species treated as a physical medium. The concept of a reactive field, introduced by Onsager[60], acting on the molecule from the direction of the adjacent species surrounding it, which it has polarised, proved to be extremely fruitful in this respect. Kirkwood[61] and Bauer and Magat[62] showed on the basis of the Onsager model that, when the infrared vibration is regarded as that of a simple oscillating dipole, then its frequencies in the vapour phase (ν_V) and in solution (ν_S) are related by the expression $(\nu_V - \nu_S)/\nu_V = C(\epsilon - 1)/(2\epsilon + 1)$. In this relation ϵ is the dielectric constant of the solvent and C is a constant. It holds best for solvents of low polarity in which the interaction between the solute and solvent molecules is slight. These theories are difficult to test quantitatively because of the impossibility of determining the coefficient C, which depends on assumptions about the dimensions and form of the overall orientation of solvent molecules around the solute molecules and cannot be found experimentally.

Plots of $(\epsilon - 1)/(2\epsilon + 1)$ against $(\nu_V - \nu_S)/\nu_V$ are straight lines for non-polar solvents, while for solvents with proton-donor or proton-acceptor properties the points deviate appreciably from linearity. Probably in those cases the effect of polarisation interactions which occur in non-polar solvents is supplemented by an effect due to the orientation of the solvent molecules or an effect caused by the formation of a molecular complex[63]. A dielectric theory of the effect of the solvent on the infrared spectra of molecules has been developed by Pullin[64,65]. He suggested that the frequency shift depends in the general case both on the dielectric constant ϵ and the refractive index n_0 of the solvent as well as on the molar volumes V of the solvent and the solute which is included implicitly in the expression for the radius of the Onsager cavity. Pullin proposed the following function $f(x, V) = (1/V)(x - 1)/(2x + 1)$, where $x = \epsilon$ or n_0^2 and V is a characteristic of the dimensions of the Onsager cavity. Buckingham[66,67] explained the effect of the solvent on the infrared spectra of molecules from the standpoint of both general and specific interactions. Bellamy and coworkers[68,69] showed that the problem of the effect of the solvent on the infrared frequencies of solid molecules cannot be solved taking into account the general effect only. Not only dielectric effects but also specific interactions, expressed in the formation of association complexes of the solute and solvent molecules, play a dominant role, while the association complexes may have various natures. Thus, when polar media (alcohol, water) are used, association complexes are formed as a result of hydrogen bonding and, according to Bellamy's postulates[70], the higher the polarity of the bond the greater the relative frequency shift.

Thus the possibility of treating the effect of the solvent on the intensities and positions of the infrared bands is very limited. In the general case specific interactions are always observed against the background of the general effect of the medium.

The spectroscopic method for the investigation of molecular association due to hydrogen bonding is fundamental; it is the only procedure which makes it possible to elucidate the distribution of atoms in the vicinity of donor and acceptor groups and the mechanism of the formation of the hydrogen bond.

The forces responsible for the formation of the hydrogen bond differ in magnitude from those which give rise to the ordinary chemical bond. In the general case the energy of the hydrogen bond consists of the electrostatic energy E_{el}, donor–acceptor interaction (with participation of the s orbital of the hydrogen atom) and π-electron interaction arising by virtue of the participation of the π orbital E_π of the hydrogen atom[71]. The role of the individual components in different types of hydrogen bonds may not be the same.

The spectra of compounds forming hydrogen bonds have been investigated in particular detail by Landsberg and coworkers[72-74], Chulanovskii and coworkers[75-80], Batuev[19-21], Stepanov[81-83], Vol'kenshtein[84], and Sokolov[85-87]. They developed a theory of hydrogen bonds on the basis of experimental studies of the spectroscopic effects of hydrogen bonds in many of the most important substances (alcohols, organic acids, etc.). The causes of the formation of the hydrogen bond were examined systematically by Sokolov[88,89]. The conditions necessary for its formation reduce to the asymmetry of the interacting groups. In order to elucidate finally the distribution of electron density in the hydrogen bridge, experimental data must be resorted to. Infrared spectra do not provide information about changes in electron density near the hydrogen atom. On the other hand, proton magnetic resonance spectra, where the displacement of the signal is very sensitive to the formation of a hydrogen bond, are more suitable for this purpose. According to Aleksandrov and Sokolov[90], the change in the screening of the proton on formation of the complex RA–H...BR′ probably depends (1) on the change in the polarity of the A–H bond (a shift of the centre of gravity of the electron cloud of this bond towards the atom A), (2) on the extension of the A–H bond, (3) on the formation of the donor–acceptor bond H...B, which leads to a shift of the centre of gravity of the cloud of the unshared pair of electrons of B towards the atom H, (4) on the effect of the electric field of the dipole of the BR′ molecule, and (5) on the effect of the unshared pair of p electrons of the atom B (or the B–R′ π bond). The increase in the proton magnetic screening constant σ due to the increase of polarity on formation of the donor–acceptor H...B bond probably plays a dominant role. Thus Sokolov[85-87,91] concentrates attention on the change in the infrared absorption spectrum of the ν_S stretching vibrations and on proton transfer processes.

When a substance dissolves, various absorption bands may show perturbation of different magnitudes and types. Two types of such perturbation have been established[76,77]—bulk-phase and local. In the bulk-phase interaction the state of the molecule is determined by a large number of surrounding molecules, and in a gradual change of the composition of the solvent the characteristics of the absorption band also gradually alter.

Local interactions are extremely varied and are of different types even in the case of a thoroughly investigated type of intermolecular interaction such as hydrogen bonding. The state of the active group of the absorbing molecule is determined by several adjacent molecules and the changes in the spectroscopic characteristics of the bands are discrete. The effect of the local intermolecular field on the infrared absorption frequency associated with the C=O stretching vibrations in ketones has been investigated by Gadzhiev[92] over a wide range of temperatures (from +80° to −180°C). The observed shifts of the C=O stretching vibration bands of ketones on lowering the temperature are accounted for by an increase in intermolecular interaction due to a decrease of the distance between the molecules and an increase in the residence time of the molecule in the state of equilibrium. The temperature variation of the shift in the infrared absorption band of the C=O group of ketones is linear.

On transition from one type of local bond to another, i.e. on breakdown of one and formation of another association complex, observed on dissolution, the following changes may occur in the vibration spectrum: (1) the stretching-vibration bands are displaced towards lower frequencies (compared with the absorption band for an isolated molecule) and the position of the maximum of the band depends on temperature—the lower the temperature the greater is the displacement of the maximum towards lower frequencies; however, exceptions are also known[77,93], when the formation of local bonds does not cause a bathochromic shift of the stretching vibration bands; (2) there is an appreciable change in absorption intensity, which is sometimes very large for the fundamental bands of the stretching vibrations involved in the formation of the molecular bond; here the discrete structure is more complex than in cases where a shift does occur; (3) the absorption band due to these bonds becomes appreciably broader.

When association complexes break down in a pure liquid or in a solution, converse changes occur in the characteristics of the stretching vibration band. The most typical difference between the molecular bonds of the newly formed association complexes on the one hand and the chemical bond in molecules on the other consists in the ready reversibility of the association process under normal conditions due to the thermal motion of molecules, a wide variety of possible interactions between molecules, and an insufficiently defined nature of the association complexes produced.

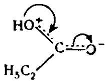
All these factors complicate our understanding of the molecular state in solutions. Furthermore, in contrast to the solid state, in liquids there is a possibility of the coexistence, with different probabilities, of various types of intermolecular hydrogen bonds, including those which do not correspond to the absolute potential energy minimum[78].

Structural changes in solutions can be investigated in greater detail by spectroscopic procedures than by physicochemical methods. In the structural analysis of the solutions the elucidation of the structural elements of molecules responsible for the intermolecular bond and its type and also the nature and strength of intermolecular association are of interest.

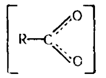
4. SPECTROSCOPIC EFFECTS OF HYDROGEN BONDS OF THE TYPE OH...O=C

Spectroscopic effects of hydrogen bonds of the type OH...O=C have been usually investigated on the basis of data for the O–H stretching vibrations, which made it possible to assess the state of the hydrogen atom alone[94]. A more detailed study of this bond indicates the necessity of elucidating the role of at least three atoms (A, H, and B) in the schematic structure of the hydrogen bond RA–H...BR′. For this, it is necessary to investigate not only the A–H spectrum but also the spectra of the R–A and B–R′ groups. On the other hand, the formation of the bond OH...O=C entails a change in the stretching vibration frequencies of both O–H and C=O groups. Although the shift is in this case smaller, the overlapping by other bands (C–H, O–H) is also less pronounced in the study of equilibria involving associated substances such as, for example, water and alcohols.

According to infrared spectroscopic data, the carboxy-groups of aliphatic acids have an asymmetric structure: the proton is located within the electron cloud of one of the oxygen atoms[95]. The properties of acids and quantum-chemical considerations[96] make it possible to attribute the following formula to propionic acid for example:



The frequency of the carbonyl group is very sensitive to interaction with other bonds[97]. Depending on the nature of the substituent in the organic group, the position of carbonyl bands can be somewhat displaced[98-100]. When an aliphatic group is replaced by an aromatic group, the band is displaced towards longer wavelengths (1690 cm^{-1} in the spectrum of benzoic acid). The presence of electrophilic substituents in the organic group gives rise to a hypsochromic shift: 1735 cm^{-1} in the spectrum of monochloroacetic acid[98] and 1730 cm^{-1} in that of α-chloropropionic acid[101]. This phenomenon can be explained directly by the mutual effects of the bonds: the partial shift of the electron to the C=O bond or, conversely, a shift of the C=O electron to an electron-acceptor group. When an electron is transferred to the C=O bond, the force constant of the latter k_{C-O} and hence the frequency are reduced, while in the opposite case they are increased. On the other hand, spectra of the ions derived from the acids do not contain such frequencies but they do include characteristic bands in the region 1510–1650 cm^{-1} (antisymmetric vibration of the COO$^-$ group) and at about 1400 cm^{-1}, corresponding to the symmetrical vibrations of this group[96,102,103]. The spectrum changes in this way because both oxygen atoms in the ion, linked to a carbon atom, become equivalent:



The carboxylate ion has a symmetrical structure in aqueous solutions of acid, where it is formed as a result of acid dissociation, and also in salts where the metal atom is equally associated with both oxygen atoms[96]. It must be noted that the stretching-vibration frequency of the carbonyl group at about 1700 cm^{-1} is due to C=O groups hydrogen bonded into dimers and is most intense in the infrared. However, this band may not always be observed or can be observed very weakly in the Raman spectrum. If the dimer formed by the association of acids has a centre of symmetry, only antisymmetric vibrations will be active in the infrared spectrum, while in the Raman spectrum symmetrical vibrations will be active[104], where the corresponding carbonyl frequency is 1660 cm^{-1}. The appearance of a frequency in the range 1660–1670 cm^{-1} in the infrared spectrum is associated with the breakdown of ring symmetry in the liquid phase as a result of the interaction between the dimers.

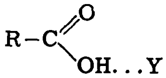
In a number of studies the effect of hydrogen bonding and association of liquid acids on the frequency and intensity of the C=O characteristic vibrations was considered[55-57,104-106]. Gillette and Daniels[106] observed a change in the structure of the C=O band over a wide temperature range in the vapour phase. The authors interpreted the structural changes of the bands as due to the simultaneous presence of monomeric and dimeric acetic acid species.

Batuev[55-57] compared the Raman spectra of liquid formic, acetic, isobutyric, and isovaleric acids at room temperature and concluded that the carbonyl group is extremely sensitive to the formation of a hydrogen bond and under its influence the C=O frequency undergoes a considerable shift, spreading into broad diffuse bands. Depending on the number and positions of the C=O absorption bands, Batuev divided acids into three groups: formic acid with frequencies at 1670 and 1724 cm^{-1}, acetic acid with frequencies of 1665, 1713, and 1740 cm^{-1}, and the remaining acids characterised by a single frequency in the form of a narrow line in the range 1660–1670 cm^{-1}. He believes that association in formic and acetic acids is largely of a polymeric type, in contrast to heavier acids, which may be regarded as dimeric. However, Smolianskii[107] observed in the infrared spectrum of liquid isobutyric acid a second component (on the high-frequency side) of absorption band due to the hydrogen-bonded C=O group. The doublet structure of the band is explained by the presence of open-chain dimers in the acid, which is confirmed by an increase in the intensity of the high-frequency component at 1720 cm^{-1} as temperature is increased.

Feneant-Emard[108] confirmed Batuev's observation in the study of the Raman spectra of acids and at the same time discovered a higher frequency, at 1760 instead of 1740 cm^{-1}. He noted that both these bands can probably be attributed to an open-chain dimer, since the adoption of the hypothesis of polymeric chain association would probably entail a very low concentration of non-hydrogen-bonded groups at the end of the chain, which could not be detected in the Raman spectrum.

Constant[109] showed by ultrasonic spectroscopy that not only acetic acid polymers but also polymers of aliphatic acids with longer chains exist. He believes that the percentage polymerisation increases with the length of the carbon chain of the acid.

Lascombe et al.[110] found from the position of the C=O band in the infrared spectra of liquid propionic, butyric, and caproic acids that the carbonyl group gives rise to a band at a lower frequency than for the free C=O group in inert solvents, in addition to the band associated with the dimer. The relative intensity of the second component in the spectra of these acids is reduced with increasing carbon chain length. These workers believe that the appearance in the infrared spectrum of the band at 1748–1755 cm^{-1}, like that of the band at 1740–1760 cm^{-1} in the Raman spectrum, is associated with the formation of polymers in which only the OH component of the carboxy-group is involved in hydrogen bonding, in agreement with Constant's data[109]. On the other hand, the intensity of the high-frequency component of the dimeric band is directly related, as noted by Feneant-Emard, to the molecular weight of the polymer. However, Lascombe et al. believe that the presence of this band cannot be accounted for solely by the existence of open-chain dimers because in this region there is also a band which is observed in the spectra of solutions when the solvent is a proton acceptor and the structure



$R-C(=O)-OH\ldots Y$

is attributed to the complex formed.

Shubin[111,112] investigated the hydroxyl band in the infrared spectra of formic, acetic, propionic, butyric, isobutyric, and isovaleric acids in the gas and liquid phases. He showed that the position and shape of the absorption bands, which characterise the bond involving the hydroxy-group and also the extinction coefficient, scarcely change on transition from the gas to the liquid phase. Formic acid was an exception. For formic acid, the band in the spectrum of the liquid phase is somewhat broader than for the gas phase, which can be accounted for by the partial chain association of the acid in the liquid phase. This suggested that the type of association of the acid in the liquid phase is the same as in the gas phase, for which dimeric association has been established by Pauling and Brockway using electron diffraction[113]. The temperature variation of the absorption maximum in the band due to the dimer makes it possible to determine the heats of dissociation of formic, acetic, propionic, butyric, isobutyric, and isovaleric acids in the gas phase. The energy of the OH...O=C bond proved to be the same for all the acids investigated (except formic) and approximately equal to 8.3 kcal $mole^{-1}$.

The relations governing the effect of adjacent atoms on the intensity and frequency of the stretching vibrations of the carbonyl group in carboxylic acids are similar to the relations characteristic of ketones. Since there have been only a few infrared spectroscopic studies of the carbonyl group in monocarboxylic acids using solvents of different types, we shall employ studies on the carbonyl group of ketones in the comparison.

Bottreau et al.[114] studied the effect of non-polar solvents (hexane) on the stretching vibration frequency of the carbonyl group of ketones. A detailed study led to the conclusion that the observed spectroscopic changes are a result of two simultaneous effects.

1. *Effect of the breakdown of ketone association complexes.* When two associated adjacent molecules

, each of which is in the electric field of the other are considered, the direction of the field displaces the electrons of the double bonds towards the oxygen atom. Dissolution in hexane leads to the separation of the dipoles and enables the displaced electrons to return to the C=O bond; this is accompanied by a progressive increase in the carbonyl vibration frequency.

2. *The Kirkwood effect.* Dissolution of ketones in the test solvent (carbon tetrachloride, hexane, cyclohexane) decreases the dielectric constant of the medium (reflected in an increase of the vibration frequency of the carbonyl group). Wishing to elucidate the contributions of the two effects, the authors eliminated the effect due to bond dissociation by hydrogen bonding the ketone molecule to phenol molecules before dilution with the solvent. This made it possible to observe the influence of the Kirkwood effect on the carbonyl frequency alone. It is easily seen that, whereas inert solvents increase the carbonyl frequency in ketones, in proton-donor solvents such as chloroform, bromoform, and butanol the C=O frequency falls as a result of the formation of a complex of the type C=O...H–C or C=O...H–O. Thus the C=O stretching vibration frequency is 1715 cm^{-1} in pure acetone, 1722 in hexane solution, 1721 in cyclohexane, 1717.5 in carbon tetrachloride, 1709.5 in chloroform, 1707 in bromoform, and 1709 in butanol. The carbonyl group in carboxylic acid monomers behave similarly.

The change in the antisymmetric C=O frequency of the acid dimer and of the C=O frequency of the monomer is different in solvents of different types. The C=O stretching vibrational band due to the acid dimers depends on the polarisability of the solvent. In solutions with a high concentration of the acid, polarisation diminishes due to the dimerisation of the acid molecules. Conversely polarisation increases in inert solvents (heptane, carbon tetrachloride) on dilution. This is caused by the presence in certain such solvents of a mixture of highly polar single acid molecules and weakly polar or non-polar dimers. These changes in the polarisation of the solution have an effect on the C=O vibration frequencies of the acid dimers, altering the ring symmetry and the frequency of the dimer carbonyl group. Solutions of acids in solvents capable of forming hydrogen-bonded complexes have been investigated to a much lesser extent and the interpretation of the results is much more complicated.

In Denisov's systematic studies[115,116] problems of the effect of the hydrogen bond of the type O–H...O=C on the stretching-vibration band of the carbonyl group in ketones were considered. Denisov showed that in liquid systems containing a strong acid (acetic, mono-, di-, and trichloroacetic, trifluoroacetic) and a ketone the formation of a mixed complex predominates over the dimerisation of acids. The absorption spectra of cyclohexanone (0.39 M) and trichloroacetic acid (0.016 M) in carbon tetrachloride contain bands due to cyclohexanone (1717 cm^{-1}), acid dimers (1751 cm^{-1}), and acid monomers (1787 cm^{-1}). On the other hand, these bands are absent from the spectrum of a mixture of cyclohexanone and trichloroacetic acid and are replaced by bands corresponding to interaction products.

Denisov assigned the 1764 cm^{-1} band to the carbonyl vibrations of the acid, the hydroxy-group of which is involved in hydrogen bonding with the ketone. The 1691 cm^{-1} band is interpreted as due to the C=O frequency of the ketone participating in hydrogen bonding with acid molecules. By investigating the dependence of the parameters of the C=O band on the properties of the components of the complex, the author showed that the spectroscopic characteristics of the C=O band of the ketone involved in hydrogen bonds of the type C=O...HO depend not only on the properties of the C=O group but also on those of the OH group. The same may be said of systems containing a strong acid and an ether[117], nitrile, ester, or another molecule with sufficiently strong electron-donating capacity.

The formation of an acid–ketone complex was observed also by Reeves[118] in a study of hydrogen bonding by proton resonance. He showed that, in a solvent with pronounced electron-donor properties such as acetone and acetonitrile, dimeric acid molecules are involved in the equilibrium between the hydrogen-bonded complex and the monomer of the type

$$[RCOOH]_2 + 2D \rightleftarrows 2RCOOH \cdot D,$$

where D is a powerful electron donor.

We may note that in the spectra of solutions of acids in solvents which are powerful proton acceptors (ethers, esters, ketones, acetonitrile, dioxan) one band is always observed[98] in the region of the stretching vibrations of the carbonyl group. Only at a concentration equal to or exceeding 10^{-1} M does a band characteristic of the dimer appear at low frequencies. One may predict that, by analogy with the behaviour of ketones in proton-donor solvents, complexes of the type C=O...H–O will form with acids, as a result of which the intensity of the acid monomer band increases relative to the dimer band and is somewhat displaced towards lower frequencies. It becomes clear that even more complex interactions will be observed in solutions where the solvent behaves both as a proton donor and acceptor.

Water molecules possess both proton-donor and proton-acceptor properties. Both these properties in water as a solvent are weak, because the majority of the hydrogen and oxygen atoms are involved in the formation of the intermolecular hydrogen bonds of water itself. The solubility of carboxylic acids in water has been investigated because of their importance in biology and chemistry. However, few acids other than formic and acetic have been investigated (spectroscopically) and only over a narrow range of concentrations. Table 1 presents spectroscopic data for two-component monocarboxylic acid–hydroxylated solvent systems. The Table shows that a band due to the C=O group in acids is sensitive to association and the formation of a hydrogen bond. Furthermore, in the study of the carbonyl stretching vibration band it appears possible to obtain data concerning the immediate environment of the COOH group, which is particularly important in the investigation of the properties of solutions in the acid extraction process. We shall consider some of these studies.

Table 1. Raman frequencies of two-component systems monocarboxylic acid–hydroxylated solvent.

Solvent	Acid	Concn. of acid	Frequency, cm^{-1}	References
H_2O	HCOOH	10–15%	1660 w.., 1710	19–21, 55–57
H_2O	HCOOH	40%	1708	119
H_2O	HCOOH	1 : 2	1712	120
H_2O	CH_3COOH	10%	1710	19–21 55–57
H_2O	CH_3COOH	dilute aqueous soln.	1710	120[a]
H_2O	CH_3COOH	conc. soln. with a small amount of water	1730, 1660, 1766 w..	120
H_2O	CH_3COOH	10 mole %	1710	121
CH_3OH	CH_3COOH	10 mole %	1707	121
C_2H_5OH	CH_3COOH	10 mole %	1707	121
C_4H_9OH	CH_3COOH	20–40 mole %	1706, 1736	121
C_4H_9OH	CH_3COOH	60–80–90 mole %	1660, 1703, 1745	121
H_2O	CH_3COOH	83.5 wt.%	1697, 1665, 1745	122
H_2O	CH_3COOH	78.8 wt.%	1690, 1667, 1745	122
H_2O	CH_3COOH	76.9 wt.%	1700, 1687	122
H_2O	CH_3COOH	65.1 wt.%	1700, 1680, 1760	122
H_2O	CH_3COOH	21.9 wt.%	1700, 1695	122
H_2O	CH_3COOH	1.3 wt.%	1695, 1705	122
H_2O	CH_3COOH	87 %	1715, 1670 w.	91[b]
H_2O	CH_3COOH	equimolar soln.	1715, 1670 w.	91
H_2O	CH_3COOH	63 %	1715, 1760 w.	91
C_4H_9OH	CH_3COOH	10^{-2} M	1710, 1754[c]	110
C_4H_9OH	CH_3COOH	1.0 M	1710, 1754[c]	110
H_2O	C_2H_5COOH	equimolar soln.	1720, 1708, w. , 1750 w.[c]	123
C_4H_9OH	C_2H_5COOH	10^{-2} M	1715, 1740[c]	110
C_4H_9OH	C_2H_5COOH	1 M	1715, 1740[c]	110
C_4H_9OH	C_3H_7COOH	10^{-2} M	1709, 1737[c]	110
C_4H_9OH	C_6H_5COOH	10^{-2} M	1708, 1737[c]	110

[a] Frequencies of 1660, 1712, and 1745 cm^{-1} were observed in the spectrum of pure acetic acid.

[b] Frequencies of 1670, 1715, and 1760 cm^{-1} were observed in the spectrum of pure acetic acid.

[c] Frequencies in the infrared spectrum are quoted.

Lascombe et al.[110] observed that acetic, propionic, valeric, hexanoic, and benzoic acids in butanol exhibit two frequencies (in particular the 1710 and 1754 cm^{-1} frequencies of acetic acid), which can be attributed to two types of complexes, the formation of which entails hydrogen bonding involving the carbonyl group (1710 cm^{-1}) and the hydroxy-group of the acids (1754 cm^{-1}), a change in the concentration from 10^{-2} M to 1 M being without effect on the observed bands. Izmailov and Kutsyna[121] observed the following changes in the Raman spectra of the same solutions (acetic acid in butanol) as the acid concentration was varied: at a concentration of 10 mole % they observed a single band at 1706 cm^{-1} which they assumed to correspond to addition products with the composition AB_2; at 20–40 mole % two frequencies were found at 1706 and 1736 cm^{-1}, the first being more intense than the second; in the spectrum of the solution at a concentration of 60 mole % three bands were observed at 1660, 1703, and 1745 cm^{-1}. The same frequencies also persist in the solution at a concentration of 80–90 mole % of the acid, the intensity of the line due to the dimer increasing continuously, which is evidence for the presence of dimeric acid molecules together with molecules linked to the solvent species. The authors assumed that in solutions of acetic, monochloroacetic, and trichloroacetic acids at low concentrations in water, methanol, or butanol the same addition products are formed since the same frequencies are observed in all these solutions: 1706 and 1710 cm^{-1} for acetic acid in alcohols and water and correspondingly at 1736 and 1728 cm^{-1} for monochloroacetic acid and 1760 and 1748 cm^{-1} for trichloroacetic acid.

Glagoleva and Ferkhlin[122] made a very thorough investigation over limited ranges of aqueous solutions of acetic acid at low concentrations. Their data demonstrate that in the presence of 33 wt. % of acid the carbonyl band is very pronounced and has a maximum at 1700 cm^{-1}. Bands are also observed at 1710 and 1680 cm^{-1}. At high dilutions, the band remains in the same position up to a concentration of 8.3 wt. % and then the maximum at 1700 cm^{-1} disappears, but the bands at 1690 and 1710 cm^{-1} persist down to an acid concentration of 1.3 wt. %. The appearance of a band at 1690 cm^{-1} is explained by the formation of hydrates. This may be evidence that the hydrogen bond between water molecules and the carbonyl group of the acid persist for a fairly long time despite the fact that at a concentration of 6.0 wt. % dissociation of the acid begins. These data suggest that solvates of several types exist in dilute solutions.

It is no less interesting to compare the data of Glagoleva and Ferkhlin[122] with those of Feneant[124] for high concentrations of the acid in the same system (both studies were based on Raman spectroscopy). According to Glagoleva and Ferkhlin[122], the band with the highest intensity is at 1700 cm^{-1} in the concentration range 87.0–63.0 wt. %, while at a concentration of 78.8 wt. % a new band appears at 1690 cm^{-1}; Glagoleva and also Izmailov and Kutsyna demonstrated the formation of monohydrates in the same concentration range. According to these authors, further dilution did not change the form of the band, but at concentrations of 62.8 and 65.0 wt. % of the acid the 1700 cm^{-1} band becomes sharper and narrower. The authors conclude that dihydrates are formed in this concentration range. However, according to Feneant[124], in the spectra of solutions at a concentration of 65 wt. % the band at 1715 cm^{-1} has the highest intensity and can be assigned to the dimeric monohydrate; on further dilution (63 wt. %) the same frequency remains the most intense and is interpreted by the authors as due to the dihydrate. According to the observations of the authors of both investigations, the band associated with the dimer disappears at these concentrations. The changes occurring in the solution are attributed to the formation of association complexes of several types.

The change in the contour of the stretching vibration band due to the C=O group in carboxylic acids on formation of an intermolecular hydrogen bond[104,107] is of considerable interest. Since the relations concerning the effect of adjacent atoms on the intensity and frequency of the C=O stretching vibrations in carboxylic acids are similar to those characteristic of ketones, the observed frequencies were assigned[123] by analogy with the C=O frequencies of ketones, in accordance with a number of investigations[114-116,125] and also in accordance with data on the stretching vibrations of the carbonyl group of acids in solvents of different types[19-21,55-57,100,106-117,110,121,122,124,126]. The spectrum of an equimolar mixture of propionic acid and water[123] (Table 1) has a characteristic band at 1723 cm^{-1} and a shoulder at about 1708 cm^{-1} on its long-wavelength slope.

The presence of a single intense band suggests that a 1 : 1 addition product with the same composition is mainly formed in the solution. Very small amounts of acid dimers and solvates of the composition A_2B and AB persist in the solution, as shown by the weak band at 1750 cm^{-1}. The carbonyl group of the acid remains free in such complexes (A is the acid and B is water).

The study of the infrared spectra of homogeneous saturated water–monocarboxylic acid (propionic, valeric, oenanthic)–heptane systems[123] over a wide range of concentrations and analysis of the results led to the following postulates and conclusions. In solutions with a high molar content of the inert solvent (heptane) (5.70–4.20 M) acid concentrations in the range 0.7–0.9 M, and water concentrations in the range 0.04–0.10 M, similar C=O frequencies (1720–1725 cm^{-1}) are observed for all the systems. Probably open-chain acid dimers, undergoing O–H...O–H and O–H...O=C interactions with water molecules, are present in such solutions and the nature of the hydrogen bond in the addition products and the structure of the association complexes differ little.

In the spectra of solutions with high contents of acids (1.00–5.00 M) and water (0.5–3.0 M) absorption bands due to the C=O group appear at 1740–1745 cm^{-1}, which indicates the presence of addition products A_2B and AB containing free carbonyl groups.

In solutions with high acid (8.0–5.0 M) and water (0.6–7.0 M) concentrations differences are observed in the structure of the hydrates of the systems investigated[123]. Hydrates with the composition AB_2 (band at about 1690 cm^{-1}) are formed mainly in solutions with propionic acid and are present in insignificant concentrations in solutions of valeric and oenanthic acids. In highly concentrated solutions of the latter bands due to acid dimers and possibly free water molecules (1715 cm^{-1}) appear. Bands of this kind are absent from the spectra of propionic acid solutions. The spectra of the postulated complexes may be formulated more precisely by studying the spectra of solutions of the deuterated derivatives[126].

The changes in the intensity of the carbonyl band were investigated by Venograd and Spurr[127] and by Huggins and Pimentel[128]. The ratios of the integral absorption coefficients of the carbonyl bands of the acid dimers and monomers measured by Venograd and Spurr are 1.15 for acetic acid, 1.36 for propionic acid, 1.22 for benzoic acid, and 1.32 for toluic acid. When complex aggregates of associated molecules are formed, the interpretation of the intensities and the widths of the band becomes much more complicated. To account for the spectra of such complexes, it is necessary to take into consideration angular deformation vibrations. Huggins and Pimentel arrived at a similar conclusion[128] and separated hydrogen-bonded systems into two classes: in the first they included systems with hydrogen-bonded complexes and in the second systems with hydrogen-bonded polymers.

A simple relation was observed between the frequency shift and the intensity of absorption by hydrogen-bonded complexes. There is a linear hydrogen bond in the complexes. When bonds of this kind are formed, an increase in the intensity of the stretching vibration bands accompanies their frequency shift. The same workers showed that the intensity does not alter on formation of a non-linear hydrogen bond. The decrease of the integral intensity of the C=O band with increasing concentrations of acid and water in the systems can probably be accounted for by the formation of a non-linear hydrogen bond in acid–water association complexes[123]. Such data lead to the conclusion that, when the system A–H...B deviates from linearity, the intensity of the bands associated with the stretching vibrations involved in the formation of hydrogen bonds does not increase.

Sokolov[86] showed that the spectroscopic effect of the hydrogen bond may be related to the proton transfer process and consequently to a change in acidity. The reason for the decrease of acidity in the homologous series of acids is a positive inductive effect[129]. A characteristic feature of the inductive effect is its rapid decay along the chain of single bonds, which is evident from the acid dissociation constants: 17.6×10^{-5} for formic acid, 1.76×10^{-5} for acetic acid, 1.34×10^{-5} for propionic acid, 1.50×10^{-5} for valeric acid, and 1.38×10^{-5} for heptanoic acid. On the other hand, the first ionisation potential of aliphatic acids[130] increases in the sequence $H < CH_3 < C_2H_5 < C_3H_7$: 11.33 eV for formic acid, 10.66 eV for acetic acid, 10.47 eV for propionic acid, and 10.22 eV for butyric acid.

The energy of the hydrogen bond formed by monocarboxylic acids depends on both factors and its constancy in the homologous series of acids ($\Delta H = 7.5-8.0$ kcal mole^{-1}) implies that the increase of the electron-donor capacity of the C=O group is compensated by a decrease of the proton-donor capacity of the O–H group.

The systematic study of the spectroscopic effects of hydrogen bonds began with the work of Gordy and Stanford[131,132] and also Searles[133] and Tamres[134]. They established that the low-frequency shift of the A–H stretching vibration band on formation of a hydrogen bond increases linearly with the basicity of the solvent.

In their study of hydroxylated substances and proton-acceptor substances (acetone, acetophenone, cyclohexanone), Singul and Ignat'eva[135] drew attention to the frequency change observed in the vibration spectra of proton acceptors. They established an inverse correlation between the shift of the C=O band and the pK_a of the hydroxylated substances. The hydroxylated solvents used were the initial members of the homologous series of saturated monohydric alcohols ranging from methanol to butanol and water and phenol, the greatest C=O frequency shift being observed when the ketone interacts with phenol. Since a linear relation was obtained for each ketone, this also characterises the different basicities of the ketones investigated.

A direct correlation was established[135] between the change in the frequency of the C=O group of acetic acid and its substituted derivatives and also substituted benzoic acids on the one hand and the acid strength in alcohol solutions on the other. A similar relation was found[123] between the frequency of the carbonyl group in carboxylic acids, participating in the formation of an acid–water complex, and their acid strength in the aqueous solution.

The linear relation between the C=O frequency shift and the pK can be explained by the relations linking the acid strength and the frequency of the carbonyl group to its polarisation and therefore any intermolecular interaction which alters the bond polarisation leads to a change in both acid strength and the carbonyl frequency.

In many cases a correlation has been observed between the spectroscopic characteristics of the C=O group and the parameters of free molecules[93,115,116]. Denisov's studies[115] showed that for the systems ketone–acid there is a correlation between the shift of the carbonyl band of the ketone and its first ionisation potential. The latter can probably serve as a measure of the relative electron-donor capacity of the ketone. As in the ketone series, the variation of the relative shift of the carbonyl band with the first ionisation potential was observed in the series of esters[137]. However, in the case of the ester carbonyl band a larger carbonyl shift occurs over a smaller range of ionisation potentials, although esters are poorer proton acceptors[138] than ketones. Probably the C=O frequency shift can serve as a measure of electron-donor capacity only within an individual class of compounds.

A number of determinations of the dimerisation energy of carboxylic acids in the gas phase as the principal characteristic of the hydrogen bond have been made[112,139]. The energy of the hydrogen bond in dimerised monocarboxylic acids does not change in the gas phase either when the molecular weight increases or when the structure of the non-carboxy-residue is altered[111,140].

The energies of the hydrogen bonds of certain acids in carbon tetrachloride solutions have been determined in a number of investigations[141-144]. However, very few data characterising the strength of the hydrogen bond of carboxylic acids in different solvents have been published[107]. The energies of the hydrogen bond in carboxylic acids per O–H...O=C bond are listed in Table 2.

Table 2. Energies of formation of O–H...O=C hydrogen bonds according to spectroscopic data.

Acid	Medium	Energy, kcal mole^{-1}	References
From acetic to valeric	gas phase	2 (8—8.5)	112
Acetic	CCl_4	2 (5.38)	141
Acetic	CCl_4	2 (5.38)	139
Isobutyric	CCl_4	2 (5.5)	107
Benzoic	CCl_4	2 (5.25)	144
Benzoic*	CCl_4	2 (8.2)*; 2 (4.2)*	145, 146
Benzoic*	$CHCl_3$	2 (6.35)	145
Isobutyric	$CHCl_3$	2 (4.2)	107

*Data on the energy of the hydrogen bond obtained by Klages and Möhler[145].

**Data of Wall and Banes[146].

Comparison of the effects of various solvents on the energy of the hydrogen bond shows that, on transition from the gas phase to the solution, even in an inert solvent such as carbon tetrachloride, there is a considerable decrease of the hydrogen bond energy. The energy of the O–H...O=C bond for solutions of acids in chloroform is even lower. Probably a change in the solvent may alter the type of equilibrium (dimer $\rightleftharpoons$ open chain dimer $\rightleftharpoons$ monomer) and the relative content of the monomer. The presence of open-chain dimers of carboxylic acids can explain the discrepancy between the bond energies for gases and solutions in carbon tetrachloride. To account for the decreased hydrogen bonding in acids dissolved in chloroform compared with the solutions in carbon tetrachloride, it is suggested[107] that the complexes are formed via $RC{=}O...HCCl_3$ hydrogen bonds and the acid monomers interact with chloroform more strongly than with carbon tetrachloride.

In solutions in hydroxylated solvents it is possible to determine only the formation constant of the complex which yields information about the average energy of the hydrogen bond in the compound, while adequate data on the energy of the individual C=O. . .H–O bond cannot be obtained. Therefore it is impossible to compare the frequency of the C=O group bound in the complex with the energy of the corresponding hydrogen bond.

The dependence of the relative shift $\Delta\nu/\nu$ of the absorption bands due to the C=O groups in acid dimers and monomers on the universal interaction function $(n^2-1)(2n^2+1)$ makes it possible to assess the strength of the interaction between the components in solution[110,123]. The effect of solvents on the frequency of the C=O group of acid dimers differs appreciably from their effect on the C=O frequency of monomers. Regardless of the nature of the solvent, plots based on the Kirkwood–Bauer–Magat formula show that all the points corresponding to the C=O frequency of the dimers are distributed near a straight line, while those corresponding to the C=O frequencies of the monomers lie to the right of the theoretical straight line. The effect of the solvent on the dimer is smaller, since the dimer is a symmetrical complex with a dipole moment close to zero because its active polar groups C=O and O–H are hydrogen-bonded. On the other hand, the effect of the medium, which leads to a decrease of the potential energy, may be regarded as a consequence of the interaction of the acid molecules with one or several of the surrounding solvent molecules.

Thus we have examined the results of many investigations[55–57,106–108,110,115–117,123,126] devoted to the effect of the hydrogen bond on the absorption bands of proton-acceptor groups in the infrared and Raman spectra. These data show that the band due to the stretching vibrations of the C=O group in ketones and monocarboxylic acids is sensitive to association and the formation of a hydrogen bond, while the change in the contour of the band due to the C=O group in carboxylic acids on formation of an intermolecular bond yields data on the immediate environment of the carboxy-group.

The increase in the number of observed bands in the region of the C=O stretching vibrations of carboxylic acids is evidence of the formation of different types of association complexes (dimer, open-chain dimer, compounds with the composition AB, A_2B, AB_2). The presence of different types of association complexes has been established on the basis of the temperature[104,107] or concentration[55–57,107,110,115–117,120–123,126] variation of the band positions. In many cases it is possible to determine the type of the association complexes in the systems by simultaneous application of infrared and Raman spectroscopic methods together with physicochemical methods[34,36,40–53,121–123].

Studies of the effect of the hydrogen bond on the infrared absorption spectra due to the stretching vibrations of proton-acceptor groups have been made only in recent years; the general form of the relation governing the force constants of such systems has not yet been elucidated. Its elucidation will provide new information about the structure of the complexes formed in the systems.

Summarising, it is noteworthy that the study of the physicochemical and spectroscopic characteristics of associated compounds and their solutions indicates a wide variety of intermolecular interactions in solutions. Comprehensive studies of the properties of a definite group of substances and the discovery of special relations will in future contribute to a general and unique solution theory.

Catalytic Electron Transfer

S.N.Zelenin and M.L.Khidekel'

The possibilities of obtaining catalysts and catalytic systems for redox hydrogen-transfer reactions are discussed. Use is made of the method of analogy with enzymatic catalysis and modern ideas on electron-transfer reactions. The general requirements to be satisfied by an "optimal" catalyst for hydrogen transfer, the conditions for rapid electron transfer, and some characteristic features of electron transfer in a biochemical oxidation chain are examined. The promising possibilities revealed by this approach for the selection of catalysts and catalytic systems for various reductions are demonstrated. The bibliography contains 206 references.

CONTENTS

I. INTRODUCTION

One possible approach to the development of a scientific basis for the preparation of catalysts and catalytic systems is to use the method of analogy with enzymes. Results obtained in enzymology make it possible to explain many features of the structure and mechanism of action of coenzymes and enzymes on the basis of the ideas of organic and coordination chemistry. This makes it possible to reach definite conclusions regarding the chemical characteristics of the components of the active centres of enzymes, the principles of their activation and the activation of substrates, and the organisation of the individual components into more complex structures. On this basis it is possible, with a sufficient degree of reliability, to formulate some of the general principles determining the structure and catalytic properties of enzymes. It appears to us that it is now possible to realise these principles and to prepare corresponding analogues and analogue systems of various levels of organisation.

It may be assumed that the development of this approach will open up extensive possibilities for the preparation of new effective catalysts and catalytic systems for various reactions.

In the present review we have considered, for the example of redox reactions, some problems of the preparation of catalysts and catalytic systems using the method of analogy with enzymes.

We shall first analyse the general requirements to be satisfied by catalysts for redox reactions. The simplest catalytic hydrogen-transfer cycle consists of a reaction between a hydrogen donor (AH_2) and a catalyst (Q) (stage 1) and the reactions of the reduced forms of the catalyst with an acceptor (B) (stage 2):

$$AH_2 + Q \xrightarrow{k_1} QH_2 + A, \qquad (1)$$

$$QH_2 + B \xrightarrow{k_2} Q + BH_2. \qquad (2)$$

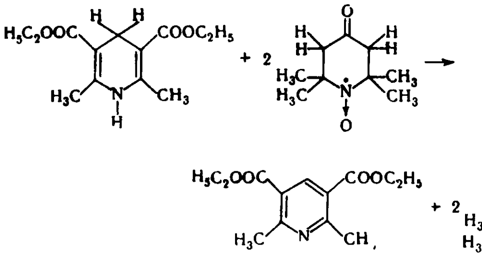
The best catalyst for the catalytic cycle corresponds to the maximal value of the rate of catalytic transfer (w).

The rate w is related to the constants k_1 and k_2 by the equation

$$w = \frac{k_1 k_2 [\mathrm{AH_2}][\mathrm{B}][\mathrm{Q}]_0}{k_1[\mathrm{AH_2}] + k_2[\mathrm{B}]} \quad . \tag{3}$$

The value of w is determined by the absolute values of the constants, and also by the ratio between them. It follows from an analysis of Eqn. (3) that if $k_1 \gg k_2$ (or $k_2 \gg k_1$), we have $w = k_2[\mathrm{B}][\mathrm{Q}]_0$ (or $w = k_1[\mathrm{AH_2}][\mathrm{Q}]_0$), that is the rate of the catalytic transfer of hydrogen in the limiting cases is proportional to one of the constants k_1 or k_2, and in the intermediate range of values of the constants, a maximum is observed in the range where k_1 and k_2 are approximately equal. For the same redox substrate pair, characterised by a definite decrease in free energy ΔF^0, the constants k_1 and k_2 are not independent, but are related to one another by the expression $\Delta F^0 = \Delta F_1^0 + \Delta F_2^0$, where ΔF_1^0 and ΔF_2^0 are the free energy changes in reactions (1) and (2). Although in general there is no simple relationship between thermodynamic and kinetic constants, it follows from the last relationship that with improvement of the acceptor properties of the catalyst (in the thermodynamic sense) there is a simultaneous deterioration in its ability to act as a donor. Thus for the given catalytic cycle there exists an "optimum" catalyst, exhibiting strong donor and acceptor properties with respect to the substrates.

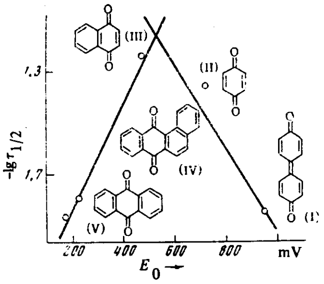
The literature contains examples illustrating the existence of an optimal dependence of the overall rate of catalytic reactions on the values of the individual constants for stages (1) and (2). Thus for the catalytic transfer of hydrogen in the reaction



(4)

the most effective catalysts correspond to a limited range of catalyst redox potentials 0.4–0.6 V.[1,2] The Figure demonstrates the dependence of the rate of the catalytic transfer of hydrogen in reaction (4) for a series of para-quinones on the redox potential of the quinone. When quinones are used as catalyst-transfer agents in hydrogenation, derivatives of 9,10-anthraquinone are more active than derivatives of 1,4-naphthaquinone and 1,4-benzoquinone[3]. A similar relationship with a catalytic efficiency maximum is also found for enzyme systems[4]. Moreover, the greater the redox potential of the quinone, the greater the rate at which it is reduced, and the lower the rate of oxidation of the corresponding hydroquinone. Analogous relationships were observed[5] in the catalytic decomposition of hydrogen peroxide by metal complexes.

It may be concluded that in general the realisation of a catalytic cycle involving two (or more) successive stages with comparable rates always leads to the existence of an optimal dependence of the overall rate of catalysis on the values of the rates of the separate stages, or, in the final analysis, on the thermodynamic characteristics of the catalysts. This principle of redox catalysis has an analogy in other types of catalysis, in particular heterogeneous catalysis[6]. For example, from the principle of energetic correspondence of Balandin's multiplet theory it follows that "if a process involving a catalyst is represented as taking place in a number of stages, the most favourable path will be that in which the energetic effects of the stages are equal".[7] Note that to obtain the "optimum" catalyst it is also necessary to satisfy the condition of a minimum value for the energetic effects of the stages.



Dependence of the rate of transfer of hydrogen in reaction (4) on the redox potential of the para-quinones used as catalysts for the reaction.

As a result, there are two requirements to be satisfied by catalysts for greatest activity in any specific reaction: firstly, it is necessary to select a catalyst which will satisfy the optimum condition for a given catalytic cycle, and secondly, the structure of the catalyst should be such that the rate constants k_1 and k_2 have the maximum possible values. For example, catalysts for reaction (4) include *o*-naphthaquinone (redox potential $E_0 = 0.58$ V) and Methylene Blue ($E_0 = 0.534$ V), which satisfy the optimum condition for the reaction. The constants k_1 and k_2 have the values 30 litre mole^{-1} min^{-1} and 30 litre mole^{-1} min^{-1} respectively for *o*-naphthaquinone and 2.6×10^3 litre mole^{-1} min^{-1} and 4.1×10^3 litre mole^{-1} min^{-1} respectively for Methylene Blue (at 30°).[8]

One possible way of predicting the values of the rates of reactions (1) and (2) is by using linear relationships between the thermodynamic and kinetic parameters of these reactions.

The large amount of data on the rate constants of redox reactions enables examples of a linear relationship between the free energy change in the redox act and the free energy of activation to be found[9-16].

Proportionality between the kinetic parameters is observed, for example, for electron-transfer reactions with similar mechanisms, when the transmission coefficient (of activated complex theory) is approximately constant in the series of reactions being compared and when the contribution of electrostatic interactions to the free energy of activation differs little on going from one reaction to another[12-17].

The reactions of a given reagent with a series of structurally similar compounds obviously satisfies these requirements. It is for such series of reactions that correlations have been observed between the free energy of activation and the change in free energy for the process.

Relationships of this kind have been found, for example, for reactions of electron transfer between Fe^{2+} and various complexes of Fe^{3+} (and other ions),[17] the reactions of the HO_2^- ion with various metal ions[5], the reaction of the Fe^{3+}

ion with various hydroquinones[5,12-16], the transfer of hydride ion between xanthone and a series of triarylmethyl cations[18], the reduction of quinones by derivatives of 1,4-dihydropyridine[19], the transfer of hydrogen to quinones from hydrazo-compounds and 1,4-dihydronaphthalene[20,21], and the reduction of various flavins by dihydrolipoic acid and dihydronicotinamide adenine dinucleotide[22]. Other examples can be found in the literature[11,23,24].

The optimum condition limits the choice of catalysts for a given reaction to a definite range of catalyst redox potentials. In this connection, important significance for redox catalysis is acquired, on the one hand, by factors favouring rapid electron transfer in reactions characterised by relatively small changes in free energy, and, on the other hand, by the principles of the functioning and organisation of the catalyst systems, since it must apparently be assumed that high rates of electron transfer in each elementary act with the above limitations can be observed only for a definite range of donors and acceptors.

The transfer of electrons in inorganic systems usually takes place at rates of $10^{-2}-10^{2}$ litre mole^{-1} s^{-1}, with activation energies of 15–21 kcal mole^{-1}.[25,26]. Rates of electron transfer equal to $10^{7}-10^{8}$ litre mole^{-1} s^{-1} and even greater than 10^{9} litre mole^{-1} s^{-1} are observed only in individual instances for simple systems.

On the other hand, for enzyme systems the rates of electron transfer are generally extremely high. For example, the oxidation of a number of metabolites in mitochondria takes place in the presence of catalyst–enzyme systems at rates of ~ $10^{7}-10^{8}$ litre mole^{-1} s^{-1}, with activation energies of 7–8 kcal mole^{-1}.[31]

Enzyme systems are distinguished by the fact that a high rate of electron flow is maintained along a chain of several catalyst–transfer agents. The decrease in the free energy of the reaction in each elementary act of electron transfer along the enzymatic chain is relatively small compared with ordinary redox systems[32].

It is natural to assume that enzymes effectively satisfy the requirements made of them as redox catalysts, and that the structure of the coenzymes and the functional groups forming part of the active centres of the enzymes are extremely well adapted to the functions of rapid electron transfer. This makes it possible to select and prepare catalysts for redox reactions by making use of data on the structure, mechanism of action, and methods of organisation of enzymes.

First of all let us consider briefly the conditions for the rapid transfer of electrons. The basic theoretical principles of the mechanism of electron-transfer reactions have been considered by Libby[33], Eyring and coworkers[25], Weiss[34], Laidler[35], Marcus[12], Halpern and Orgel[36], Levich and Dogonadze[37,38], and others[39-41]. Excellent reviews of experimental results and theoretical conclusions have been published[42-45].

II. CONDITIONS OF RAPID ELECTRON TRANSFER

1. Thermodynamic Criterion of Transfer

According to this criterion, the greater the decrease in the free energy of a reaction, the greater the probability of a high reaction rate. The possibility of using this criterion in redox catalysis is limited, as can be seen from the foregoing discussion.

It may also be noted that the rate of a redox reaction may vary considerably, depending on the detailed mechanism of the process. Thus despite favourable thermodynamic relationships at room temperature, electron transfer does not take place without catalysts in the systems $Sn^{II}-Fe^{III}$, $Tl^{I}-Ce^{IV}$, dihydronicotinamide adenine dinucleotide (and its simple analogues)—molecular oxygen, sodium hydridoborate—nitroso-compounds, etc.[46-49]

2. Principle of Equivalent Exchange by Electrons[50-52]

According to this principle, first put forward by Shaffer, a reaction is rapid if in the course of the reaction the molecules of the oxidising agent and reducing agent respectively take up and give up the same number of electrons. If these numbers differ, the reaction is slow. This criterion is of considerable importance for the qualitative prediction of the rates of redox reactions. It leads to an extremely important consequence, directly related to redox catalysis: reactions in which there is equivalent exchange by electrons and which take place at a low rate will be accelerated by compounds capable of acting simultaneously as one-electron and two-electron oxidising agents and reducing agents.

In enzymatic catalysis, extensive use is made of structures capable of undergoing reversible one-electron and two-electron oxidation and reduction (flavones, quinones, cobalamines).[53-55]

Until recently, only isolated examples of catalytic reactions in which the principle of equivalent exchange is observed had been published[50-52,56-58].

This principle has been applied most fully and extensively in work on the development of new catalysts and catalytic systems for various redox reactions[1,2,59-63].

For example, it has been shown that the rate of the reaction between dihydropyridine compounds (hydride reducing agents) and molecular oxygen or the stable radical of 2,2,6,6-tetramethylpiperidone-4 (a one-electron oxidising agent) is increased considerably in the presence of flavins, quinones, and similar compounds[1,2,59]. The selection of a catalyst may be made on the basis of the values of the redox potentials[1,2]. It has been found that this type of catalysis may extend to other reducing agents: metal hydrides and molecular hydrogen activated by hydrogenation catalysts[3,59,62-66]. In the presence of these catalysts it is also possible, by means of hydride reducing agents, to reduce aromatic nitroso- and nitro-compounds, compounds with positive halogen, and complex compounds of metals with variable valency[60-62,66].

When Shaffer's principle is used, it is necessary to make allowance for the fact that the types of reacting compounds, ligands, and medium influence the ability of, for example, the donor to act as a hydride or one-electron reducing agent. Thus a change in the medium, influencing the stability of the intermediate states of oxidation of the catalyst or substrate, and complex formation, leading to stabilisation of intermediate states of oxidation, may alter both the mechanism and the rate of a redox reaction.

The catalytic oxidation of the dianions of organic compounds in common media was studied by Russell and coworkers[67]. The increase in the rate of the catalytic transfer of hydrogen as a result of the possible formation of a complex of the donor with a π-acceptor and a complex of an intermediate state of the catalyst with a metal ion has been studied[68,69].

3. Energy of Coulombic Interaction and Energy of Franck–Condon Rearrangement

The energy of the Coulombic interaction between the donor and the acceptor and the energy of the Franck–Condon rearrangement, that is the energy required for rearrangement of the ligand and solvate environment of the donor and acceptor in the change to the activated complex, appear in the free energy of activation of the redox reaction and determine it completely[12-16,42]. A decrease in the sum of these two terms leads to an increase in the rate of electron transfer.

As a rule, the rates of electron transfer between oppositely charged ions or between an ion and a neutral molecule are much greater than those between ions of the same sign. For example, the rate of the reaction of Fe^{2+} with $IrCl_6^{2-}$ is greater by an order of magnitude than the rate of the reaction of Fe^{2+} with the 1,10-phenanthroline complex of Fe^{3+}, which has the same ΔE^0 value[17]. The activation energies of these reactions are comparable (1.9 kcal $mole^{-1}$ and 0.8 kcal $mole^{-1}$), but the entropy of activation is much smaller for $IrCl_6^{2-}$ than for the phenanthroline complex of Fe^{III}.

Very high values (~ 10^9 litre $mole^{-1}$ s^{-1}) are observed for the rates of exchange by electrons in both the forward and back directions in the tris-(4,7-dimethyl-1,10-phenanthroline) Fe^{II}–$IrCl_6^{2-}$ system[27]. The reactions of Fe^{3+} with the anions of hydroquinones is more rapid than the same reactions in acid media[12-16]. The rate constants for the disproportionation of neutral benzosemiquinones and the anions of benzosemiquinones are 10^9 litre $mole^{-1}$ s^{-1} and 5×10^6 litre $mole^{-1}$ s^{-1} respectively[70].

A fact of importance for redox catalysis is that the rate of electron transfer between ions of identical sign is usually increased if the bridging group in the activated complex (that is the group joining the donor and the acceptor) is a ligand with the opposite sign (Cl^-, Br^-, I^-, OH^-, etc.).[42,71,72] The dimensions of the bridging group influence the forces of electrostatic repulsion between ions of the same sign[42,43,72].

Let us now consider the factors which decrease the energy of the Franck–Condon rearrangement. Firstly, if the reagents have similar structures and show little change in the solvate sheath, the rate of electron transfer in these systems will be maximal[34]. This explains the rapid electron transfer between the MnO_4^{2-} and MnO_4^- ions, which have identical structures, and the slow exchange between AsO_4^{3-} and AsO_3^{3-}, which have different structures. Secondly, since the greatest contribution to the energy of the Franck–Condon rearrangement is made by the energy used in the rearrangement of the inner and outer coordination spheres of the reagents, the introduction of, for example, the iron ion into the rigid structure of the porphyrin in cytochromes increases its ability to undergo redox reactions, compared with hydrated iron[34]. High rates of electron transfer (10^8–10^9 litre $mole^{-1}$ s^{-1}) are observed between ions containing bulky ligands with extensive π-electron systems[17,27]. The activation energies of these reactions are very low and coincide with the activation energies of reactions whose rates are limited by diffusion. Thirdly, strong electronic interaction between the reagents and a bridging group, in Sutin's opinion[44], can stabilise the activated complex and decrease the total free energy required for rearrangement of the inner and outer coordination spheres of the reagents on electron transfer.

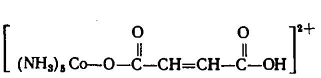
Finally, according to Libby[33], the rate of electron exchange is increased if it is possible to produce an activated complex whose geometry remains symmetrical to within the vibrational amplitudes involved in zero point motion ("symmetry principle").

4. Degree of Electronic Coupling Between the Reagents (Linearity of the Trajectory of the Electrons)[73]

The existence of an activated complex and low values for the Coulombic repulsion and the energy of the Franck–Condon rearrangement do not guarantee high rates of electron transfer—the possibility of sufficient electronic interaction between the reagents in the activated complex is necessary. In this connection it is important to emphasise the significance of bridging groups for the electronic coupling of reagents. Bridging groups provide orbitals of suitable symmetry, in which the electrons of the reducing agent may be delocalised and then transferred to the oxidising agent. If an electron moves from a t_{2g} orbital of the reducing agent to a t_{2g} orbital of the oxidising agent, we should expect easy transfer through bridging groups containing π-electrons, since these orbitals effectively overlap the π-orbitals of the bridging group. If the transfer involves e_g orbitals, the limitations of symmetry greatly reduce the efficiency of the process. Thus for redox catalysis it is important that the catalyst be a compound–bridging group with a structure ensuring the necessary electronic coupling between the reagents through the electronic system of the catalyst and the formation of various complexes (chelates, π-complexes, etc.).

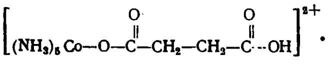
Published data show that the existence, in the bridging group, of positions for the additional binding of reagents in the activated complex favours electron transfer[74,75]. For Co^{III} complexes containing bridging groups capable of forming chelate structures with the Cr^{II} cation–reducing agent, the observed rates of transfer are higher than those for Co^{III} complexes whose bridging groups do not have positions for binding Cr^{II}.[74,75]

As a rule, bridging groups containing π-systems favour electron transfer to a greater extent than bridging groups containing σ-systems[71,76]. The classical example illustrating this conclusion was described by Taube[71]: the rate of reduction of the complex



$$\left[(NH_3)_5Co{-}O{-}\overset{\overset{O}{\|}}{C}{-}CH{=}CH{-}\overset{\overset{O}{\|}}{C}{-}OH\right]^{2+}$$

by the Cr^{II} ion is greater by two orders of magnitude than the rate of reduction of the complex



$$\left[(NH_3)_5Co{-}O{-}\overset{\overset{O}{\|}}{C}{-}CH_2{-}CH_2{-}\overset{\overset{O}{\|}}{C}{-}OH\right]^{2+}.$$

A high rate of electron exchange was observed in the reduction of the Fe^{3+} ion by the complex $(Fe-N_3)^{2+}$ in aqueous medium[77]. The bridging group provides its unshared pairs for bonding with the metal ion. The rate of electron transfer in the $Co(phen)_3^{2+}$–$Co(phen)_3^{3+}$ system is greater by six orders of magnitude than that in the corresponding ammines[71] (phen represents 1,10-phenanthroline).

A higher rate of electron transfer is observed in the case of the hexakis(phenyl isonitrile) complexes of Mn^+ and Mn^{2+}, compared with the ethyl and t-butyl isonitrile complexes[78]. It is assumed[78] that the activated complex has a structure in which there is overlap of the π-system

Rate constants for electron transfer in various reactions of organic compounds with the corresponding radical-anions.

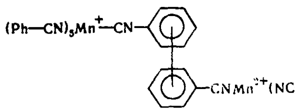
of the benzene rings and which cannot be achieved in the case of alkyl isonitrile ligands

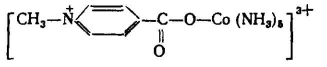


An unusually high rate of electron transfer is observed between tris-(4,7-dimethyl-1,10-phenanthroline)-Fe^{II} and hexachloroiridate(IV).[27] The rate constants for transfer in the forward and back directions are 10^9 litre mole^{-1} s^{-1} and 4×10^9 litre mole^{-1} s^{-1} respectively. The most probable mechanism of transfer involves delocalisation of the electron over all three phenanthroline ligands and overlap of the appropriate orbitals of the chloride ions with the π-system of the phenanthroline ligands. The high rate of electron transfer suggests that the overlap is sufficient to make possible the ready transfer of an electron, accompanied by rearrangement of the ligands in the solvate sheaths. High rates of electron exchange are observed between neutral organic molecules and their ions[28,79-92].

All the organic systems of this type which have been studied up to the present have extensive electronic systems, the ready overlap of which ensures high rates of transfer. The values of various rate constants for electron transfer between radical-ions and neutral molecules are given in the Table.

The above discussion leads to the following qualitative conclusion—the more extensive the conjugated system in the organic compound, the greater the rate of transfer. The rate constants for the reaction increase in the order: benzene < naphthalene ~ anthracene. An important feature is that in the reactions given in the Table, the change in free energy is equal to zero.

The transfer of electrons through bridging groups may be accompanied by oxidation or reduction of these groups[93-96]. Sometimes the lifetime of these states is greater than the half-reaction time for the individual electronic reactions, and sometimes it is so great that chemical changes in the bridging group are possible, for example cis–trans isomerisation in the reduction of the pentamminemalato-complex of Co^{III} by Cr^{II} ions[92,94]. The rapid reduction, by Cr^{II} ions, of the complex



takes place with the intermediate formation of the radical-cation, stabilised by conjugation[95,96]. The easier the reduction and oxidation of the bridging group, the greater the observed rate of electron transfer[74,93-96]. The ligands which are readily reduced and oxidised are generally extensive conjugated systems.

5. Spin Preservation Rule

Spin preservation is an important factor influencing the rate of redox reactions: systems for which changes in spin are expected are characterised by low rates of electron transfer. Preservation of spin on electron transfer to the activated complex requires the use of high-lying excited electron orbitals, so that high rates are impossible. The difference in the rates of reactions involving molecules with more than one unpaired electron can apparently be explained on the basis of this forbidden case[97].

---o0o---

The above conditions for rapid electron transfer can be used in the selection of catalysts for the catalytic cycle described above [reactions (1) and (2)]. Since its characteristic feature is that the most effective catalysts have redox potentials lying in a definite range, an important significance for the estimation of the rate constants k_1 and k_2 is acquired by an equation obtained by Marcus[12-16], relating the rate constant of the forward reaction k_{12} between a donor A^- and an acceptor B

$$A^- + B \underset{k_{21}}{\overset{k_{12}}{\rightleftarrows}} A + B^-$$

to the equilibrium constant K_{12} (it also defines the redox potential) and the rate constants of the one-electron exchange reactions k_{11} and k_{22}

$$A^- + A \overset{k_{11}}{\rightleftarrows} A + A^-$$

$$B^- + B \overset{k_{22}}{\rightleftarrows} B + B^-$$

The constants k_{11} and k_{22} may either be measured by physical methods (EPR, NMR) or predicted on the basis of the conditions for rapid transfer.

Following Marcus, we can write

$$K_{12} = (k_{11}k_{22}k_{12}\cdot f)^{1/2} \qquad (5)$$

where

$$\ln f = \frac{(\ln K_{12})^2}{4\ln(k_{11}\cdot k_{22}/z^2)},$$

z is the frequency of bimolecular collisions in the solution ($z \sim 10^{11}$ litre mole^{-1} s^{-1} and f is often close to unity).

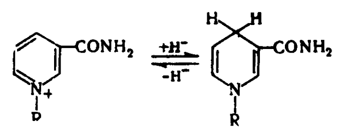
Although the theoretical calculations were carried out by Marcus for a definite model of the reaction, in which rupture or formation of chemical bonds does not take place (electron transfer by the so-called outer-sphere activated complex mechanism) it must be assumed that its conclusions can be extended to many systems. This conclusion is confirmed by experimental results[17,42,85,98]. For example, Eqn. (5) has been used to estimate the relative rate constants for redox reactions of biologically important quinones—vitamins *K* and *E*—compared with 1,4-naphthaquinone and duroquinone. The relationship between these constants and the length of the side chain of vitamins *K* and *E*, and the possibility that they take part in the biochemical respiration chain as electron transfer catalysts has been discussed on this basis[85]. In simpler systems, quinones in fact act as effective catalysts for the transfer of an electron from various reducing agents to a large number of acceptors[1,3,59,61,63,66,99-101].

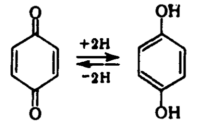
In concluding this section, we may point out that despite the large number of redox reactions studied, there are extremely few examples of catalytic reactions in which criteria of rapid electron transfer have been used. At the same time, enzymatic redox catalysis is a process which is organised in a definite fashion and in which conditions for rapid electron transfer are realised and use is made of structural elements which are well adapted for carrying out the functions of catalysts for redox reactions. Consequently, it is of interest to examine the general principles of the construction and functioning of enzymes of redox reactions, with the aim of producing new catalysts and catalytic systems on this basis.

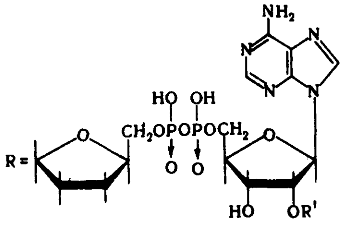
III. SOME CHARACTERISTIC FEATURES OF ENZYMATIC TRANSFER OF ELECTRONS (HYDROGEN)

1. Structure of Groups in the Active Centre of Enzymes (Coenzymes)

Of the coenzymes used in enzymatic redox catalysis, of which there is a limited number[102], mention may be made of nicotinamide adenine dinucleotide (NAD), nicotinamide adenine dinucleotide phosphate (NADP), flavin mononucleotide (FMN), flavin adenine dinucleotide (FAD), metal–porphyrin complexes, ascorbic acid, lipoic acid, coenzyme Q (ubiquinone), vitamin K, and vitamin B_{12}, the structures and reactions of which are given below:

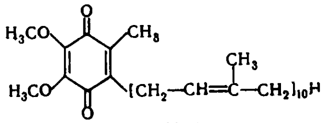




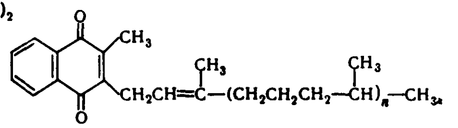


NAD : R' = H

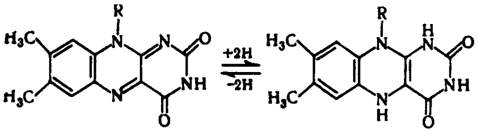
NADP : R' = —P(OH)₂ → O

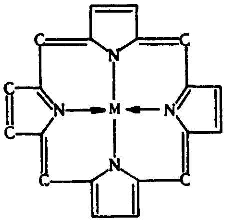


ubiquinone



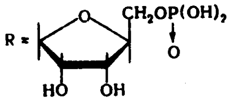
Vitamin K_n



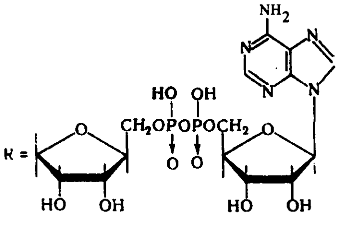


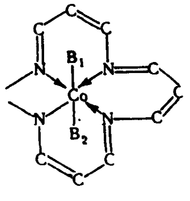
metalloporphyrin

FMN



FAD





Vitamin B_{12}

The coenzymes show the following characteristic structural features.

The highly universal action of coenzymes[103] is due to the fact that in these coenzymes, the properties of various classes of compound are combined. All the coenzymes are (or contain) conjugated heterocyclic systems with acid–base centres and various groups adapted for reversible bond and complex formation. As a result, they may be effective bridging groups (catalysts) or contain such groups.

The presence in the coenzymes of extensive π-electron systems is directly related to their catalytic functions. In Bersuker's opinion[104], redox enzymes can be regarded as characteristic electronic systems of high capacity, since they can readily take up and give up electrons without significant change in energy. For example, the iron–porphyrin complex can act as a powerful acceptor and also as a no less powerful donor, taking effective part in electron transfer. On the other hand, conjugated systems can increase the rates of electron transfer as a result of conduction through the system of π-bonds.

The ready conversion of one systems of conjugated bonds into another is responsible, for example, for the functioning of the coenzymes NAD, NADP, FMN, FAD, and also coenzymes with quinone structures. Here, an apparently general principle is the principle of minimal breakdown of the π-system of the coenzyme with the introduction of the entire conjugated system into the reaction. Calculations[105-107] show that the oxidised form of the coenzyme is a very effective electron acceptor, and the reduced form an effective electron donor. The formation of various complexes with the coenzyme alters its donor–acceptor properties considerably (see, for example, the review of the flavins[108]).

The possibility of maintaining a steady-state concentration of catalytically active forms (semiquinones – QH) through the equilibrium between the completely oxidised (Q) and reduced (QH_2) forms of the coenzyme (flavins and quinones) $QH_2 + Q \rightleftharpoons 2QH$, in which the rates of electron exchange between the various oxidised forms of the coenzyme are extremely high[85], is an important property of enzyme–transfer agents.

In the case of vitamin B_{12}, the highly reactive state of Co^{II}, with one or several unpaired electrons, exists[55] as a result of the equilibrium $Co^{II} + Co^{I} \rightleftharpoons 2Co^{II}$.

The various possibilities for stabilisation of the catalytically active forms of coenzymes by delocalisation of the unpaired electrons over the conjugated systems, and the formation of complexes with metal ions or π-acceptors, are also related to the characteristic features of the structure of coenzymes[108-116].

2. Role of π-Complexes in Enzymatic Catalysis[117-122]

The formation of π-complexes leads firstly to an increase in the extent of the conjugated system and hence to the possibility of electron transfer over considerable distances, and secondly to stabilisation of the catalytically active forms of the coenzymes.

Most of the available published data on this subject relates to the detection and identification of the π-complexes of dihydronicotinamide adenine dinucleotides, flavins, quinones, and other coenzymes with conjugated systems. The biological role of coenzymes is undoubtedly due to their ability to form various π-complexes.

Thus it is assumed[123-125] that the transfer of electrons in mitochondria and chloroplasts is brought about by π-complexes of the metalloporphyrin–quinone or chlorophyll–quinone types respectively. The values of the measured formation constants for the formation of π-complexes between vitamin K_3 and biologically important electron donors—Co-mesoporphyrin-IX-dimethyl ether and chlorophyll—show that these complexes are quite capable of existing under the conditions of enzymatic reactions and of influencing electron transfer.

The formation of π-complexes between NAD-H_2 and flavins has been studied[110,125]; identical π-complexes may also be obtained in the reaction of reduced flavin with NAD.

Molecular complexes of NAD and its simple analogues with various electron donors, I^-, indole, tryptophan, and serotine† have been studied[126].

Of considerable importance for an understanding of the role of π-bonding in enzymatic catalysis are various facts[127-129] which indicate electronic interaction of the "charge transfer" type between the adenine and nicotinamide (or isoalloxazine) rings within the enzyme itself.

Study of the complexes of indole with the pyridinium ion showed that the absorption spectra of these systems are similar to the spectra of the enzyme glyceral-3-phosphate dehydrogenase. It is suggested[130] that the bond between NAD and the protein in the enzyme is produced as a result of the formation of a π-complex. Similarly, the bond between flavin and a protein may be produced through a π-complex with tyrosine[131,132]. A large number of π-complexes are formed by the isoalloxazine ring, which can often be regarded not only as an electron acceptor (complexes with purines, HI, dihydropyridines, hydroquinones, phenols, and other compounds) but also as a π-electron donor (complexes with tetracyanoethylene or 2,3-dichloro-5,6-dimethyl-1,4-benzoquinone). Dimethylalloxazine, for example, behaves in this way, and the ability of this compound to act as donor or acceptor shows a correlation with the energies of the higher occupied and lower vacant orbitals[183]. Isoalloxazines and related dyes are known to form molecular complexes with purines, pyrimidines, indoles, phenols, and other compounds of biological interest[110,134-137].

Finally, molecular complexes of quinones are widely known[121,138-140]. The complexes of quinones with flavins and cytochromes are of greatest interest, since they are active groups of enzyme–transfer agents, which come into direct contact in electron transfer processes.

Although it can definitely be stated that the π-complexes of many redox coenzymes take part in biochemical reactions as intermediate structures, there is almost no direct proof of this. Some of the difficulty is due to the fact that even in those instances where the accumulation of reaction products takes place in the same sense as the change in the concentration of the intermediate π-complex[140], it cannot be guaranteed that the chief reaction path is that involving the formation of the π-complex, and does not by-pass it.

$$A + B \xrightarrow{(\pi\text{-complex})} \text{products}$$

---

† It is not clear whether seroten or serotonin is intended here (Ed. of Translation).

It can be said that the factors corresponding to the formation of π-complexes favour electron transfer from the donor to the acceptor.

It may be noted that the existence of π-bonding between the substrate and the enzyme tyrosinase under anaerobic conditions[120] shows that this complex is apparently an intermediate in the oxidation of substrates by molecular oxygen. The examples of the participation of NAD and FAD in intramolecular complexes, in π-complexes with aromatic aminoacids, and in complexes with one another may indicate not only the nature of the bonding between the coenzyme and the apoenzyme, but also the existence of intermediate catalytically active states involving reducing agents, for example NAD-H_2 (source of hydrogen) and the hydrogen acceptor FMN, FAD, or quinone.

3. Role of Semi-quinones in Enzymatic Catalysis

As indicated above, a characteristic feature of enzymatic catalysis is the existence of a steady-state concentration of catalytically active intermediate forms (semi-quinones, Co^{II}, etc.) through the equilibrium between the completely oxidised and reduced forms of the coenzyme. The maintenance of a steady-state concentration of catalytically active forms is due to the structural characteristics of the coenzymes. In this connection, a factor of considerable importance in redox catalysis by enzymes undoubtedly is the possibility of additional stabilisation of intermediate radical and highly active biradical states of the coenzymes, and also reactive low-valency and other states of metal ions, as a result of the inclusion of the corresponding π- or d-electrons in conjugated systems of sufficient extent.

At an early date, Michaelis[141] suggested the existence of radical–enzyme complexes as a necessary condition for the essential one-electron transfer in enzymatic redox reactions.

Current data indicate that there is stabilisation of the radicals as a result of the formation of π-complexes under conditions of both non-enzymatic[108-116] and enzymatic[111-113,115,116] reactions. Stable complexes of flavin radicals with iodine and phenol were recently obtained[114].

It may be assumed that in many instances the detection of radicals under the conditions of enzymatic reactions is related to additional delocalisation of the unpaired electron either on a suitable conjugated system of the protein or on suitable orbitals of the metal ion.

The chief theories on the role of free radicals are associated with the name of Michaelis, who considered that all biological redox reactions must have a stage involving one-electron transfer, the intermediate compounds being free radicals[141].

At the present time, the role of radical intermediate forms in enzymatic catalysis remains the subject of a large amount of discussion[112,113,115,116,141,142], since even with modern methods of study it is not always possible to relate the facts of the detection, identification, and behaviour of radicals under various conditions to the actual mechanism of enzymatic catalysis. The problem is also complicated by the variety of ways in which free radicals can be stabilised and destabilised, for example by π-bonding, complex formation with metal ions, concurrent chemical reactions which do not affect the free valency, etc.

As already indicated, a characteristic feature of the reversible flavin–dihydroflavin reaction and the analogous quinone–hydroquinone reactions is the ready formation of free radicals as intermediate compounds. The mechanism of formation of radicals in these systems is based on the equilibria

$$QH_2 + Q \underset{k_{21}}{\overset{k_{12}}{\rightleftarrows}} [QH_2 \cdot Q] \underset{k_{32}}{\overset{k_{23}}{\rightleftarrows}} 2\,QH,$$

where QH_2, QH, Q, and $[QH_2.Q]$ represent the reduced, the semi-quinone, and the oxidised forms of the flavin or quinone, and the intermediate complex, which is usually a π-complex.

Depending on the medium, these equilibria are superimposed on the reversible reactions of addition and removal of a proton from the various forms of flavin or quinone[112,115,116,144,145]. In aqueous and aqueous-alcoholic media, hydroxide ions may act as possible reducing agents to semi-quinones[146-149].

The temperature-jump method has been used to study the reaction between FMN and FMN-H_2 at pH = 4.7 and a temperature of 298°K.[150] The values of the constants k_{12}, k_{21}, k_{23}, and k_{32}, equal to $> 10^9$ litre $mole^{-1}\ s^{-1}$, $> 10^6\ s^{-1}$, $5 \times 10^3\ s^{-1}$, and $6 \times 10^6\ mole^{-1}\ s^{-1}$ respectively, show that the rates of electron transfer in the two directions approximately coincide. The data on the isotope effect evidently indicate that transfer of an electron to the intermediate complex is less probable than transfer of a hydrogen atom.

It is of particular interest to compare the rates of one-electron exchange and transfer of hydride ion in quinone–hydroquinone systems. The constants k_{21} and k_{23} can apparently be regarded as proportional to the rates of hydride ion transfer and one-electron exchange, since in the intermediate complex the hydrogen atoms which undergo exchange are equivalent with respect to the two flavone (or quinone) rings, present in the complex.

If this is so, the rate of transfer of two electrons in the FMN–FMN-H_2 system is much greater than the rate of exchange by an electron in the same system. It may be assumed that the rates of electron transfer are markedly dependent both on the structure of the flavin or quinone and on the nature and degree of the binding of the coenzymes in reactions of enzymatic catalysis.

Unfortunately, in other systems these rate constants for electron transfer are unknown, although the rates of one-electron transfer in the forward and back directions have been measured[70,151-155]:

$$QH_2 + Q \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} 2\,QH\ .$$

The values of the constants k_1 and k_{-1} are fairly high (10^7–10^{10} $mole^{-1}\ s^{-1}$).

Usually, as expected, the $QH^\cdot$ radical disproportionates much more rapidly than its deprotonated form $Q^\cdot$.[70,155]

The complexity of the study of electron transfer in the Q + QH_2 system is also due to the need to make allowance for redox reactions of exchange by electrons

$$Q + QH \rightleftarrows QH + Q$$
$$QH + QH_2 \rightleftarrows QH_2 + QH\ .$$

This reaction takes place at a high rate (values of the constants up to 10^{10} litre $mole^{-1}\ s^{-1}$) (see Table on page 107 and Refs. 28 and 85).

The oxidised, semi-quinone, and reduced forms of the flavins or quinones readily form various complexes: π-complexes with one another and various π-acceptors and π-donors, and complexes with metal ions and other complex-forming species[108,110-114,120,121,124-141,157-159].

As a result of complex formation, there is an increase in the effective concentration of intermediate radical forms.

For example, the maximal concentration of flavosemiquinones is observed in acidic and alkaline media[115,116] and does not exceed several percent of the total concentration of flavin, whereas the maximum concentration of flavosemiquinones in the presence of various metal ions is observed in neutral media and may amount to almost 100% of the flavin concentration[113].

The oxidised form of flavin reacts specifically with a metal ion, whereas the reduced form is inert[113]. Thus flavin forms very stable chelates only with Ag^+ and Cu^+ ions, and in the complex of flavin with Cu^+, reversible electron transfer takes place between the partners. The spectra of the complexes $[Fl^-.Cu^+] \Longleftrightarrow [Fl^{2\circ}.Cu^{2+}]$ and $[Fl^-.Ag^+]$ correspond to the isoelectronic spectrum of the protonated flavosemiquinone $[Fl^{\cdot}.H_2^+]$.[160,161]

Fe^{2+} and MoO^{3+} ions react equally strongly with flavin, but in contrast to the situation with the Ag^+ and Cu^+ compounds, the flavin in the complexes with Fe^{2+} and MoC^{3+} is completely reduced to the semiquinone[113,162].

It should be emphasised that the semiquinones of flavins are able to form complexes with, as a rule, many more metal ions than the oxidised or reduced forms[163,164]. With diamagnetic metal ions (Zn^{2+}, Cd^{2+}) the flavosemiquinone gives an EPR spectrum with a hyperfine structure which is quite different from that of free flavosemiquinone, although the absorption spectra in the visible range are approximately identical[159,163,165]: this indicates a marked change in the electron density in the flavosemiquinone on complex formation with metal ions.

It has been suggested that the role of metal ions in enzymatic catalysis possibly involves the stabilisation of the flavin semiquinone[163].

Bray and coworkers[166], in a study of reactions catalysed by xanthine oxidase (a flavin enzyme containing Fe and Mo), showed by the EPR method that in the anaerobic reduction of xanthine oxidase and the aerobic oxidation of xanthin, the flavosemiquinone and Mo^V are formed as intermediate products. The results indicate that this radical is joined to the protein or the metal[166].

In view of the marked ability of semiquinones to form various complexes, proofs of direct electron transfer in systems containing flavins and quinones must be approached with some caution.

Study of the EPR spectrum of the π-complex [NAD-H_2.FMN] [167] showed the presence of free radicals, associated only with the flavin part of the complex. This was explained on the basis of the following reaction scheme

$$\text{NAD-H}_2 + \text{FMN} \rightleftharpoons [\text{NAD-H}_2^{\dot{+}}.\text{FMN}^{\dot{-}}] \rightleftharpoons \text{NAD-H}_2^{\dot{+}} + \text{FMN}^{\dot{-}}$$
$$2\text{NAD-H}_2^{\dot{+}} \rightleftharpoons \text{NAD-H}^+ + \text{NAD-H}_2 + \text{H}^+$$
$$\text{FMN}^{\dot{-}} + \text{H}^+ \rightleftharpoons \text{FMN-H}^{\cdot}.$$

The intermediate free radical NAD-$H_2^{\dot{+}}$ immediately undergoes disproportionation, to form the completely reduced and oxidised pyridine nucleotides. Thus the result of the overall reaction is the reduction of FMN at the expense of the NAD-H_2, to the semiquinone, without the formation of free radicals of NAD-H_2.

On the other hand, there exists the possibility of complete reduction of the flavin in the π-complex, the formation of semiquinones through the equilibirium between the oxidised and reduced forms of the flavin, and stabilisation of the resulting flavosemiquinone by its inclusion in a π-complex with the oxidised form of nicotinamide adenine dinucleotide.

This mechanism of stabilisation of semiquinones may also be realised in reactions of N-benzyldihydronicotinamide with quinones, where semiquinones have been detected[168]. The authors cited consider that this proves one-electron transfer, since the semiquinones were not detected by the EPR method under the same conditions in the quinone–hydroquinone system. Allowance must be made, however, for the fact that the reaction between dihydropyridine and 1,4-benzoquinone is fairly slow[169], whereas the attainment of equilibrium in the quinone–hydroquinone system is a very rapid process[70,134-137,151-156]

Because of complex formation, it is not always possible to observe correlations between the appearance of an EPR signal and the absorption bands assigned to the semiquinone[112]. It was found, for example, that the absorption spectra of the enzyme lipoyl dehydrogenase are the same for the reduction by dithionite and by the substrate, but an EPR signal is not observed, because of the formation of a complex between the flavosemiquinone and a sulphur-containing radical, formed in the enzyme. This complex plays a central role in processes catalysed by the enzyme lipoyl dehydrogenase; it is a catalytically active intermediate complex. The completely reduced enzyme is catalytically inert, at least in reactions with physiological substrates.

In a study of the mechanism of action of the oxidase of D-aminoacids it was found that the catalytically active intermediate product is a complex between the semiquinone form of the flavin and a radical of the aminoacid; in agreement with this, the concentration of the flavosemiquinone increased with increase in the concentration of the aminoacid[112].

Although many conclusions are still controversial, it may be taken that the formation of complexes by radicals increases the effective concentration of the radicals—this may have a significant influence on the overall rate of electron transfer[170].

On the other hand, complex formation by radicals may alter considerably the electron distribution in the radicals[113,159,170] and this in turn influences the rate and specificity of the process.

Ehrenberg[115,116] detected free radicals by means of the EPR method in the reaction between "old yellow" enzyme and NAD-H_2. He showed that the radicals are combined with a slowly vibrating protein molecule. The unpaired electron is localised chiefly in that part of the isoalloxazine molecule which is not combined with the protein. This electron density distribution is extremely sensitive to the smallest changes in the structure of the environment of the radical.

The action of the enzyme on the free radicals formed in a number of instances from the substrates is of interest[171]. Nakamura[172] established that in the oxidation of hydroquinone by the copper-containing enzyme laccase, a semiquinone is formed as the primary reaction product. The formation of free radicals in the oxidation of hydroquinone, pyrogallol, pyrocatechol, and other compounds was observed by a number of authors in processes involving peroxidase[173] and phenol oxidase[174].

Work illustrating the specific behaviour of semiquinones compared with other redox forms is of particular interest.

The important role of semiquinones is emphasised by Yamasaki and Ohnishi[153], who showed that the rate of the reduction of cytochrome C by hydroquinone is greatly increased in the presence of quinone. This increase was attributed to the formation of para-benzosemiquinone. The reduction of cytochrome C by the semiquinone is rapid and plays an important role in the redox equilibrium between the ferro-ferricytochrome C and quinone–hydroquinone systems. A kinetic study by the EPR method showed the following reaction mechanism:

$$QH_2 + Q \rightleftarrows 2QH$$

QH + ferricytochrome C ⇌ quinone + ferrocytochrome C.

The same result was previously obtained in a study of simpler systems[175].

The rapid reduction of cytochrome C in reactions of oxidases (peroxidase, ascorbic acid oxidase), which catalyse the two-stage oxidation of hydrogen donors, is also associated with the formation of semiquinone free radicals from the donor molecule[176].

The autocatalysis of the oxidation of reduced flavin by molecular oxygen may indicate a high rate of reaction of the flavosemiquinone with oxygen, compared with the reduced flavin[177]. The addition of the oxidised flavin to the FMN-H_2–O_2 system increases the rate of oxidation[177].

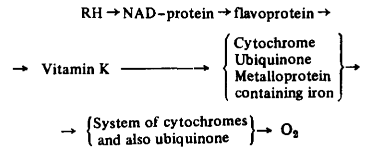
This was proved experimentally with other systems. An interesting feature is the behaviour of the semiquinone of thionine (a dye structurally similar to the flavins) in the reduction of the Fe^{3+} ion. The rate constants[151] for the oxidation of thionine semiquinone and its reduced form by Fe^{3+} ions are 7.9×10^4 litre mole^{-1} s^{-1} and 2.6×10^2 litre mole^{-1} s^{-1} respectively.

The reactivity of the semiquinone is determined by many factors. Thus it has been established that the flavin semiquinone produced by the action of various flavoproteins is oxidised by hexacyanoferrate(III) with great difficulty in the presence of a substrate; is however the substrate is absent, the oxidation is instantaneous[162,170,178].

Various flavosemiquinones are so strongly stabilised by a protein or a metal ion that they undergo extremely slow oxidation by molecular oxygen, and reduction by $S_2O_4^{2-}$ ions[112,113].

4. Catalytic Electron Transfer Chains

A characteristic feature of enzyme catalysis is the use of so-called catalytic chains, that is systems consisting of several enzymes[31,179,180]. For example, the oxidation of a number of metabolites in mitochondria takes place in the presence of a system of catalysts consisting of nicotinamide adenine nucleotide enzymes, flavoproteins, quinones, cytochromes, and metalloproteins. The chief sections of this chain are shown in the following scheme:



At different ends of the respiratory hydrogen transfer chain, there is preliminary activation of the substrates: the hydrogen donor RH and the hydrogen acceptor molecular oxygen, and electron transfer along the chain takes place at a very high rate (10^7–10^8 mole^{-1} s^{-1}, activation energy 7–8 kcal mole^{-1} [31]) and is highly specific. The term activation is understood to mean the formation of enzyme–substrate complexes in which the necessary rearrangement of the electronic structure of the hydrogen donor or acceptor and an orientation of the reagents convenient for the reaction take place. The formation of enzyme–substrate complexes leads to an increase in the rate and specificity of the enzymatic reaction. In particular cases a coenzyme may act as substrate.

It should first of all be emphasised that the key sections of the respiratory chain are those in which interaction of pyridine nucleotide and flavin enzymes with hydrogen donors and acceptors (particularly molecular oxygen), and also reaction of these enzymes with one another, take place. It is the study of these sections which may show why redox systems use not one universal catalyst but a chain of catalysts. This problem of course applies to other biochemical systems. It is natural to assume that the chief advantages of the catalytic chain lie in the fact that these chains are best able to satisfy the specific conditions of the reaction—the rates of electron transfer along the chain are high, and the reagents are activated and separated in space. This makes it possible to overcome the limitations imposed by the diffusion of reacting species to the active centre and also to generate reaction products in definite positions, so that their possible influence on the course of the reaction may be reduced to a minimum[179].

We may note the characteristic features of the biochemical respiratory chain given above. In the initial section of the chain, the substrate is oxidised by the direct transfer of hydrogen to the nicotinamide coenzyme. Most of the data on the mechanism of oxidation under the conditions of both model and enzymatic reactions indicates that hydrogen is transferred to nicotinamide coenzymes in the form of hydride ion[181], but no specific theories regarding the details of the mechanism of this reaction exist[102].

The final substrate of the electron transfer chain is molecular oxygen in aerobic organisms and nitrates and nitrites in anaerobic organisms. The mechanism of the reduction of these acceptors is apparently a one-electron mechanism (see Ref. 182 for oxygen).

Most of the available data[180] indicate that systems involving cytochromes function as one-electron transfer agents, although other possibilities can be pictured. For example, it was recently shown that the ferrogem–ferrigem electrode reaction is a two-electron process[186]. [This reference does not mention the stated reaction. (Ed. of Translation)].

Flavin and quinone-containing enzymes, on the other hand, take part in both one-electron and two-electron reactions. Under ordinary conditions, for example, flavins are apparently reduced by a hydride-ion mechanism under the influence of NAD-H_2,[22,53,54,181,184,185] and dihydrolipoic acid[22]. The dependence of the hydride-ion and hydrogen-atom mechanisms for the reduction of quinones on the reaction conditions has been discussed[186].

From the reduced nicotinamide coenzymes NAD-H_2 and NADP-H_2, hydrogen is transferred chiefly by a hydride-ion mechanism to many substrates, including flavins and quinones[53,54,181,187].

This fact is of importance in the explanation of the high rates of electron transfer in redox chains involving dihydropyridine and flavin enzymes. It may be assumed that in the catalytic chains the process is separated into stages differing in their chemical mechanisms—at one end of the chain, hydride ion is transferred from the substrate to the nicotinamide coenzyme, and at the other end, one-electron reduction of the acceptor takes place. Between the two ends of the chain there are systems containing flavin and quinone coenzymes capable of being reduced by a hydride-ion mechanism and oxidised with transfer of a hydrogen atom or an electron[53,54].

The separation of the process into stages with different chemical mechanisms not only leads to an increase in the rate of electron transfer as a result of observation of the principle of equivalent exchange by charges, but also ensures specificity of the reduction process relative to substrates which tend to undergo definite types of interaction.

IV. CATALYTIC ASPECTS OF ELECTRON TRANSFER

The conclusions reached in the previous sections are extremely useful in the search for catalysts for electron transfer reactions. We shall illustrate this for the examples already mentioned in the present review.

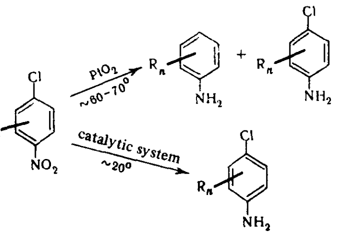
The rates of reactions of hydrogen transfer from reducing agents chiefly of the hydride type to probable one-electron acceptors, according to Shaffer's principle, should be increased by compounds capable of acting as one- and two-electron oxidising agents and reducing agents. In enzymatic catalysis, coenzymes with quinone and isoalloxazine structures, and also vitamin B_{12}, are compounds of this type.

For example, if dihydropyridine compounds, which are predominantly hydride ion donors[19,187-201] and whose reducing power is no less than that of molecular hydrogen[202], are used, the range of compounds reduced by NAD-H_2 and its models is greatly extended, and the rates of hydrogen transfer are increased in the presence of flavins, quinones, and similar dyes as catalysts[1,2,59-61]. Molecular oxygen[59], the stable radical of 2,2,6,6-tetramethylpiperidone-4 N-oxide[1,2], nitro- and nitroso-compounds[60,61], nitramine[61], N-bromosuccinimide[61], the acetylacetonato-compounds of Co^{III}, Fe^{III}, MoVI, and V^{V}, and also cyclopentadienyltitanium dichloride and cyclopentadienylvanadium dichloride[61]. The results obtained made it possible to apply the same principles of searching for organic catalysts with the isoalloxazine and quinone structures to the reaction of transfer of hydrogen from metal hydrides[59,61,63], organoelemental hydrides[203], formamidinesulphinic acid[62], dianions (organic and inorganic),[62] etc.

The next step in the use of the analogies with enzymes in catalysis is the development of catalytic systems which are more effective than the individual components[3,61,64-66,68,69]. Thus by taking account of the ability of the dihydropyridine ring to form π-complexes with various π-acceptors, it has been possible to find catalytic systems including π-acceptors and catalyst–transfer agents and having a higher efficiency in reaction (4) than the individual components of the system[69]. Published work[69] indicates that the mechanism of action of these catalytic systems apparently involves the formation of a π-complex between the reducing agent (1,4-dihydropyridine or cyclohexa-1,4-diene) and a π-acceptor (tetracyanoethylene, tetracyanoquinodimethane, 1,3,5-trinitrobenzene, etc.), in which there is a change in the ability of the reducing agent to act as a hydride ion and hydrogen atom (electron) donor.

Other effective catalytic systems for reaction (4), consisting of a catalyst–transfer agent and a metal ion, increase the rate of reduction of 2,2,6,6-tetramethylpiperidone-4 N-oxide and oxygen, possibly as a result of the ability of the semiquinones to form complexes with metal ions[68].

Catalytic hydrogenation systems, in the presence of which there is a marked change in both the rate and the specificity of hydrogenation[9,64-66,203,204], are of considerable interest. Catalytic systems of the first type consist of ordinary hydrogenation catalysts (heterogeneous or homogeneous) and catalyst–transfer agents, which can include quinones[3,66] and dimethylglyoximato-complexes of cobalt[64,65] and rhodium[203]. These catalytic systems are many times more effective in the hydrogenation of nitro-, nitroso-, azo-, azoxy, and hydrazo-compounds, compared with ordinary catalysts. In the hydrogenation of various halogenonitrobenzenes in the presence of, for example, the PtO_2 – sodium anthraquinone-2-sulphonate catalytic system, the rate of reduction of the nitro-group increases, and the dehalogenation is completely suppressed, since the hydrogenation takes place at room temperature, and in the presence of a transfer agent there is a decrease in the duration of contact between the substrate and the heterogeneous catalyst[205]:



Other catalytic hydrogenation systems, instead of catalyst–transfer agents, contain activating substrates as a result of the formation of various complexes[204,206]. On this basis, selective catalytic systems have been developed for the hydrogenation of unsaturated ketones, acrolein, and cinnamaldehyde.

These results lead to the following conclusions.

1. In a number of instances it is possible to obtain effective catalysts for various reactions on the basis of an analysis of the characteristic features of the structure and mechanism of action of enzymes.
2. For the rational selection of catalysts for a given process, it is necessary to take account of the thermodynamic characteristics of the catalyst and the structural correspondence between the reagents and the components of the catalytic systems in the limiting stage of the process.
3. The use of catalyst–transfer agents in redox reactions is extremely promising for carrying out various chemical processes at a high rate with high specificity under mild conditions.

Reactions of Aziridines with Ring Expansion

F.N.Gladysheva, A.P.Sineokov, and V.S.Etlis

The review gives a systematic account of the literature on the reactions of aziridines with the expansion of the three-membered ring by intramolecular and intermolecular cyclisation mechanisms. The intermolecular interaction of aziridines with aldehydes and ketones, CO_2, COS, and CS_2, and with isocyanates and isothiocyanates with formation of five-membered heterocyclic compounds (oxazolidines, thiazolidinones, thiazolidinethiones, imidazolidinones, and others) is discussed. The isomerisation of *N*-vinyl and *N*-acyl derivatives to the corresponding pyrrolines, oxazolines, and other five-membered heterocyclic compounds as well as dimerisation reactions of aziridines and their interaction with epoxy ethylene and nitrones are discussed.
The bibliography includes 88 references.

CONTENTS

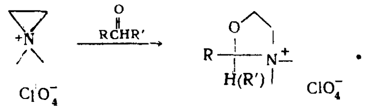
I. INTRODUCTION

The simplest nitrogen-containing three-membered heterocyclic compounds (aziridines) are extremely reactive[1-3]. They readily undergo addition reactions both with retention and opening of the aziridine ring. Under the action of acids, anhydrides, alcohols, amines, mercaptans, and other compounds, the three-membered ring opens and various *N*-substituted compounds are formed. In contrast to epoxy- and thioepoxy-alkanes, aziridines can react as amino-compounds with participation of the free electron pair of the nitrogen atom and the retention of the ring. They form aziridinium salts, add to the C=C double bond of keten, to activated double bonds of acrylic esters, and to conjugated double bonds of diene hydrocarbons, are acylated by acid anhydrides and chlorides to *N*-acylaziridines, cause ring opening of epoxyethane and ethylene sulphide, are dimerised to *N*-aminoethylaziridines, etc. A systematic account of the above reactions is given in the monograph of Gembitskii et al.[3], which contains the most complete description of the structure, properties, and methods of synthesis of aziridines and their reactions. Among the wide variety of the reactions of aziridines, a special place is occupied by reactions involving the expansion of the three-membered ring, which may be regarded as intermolecular and intramolecular interactions. The present review gives a systematic account of the literature on this problem up to 1968 inclusive.

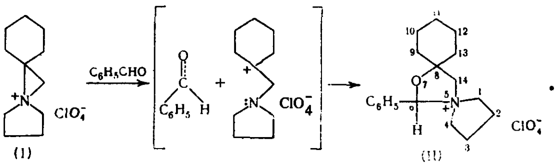
II. INTERMOLECULAR CYCLISATION

1. Reactions of Aziridines with Aldehydes and Ketones

The expansion of the aziridine ring in reactions with aldehydes and ketones was observed for the first time with aziridinium salts. Aziridinium salts were obtained by the nucleophilic attack of diazomethane on iminium compounds[4,5]. The proposed mechanism of the reaction of aziridinium salts with aldehydes[6] postulates the conversion of the three-membered cyclic ion to a five-membered ion with participation of the carbonyl group of the aldehyde or ketone:

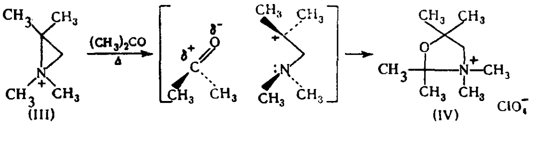


The mechanism consists of the opening of the aziridine ring to give a more stable positively charged tertiary β-aminocarbonium ion, which reacts with the polarised carbonyl group forming five-membered heterocyclic compounds—oxazolidinium salts. Thus, on heating, 5-azoniadispiro[4, 0, 5, 1]dodecane perchlorate (I) in an excess of benzaldehyde at 60°C for 48 h, a new compound was isolated—6-phenyl-5-azonia-7-oxaspiro[4, 2, 5, 1]tetradecane perchlorate (II):



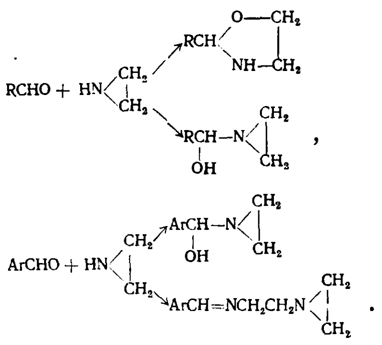
The infrared spectra of the compound isolated did not show absorptions characteristic of ^+N-H or C=O bonds, which is evidence that the C=O bond breaks with formation of a five-membered heterocycle.

The above reaction is general, this being confirmed by the reaction of benzaldehyde with analogues of compound (I). Aziridinium perchlorate reacts with a number of aliphatic cyclic and aromatic ketones[7]. Thus the reaction of 1,1,2,2-tetramethylaziridinium perchlorate (III) on heating in an excess of acetone has been investigated. Analysis and NMR spectra indicate that the final reaction product is 2,2,3,3,5,5-hexamethyloxazolidinium perchlorate (IV):

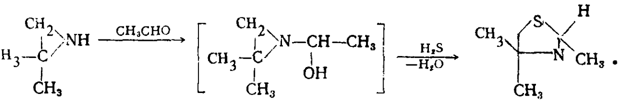


The reaction of the perchlorate (III) was carried out with cyclopentanone, cyclohexanone, methyl phenyl ketone, and other (cyclic and aromatic) ketones with heating to 65°C for 12–24 h. In each case stable oxazolidine derivatives were isolated and characterised. The interaction of aziridines unsubstituted at the nitrogen atom (in the form of free bases) with aldehydes does not lead to oxazolidines, as suggested by Doughty[8].

A number of investigations[9–15] have clearly demonstrated that under these conditions there is a possibility of the formation of *N*-aziridinemethanols or in certain cases *N*-(arylidene-β-aminoethyl)aziridines:



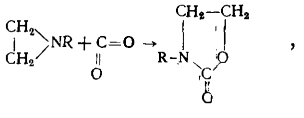
The formation of 2,4,4-trimethylthiazolidine[16] was observed in the reaction of acetaldehyde with 2,2-dimethylaziridine followed by saturation with hydrogen sulphide. One of the two possible mechanisms of reactions of this type postulates the formation of 2-alkyl-*N*-hydroxyaziridines, which yield thiazolidines under the action of hydrogen sulphide. In the second mechanism aziridine is converted into an amino-thiol, which is then converted into thiazolidine under the action of the carbonyl compound. The first mechanism is to be preferred in the case of the highly reactive acetaldehyde:



2. Interaction of Aziridines with Carbon Dioxide, Carbon Oxysulphide, and Carbon Disulphide

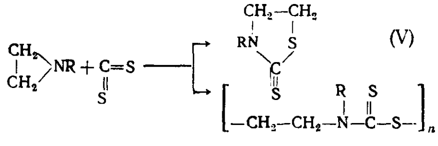
Oxirans and thi-irans react with carbon dioxide and its sulphur analogues with expansion of the three-membered rings[17]. In the reaction with carbon dioxide at room temperature, unsubstituted aziridine polymerises vigorously[18] and in the reaction with carbon monoxide, carbon oxysulphide, and carbon disulphide, it gives rise to thermoplastic resins[3].

Carbon dioxide does not react with aziridines in the absence of a catalyst. On heating with carbon dioxide in the presence of tetraethylammonium bromide (TEAB), equimolar amounts of *N*-arylaziridines give high yields of *N*-aryloxazolidinones[19,20]:

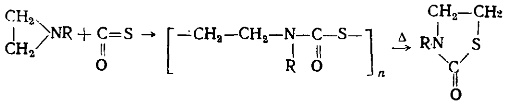


where R = C_6H_5, p-$CH_3C_6H_4$, o-$CH_3OC_6H_4$, or p-$CH_3OC_6H_4$. In the reaction of *o*- and *p*-methoxyphenylaziridines the corresponding *NN'*-diarylpiperazines were isolated as side products in yields up to 40%. In the reaction of *o*-tolylaziridine with carbon dioxide the formation of an oxazolidinone was not observed, the aziridine being dimerised due to the catalytic effect of TEAB.[21] Unsubstituted aziridine and its *C*-derivatives react with carbon disulphide forming thiothiazolidinones[22].

The reaction of carbon disulphide with *N*-arylaziridines under the conditions described for the reaction with carbon dioxide[19,20] leads to the expansion of the aziridine ring to that of *N*-arylthiazolidinethiones (V) (8–15%):



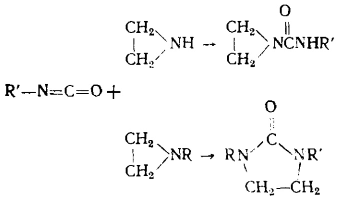
The main reaction products are characteristic copolymers of *N*-arylaziridines and carbon disulphide in molar proportions of 1 : 1. These copolymers are thermally unstable and on heating to 200–250°C dissociate with formation of the corresponding *N*-arylthiazolidinethiones (V) in a yield of 40–50%. The reaction of *N*-arylaziridines with carbon oxysulphide leads to the formation of ring expansion products only via the stage involving the copolymerisation of the reactant under the reaction conditions:



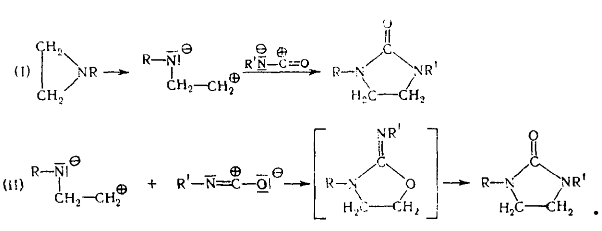
The thermal dissociation of the copolymers at 250°C leads to the formation of *N*-arylthiazolidinones (VI).

3. Interaction with Isocyanates and Isothiocyanates

The isocyanate molecule with the bond system N=C=O can react with aziridines with dissociation of the C=N or C=O bond. Aziridines unsubstituted at the nitrogen atom add to the C=N bond with formation of *NN'*-ethyleneureas[23–25]. In the reactions of *N*-substituted aziridines with isocyanates[26] the expansion of the aziridine rings to that of imidazolidinones was observed:

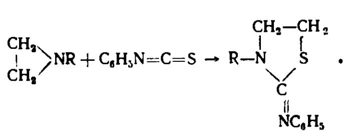


The reaction was carried out in the presence of a catalyst (lithium halides) at a temperature in excess of 100°C in an inert solvent. The interaction of *N*-acyl- and *N*-alkyl-aziridines with *N*-aryl, *N*-cyclohexyl, *N*-acyl, and *N*-sulphonyl isocyanates was investigated. For certain *N*-aryl and *N*-alkyl isocyanates, a competitive trimerisation reaction catalysed by tertiary amines was observed. The following two reaction mechanisms were proposed:



In the first mechanism the cleavage of a C–N bond of aziridine followed by the addition of the ion formed to the polarised N=C bond of the isocyanate with subsequent formation of an imidazolidinone is postulated. According to the second mechanism, an intermediate 2-imino-oxazolidine is formed and converted into a 1,3-disubstituted imidazolidin-2-one. The second mechanism is comparable with the mechanisms of the analogous reactions of epoxyethane[27].

Unsubstituted aziridines with an active hydrogen atom react with isothiocyanates with formation of *NN*-ethylenethioureas[28,29]. *N*-Aryl-substituted aziridines dissociate the C=S bond of the isothiocyanate in the presence of tetraethylammonium bromide, and are converted into the corresponding 3-aryl-2-phenyliminothiazolidines[21]:



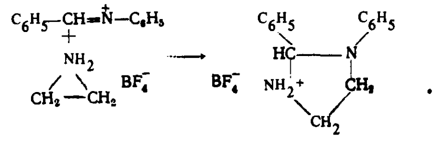
where R = C_6H_5, *o*-$CH_3C_6H_4$, *p*-$CH_3C_6H_4$, *o*-$CH_3OC_6H_4$, or *p*-$CH_3OC_6H_4$.

The infrared spectra of the compounds isolated show an intense absorption band in the region of 1632 cm^{-1}, which has been assigned to the vibration of the C=N bond.

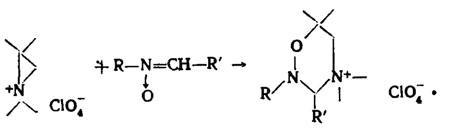
The reaction of *N*-phenylaziridine with methyl isothiocyanate under analogous conditions led to the isolation, together with 2-methylimino-3-phenylthiazolidine, of trimethyltrithioisocyanurate—the product of the trimerisation of the isothiocyanate. A similar reaction takes place with epoxyalkanes[30].

4. Interaction with Schiff Bases and Nitrones

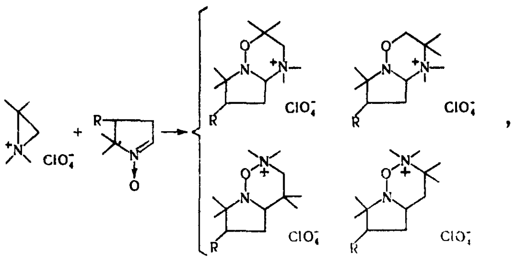
The possibility of the reaction of aziridine with the C=N bond of isocyanate is confirmed by the reaction of its derivatives with Schiff bases. Aziridinium salts readily add to the C=N bond of *N*-benzylideneaniline[31] with formation of 1,2-diphenylimidazolinium fluoroborate:



Nitrones, the structure of which includes the group C=$\overset{\overset{O}{\uparrow}}{N}$, add to aziridine derivatives with formation of six-membered adducts in proportions of 1 : 1.[32]

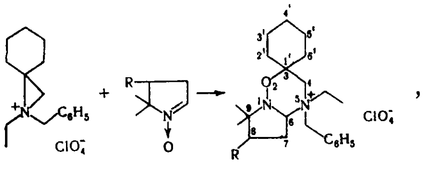


1,3-Dipolar addition to olefinic or acetylenic bonds with formation of isoxazolidine derivatives is characteristic of nitrones. Their interaction with aziridines can be explained similarly. Thus, the reaction of 1,1,2,2-tetramethylaziridinium perchlorate with 5,5-dimethyl- and 4,5,5-trimethyl-Δ^1-pyrroline-1-oxides at room temperature over a period of five days leads to the formation of one of a number of 1 : 1 adducts, since, depending on the course of the reaction, the C–N⁺ bond of aziridine can disssociate in different ways:



where R = H or CH_3.

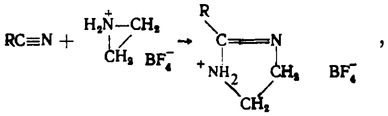
Under analogous conditions, 1-benzyl-1-ethyl-1-azoniaspiro[2,5]octane perchlorate gives rise to even more complex 1 : 1 adducts. Their analysis and infrared spectra confirm the formation of 5-benzyl-5-ethyl-8,9,9-trimethyl-1-aza-5-azonia-2-oxabicyclo[4,3,0]nonane-3-spiro-1′-cyclohexane perchlorate:



where R = H or CH_3.

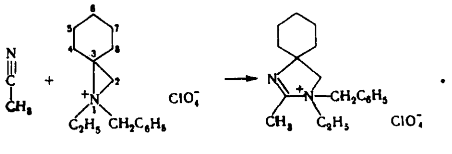
5. Interaction with Nitriles

The expansion of the aziridine ring is observed in the interaction with the C≡N bond of nitriles. Thus in the reaction between aziridinium tetrafluoroborate and various nitriles[31] the corresponding imidazolidinium salts were isolated:



where R = CH_3, C_6H_5, or $C_6H_5CH_2$.

After heating 1-benzyl-1-ethyl-1-azoniaspiro[2,5]octane perchlorate with acetonitrile[33], a new compound was isolated—3-benzyl-3-ethyl-2-methyl-1-aza-3-azoniaspiro[4,5]dec-1-ene perchlorate, the infrared spectrum of which contains the absorption band $\nu_{C=N}$ = 1715 cm^{-1}. The structure of the compound was also demonstrated by NMR spectroscopy.

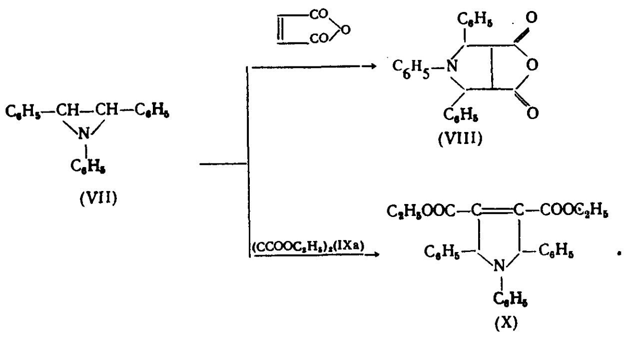


6. Interaction of Aziridines with Alkenes and Alkynes

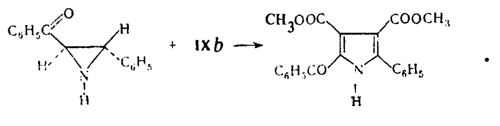
Aziridine ring expansion reactions are most often preceded by the rupture of the ring at carbon–nitrogen bonds. However, the carbon–carbon bond of the aziridine ring can also break with subsequent ring expansion. Such reaction takes place with reactive alkenes and alkynes[34–39].

The interaction of 1,2,3-triphenylaziridine (VII) with maleic anhydride takes place with formation of an expansion product of the three-membered ring in 94% yield, formed as a result of the dissociation of the C–C bond of aziridine and addition to the C=C bond of maleic anhydride[34]. The structure of the adduct (VIII) isolated was demonstrated by analysis and infrared spectroscopy.

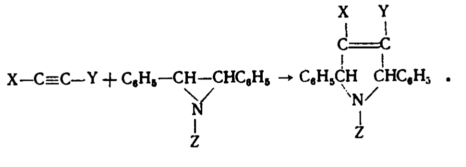
An example of the dissociation of the C–C bond in compound (VII) is provided by its reaction with diethyl acetylenedicarboxylate (IXa), which led to the isolation of a 98% yield of the pyrroline (X):



When *trans*-3-benzoyl-2-phenylaziridine was heated with dimethyl acetylenedicarboxylate (IXb) in xylene for 18 h, 2-benzyl-5-benzoyl-3,4-dimethoxycarbonylpyrrole was obtained in 80% yield[35]:



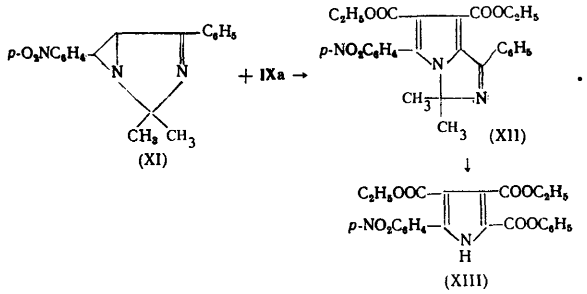
The interaction of triarylaziridines with various alkynes has been investigated[38]. When the reactions are carried out in toluene solution at room temperature (5 to 15 h), the corresponding Δ^3-pyrrolines are obtained in high yields:



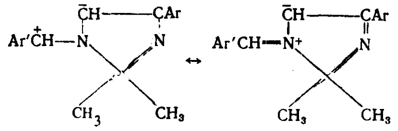
where X, Y = $COOC_2H_5$ and Z = C_6H_5; X = $COOC_2H_5$, Y = H, and Z = C_6H_5; X, Y = C_6H_5CO and Z = C_6H_5; X, Y = CF_3 and Z = C_6H_5; X, Y = $COOC_2H_5$ and Z = p-BrC_6H_4; X, Y = C_6H_5CO and Z = p-BrC_6H_4.

The reaction of aziridine with di(trifluoromethyl)acetylene was carried out in a sealed tube at 200°C for 12 h. The structures of the compounds isolated were confirmed by analysis of the infrared spectra. Their further chemical reactions were also studied.

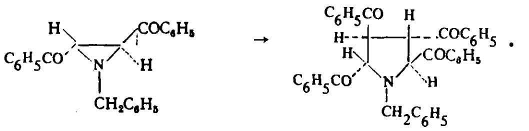
Similar interactions of aziridines with alkenes and alkynes, leading to the dissociation of the C–C bonds, were observed also in more complex heterocyclic systems[40]. When 1,3-diazabicyclo[3,1,0]hex-3-ene (XI) was heated in xylene with compound (IX), the diethyl ester of 3,3-dimethyl-5-(*p*-nitrophenyl)-1-phenyl-3*H*-pyrrolo[1,2-*c*]imidazole-6,7-dicarboxylic acid (XII) was obtained in a quantitative yield[38]:



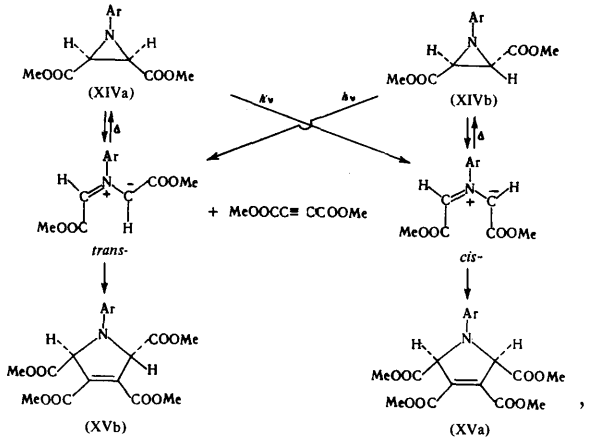
The structure of compound (XII) was demonstrated by acid hydrolysis to the diethyl ester of 2-benzoyl-5-*p*-nitrophenylpyrroledicarboxylic acid (XIII) and acetone. The authors also synthesised and characterised the adducts (XI) with diethyl fumarate, diethyl azodicarboxylic ester, *N*-phenylmaleimide, and also *cis*- and *trans*-dibenzoylethylene. It was postulated that this interaction is preceded by the rearrangement of compound (XI), to a 1,3-dipolar compound which then reacts in this form:



Attempts were also made earlier to account for the mechanism of this type of interaction by the 1,3-cycloaddition of the reactants to the aziridine derivatives[36]. 1-Benzyl-2,3-*trans*-dibenzoylaziridine is converted into *trans*-dibenzoylethylene (34% yield) and a certain amount of a ring expansion product—1-benzyl-1,2,3,4-(all-*trans*)-tetrabenzoylpyrrolidine:



The formation of the five-membered planar ring of the aziridine ring-expansion products gives rise to *cis*- and *trans*-isomerism. When dimethyl esters of 1-(4-methoxyphenyl)aziridine-2,3-dicarboxylic acid (XIVa, b) are heated in an excess of a "dipolarophile" ($CH_3OOCC{\equiv}CCOOCH_3$), a mixture of *cis*- and *trans*-isomers of the tetraesters (XVa, b)[39] is obtained, the proportions depending on the reaction conditions. The equilibrium between the *cis*- and *trans*-isomers has been investigated by NMR spectroscopy



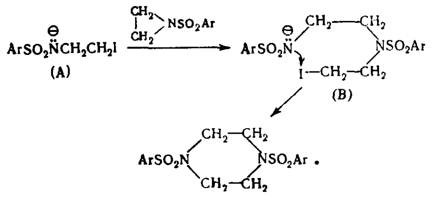
where Ar = $C_6H_4OCH_3$.

The thermal interaction of aziridines with a "dipolarophile" without solvent at 100–120°C takes place with the inversion of the configuration of the aziridine, while in the photochemical reaction the configuration is preserved. Thus, when 1 mole of compound (XIVa) and 10 moles of (IXb) were heated at 100°C for 14 h, compound (XVb) was isolated in 88% yield; under analogous conditions, compound (XIVb) is converted into compound (XVa) in 71% yield. Under the conditions of the photochemical reaction, compound (XIVb) is converted into compound (XVb) in 69% yield.

7. Dimerisation of Aziridine Derivatives and Interaction with Epoxyethane

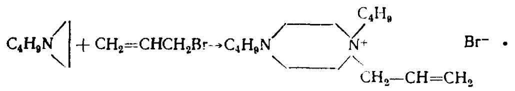
Oxygen- and sulphur-containing three-membered heterocyclic compounds dimerise under certain conditions to the corresponding dioxans[2] and dithians[41]. Aziridines also dimerise. The conversion of 1-methylaziridine into 1,4-dimethylpiperazine has been described[42]. The formation of piperazine derivatives in reactions of β-chloroethylamines has been observed. Kinetic studies of such reactions led to the conclusion[43,44] that chloroethylamines initially cyclise to aziridinium salts as intermediates, which then react further to give salts derived from piperazine. Piperazine derivatives were isolated after rearrangement of aziridines under the action of acids[45,46] and as side products in the isomerisation of aziridine derivatives[47].

1-Aroyl-2-alkylaziridines, 1-arylsulphonylaziridines, and 1-arylaziridines dimersie under the catalytic action of iodine. It is suggested that the first stage in the formation of piperazines[47] is a bimolecular substitution reaction of aziridine to give an ion derived from 2-iodoethylamine. Thus 1-arylsulphonylaziridines give rise to an ion (A) derived from *N*-(2-iodoethyl)arylsulphonimide, which attacks the methylene carbon of a second molecule of 1-arylsulphonylaziridine with formation of an intermediate ion (B):

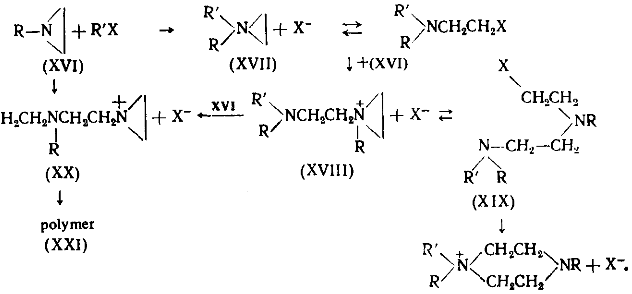


Piperazine is formed when an iodide ion is split off from the ion (B). The dimerisation of aziridine-1-carboxanilide to *NN*-di(phenylcarbamoyl) piperazine takes place similarly.

Dick[48] investigated the effect of alkylating agents on aziridine and succeeded in isolating piperazine derivatives. When allyl bromide is heated with 9 moles of *N*-butylaziridine in dry acetone, 1-allyl-1,4-di-*N*-butylpiperazinium bromide is formed in 96% yield:



Other alkylating agents have also been used: methyl iodide, methyl *p*-toluenesulphonate, ethyl *p*-toluenesulphonate, and ethyl bromide. The results of the experiments clearly show that in their reaction with aziridines alkylating agents favour the formation of piperazines. The mechanism of the opening of the ring of 1-alkylaziridines is known to involve catalysis by alkyl halides, including S_N2 attack by the nucleophilic agent on the aziridine ring. The following mechanism is proposed for the formation of piperazines:



Aziridine (XVII) forms a dimer (XVIII) by an S_N2 reaction. Then, if X^- is a powerful nucleophilic agent, compound (XVIII) reacts with it to form compound (XIX), which cyclises. However, if X^- is a weak nucleophilic agent, for example the toluenesulphonate ion, compound (XVII) is not converted into compound (XIX) but causes ring opening in the next aziridine molecule, forming the trimer (XX) and then polymeric compounds (XXI). It is known that under certain conditions the reactions of acids or alkylating agents with aziridine derivatives yield polyaziridines. The reaction of aziridines with alkylating agents is significantly influenced by the solvent. For example, acetone favours the formation of piperazine, while more polar solvents favour the polymerisation (XVIII) → (XX) → (XXI).

The formation of 1,1-dialkylaziridinium salts of type (XVII) when aziridine interacts with alkylating agents was demonstrated also in earlier studies[49,50].

The dimerisation of *N*-aryl derivatives of aziridines was observed when the latter were heated in the presence of a catalytic amount of tetraethylammonium bromide. The coupling of two three-membered heterocycles—*N*-arylaziridine and epoxyethane[51]—has been reported. Since the dimerisation of aziridine may compete with this type of interaction, the reaction was carried out in a large excess of epoxyethane:

$$\mathrm{Ar{-}N}\left\langle\begin{matrix}\mathrm{CH_2}\\ |\\ \mathrm{CH_2}\end{matrix}\right. + \left.\begin{matrix}\mathrm{CH_2}\\ |\\ \mathrm{CH_2}\end{matrix}\right\rangle\mathrm{O} \xrightarrow{\text{TEAB}} \mathrm{ArN}\left\langle\begin{matrix}\mathrm{CH_2{-}CH_2}\\ \mathrm{CH_2{-}CH_2}\end{matrix}\right\rangle\mathrm{O},$$

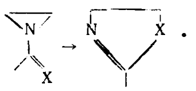
where Ar = C_6H_5, *o*-$CH_3C_6H_4$, *p*-$CH_3C_6H_4$, *o*-$CH_3OC_6H_4$, or *p*-$CH_3OC_6H_4$.

In the reactions of *N*-(*o*-methylphenyl)- and *N*-(*o*-methoxyphenyl)aziridines, *NN'*-diarylpiperazines were isolated in 30% yield together with morpholines. Ethylene sulphide does not take part in this reaction, undergoing quantitative polymerisation.

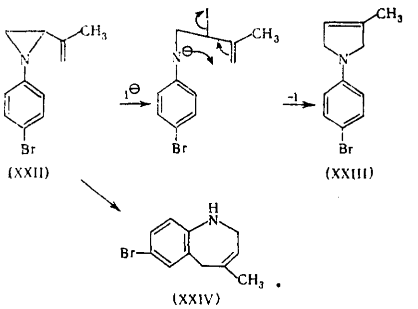
III. INTRAMOLECULAR CYCLISATION

1. Rearrangement of *N*-Vinyl Derivatives of Aziridines

Substituted aziridines undergo reactions typical for their hydrocarbon analogues—cyclopropanes. Under the action of nucleophiles and acids on heating, vinylcyclopropane isomerises to cyclopentene[52]. Similar processes have been observed for vinylaziridines:



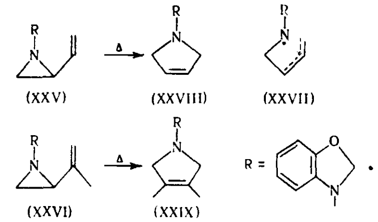
When *N*-methylvinyl(*p*-bromophenyl)aziridine (XXII) was heated with sodium iodide in dry acetone, 1-(*p*-bromophenyl)-3-methyl-3-pyrroline (XXIII) was isolated[53]:



(XXII) (XXIII) (XXIV)

The authors suggest that the mechanism of this reaction involves nucleophilic attack on aziridine by I⁻ with opening of the aziridine ring and subsequent displacement of iodine and formation of compound (XXIII). However, when *N*-vinylaziridine (XXII) is heated in xylene without a catalyst, the isomeric compound (XXIV), which is not a product of the expansion of the aziridine ring, is formed in a high yield. The structure of compound (XXIV) was demonstrated by the presence in its infrared spectrum of an absorption band characteristic of the NH group and also by the formation of the corresponding derivatives of phenylthiourea on heating with phenyl isothiocyanate.

Certain *N*-substituted 2-vinylaziridines [(XXV) and (XXVI)] undergo pyrolytic isomerisation in decalin solution at 180°C:[54]



(XXV) (XXVIII) (XXVII)

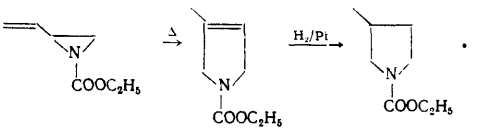
(XXVI) (XXIX)

The products of the expansion of the aziridine ring (Δ^3-pyrrolines) are formed in 80% yield. The mechanism of their formation can be accounted for by postulating the opening of the aziridine ring with dissociation of the C–N bond. The reaction proceeds via the intermediate formation of the aza-allyl biradical (XXVII), the stability of which is higher than that of the alkylallyl biradical formed in the rearrangement of vinylcyclopropanes to cyclopentenes[52].

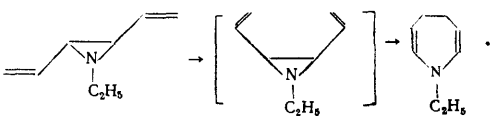
Comparison of the rates of conversion of the aziridines (XXV) and (XXVI) by heating in decalin at 150°C for 1 h shows that compound (XXVI) isomerises to compound (XXIX) to an extent of 100%, while the isomerisation of compound (XXV) to compound (XXVIII) takes place to the extent of 60% only. This can be explained by the greater stability of the tertiary allyl radical compared with the secondary radical.

The above aziridines (XXV) and (XXVI) are converted into Δ^3-pyrrolines under the action of a nucleophilic agent (sodium iodide) in boiling acetone with a yield of only 2% over a period of 24 h. In this case ring opening is not facilitated by the negative charge on the nitrogen atom. The conversion of three-membered rings into five-membered rings is possible only when the three-membered system is activated[55].

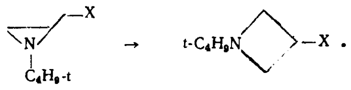
N-Ethoxycarbonyl-2-methyl-2-vinylaziridine isomerises in a gas-chromatographic column at 100°C or above with formation of *N*-ethoxycarbonyl-3-methyl-Δ^3-pyrroline[56]:



The presence of two vinyl substituents at the carbon atoms of aziridines leads to an unusual reaction involving the expansion of the three-membered ring to a seven-membered ring[57]: 2,3-divinylaziridine is converted into *N*-ethyldihydroazepine:



According to the latest literature data[58], certain aziridines rearrange to azetidine derivatives as a result of solvating ionisation:

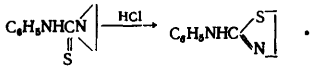


where X = OTs, OH, OC_2H_5, or Br.

2. Isomerisation of Aziridine Derivatives

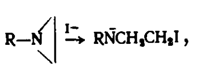
The isomerisation of aziridine derivatives, which is an example of intramolecular cyclisation, constitutes the most thoroughly investigated type of rearrangements of aziridines. The rearrangement of *N*-acyl derivatives of aziridines, *NN'*-ethyleneureas, and thioureas, obtained by the interaction of aziridines unsubstituted at the nitrogen atom with isocyanic acid esters, benzoyl and thiobenzoyl chlorides, chlorocarbonic acid esters, and other compounds, led to the synthesis of many five-membered heterocyclic derivatives—oxazolines, oxazolidinones, thiazolidinones, imidazolidinones, and others.

In 1895 Gabriel[28] observed for the first time the conversion of aziridine-1-thiocarboxanilide into 2-anilino-Δ^2-thiazoline under the action of concentrated hydrochloric acid:

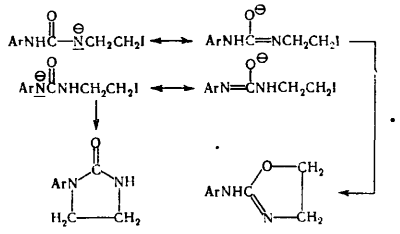


Later it was established that this type of reaction takes place readily in the presence of various nucleophilic agents which facilitate the dissociation of the C–N bond of the three-membered ring of aziridine.

Heine[59] proposed a mechanism for the nucleophilic catalytic isomerisation of aziridine derivatives, in which the formation of an anion derived from 2-iodoethylamine in the reaction in the presence of sodium iodide is postulated:



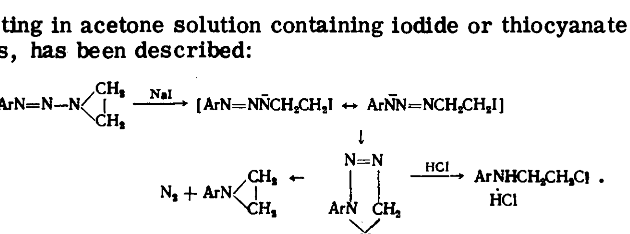
where R = ArCO, ArC=NR′, $\mathrm{Ar_2N\underset{\|\atop O}{C}}$–, or ArN=N–. The subsequent reaction of the anions formed can take place in different ways[47]; cyclisation may precede the tautomeric conversion of anions when there is a hydrogen atom at the nitrogen atom of *NN'*-ethyleneiminoureas:



(XXX) (XXXI)

For example, in the isomerisation of aziridine-1-carboxanilide in acetone solution in the presence of sodium iodide a mixture of products was isolated. The use of a small amount of acetone and an excess of sodium iodide leads to the formation of 1-phenylimidazolidin-2-one (XXX) in 85% yield. In an excess of acetone with a small amount of sodium iodide compound (XXX), the aziridine dimer, and a small amount of 2-anilino-Δ^2-oxazoline (XXXI) are formed.

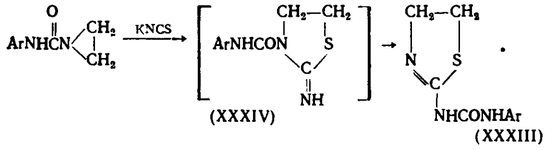
The synthesis of certain 1-arylazoaziridines[60], which are converted into 1-aryl-Δ^2-1,2,3-triazolines (XXXII) on heating in acetone solution containing iodide or thiocyanate ions, has been described:



(XXXII)

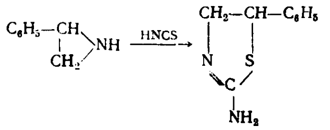
The products of the rearrangement of compound (XXXII) in turn serve as starting materials for the synthesis of a wide variety of *N*-arylaziridines which are difficult to obtain in other ways.

It should be noted that, apart from its catalytic effect, the thiocyanate ion can interact with aziridines, also yielding ring-expansion products. Thus, aziridine-1-carboxylic acid arylamides kept for 30 h in acetone with potassium thiocyanate are converted into 2-(3-arylureido)-Δ^2-thiazolines (XXXIII)[24], which are formed via the intermediate 2-imino-3-arylcarbamoyl-thiozilidines (XXXIV):

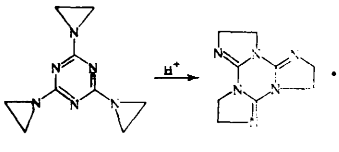


(XXXIV) (XXXIII)

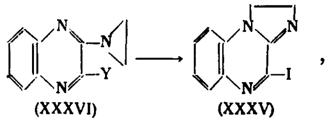
The mechanism of this interaction is consistent with the data of Gabriel[61], who described the effect of thiocyanic acid on 2-phenylaziridine:



The isomerisation of 2-alkyl-1-aroylaziridines, aziridine-1-thiocarboxanilides, and 1-arylsulphonylaziridines under the action of sodium iodide and thiocyanate ions in acetone[47] leads to the corresponding oxazolines and thiazolines—products of intramolecular cyclisation. 2,4,6-Tri-(1′-aziridino)-*s*-triazine isomerises on refluxing in acetonitrile solution in the presence of triethylammonium chloride to 2,3,6,7,10,11-hexahydrotrisimidazo-*s*-triazine:



New heterocyclic systems—1,2-dihydroimidazo[1,2-*a*]-quinoxamines (XXXVa, b)—have been obtained by the isomerisation of (1′-aziridino)quinoxamines (XXXVIa, b):[62]

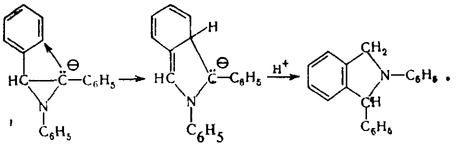


(XXXVI) (XXXV)

where (a) Y = Cl and (b) Y = CH_3O.

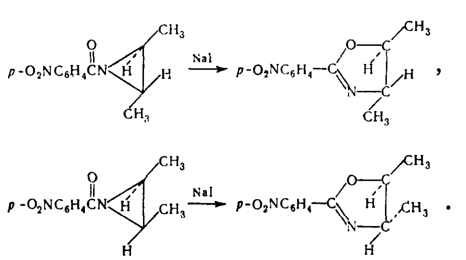
The conversion of compound (XXXVIa) into (XXXVa) takes place readily in acetone containing sodium iodide, while compound (XXXVIb), is converted into compound (XXXVb) in acetone solution containing sodium methoxide. The analogous isomerisation of 1-(*N*-arylbenzimidazolyl)-aziridine can be used to synthesise Δ^2-imidazolines[63].

The isomerisation of 1,2,3-triphenylaziridine is one of the first examples of carbanionic rearrangement involving the aziridine ring[64]. When 1,2,3-triphenylaziridine was heated in toluene in the presence of potassium t-butoxide in a sealed tube at 180°C, 1,2-diphenylisoindoline was isolated. The reaction may take place via the formation of the carbanion (XXXVII), which, after attack on the benzene ring, can be converted into the intermediate complex (XXXVIII); this undergoes a tautomeric conversion into 1,2-diphenylisoindoline:



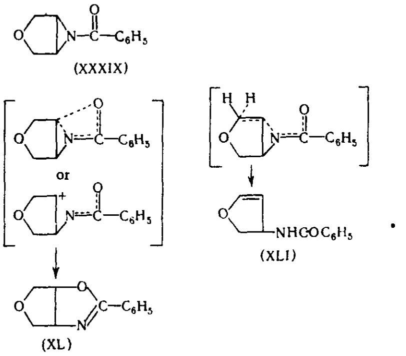
(XXXVII) (XXXVIII)

The isomerisation of certain 2,3-substituted *cis*- and *trans*-1-(*p*-nitrobenzoyl)aziridines, which are converted into the corresponding oxazolines under the action of iodide ions[65], is striking. The stereochemistry of this reaction has been investigated. In acetone solution containing iodide ions *trans*-2,3-dimethyl-1-(*p*-nitrobenzoyl)-aziridine isomerised to *trans*-4,5-dimethyl-2-(*p*-nitrophenyl)-Δ^2-oxazoline in 96% yield, while the *cis*-derivative of aziridine was converted into the corresponding *cis*-derivative of oxazoline:



The acid-catalysed isomerisation of 2,2-dimethyl-1-(*p*-nitrobenzoyl)aziridine[66] can take place via the intermediate formation of the tertiary carbonium ion $[ArCoNHCH_2\overset{+}{C}(CH_3)_2]$.

The isomerisation has been observed also for more complex bicyclic aziridines (XXXIX), which also yield ring-opening products on heating in the presence of sodium iodide. The high probability of the rearrangement of aziridines into the corresponding oxazolines via the formation of amides has been demonstrated[67]:

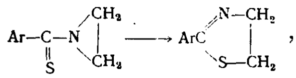


(XXXIX) (XLI) (XL)

When the aziridine derivative 6-aza-3-oxabicyclo[3,1,0]-hexane (XXXIX) and also its 6-methyl and 6-benzyl derivatives are heated, the oxazolines (XL) are formed but not the amides (XLI). The amide formed could be easily isolated under the experimental conditions, since it was shown that the amides are higher-melting less soluble products, which are more readily crystallised than oxazolines; the NMR spectra of compound (XL) differ from those of the isomeric amide (XLI). The hypothesis that the initially formed amide (XLI) cyclises under the reaction conditions is also unlikely, since it has been established that amides of this kind are stable on heating and cyclise to oxazolines only in concentrated sulphuric acid at room temperature[68].

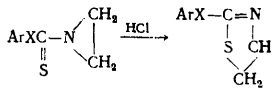
The oxazolines (XL) were also isolated after heating the benzoyl derivative of compound (XXXIX) with sodium iodide in acetone or acetonitrile. The mechanism of their formation is of the type of the isomerisation, described above, with formation of an ion derived from an iodoalkylamine[9].

Further studies[69] confirmed these findings in more complex heterocyclic systems. Conditions were found for the synthesis of 2,2-dimethyl-1-(*p*-nitrobenzoyl)-1-aza-spiro[2,5]octane and 1-azaspiro[2,4-]heptane, which yield the corresponding *N*-nitrobenzoyl derivatives. The isomeric *N*-cycloalkenylmethyl-*p*-nitrobenzamides readily isomerise to spiro-oxazolines. Picric and *p*-toluenesulphonic acids have also been used as nucleophilic agents for the isomerisation; in their presence 1-thioaroylaziridines were converted into 2-arylthiazolidines in benzene solution[70]:



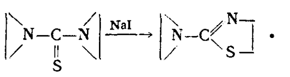
where Ar = p-ClC_6H_4, p-$CH_3C_6H_4$, or p-$CH_3OC_6H_4$.

1-(Aryloxythiocarbonyl)- and 1-(aryldithiocarbonyl)-aziridines readily polymerise on standing at room temperature and are converted into 2-aryloxythiazolines and 2-arylthiothiazolines by treatment with hydrochloric acid at 20°C:

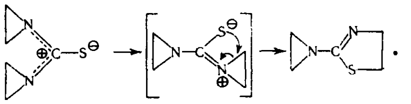


where X = O or S.

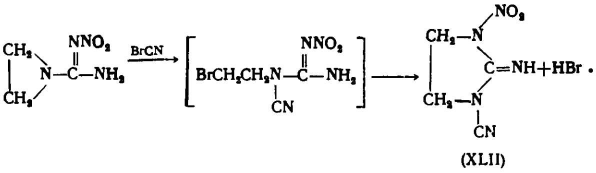
The extremely reactive 1,1′-(thiocarbonyl)bisaziridines readily isomerise in the presence of sodium iodide to a product formed as a result of the expansion of one of the aziridine rings[71,72]:



The reaction takes place quantitatively in 30 min at room temperature. The high reactivity of the bisaziridine can be explained by the high polarisation of the thiocarbonyl group in which the charge is delocalised between both aziridine nitrogen atoms:

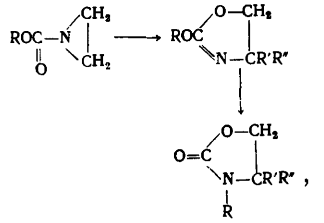


1-Nitroamidinoaziridines, obtained by the reaction of 2-methyl-1-nitro-2-thiopseudourea with aziridine and its 2-methyl derivative are examples of aziridines capable of isomerisation reactions[73]. In an acid medium the compounds isolated were converted into alkylnitroguanidines, while their cyanobromination leads to the formation of five-membered heterocycles—3-cyano-2-imino-1-nitro-imidazolidine (XLII) and 2-amino-1-nitroimidazolidinium bromide (XLIII)—in high yields. The cyanobromination of 1-nitroamidinoaziridine evidently takes place via the intermediate formation of *N*-(2-bromoethyl)-*N*-cyanonitroguanidine, which cyclises by an S_N2 mechanism with formation of compound (XLII) in 43% yield. The hydrogen bromide evolved reacts with aziridine to form 2-bromoethyl-3-nitroguanidine, which readily cyclises to compound (XLIII) in 41% yield.



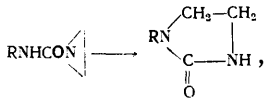
(XLII)

The aziridine derivatives of formic acid isomerise to oxazoline and oxazolidinone derivatives[74]. In this case the catalyst is sodium iodide in an aprotic solvent; an increase in the relative amount of sodium iodide in the initial mixture of reactants in excess of 0.1 mole leads to a decrease of the yield of the isomerisation products:

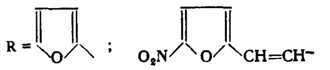


where R′ = R″ = H or R, R′, and R″ are hydrocarbons with more than 8 carbon atoms.

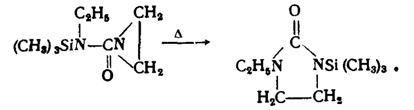
Japanese investigators[75] observed the isomerisation of *N*-[*β*-(5-nitro-2-furyl)vinyl]- and *N*-(2-furyl)-ethyleneureas at room temperature in acetone or acetonitrile solution in the presence of sodium iodide. The structure of the imidazolidin-2-ones formed in 85–90% yield was demonstrated by analyses, infrared spectroscopy, and syntheses. The mechanism of the rearrangement is consistent with that described previously:



where

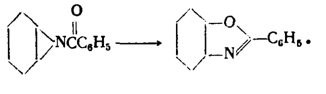


The aziridine ring-expansion reaction has been observed for ethyleneureas containing silicon atoms together with the aziridine ring[76]. *N*-Silylaziridines were obtained by the reaction of aziridine and trimethylchlorosilane. Their subsequent reaction with isocyanates leads to the formation of *N*-silylethyleneureas, which form imidazolidine derivatives of silicon on heat treatment:

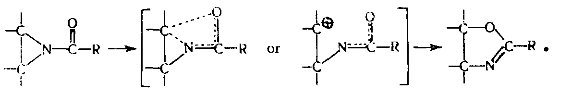


The structure of the imidazolidinones isolated was demonstrated by NMR spectroscopy, solvolysis of the product at the Si–N bond, and infrared spectroscopy of the decomposition products.

Many compounds, which readily isomerise under the influence of nucleophilic catalysts, undergo pyrolytic isomerisation to the corresponding ring-expansion products. Thus Gabriel[28] noted that redistilled 1-benzoylaziridine is converted on heating in a sealed tube to 240°C into 2-phenyl-Δ^2-oxazoline. The pyrolysis of *N*-benzoyl-*cis*-cyclohexeneimine leads to *trans*-4,5-tetramethylene-2-phenyl-Δ^2-oxazoline in 20% yield[59]:

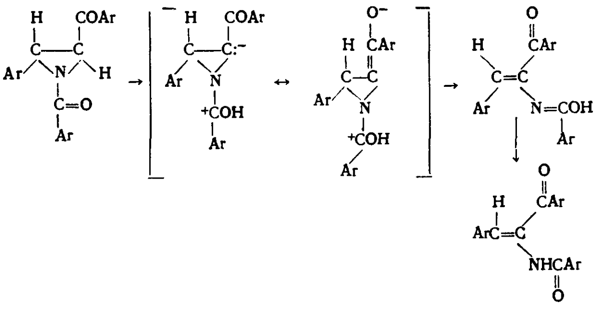


The thermolysis of the corresponding *cis*- and *trans*-1-(*p*-nitrobenzoyl)-2,3-diphenylaziridines leads to the *cis*- and *trans*-derivatives of oxazoline[66]. The mechanism of the pyrolytic isomerisations to oxazolines probably includes a four-centre displacement[59] or the intermediate contraction of the ion pair[67]:



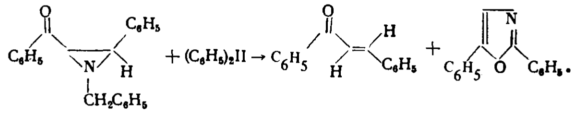
The study of the pyrolytic isomerisation of 1-acylaziridines taking into account stereochemical and kinetic data[66,77] led to the hypothesis that this intramolecular rearrangement consists of *cis*-elimination, including the displacement of the proton from the alkyl group to the amide oxygen. This displacement is impossible in the absence of an alkyl group at an aziridine carbon atom in 1-aroylaziridines or in the presence of steric factors preventing the formation of a bond between the amide oxygen and a proton.

On heating in boiling xylene, 1,3-diaroyl-2,3-arylaziridines[66] are converted into *α*-benzamidobenzoylacetophenone. In this case oxazolines are not formed, since there is a possibility of the displacement of the acid aziridine hydrogen atom to the amide oxygen atom and a reaction involving the dissociation of the carbon–nitrogen bond of the ring:

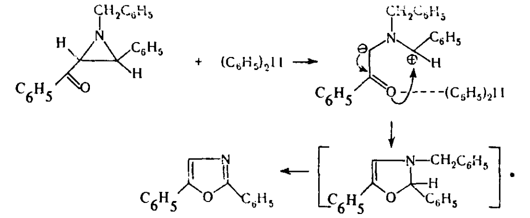


The isomerisation of aziridine derivatives involving the dissociation of the C–C bond of aziridine is known[78-81]. *trans*-3-Benzoyl-1-benzyl-2-phenylaziridine is converted into *trans*-benzylideneacetophenone (73% yield) and

2,5-diphenyloxazole (7% yield) on heating with diphenyliodonium iodide:



The following mechanism has been proposed for the isomerisation of aziridines to ring-expansion products[79]:

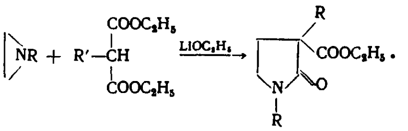


Diphenyliodonium iodide behaves as a Lewis acid and interacts with the C=O group, protonating the aziridine ring. The reaction of diphenyliodonium iodide with 2-benzoylaziridine yielded 2,5-diaryloxazoles and *αβ*-substituted ketones[80]. The aziridine ring-expansion product was not isolated when the reaction was carried out in anhydrous acetone and therefore the possibility of the formation of 2,3-dihydro-oxazoles cannot be explained, like the isomerisation of *N*-aroylaziridines, by the Heine mechanism. One of the possible mechanisms involves the interaction of diphenyliodonium iodide with the carbonyl group of the aziridine substituent and the dissociation of the aziridine C–C bond.

3. Interaction of Aziridines with Malonic Ester

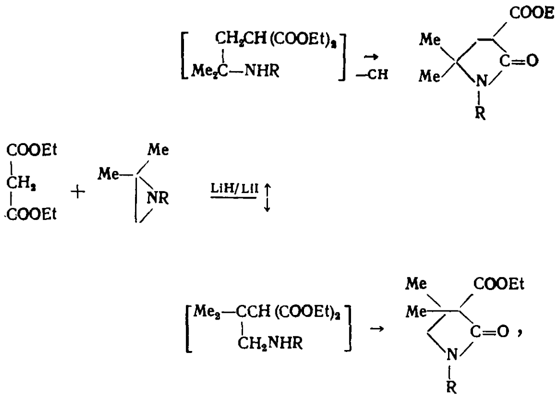
The reaction of aziridines with malonic ester leads to the formation of ring-expansion products—substituted pyrrolidinones. The first step in this reaction is aminoethylation, the subsequent intramolecular cyclisation with elimination of alcohol leading to the formation of pyrrolidinone derivatives.

In the reaction of *N*-phenylaziridine with malonic ester in the presence of lithium ethoxide, 3-ethoxycarbonyl-1-phenylpyrrolidin-2-one is formed[82,83]:



The reaction of 1-(*β*-phenylethyl)aziridine was carried out similarly[85]. In the presence of an excess of malonic ester aziridine is protonated. Under the influence of the enolate of malonic ester, the occurrence of competing processes is possible: *N*-alkylation (dimerisation of aziridine) and *C*-alkylation—formation of 3-ethoxycarbonyl-1-phenylethyl-pyrrolidin-2-one in 30% yield.

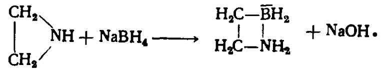
When malonic ester was heated with 2,2-dimethyl-1-(*β*-phenylethyl)aziridine in benzene[85] in the presence of LiH and LiI, 2-ethoxycarbonyl-5,5-dimethyl-1-(*β*-phenylethyl)pyrrolidin-2-one was isolated and then converted by alkaline hydrolysis into 5,5-dimethyl-1-(*β*-phenylethyl)-pyrrolidin-2-one:



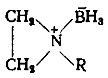
where R = $C_6H_5CH_2CH_2$.

Analysis and the NMR spectra led to the conclusion that the interaction of asymmetric aziridines with malonic ester involves an unsubstituted carbon atom with subsequent cyclisation to pyrrolidinone derivatives.

Earlier it was reported that unsubstituted aziridine reacts with sodium borohydride to forma four-membered heterocycle[86]:



Later investigations of this reaction confirmed the formation of aziridine salts (aminoboranes) in this process[87]:



---o0o---

Whilst the present review was in the press, a paper dealing with the isomerisation of 1-(*p*-nitrobenzoyl)-2-vinylaziridine to a seven-membered derivative was published[88].

Acyl Isocyanates

K.A.Nuridzhanyan

The methods of preparation and the reactions of acyl isocyanates are considered. The bibliography includes 197 references.

CONTENTS

I. INTRODUCTION

The advances in the chemistry of organic isocyanates have been reviewed fairly regularly[1-5] but these reviews dealt only with aryl and alkyl isocyanates. Recently new classes of compounds in which the isocyanate group is linked to silicon[6,7], phosphorus[6,8-13], difluorophosphoryl, fluorocarbonyl[14] and thioacyl[15-20], sulphonyl[21], etc. groups have been discovered and their properties investigated. The chemistry of each of these classes of isocyanates is fairly specific and requires a separate review. A recent review dealing with the chemistry of acyl and sulphonyl isocyanates, isothiocyanates, and isoselenocyanates[22] emphasises the similarity of the properties and not the specific features of the individual classes of isocyanates. Consequently reviews of such general type and those on specific branches of the chemistry of isocyanates are not mutually exclusive, supplementing one another. The inevitable repititions can be justified in each case by a new approach to the analysis of the literature data and new conclusions.

Such a special review on the chemistry of sulphonyl isocyanate was published recently[21] but the advances in the chemistry of acyl isocyanates have not as yet been reviewed.

Acyl isocyanates were obtained for the first time in 1862 by Schützenberger[23,24], i.e. 13 years after Würtz's discovery of organic isocyanates[24]; however, convenient methods for their synthesis became available only recently[26], which stimulated more extensive studies on these compounds.

Acyl isocyanates are chemically more reactive than the widely known[2,3] isocyanic acid esters. The presence of the additional acyl carbonyl group R–CONCO not only increases the reactivity but is also responsible for the ability of these compounds to undergo various reactions involving the formation of heterocycles.

In view of the above considerations, the author assumed that the present review, which deals with the syntheses, properties, and applications of acyl isocyanate and covers the literature up to January 1st, 1968, will be of interest and will stimulate further development of the chemistry of this interesting class of organic compounds.

II. METHODS OF SYNTHESIS OF ACYL ISOCYANATES

The available methods for the preparation of acyl isocyanates can be divided into two types: syntheses where the NCO group is already present in the starting materials and syntheses where it is produced in the course of the reaction.

1. Synthesis by the Reaction of Carboxylic Acid Chlorides with Cyanate Salts

Acetyl isocyanate, together with acetonitrile, was obtained by the reaction of silver cyanate[23,24] or mercury fulminate[27] with acetyl chloride. Under the same conditions, the reaction of silver cyanate and benzoyl chloride yields only benzonitrile[23]. The reaction of mercury fulminate with benzoyl chloride[28,29] or of silver fulminate with benzoyl bromide[30] followed by treatment of the reaction products with water led to the isolation of dibenzoylurea and a product melting at 107°C[28,29], which eventually proved to be (not until 1954) 3, 5-diphenyl-1, 2, 4-oxadiazole[31].

Acetyl and benzoyl isocyanates were obtained in a pure form for the first time in 1903 by slow addition of silver cyanate to an excess of the chloride of the corresponding acid with rapid distillation of the isocyanate produced[32,33].

Billeter's method[32,33] was subsequently improved by Hill and Degnan[34-36] and then by Areus and Prydol[37,38] and until 1962 remained virtually the only method for the synthesis of acyl isocyanates[31,39-42]. In 1963 Steyermark proposed a more convenient method for the preparation of acyl isocyanates by the reaction of carboxylic acid halides with cyanic acid in the presence of organic bases. The yield of acyl cyanates reaches 90%, but in a number of cases the process is complicated by the formation of polymeric products[43,44].

2. The Reaction of Phosgene and Phosgene-Forming Compounds With Acid Amides

The first attempts to prepare acyl isocyanate from carboxylic acid amides were unsuccessful[45-47]. Later, Waltmann and Wolf[48-51] shows that in an autoclave at 150°C a mixture of the amide and phosgene or trichloromethyl formate and other phosgene-forming compounds (among which oxalyl chloride may also be included[52]) in the presence of pyridine forms acylcarbamoyl chloride, which on heating in benzene with calcium oxide yields acyl isocyanate. However, this method did not become as important in the synthesis of isocyanates as the reaction of amines with phosgene[2,3].

The reaction of acid amides with oxalyl chloride proved to be more promising for the synthesis of acyl isocyanates[26,47,53-70]:

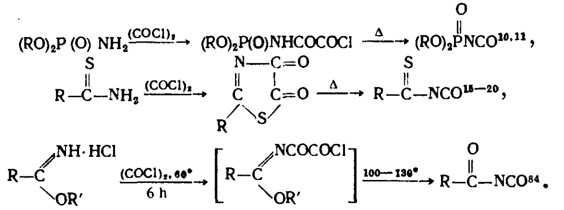
$$RCONH_2 + (COCl)_2 \xrightarrow{-2HCl, -CO} RCONCO.$$

The effect of oxalyl chloride on amides was investigated even earlier[71]: with a 1:2 reactant ratio, diacylurea was obtained[47,71,72], the thermal decomposition of which resulted in the formation of an amide, diacetamide, a nitrile, cyanuric acid, and carbon dioxide[73], while with a 1 : 1 reactant ratio the products were 2-alkylideneoxazolidine-4, 5-dione[47,74–78] and others.

Speziale and Smith[26,47,55] showed that, when the products of the reaction of oxalyl chloride with amides are subjected to thermal decomposition in a vacuum at fairly low temperatures with simultaneous distillation of the decomposition products, aroyl isocyanates are obtained in high yields. The yield of aliphatic acyl isocyanates is usually lower, and in the case of propionyl isocyanate it amounted to only 0.8%[55].

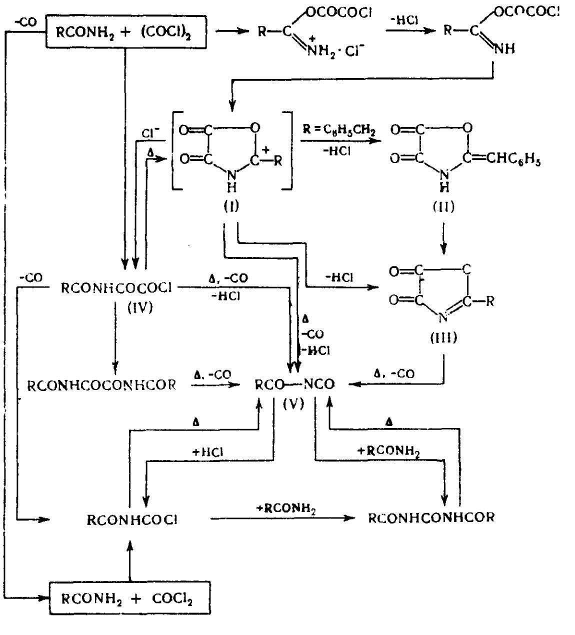
The above method of preparation of aroyl isocyanates was improved by Neidlein[70]. After these investigations, there was a considerable increase of interest also in the chemistry of oxalyl chloride[79–82], which was successfully used in the synthesis of other classes of acyl isocyanates:

$$RSO_2NH_2 \xrightarrow{(COCl)_2} RSO_2NHCOCOCl \xrightarrow{\Delta} RSO_2NCO^{83},$$



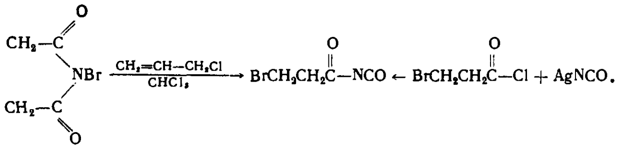
In the reaction of oxalyl chloride with carboxylic acid amides an *O*-aclyation product is probably formed initially and is then converted, with elimination of HCl and CO, either via the intermediate formation of compounds (II), (III), or (IV) or directly, into the acyl isocyanate (V). The low yield of alkanoyl isocyanates compared with that of aroyl isocyanates can probably be accounted for by the different stabilities of compounds (I). By analogy with 2-alkylideneoxazolidine-4, 5-dione[76], aryl-containing compounds (I) are more resistant to attack by the chloride ion than their alkyl analogues (Scheme 1)[68].

Scheme 1



For this reason the aryl compound decomposes only on heating in a vacuum and compound (V) is formed in a high yield. The alkyl derivative of compound (I) decomposes already under the reaction conditions with formation of compound (IV), which then enters into a number of side processes (Scheme 1)[66].

The method of preparation of β-bromopropionyl isocyanate by the rearrangement of *N*-bromosuccinimide is in a class by itself[85–88]:



The reaction takes place only in the presence of chloroform or bromoform and certain halogeno-olefins (allyl chloride and bromide, methylallyl chloride, 2, 3-dibromopropene, 3-bromo-2-t-butylpropene) in the presence of benzoyl peroxide. In the presence of crotyl bromide, 1-bromopropene, $\alpha\alpha\alpha$-trichlorotoluene, and a number of other olefins the reaction does not occur. The maximum yield of β-bromopropionyl isocyanate (70%) is attained on refluxing in chloroform for 4 h equimolar amounts of *N*-bromosuccinimide, allyl chloride, and a catalytic amount of benzoyl peroxide[88]. The product was also isolated in 16% yield in the photochemical bromination of 1, 4-*endo*-oxocyclohexane with *N*-bromosuccinimide in carbon tetrachloride. The reaction is of a radical type; this type of rearrangement does not occur with either chloro- or iodo-succinimides[86].

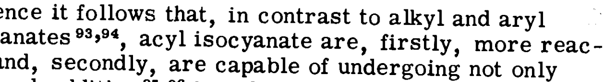
III. PROPERTIES OF ACYL ISOCYANATES

1. Physical Properties

Acyl isocyanates are colourless or yellowish liquids or low-melting solids which can be distilled in a vacuum. They have a sharp odour, and are readily hydrolysed by atmospheric moisture; they dissolve in the majority of organic solvents. Their infrared spectra[89,90] contain absorption bands at 2244 ± 1 cm^{-1} (asymmetric vibrations of the O=C=N group) and 1430 cm^{-1} (symmetrical vibrations of the O=C=N group); the bands at 1740 and 1050 cm^{-1} correspond to the vibrations of the C=O and C−N bonds in the group R−C(O)−N=; the bands due to the deformation vibrations of O=C=N and NC=O groups are located respectively at 632 and 570 cm^{-1}.

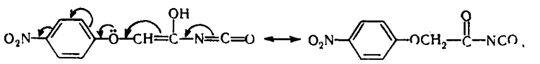
2. Chemical Properties

The characteristic features of the chemical properties of acyl isocyanates are a result of the charge and electron density distribution in the group CONCO, which may be described by the resonance of the following valence structures[91,92]:



$$R-\overset{\overset{O}{\|}}{C}-N=\overset{+}{C}-\bar{O} \leftrightarrow R-\overset{\overset{O^-}{|}}{C}=N-\overset{+}{C}=O \leftrightarrow R-\overset{\overset{O}{\|}}{C}-N=C=O \leftrightarrow R-\overset{\overset{O}{\|}}{C}-\bar{N}-\overset{+}{C}=O.$$

Hence it follows that, in contrast to alkyl and aryl isocyanates[93,94], acyl isocyanate are, firstly, more reactive and, secondly, are capable of undergoing not only 1, 2-cycloaddition[95,96] but also 1, 4-cycloaddition[91,92,97–99] reactions. In some cases the presence of the acyl group may be the cause of other more special properties of acyl isocyanates. Thus the surprisingly effective transmission of the influence of substituents on the reactivity of aryloxyacetyl isocyanates may be accounted for by the possibility of their tautomerism[68]:

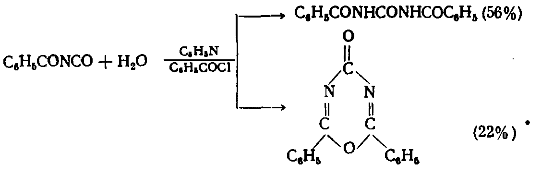


which evidently cannot occur in the case of aryloxyethyl isocyanates.

A. Reactions at Oxygen–Hydrogen and Sulphur–Hydrogen Bonds

The reaction with water of acetyl isocyanate[27], β-bromopropionyl isocyanate, etc.[85,86] yields the corresponding amides and carbon dioxide, the conversion of benzoyl isocyanate being to the extent of 75% into the amide and to the extent of 25% into dibenzoylurea[32].

In 1*N* sodium hydroxide solution benzoyl isocyanate forms only benzamide[37], while in a mixture with aqueous pyridine and benzoyl chloride it gives 56% of dibenzoylurea and 22% of 4-oxo-2,6-diphenyl-1,3,5-oxadiazine[31]. The last product is formed also under anhydrous conditions when the reaction is catalysed by an *N*-substituted pyridinium salt[92,100].



Acids react with acyl isocyanates with much greater difficulty. Thus the reaction with dialkyl phosphites takes place only in the presence of sodium ethoxide or catalytic amounts of triethylamine at 80–90°C over a period of 4 h.[101] The reaction of hydrogen chloride with acyl isocyanates gives the corresponding acylcarbamoyl chlorides[27,48-51].

The reaction of alcohols with acyl isocyanates has been most thoroughly investigated. It has been shown that they react more vigorously than phenols[66], giving good yields of acyl carbamates[26,27,32,38,55-57,60,64,66,68,85,88,101-104].

Polyhydric alcohols form with acyl isocyanates products corresponding to different degrees of addition—monoacyl, diacyl, etc. carbamates[88,102,105,106].

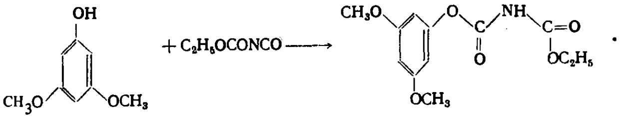
It has been erroneously assumed that the reaction of acetyl isocyanate with glycol gives a bis-addition product, while benzoyl isocyanate forms only the monoaddition product even when present in an excess. Later it was shown[106] that, regardless of their structure, acyl (and aroyl) isocyanates react with polyhydric alcohols to form as a rule polyaddition products, while with phenols monoaddition products are obtained. Thus, regardless of their structure, the reactant ratio, and the presence or absence of water in the reaction medium, the reaction of acyl (and aroyl) isocyanates with glycerol yields only products of addition to all three hydroxy-groups. Monoaddition could be achieved only by the action of 2,4-dichlorophenoxyacetyl isocyanate on isopropylidene-glycerol with subsequent ethanolysis of the product[106].

The presence in the alcohols of other functional groups—halogen atoms[55,57,66,88,102,105,107] and nitrile[88,102], carbonyl[88], carboxy-[102], dimethylamino-[57], xanthogenyl and dithiocarbamoyl groups[107,108], or unsaturated carbon–carbon bonds[55,57,66,88,102]—does not usually alter the normal course of their addition to acyl isocyanates.

However, if the alcohol molecule contains another functional group where the electron density at the constituent atom is higher than at the oxygen atom, for example NH_2, then the acyl isocyanate reacts preferentially with this group rather than with the hydroxy-group. The reaction with ethanolamine takes place stepwise in this way[39,105,106]:

$$HOCH_2CH_2NH_2 \xrightarrow{RCONCO} RCONHCONHCH_2CH_2OH \xrightarrow{RCONCO} RCONHCONHCH_2CH_2OCONHCOR\,.$$

Alkoxycarbonyl isocyanates react with 3,5-disubstituted phenols in two ways, depending on the electron-donor properties of the substituents: if the substituents are powerful donors (R_2N), then the isocyanate adds to a carbon atom of the aromatic ring (see Russ. p. 133), but if their electron-donor properties are less pronounced (OCH_3), then normal addition to the OH group takes place[109]:



Oximes, which are more basic than phenol[110], react with acyl isocyanates just as vigorously as alcohols and at room temperature form as a rule stable crystalline acyl carbamoyloxyoximes[111-113]:

$$\rangle C{=}N{-}OH + RCONCO \xrightarrow{20^\circ} RCONHCOON{=}C\langle\ .$$

However, the corresponding derivatives of acetaldoxime can be obtained only at 0°C, since at 20°C they readily decompose[111].

The reactivity of oximes depends to a considerable degree on the steric configuration of the substituent in the *cis*-position relative to the hydroxy-group and to a lesser extent on the bulk of the *trans*-substituent and the electronic effects of the substituents. For this reason, ketoximes are less reactive than aldoximes and among the latter the *syn*-isomer is the more reactive[112].

The reaction of acyl isocyanates with *syn*- and *anti*-benzaldoximes yields only *syn*-acylcarbamoylbenzaldoxime[111].

Mercaptans react with acyl isocyanates less vigorously than their oxygen analogues, forming the corresponding thiolocarbamates[26,56,58,66]:

$$R{-}SH + R'CONCO \xrightarrow{20^\circ} R'CONHCOSR\,.$$

The reaction of terephthaloyl di-isocyanate with thiophenol yields terephthaloyl bis(phenylthiolocarbamate)[98].

B. Reactions at Nitrogen–Hydrogen Bonds.

Ammonia and primary and secondary amines react vigorously with acyl isocyanates at room temperature with formation of the ureides of the corresponding acids[26,32,38,39,42,57,68,84,85,88,101,103]. With increase of the basicity of the amines, their reactivity also rises[67,68].

By virtue of the exceptional ease and completeness of this reaction, it is frequently used to identify new acyl isocyanates[27,43,47,56,59]. Bis-acyl isocyanates also react readily with amines[98].

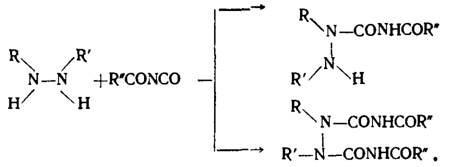
Polyfunctional compounds containing, apart from the amino-group, multiple bonds[68] and HO,[39,105,114] NO_2,[67,114] Me_2N,[67] COOEt, COOH,[114] and other groups form primarily ureides. When the molecule contains two amino-groups or an amino-group and a hydroxy-group, initially one NH_2 group reacts completely[39,106], and then, in the presence of an excess of acyl isocyanate, addition to the second NH_2 or OH group takes place[105,106,114].

Hydroxylamine and its derivatives react with acyl isocyanates in the same way as other amino-alcohols with formation of hydroxy- or alkoxy-ureas[40,62,69,114]:

$$RO{-}NH_2 + R'CONCO \rightarrow RONHCONHCOR'.$$

The reaction takes place readily not only with the free bases[62,69,114] but also with hydroxylammonium salts in the presence of pyridine[40].

Like other diamines[32,105,114], *hydrazine and its derivatives* can react with acyl isocyanates to form two series of compounds[32,38,61,115,116]:



However, the mode of reaction depends little on the reactant ratio; the decisive factors here are the nature of the acyl isocyanate and the substituents and the nitrogen atoms of the hydrazine. Hydrazine hydrate contains two equivalent (as regards nucleophilic properties) nitrogen atoms and therefore its reaction with benzoyl isocyanate yields only 1, 6-dibenzoylurea[38].

The basicities of the two nitrogen atoms in arylhydrazines are not the same and therefore the nitrogen atom furthest removed from the aryl group enters into the reaction[38].

The structure of 4-benzoyl-1-phenylsemicarbazide obtained for the first time in this way by Billeter[32] was subsequently demonstrated by Arcus and Prydal[38], who showed at the same time that 4-nitro- and 2, 4-dinitrophenylhydrazines also react. The reaction with terephthaloyl di-isocyanate takes place similarly but involves two isocyanate groups[98].

Thus aroyl isocyanates[32,38,98] form with hydrazine monoaddition products. In contrast to them, acyl isocyanates tend to form diadducts[32,61,69,115,116].

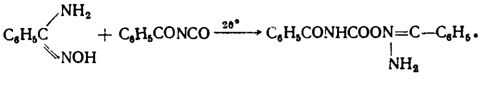
However, α-halogenoacyl isocyanates react with phenyl- and 4-nitrophenyl-hydrazines to form both di- and monoaddition products, the yield of which varies with the reaction ratio[115].

The more reactive aryloxyacetyl isocyanates readily form in high yields (similarly to aroyl isocyanates) predominantly monoadducts with phenyl- and 4-nitrophenylhydrazines[61,69]. In contrast to the latter, the reactions with 2, 4-dinitrophenylhydrazine of all acyl isocyanates, regardless of their structure, result only in monoaddition products[115].

The reaction of aldehyde and ketone hydrazones with acyl isocyanates in molar proportions of 1 : 1 results in ready formation of the corresponding 4-acylsemicarbazones[117,118] and the reaction in proportions of 2 : 1 yields of diadducts, which probably have the structure of 3-alkylideneamino-1, 5-diacylbiuret[119]:

$$R_2C{=}NNH_2 + 2R'CONCO \rightarrow R'CONHCO\underset{\displaystyle N{=}CR_2}{N}CONHCOR'.$$

Initially it was postulated that the reaction of acyl isocyanates with *amidoximes* results in the formation of *N*-(acylcarbamoyl)amidoximes[120], but NMR and infrared spectroscopic measurements showed that the addition is exclusively to the oxygen atom:



$$C_6H_5C\begin{matrix}\nearrow NH_2\\ \searrow NOH\end{matrix} + C_6H_5CONCO \xrightarrow{20^\circ} C_6H_5CONHCOON{=}\underset{\displaystyle NH_2}{C}{-}C_6H_5.$$

Acyl isocyanates react with *acid amides* with greater difficulty than with the compounds examined above, containing N–H, O–H, or S–H bonds. The reaction takes place on heating and leads to the formation of the corresponding diacylureas[27,28,30,32,45,71,121-123].

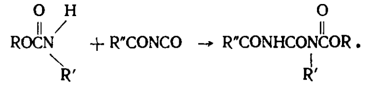
Sulphonamides form with acyl isocyanates *N*-sulphonyl-*N′*-acylureas[32,124]:

$$R{-}SO_2NH_2 + R'CONCO \rightarrow R'CONHCONHSO_2R.$$

The reaction of *thiobenzamide* and benzoyl isocyanate on refluxing in benzene yields *N*-benzoyl-*N′*-thiobenzoylurea[125]:

$$C_6H_5\overset{\displaystyle S}{\overset{\|}{C}}{-}NH_2 + C_6H_5CONCO \rightarrow C_6H_5CONHCONH{-}\overset{\displaystyle S}{\overset{\|}{C}}{-}C_6H_5.$$

Carbamates react with acyl isocyanates more readily than carboxylic acid amides, forming in all cases, in contrast to aryl isocyanates[126-128], the corresponding acyl allophanates[61,69,114,129]:



$$RO\overset{\displaystyle O}{\overset{\|}{C}}N\begin{matrix}\nearrow H\\ \searrow R'\end{matrix} + R''CONCO \rightarrow R''CONHCO\underset{\displaystyle R'}{N}\overset{\displaystyle O}{\overset{\|}{C}}OR.$$

Ureas[35] *and thioureas*[36] react with acyl isocyanate, forming respectively acylbiurets and acylthiobiurets[33-36,39].

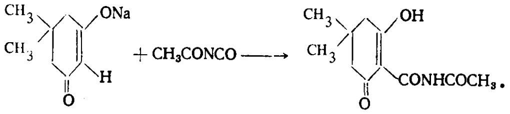
Hydrazoic acid reacts vigorously with acyl isocyanates giving high yields of acylcarbamoyl azides which are stable at room temperature[130,131]:

$$N{\equiv}N{=}N{-}H + RCONCO \rightarrow RCONHCON_3.$$

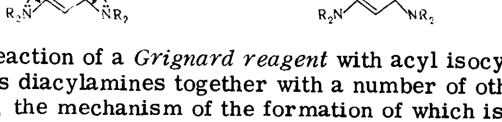
The reaction with terephthaloyl di-isocyanate takes place similarly[98].

C. Reactions at Carbon–Hydrogen Bonds and with Grignard Reagents

The carbon–hydrogen bond can be readily involved in the reaction with acyl isocyanates if the electron density at the carbon atom is sufficiently high. This reaction usually gives acylamides[109,132]. Thus in the synthesis of tetracycline an acetylcarbamoyl substituent was introduced into dimedone with the aid of acetyl isocyanate[132]:



Ethoxycarbonyl isocyanate enters into a similar reaction with somewhat greater difficulty[132]. Thus the reaction with 3, 5-di(dialkylamino)phenol yields 2, 4-dialkylamino-6-hydroxybenzoyl carbamates[109]:



The reaction of a *Grignard reagent* with acyl isocyanates also gives diacylamines together with a number of other products, the mechanism of the formation of which is still obscure[133]:

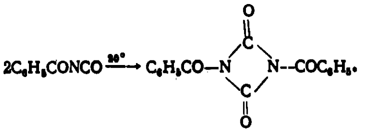
$$\begin{aligned}RMgX + C_6H_5CONCO \xrightarrow{20^\circ} C_6H_5CONHCOR + C_6H_5COR + C_6H_5CONHCONHCOC_6H_5 +\\ + C_6H_5CONHCONH_2 + C_6H_5CONH_2 + C_6H_5CONHCOC_6H_5.\end{aligned}$$

The composition of the reaction products depends on the ratio and order of addition of the starting materials and the nature of the organic group and the halogen in the organomagnesium compound.

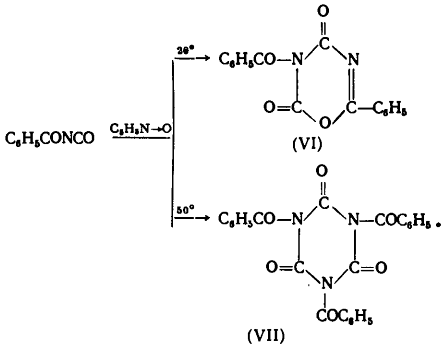
D. 1,2- and 1,4-Cycloaddition Reactions

a. Dimerisation and trimerisation of acyl isocyanates. Both 1,2- and 1,4- cycloaddition reactions are characteristic of acyl isocyanates[99] and therefore in the presence of the usual catalysts for the polymerisation of isocyanates (pyridine[134], triethylamine[135], and others) two series of dimers and the corresponding trimers are formed[92,98,100].

By treating benzoyl isocyanate with pyridine, Neidlein[98] obtained 82% yield of the benzoyl isocyanate dimer (1,3-dibenzoyluretidine-2,4-dione):

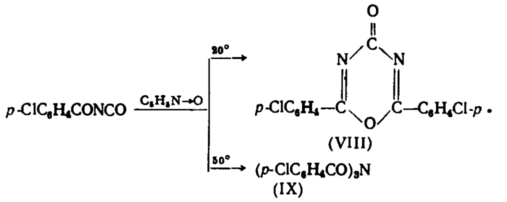


By the action of pyridine 1-oxide on benzoyl isocyanate at 20° and 50°C, Tsuge and Mizuguchi[92,100] obtained respectively the isomeric dimer [5-benzoyl-4,6-dioxo-2-phenyl-1,3,5-oxadiazine (VI)] and trimer [tribenzoyl isocyanurate (VII) (m.p. 162°C)]:



(VI)
(VII)

The polymerisation reaction is influenced not only by temperature but also by the nature of the catalyst and the substituent in the benzene ring[92,100]. Thus when p-chlorobenzoyl isocyanate is treated with pyridine 1-oxide at 20°C, the product is 2,6-di-(p-chlorophenyl)-4-oxo-1,3,5-oxadiazine (VIII), while at 50°C tri-(p-chlorobenzoyl)amine (IX) is formed:



(VIII)
(IX)

Similarly at 50°C p-nitrobenzoyl isocyanate yields tri-(p-nitrobenzoyl)amine together with a small amount of 2,6-di-(p-nitrophenyl)-4-oxo-1,3,5-oxadiazine.

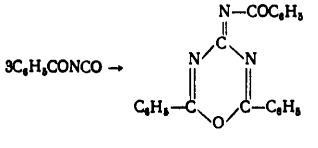
In the presence of tin tetrachloride benzoyl and p-methoxybenzoyl isocyanate are converted into the corresponding trimers.

Triethylamine converts benzoyl isocyanate at 50°C into the dimer (VI); at 80°C 2,4-diphenyl-6-oxo-1,3,5-oxadiazine is formed together with a small amount of tribenzoylamine and triphenyl-*s*-triazine.

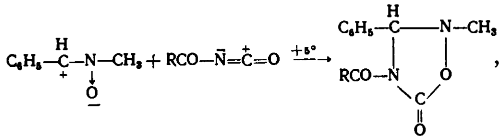
Under these conditions, p-methoxybenzoyl isocyanate forms a trimer and p-chloro- and p-nitro-benzoyl isocyanates are converted into the corresponding 6-oxo-1,3,5-oxadiazines.

Regardless of the nature of the substituent in the acyl isocyanate, N-substituted pyridinium salts in all cases lead to the formation of the same products—2,6-diaryl-4-oxo-1,3,5-oxadiazines[92,100].

Phospholen oxides convert benzoyl isocyanate into 4-benzamido-2,6-diphenyl-1,3,5-oxadiazine[136]:



b. 1,2-Cycloaddition reactions. The reaction of *N-methyl benzaldoxime* with acyl isocyanates yields 1,2-cycloaddition products—4-acyl-2-methyl-3-phenyl-1,2,4-oxadiazolidin-5-one[95,99]:



where R = C_6H_5 or CH_2Cl.

Carbodi-imides add to benzoyl isocyanate with formation of 1-benzoyl-4-phenylimino-1,3-uretidin-2-one[95,99]:

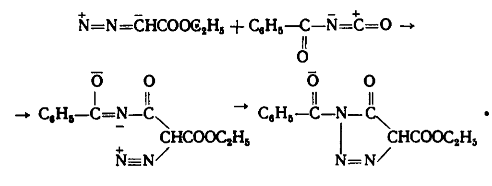
$$RN{=}C{=}NR + C_6H_5CO{-}\bar{N}{=}\overset{+}{C}{=}O \rightarrow \begin{array}{l} RN{=}C{-}NR \\ C_6H_5CON{-}C{=}O \end{array},$$

where R = C_6H_5 or C_6H_{11}.

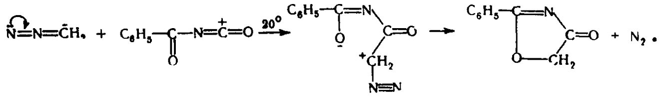
1,3-Dienes (butadiene, isoprene, 2,3-dimethylbutadiene, cyclopentadiene, etc.) react with acyl isocyanates similarly to carbodi-imides, forming the corresponding β-lactams[96]:

$$CH_2{=}CH{-}CH{=}CH_2 + C_6H_5CONCO \xrightarrow{0-40^\circ} \begin{array}{l} CH_2{=}CH{-}CH{-}CH_2 \\ C_6H_5CON{-}C{=}O \end{array}.$$

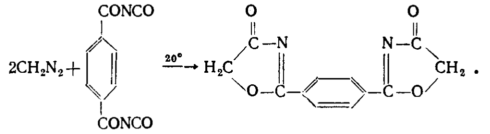
Diazoacetic ester, which may be regarded as a 1,3-dipole, forms with benzoyl isocyanate the ethyl ester of 1-benzoyl-5-oxotriazole-4-carboxylic acid. Probably the reaction takes place in two stages: initially an adduct is formed, which then undergoes intramolecular cyclisation[91]:



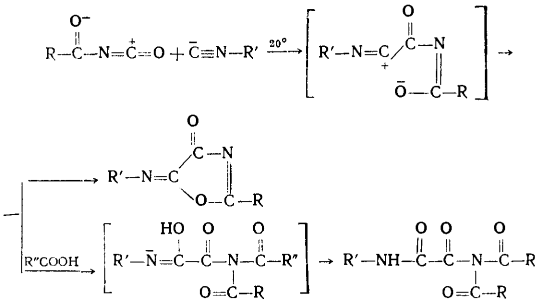
c. 1,4-Cycloaddition reactions. In contrast to diazoacetic ester, *diazomethane* reacts with benzoyl isocyanate as a 1,1-dipole[91], which results in the formation of 2-phenyl-4-oxazolone. Here too the initially formed adduct undergoes subsequently intramolecular cyclisation[97-99]:



Similarly the reaction of terephthaloyl di-isocyanate with diazomethane readily yields 1,4-di-(4-oxo-Δ^3-oxazolin-2-yl)benzene[98]:



Isonitriles, which are also 1,2-dipoles[91,99,137], react with acyl isocyanates to give 2-aryl(alkyl)-5-aryl(alkyl)-imino-oxazolin-4-ones. The reaction evidently takes place as in the preceding cases, via an intermediate adduct, which, in the absence of other reactants, undergoes subsequent intramolecular cyclisation[91]. However, when the reaction mixture contains an acid, the latter probably prevents the cyclisation of the intermediate, forming a second intermediate which is subsequently converted into a linear mixed amide[138]:

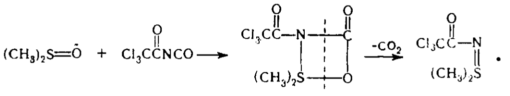


where R = R′ = R″ = C_6H_5 or C_6H_{11}.

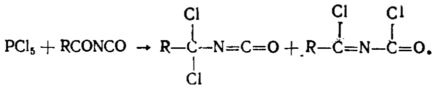
Di-isonitriles react similarly. 1,4-Di-isocyanobenzene and 1,4- and 1,3-di-isocyanocyclohexanes readily react with benzoyl isocyanate to form a mixture of the *cis*- and *trans*- isomers respectively of 5,5′-(*p*-phenylenedinitrilo)bis(2-phenyl-2-oxazolin-4-one and 5,5′-[1,3(or 1,4)-cyclohexylenedinitrilo)bis(2-phenyl-2-oxazolin-4-one[137].

E. Substitution Reactions

a. Reactions with elimination of CO from the isocyanate group. The reaction of *dimethyl sulphoxide* with dichloroacetyl isocyanate at 20°C in ether and with trichloroacetyl isocyanate (mixture refluxed in acetonitrile) gives high yields of the corresponding *N*-acylsulphimines[139]. By analogy with sulphonyl isocyanates[140], the reaction of acyl isocyanates probably takes place via 1,2-cycloaddition with subsequent elimination of carbon dioxide:



b. Reactions with elimination of an oxygen atom. *Phosphorus pentachloride chlorinates* acyl isocyanates in different ways depending on the nature of the acyl group, but this always involves only the elimination of one oxygen atom from the acyl carbonyl[141,142]. On prolonged heating with phosphorus pentachloride, mono-, di-, and tri-chloro acetyl isocyanates form a mixture of αα-dichloroalkyl isocyanate and α-chloroalkylidenecarbamoyl chloride:



$$PCl_5 + RCONCO \rightarrow RCCl_2-N{=}C{=}O + R-CCl{=}N-CCl{=}O.$$

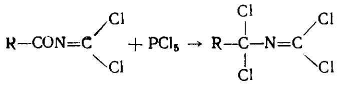
Under these conditions, benzoyl isocyanate yields only α-chlorobenzylidenecarbamoyl chloride[141,142]:

$$PCl_5 + C_6H_5CONCO \xrightarrow{132^\circ} C_6H_5-CCl{=}N-CCl{=}O.$$

More extensive chlorination of benzoyl isocyanate could not be achieved[141]. The dichlorides of *N*-acylisonitriles have been obtained by the chlorination of acyl isothiocyanates[141-146]:

$$RCONCO \not\rightarrow RCONCCl_2 \leftarrow RCONC(SCl)Cl \leftarrow RCONCS.$$

On heating with phosphorus pentachloride, the dichlorides yield products corresponding to more extensive chlorination of acyl isocyanates[141,142]:



$$R-CON{=}CCl_2 + PCl_5 \rightarrow R-CCl_2-N{=}CCl_2.$$

IV. APPLICATIONS OF ACYL ISOCYANATES

Higher (stearyl, palmityl, etc.) acyl isocyanates have been patented as agents for imparting water-repellent properties to textiles[48-51]. The possibility of using acyl isocyanates for the synthesis of polymers[147] and for the identification of alcohols[88] is being investigated. Acyl isocyanates are used in preparative organic chemistry for the synthesis of a wide variety of different classes of compounds: ureides[42,56,57,59,104,114,121-124,148], acyl carbamates[60,102,104,108,115,149-156], acyl thiolcarbamates[58,157], acylbiurets[34-36], acyl alkoxyureas[40,158], acyl allophanates[68,129], acylsemicarbazides[61,69,115], acylcarbamoyliminophosphoranes[130], *N*-alkylidene-1-aminohydantoins[117], 1,5-diaryl-3-hydroxy-1,2,4-triazoles[38], benzoxazines[109], and other heterocyclic compounds[108,159,160] with biological activity[148,150-156,161,162-179]. Halogenoacyl carbamates obtained in this way have been patented as stabilisers for photographic emulsions[104].

---o0o---

During the period when this review was being dealt with by the editors, the following papers were published.

1. *On the methods of preparation*: from oxalyl chloride and imino-esters[180,181] or chloroimino-esters[182] of carboxylic acids or the amides of chrysanthemic acid[183] and from trifluoroacetic anhydride and isocyanic acid[184].

2. *On chemical reactions*: with hydrazines[185,186], alcohols, mercaptans and amines[187-189], enamines[190], ethyleneimine[191], 2-aminothiazoles[192], *N*-(trimethylsilyl)-dialkylamines[193], hydroperoxides[194], substituted ketens[195], perchloric acid[196], and dienes[197].

Polymerisation of Allyl Compounds

V.I.Volodina, A.I.Tarasov, and S.S.Spasskii

The review deals with the advances in the theory of the formation of allyl polymers and their practical applications. Until recently there was only limited interest in allyl polymers because with the usual free-radical initiation allyl compounds polymerise with difficulty and yield polymers with a low molecular weight. The principal cause of the formation of low-molecular-weight polymers is degradative chain transfer to the monomer, as a result of which the kinetic chain is terminated. A property of the degradative chain transfer is the constancy of *dM/dP*, i.e. a linear relation between the amount of peroxide decomposed and the amount of monomer polymerised. In addition to degradative chain transfer, a characteristic feature of allyl monomers is effective chain transfer, which depends on the structure of the monomer.

The polymerisation of diallyl compounds has a cyclolinear mechanism, which leads to the formation of macromolecules with alternating cyclic and linear units.

The behaviour of allyl monomers in copolymerisation reactions is determined by their low reactivity compared with that of the majority of vinyl monomers. The chemical structure of allyl monomers does not as a rule have a significant influence on their reactivity.

In recent years polymers based on allyl monomers have found many applications in engineering. Copolymerisation with other monomers and polymers yielded materials with high mechanical strength, thermal and chemical stability, and good insulating and adhesive properties. They are used as fibres, films, coatings, optical glasses, binders for reinforced plastics, etc.

The bibliography includes 386 references.

CONTENTS

I. INTRODUCTION

Allyl polymers are obtained by the polymerisation and copolymerisation of allyl compounds, which are characterised by the presence of the allyl group $CH_2=CH-CH_2$. The name of these compounds arises from the fact that they are the principal component of the essential oil of garlic–diallyl sulphide.

In recent years there has been increased interest in allyl resins because of their exceptional physical and electrical properties. They have found extensive application in electronic and electrical engineering industries (insulators, connecting sleeves, gas-tight seals, etc.)[1]. The diallyl phthalate and diallyl isophthalate pre-polymers are thermosetting resins with thermal and chemical stability and exceptional insulating properties; articles made from them are characterised by their dimensional stability[2].

Reinforced materials based on these resins exhibit stability of mechanical strength in prolonged use over a wide range of temperatures and humidities[3].

There is a considerable promise of development for phosphorus-containing allyl polymers, which are used as fire-resistant materials[4].

Allyl monomers are used in coatings and copolymers based on them are used to improve the thermal stability and the resistance to wear of certain materials.

The above wide range of the applications of allyl polymers accounts for the interest in them. However, the extensive data and practical experience accumulated in recent years have not been reflected in Soviet reviews or monographs. Abroad there have also been very few such publications[1,5,6].

II. ALLYL POLYMERISATION

All known methods of initiation are used in the polymerisation of allyl compounds. However, the effectiveness of the initiating agents is not the same. In the presence of free-radical initiators, allyl compounds polymerise with difficulty and give polymers in low yields and with low molecular weights[7]. This applies to a lesser extent to diallyl compounds, which form three-dimensional structures even at relatively low conversions.

Ionic catalysts are more effective. In their presence certain allyl compounds form polymers with very high molecular weights.

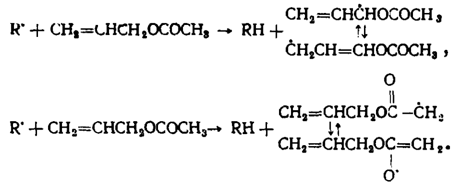
The use of γ-radiation also makes it possible to obtain allyl polymers with high molecular weights. For certain allyl monomers, this is the only method of polymerisation.

1. Radical Polymerisation

The same elementary steps are characteristic of the free-radical polymerisation of allyl and vinyl monomers, but for the former the chain transfer from the growing radical to the monomer leads not only to the termination of the growing radical but also to the cessation of the chain reaction. Bartlett, Gaylord, Eirich, Walling, and others[4,8-28] have investigated the mechanism and kinetics of the radical polymerisation of allyl compounds.

In the radical polymerisation of allyl monomers, benzoyl peroxide is most often used as an initiator. Gaylord, Nozaki, and others[23-25] showed that the decomposition of benzoyl peroxide in allyl alcohol, allyl bromide, and allyl esters is a first-order reaction, the rate constant of which increases with the initial concentration of the peroxide. The rate of decomposition of benzoyl peroxide in allyl esters is not the same, decreasing in the sequence allyl trimethylacetate > allyl propionate > allyl acetate > allyl ethyl carbonate.

In the initiation of the polymerisation of allyl acetate with benzoyl peroxide there is a possibility of the formation of two types of radicals, which are incapable of chain propagation because they are stabilised by conjugation[13]:



$$R^{\cdot} + CH_2{=}CHCH_2OCOCH_3 \rightarrow RH + \begin{matrix} CH_2{=}CH\dot{C}HOCOCH_3 \\ \uparrow\downarrow \\ \dot{C}H_2CH{=}CHOCOCH_3 \end{matrix},$$

$$R^{\cdot} + CH_2{=}CHCH_2OCOCH_3 \rightarrow RH + \begin{matrix} CH_2{=}CHCH_2O\overset{\overset{O}{\|}}{C}-\dot{C}H_2 \\ \downarrow\uparrow \\ CH_2{=}CHCH_2O\underset{\underset{O^{\cdot}}{|}}{C}{=}CH_2 \end{matrix}.$$

On this basis, Bartlett and Altschul[13] proposed a mechanism for the radical polymerisation of allyl monomers and found that the ratio of the amount of monomer consumed to the amount of benzoyl peroxide decomposed is constant. This discovery constituted an important milestone in the development of the theory of the radical polymerisation of allyl compounds. Later Gaylord and Eirich[25] gave a more complete polymerisation mechanism, for example with allyl acetate:

$$(C_6H_5COO)_2 \xrightarrow{k_1} 2C_6H_5COO^{\cdot}, \quad (1)$$

$$C_6H_5COO^{\cdot} + CH_2{=}CHCH_2OCOCH_3 \xrightarrow{k_a} C_6H_5COOCH_2\dot{C}HCH_2OCOCH_3, \quad (2)$$

$$C_6H_5COO^{\cdot} + CH_2{=}CHCH_2OCOCH_3 \xrightarrow{k_b} C_6H_5CH_2\dot{C}HCH_2OCOCH_3 + CO_2, \quad (3)$$

$$C_6H_5COO^{\cdot} + CH_2{=}CHCH_2OCOCH_3 \xrightarrow{k_c} C_6H_5COOH + CH_2{=}CH\dot{C}HOCOCH_3\ (r), \quad (4)$$

$$C_6H_5COO^{\cdot} + CH_2{=}CHCH_2OCOCH_3 \xrightarrow{k_d} C_6H_5COOH + CH_2{=}CHCH_2OCO\dot{C}H_2\ (\gamma), \quad (5)$$

$$R_n + CH_2{=}CHCH_2OCOCH_3 \xrightarrow{k_2} R_nCH_2\dot{C}HCH_2OCOCH_3, \quad (6)$$

$$R + CH_2{=}CHCH_2OCOCH_3 \xrightarrow{k_3} RH + CH_2{=}CH\dot{C}HOCOCH_3\ (r), \quad (7)$$

$$R + CH_2{=}CHCH_2OCOCH_3 \xrightarrow{k_4} RH + CH_2{=}CHCH_2OCO\dot{C}H_2, \quad (8)$$

$$r + r \xrightarrow{k_5} r - r, \quad (9)$$

$$\gamma + \gamma \xrightarrow{k_6} \gamma - \gamma, \quad (10)$$

$$r + \gamma \xrightarrow{k_7} r - \gamma. \quad (11)$$

Kinetic analysis of this mechanism led to an expression, which essentially confirms the finding of Bartlett and Altschul:

$$\frac{dM}{dP} = 2\left[1 + \frac{(k_2 + k_3 + k_4)(k_a + k_b)}{k^0 (k_3 + k_4)}\right] = \text{const},$$

where $k^0 = k_a + k_b + k_c + k_d$.

In the study of the polymerisation of allyl trimethylacetate the authors of this mechanism observed, and other investigators confirmed[11,14,26,28], that the kinetics of the polymerisation of certain allyl monomers are significantly affected by radical substitution reactions. Therefore, Gaylord and Eirich[25] modified the kinetic mechanism, replacing reactions (5), (8), (10), and (11) by others corresponding to a radical-substitution mechanism:

$$C_6H_5COO^{\cdot} + CH_2{=}CHCH_2OCOC(CH_3)_3 \xrightarrow{k_d'} CH_2{=}CHCH_2OCOC_6H_5 + (CH_3)_3CCOO^{\cdot}, \quad (12)$$

$$R + CH_2{=}CHCH_2OCOC(CH_3)_3 \xrightarrow{k_4'} CH_2{=}CHCH_2R + (CH_3)_3CCOO^{\cdot}, \quad (13)$$

$$(CH_3)_3CCOO^{\cdot} + CH_2{=}CHCH_2OCOC(CH_3)_3 \xrightarrow{k_{4a}} (CH_3)_3CH + CH_2{=}CH\dot{C}HOCOC(CH_3)_3\ (r), \quad (14)$$

$$(CH_3)_3CCOO^{\cdot} + CH_2{=}CHCH_2OCOC(CH_3)_3 \xrightarrow{k_{4b}} CH_3{=}CHCH_2C(CH_3)_3 + CO_2 + (CH_3)_3CCOO^{\cdot}. \quad (15)$$

In the steady state

$$\frac{dM}{dP} = \frac{2}{k^0}\left[(k_a + k_b + k_c) + \frac{(k_2 + k_3)(k_a + k_b)}{k_3 + k_4'} + k^{*}\right] = \text{const},$$

where

$$k^{*} = k_d' + \frac{k_4'(k_a + k_b)}{k_3 + k_4'}.$$

Probably both mechanisms of allyl polymerisation can occur independently, since they show significant differences.

The main conclusion which follows from the mechanisms is the constancy of *dM/dP*, i.e. a linear relation between the amount of benzoyl peroxide consumed and the amount of monomer polymerised. This implies that in the polymerisation of allyl monomers the rates of chain propagation and termination are similar. Such a rate of chain termination can be explained by chain transfer to the monomer, which results in the formation of radicals stabilised by conjugation and incapable of chain propagation. This type of chain transfer is called degradative and the constancy of *dM/dP* is its characteristic property.

The occurrence of degradative chain transfer was demonstrated experimentally by Bartlett and Tate[19] in the polymerisation of deuterium-substituted allyl acetate $CH_2{=}CHCD_2OCOCH_3$.

When ordinary hydrogen is replaced by deuterium in allyl acetate, the rate of polymerisation increases by a factor between 1.93 and 2.89.

The molecular weight of the deuteriated polymer increases by a factor of 2.38. On the other hand, it is known that the rate of dissociation of hydrogen in a radical substitution reaction is approximately three times higher than for deuterium. On this basis, one may assert that chain termination occurs as a result of the interaction of the growing polymeric radical with the monomer.

Characteristic allyl polymerisation is observed even when the α-methyl group is located in the side-chain of the monomer. Thus isopropenyl acetate polymerised in the presence of benzoyl peroxide gives a polymer with a low molecular weight[22].

As well as degradative chain transfer, the polymerisation of allyl monomers exhibits effective chain transfer where allyl radicals can combine with monomers and thus propagate the chain reaction[10,11,14,15,25,26]. Sakurada and Takahashi[15] proposed a kinetic mechanism taking into account the effective chain transfer and derived an equation for the quantitative determination of the degradative chain transfer allowing for the effective transfer:

$$\frac{k_D}{k_D + k_T} = \frac{2\overline{DP}}{\left[\frac{dM}{dP}\right]_0 + 2},$$

where k_D and k_T are the rate constants for the degradative and effective chain transfer of the growing polymer radical to the allyl monomer and $\overline{DP}$ is the average degree of polymerisation.

The quantity $k_D/(k_D + k_T)$ for allyl esters and ethers decreases in the sequence allyl ethyl ether > allyl carbonate > allyl acetate > allyl propionate > allyl trimethylacetate > allyl laurate > allyl benzoate > allyl chloroacetate.

In the polymerisation of the first three allyl esters about 50% of the chain transfer reactions are effective. The more effective chain transfer in allyl chloride and allyl chloroacetate (65–86%) results from the formation of halogen-containing reactive radicals: $CH_2{=}CH\dot{C}HCl$ and $CH_2{=}CHCH_2OCO\dot{C}HCl$. Gaylord[11] observed that the contribution of effective chain transfer reactions in the polymerisation of allyl acetate is only 24%. The explanation is that, of the two resonance structures of the allyl radicals $CH_2{=}CH\dot{C}H \rightleftharpoons \dot{C}H_2{-}CH{=}CH_2$ in allyl acetate, the secondary (left-hand) radical is more stable, while in methylallyl acetate the primary (right-hand) radical of the pair

$$CH_2{=}CH-\underset{\displaystyle CH_3}{\underset{|}{\dot{C}}}- \rightleftarrows \dot{C}H_2-CH{=}\underset{\displaystyle CH_3}{\underset{|}{C}}\ \cdot$$

is more stable by virtue of the effect of the electron-donating methyl group. Since the primary radical is more reactive than the secondary radical, it participates more in the effective chain transfer, which in this case reaches 86%.

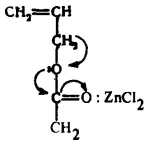
Walling and coworkers[17,18] showed that the degradative chain transfer can be significantly suppressed by the polymerisation of allyl monomers under pressure. When the pressure is changed from 1 to 8 atm, the overall rate of polymerisation increases by a factor of 5. The average degree of polymerisation also rises and the rate of chain termination falls.

This is evidence that the kinetic chain lengthens and chain transfer to the monomer becomes less degradative.

2. Complex–Radical Polymerisation

In a number of studies[29-31] attention has been drawn to the acceleration of the radical polymerisation of certain vinyl compounds in the presence of co-ordination-unsaturated metal halides such as LiCl, $ZnCl_2$, etc.

It has been suggested that this type of polymerisation be referred to as complex–radical polymerisation[32]. A similar acceleration is observed in the polymerisation and copolymerisation of allyl monomers[32-34]. It follows from the experimental data obtained in these studies that metal halides form complexes with the functional groups of the monomers. In the allyl acetate–$ZnCl_2$ complex the bond is formed largely via the group C=O, which leads to the shift of electron density over the entire group $-CH_2-O-\overset{\displaystyle O}{\overset{\|}{C}}-$. The structure of the allyl acetate–$ZnCl_2$ complex can be represented thus:



On the basis of this mechanism, it is difficult to explain the change in the activity of the double bond of the monomer or the activity of the chain propagation radicals under the influence of $ZnCl_2$. Furthermore, the increased rate of chain propagation when other conditions are identical should result in an increase of chain length, which is not observed experimentally. The increased rate of polymerisation may be due to the decreased probability of the degradative chain transfer of the monomer molecules in the complex. Another possible explanation of the increased rate is activation of the allyl radical in the complex, as a result of which it becomes capable of dissociating the double bonds of the monomer molecules, i.e. degradative chain transfer is transformed into effective chain transfer.

The conditions for chain propagation can be established because short-range order arises in the systems monomer–$ZnCl_2$ particularly at high concentrations of the complex-forming agent, as in labile polymerisation seeding agents[32]. One cannot exclude the possibility that the characteristic features of the polymerisation of allyl monomers can be accounted for by the simultaneous operation of all these factors. Thus, under the influence of the complex-forming agent, a significant change in the type of allyl polymerisation is observed. This provides a wide scope for the regulation of polymerisation processes initiated by radical agents.

3. Radiation-induced Polymerisation

Radiation-induced polymerisation is one of the most promising methods for the preparation of allyl polymers with high molecular weights. Dolmatov and Polak[35-38] investigated the mechanism and kinetics of such polymerisation. Radiation-induced allyl polymerisation can be largely described by a radical mechanism[39-44].

The kinetic mechanism takes into account the chain initiation by radicals produced by the radiolysis of the monomer, polymer, and the solvent. Chain propagation takes place via the monomer and polymer and its termination is mainly the result of degradative chain transfer to the monomer—with formation of an allyl radical incapable of chain propagation.

In the analysis of this mechanism Dolmatov[38] introduces the following simplifying assumptions.

1. The reactivity of radicals formed in the radiolysis of the monomer, polymer, and solvent is the same.
2. The overall rate of radiolysis consists of the sum of the rates of radiolysis of the monomer, polymer, and the solvent.

Polymerisation mechanism (M is the monomer, P the polymer, S the solvent, and I the inhibitor):

$$A_1{=}CH_2{=}CH-\dot{C}H_2,\quad A_2{=}CH_2{=}CH\dot{C}H-OH\,.$$

Initiation $$M \xrightarrow{k_d^m} R^{\cdot} + A_1$$

$$P \xrightarrow{k_d^p} R^{\cdot}$$

$$S \overset{k_d^s}{-} R^{\cdot}$$

Chain propagation $$R^{\cdot} + M \xrightarrow{k_i} RM^{\cdot}$$

$$RM^{\cdot} + M \xrightarrow{k_p} R\dot{M}_n$$

$$R\dot{M}_n + P \overset{k_p'}{-} R\dot{M}_n$$

Chain termination $$R\dot{M}_n + M \xrightarrow{kt} P + A_2 \quad \text{(by monomer)},$$

$$R^{\cdot} + I \xrightarrow{k_n} RI \quad \text{(by inhibitor)}.$$

The radiolysis of allyl alcohol in the solid phase[39] and in aqueous solution[40] and also the radiolysis of other allyl derivatives takes place predominantly at the All–X bond with formation of an allyl radical having the structure $CH_2{=}CH-\dot{C}H_2$, which is denoted by A_1. With allyl alcohol, the polymerisation is initiated by the $\dot{O}H$ radical, since it adds to the double bond of allyl alcohol more effectively than it removes the labile hydrogen atom from the α-methyl group[41]. In the chain termination the allyl radical $CH_2{=}CH\dot{C}HOH$, denoted by A_2, is formed.

The recombination of the allyl radicals A_1 and A_2 results in the formation of a certain number of molecules of allyl dimers, the participation of which in chain propagation leads to the formation of a reactive polymer containing a reactive allyl double bond. The concentration of such diallyl molecules is directly related to the length of the kinetic chain.

The kinetic mechanism of polymerisation in the solid phase is elucidated by the transition state method taking into account the change in the volume of the system as a result of contraction. The rate of conversion in the solid phase is determined from the usual set of equations supplemented by the contraction equation:

$$\frac{dW}{dt} = 100\,\%\,\frac{k_p}{k_t}J\cdot\frac{k_d^m n + k_d^p p}{n_0}\ ,$$

where J is the radiation dose rate, n_0 and n are the numbers of moles of the monomer before irradiation and at time t, and p is the number of moles of the polymer in monomer units.

The variation of the yield of the monomer with the duration of irradiation is linear[35], the initial rate of conversion is therefore equal to the rate of conversion at any other stage. This is possible when $k_p^m = k_d^p$.

The equality of the rate constants for the radiolysis of the monomer and the polymer implies the equality of the radiochemical yields of the corresponding radicals. Thus the rate of conversion can be written in the form

$$\frac{dW}{dt} = 100\,\%\,\frac{k_d^m k_p}{k_i}\,J\,,$$

i.e. the rate of conversion is constant, independent of the yield of the polymer, and directly proportional to the radiation dose rate.

The degree of polymerisation of allyl monomers increases with the yield of the polymer. If the initiating effect is due solely to the hydroxy-radical, then in the initial stage the degree of polymerisation should be equal to the degree of polymerisation of allyl alcohol initiated by hydrogen peroxide (about 5–10). Indeed at 52.5°C k_p/k_t = 10.2 and it is evident from the work of Dolmatov and Polak[36] that the limiting viscosity number hardly changes up to 80% conversion. At this conversion a polymer with an average degree of polymerisation in excess of 340 begins to form. The participation of the oligomer in polymerisation leads to a branched polymer, which is reflected in a low value of the limiting viscosity number and a higher Huggins constant[36].

4. Ionic Polymerisation

Friedel–Krafts and Ziegler–Natta catalysts are used for the ionic polymerisation of allyl compounds[45–61]. The rate of polymerisation by catalysts of this type depends to a considerable degree on the structure of the allyl compound. However, a distinct correlation has not yet been established between the structure and the capacity of allyl polymers for polymerisation.

In the polymerisation of allylbenzene and allylcyclohexane[48] on chromium oxide catalysts it was found that the rate of polymerisation increases when the benzene ring is replaced by the alicyclic cyclohexane ring. The explanation is that the allyl group in allylcyclohexane is adsorbed on the surface of the catalyst with the major plane of the cyclohexane ring oriented parallel to the surface, while in the case of allylbenzene the allyl group is displaced from the surface of the catalyst.

The degree of adsorption of allylbenzene exceeds by a factor of approximately 3 that of allylcyclohexane. Therefore it is possible that the stable adsorption of the benzene ring with displacement of the allyl group from the surface hinders the interaction between the electrons of the double bond of the monomer and the electron orbitals of the catalyst. This may be the cause of the inertness of the chromium oxide catalyst. The polymerisation of allylcyclohexane can be accounted for by the planar disposition of the molecules on the surface of the chromium oxide catalyst.

The polymerisation of allyl ethers of allyl-substituted phenols on Friedel–Krafts catalysts[59–61] involves only the allyl ether group, while the allyl side groups are not polymerised. Therefore initially thermoplastic resins are produced, which are then converted into thermoreactive resins in the presence of benzoyl peroxide as a result of cross-linking via the allyl side groups. Ziegler–Natta catalysts were used in the polymerisation of allyl acrylate, allyl methacrylate, allyl chloride, and allylbenzene[46,47,49,51,52,54].

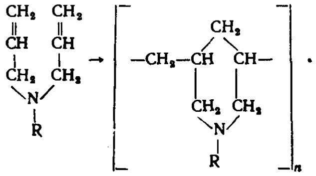
According to D'Alelio et al.[46], the amount of the cationic component $TiCl_4$ in the mixture plays a decisive role in the polymerisation of allylbenzene on these catalysts. The optimum ratio tri-isobutylaluminium : titanium tetrachloride is 1 : 1. With increase of this ratio, the isomerisation of allylbenzene to propenylbenzene predominates. Apart from the ratio $AlR_3 : TiCl_4$, the polarity and the polarisability of the monomer, steric factors, etc. play a significant role in polymerisation on Ziegler–Natta catalysts.

The polymerisation of diallyldimethylsilane and diallylmethylphenylsilane[55] on Ziegler–Natta catalysts in n-heptane yielded solid rubberlike products soluble in benzene at room temperature. The residual degree of unsaturation of these polymers was 12–40%. Polymers obtained with $Al(C_2H_5)_3 : TiCl_4 > 1$ had the lowest degree of unsaturation.

5. Cyclopolymerisation

A characteristic feature of the polymerisation of allyl monomers is a cyclic polymerisation mechanism, investigated for the first time by Butler[62]. Cyclopolymerisation (alternating intra- and inter-molecular polymerisation) occurs with a wide range of monomers when the familiar catalytic systems are used under particular conditions[42,62–79]. Cyclolinear polymers are obtained mainly in the polymerisation of diallyl compounds. This is consistent with Butler's assertion[78] that the main type of chain propagation in the polymerisation of symmetrical 1,6-dienes involves cyclisation, which leads to the formation of a small number of cross links and also residual double bonds. Symmetrical 1,5-dienes polymerise analogously[80]. Butler[63] explains the tendency towards cyclopolymerisation by the fact that the process takes place with a smaller energy expenditure than the intermolecular chain propagation. The lower energy pathway may arise as a result of the electronic interaction between the double bonds of the 1,6-diene or between the reaction centres formed in the interaction between the initiator and the intramolecular double bond.

Matsoyan et al.[66] investigated the capacity of N-substituted tertiary diallylamines and diallylamides for cyclic polymerisation as a function of the nature of the substituent. When polar substituents with electronegative groups are attached to the nitrogen atom of diallylamine, the products are capable of polymerisation in the presence of free-radical initiators with formation of piperidine rings in the main chain:

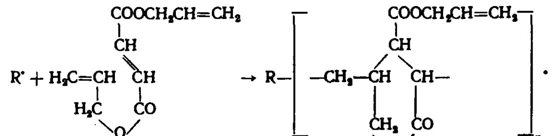


This is associated with the polarisability of allyl groups caused by the displacement of π-electron density of the double bond under the influence of the electron-acceptor substituent.

It is interesting to note that the only substituted diallylamines capable of polarisation are those where the electron-acceptor substituents C=O, C≡N, and SO_2 are linked directly to the nitrogen atom. An increase of the electron-acceptor effect of the substituent favours polymerisation. For example, the effect of substituents in *NN*-diallylamides can be arranged in the following sequence:

$$ClCH_2CO > CH_3CO > CH_3CH_2CO.$$

The studies of Arbuzova and coworkers[81-83] showed that cyclolinear polymers are not obtained solely in the interaction between two allyl groups but also in the interaction between an allyl and a maleate group if their conformation in the molecule is favourable for the formation of five- and six-membered rings:



Cyclisation in the interaction between two allyl groups with formation of ten- or eleven-membered rings is less likely for conformational reasons, for example because of internal steric hindrance to ring closure.

6. Copolymerisation

The nature of the involvement of allyl monomers in copolymerisation depends on their low reactivity compared with the majority of vinyl monomers. Analysis of data on the relative reactivities of monomers in copolymerisation shows that in the vast majority of cases the copolymerisation constants for allyl monomers are zero or significantly less than the constants for vinyl monomers. Because of this allyl monomers enter into the copolymer only as separate units and therefore the copolymer cannot contain more than 50 mole % of the allyl monomer. Only in copolymerisation with relatively inactive vinyl compounds (vinyl acetate, maleic anhydride) do allyl monomers exhibit a fairly high reactivity. In the copolymerisation of diallyl phenylphosphonate with lauryl methacrylate at 140°C the composition of the monomer mixture was found to influence the relative reactivities. In the mixture with 39–92 mole % of lauryl methacrylate (M_1), $r_1 = 6.30 \pm 0.30$ and $r_2 = 0.002 \pm 0.3$, while with 27–46 mole % $r_1 = 3.80 \pm 0.40$ and $r_2 = -0.21 \pm 0.02$. It is suggested that this finding and also the appreciable negative value of r_2 can be explained by the effect of the penultimate unit of the chain on the rate of copolymerisation when the unit consists of the allyl monomer.

The copolymers of allyl monomers with unsaturated compounds are of considerable practical importance. This problem will be discussed in detail below.

In conclusion of this section, the following points should be noted. Judging from the copolymerisation constants, the chemical structure of allyl monomers does not influence their reactivity. However, this finding is probably not uncontroversial. All the investigators who have studied the copolymerisation of allyl and vinyl monomers calculated the constants from differential or integral equations for the composition of the copolymers taking into account only those elementary steps which lead to chain propagation but not to chain termination. For the copolymerisation of vinyl monomers, this assumption is to some degree justified. However, in the copolymerisation of allyl monomers the chain termination rate constant is so large that it is probably comparable with the chain propagation rate constant; for this reason, in the calculation of the ratio of the true chain propagation rate constants it must be taken into account. This problem is not dealt with in the literature and still awaits a solution. Only then will it be possible to assess unambiguously the reactivities of allyl monomers and their dependence on chemical structure.

III. POLYMERISATION OF VARIOUS CLASSES OF ALLYL COMPOUNDS

1. Polymerisation of Allyl Ethers

Allyl ethers $CH_2=CHCH_2OR$ were investigated long before their use in polymer chemistry. In 1944 Nichols and Yanovsky[84,85] observed that, on being kept in air, allyl ethers yield infusible and insoluble resins.

This was the beginning of intense studies on the polymerisation and copolymerisation of allyl ethers and their employment in various branches of industry as adhesives, coatings for wood, glass, metal, and textiles, and as moulded articles with exceptional mechanical strength, resistance to wear, thermal and chemical stability, and resistance to the action of solvents and light.

Allyl ethers derived from polyhydric alcohols are polymerised under the action of oxygen at high temperatures[84, 86-90]. As polymerisation proceeds, the solubility of the polymers in acetone diminishes and their viscosity increases.

Prolonged heating of the polymers in the presence of oxygen leads to insoluble infusible resins. Earlier attempts to polymerise allyl ethers in the presence of 5% benzoyl peroxide were unsuccessful[84]. They began to gel only on addition of 15% of benzoyl peroxide. Later papers[91,92] report the preparation of polymers of allyl ethers initiated by peroxide catalysts. In the solid-phase polymerisation of the diallyl ethers derived from tri(hydroxymethyl)propane using peroxide initiators, the products are transparent colourless solid thermoreactive resins insoluble in the majority of organic solvents. The capacity of allyl ethers for polymerisation to thermoreactive resins resistant to the action of solvents, oils, and high temperatures, and their compatibility with a large number of resins and plasticisers permit their employment in the manufacture of resins with high rigidity[93-95] and also as decorative coatings[86,96].

Allyl ethers readily copolymerise with other monomers in the presence of benzoyl peroxide. The copolymerisation of allyl ethyl and allyl butyl ethers with vinyl acetate was reported by Sakurada and Takahashi[97]. Copolymers of allyl glycidyl ether and vinyl acetate have been obtained in benzene at 75°C.[98] Allyl trifluoroethyl ether was copolymerised with maleic anhydride at 70°C in the presence of benzoyl peroxide[99]. The triallyl ether of glycerol and other allyl ethers derived from polyhydric alcohols were copolymerised with vinyl chloride in suspension in an autoclave at 51°C.[100]

Britton and Davis[101] copolymerised vinyl chloride with allyl epoxyalkyl and allyl hydroxyalkyl ethers. Losev[102] employed boron trifluoride together with benzoyl peroxide as a catalyst in the copolymerisation of vinyl chloride with diallyl ethers.

Fisher[103] also reported the use of boron trifluoride as an initiator in the copolymerisation of allyl glycidyl ether with maleic anhydride. The resin formed is then hardened at 110°C for 48–144 h in the presence of benzoyl peroxide. The copolymers may be used as binders for reinforced plastics and as film-forming agents stable up to 260°C. The copolymers of allyl ethers with vinyl acetate, vinyl chloride, vinylidene chloride, styrene, acrylonitrile, butadiene, and acrylic esters have found many applications. The properties of typical copolymers of allyl ethers with other monomers are listed in Table 1.

Table 1. Copolymers of allyl ethers and their properties.

Monomer	Comonomer	Applications of copolymers
Allyloxyethane	Acrilonitrile	Films and fibres with good dyeing properties
Allylpentaerythritol	Acrylonitrile	Thickening agent for non-polar solvents
Allyl glycidyl ether	Vinyl acetate	Surface coatings
Allyl-starch	Styrene	Surface coatings
Diallyl ether of ethylene glycol	Vinyl chloride	Insulation for wires and cables
Triallyl ether of glycerol	Vinyl chloride	Ditto
2-Chloroallyl ether	Methyl methacrylate Butyl methacrylate	Thermosetting coatings for electrical devices, motorcars, and external metallic sheeting
Monoallyl ether of glycerol	Methyl methacrylate Butyl methacrylate	Ditto

Although the copolymerisation of allyl ethers has been as yet inadequately investigated, the use of allyl compounds containing other functional groups (hydroxy-, epoxy-, and ethylene groups) has acquired increasing importance. Even small amounts of allyl ethers added to other monomers considerably improve the physical and mechanical properties of the polymers.

Bifunctional allyl monomers are used for the modification of the existing polymers. They make it possible to obtain copolymers with improved resistance to wear and to the effect of light and solvents.

Valuable polymeric materials have been obtained by the copolymerisation of unsaturated maleate oligoesters with ethers[104–115]. Such compositions harden rapidly in air at room temperature. Light-coloured films with high impact strength, chemical stability, and resistance to wear are obtained. The physical and chemical properties of the copolymers permit their use also in cast compositions, in laminate plastics, and as casting moulds. The copolymers of the unsaturated oligoesters with diallyl phthalate and allyl ethers of glycerol and starch are used[116] as adhesives and binders for emery paper. Allyl ethers of polyhydric alcohols [tri(hydroxymethyl)propane, pentaerythritol, glycerol] react with the unsaturated oligoesters to give copolymers with exceptional water resistance and satisfactory dielectric properties[110,114,115].

Recently much attention has been devoted to unsaturated allyl oligoesters and their copolymers. Unsaturated allyl oligoesters with an allyl bond in the side chain are obtained by the reaction with dibasic acids or their anhydrides of polyhydric alcohols such as allylglycerol and allylglycidol with their hydroxy-groups partly converted into allyl ether groups[117–125].

Such oligoesters are converted into insoluble and infusible polymers by treatment with cobalt naphthenate in the presence of air at room or elevated temperatures[108,111,112,123,125]. However, the homopolymers of allyl oligoesters have not found practical applications.

Sorokin and Gershanova[106] studied the copolymerisation of unsaturated allyl oligoesters with allyl glycidyl ether. They synthesised the oligoesters from allyl glycidyl ether and dibasic acids (maleic, phthalic, and adipic). The copolymerisation was carried out in the presence of redox and peroxide initiators. The authors note that varnish compositions based on the oligoesters obtained from maleic acid and allyl glycidyl ethers harden at room temperature and exhibit fairly satisfactory hardness and degree of solidification. Partial replacement of maleic acid by adipic or phthalic acid in the oligoester lowers the rate of hardening of the varnish compositions.

It has been established by infrared spectroscopy that the copolymerisation involving the double bonds is accompanied by the interaction of the glycidyl groups of the allyl glycidyl ether with the terminal carboxy- or hydroxy-groups of the oligoester.

In their study of mixed allyl-maleic oligoesters, Jenkins et al.[107] showed that an increased content of allyl groups in the oligoester lowers the maximum molecular weight which may be obtained without gelling. This also determines the maximum number of utilisable allyl groups. For the oligoester obtained from propylene glycol, the allyl ether derived from glycerol, and equimolar amounts of maleic and phthalic acids this number is four. When the maleic acid content was less than 25 mole % of the total content of acids, gelling was not observed and it was possible to obtain oligoesters with a high molecular weight.

For polyester varnishes the authors also employed as the allyl component involatile polymerisable compounds of the diallyl ether derived from glycerol and the acetic, adipic, and pyromellitic esters of the diallyl derivative of glycerol.

The copolymerisation of allyl oligoesters with maleic-fumaric oligoesters is described in the publications of Tarasov and coworkers[117–120,126–128] and others[124]. Copolymers with satisfactory physical and mechanical properties have been obtained[117], and may be employed as binders for reinforced plastics. It has been shown[129] that poly(allylglyceryl phthalate-adipate) does not polymerise in the presence of 2% of benzoyl peroxide even at 150°C. The addition of small amounts of the fumaric oligoester (about 10%) leads to the formation of a copolymer even at 80°C. The participation of allyl groups in the copolymerisation reaction has been shown by the fact that the product does not dissolve in organic solvents. Furthermore, bromination of the products of the alkaline hydrolysis of the copolymers reveals the presence of only a fraction of the initial fumaric and allyl double bonds.

2. Polymerisation of Allyl Esters

The allyl esters of mono- and di-carboxylic acids were obtained for the first time in 1885 by Zinin[130] by the double decomposition of the silver salts of aliphatic acids with allyl iodide. Until 1940 there were no data on the use of allyl esters, since allyl alcohol was not readily available. The polymerisation of allyl esters began to acquire practical importance starting with 1941–1942. The allyl esters of carboxylic acids have been used in polymer chemistry in two ways: (1) as monomeric additives to polymers; (2) as partially polymerised thermosetting resins (pre-polymers).

The polymers of allyl esters have found application in those cases where the following properties are necessary: chemical stability, particularly with respect to oxidising agents, exceptionally low dielectric losses, low moisture absorption, low rate of cross-linking after fusion, resistance to wear, and thermal stability.

The allyl esters of phthalic, isophthalic, maleic, fumaric, succinic, diglycolic, itaconic, acetic, and other acids are most frequently used[131-237].

Allyl esters can be polymerised in the presence of various initiating systems (peroxides, ionic polymerisation catalysts, and under the influence of γ-radiation). Among the most widely used and most important monomers are diallyl phthalate and diallyl isophthalate[131-168]. The kinetics of the polymerisation of diallyl phthalate were investigated by Oiwa, Lalau-Keraly, etc.[154-159,168]. They showed that the residual degree of unsaturation in the polymerisation of diallyl phthalate in the presence of benzoyl peroxide and di-t-butyl peroxide depends very little on the catalyst and temperature but does depend strongly on conversion. With increase of conversion, the residual degree of unsaturation falls.

In the initial stage of the polymerisation of diallyl phthalate in the presence of peroxide initiators about 43% of cyclic structures is formed. The structure of the polymer has been confirmed on the basis of the rate of disappearance of C=C bonds revealed by infrared spectroscopy in the region of 1644 cm^{-1}.[165]

In the polymerisation of diallyl phthalate the duration of the hardening process and the contraction of the polymer are very considerable[132]. For this reason, diallyl phthalate is rarely used for the synthesis of a homopolymer. Instead it serves for the preparation of a pre-polymer which is readily moulded, exhibits satisfactory fluidity, and hardens rapidly[147-153]. Diallyl phthalate and diallyl isophthalate pre-polymers are stable on storage and when employed as compositions with catalysts which decompose at high temperatures. On heating and at high pressures (in casting, in the preparation of laminate materials), they soften, flow, and are cross-linked to give three-dimensional insoluble resins.

Diallyl esters of fumaric and maleic acids are also of interest for a wide variety of engineering applications[81-83, 169-183,229]. The mechanism of the formation of polymers based on mono- and di-allyl esters of maleic acid was investigated by Arbuzova et al.[81-83] They established that in the polymerisation of monoallyl maleate and diallyl maleate five- and six-membered lactone units are formed, and with increase of the polymerisation temperature the content of five-membered rings increases. On the other hand, the polymerisation temperature and the nature of the initiator do not affect the degree of cyclisation. With monoallyl maleate, it is 63–64% and, with diallyl maleate, it is almost 100%. The cyclolinear polymers obtained are converted on further polymerisation in the presence of initiators into three-dimensional polymers, which are very hard and exhibit high thermal stability.

The polymerisation of allyl acrylate and allyl methacrylate has been investigated by Schulz, Kawai, Gindin, and others[51,54,74,184-209]. The polymerisation of allyl acrylate in benzene solution with a radical polymerisation initiator yielded a brittle vitreous polymer soluble in benzene and pyridine. The polymer does not soften on heating and hydrolyses only in molten sodium hydroxide–potassium hydroxide. A study of the structure of the polymer showed that 24.2% of the structural units are linked via acrylic groups, 17.2% are linked via allyl groups, and the remaining 58.6% form lactone groups as a result of cyclopolymerisation[186].

The anionic polymerisation of allyl acrylate gives a product with a low molecular weight, which is isotactic to a fairly high degree. Only acrylic double bonds participated in the linear polymerisation; the allyl bonds were involved only in the cross-linking, which occurred when the polymer was stored in air[51]. Similar results were obtained by Gindin et al.[185] in the polymerisation of allyl acrylate under the influence of benzoyl peroxide and ultraviolet light.

Compared with the acrylate, the polymerisation of allyl methacrylate shows certain characteristic features. When azobisisobutyronitrile is used as an initiator, allyl methacrylate polymerises to a product without rings in the chain, which is insoluble in the usual organic solvents[187]. In the polymerisation of allyl methacrylate under the influence of ultraviolet light, Cohen et al.[236] also showed that the polymerisation is not accompanied by cyclopolymerisation. This can be accounted for by resonance stabilisation of the allyl groups as a result of degradative chain transfer, which leads to the cross-linking of the polymer.

In the anionic polymerisation of allyl methacrylate[54] a linear soluble polymer containing allyl groups as branches from the polymer chain is formed. The linear polymers of allyl methacrylate are classified as "self-reactive", yielding polymers which harden on heating or in the presence of radical initiators. Only the copolymers of allyl methacrylate with other monomers have found applications.

Allyl acetate has been homopolymerised[10,18,210-213], largely in order to investigate the kinetics of allyl polymerisation, as mentioned above. This polymer has not found practical application, since it has low molecular weight and poor mechanical properties.

Polymers based on the diethylene glycol–diallyl carbonate system are produced in the presence of free-radical polymerisation initiators as light-coloured castings with exceptional optical properties, high chemical stability, and resistance to wear[237]. The polymerisation of this monomer is inhibited by air and therefore the castings are obtained between glass plates separated by plastic spacers. The diethylene glycol–diallyl carbonate polymers are produced in the manufacture of optical lenses and glass for spectacles, and as coatings for expensive ultraviolet and infrared glasses[6].

Apart from the applications of the polymers of allyl esters, their copolymers with other monomers and unsaturated oligoesters have found many applications in engineering.

The addition of 0.01–0.3% of diallyl phthalates (*o*-, *m*-, and *p*-isomers) to vinyl chloride makes it possible to prepare a polymeric material with mechanical properties 4–10% better than those of poly(vinyl chloride) itself[141]. Diallyl phthalates are frequently used instead of styrene in mixtures with unsaturated oligo-glycol maleates[142]. Articles with homogeneous surfaces and much smaller contraction can be obtained by casting. Diallyl phthalate imparts mechanical strength and thermal stability to oligoester resins and improves their dielectric properties.

The copolymerisation of diallyl maleate and diallyl fumarate with methyl methacrylate and styrene in the presence of a mercaptan and peroxides yields in pregnating powders[183], which can be moulded under pressure of 7 kg cm^{-2}. The copolymer of diallyl maleate with 0.05–0.3% of vinyl chloride is used as an electrical insulator[180]. The copolymer of diallyl maleate and chlorotrifluoroethylene has good adhesive properties[182].

Diallyl fumarate and diallyl maleate are also used with styrene in compositions containing unsaturated oligoesters, which are employed to prepare reinforced plastics[173]. The addition of diallyl phthalate and diallyl maleate to poly(vinyl chloride) imparts hardness to the polymeric materials[176].

Allyl acrylates and allyl methacrylates copolymerise with methyl methacrylate, vinyl chloride, acrylonitrile, polyethylene, etc.[196-208]. The copolymerisation of allyl methacrylate (20%) with methyl methacrylate in the presence of benzoyl peroxide yields polymers with higher softening temperatures than that of poly(methyl methacrylate).[200-202]

The copolymers of allyl furylenemethacrylate with styrene, vinyl acetate, acrylonitrile, and methyl methacrylate have been suggested as plasticisers[197].

The copolymers of acrylonitrile, methyl methacrylate, and methacrylamide, modified with allyl methacrylate, exhibit exceptional mechanical properties (for example, a bending resistance of 1849 $kg\ cm^{-2}$).

The copolymerisation of allyl acrylate (1–15%) with acrylonitrile gives transparent castings[207]. Allyl acrylate is used as a cross-linking agent in the irradiation of polyethylene and polypropylene[209].

The copolymerisation of allyl acetate with other monomers[6,214-216] has been carried out largely to investigate the mechanism of the copolymerisation and to determine the relative reactivities.

3. Polymerisation of *N*-Allyl Derivatives

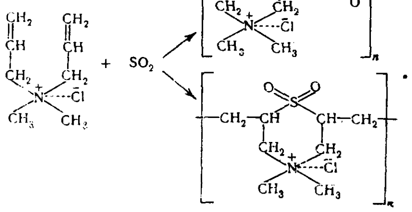
In recent years much attention has been devoted to the study of the polymerisation and copolymerisation of *N*-allyl derivatives (*N*-substituted diallylamines, diallylammonium, salts, *N*-allylamides, *N*-allylimides, triallyl cyanurates, hexa-allylmelamines, etc.)[66,238-289]. The interest in this class of compounds arises from the practical value of the polymers and copolymers of *N*-allyl derivatives (particularly those based on triallyl cyanurate and triallyl isocyanurate).

Butler has shown that the polymerisation of diallylammonium salts in aqueous solutions in the presence of t-butyl hydroperoxide or an azo-initiator leads to the formation of cyclolinear polymers[78,79].

The polymerisation of diallyl- and diallyldimethylammonium bromides[258] yields saturated linear soluble polymers with repeating *N*-substituted piperidinium halide units together with methylene groups.

The ability of diallyl derivatives of quaternary ammonium salts to undergo radical polymerisation is associated with the polarisability of the allyl groups due to the displacement of the π-electron density of the double bond by the electron-accepting nitrogen atom of the ammonium group. In the presence of radical-polymerisation initiators these monomers copolymerise fairly readily with styrene, acrylonitrile, and other monomers.

In the copolymerisation of diallyl-ammonium halides with sulphur dioxide[73], water-soluble cationic polysulphones are formed:



These copolymers do not melt but decompose at 180°C and lose about 40% of their weight at 190°C in 3 h. They are unstable to sodium hydroxide.

The mechanism of the polymerisation of *N*-substituted diallylamines was discussed in detail above[66]. It is noteworthy that the polymerisation of these monomers involves a cyclic mechanism with formation of piperidine rings in the main polymer chain, as in the polymerisation of quaternary diallyl-ammonium salts. Among the cyclic polymerisation products of *N*-substituted diallylamines, *NN*-diallylacetamide, *NN*-diallylbenzamide, *NN*-diallylpropionamide, etc., polyallylcyanamide is of particular interest, being distinguished by low solubility and a high melting point.

Ostroverkhov et al.[238] established that tertiary diallylamines and diallylamides form in the presence of radical initiators polymers with low molecular weights and low softening temperatures which are readily soluble in organic solvents. The low tendency of diallylamides to polymerise can be explained by the vigorous chain termination reaction with participation of the hydrogen atom of the allyl group.

In the presence of anionic and cationic catalysts diallylamides and tertiary diallylamines did not yield polymers either in the solid state or in solution. Allylamines have been recently polymerised by irradiation with cobalt-60 γ-rays.[44] The homopolymers of allylamines and allylamides have not found practical application. It is mainly their copolymers with other monomers and polymers which are used in industry.

The copolymers of triallylamine with acrylic acid have been obtained at 50°C in an atmosphere of nitrogen in the presence of 2% azobisisobutyronitrile. They are excellent thickening agents for latex dyes[242].

The copolymers of diallylamine and acrylonitrile are used as fibres which are more readily dyed than polyacrylonitrile[243].

The copolymers of allylamines with styrene and butadiene have been recommended as hardening agents for epoxy- and ion-exchange resins[239].

Diallylamine introduced into poly(vinyl chloride) in an amount of 0.01–0.3% increases its molecular weight and improves its physical and mechanical properties[230].

Much work has been done on the polymerisation and copolymerisation of triallyl cyanurate, triallyl isocyanurate, and hexa-allylmelamine[248,263-294]. The vitreous polymers obtained in the presence of free-radical polymerisation initiators, are colourless, solid (but brittle), and readily cracked.

Clampitt[265] observed by infrared spectroscopy that in the course of its polymerisation triallyl cyanurate isomerises to triallyl isocyanurate.

Poly(triallyl isocyanurate) has a higher decomposition temperature (377°C) than poly(triallyl cyanurate) (321°C) and higher stability on heating in air and in an atmosphere of nitrogen. Therefore conditions for the hardening of triallyl cyanurate are chosen so that the latter isomerises to triallyl isocyanurate. However, despite their high thermal stabilities, the homopolymers have not found practical application because of their brittleness.

Solid polymeric materials with high thermal stability have been obtained by the copolymerisation of methyl methacrylate (5–50%) with triallyl cyanurate[284,286].

In the presence of peroxide or ionic catalysts allyl derivatives of cyanuric and isocyanuric acids copolymerise with vinyl monomers, dienes, etc. Solid thermostable copolymers insoluble in organic solvents are obtained[282].

The copolymers of triallyl cyanurate, diallyl itaconate, styrene, and methyl methacrylate are used in high-speed military aviation[287]. Triallyl cyanurates and triallyl isocyanurates are introduced into oligoesters to improve their thermal stability and mechanical properties[291–293]. When triallyl cyanurate (2–5 weight units) is introduced into polyethylene to increase the effectiveness of cross-linking, a copolymer with a high melting point is obtained[277].

The polymerisation and copolymerisation of other *N*-allyl derivatives of heterocycles have been less investigated. Only *N*-allyl-α-pyrrolidinone, *N*-allyl-α-piperidinone, and *N*-allyl-α-caprolactam have been polymerised[290]. These monomers hardly polymerise in the presence of 10% benzoyl peroxide at 60°C over a period of 60–100 h. On addition of not less than 5% of azobisisobutyronitrile, *N*-allyl-α-pyrrolidinone and *N*-allyl-α-caprolactam undergo stepwise polymerisation with formation of low-molecular-weight products and trimers in low yields (10–25%). The polymerisation of *N*-allylsuccinimide and *N*-allylphthalimide, in the solid phase and in solution, under the influence of cobalt-60 γ-radiation was reported recently[261]. The polymerisation products have a low molecular weight; the degree of polymerisation is about 10.

4. Polymerisation of Allyl Monomers with Organic Derivatives of Different Elements as Substituents

This class of compound includes allyl derivatives of silicon, titanium, germanium, tin, phosphorus, sulphur, and other elements[7,42,43,68,291–340]. Polymers based on these compounds have attracted attention because they should exhibit high thermal stability and the phosphorus containing polymers should exhibit self-extinguishing properties. The polymerisation of alkenylsilanes containing one allyl or methylallyl group takes place with difficulty[341]. Mironov and Petrov[342] described the polymerisation of alkylmethylallyl- and allyloxy-silanes on platinised charcoal. Later Korshak et al.[343] established that the polymers based on alkylsilanes have different structures depending on the polymerisation initiator. The polymers obtained in the presence of peroxide catalysts contain Si–H bonds, while those obtained in the presence of platinum catalysts do not.

Lyashenko et al.[43] showed that polymers produced in the presence of benzoyl peroxide at 200°C have structures analogous to those obtained at 100°C in the presence of cobalt-60 γ-radiation. The authors observed that the tendency to polymerise increases with the number of allyl groups in alkenylsilanes. Monoallylsilanes exhibit different activities in polymerisation reactions depending on the nature of other groups linked to the silicon atom. Diethylallylsilane does not polymerise in the presence of benzoyl peroxide over a period of 10 h, ethylallylphenylsilane polymerises to a liquid polymer, while ethyldiallylsilane and triallylsilane give crystalline products, the latter being formed in 30 min.

In the polymerisation of diallylsilanes under the influence of cobalt-60 γ-radiation, Gusel'nikov et al.[42] established that the reaction involves inter- and intra-molecular mechanisms. The cyclolinear polymers formed are soluble in organic solvents.

Using Ziegler–Natta catalysts, Topchiev, Bogomol'nyi, Kolesnikov, and others[68,300–303,308] obtained rubberlike products containing unsaturated groups in the side chains. The dominant units in the polymer chain are silicon-containing rings alternating with methylene groups. The copolymers of allylsilanes with other monomers obtained in the presence of Ziegler–Natta catalysts were found to have a constant melting point and high stability when worked. The hardened copolymers did not dissolve in boiling heptane. They have been used as elastomers[305].

There are only isolated data on the polymerisation of the allyl derivatives of titanium, tin, and germanium[50,308,310,311]. A polymer decomposing without fusion above 400°C was obtained from allyl trimethyl titanate in the presence of boron trifluoride or compounds capable of yielding boron trifluoride[50]. The copolymerisation of allyl derivatives of titanium with vinyl acetate gave water-resistant enamels[311].

The polymerisation of diallyldimethylgermane takes place in the presence of triethylaluminium and titanium tetrachloride with formation of a coloured oil in about 50% yield. The molecular weight of the polymer is 270. It is suggested that in this case the main polymerisation product is a cyclic dimer[308].

The polymerisation of phosphorus-containing allyl monomers and their copolymerisation with other monomers and polymers have been investigated by Kamai, Toy, Berlin, Laible, Kennedy, and others[7,67,238,294,296–298,312–334]. The ability of phosphorus-containing allyl monomers to undergo radical polymerisation as a function of the nature of the substituents has been investigated by Kamai[297] and later by Toy[296] using as an example the allyl esters of phosphonic acid. They showed that steric hindrance, the polarity of the substituents, and the presence or absence of inhibiting groups can greatly modify the polymerisation characteristics of the monomers, their effect diminishing on going from allyl to methylallyl esters.

Table 2. Groups of polymerisable diallyl compounds of the type $R-P(O)(OCH_2CH=CH_2)_2$.

First group		Second group	
R	Taft's constant σ^* (Ref.344)	R	Taft's constant σ^*
$H-$	0.49	CH_3-	0
C_6H_5-	0.60	C_2H_5-	—0.1
$C_6H_5CH_2-$	0.22	$n\text{-}C_3H_7-$	—0.115
C_6H_5-O-	2.38	$n\text{-}C_4H_9-$	—0.13
$(CH_3)_2C=CH-$	—	$(CH_3)_2CH$	—0.38

Monomers can be divided into three groups in relation to their capacity for the formation of polymers. The first group includes monomers which polymerise to a solid vitreous product. These are monomers in which the substituent at the phosphorus atom is an electron acceptor. When the substituents are electron donors, the monomers polymerise either to gels or solid but elastic polymers. These constitute the second group (Table 2). The third group includes monomers which polymerise to a liquid product or do not polymerise at all under the influence of peroxide initiators. These are *NN'*-dimethylallylphenylphosphonamide, diallylthiophenylphosphonamide [*NN*-diallylphosphonothionic diamide ? (Ed. of Translation)], diethyl *N*-allylphosphoramidate, and others. The polymerisation passivity of compounds in the third group is due to the inhibiting effect of sulphur and amide groups in the monomers.

Diallyl *NN*-dimethylphosphoramidate ? (Ed. of Translation)] not only does not polymerise but is actually capable of retarding the polymerisation of other diallyl esters.

The interest in polymers of this class arises from their flame-resistant properties.

Toy and Cooper[296] believe that the phosphorus content in allyl monomers is not the sole factor determining the flame-resistant properties of polymers. The polymers of diallyl phenylphosphonate (13% of phosphorus) and diallyl methylphosphonate (17.6% of phosphorus) are more flame-resistant than the polymer of diallyl phosphite (19.2% of phosphorus). However, the authors do not quote other reasons to account for their flame-resistant properties.

In engineering, applications are found mainly for the copolymers of phosphorus-containing allyl monomers with other monomers and polymers. The copolymerisation of diallyl phenylphosphonate with vinyl acetate and methyl methacrylate yielded a transparent polymer with self-extinguishing properties[323].

Phosphorus-containing allyl monomers are introduced into unsaturated oligoesters to make them flame-resistant. The copolymers based on these components have good mechanical and dielectric properties in addition to being flame-resistant[298,333].

5. Polymerisation of Allyl Alcohol and Allyl Halides

Poly(allyl alcohol) was obtained for the first time by the reduction of poly(n-butyl acrylate) with lithium aluminium hydride in dry tetrahydrofuran[345]. The degree of reduction was more than 95%, the molecular weight was 15 900, and the intrinsic viscosity in dimethyl sulphoxide was 0.436.

Poly(allyl alcohol) of low molecular weight is obtained by the polymerisation of allyl alcohol in the presence of a large amount of benzoyl peroxide[346,347]. Poly(allyl alcohol) with an average degree of polymerisation $\overline{DP} = 20$ is soluble in water, methanol, and other organic solvents. With $\overline{DP} = 200$, the polymer shows limited miscibility in water but is readily soluble in methanol, while with $\overline{DP} = 400$ it is soluble only in a mixture of concentrated hydrochloric acid and methanol in dioxan.

Poly(allyl alcohol) of high molecular weight ($\overline{DP} = 370$) has been obtained by irradiating allyl alcohol with cobalt-60 γ-rays. Allyl alcohol with $\overline{DP} = 10^3-10^4$ can be obtained by radiation-induced polymerisation. Poly(allyl alcohol) is a highly branched polymer with a low intrinsic viscosity. It is thermostable and thermoplastic, can be pressed into sheets on heating, and fibres can be readily formed from its melt. Crystalline poly(allyl alcohol) with a melting point of 210–222°C has been obtained by the polymerisation of allyl alcohol in the presence of boron trifluoride at −78°C in petroleum ether[50].

Practical applications have been found mainly for the copolymers of allyl alcohol with other monomers[348-367]. When allyl alcohol is copolymerised with styrene (15–80%), transparent solid polymers are formed and are used as coatings which are colour-fast on heating[353,368]. The copolymers of allyl alcohol and styrene have been used to prepare films with good adhesive properties, resistance to water, dilute alkalis, methanol, and detergents[354,356,357]. These copolymers can serve as binders for the preparation of articles with fibrous fillers[355]. Filled copolymers of styrene, allyl alcohol, and maleic acid are used as facing plates and other constructional materials[359]. Copolymers of allyl alcohol and acrylonitrile have been used as fibres[362].

The polymers of allyl halides (allyl chloride and allyl bromide) are obtained by polymerisation in the presence of peroxides and Ziegler–Natta catalysts and by γ-irradiation[369-375]. High-molecular-weight compounds are obtained only when the monomers are irradiated with cobalt-60 γ-rays.

Polymerisation of allyl chloride on a Ziegler–Natta catalyst yielded a pale-yellow polymer melting at 70–110°C. It contained double bonds formed as a result of the elimination of HCl from the polymer molecules[370].

Polymers of allyl chloride are also obtained in benzene or toluene in the presence of 0.2–0.5% (relative to the monomer) of metallic aluminium[376].

The polymerisation of allyl iodide under the action of γ-radiation yields mainly dimers[370]. The monomers are used in the polymerisation of ethylene to regulate the molecular weight of the polymer[377,378].

6. Polymerisation of Aromatic Allyl Compounds

Korshak and coworkers have investigated the synthesis, polymerisation, and copolymerisation of allyl-containing polyarylates[379-386]. The formation of allyl-containing polyarylate structures under the influence of heat takes place at a temperature in excess of 230°C with a considerable yield of the three-dimensional product. At the beginning of the reaction the β-polymer forms, which is then converted into the γ-polymer. The polymers obtained under conditions ensuring the maximum degree of cross-linking (267°C, 7 h) have an extensive region of elastic deformations, the upper limit of which occurs at temperatures above 500°C. It has been noted that the deformations diminish with increase in the number of cross-links.

The copolymerisation of allyl-containing polyarylates with various vinyl and allyl monomers reduces the thermal stability of the polyarylates. However, in some cases (diallyl phthalate, styrene, etc.) this happens to only a slight extent. It was found that styrene is a poor cross-linking agent and this is why only a small amount of the cross-linked polymer forms at high concentrations of the polyarylate in styrene solution.

Methyl methacrylate, allyl methacrylate, and ethylene dimethacrylate are effective cross-linking agents for allyl-containing polyarylates.

Some of the copolymers have good mechanical and thermal properties. For example, the copolymer with diallyl phthalate has a bending strength of 1190 kg cm^{-2} which hardly changes after 6 h at 250°C. Copolymers of 2-allylphenol with methyl methacrylate and with ethylene dimethacrylate retain a fairly high strength after heat treatment at 300°C in the presence of air. Furthermore, these copolymers exhibit high heat resistance (above 500°C) and thermal stability.

Investigation of Solutions of Cellulose

S.N.Danilov, T.I.Samsonova, and L.S.Bolotnikova

This review deals with studies of cellulose solutions. Various solvents for cellulose are characterised in detail. On the basis of the experimental results it is concluded that stable compounds are formed as a results of the reaction of cellulose with complex-containing solvents. The part played by complexes and alkalis present in the solvent in the dissolution of the cellulose is shown.

Various methods of fractionation and the principal relations between the characteristic viscosity and molecular weight of cellulose in various solvents are considered.

In the section dealing with the dimensions and form of the cellulose macromolecules it is shown that cellulose is of much greater dimensions than flexible synthetic polymers, owing to the greater size of the monomeric unit, the considerable extension of the macromolecules in the solution, and the reaction of cellulose with the solvent.

CONTENTS

1. SOLVENTS FOR CELLULOSE

The peculiarities of the structure of cellulose macromolecules, the regularity of its structure, and the strong intermolecular interactions, are due to the presence of hydrogen bonds, which results in cellulose being insoluble in water and organic solvents. It is soluble in aqueous solutions of complexes of bivalent and tervalent metals, certain salts, and concentrated acids (phosphoric acid).

The most widely used of the solvents containing complexes is a solution of the amminecopper complex, first obtained by Schweizer in 1857.[1] This solvent contains compounds formed in the reaction of copper hydroxide with ammonia and of the general formula $Cu(NH_3)_m(OH)_2$, with the tetramminecopper complex $Cu(NH_3)_4(OH)_2$ predominating.

When this solvent is stored in air for even a rather short period there is a change in composition owing to oxidation of ammonia to nitrous acid and beyond, as is shown by the appearance in the solution of ammonium nitrates and nitrites on storage[2] and the copper concentration drops owing to the separation of copper hydroxide. Danilov and coworkers[2-4] investigated the processes in the oxidation of amminecopper solutions of cellulose. In these solutions oxygen attacks both the ammonia and the cellulose as a vigorous carrier of oxygen is present—the copper ion in the tetrammine complex[5,6].

The oxidation of both the solvent itself and of solutions of cellulose in it can be suppressed by the introduction of additions of organic (sucrose, glucose, mannitol, tartaric acid) or inorganic (sulphite, thiosulphate) substances. These additions stabilise the amminecopper complex and lessen the oxidisability of the ammonia. The oxidative degradation of cellulose in a solution of amminecopper complex can be prevented by the addition of metallic copper to the solution, as this vigorously bonds the oxygen[6-12]. Additions of inhibitors greatly reduce the oxidisability of cellulose but do not eliminate it.

Cellulose concentrations of only 3–4% can be obtained by direct dissolution of cellulose in a solution of the amminecopper complex. To prepare more concentrated solutions, cellulose is mixed with a basic copper salt and ammonia solution. As the cellulose dissolves, additional amounts of the basic copper salt pass into the solution. Cellulose solutions with a concentration of over 12% can be obtained in this way. Foreign ions have a considerable effect on the solubility of basic copper salts in ammonia. Thus, copper hydroxide dissolves better in ammonia in the presence of sodium and ammonium sulphates[7].

Traube[12] obtained the ethylenediaminecopper complex by replacing ammonia by ethylenediamine (ED). This system is more stable than the solution of the amminecopper complex and there is less oxidation of solutions of cellulose in it. However, the solubility of cellulose in solutions of the ethylenediaminecopper complex is less than in solutions of the amminecopper complex[13]. According to Marx[14] the maximum possible concentrations of cellulose of various degrees of polymerisation reach 0.6–1.2 g per 100 ml on varying the degree of polymerisation from 6000 to 1500.

Unlike amminecopper solution, where a large excess of ammonia is used, solutions of the ethylenediamine complex dissolve cellulose at a strictly definite ratio of ethylenediamine to copper, en : Cu, which should be 2.[12,15] In instances when this ratio exceeds 2, that is, the en solution is not saturated with copper hydroxide, the solubility of cellulose is less. Since the solvent should always have a strictly defined composition this complicates its preparation. The information about the variation of the characteristic viscosity $[\eta]$ with the composition of the solution of ethylenediaminecopper complex is rather contradictory. Thus, Marx[14] thinks that the en : Cu ratio can be varied from 1.69 to 2.75 (0.5 g-ion copper/litre) without affecting the viscosity. According to Wilson[15], en : Cu should lie within the limits 2.00 ± 0.04, and the copper concentration 1.00 ± 0.1 M, for the change in relative viscosity not to exceed 1%. In studying the formation of the ethylenediaminecopper complex in aqueous solution, Vink[16] found that the existence of complexes of composition $Cuen_2^{2+}$, $Cuen^{2+}$, and $Cuen_3^{2+}$ is possible. He showed that at the ethylenediamine : copper ratio of 1.82 the following complexes can exist in the solution: $Cuen_2^{2+}$ 69.5%, $Cuen_2OH^+$ 9.3%, $Cuen(OH)_2$ 21.2%, that is, the complex $Cuen_2$ predominates in the solution. Like the solutions of amminecopper complex, solutions of the ethylenediaminecopper complex are unstable, although to a lesser degree[17,18]. Measurement of the viscosity of cellulose in solutions of the ethylenediamine complex also must be done in the absence of atmospheric oxygen[18].

Vink[19] observed, in studying the kinetics of oxidative destruction of cellulose in a solution of the ethylenediamine-copper complex, that the cellulose concentration has no effect on the rate of destruction. The rate is a maximum in the first day after the preparation of the solution but then decreases, owing to the formation of inhibitors in the ethylenediaminecopper solution. Two compounds were isolated: glyoxal dioxime HO–N=CH–CH=N–OH and hydroxyiminoacetic acid HO–N=CH–COOH. In investigating these and other oximes it was observed that hydroxyiminoacetic acid has the greatest inhibiting action. In addition to inhibitors, accelerators of the oxidation were found—dimethylglyoxime. It is noteworthy that ethylenediamine itself is not oxidised by oxygen; its oxidation, leading to the formation of inhibitors, takes place only in the presence of copper.

The use of solutions of ethylenediaminenickel[20] and ethylenediaminecobalt[21] complexes as solvents does not have any advantages over the ethylenediaminecopper complex. The presence of nickel and cobalt ions, which can be oxidised from the bivalent to the tervalent state, increases the destruction of the cellulose. Furthermore, these solvents are unstable and they are made in an atmosphere of nitrogen, to avoid the formation of cobalt(III) and nickel(III) hydroxides, which give complexes with ethylenediamine which do not dissolve cellulose. The solubility of the latter in these solvents is low.

Ethylenediamine also forms a complex with zinc and the aqueous solution of this compound dissolves cellulose[22,23]. However, the solvent is stable only at low temperatures.

Unlike the above solvents an aqueous solution of the ethylenediaminecadmium complex[24,25] (Cadoxene) is stable for an almost unlimited time, but cellulose does not oxidise much in it[26,27].

A solution of the ethylenediaminecadmium complex was first obtained in 1957 by Jayme[24,25] by saturating ethylenediamine solutions of various concentrations with basic cadmium salts, cadmium hydroxide at low temperatures, or cadmium oxide at room temperature and at 3–7°C.[28] This can be used as a solvent for cellulose with polymerisation degrees < 1200. To improve the dissolution of the cellulose, Jayme[29] suggested the preliminary swelling of the cellulose in water, but Henley[30] increased the solubility of cellulose by the addition of 0.2–0.5 mole sodium hydroxide to the Cadoxene. It is then possible to dissolve cellulose with a polymerisation degree of 5500. The maximum concentration of cellulose with degree of polymerisation 1200 reaches 4%. Nadziakiewics and Jedlinska[31] also added sodium hydroxide to the solution to improve the solubility of cellulose. However, addition of sodium hydroxide leads to an increase in the destruction of cellulose in Cadoxene[28,32].

Donetzhuber[33] showed the advantage of using a low temperature in the dissolution of cellulose in Cadoxene.

Bolotnikova and Samsonova[34,35] obtained Cadoxene which dissolves cellulose with degree of polymerisation 2000, by saturating a solution of ethylenediamine with cadmium oxide at 0°C for 1 h. In the dissolution of cellulose with a degree of polymerisation > 5000 it is desirable to reduce the temperature to between 0° and −50°C. The maximum concentration of cellulose at DP $\simeq 1200$ is 6–7%.[36]

Cellulose undergoes comparatively little oxidation in a solution of the ethylenediaminecadmium complex[26,34,37]. The presence of foreign ions (Cu^{2+}, Co^{2+}, Fe^{3+}, Ni^{2+}) as impurities accelerates the destruction of cellulose[37], therefore cotton cellulose is oxidised less than sulphite.

Among other methods for making Cadoxene that of Reimers[38] merits note. Ethylenediamine is passed through a column filled with a mixture of sand and cadmium oxide. A solution of the ethylenediaminecadmium complex of the desired cadmium concentration is obtained after 15 min.

An alkaline solution of sodium tartratoferrate complex is another solvent which is used for cellulose. Frank[39] was the first to investigate the complex present in this solvent. The formation of two complexes is possible in the Fe^{III}–tartaric acid–NaOH system, $[(C_4H_2O_6)Fe]Na$ and $[(C_4H_3O_6)_3Fe]Na_6$ at $Fe(OH)_3$: tartaric acid : NaOH molar ratios of 1 : 1 : 1 and 1 : 3 : 6 respectively. Jayme and Verburg[40] found the compositions of mixtures of components with the greatest dissolving power; the complex $[(C_4H_3O_6)_3Fe]Na_6$ is formed. The Na in this can be replaced by K and Li,[41] but the replacement of the tartaric acid by other organic acids: malic, oxalic, lactic, citric, or salicylic, does not lead to the formation of complexes which dissolve cellulose, since the complex is precipitated when the alkali is in excess[42].

Jayme and Bergman[43] proposed two methods for the preparation of a solution of sodium tartratoferrate complex (STFC). The reaction of stoichiometric amounts of an iron(III) salt and tartaric acid in the presence of an excess of sodium hydroxide gives the complex $[(C_4H_3O_6)_3Fe]Na_6$, which is separated by precipitation with alcohol. Then this very hygroscopic complex dissolves in the alkali solution and sodium tartrate is added for stabilisation. However, the most widely used method for making STFC is from tartratoferric acid, insoluble in water[43]. This is dissolved in a solution of alkali and sodium hydrogen tartrate, and the sodium hydrogen tartrate is added in slight excess to stabilise the solution. Two STFC solutions are used for dissolving cellulose with a high degree of polymerisation: one which brings about the swelling of cellulose contains 300 g litre^{-1} STFC, 1.0 N NaOH, and 35 g litre^{-1} sodium tartrate, and the composition of the second solution is 480 g litre^{-1} STFC, 3.0 N NaOH, and 25 g litre^{-1} sodium tartrate. On mixing these two solutions a solvent with optimal dissolving ability is obtained[44]. Valtasaari[45] obtained an alkaline solution of STFC by a simplified method—mixing iron nitrate, tartaric acid, and sodium hydroxide without isolating the pure complex. However, this solvent is suitable only for dissolving cellulose with a degree of polymerisation up to 1500, since foreign ions in this solvent reduce the solubility of cellulose[46]. All other methods for making STFC are only modifications of the methods of Jayme, Bergman, and Valtasaari[47–50]. Solutions of cellulose in an alkaline solution of STFC are fairly stable[51–54]; $[\eta]$ for sulphite cellulose with a degree of polymerisation of 1400 did not change in two days[53], there is only a change in the slope of the relation $\eta_{sp}/c = f(c)$, where c is the concentration in g/100 ml and η_{sp}/c is the reduced viscosity, which shows a change in the interaction of cellulose with the solvent. After 4 days $[\eta]$ had changed by $\sim 6\%$. An investigation of the kinetics of destruction of cellulose in STFC solution[54] showed that it does not depend on the concentration of cellulose in the solution but increases with the temperature. The rates of destruction of cellulose in STFC solution in an atmosphere of nitrogen, air, and oxygen are in the ratio 1 : 3 : 9. An analysis of the oxidation products of cellulose by gas chromatography showed that the oxidation takes place mainly at carbon atoms 2 and 3. Jayme and coworkers[55] later found rather pronounced destruction of cellulose in STFC solutions.

An alkaline solution of biuretcopper complex in which cellulose can also dissolve is formed on mixing copper hydroxide and biuret in 1 : 2 ratio in the presence of potassium hydroxide[56]. Increasing the copper : biuret ratio from 2 to 4 leads to a decrease in the solubility of the cellulose. On replacing the potassium hydroxide by sodium hydroxide the biuretcopper complex dissolves more slowly and to a lesser extent. The solvent is unstable. On storing it for 2–3 weeks the odour of ammonia appears, indicating decomposition of the biuret. The presence of cellulose in the solution of the complex accelerates its decomposition although the solubility of cellulose is unchanged. This is probably because an amminecopper complex is formed in the decomposition of the biuretcopper complex. There has not been a quantitative study of the stability of solutions of cellulose in the biuretcopper complex, although Jayme and Lang[56] noted a significant decrease in the viscosity of cellulose solutions during storage.

As has been shown[57–59], quaternary ammonium bases with a molecular weight over 150 dissolve cellulose, and those with a lower molecular weight cause it to swell. Each organic base can dissolve cellulose only at a definite concentration of the base in water, and this concentration is less the higher the molecular weight of the base. Tetramethylammonium hydroxide ($M = 91$) and trimethylpropylammonium hydroxide ($M = 119$) do not dissolve cellulose at any concentration. Tetraethylammonium hydroxide at a concentration of 35–40% in water dissolves cellulose with $M < 250\,000$. The best solvents are the quaternary ammonium bases containing benzyl radicals[59].

Of the other solvents for cellulose mention must be made of phosphoric acid and sodium hydroxide, but their use is limited, since they only dissolve cellulose with moderate degrees of polymerisation. 82–84% solutions of phosphoric acid have been proposed for the dissolution of cellulose by Ekenstamm[60,61]. In studying the effect of various conditions on the solubility of cellulose in phosphoric acid, Danilov and Gintse[62] found that the solubility curve has two maxima, between which there is a region of incomplete solubility. The position of these maxima correspond to the concentrations of acid at which it exists in the form of monohydrate and hemihydrate. When preliminary swelling of the cellulose in water or dilute phosphoric acid is employed dissolution also takes place in the range of compositions between the maxima. Drawbacks of phosphoric acid as a solvent are its own high viscosity and the fact that it can only dissolve celluloses with polymerisation degrees in the range 700–800, or at lower temperatures degrees of polymerisation up to 1200–1500.[60,61]

At a concentration of 10–12% sodium hydroxide can dissolve specimens of cellulose with a degree of polymerisation up to 350. Solutions of cellulose in alkali undergo strong oxidative destruction[4,63–65].

Cellulose dissolves when heated in solutions of certain salts, such as lower chlorides and thiocyanates, but solutions of cellulose in salts have hardly been investigated.

A quite recent proposal[66] was to dissolve cellulose and other polysaccharides in *NN*-dimethylformamide and *NN*-dimethylacetamide to which N_2O_4 and NOCl have been added. To dissolve cellulose in dimethylformamide the molar ratio of N_2O_4 to cellulose must be greater than 3 : 1 and the ratio of NOCl to cellulose greater than 8 : 1. The cellulose is first suspended in the dimethylformamide and then N_2O_4 or NOCl introduced. In contact with moist air cellulose is precipitated. Cellulose can be isolated from these solutions with water or lower alcohols. In the absence of moisture solutions of cellulose in these solvents are stable.

2. INTERACTION OF CELLULOSE WITH SOLVENTS WHICH CONTAIN COMPLEXES

In dissolving cellulose it is necessary to break the strong intermolecular interactions due to a large number of hydrogen bonds. The weakening of the intermolecular interaction is facilitated by solvation—the reaction of the hydroxyl groups of the cellulose with the solvent with the formation of a monosolvate sheath[67–69]. However, the hydrogen bonds in cellulose are not destroyed completely during solvation. On using solvents which contain complexes of metals a compound of cellulose and the solvent is formed and this together with hydration leads to the breaking of the hydrogen bonds and dissolution of the cellulose.

The greatest number of studies has been devoted to elucidating the mechanism of the dissolution of cellulose in a solution of the amminecopper complex. The first investigations in this direction were made by Traube[70–72] who studied the reaction of the amminecopper and ethylenediaminecopper complexes with tartaric acid and glycerol. He applied the results of his investigations to cellulose and suggested the existence of a complex of cellulose and the amminecopper compound of composition $[(C_6H_8O_5)_2Cu][Cu(NH_3)_4]$, where the ratio $C_6H_{10}O_5 : Cu = 2 : 1$. However, this does not fit in with modern views about the coordination numbers of copper. Hess and Messmer[73,74] also thought that the dissolution of cellulose in a solution of amminecopper complex yielded a compound of the alkoxide type, $[C_6H_7O_5Cu]_2[Cu(NH_3)_4]$, in which copper is present in both the anion and the cation. The formation of an alkoxide compound of copper with cellulose was not demonstrated by these investigators and is not very probable. Their papers do not give any evidence of a different type of bonding of the copper in the cation and anion[75].

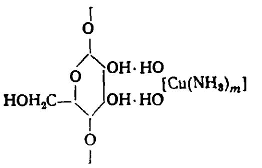
Danilov and Okun'[76–77] investigated amminecopper solutions of cellulose, hydroxyethylcellulose, methyl cellulose, alginic acid, sugars, and polyhydric alcohols. The investigation of electrophoresis and ionic exchange on cation- and anion-exchange resins, and also the study of the composition of precipitates obtained from solutions of cellulose in the amminecopper complex, the investigation of the absorption spectra of a solution of the amminecopper complex, cuprophane and Cellophane films, and solutions of cellulose and other polyhydroxy-compounds showed that copper is not present in the anion. Copper was deposited only on the cathode and exchange of ions on the anion-exchange resin was not observed, whereas the copper and ammonia were completely absorbed on the cation-exchange resin and cellulose was precipitated.

On the basis of their experimental results, Danilov and Okun' concluded that the compound formed in solutions of cellulose in amminecopper complex is not an alkoxide but a molecular compound of variable composition:

$$(C_6H_{10}O_5)_x[Cu(NH_3)_m(OH)_2]_y(H_2O)_z.$$

From a study of the optical rotation and electrical conductivity of amminecopper solutions of 17 glucosides, Reeves[78] suggested that in the solution a cyclic complex is formed between tetra-amminecopper and neighbouring hydroxyl groups of the glucosides. Glucosides without a glycollic grouping do not dissolve in the amminecopper complex.

To find the composition of the compound which is formed in the dissolution of cellulose in a solution of the amminecopper complex, Arkhipov[79] used polarimetric and conductometric methods and also determined the change in the copper concentration on the introduction of cellulose into the water–ammonia–copper hydroxide system. Thermodynamic quantities were calculated: the equilibrium constant of the reaction, the heat of reaction, the free energy change, and the change in entropy of the system. All these results show the formation of a molecular compound:



The nature of the reaction of cellulose with the ethylenediaminecopper complex is thought by Traube[71] and Jolley[80] to be analogous to interaction with the amminecopper complex.

Gralen and Linderot[81] used a spectrophotometric method to determine the optical density of solutions of glucose in solutions of amminecopper and ethylenediamine complexes at wavelength 330 mμm and various molar volumes of the components. These results were compared with optical densities of solutions of the components. Maximal difference in the optical densities was obtained at the glucose : copper ratio of 1 : 1 for solutions of glucose on the amminecopper complex and 4 : 6 for solutions of glucose in the ethylenediamine complex. Gralen and Linderot considered that these results confirmed Hess's alkoxide formula.

Comparatively recently Vink[82] investigated the formation of polysaccharidemetal complexes in solutions of cellulose in ethylenediaminecopper and ethylenediaminecadmium complexes. He subjected the cellulose solutions, diluted with water, to dialysis through Cellophane membranes. The difference in concentration of ethylenediaminecopper complexes on the two sides of the membrane was determined spectrophotometrically. Cellulose and dextran were used. The latter is soluble in water and therefore the composition of the ethylenediaminecopper complex can be varied within wide limits. The use of cellulose is limited to a narrow range of solvent compositions in which it can be dissolved. All the main experiments were made with dextran and then the results of these experiments were extended to cellulose.

Vink began from the assumption that the reaction of cellulose and dextran with ethylenediaminecopper complex can be effected either by the formation of a complex:

$$R'(OH)_2 + Cuen_2^{2+} + 2OH^- \rightleftharpoons R'O_2Cuen + en + 2H_2O, \qquad (1)$$

or by the scheme:

$$ROH + OH^- \rightleftarrows RO^- + H_2O. \qquad (2)$$

The degree of bonding β' of the metals, in this instance copper, was calculated by the formula:

$$\frac{\beta'}{1-\beta'} = K_1[OH^-] + K_2\frac{[Cuen_2^{2+}][OH^-]^2}{[en]}, \qquad (3)$$

where the values of the equilibrium constants K_2 and K_1 determine the relative importance of reactions (1) and (2).

The degree of bonding of the ethylenediaminecopper complex is almost independent of the concentration of the polymer in the solution, although it is somewhat higher for dextran than for cellulose. It was found that at low concentrations of ethylenediamine in the solution (up to 6%) the predominant reaction is the formation of a complex by reaction (1). On increasing the ethylenediamine concentration the second term in Eqn. (3) decreases and complex formation is replaced by reaction according to Eqn. (2), represented by the first term in the right-hand side of Eqn. (3). Cellulose dissolves in ethylenediaminecopper complex at the ratio en : Cu = 2 (6% ethylenediamine, copper concentration 0.5 M). On increasing the en concentration the ethylenediaminecopper complex does not dissolve cellulose. At high ethylenediamine concentrations (~ 25–40%) and a copper concentration of $\nless$ 0.35 M dissolution of cellulose again takes place, which shows the active role of en in the dissolution mechanism.

For solutions of cellulose and dextran in cadmiumethylenediamine complex it was found that within the limits of experimental error the rate constant of the reaction for complex formation is 0. Vink concluded that a complex of cellulose and Cadoxene is not formed, but formation of a compound by reaction (2) occurs. The degree of bonding of cadmium is lower than that of copper, and is the same for cellulose and dextran.

Lindberg and Swan[83] studied the composition of the compound formed in a solution of cellulose in Cadoxene by using the same method as Reeves[78], that is, they studied the change in the optical rotation of solutions of several glucosides and xylosides in Cadoxene and in a 28% solution of en. They think that a complex is formed between the hydroxyls of cellulose and the Cadoxene. A change in the optical rotation of the solution after it had been stored for 24 h was noted. No suggestions were made as to whether this is the consequence of the destruction of the cellulose in the solution or of a change in the state of the solution. A study by paper electrophoresis of a solution of methyl-β-D-glucopyranoside and of several sugars in 10% aqueous solution of Cadoxene (0.55% Cd) showed their low electrophoretic mobility, in good agreement with the results of electrophoresis in aqueous solutions of NaOH.[84]

Vink[82] suggests that the mechanism of dissolution of cellulose in Cadoxene is similar to the mechanism of its dissolution in quaternary ammonium bases. The large $Cden_3^{2+}$ ion in permeating into the cellulose causes its swelling and dissolution. The free ethylenediamine can form molecular compounds with cellulose[85,86].

Jayme and Verburg[41] studied the dissolution of cellulose in alkaline solutions of the sodium tartratoferrate complex[41]. They suggested that the solubility is determined by the swelling of cellulose in NaOH, which in the presence of STFC is so pronounced that dissolution takes place. In carrying out sedimentation and diffusion measurements, Jayme and coworkers[51] started from the fact that reaction between cellulose and STFC ends in addition. By measuring the vapour pressure it was shown that on adding cellulose to the solvent the activity of its components falls. Valtasaari[45] explained the solubility of cellulose in STFC by the direct combination of the cellulose with the iron. Bayer and coworkers[87] studied complex formation in the tartratoferric acid–alkali system from the change in optical rotation and light absorption as a function of the molar ratio of the components. It was found that the optimal Fe^{3+} : tartrate ratio for complex formation is 1 : 4.5. However, a system of this composition does not dissolve cellulose. For good dissolution of cellulose the Fe : tartrate ratio should be 1 : 3. This solution is stable but it contains insufficient tartrate for the complete saturation of the coordinate bonds of the iron. In place of the missing tartrate, water molecules and possibly hydroxide ions from the alkali are bonded with the iron. In the dissolution of cellulose the hydroxyl groups at carbon atoms 2 and 3 displace water molecules and hydroxide ions and form a new chelate compound. In this the hydrogen bonds of the cellulose are broken, destroying the physical structure, and the cellulose enters the solution. Tartrate ions are not displaced from their compounds with iron.

The general structure of the complex, which consists of iron and tartrate ions and of cellulose, cannot be found at present as the nature of the structure existing in the solvent is not known accurately.

3. FRACTIONATION OF CELLULOSE

The molecular weight distribution of cellulose is now mainly determined by the fractionation of its nitrates[88-91]. However, the fractionation of cellulose nitrate under conditions under which the usual polymers are fractionated leads, as Marx showed[92], to destruction, and this is the greater the higher the molecular weight[93]. The fractionation of cellulose nitrate is a long operation and takes 7–10 days. This is also insufficient, since the destruction of cellulose nitrate increases the longer the solution is kept. The breakdown is accelerated by rise in temperature and by alkali metal ions leached out of the glass[93]. In addition it is difficult to obtain completely substituted cellulose nitrate and therefore during fractionation separation will take place both by molecular weights and by degrees of substitution. Therefore it is important to carry out the fractionation of the cellulose by a direct method. Attempts were made to use all the present solvents for the fractionation of cellulose.

In the fractionation by the dissolution method a change in the solubility of cellulose in solutions of alkalis is brought about either by reducing the temperature from 20° to −12°C[94-96] or by change in the alkali concentration[97]. Acetone was used as precipitant in the fractionation of solutions of cellulose in alkalis by the precipitation method[98]. But only cellulose of a moderate degree of polymerisation is soluble in alkali and in alkaline medium it undergoes marked destruction in the presence of air.

Phosphoric acid can be used as solvent in the fractionation of cellulose of moderate degree of polymerisation. The method is based on the fact that at phosphoric acid concentrations from 72 to 83% macromolecules of cellulose of different sizes are dissolved[61]. The solubility of cellulose in phosphoric acid depends on the temperature and increases as the temperature is reduced[99]. According to Akim[100], who studied the polydispersity of celluloses by their fractional dissolution in phosphoric acid, seven or eight fractions can be obtained in 3–4 h. In the fractionation of cellulose in phosphoric acid solutions hydrolysis of cellulose is possible.

The method of fractionating cellulose from its solutions in sulphuric acid[101] is based on the ability of cellulose to be precipitated from such solutions at temperatures from −15° to −20°C on varying the concentration of the acid. A drawback of this method also is the pronounced hydrolysis brought about by the action of sulphuric acid and the possibility of obtaining a total of three or four fractions.

In the fractional dissolution of cellulose in solutions of amminecopper and ethylenediaminecopper complexes a change in the solubility of the cellulose was brought about[102] by the use of amminecopper solutions with different copper concentrations. Coppick and coworkers[98] and Müller and Rogers[103] separately treated several specimens of cellulose with a constant volume of solvent but with different copper concentrations, and Shulyatikova and Mandel'baum[104] varied the absolute amount of copper in the solvent used for dissolving the cellulose. In all the above instances it is thought that dissolution of cellulose with different degrees of polymerisation depends on the concentration of copper in the solution.

Sihtola and coworkers[105] checked this in the following manner. Different amounts of ammonia were added to a solution of cellulose in amminecopper complex, and the concentration of copper in the solution was altered, during which part of the cellulose was precipitated from the solution. Then its characteristic viscosity was determined. Another part of the cellulose left in the solution was precipitated with acid and $[\eta]$ was again measured. It was thus shown that although the concentration of copper in the solution was varied the characteristic viscosity of the precipitates hardly altered, that is, fractional separation did not occur.

The precipitants used for the fractional precipitation of cellulose from its ethylenediammine copper solutions are acids[106] and organic substances (glycerol, propanol, ethanol).[105] As Sihtola and coworkers[105] showed, breakdown of the complex occurs if acid is used to precipitate the cellulose. Usually three or four fractions are obtained, the first of which contains about two-thirds of the weight of the cellulose taken for fractionation. When glycerol and propanol are used to precipitate cellulose from its ethylenediaminecopper solutions the fractionation occurs according to molecular weights. However, it was concluded[105] that solutions of cellulose in the ethylenediaminecopper complex cannot be used for fractionating the cellulose with the aim of determining its molecular weight distribution, owing to the destruction of the dissolved cellulose by atmospheric oxygen.

In recent years Jayme and coworkers used the method of fractional dissolution for fractionation of cellulose from its solutions in Cadoxene[28] and an alkaline solution of the sodium tartratoferrate complex[107]. This was done by adding solvent with various cadmium contents to known weights of cellulose. After shaking for a fixed period the insoluble part was separated by centrifuging. Cellulose was precipitated from the solution left after centrifuging, washed, and its weight and degree of polymerisation determined. The values of $[\eta]$ and the weight of substance extracted were used to construct a molecular weight distribution curve.

Bolotnikova and coworkers[108] used glycerol solutions as precipitants for the fractionation of cellulose from solutions in Cadoxene. It was shown that separation into molecular weight fractions takes place. Specimens of sulphite cellulose with $[\eta] = 4.9$ were separated into 8–10 fractions with $[\eta]$ from 6.1 to 2.2. To decrease the dwell time of the cellulose in the solution centrifuging was used to separate the fractions. In preliminary experiments on the reprecipitation of cellulose from solutions in Cadoxene it was shown that the destruction of cellulose during this is insignificant and $[\eta]$ varies by $\sim 9\%$.

Laamanen and Sihtola[109] used a 75% solution of propanol as precipitant for the fractionation of cellulose from solution in Cadoxene. This method was also employed by Kostnikova and coworkers[110], who showed agreement with the results of fractionation through the nitrates.

A paper recently appeared on the possibility of obtaining a molecular weight distribution curve for cellulose by gel chromatography on polyacrylamide gel[111]. The concentration of cellulose in the eluate was determined by Vasseur's method[112]. Specimens with degree of polymerisation 780, 1180, and 2000 were isolated as were two 50 : 50 mixtures of these specimens having degrees of polymerisation (DP) of 780 and 1180 and of 780 and 2000.

Various precipitants have been used for the fractional precipitation of cellulose from its solutions in the alkaline sodium tartratoferrate complex. Thus glycerol[53,113,114], water–methanol mixture (but up to 20% of the cellulose could not be precipitated with this[115,116]), isopropyl alcohol[117], and glycol[117] have been used. Edel'man observed good agreement between distribution curves obtained in the fractionation of cellulose from solutions in STFC and by the nitrate method, when cellulose solutions taken for fractionation had concentrations $\ngtr$ 0.2 g per 100 ml.

4. RELATION BETWEEN THE CHARACTERISTIC VISCOSITY AND MOLECULAR WEIGHT

The direct determination of the molecular weight of cellulose is hindered by the strongly acid and strongly alkaline nature of its solvents. The determination of molecular weight in solutions of complexes is complicated by the fact that in all the measurements (sedimentation, diffusion, light scattering) the kinetic species is a compound of cellulose with the complex, but as already mentioned there is no single opinion about the composition of the complex.

Gralen[118] determined the molecular weight of cellulose and its derivatives (xanthogenates and nitrates) using sedimentation and diffusion. Polydisperse specimens of cellulose were studied. The molecular weight was determined in the absence of air. Anomalies were observed in diffusion measurements on amminecopper solutions of cellulose but these were not noted for solutions of nitrates and xanthogenates. The diffusion process was retarded and began only after 2–3 days. Such an initial retardation of diffusion is explained[119] by the fact that some part of the copper is bound with the cellulose and diffuses together with it. The concentration of copper in the solution is less than that in the solvent. This also causes an apparent slowing of the diffusion owing to contradiffusion. In calculating the molecular weight Gralen started from Hess's ideas about the structure of the cellulose complex. Gralen gives his observations on the difference between the refractive index determined in sedimentation and diffusion measurements and with the aid of differential prisms. The author suggested that in the first instance the refractive index of the cellulosecopper compound changes, and in the second that of cellulose itself. The approximate conclusion was drawn that this difference corresponds to one atom of copper per glucose residue. From Gralen's results on molecular weight and characteristic viscosity in an amminecopper complex, Hermans[120] derived a relation between $[\eta]$ and molecular weight (M). This relation is shown in Table 1, Eqn. (4).

Michil[121] determined the molecular weight of cellulose from its nitrates when deriving the relation between characteristic viscosity and molecular weight of cellulose in solutions of the amminecopper complex. He calculated the molecular weight of the cellulose nitrate from the relation $[\eta] = f(M)$, determined by Hunt and coworkers[122] and by Holzer and coworkers[123] from results on light scattering. The molecular weights calculated from the relation obtained by Michil for amminecopper solutions of cellulose—Eqn. (5) in Table 1—agree well with the molecular weights measured by Gralen.

Table 1 also gives the relation between $[\eta]$ and M for amminecopper, Eqn. (6), and ethylenediaminecopper, Eqn. (8), solutions obtained by Marx[14]. The degree of polymerisation used in the derivation of these relations was determined from the viscosity of cellulose nitrates and calculated by the Schulz and Marx equation[124]:

$$[\eta]_g = 1.8\cdot 10^{-3} P_w^{0.9}\,\mathrm{cm}^3\,\mathrm{gf}^{-1},$$

where P_W is the weight-mean degree of polymerisation and $[\eta]_g$ was determined at a rate of 500 s^{-1}.

Immergut and coworkers[125] found a relation between characteristic viscosity and molecular weight for solutions of cellulose in amminecopper and ethylenediaminecopper complexes—Eqns. (7) and (9) in Table 1. Polydisperse specimens of cellulose with degrees of polymerisation from 100 to 3000 were investigated. The molecular weights of the cellulose were determined from measurements of the osmotic pressure in solutions of the corresponding cellulose nitrates (polydisperse and fractionated specimens). These investigators attempted to determine the molecular weight of celluloses (DP 408 and 166) in a solution of the ethylenediaminecopper complex with the aid of osmometry. Membranes of poly(vinylbutyral) and poly(chlorotrifluoroethylene) were used. The values of the number-mean molecular weights thus obtained agreed well with those calculated from the relations they obtained.

Table 1. Relation between characteristic viscosity and molecular weight for cellulose in various solvents.

Solvent	Specimens of Cellulose	Temp., °C	Relation $[\eta] = f(M)$, 100 ml g^{-1}	Method	Ref.
Amminecopper complex	polydisperse	25	$[\eta]=0.77\cdot10^{-2}\ P^{0.81}$ (5)	NC_{ls}	121

Note. The fifth column gives the method used for determining the molecular weight in the scaling relation $[\eta] = f(M)$: sd, sedimentation and diffusion; ls, light scattering; os, osmometry; NC, molecular weight determined viscosimetrically by conversion of the cellulose into cellulose nitrate; and the subscript shows by which method the relation $[\eta] = f(M)$ was found for cellulose nitrate.

Vink[126] found that solutions of cellulose in the ethylenediaminecopper complex can be diluted with water. Such solutions do not dissolve more cellulose but neither does precipitation of the cellulose take place. Therefore for determining the partial specific volume of cellulose Vink used dialysed solutions and converted the Svedberg formula for calculating the molecular weight of cellulose from sedimentation and diffusion measurements in such a way that the calculation gave the molecular weight not of the cellulosecopper complex (like Gralen), but of the cellulose itself:

$$M = \frac{RTS_x^0}{D_x^0 M_x/M\,(1-\bar{V}_x\rho)},$$

where R is the universal gas constant, T the temperature, S_x^0 the sedimentation constant, and D_x^0 the diffusion constant for the compound of the solvent with cellulose, extrapolated to infinite dilution, ρ the density, $\bar{V}_x$ the partial specific volume, M_x the molecular weight of the compound of cellulose with the solvent. Vink[126] determined the value of

$$\frac{M_x}{M}(1-\bar{V}_x\rho)$$

experimentally by dialysis of cellulose solutions of various concentrations. Anomalies in the diffusion experienced by Gralen[118] were avoided by Vink in the following manner. To prevent counterdiffusion of copper ion from the solvent to the solution he diluted the solvent with a little water. The molecular weights obtained by Vink were compared with those calculated by Marx' equation[14] and showed good agreement. Vink also determined the molecular weights by osmometry and found the relation between $[\eta]$ and M, Table 1, Eqn. (10).

Henley[27] used Vink's method when investigating solutions of cellulose in solutions of the ethylenediaminecadmium complex. The cellulose solutions were diluted with water in 1:1 ratio and contained alkali. Owing to the difficulty in obtaining fractions, Henley used polydisperse specimens obtained by acid hydrolysis of linters with polymerisation 5800. In such treatment a statistical molecular weight distribution with ratio $M_w:M_n = 2$ should be established, where M_w is the weight-mean and M_n the number-mean molecular weight. The relation between the molecular weight and $[\eta]$ obtained by Henley from the sedimentation and diffusion results are given in Table 1, Eqn. (11). Henley also determined the molecular weight of cellulose by a light scattering method. In studying the light scattering of solutions of cellulose in Cadoxene the increment in refractive index was determined after equilibrium dialysis at wavelengths of 5460 and 4358 Å; it was 0.183 and 0.186 ml g^{-1} respectively. The intensity of scattering was measured over the range of angles from 45° to 135°; the $[\eta] = f(M)$ relation—Table 1, Eqn. (12)—was found from the results on molecular weights and $[\eta]$.

Henley employed the usual Cellophane membranes in measuring the osmotic pressure of solutions of cellulose in Cadoxene diluted with water. Since it was assumed that $M_w:M_n = 2$, the values of M_w and M_n gave the viscosity-mean molecular weight and the relation $[\eta] = f(P_v)$, where P_v is the viscosity-mean degree of polymerisation, Table 1, Eqn. (13).

Bolotnikova and Samsonova[127] found the relation between $[\eta]$ and M for fractionated and polydisperse specimens of cellulose in solutions of the ethylenediaminecadmium complex not diluted with water. The molecular weights of cellulose were determined from the viscosity of their nitrates.

The molecular weight of the cellulose nitrates was determined by the relation:

$$[\eta]=2.8\cdot10^{-5}\ M_{ww}^{1.00},$$

obtained by Meyerhoff[128,129] in investigating the sedimentation and diffusion of fractionated and polydisperse specimens of cellulose nitrate in acetone at 20°C. The molecular weights of several specimens of cellulose nitrate were determined by sedimentation and diffusion methods and their values agreed with those calculated by Meyerhoff's equation.

It was observed that there is a decrease in the slope of the relation between lg $[\eta]$ and lg M in the range of high molecular weights. Consequently this relation was found for two ranges of molecular weights. For fractionated specimens of cellulose with a molecular weight up to 400 × 10^3—that is, up to $[\eta] = 10$ g per 100 ml—the relation is described by the equation:

$$[\eta]=5.93\cdot10^{-5}\ M^{0.94}\quad(100\text{ ml g}^{-1}),$$

and in the range of molecular weights greater than 300 × 10^3 by

$$[\eta]=9.33\cdot10^{-4}M^{0.72}\quad(100\text{ ml g}^{-1}).$$

This difference in the values of the constants K and α in the Mark–Kuhn–Houwink equation $[\eta] = KM^{\alpha}$ between the low- and high-molecular weight ranges are due to the fact that at low degrees of polymerisation the final configuration of the coil has not been reached and the asymmetry of the molecules gradually decreases with increase in the molecular weight. Furthermore it can also be explained by the observed deterioration in the quality of the solvent for cellulose with a higher molecular weight. Brown and Wirkström[130] obtained similar results about the different nature of the relation between $[\eta]$ and M; they observed that at DP < 250 the conformation undergoes changes and the behaviour of the molecule departs from the behaviour of the coil. This agrees with the theories of the Kuhns, a verification of whose equations shows[131] that there is a change from the value $\alpha = 1$ in the range of low molecular weights to the value $\alpha = \frac{1}{2}$ in the range of high molecular weights, α being the exponent in the equation $[\eta] = KM^{\alpha}$. This change is due to a change in the trapping of the solvent in the coil of the chain molecule.

Vink[132] studied the behaviour of low-molecular-weight cellulose and oligosaccharides. For the oligosaccharides was determined in water, Cadoxene, and sulphuric acid. For degrees of polymerisation up to 150 a linear relation between $[\eta]$ and M was obtained. At lower degrees of polymerisation (< 100) the slope of the straight line $[\eta] = f(M)$ increases and consequently α also increase; the maximal value being $\alpha = 1.3$ at DP = 15. As has been shown[132], this behaviour of the molecules follows from their tendency to approach a prolate ellipsoidal form as the molecular weight is decreased.

Claesson and coworkers[51] made a diffusion and sedimentation investigation of solutions of cellulose in an alkaline solution of the sodium tartratoferrate complex which had been diluted with water; the relation between $[\eta]$ and M was obtained, Table 1, Eqn. (18). Later Valtasaari[133] obtained the $[\eta] = f(M)$ relation for solutions of cellulose in an alkaline solution of STFC by a light scattering method. This relation is also given in Table 1, Eqn. (19). Other relations between $[\eta]$ and M obtained by calculations from measurements of $[\eta]$ in two solvents, have been published[134].

5. DIMENSIONS AND FORM OF CELLULOSE MACROMOLECULES IN SOLUTION

Cellulose, like many synthetic polymers, is a linear unbranched polymer. However, the properties of cellulose solutions show a difference from those of flexible polymers, for example, those of the vinyl series. Thus it is well known that cellulose has a comparatively high characteristic viscosity ($[\eta]$), low sedimentation constant (S_0) and diffusion coefficient (D_0). Many of these properties, for example, $[\eta]$, are functions of the absolute dimensions of the macromolecules in the solution.

The dimensions and form of the cellulose macromolecules in solution are determined on the one hand by the size and structure of the monomeric unit, which is anhydro-*d*-glucose of cyclic structure, linked by a β-1,4-bond, and on the other hand by the presence of three free hydroxyl groups, which determine the existence of both intra- and inter-molecular hydrogen bonds and also the specific nature of the interaction with the solvent.

To separate the influence of the solvent from the influence of the proper characteristics of the molecules, it is necessary to know the unperturbed dimensions in θ-conditions, that is, when the behaviour of the solution becomes ideal and the second virial coefficient equals zero.

The unperturbed dimensions depend on the size of the monomeric units, the lengths of the bonds between them, the valence angle, and steric and energetic hindrances to rotation around the intermonomeric bond. However, for cellulose it is experimentally difficult to attain the θ-condition, since the complexes in which cellulose is soluble exist in a narrow range of component concentrations and temperatures.

Samsonova and coworkers[135] calculated the unperturbed root mean square distances between the ends of the chain $\langle h_0^2\rangle^{1/2}$ for cellulose in Cadoxene by the Stockmayer–Fixman equation[136], by introducing the additional function $\Phi_0/\Phi(M)$[137]:

$$[\eta]\cdot\Phi_0/\Phi(M) = K_\theta M^{1/2} + 0.51B\Phi_0 M, \tag{20}$$

where

$$K_\theta = \Phi_0\left(\frac{h_0^2}{M}\right)^{3/2}, \Phi_0$$

Φ_0 is the universal Flory constant equal to 2.86×10^{21} for a statistical gaussian coil, $\langle h_0^2\rangle^{1/2}$ is the unperturbed root mean square distance between the ends of the chain, M the molecular weight, B a parameter which characterises the polymer–solvent interaction and is proportional to the second virial coefficient, and $\Phi(M)$ is a function depending on the molecular weight introduced by Eizner and Ptitsyn[138] for the Flory constant with rigid macromolecules which are permeated by the solvent:

$$\Phi(M) = \frac{\Phi_0}{\left[\varphi(\lambda, n) + \frac{45}{32}\sqrt{\frac{2\pi}{3}}\frac{1}{3-\sqrt{2}}\frac{b_0}{r_0}\sqrt{\frac{\lambda}{n}}\right]\varkappa^{1/2}(n/\lambda)}. \tag{21}$$

Here λ is the correlation length, equal to a/b_0, a the persistent length[139], b_0 the "dry" length of monomeric unit, found by an X-ray method to be 5.15 Å, and n is the degree of polymerisation.

It has been shown experimentally[27,140-143] for cellulose and its derivatives that Φ_0 depends on the molecular weight and only becomes constant at rather high molecular weights. This is explained by the great extension of the macromolecules in solution in the range of low molecular weights, so that gaussian statistics are attained only at high degrees of polymerisation when further interaction is small. It can be suggested that a change in Φ arises from the dependence of the permeability of these molecules on molecular weight.

Table 2 gives results on $\langle h_0^2\rangle^{1/2}$. Henley[27] calculated the unperturbed dimensions of cellulose macromolecules from the values of the Flory swelling coefficient α, which characterises the interaction of the polymer with the solvent and is equal to the ratio of the root mean square dimension of the disordered coil to the corresponding dimension of the unperturbed molecule

$$\alpha = \frac{(h^2)^{1/2}}{(h_0^2)^{1/2}},$$

and the value of $\langle h^2\rangle^{1/2}$ is the root mean square distance between the ends of the chain. The Henley swelling coefficient was calculated by the Orofino–Flory equation[144] from the experimental results for the second virial coefficient determined by the light scattering method and from the root mean square radius of gyration of the chain $(\overline{R}^2)^{1/2}$.

Table 2. Dimensions of the macromolecules of cellulose and its derivatives calculated by Eizner and Ptitsyn's theory[138].

System	$[\eta]$	n	λ	$(h^2)^{1/2}$	$(h_0^2)^{1/2}$	$h_{max}/(h^2)^{1/2}$	α

	2.55	1800	330	810	660		1.22	

* The values are approximate, since in calculating $\langle h_0^2\rangle^{1/2}$ the Stockmayer–Fixman theory was used, which cannot be employed in the investigated ranges of molecular weight for cellulose and its derivatives[148].

The value of $(\overline{R}^2)$ is the mean square of the distances r_i of all the elements of mass (atoms) of the chain from its centre of inertia[145];

$$(\overline{R}^2) = \frac{1}{N}\sum r_i^2,$$

where N is the number of units in the molecule. At sufficiently high molecular weights, when a gaussian distribution inside the macromolecule has been reached, statistical theory leads to the following relation:

$$(\overline{R}^2)^{1/2} = \frac{1}{6}h^2.$$

Henley[27] determined $(\overline{R}^2)^{1/2}$ experimentally for solutions of cellulose in Cadoxene diluted with water from the slope of the scattering relation at zero concentration (Table 3) and calculated it from values of S_0, D_0, $[\eta]$, and M. However, good agreement between the calculated and experimentally determined values was not obtained, except for the calculation of $(\overline{R^2})^{1/2}$ from $[\eta]$ and M. Samsonova and coworkers[135] calculated the mean square distance between the ends of the chain according to the Eizner and Ptitsyn theory[138], in which the rigidity and finite length of the chain are allowed for by introducing two functions $\varphi(\lambda,n)$ and $\kappa(n/\lambda)$; $\kappa(n/\lambda)$ takes into account the factor of chain rigidity and the function $\varphi(\lambda,n)$ allows for possible departures from gaussian statistics at low degrees of polymerisation.

Information about the sizes of cellulose macromolecules of various molecular weights is given in Tables 2 and 3, which also gives for comparison the dimensions of cellulose derivatives in various solvents[27,135,140–143]. It also gives values of the swelling coefficient α, which takes into account the contribution of the effect of the interaction of the polymer with the solvent. It was found that the dimensions of the macromolecules of cellulose and its derivatives in solution are appreciably greater than those of synthetic polymers at the same degree of polymerisation. The greater dimensions of the macromolecules of cellulose and its derivatives are due firstly to the greater size of the monomeric units $b_0 = 5.15$ Å (for polystyrene $b_0 = 2.54$ Å), and secondly to the greater elongation of the macromolecules owing to restricted rotation around the C–O bond between monomer units. This was shown for both cellulose[27] and its derivatives[140–143,146] by a comparison of $\langle h_0^2\rangle^{1/2}$ calculated from the experimental results with the values of $\langle h^2\rangle_f^{1/2}$ calculated assuming free rotation around the bond between monomer units. It was found that $\langle h_0^2\rangle_f^{1/2}$ is 2–3 times greater than $\langle h_0^2\rangle_f^{1/2}$ (Tables 3–6) and the ratio $\langle h_0^2\rangle^{1/2}/\langle h^2\rangle_f^{1/2}$ increases with decrease in molecular weight, showing the change in the elongation of the macromolecule with M. Furthermore, the restriction of rotation around the intermonomeric bond is shown by the high values of $\cos\Phi$[27,140–143] which is a parameter of steric hindrance. At sufficiently high values of n an analysis of hindrances to rotation can be made by using the equation:

$$h_0^2 = N\bar{b}_0^2\left(\frac{1-\cos\theta}{1+\cos\theta}\,\frac{1+\cos\Phi}{1-\cos\Phi}\right), \tag{22}$$

where N is the total number of units, θ the oxygen valence angle in cellulose and its derivatives (~ 110°), and Φ the angle between the planes of successive bonds. When rotation around the C–O bond is unrestricted, $\cos\Phi = 0$, and in the absence of free rotation with maximal elongation $\cos\Phi = 1$. For cellulose $\cos\Phi = 0.78$,[27] that is, the steric hindrances in the cellulose chain should be one of the factors which determine the form of the cellulose molecules in the solution. For amylose $\cos\Phi = 0.81$[147] and for hydroxyethyl cellulose[143] $\cos\Phi = 0.89$. In the last instance the high value of $\cos\Phi$ is due to the presence of additional hindrances, owing to the hydroxyethyl side-groups having approximately the same length as the monomeric unit b_0.

Table 5. Comparison of A_m and b for cellulose and its derivatives.

Table 4 gives the dimensions of the macromolecules of various polysaccharides calculated by the Eizner–Ptitsyn theory[128,135,137,149–153]. On comparing the results given in Tables 2–4 we see that the dimensions of almost all the polysaccharides, except cellulose nitrate and hydroxyethyl cellulose in water, are approximately the same at the same degrees of polymerisation, as is shown by the almost equal values for the correlation lengths λ and for the persistent length a. This shows that polysaccharides having a β-1-4

Table 4. Dimensions of the macromolecules of various polysaccharides calculated by the Eizner–Ptitsyn theory.

No.	Polymer	Solvent	M_0	Range of $[\eta]$, dl g^{-1}	Range of SP	λ	a	$(R^2)_z^{1/2}$, Å	Reference
1	birch xylan	90% DMSO	149	0.24—0.88	55—194	6.6	34.2	48—102	149

14	"	cyclohexane	52.1	0.18—0.40	433—2260	6.0	9.8	44—103	153

bond, and also an α-1-6 bond in the example of galactomannates, have the same configuration, which is almost independent of the lateral substituent groups.

The small differences in λ, for example, for acetylcellulose ($\lambda = 11-14.7$) can be explained by the difference in the degrees of polymerisation, since with increase in n the effect of excluded volume begins to be apparent. An especially pronounced dependence of λ on DP was observed for cellulose nitrate[135]. The lower rigidity of pentosans compared with hexosans can be explained by the fact that xylan, which has five carbon atoms has greater free rotation around the ether bond than hexosans. True, at the low value of $\lambda = 6.6$ xylan can have too low a DP. The value of $\lambda = 2.7$ for xylan from canadian spruce is thought to be erroneous by the investigators themselves[150], probably owing to errors in the molecular weight determination by the light scattering method, where the effect of lignin impurities and of the aggregation of the particles should appear.

Table 6. Parameters which characterise the undisturbed state for cellulose and its derivatives in Cadoxene and polystyrene in toluene.

Polymer	b, Å	A_m, Å	A_m, mol. units	$(\overline{h_0^2})^{1/2}/(\overline{h^2})_f^{1/2}$	Reference
Cellulose	19	70	14	2.7	27
Hydroxyethylcellulose	18	62	12	2.4	141
Sodium carboxyethylcellulose	18	60	12	2.4	140
Polystyrene in toluene	8.6	33	13	2.2	156, 157

The comparatively low value of λ for cellulose caproate is explained by the fact that it was obtained under θ-conditions.

The other values given in Tables 2 and 5, show the degree of elongation or the flexibility of the macromolecules. The relation $h_{\max}/\langle h^2\rangle^{1/2}$ characterises the degree of convolution of the macromolecules, where $h_{\max}$ is the contour length of the completely extended molecule $= nb_0$. $A_m = h^2/h_{\max}$ is the effective length of the Kuhn statistical segment, which is a measure of the short-range interactions affecting the length of the segment and characterising the chain "rigidity". Here the "rigidity" of the chain signifies the elongation owing to restricted rotation around the intermonomeric bond rather than resistance to deformation. $b = (h^2/n)^{1/2}$ is the effective length of the monomeric unit just as the persistent length a[139] is a measure of the "rigidity" of the chain.

A comparison of these quantities shows that cellulose has the same degree of convolution, or the inverse quantity, degree of elongation, as its derivatives, with the exception of cellulose nitrate and of hydroxyethyl cellulose in water. The great extension of the macromolecules of cellulose nitrate is due to the presence of the strongly polar NO_2 groups, and that of hydroxyethyl cellulose in water to the presence of intramolecular hydrogen bonds, which have a considerable effect on free rotation around the intermonomeric bond. Here solutions of hydroxyethyl cellulose in water are very stable; they can be heated to boiling or large quantities of precipitant (salts or dimethyl sulphoxide) can be added without precipitation of the polymer—a difference from methyl cellulose[154]. The addition of precipitant has no effect on the change in the molecular elongation of the hydroxyethyl cellulose. This independence of the composition of the solvent can be explained by the presence of intramolecular hydrogen bonds, which play a large part in the form of the macromolecules in solution. An increase in the hydrophobic nature of the substituents in ethylhydroxyethylcellulose leads to less extension, and an increase in the degree of substitution in methyl cellulose (28% methoxy-groups) to a more compact structure.

For sodium carboxymethylcellulose the dimensions and form of its macromolecules in solution depend on the ionic strength of the solvent. At a high ionic strength (in Cadoxene and 1 N NaCl) the CMC molecule behaves like cellulose and other uncharged derivatives of cellulose in Cadoxene and has the same dimensions. It is less extended than hydroxyethyl cellulose in water. With decrease in the ionic strength the dimensions of the coil increase considerably, by approximately a factor of 2 (for a change in ionic strength from 0.2 M NaCl to 0.005 M NaCl) owing to interaction between the charged groups.

The great dimensions of the macromolecules of cellulose and of derivatives in real, that is, non-ideal, solutions is due to the considerable spreading of the molecules due to interaction with the solvent, which has been characterised[27,135,140–143] by the swelling coefficient α, which is the effective excluded volume. Here the nature of the interaction with Cadoxene is the same for both cellulose and those derivatives which are soluble in the solvent.

The swelling coefficient is rather high (1.4) but less than the values given in the tables for specimens with low n, which suggests that a gaussian distribution of the segments inside the coil is not achieved. The low value of α for hydroxyethyl cellulose in water again suggests a more elongated form for the macromolecules.

Water has a great affinity for the hydroxyl groups and forms a compact solvate layer around the macromolecule which decreases with increase in temperature.

The size of the cellulose macromolecules in Cadoxene is also affected by the fact that Cadoxene does not simply solvate the cellulose but forms a more stable compound with it than the solvates. The existence of a compound of cellulose with the solvent the electronic polarisability of which is sufficiently high suggests a high value for the increment in refractive index dn/dc which is approximately 0.18 for cellulose in Cadoxene[27] and in sodium tartratoferrate complex[52].

The second virial coefficient for cellulose[27] and its derivatives in Cadoxene[140–143] is rather high ($A_2 = 10-17 \times 10^{-4}$) which suggests good interaction of the polymer with the solvent. Since the presence of hydrogen bonds in cellulose requires very polar solvents for its dissolution, it is natural that after the cellulose has dissolved these solvents become "good" in the thermodynamic sense in relation to the cellulose macromolecules. An analysis of the thermodynamic parameters for the interaction of the polymer with the solvent showed that cellulose and its derivatives have a negative entropy of mixing[142,155], which shows the compact arrangement of the solvent molecules around the polymer segments. The nature of the interaction of cellulose and its derivatives with the solvent depends on the degree of polymerisation, the temperature, the degree of substitution (in the cellulose derivatives) and also the nature of the solvent.

The strongly negative temperature coefficient of the characteristic viscosity for cellulose and its derivatives shows a decrease in the elongation of the macromolecules with increase in temperature, which is mostly connected with the weakening of the polymer–solvent bond. This is also shown by the change in α with temperature. Furthermore, the values of α and A_2 depend on the degree of polymerisation[27,140–143,146].

On comparing the unperturbed dimensions of cellulose and its derivatives with polystyrene we see that the flexibility of cellulose in solution is not very different from the flexibility of polystyrene, the number of monomeric units in the equivalent Kuhn statistical segment is almost the same but a greater degree of polymerisation for cellulose and its derivatives is needed only to achieve the conformation of a statistical coil.

Types of Reaction Undergone by Coordinated Ligands and the Factors Influencing the Change in Their Reactivity†

Yu.N.Kukushkin

The influence of the following factors on the reactivity of coordinated ligands (chiefly nitrogen-containing ligands) is examined: 1) the nature of the metal ion; 2) displacement of the electrons of the ligand to the central ion; 3) change in the stability of the complexes formed in the reaction relative to that of the original complexes; 4) the charge of the ionic complexes; 5) the influence of π-dative bonding by one ligand to the central atom on the reactivity of another ligand in the same complex; 6) stabilisation of one of the tautomeric forms of a ligand as a result of complex formation with metal ions; and 7) stabilisation of the deprotonated form of a ligand by complex formation. Examples of the masking of individual functional groups by complex formation and the manifestation of new chemical properties of the ligand as a result of coordination are examined. It is shown that in a number of instances the metal ion can be regarded as a matrix on which the synthesis of an organic molecule takes place. Reactions involving "insertion" into a metal-ligand bond are discussed. The bibliography contains 93 references.

CONTENTS

I. INTRODUCTION

In recent years, chemists in various countries have been paying increasing attention to the study of the chemical behaviour of molecules or ions in the inner sphere of complex compounds of various metals; a number of reviews[1-5] and a collection of papers[6] have been published. The chief aim of the study of the reactivity of coordinated ligands is the development of a theory of homogeneous catalysis involving metal complexes. A recent review[7] published in the Soviet Union contains material which is also directly related to this question.

---

† This review is based on a paper presented at a symposium on "The Properties of Organic Ligands in Complexes with Metals", held at Zelenogorsk (Leningrad) in December, 1968.

The aim of the present review was not to present all the factual material available in the literature. The author has tried, on the basis of specific examples, to demonstrate the factors influencing the reactivity of chiefly nitrogen-containing ligands.

II. CHANGE IN THE ACID-BASE PROPERTIES OF LIGANDS UNDER THE INFLUENCE OF A METAL ION

One of the first chemists to raise the question of the change in the properties of ligands when they are introduced into a complex with metal ions was A. A. Grinberg. As early as 1927, he presented a paper entitled "The Change in the Reactivity of Molecules Bound in Complexes".

No one is now surprised by the fact that ammonia, on entering a complex, "loses" its basic properties and exhibits acidic properties. The theory of the acid-base properties of complex compounds was to a considerable extent developed by Grinberg[8]. It is quite familiar, and there is no need to dwell on it.

The influence of the difference in the mobilities of the protons on the nitrogen atom in various reactions of coordinated ammonia can be demonstrated for the example of its reaction with chlorine. It has been established that an ammonia molecule in the inner sphere of Pt^{IV} complexes can be converted into dichloroamine[9]:

$$[PtCl_3(NH_3)_3]^+ \xrightarrow{Cl_2} [PtCl_3(NH_3)_2(NCl_2H)]^+$$
$$[PtCl_3(NH_3)_2(NCl_2H)]^+ \rightarrow [PtCl_3(NH_3)_2(NCl_2)]^0 + H^+$$

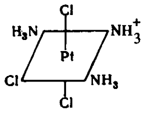
The hydrogen atom in the dichloroamine is so labile that complexes containing the dichloroamido-group NCl_2^- are usually isolated in the solid phase.

Table 1. Acidic dissociation constants of amine complexes of Pt^{IV} and the instability constants of their silver and thallium salts.

Type of complex	$K^*_{H^+}$	K_{Ag^+}	K_{Tl^+}
$[PtCl_2(NH_3)_3(NH_2M)]^{2+}$	6.0×10^{-12}	–	1.5×10^{-4}
$[PtCl(NH_3)_4(NH_2M)]^{3+}$	7.9×10^{-9}	1.3×10^{-8}	(2.0×10^{-6})
$[PtBr(NH_3)_4(NH_2M)]^{3+}$	5.6×10^{-9}	1.2×10^{-8}	–
$[Pt(NH_3)_5(NH_2M)]^{3+}$	1.2×10^{-7}	4.9×10^{-8}	3.6×10^{-4}
$[PtCl(NH_3)_3Py(NH_2M)]^{3+}$	1.2×10^{-7}	5.7×10^{-7}	3.7×10^{-4}
$[PtCl(NH_3)_2Py_2(NH_2M)]^{3+}$	1.6×10^{-6}	2.2×10^{-5}	5.5×10^{-4}
$[PtClPy_4(NH_2M)]^{3+}$	6.0×10^{-5}	3.2×10^{-5}	3.2×10^{-3}

*The acidic dissociation constants are taken from Refs. 19 and 20. The constants for the hexammine is taken from more accurate data[21].

Of the three ammonia molecules in the ion



the greatest lability is shown by the molecule of the Cl–Pt–NH_3 axis. It is this molecule which is converted into dichloroamine. It has been shown[10,11] for a large number of examples that when several coordinated molecules are present, conversion into chloroamines (or bromoamines) is undergone first of all by the molecules in which the protons have the highest lability.

The establishment of the relationship between the acidic properties of complex compounds and the ability of amines to undergo conversion into chloroamines led to the prediction[12,13] of the possibility of preparing chloroamine compounds from amine compounds of palladium(IV), gold(III), and various other metals. A chloroamine compound of palladium was prepared by Babaeva and Khananova[14], and a gold compound by Kukushkin and Zorina[15].

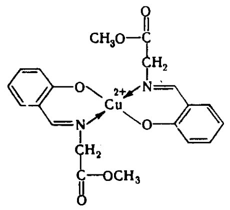
In joint work with Grinberg[16] it was shown that in Pt^{IV} complexes the hydrogen atoms of the ammonia molecules can be replaced by silver, and in work with Rabinovich and Goloseeva[17,18] it was established that this replacement can also be achieved with thallium. It was also shown[17,18] that with increase in the acidic properties of the ammines there is a decrease in the stability of both the silver and the thallium derivatives. For the thallium derivatives, a levelling of the instability constants was observed, but the overall tendency for the stability to change remained.

It can be seen from Table 1 that the silver derivatives are much more stable than the thallium compounds. This corresponds to the stabilities of silver and thallium ammines. The instability constant of $Ag(NH_3)^+$ is 6.3 × 10^{-4}, and that of $Tl(NH_3)^+$ is 8.3.

The factors determining the acidic properties of amine complexes probably retain their significance in the dissociation of the corresponding silver salts. Two of the main factors influencing the acidic properties of inner-sphere ligands are the charge of the central ion and the charge of the ionic complex. It will be seen from what follows that both of these factors are extremely important for the reactivity of coordinated ligands.

III. CHANGE IN REACTIVITY AS A RESULT OF THE DISPLACEMENT OF THE ELECTRONS OF THE LIGAND TO THE CENTRAL ATOM

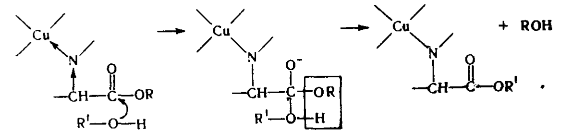
Pfeiffer and coworkers[22] carried out the trans-esterification of the ester fragment of the Schiff's base of an aminoacid, coordinated to the bivalent copper ion. These trans-esterifications took place at a much higher rate within the complex



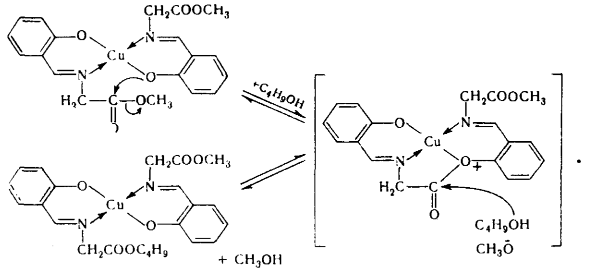
than in the free esters. For example, the replacement of the methoxy group by the butoxy group took place in 10 min in the complex dissolved in butanol.

Much later, Verter and Frost[23] continued Pfeiffer's studies with this and similar compounds. In addition to a large number of trans-esterifications within the complexes, Verter and Frost were able to carry out the amidation of coordinated Schiff's bases; in particular, they were able to replace the methoxy group CH_3O by the butylamino group C_4H_9NH.

There are two views regarding the mechanism of these reactions. Martell and Calvin[24] attribute this marked increase in the rate of trans-esterification to the displacement of electrons from the carbonyl carbon towards the copper atom under the influence of the donor–acceptor bond between the ligand and the central atom. This displacement should facilitate the reaction of the electron-donating oxygen atom of the solvent molecule with the carbon of the carbonyl group. The mechanism of this reaction can be represented schematically as follows:

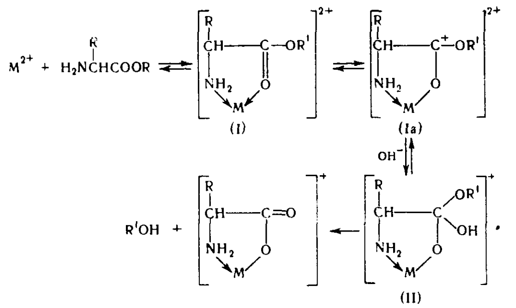


The reaction mechanism proposed by Verter and Frost[23] assumes the mutual influence of the ligands in the complex



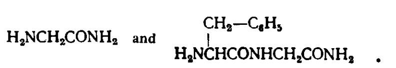
The carbonyl of the ester group is attacked by the oxygen atom of the aldehyde fragment of another ligand with the formation of an intermediate structure of the lactone type. This reaction should be reversible, but with the high active mass of the solvent alcohol it moves preferentially in one direction.

Kroll[25] studied the catalytic action of bivalent heavy metal ions on the hydrolysis of the esters of aminoacids. The rates of these reactions are extremely low in the absence of metal ions, which produce a marked increase in the reaction rates. In Kroll's opinion, the catalytic increase in the rate of hydrolysis of the aminoesters can be explained schematically as follows:



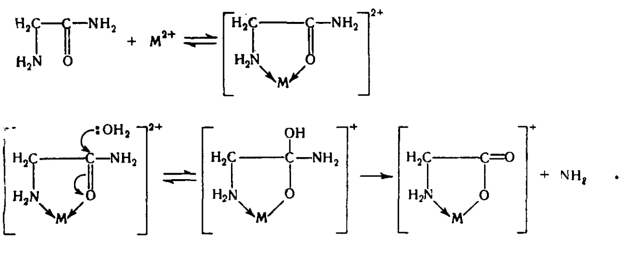
The proposed mechanism is based on the principle that the ligand in the coordinated state (I) and (Ia) exhibits a higher affinity for the hydroxide ion than the free ester. In other words, coordination increases the electrophilic nature of the reaction centre. The intermediate unstable complex (II) decomposes to the alcohol and the complex of the aminoacid, dissociation of which completes the cycle of catalytic reactions. For a series of bivalent ions, Kroll established a correspondence between the tendency to form complexes and the catalytic effect of the ions.

The catalytic influence of Cu^{II} on hydrolysis and isotopic exchange of oxygen in aminoesters was also studied by Bender and Turnquest[26]. Meriwether and Westheimer[27] studied the catalytic influence of bivalent copper, nickel, and cobalt ions on the hydrolysis of the amides

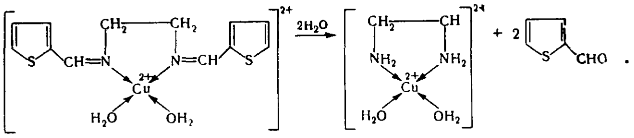


$$H_2NCH_2CONH_2 \text{ and } H_2N\underset{}{\overset{CH_2-C_6H_5}{\overset{|}{C}}}HCONHCH_2CONH_2 \ .$$

The views of these authors[26,27] regarding the mechanism of the catalysis of these reactions essentially coincide with the mechanism put forward by Kroll[25]. The catalysis of the hydrolysis of aminoacetamide can be represented as follows:

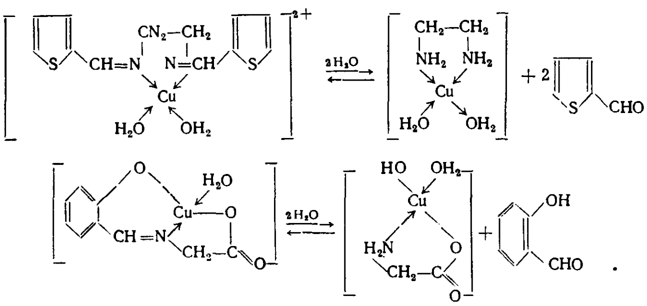


Bailar and Eichhorn[28] established the catalytic action of copper ions on the hydrolysis of the Schiff's base formed from thiophene-2-aldehyde and ethylenediamine:



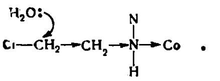
Under similar conditions but in the absence of Cu^{II}, the hydrolysis of this Schiff's base is very slow. Bailar (like Kroll) considers that the catalytic influence of copper is due to the increase in the electrophilic character of the unsaturated carbon atom as a result of the formation of a donor–acceptor bond. This facilitates attack on the reaction centre by a water molecule.

Eichhorn[29] studied the influence of complex formation on the stability, with respect to hydrolysis, of the Schiff's bases formed by thiophene-aldehyde with ethylenediamine and by salicylaldehyde with glycine. He established that copper facilitates the hydrolysis of the former and hinders the hydrolysis of the latter. The hydrolysis of the copper complex of the Schiff's base formed by thiophene-aldehyde with ethylenediamine gives the ethylenediamine complex. Both the initial and the final complexes contain one ring, and the factor determining the relative stability of these complexes is the electron distribution.



As a result of the hydrolysis of the Schiff's base formed by salicylaldehyde and glycine, the complex is converted from a dicyclic to a monocyclic compound. The difference in the stabilities of the dicyclic and monocyclic complexes probably has a greater influence on the reactivity of the original compound than the change in the polarisation of the nitrogen atom. Thus this example shows the need to make allowance for another factor—*the stabilities of the original complexes and reaction products.*

The influence of coordination on the hydrolysis of halogenoalkylamines has been studied[30]. It has been established that in the ionic complex $[Co(H_2O)(Cl-CH_2-CH_2-NH_2)en_2]^{3+}$ the hydrolysis of β-chloroethylamine is 50 times more rapid than the hydrolysis of the free halogenoalkylamine. The displacement of the electron pair of the nitrogen atom towards the cobalt as a result of the formation of a donor-acceptor bond acts like an inductive effect



The influence of the coordination of unsaturated aliphatic amines on the addition of hydrogen halides to the amines has been studied[31]. It has been shown that allylamine in the complex *cis*-$[CoClen_2(NH_2CH_2CH{=}CH_2)]Cl_2$ gives a mixture of the γ- and β-isomers. The relative quantities of the isomers obtained from free and coordinated allylamine are given in Table 2.

Table 2. Influence of coordination on the order of attachment of hydrogen halides to allylamine.

Compound	Hydrogen halide	Relative concentration	
		β-isomer, %	γ-isomer, %
$CH_2{=}CHCH_2NH_2$	HCl	55	45
$[CH_2{=}CHCH_2N(C_2H_5)_3]Cl$	HCl	17	83
cis-$[CoCl(CH_2{=}CHCH_2NH_2)en_2]Cl_2$	HCl	42	58
cis-$[CoBr(CH_2{=}CHCH_2NH_2)en_2]Br_2$	HBr	38	62

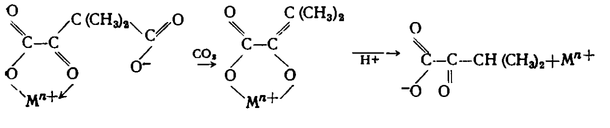
Thus the displacement of electrons towards the cobalt directs the addition along a path which does not correspond to Markovnikov's rule

The effect of coordination to the cobalt atom, however, is much weaker than the effect produced by the attachment of a proton to the amino-group.

A large number of published papers have been devoted to the catalytic decomposition of ketoacids under the influence of both enzymes and ions of various metals. Catalysis of the decarboxylation by metal ions is observed for di- and tricarboxylic ketoacids. The rate of the decarboxylation of monocarboxylic ketoacids or nitroacetic acid is not increased by metal ions, and is sometimes even decreased[32,33].

The decomposition of α,α-dimethyloxalacetic acid[34,35] and oxalacetic acid[32,36-42], and the catalytic decarboxylation of acetonedicarboxylic acid[43] and oxalosuccinic acid[37] have been studied.

The mechanism of the decarboxylation is probably the same for these acids. Many authors are of the opinion that an intermediate chelate complex is formed in the decarboxylation. This was first shown in Refs. 34, 35, and 37. A decarboxylation mechanism was proposed by Steinberger and Westheimer[35], who consider that the formation of coordinate bonds by the dicarboxylic acid with the metal ions leads to withdrawal of the electrons from the non-coordinated carboxyl group. This is the reason for the increase in the ease of decarboxylation:

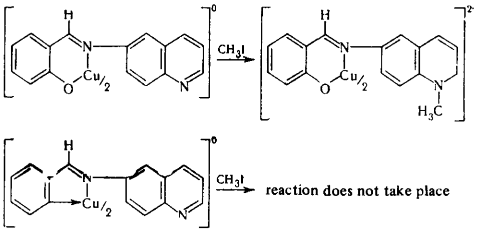


With ketoacids, which can give an enol form, the initial formation of an enol chelate is assumed.

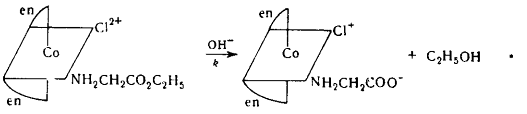
Pedersen[33,38] also considers that a reason for the spontaneous decomposition of nitroacetic acid is the displacement of the electrons from the carboxyl group to the nitro-group. The mechanism of catalysis examined above explains the decrease in the rate of decarboxylation of monocarboxylic acids (or the absence of catalysis) under the influence of metal ions. In this instance the attachment of the metal leads to a displacement of electrons towards the carboxyl group.

IV. INFLUENCE OF THE CHARGE OF THE IONIC COMPLEX ON THE REACTIVITY OF A COORDINATED LIGAND

A striking example of the influence of the charge of an ionic complex on the reactivity of a ligand is provided by the alkylation of the nitrogen atom in a quinoline group. Thus it has been shown[44] that the alkylation of this group by methyl iodide in a neutral complex is comparatively rapid, whereas almost no alkylation takes place in a cationic complex



Hay and coworkers[45,46] showed that in a cationic complex with Co^{III}, ethyl glycinate is hydrolysed with a rate constant $k = 3.5 \times 10^3$ litre mole^{-1} min^{-1}:



Under the same conditions, the rate constant for the the hydrolysis of the free ester is $k' = 38$ litre mole^{-1} min^{-1}:

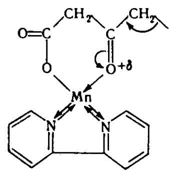
$$H_2NCH_2CO_2C_2H_5 + OH^- \xrightarrow[k']{} H_2NCH_2CO_2^- + C_2H_5OH \; .$$

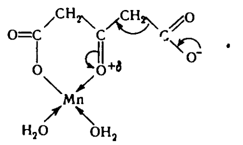
Thus the introduction of the ester into an ionic complex of Co^{III} with a charge of +2 increases the reaction rate by a factor of about 100. This effect can be attributed to electrostatic interaction: the positive charge of the complex facilitates attack by the hydroxide ion.

V. INFLUENCE OF π-DATIVE BONDING BY ONE OF THE LIGANDS TO THE CENTRAL ATOM ON THE REACTIVITY OF ANOTHER LIGAND IN THE SAME COMPLEX

It has been established[43,47] that the 1,10-phenanthroline complexes of Mn^{II} have a much higher catalytic activity with respect to the decarboxylation of dicarboxylic acids than the hydrated maganese ion. An analogous phenomenon was observed by Hay and Leong[48], who showed that the decarboxylation of acetonedicarboxylic acid in the

2,2′-bipyridyl complex of Mn^{II} is about 10 times more rapid than that in the corresponding aquo-complex.



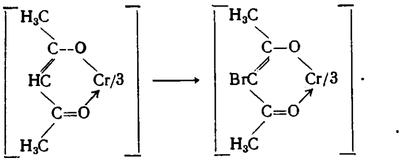


The authors cited consider that the increase in the reaction rate is due to the formation of a π-dative bond by manganese with 1,10-phenanthroline or 2,2′-bipyridyl. The formation of a π-dative bond should increase the positive effective charge of the central ion and hence facilitate decarboxylation.

VI. STABILISATION OF ONE OF THE TAUTOMERIC FORMS OF A LIGAND BY COMPLEX FORMATION WITH METAL IONS

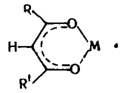
Grinberg and coworkers[49] studied the hydrolysis of dimethyl hydrogen phosphite in the free state and in a platinum(II) complex, and concluded that in dimethyl hydrogen phosphite coordinated to Pt^{II}, the phosphorus atom is in the tervalent state, whereas in the free acid it is in the quinquevalent state. As a result, the coordinated acid has a much stronger acidity than the free acid.

β-Diketones provide the classical example of keto–enol tautomerism. The enol forms have a high tendency to form complexes. The first study of the reactivity of coordinated β-diketones (more accurately, their enol forms) was apparently that of Reihlen[50], who established that the action of bromine on the acetylacetonato-compound of chromium (in alcoholic solution) leads to the replacement of the hydrogen on the central carbon atom by bromine:

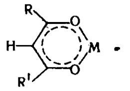


At the time, Reihlen regarded this reaction as confirming Mayer's hypothesis regarding the reactivity of keto–enol forms in tautomeric equilibrium.

In recent years, the complexes of metals with β-diketones have been attracting the attention of chemists from the theoretical viewpoint. Structural data show that the C–C, C–O, and M–O distances in β-dicarbonyl chelates are equivalent[51]. On this basis, the β-dicarbonyl chelates are regarded as forms stabilised by resonance:

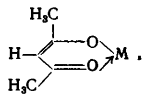


Some authors go further, and regard the β-dicarbonyl complexes of metals as pseudo-aromatic compounds[52]:



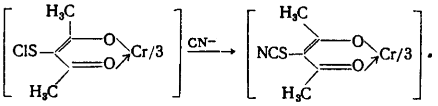
On this basis, many authors are studying the replacement of hydrogen in the pseudo-aromatic ring: halogenation, acetylation, nitration, and the introduction of thiocyanato-groups into the aromatic ring[52–58].

Kluiber[59] studied the action of sulphur dichloride on compounds with the general formula

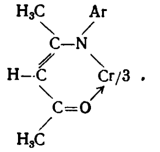


This reaction was studied for the acetylacetonato-compounds of Al^{III}, Cr^{III}, Co^{III}, and Be^{II}. This study showed that the hydrogen on the central carbon atom can be replaced by the –SCl group. An interesting feature is that the usual products of the reaction of sulphur dichloride with enols similar to acetylacetone are sulphides. It is believed that sulphides are formed through an intermediate R–SCl compound. In Kluiber's opinion, the preservation of the –SCl group in this instance is due to the steric protection of this group by the adjoining methyl groups.

The action of cyanide ions on the chromium complex obtained in this way converts the –SCl group into a thiocyanato-group according to the scheme



The same chromium compound was also obtained by the direct reaction of the acetylacetonato-compound of chromium with thiocyanogen. Collman and Kittleman[60] prepared a large number of complexes of Cr^{II} with β-ketoimines with the general formula



The central carbon atom in the β-ketoimines in the chromium complexes, as in the complexes formed by β-diketones, undergoes bromination by N-bromosuccinimide. Nitration and formylation of inner-sphere β-ketoimines does not take place, however, because of the lower stability of the ketoimine complexes compared with the compounds formed by the diketones.

VII. STABILISATION OF THE DEPROTONATED FORM OF A LIGAND BY COMPLEX FORMATION

It is known that the azo-coupling of derivatives of phenol and diazonium ions takes place more readily in alkaline medium, because of the high reactivity of the corresponding phenolato-compounds. Azo-coupling often does not take place at all in acid medium. Kuznetsov[61] gives a number of examples of the influence of complex formation on the ability of various derivatives of phenol to undergo azo-coupling. Thus pyrocatechol in acid solutions is almost unable to couple with diazobenzenesulphonic acid. In the presence of salts of gallium, aluminium, and more particularly zirconium and germanium, azo-coupling takes place even in the presence of mineral acids. Moreover, the production of azo-compounds from, for example, pyrocatechol in alkaline medium is made difficult by its oxidation under the influence of the diazonium ion, and this decreases considerably the yield of the product. In the presence of the ions of the above metals, oxidation of pyrocatechol by diazonium salts does not take place. The influence of metals on this reaction is associated with the formation of inner-complex salts, in which the proton of the phenol group is replaced by a metal ion.

Like pyrocatechol, 8-quinolinol undergoes almost no coupling with diazobenzenesulphonic acid in mineral acid, but this coupling takes place when the 8-quinolinol is combined in a copper complex.

Azo-coupling is not facilitated by complex formation with all metals, however. The rate of the reaction of 8-quinolinol with diazobenzenedisulphonic acid is decreased by aluminium salts. In the presence of aluminium salts, this reaction takes place very slowly, even in the presence of sodium acetate. Kuznetsov attributes this to the difference in the nature of the O–Cu and O–Al bonds. This sharp difference, however, may be due to the higher charge of the aluminium complex compared with the copper complex. A higher positive charge on the complex should hinder the attack of the diazonium cation on the coordinated 8-quinolinol molecule.

An example of the influence of a metal ion on reactivity as a result of stabilisation of the deprotonated form of a ligand is provided by the reaction of 4-dimethylaminophenyldiazonium chloride with chromotropic acid. The dye is obtained in 58% yield, the substitution taking place in the 4-position of chromotropic acid (1,8-dihydroxynaphthalene-3,6-disulphonic acid). When the calcium complex of this acid is used, the yield can be increased to 90%.[62]

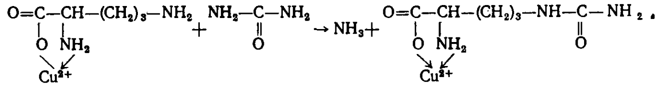
The halogenation (chlorination and bromination) of 8-quinolinol in its complexes with Cr^{III}, Co^{III}, Fe^{III}, and Cu^{II} gives the same products as the halogenation of free 8-quinolinol (for example, 5,7-dichloro-8-quinolinol). Jones[63] reports that in the chlorination of free 8-quinolinol, the yield of the dichloro-derivative does not exceed 30%. In the chlorination of inner-sphere 8-quinolinol, however, the yield of the dichloro-derivative is 80–90%. Jones also attributes this to the presence of the phenolato-form in the complex. Moreover, the metal protects the functional groups from oxidation.

Fernando and coworkers[64] emphasise that the influence of complex formation on the reactivity of aromatic ligands should be estimated not only from the reaction products, but also on the basis of a quantitative comparison of the reaction rates[65,66]. Quantitative studies[64] showed that the rate of the iodination of 8-quinolinol-5-sulphonic acid decreased on formation of complexes. The influence of the complex-forming species was established, and it was also possible to arrange the metal ions in the order of their decreasing influence: $Cu^{2+} > Ni^{2+} > Co^{2+} > Fe^{2+} > Zn^{2+} > Mn^{2+}$.

VIII. ELIMINATION OF THE CHARACTERISTIC PROPERTIES OF LIGANDS AS A RESULT OF COORDINATION AND THE USE OF THIS PHENOMENON TO MASK INDIVIDUAL FUNCTIONAL GROUPS

On coordination, amines may lose the properties associated with the presence of the free pair of electrons. The nitro-group in Pt^{IV} complexes can no longer be oxidised by permanganate. The toxicity of the cyanide ion is reduced or eliminated completely. The fact that complex formation may eliminate completely the ability of various functional groups to react, without altering significantly the reactivity of non-coordinated functional groups, particularly if these are at a distance from the point of coordination, makes it possible to use this phenomenon in preparative work.

For example, it is believed that citrulline $H_2NCONH(CH_2)_3CH(NH_2)COOH$ is present in various proteins, in which it takes part in the formation of urea. Kurtz[67,68] carried out this reaction in the opposite direction by means of complex formation. He prepared the copper complex of ornithine (as a result, the α-amino-group was masked) and carried out the condensation of this complex with urea:



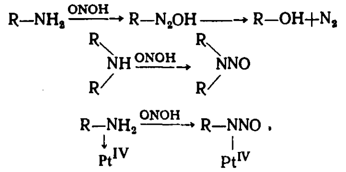
$$O{=}C{-}CH{-}(CH_2)_3{-}NH_2 + NH_2{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}NH_2 \rightarrow NH_3 + O{=}C{-}CH{-}(CH_2)_3{-}NH{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}NH_2\,,$$

The copper was then removed from the complex by the action of hydrogen sulphide, to give citrulline. Kurtz prepared various aminoacids in this way. The efficiency of the masking action of the metal ions depends to a marked extent on the stability of the complex.

IX. MANIFESTATION OF NEW CHEMICAL PROPERTIES BY THE LIGAND AS A RESULT OF COORDINATION

An example of the manifestation of new chemical properties by a ligand is provided by the azo-coupling of 1,10-phenanthroline and diazosulphanilic acid. 1,10-Phenanthroline cannot couple with diazonium salts, but in its complex with bivalent iron it undergoes vigorous coupling with the diazonium salts of sulphanilic acid and *p*-nitroaniline-*o*-sulphonic acid[69].

It is well known that the nitrosylation of free primary amines gives unstable diazo-compounds, which decompose with the formation of an alcohol and the liberation of nitrogen, whereas secondary amines form stable nitroso-compounds:



$$R{-}NH_2 \xrightarrow{ONOH} R{-}N_2OH \longrightarrow R{-}OH+N_2$$

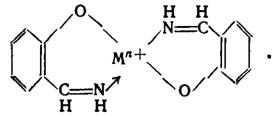
$$R_2NH \xrightarrow{ONOH} R_2NNO$$

$$\underset{\displaystyle Pt^{IV}}{\underset{\downarrow}{R{-}NH_2}} \xrightarrow{ONOH} \underset{\displaystyle Pt^{IV}}{\underset{|}{R{-}NNO}}\,,$$

Chernyaev and Andrianova[70] showed that coordinated primary amines may exhibit the properties of secondary amines in nitrosylation. For example, aliphatic amines in a Pt^{IV} complex form stable nitroso-compounds. They exhibit the properties of secondary amines because of the fact that the nitrogen forms a bond with the platinum atom, instead of a second alkyl radical.

X. CHANGE IN THE REACTIVITY OF COORDINATED SCHIFF'S BASES

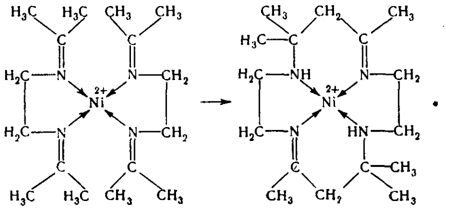
Complexes of metals with Schiff's bases are extremely widely encountered. They are obtained both from previously prepared Schiff's bases and by the action of aldehydes and ketones on the amino-complexes of metals. Sometimes, complex formation leads to the stabilisation of aldimines which are unstable in the free state. Thus Pfeiffer[71] prepared salicylideneimine in complexes of zinc, copper, and nickel. The complexes can be represented by the following general formula:



.

Salicylideneimine is unstable in the free state and cannot be prepared.

An interesting series of studies was carried out by Curtis and coworkers[72-77] on the reaction of cyclic amine-complexes of nickel and copper with acetone and aliphatic aldehydes. They established that the Schiff's bases formed initially undergo inner-complex aldol condensation with the formation of a macrocyclic ligand. This condensation is catalysed by bases:

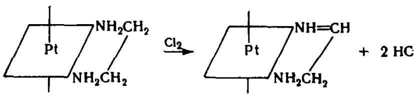


Since the reaction of aldehydes with inner-sphere amines leads to the formation of water, these reactions should most probably be carried out in anhydrous media. The amine-complexes of platinum are generally sparingly soluble in non-aqueous solvents. Various chloroamine-complexes of platinum, however, are soluble in polar organic solvents. In particular, the complex $[PtCl(NO_2)_2(NCl_2)(NH_3)_2]$ is soluble in acetaldehyde.

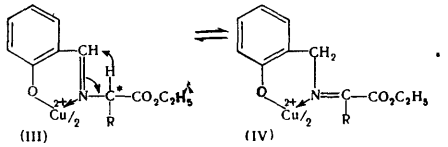
It has been established[78] that an inner-sphere ammonia molecule in $[PtCl(NO_2)_2(NCl_2)(NH_3)_2]$ is converted into acetaldimine on reaction with acetaldehyde. In the presence of active chlorine, however, the inner-sphere acetaldimine is converted into acetonitrile. The reactions can be represented schematically as follows:

$$\begin{array}{c}
Cl_2N{-}Pt \leftarrow NH_3 + CH_3CHO \rightleftarrows Cl_2N{-}Pt \leftarrow NH{=}CHCH_3 + H_2O \\
Cl_2N{-}Pt \leftarrow NH{=}CHCH_3 + 2H_2O \rightleftarrows H_3N \rightarrow Pt \leftarrow NH{=}CHCH_3 + HClO + ClO^- \\
H_3N \rightarrow Pt \leftarrow NH{=}CHCH_3 + OCl^- \rightarrow H_3N \rightarrow Pt \leftarrow N{\equiv}C{-}CH_3 + H_2O + Cl^- \\
\hline
Cl_2N{-}Pt \leftarrow NH_3 + CH_3CHO \rightarrow H_3N \rightarrow Pt \leftarrow N{\equiv}C{-}CH_3 + HClO + Cl^-
\end{array}$$

The dehydrogenation of inner-sphere ligands under the influence of chlorine was observed earlier[79]. It was established that the reaction of chlorine with ethylenediamine in a Pt^{IV} complex may lead to the formation of aminoacetaldimine:



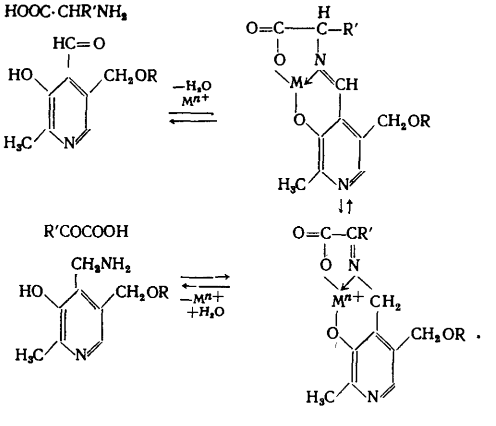
The important role of complex formation in the change in the reactivity of Schiff's bases is shown by the work of Pfeiffer and coworkers[80], who showed that when a chelate Cu^{II} complex is formed with an optically active Schiff's base formed from an aminoester and salicylaldehyde, rapid racemisation takes place. This can be attributed to the existence of an inner-complex tautomeric equilibrium:



(III) (IV)

The loss of the asymmetry of the optically active carbon atom takes place on formation of structure (IV). The reverse conversion of complex (IV) the complex (III) should produce equal quantities of the two optically active antipodes.

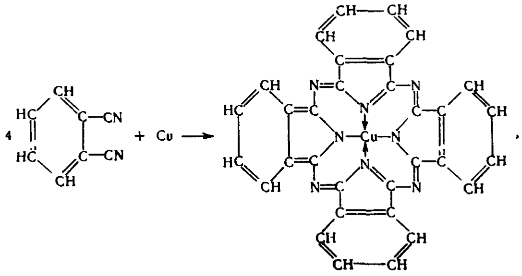
An inner-complex tautomeric equilibrium is the chief stage in the mechanism of catalytic trans-amination between pyridoxal and an aminoacid, proposed by Snell[81]. In his opinion, trans-amination gives a Schiff's base, stabilised by coordination to the metal ion, after which the double bond is displaced to the carbon atom of the aminoacid:



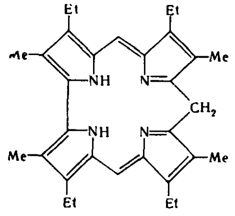
It is considered that trans-amination is extremely important in biology, since it provides an extremely probable means of producing a bond between carbohydrates and proteins.

XI. THE METAL IONS AS A MATRIX ON WHICH AN ORGANIC MOLECULE IS SYNTHESISED

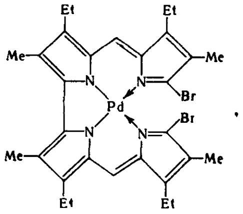
The preparation of metal-containing phthalocyanines from a metal and the dinitrile of phthalic acid takes place much more readily than the direct preparation from the free bases[3]:



A striking example of the matrix effect of a complex-forming metal is provided by the preparation of compound (V). This compound could not be prepared for a long time, but was eventually readily prepared by the reaction of formaldehyde with the palladium(II) complex (structure VI):[82]



(V)

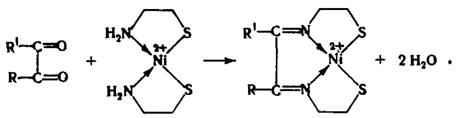


(VI)

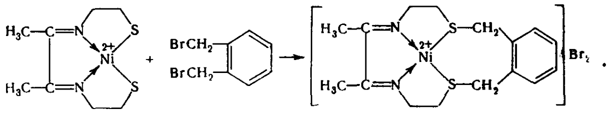
It is assumed that by following the route of ring closure in complex (VI), it is possible to introduce O, NH, or S in place of the methylene group.

The reaction between β-mercaptoethylamine and α-diketones usually gives thiazolidines as chief product, with only small quantities of the α-diimines[83]. Busch[84] showed that if the β-mercaptoethylamine is present in an

Ni^{II} complex, it reacts with α-diketones to form the inner-sphere α-diimine in 70% yield:



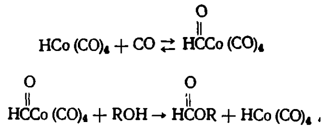
Busch then used this complex as a template for the subsequent preparation of a polycyclic chelate[85]. He carried out the following reaction:



which was made possible by the fixation of the sulphur atoms in the cis-position.

XII. REACTIONS INVOLVING "INSERTION" INTO A METAL- LIGAND BOND

Extensive material has now accumulated on reactions involving the "insertion" of various molecules in a metal–ligand bond. The "insertion" of carbon monoxide, alkenes, acetylene derivatives, etc. has been studied[86]. For example, the reaction of carbon monoxide and methanol with cobalt carbonyl hydrides leads to the formation of an ester of formic acid. It is considered[87–89] that the reaction mechanism can be represented as follows:



$$HCo(CO)_4 + CO \rightleftarrows HC(=O)Co(CO)_4$$

$$HC(=O)Co(CO)_4 + ROH \rightarrow HC(=O)OR + HCo(CO)_4\,.$$

An interesting reversible carbonylation of an alkyl manganese pentacarbonyl was carried out by Coffield and coworkers[90]:

$$CH_3Mn(CO)_5 + Co \rightleftarrows CH_3COMn(CO)_5\,.$$

It was subsequently shown[91] that the "insertion" into the manganese–alkyl bond involves chiefly a carbonyl which is already coordinated to manganese, and not a carbonyl from the outer sphere.

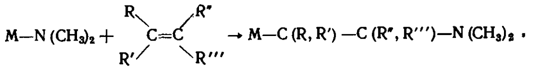
Booth and Chatt[92] carried out the carbonylation of alkyl and aryl compounds of platinum and palladium. The following are examples of the reactions which they carried out:

$$trans\text{-}[PdCH_3X(PEt_3)_2] \rightarrow trans\text{-}[PdCOCH_3X(PEt_3)_2]$$

$$[Pt(CH_3)_2(PEt_3)_2] \xrightarrow{CO} [Pt(COCH_3)_2(PEt_3)_2]\,.$$

Chandra and coworkers[93] showed that "insertion" into a metal–nitrogen bond can be carried out. They carried out a number of reactions of two types:

$$M{-}N(CH_3)_2 + RC{\equiv}CR' \rightarrow M{-}C(R){=}C(R'){-}N(CH_3)_2$$



$$M{-}N(CH_3)_2 + RR'C{=}CR''R''' \rightarrow M{-}C(R,R'){-}C(R'',R'''){-}N(CH_3)_2\,.$$

When the hydrocarbons contain groups which show a clearly defined ability to attract electrons, these reactions take place under mild conditions.

---o0o---

In conclusion it should be noted that other factors, in addition to those listed above, influencing the reactivity of ligands may be detected. The detection of additional factors may be made primarily by analysing data on the reactivity of unsaturated organic molecules, since almost no discussion of π-complexes has been given in the present review.

It has already been noted that the change in the reactivity of ligands in complexes sometimes results from several factors. This is apparently the most widely encountered case. The author has encountered considerable difficulty in selecting examples which might illustrate individual factors as far as possible in pure form. Thus the assignment of reactions to various classes may be a subject for discussion.

From the viewpoint of the development of a theory of homogeneous catalysis involving metal complexes, quantitative data characterising the change in reactivity are of considerable importance. Unfortunately, few data of this kind have yet been published. It is to be hoped that with increase in the interest of this problem, the work carried out will be more quantitative in character. One possible approach to this is by the extensive use of correlation equations of the type corresponding to Hammett's equation.

The Intramolecular Hydrogen Bond and the Reactivity of Organic Compounds

I.D.Sadekov, V.I.Minkin, and A.E.Lutskii

Numerous new data on the effect of intramolecular hydrogen bonds on the reactivity of organic compounds are reviewed systematically.
The bibliography comprises 200 references.

CONTENTS

1. INTRODUCTION

An enormous number of investigations have been made recently on the nature and properties of hydrogen bonds. In the vast majority of these the effects of hydrogen bonds on different physical properties (on electronic, vibration, and NMR spectra, dipole moments, etc.) are investigated. A number of monographs and reviews are devoted to data obtained in this field. There is much less information about the effect of hydrogen bonds on the chemical properties of the molecules involved in them. Such information is scattered in various sources and only two attempts have been made to review it[1,2]. Subsequently many new communications on the role of hydrogen bonds in various chemical reactions appeared. The principal aim of the present review is to give a general and systematic account of these data.

In view of the large number of new facts, the scope of the review had to be restricted to only one type of hydrogen bond—the intramolecular hydrogen bond (i.h.b.). The qualitative nature of the available literature data on the effect of intramolecular hydrogen bonds on the reactivity of organic compounds and as a rule the lack of sufficiently systematic studies precludes the treatment of these data on the basis of any one general concept. Numerous conclusions concerning the effect of intramolecular hydrogen bonds on chemical properties arrived at in this review or by the authors of the papers quoted are based on comparisons and analogies, the generality of which cannot always be demonstrated, for example those based on the identification of the properties of hydroxy- and alkoxy-derivatives, *o*- and *p*-substituted benzenes, etc.

However, this approach reflects not only the level attained in the modern analysis of the effect of intramolecular hydrogen bonds on reactivity but also the exceptional complexity of the problem. In principle, the difficulty of investigating this problem consists in the fact that the intramolecular hydrogen bond, the effect of which on reactivity has to be elucidated, should be regarded as a comparatively small perturbation in relation to factors which determine the mode and type of reaction, since usually the energy of the intramolecular hydrogen bond is almost ten times smaller than the energy of activation for the corresponding chemical reactions.

Bearing this in mind, our aim was to collect the principal facts relevant to the problem under consideration and to describe them systematically.

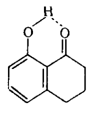
2. EFFECT OF THE INTRAMOLECULAR HYDROGEN BOND ON THE ACIDITY OF THE HYDROXY-GROUP

The hydrogen atom of the hydroxy-group involved in an intramolecular hydrogen bond is linked to the molecule much more strongly than in the absence of such a bond. As a result, the removal of such a proton from the molecule is more difficult than in the case of a non-chelated hydrogen atom. For this reason *ortho*- or *peri*-hydroxy-compounds with substituents capable of functioning as electron acceptors are weaker acids than the analogous compounds with *para*-substituents. Salicylaldehyde which contains a strong intramolecular hydrogen bond[3,4] has $pK_a = 8.14$ (in water), while the pK_a of the isomeric *p*-hydroxybenzaldehyde is 7.45.[5,6] If it is assumed that the transmission of electronic effects from the *ortho*- and *para*-positions is approximately the same, it becomes clear why 4-chloro-2-hydroxybenzaldehyde ($pK_a = 7.18$) is a weaker acid than 2-chloro-4-hydroxybenzaldehyde ($pK_a = 6.60$), which has no hydrogen bond[7].

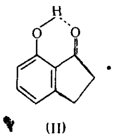
The acidity of *o*-hydroxyacetophenone is lower than that of *p*-hydroxyacetophenone (their pK_a's are 10.07 and 7.87 respectively[6,8]). The higher dissociation constant of salicylaldehyde compared with *o*-hydroxyacetophenone is consistent with the relative strengths of the intramolecular hydrogen bonds, which can be estimated from the infrared spectra ($\Delta\nu_{C=O}$, determined by the intramolecular hydrogen bond, is 38 cm^{-1} for the first compound and 45 cm^{-1} for the second). The relative p*K*a's of α-naphthol derivatives have been determined[9]. 1-Hydroxy-2-naphthaldehyde (pK_a = 8.85) and 1′-hydroxy-2′-acetonaphthone (pK_a = 10.9), which have powerful intramolecular hydrogen bonds[2], are weaker acids than 1-hydroxy-4-naphthaldehyde (pK_a = 8.75) and 1′-hydroxy-4′-acetonaphthone (pK_a = 9.6) where a hydrogen bond is impossible.

Although the acid dissociation constants of the *o*-hydroxycarbonyl compounds were measured by different investigators and under different conditions, nevertheless it is clear that the *o*-hydroxycarbonyl derivatives of naphthalene are usually weaker acids than the corresponding benzene derivatives. The explanation of this should be sought in the greater strength of the hydrogen bond in the naphthalene series compared with benzene derivatives.

The strong intramolecular hydrogen bond in 8-hydroxy-1-tetralone(I) is the reason why this compound is a weaker acid (pK_a = 11.14) than 6-hydroxy-1-tetralone (pK_a = 7.74) and similarly 7-hydroxy-1-indanone (II) is a weaker acid (pK_a = 8.43) than 5-hydroxy-1-indanone (pK_a = 7.53):[10]



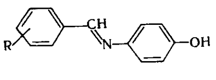
(I)



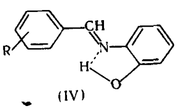
(II)

As a result of the strong intramolecular hydrogen bond between hydroxy- and nitro-groups, the acidity of 2-nitro-1-naphthol is lower than that of 4-nitro-1-naphthol[5]. According to spectrophotometric determinations[11,12], the p*K*a of 2-nitro-1-naphthol is 8.72, which corresponds to a dissociation constant 8 times higher than for 1-naphthol, while the p*K*a of 1-nitro-2-naphthol is 9.02, i.e. the dissociation constant is 14 times higher than that of 2-naphthol. This non-equivalent increase of acidity has been attributed to a stronger intramolecular hydrogen bond in 1-nitro-2-naphthol compared with its isomer. It is noteworthy that, apart from the intramolecular environment, acid dissociation constants are greatly influenced by the solvent in which the p*K*a is determined. Thus, the anomalously low acid dissociation constants of 2,4- and 2,5-dinitrophenols in benzene compared with their values in water have been explained as the result of a stronger hydrogen bond in the molecules of these substances in benzene solution[13].

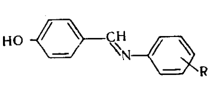
An example characterising the effect of intramolecular hydrogen bonds of different strengths on acidities is quoted by Minkin et al.[14], who measured the p*K*a's of Schiff bases of four types (III–VI):



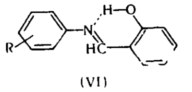
(III)



(IV)



(V)



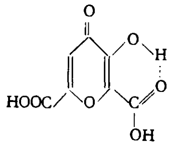
(VI)

The corresponding p*K*a's (in 98% methanol) are listed in Table 1. The reduced acidity of (VI) compared with (V) and of (IV) compared with (III) is undoubtedly associated with the effect of the hydrogen bond. The order of magnitude of the p*K*a values is consistent with the concept of the greater strength of the hydrogen bond in the six-membered ring of (VI)[15,16,17] compared with the five-membered ring of (IV).[18,19,20]

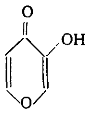
Table 1.

Type of Schiff base	pK_a					
	$R=N(CH_3)_2$	$R=OCH_3$	R=H	$R=CH_3$	R=I	$R=NO_2$
III	10.60	10.49	10.42	—	10.33	10.18
IV	11.02	—	10.88	10.92	—	10.71
V	—	9.84	9.73	9.79	9.63	—
VI	—	—	11.03	11.09	10.95	10.82

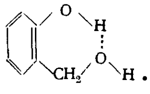
The presence of intramolecular hydrogen bonds in hydroxy-acids increases the dissociation constant of the carboxy-group but significantly lowers that of the chelated hydroxy-group. Whereas $K_a = 3.5 \times 10^{-10}$ for the phenolic hydroxy-group in *p*-hydroxybenzoic acid, salicylic acid, in which there is a strong intramolecular hydrogen bond, has $K_a = 1.5 \times 10^{-14}$. The same thing is also observed for the esters of *p*- and *o*-hydroxy-benzoic acids: the p*K*a's of the *o*- and *p*-isomers are 9.2 and 8.34 respectively[21]. The sharply reduced ionisation constant of the phenolic hydroxyl in meconic acid (VII) ($K_a = 1.5 \times 10^{-10}$) compared with pyromeconic acid (VIII) ($K_a = 2.2 \times 10^{-8}$) is evidence[22] of the presence of intense chelation in the first compound between the OH and COOH groups:



(VII)



(VIII)



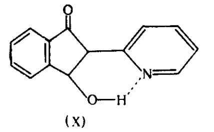
(IX)

The *peri*-sulpho-groups in phenylazonaphthols behave similarly[23].

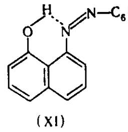
It has been found that not only powerful electron-accepting groups such as >C=O, $-NO_2$, >C=N–, and –COOH, which form strong hydrogen bonds, are capable of reducing the acid strength. Even a weak electron-accepting substituent, such as the hydroxymethyl group, forms an intramolecular hydrogen bond with the phenolic hydroxyl in (IX) and weakens its acid properties. The p*K*a of *p*-hydroxymethylphenol is lower by 0.1–0.15 units than the p*K*a of phenol itself. (9.94 for phenol and 9.82 for *p*-hydroxymethylphenol)[24]. If the effect of the hydroxymethyl group in compound (IX) were mainly inductive, one might expect that the p*K*a value for this compound would be approximately the same as for the *para*-isomer. However, the p*K*a of *o*-hydroxymethylphenol (IX) is lower by only 0.02–0.05 units than the value for phenol itself. The reason for this is the presence of an intramolecular hydrogen bond in compound (IX).[25,26]

A similar situation exists also in di-(*o*-hydroxyphenyl)-methanes[27,28]. The behaviour of 2,2′-dihydroxybiphenyl is very similar to that discussed above. Whereas the higher value of the first ionisation constant of this compound (pK_{a1} = 7.56)[29] compared with *o*-phenylphenol (pK_a = 9.97)[30] may be attributed to an intramolecular hydrogen bond in the neutral molecule[31], the much lower value of the second ionisation constant (K_{a1}/K_{a2} = 106) can be accounted for by a strong hydrogen bond in the monoanion.

The effect of the intramolecular hydrogen bond is shown in the fact that many phenols with such a bond do not form normal salts under the usual conditions. Thus 2-(2′-pyridyl)indane-1,3-dione (X) is insoluble in aqueous sodium bicarbonate and is not titrated with alkali in an aqueous dioxan mixture[32]. Certain *peri*-hydroxyazo-dyes (XI) behave similarly. They are all insoluble in aqueous solutions of alkali[33]. Many other examples of similar behaviour of phenols have been quoted[1-4,34]:



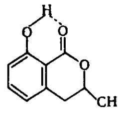
(X)



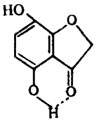
(XI)

3. ALKYLATION OF HYDROXY-COMPOUNDS

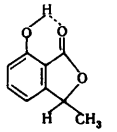
The presence of an intramolecular hydrogen bond in the molecule is the reason for the difficulty and sometimes the impossibility of obtaining ethers derived from the hydroxy-groups involved in the hydrogen bond by treatment with diazomethane under the usual conditions. This property of chelated groups is sometimes used to establish the structures of hydroxyanthraquinones, hydroxyflavones, hydroxyxanthones, etc., although in certain cases such *peri*-chelated hydroxyls may be methylated by prolonged heating with a large excess of diazomethane. A particular example of such "normally" methylated compounds, is mellein—3,4-dihydro-8-hydroxy-3-methylisocoumarone (XII).[35] Under the action of diazomethane, it is readily converted into the methoxy-derivative, although its OH group is involved in a strong hydrogen bond:



(XII)

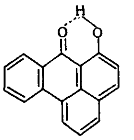


(XIII)

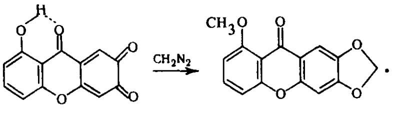


(XIV)

Other compounds where the proton of a chelated hydroxy-group can be comparatively readily replaced by methyl under the action of an ethereal solution of diazomethane are 4,6-dihydroxy-3-coumarone (XIII),[36] 7-hydroxy-3-methylphthalide (XIV),[37] 3,6-dihydroxyphthalic anhydride, 3,6-dihydroxyphthalimide,[38] 1-benzoyl-2-naphthol, and 6-hydroxymesobenzanthrone (XV):[39]



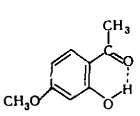
(XV)



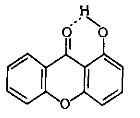
(XVI) (XVII)

8-Hydroxy-2,3-quinoxanthone (XVI) is methylated in an unusual way, being converted under the action of diazomethane in an ethereal solution into compound (XVII).[40] It is interesting that in the majority of the normally methylated compounds the carbonyl group is located in a five-membered ring.

The vast majority of chelated phenols are not methylated, and in the presence of several hydroxy-groups in the molecule only those not involved in hydrogen bonding are substituted. *o*-Hydroxyacetophenone, *o*-hydroxybenzophenone, 2-hydroxy-4-methoxyacetophenone (XVIII),[39] 1-hydroxy-9-xanthone (XIX),[41] and the diethyl ester of meconic acid[22] are not methylated at all by diazomethane in ethereal solution:



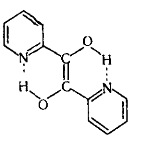
(XVIII)



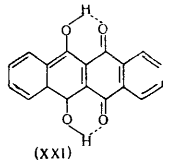
(XIX)

All attempts to methylate 2-pyridoin (XX)[42,43] were also unsuccessful. Diazomethane in ether has altogether no effect on this compound and in the reaction with sodium and methyl iodide or with dimethyl sulphate and alkalies, the only products are picolinamide in the first case and methyl picolinate in the second.

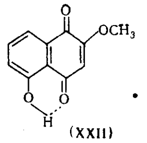
Examples of this kind among quinones are fairly numerous. The hydroxy-groups of alizarin methylated in the 2-position[1], 6,11-dihydroxy-5, 12-naphthacenequinone (XXI),[44] and 2-methoxyjuglone (XXII)[45] do not react with diazomethane:



(XX)

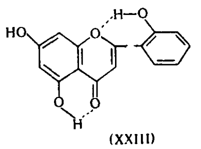


(XXI)

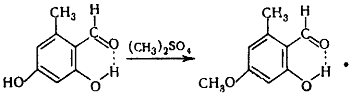


(XXII)

A very characteristic feature of polyhydroxy-compounds is selective alkylation of the free hydroxyls. In chromanone, flavanone[46], and polyhydroxyflavone[40] derivatives diazomethane methylates all the hydroxy-groups with the exception of the group in the 5-position. Similar results were obtained in the reaction with dimethyl sulphate in alkali at room temperature[46]. It has been shown[47] that the 2′-hydroxy-group in flavanones behaves similarly to the 5-hydroxy-group. Thus methylation of 2′,5,7-trihydroxyflavanone (XXIII) with dimethyl sulphate in acetone in the presence of potassium carbonate gives only 2′,5-dihydroxy-7-methoxyflavanone:



(XXIII)



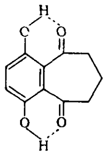
(XXIV) (XXV)

The only product of the methylation of 2,4,5-trihydroxyacetophenone with dimethyl sulphate is 2-hydroxy-4,5-dimethoxyacetophenone[48], while 2,4-dihydroxydeoxybenzoin yields only 2-hydroxy-4-methoxydeoxybenzoin[49]. A similar situation exists in substituted resacetophenones and nitroresorcinols where methylation with dimethyl sulphate of the hydroxyl chelated with the nitro- or carbonyl group is very difficult[49,50]. Methylation with dimethyl sulphates of the *o*-orsellinaldehyde (XXIV) leads to everninaldehyde (XXV).[51]

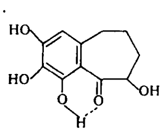
Sometimes the inability of chelated hydroxy-groups to be methylated is used for their protection in many syntheses. Thus Baker and Savage[52] showed that the 1,2-methylene ether of pyrogallol can be obtained by converting pyrogallol into pyrogallol-4-carboxylic acid, which yields 2-hydroxy-3,4-methylenedioxybenzoic acid under the action of dimethyl sulphate. The decarboxylation of this compound on heating with copper chromite gave the required product. The 1,2-dimethyl ether of pyrogallol was synthesised similarly.

Similar results were obtained in the study of the methylation[45] of a series of derivatives of polyhydroxy-1,4-naphthoquinones: juglone (5-hydroxy-1,4-naphthoquinone) and naphthazarin (5,8-dihydroxy-1,4-naphthoquinone). Under all the conditions investigated, the *peri*-hydroxy-groups in the 5- and 8-positions, which are linked by strong hydrogen bonds, are not methylated by diazomethane, while all other hydroxy-groups are readily converted into methoxy-groups. Thus, in the reaction with diazomethane 2-hydroxyjuglone gives 2-methoxyjuglone, 3-hydroxyjuglone gives 3-methoxyjuglone, and 6-ethyl-7-hydroxy-2-methoxyjuglone gives 6-ethyl-2,7-dimethoxyjuglone. Hydroxynaphthazarins behave similarly.

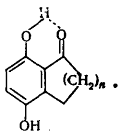
The behaviour of polyhydroxyindanones, tetralones, and 1,2-benzocycloheptanones is unusual. Like all *peri*-chelated hydroxy-ketones, 1′,4′-dihydroxy-1,2-benzocyclohepta-3,7-dione (XXVI) does not react with diazomethane[53]. However, 1′,2′,3′,4′-tetrahydroxy-1,2-benzocycloheptan-3-one (XXVII) is readily converted into the 2′,3′,4′-trimethyl ether, the *peri*-hydroxy group of which cannot be alkylated,[54]:



(XXVI)



(XXVII)



(XXVIII)

At the same time, 5,8-dihydroxytetralone is not methylated with diazomethane even at the free hydroxy-groups in the 5-position[55]. An anomalous feature is that the reaction of diazomethane with 4,7-dihydroxyindanones (XXVIII, $n = 1$), 4,7-dihydroxytetralones (XXVIII, $n = 2$), and 4,7-dihydroxybenzocycloheptanones (XXVIII, $n = 3$) does not result in the methylation of any of the hydroxy-groups even on prolonged contact at low temperatures in various solvents[38]. The behaviour of these compounds in reactions with phenyl isocyanate is also anomalous[38].

4. THE STRENGTH OF CARBOXYLIC ACIDS

When hydrogen bonds are formed in molecules of organic carboxylic acids, the dissociation constants of the latter may increase or decrease. They increase when the carboxy-group behaves as a proton acceptor (by virtue of its carbonyl oxygen) and they decrease in those cases where the hydroxyl of the carboxy-group behaves as a proton donor in the hydrogen bond. Examples of compounds of the first type are the *o*-hydroxy-acids of the benzene and naphthalene series. Salicylic acid is much stronger than the *m*- and *p*-isomers[21,56–58]. The introduction of a second hydroxy-group in the *o*-position results in an even greater increase of the dissociation constant. 2,6-Dihydroxybenzoic acid is stronger than phosphoric acid. The acid dissociation constants K_a in water are listed in Table 2.

The much higher dissociation constant of salicylic acid [compared with isomers (Ed. of Translation)] cannot be explained by the electronic effect of the hydroxy-group, since it should be approximately the same for the *o*- and *p*-positions. Nor can one invoke the *ortho*-effect to account for this phenomenon[59]. Although the higher dissociation constants K_a of the *o*-substituted benzoic acids compared with the *p*-isomers due to the destabilisation of the unionised acid by steric factors[57] is observed also on introduction of other *o*-substituents, incapable of formation of hydrogen bonds, the increase is much less. Thus, whereas the K_a values for the *o*-isomers of toluic and chlorobenzoic acids, for example, exceed the values for the *p*-isomers by factors of 2.9 and 10.5,[60] K_a for *o*-monohydroxybenzoic acid is higher than the corresponding value for the *p*-isomer by a factor of 40. Nor should one forget that the bulk of the hydroxy-group is much smaller than that of the majority of other *o*-groups and yet its effect on K_a is much greater. The polar effect is itself too small to account for the considerable difference between the dissociation contants of *o*- and *p*-hydroxybenzoic acids. This is evident from the fact that the K_{a1} for *o*- and *p*-phthalic acids, which are 1.1×10^{-3} and 2.9×10^{-4}, and for *o*- and *p*-aminobenzoic acids, 1.1×10^{-5} and 1.4×10^{-5}, differ much less than in the case of hydroxy-acids[60].

Table 2.

Acid	$10^5 K_a$	$K_a/K_{a(C_6H_5COOH)}$
Benzoic	6.30	1
m-Hydroxybenzoic	8.33	1.32
p-Hydroxybenzoic	2.62	0.42
o-Hydroxybenzoic	105	16.7
2,6-Dihydroxybenzoic	6000	952

The only acceptable explanation of the anomalously high K_a value for salicylic acid is the existence of an intramolecular hydrogen bond in its molecule[3]. The intramolecular hydrogen bond is of course present both in the undissociated acid and in the anion[61,62]. However, since it is to be expected that it is stronger in the anion than in the acid, the stabilisation of the former will be significant and the equilibrium will be displaced towards the dissociated form. An indirect confirmation of this hypothesis is provided by the dissociation constants of methoxybenzoic and 3-methoxy-2-naphthoic acids[21] listed in Table 3.

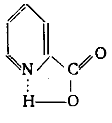
Table 3.

Acid	$10^5 K_a$	$K_{a(OH)}/K_{a(OCH_3)}$
p-Methoxybenzoic	3.20	0.81
o-Methoxybenzoic	8.06	13.00
3-Methoxy-2-naphthoic	15	13.1

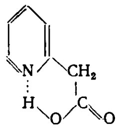
It should be noted, that on the basis of K_a measurements for substituted salicylic acids in benzene, Dunn and Penner[63] regard the above explanation of the unusual strength of salicylic acid as a serious oversimplification.

The anomalously high pK_a values for methylsubstituted pyrrole-2-carboxylic acid compared with the 3-isomers (Table 4)[64,65] have been attributed to the existence of intramolecular hydrogen bonds in the anions of the former compounds. Although intramolecular hydrogen bonds of this kind have not been found in the corresponding ester or in 2-acetylpyrrole, the more pronounced nucleophilic properties of the carboxylate anion may result in this type of interaction[64].

While in the examples considered above the intramolecular hydrogen bond is responsible for the increase of the acid dissociation constant, in many 2-substituted acids with heterocyclic substituents the hydrogen bond has the opposite effect. The σ-constant of the 2-pyridyl group calculated from the K_a of picolinic (XXIX) and pyridine-2-acetic (XXX) acids proved to be anomalously low compared with the σ-values calculated from data for other reaction series. This is explained by the presence of an intramolecular hydrogen bond between the hydrogen atom of the hydroxy-group and the nitrogen atom, which stabilises the acid and increases the pK_a value[66]:



(XXIX)

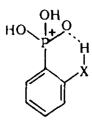


(XXX)

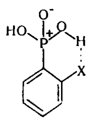
Table 4. pK_a values for substituted pyrrolecarboxylic acids.

Position of COOH	R	pK_a
2	H	4.40
3	H	4.95^{18}; 5.00^{56}
2	3-CH_3	4.60
2	4-CH_3	5.10
2	5-CH_3	5.00
3	2-CH_3	5.80
3	4-CH_3	5.60
3	5-CH_3	5.35

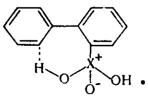
Jaffe's examination of the acid dissociation constants of *o*-substituted phenylphosphonic acids[67] led to the hypothesis that, depending on the nature of the *o*-substituent, the P=O group can behave as an acceptor [compound (XXXI)] or a donor [compound (XXXII)] in the hydrogen bond:



(XXXI)



(XXXII)



(XXXIII)

When the P=O group behaves as an acceptor, the negative charge of its oxygen atom decreases and the acid strength increases. This effect is clearly seen in 2-hydroxy-4-nitrophenylphosphonic acid, where the difference between the experimental pK_a and the value calculated on the assumption that the polar and inductive effects are the same in the *o*- and *p*-positions reaches −0.18 in water and −0.64 in 50% alcohol.

On the other hand, if the P=O group behaves as a donor in the hydrogen bond, its oxygen atom assumes a partial negative charge and therefore the first dissociation constant of the phosphonic acid increases. This effect, which is weaker than the first, obtains in *o*-methoxyphenylphosphonic acid (ΔpK_a in water +0.10 and in alcohol +0.25). The effect of substituents on the second dissociation constants of the above compounds is also interpreted from the standpoint of this mechanism.

Hydrogen bonds with benzene rings as proton acceptors are fairly weak[68–73]. Nevertheless the large differences between the pK_a values of *o*-biphenylylphosphonic (XXXIII, X = P) (pK_a = 3.78) and phenylphosphonic (pK_a = 1.83) acids[67,74] and *o*-biphenylylarsonic (XXXIII, X = As) (pK_a = 4.29) and phenylarsonic (pK_a = 3.47) acids[75] have been attributed to the intramolecular hydrogen bonds between the acid hydroxy-groups and the π electrons of the aromatic system[67].

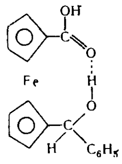
Intramolecular hydrogen bonds have some effect also on the dissociation constants of organic acid salts. When a hydroxy- or amino-group capable of formation of hydrogen-bonded bridges is present in the salt anion, the dissociation constant of the salt is greatly increased. This has been found, in particular, for magnesium, calcium, strontium, and barium salts of glycollic acid, glycine, etc.[76]

5. ESTERIFICATION REACTIONS

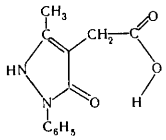
The rate and mode of esterification reactions depends significantly on the presence of intramolecular hydrogen bonds in the reactant molecules. Measurements of the rate constants for the interaction of substituted benzoic acids with *p*-tolyldiazomethane in toluene or ethyl acetate solutions showed that salicylic acid is the most reactive[77]:

$$RCOOH + N_2C(C_6H_4CH_3)_2 \rightarrow RCOOCH(C_6H_4CH_3)_2 + N_2.$$

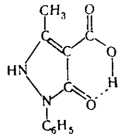
In an analogous reaction with diphenyldiazomethane in toluene at 30°C, among all ferrocenecarboxylic acids with heteroannular CH_3CO, C_2H_5, C_6H_5, $C_6H_5CH_2$, and $C_6H_5CH(OH)$ substituents, 1-(α-hydroxybenzyl)ferrocene-1′-carboxylic acid was esterified with the highest rate constant[78]. It has been shown[79] that diphenyldiazomethane attacks the carboxy-group at the O–H bond. Therefore the high reactivities of salicylic acid[77] and 1-(α-hydroxybenzyl)ferrocene-1′-carboxylic acid (XXXIV)[78] can be explained by the formation of an intramolecular hydrogen bond between the hydroxy-group of the substituent and the carbonyl oxygen, which inhibits the rotation of the COOH group and increases the rate of its reaction with diaryldiazomethanes:



(XXXIV)



(XXXV)



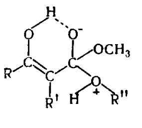
(XXXVI)

The sharp difference between the reactivities of *cis*- and *trans*-2-hydroxycyclohexane-1-carboxylic acids and their derivatives is attributed to the presence of a hydrogen bond in the *cis*-isomer[80]. The higher rate of reaction with diazomethane of antipyrineacetic acid (XXXV) compared with antipyrinecarboxylic acid (XXXVI) is a consequence, according to the author[81], of the greater lability of the seven-membered chelate ring in compound (XXXV) compared with the six-membered ring in compound (XXXVI). It is believed that the higher reactivity of β-keto-esters in transesterification reactions (RCOOR′ + R″OH → RCOOR″ + R′OH) may be due to a hydrogen bond in the transition state (XXXVII) of the reaction[82,83]. Indeed, while the transesterification of methyl- and ethyl-substituted β-keto-esters takes place under mild conditions in the absence of a catalyst, the transesterification of disubstituted β-keto-esters incapable of enolisation and hence of the formation of intramolecular hydrogen bonds does not take place under these conditions.

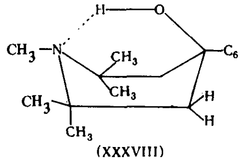
A chelated phenolic hydroxyl is probably more readily acylated than alkylated[40]. However, the formation of esters (particularly under the usual conditions) is also anomalously slow or does not occur at all when the molecule contains hydrogen-bonded hydroxyls. Thus in the benzoylation of phenol and its substituted derivatives it was found that *o*-nitrophenol is esterified at the lowest rate, while the esterification of the *m*- and *p*-isomers is somewhat faster than that of phenol itself[1]. In polyhydroxyanthraquinones the chelated *peri*-hydroxyls are acetylated much more slowly than others[1].

Many compounds with a strong intramolecular hydrogen bond are not acetylated at all under the usual conditions (acetylation with acetic anhydride at room temperature with addition of several drops of pyridine). This has been established for 4-chlorosalicylaldehyde[1], 5-fluoro-2-nitrophenol[1], 2-hydroxy-3-methyl-5-nitrobenzaldehyde[49], 2,3,5-trinitrophenol[49], and α-hydroxybenzylideneacetophenone[49].

The unsuccessful attempts to obtain the acetyl derivatives of compound (XXXVIII) are due to the presence of the strong intramolecular hydrogen bond in the latter ($\Delta\nu_{OH} = 205\ cm^{-1}$).[84]

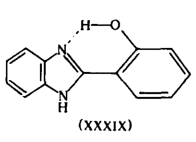


(XXXVII)

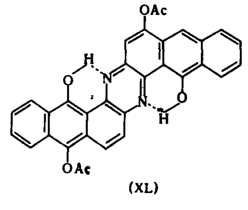


(XXXVIII)

The selective acetylation of hydroxy-groups in polyhydroxy-compounds is also due to the involvement of some of these in intramolecular hydrogen bonds. Thus in the acetylation of 2,4-dihydroxybenzoic acid and the corresponding aldehyde only the 4-acetoxy-2-hydroxy-derivative is obtained[1] and 2,4,6-trihydroxybenzaldehyde gives only the 4,6-diacetyl derivative[1]. Acetylation of polyhydroxy-substituted flavones, isoflavones, chromones, and flavanones under mild conditions does not involve the hydroxy-groups in the 5-position because of its strong hydrogen bond with the *peri*-carbonyl oxygen atom[40] (under more severe conditions—heating at 100°C—this hydroxyl is also acetylated). Acetylation with acetic anhydride of 1′,2′,3′,4-tetrahydroxy-1,2-benzocycloheptan-3-one (XXVII) gives 2′,3′,4-triacetoxy-1-hydroxy-1,2-benzocycloheptan-3-one[84], while the acetylation of 2-(*o*-hydroxyphenyl)benzimidazole (XXXIX) takes place at the nitrogen atom[85] (there is a strong intramolecular hydrogen bond between the hydroxy-group and the imine nitrogen atom[86]):



(XXXIX)



(XL)

The reductive acetylation (with zinc and acetic anhydride) of the non-linear isomer of indanthrone yields only the diacetyl derivative (XL) since the remaining hydroxy-groups are linked by strong hydrogen bonds[87].

To elucidate the effects of intramolecular hydrogen bonds on the rate of acetylation, the kinetics of the reaction of certain cholinolytic substances with acetyl chloride have been investigated[88] at 30°C in chloroform solution. The kinetic data together with infrared spectroscopic data[89] are presented in Table 5. A particularly important feature of these results is that the spectroscopic measurements were made approximately under the same conditions (carbon tetrachloride as a solvent) as the kinetic experiments.

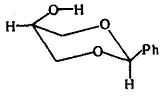
Table 5.

Compound	ν_{OH}, cm^{-1}	$k_{acetylation}$, litre $mole^{-1}$ min^{-1}
(1) $(C_6H_5)_2C(OH)CH_2OC_2H_5$	3484^*_{33}	0.50
(2) $(C_6H_5)_2C(OH)C_2H_5$	—	0.50
(3) $(C_6H_5)_2C(OH)COOCH_2CH_2N(C_2H_5)_2$	3534_{31} 3610_{64}	1.42
(4) $(C_6H_5)_2C(OH)COSCH_2CH_2N(C_2H_5)_2$	3534_{57} 3610_{30}	9
(5) $(C_6H_5)_2C(OH)CONHCH_2CH_2N(C_2H_5)_2$	3378_{38} 3623_{73}	1.50
(6) $(C_6H_5)_2C(OH)CON(CH_3)CH_2CH_2N(C_2H_5)_2$	3378_{33} 3610_{80}	1.90
(7) $(C_6H_5)_2C(OH)CH_2OCH_2CH_2N(C_2H_5)_2$	3155_{38} 3610_{75}	0.29
(8) $(C_6H_5)_2C(OH)CH_2CH_2N(C_2H_5)_2$	3226_{34} 3610_{84}	0.35

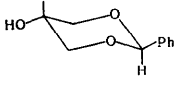
*The subscripts denote the percentage transmission in 0.02 M solutions in carbon tetrachloride.

The complexity of the structures of the compounds chosen and the presence in them of substituents of different electronic types complicates the interpretation of the results. Nevertheless it is clear that the rate of acetylation of the thioester (4) is much higher than that of the ester (3), while the rates for the corresponding amides are much lower. This is fully consistent with the spectroscopic finding that the hydroxyl in (4) is less strongly linked and those in (5) and (6) are more strongly linked by intramolecular hydrogen bonds than the hydroxyl in (3). One cannot of course dismiss the possibility of some influence of the ester, thioester, and amide groups on the lability of the hydrogen atom in the hydroxy-group. Similarly the lower rate of reaction of (7) and (8) compared with (1) and (2) respectively can be explained by stronger intramolecular hydrogen bonds in the latter.

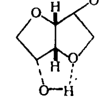
The accelerating effect of hydrogen bonds on the esterification of alcohols has also been described. Such an effect has been noted by Buck et al.[90] in a study of the esterification of 5-hydroxy-1,3-dioxan derivatives with *p*-phenylazobenzoyl chloride. *cis*-5-Hydroxy-2-phenyl-1,3-dioxan (1,3-benzilideneglycerol) and (XLI) reacts with *p*-phenylazobenzoyl chloride almost six times faster than the *trans*-isomer (XLII). This is because the intramolecular hydrogen bond in compound (XLI) (in carbon tetrachloride solutions $\Delta\nu_{OH_{cis}} = 3590\ cm^{-1}$ and $\Delta\nu_{OH_{trans}} = 3633\ cm^{-1}$) increases the basicity of the oxygen atom of the hydroxy-group and thereby increases the rate of esterification:



(XLI)



(XLII)



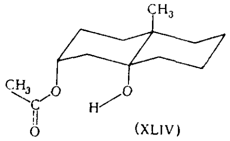
(XLIII)

This is confirmed by the behaviour of 4-phenylcyclohexanols. Since only intermolecular hydrogen bonds may exist in solutions of these compounds, the reactivity of both isomers should be enhanced, but, since in the *cis*-isomer the hydroxy-group is sterically more inaccessible, the greatest increase in rate should be expected for the *trans*-isomer. Indeed, at 37°C *trans*-4-phenylcyclohexanol reacts almost 7 times faster than the *cis*-isomer.

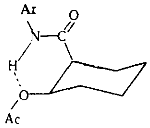
Of the two hydroxy-groups in 1,4,3,6-dianhydro-α-gluticol (XLIII) the 5-hydroxy-group, involved in an intramolecular hydrogen bond, is the more reactive. In particular, the formation of the *p*-toluenesulphonyl derivative involves mainly the 5-hydroxy-group (after interaction with *p*-toluenesulphonyl chloride for 46 h the mixture has the following composition: 11.7% of the 2-monosubstituted derivative, 11.7% of the 2,5-disubstituted derivative, and 45.4% of the 5-monosubstituted derivative [91]); in the esterification with *p*-phenylazobenzoyl chloride the 5-monosubstituted derivative is also mainly formed (after 22 h the reaction mixture contains 12% of the 2-monosubstituted derivative, 9% of the 2,5-disubstituted derivative, and 36% of the 5-mono-substituted derivative [90]).

6. HYDROLYSIS OF ESTERS

Barton [92] established that esters of equatorial alcohols of the cyclohexane series are hydrolysed more readily than the epimeric axial esters. However, this general rule does not hold if the hydroxy- and ester-groups in the monoesters of the diols approach one another under the influence of the molecular environment to such an extent that an intramolecular hydrogen bond is formed. Such a hydrogen bond greatly facilitates the hydrolysis of axial esters compared with the equatorial esters. This phenomenon was discovered for the first time by Henbest and Lovell [93,94]. In a study of the hydrolysis of 3-acetoxy-5-hydroxysteroids in aqueous potassium bicarbonate they found that the *cis*-diaxial hydroxy-esters of the cholestane and coprostane series are hydrolysed (under the same conditions) to a much greater extent than the corresponding equatorial esters. These results were explained by the formation of a six-membered ring with a hydrogen bond between the hydroxyl in the 5-position and the alcoholic oxygen of the axial ester (XLIV):



(XLIV)



(XLV)

According to the authors, such a hydrogen bond increases the reactivity of the ester group in relation to the nucleophilic agent introduced into the reaction [94]. The decrease of the OH and $\geqslant$C–O vibration frequencies and the increase of the carbonyl frequency in the infrared spectra of acetoxy-alcohols of type (XLIV) confirmed the hypothesis that intramolecular hydrogen bonds of this type are present.

A study of the infrared spectra (with high resolution in the region of the hydroxyl stretching vibrations) of certain 1,3-hydroxy-acetates of the bicyclononane and bicyclononene series was carried out by Johnson and coworkers [95]. The authors believe that the slight shift of the hydroxyl band ($\Delta\nu_{OH}$ = 15 cm^{-1}) cannot be assigned to the hydrogen bond with the carbonyl oxygen because, like Henbest and Lovell [93,94], they attribute this shift to the hydrogen bond with the ester oxygen. Furthermore, the >C=O frequency in the intramolecularly hydrogen-bonded compounds investigated is usually enhanced, while involvement in an intramolecular hydrogen bond always reduces it.

The hydrogen bond is also responsible for the higher reactivity of derivatives of *cis*-2-hydroxycyclohexanecarboxylic acid compared with the *trans*-isomers. Thus the *cis*-acetoxy-*p*-toluidide (XLV) is hydrolysed much more rapidly than the corresponding *trans*-isomer [80].

Similarly the base-catalysed methanolysis of 7- and 16-acetoxy-derivatives of germine is facilitated by the presence of hydroxy-groups in the 14- and 20-positions [96], while the methanolysis of the 16-acetoxy-derivative of cevine is facilitated by the hydroxy-group in the 20-position [97].

Table 6.

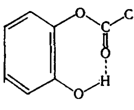
Compound	10^3k, litre mole^{-1} s^{-1}
3β-Methoxycholestan-4β-yl acetate	2.7
4β-Hydroxycholestan-3β-yl acetate	22
3β-Hydroxycholestan-4β-yl acetate	24
Cholestan-3β-yl acetate	1.3

A study has been made [98,99] of the kinetics of the alkaline hydrolysis of cholestan-3β-yl acetates at 30°C in 20% aqueous dioxan containing sodium hydroxide. The results are presented in Table 6, which shows that the rate of hydrolysis of the 3β-acetate increases by a factor of 8 or 9 when a 4β-hydroxy-group is introduced into the molecule. The replacement of the 3β-hydroxy-group by a methoxy-group (the inductive effect of which is approximately the same as that of the hydroxy-group) reduces the rate of hydrolysis of the 4β-acetate by a factor of 19.

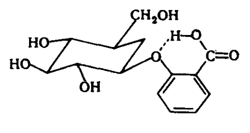
In a study of the rate of alkaline hydrolysis of a number of monoglycyl derivatives of *cis*- and *trans*-tetrahydrofuran-3,4-diols it was found [100] that, whereas the *trans*-hydroxy-group increases the rate of alkaline hydrolysis (at 30°C) by a factor of 2.3, the increase due to the *cis*-hydroxy-group is by a factor of 6.7. However, in contrast to Henbest and Lovell [93,94], the enhanced reactivities of the monoglycinates derived from the *cis*-3,4-diols are attributed [100] to a hydrogen bond with the carbonyl oxygen. It is noteworthy that, although Johnson and coworkers [95] do assert on the basis of infrared spectroscopic measurements that the hydrogen bond in the ground state is formed with the ester oxygen, they believe nevertheless that the kinetically important species may be those where the carbonyl oxygen behaves as the proton acceptor.

The sharp increase of the rate of hydrolysis on formation of a hydrogen bond between a hydroxy-group and a carbonyl or methoxy-carbonyl group was noted in a study of the hydrolysis of indole alkaloids [101,102]. However, because of the complexity of the compounds (yohimbine, corynanthine, methyl reserpate, etc.), the rate of hydrolysis of which is influenced considerably not only by the intramolecular hydrogen bond but also by the concentrations of the conformers and the rates of their interconversions, it is difficult to interpret the quantitative data obtained in this investigation. Examples of the acceleration of alkaline hydrolysis of esters are known also for many other types of compound [103]. Hansen [104] investigated the rate of alkaline hydrolysis of a number of phenols at 25°C in 0.07 M $KClO_4$. The value of lg k_2 (k_2 is a second-order rate constant in litre mole^{-1} s^{-1}) are listed in Table 7.

The much higher rate of hydrolysis of phenyl acetate (by a factor of 700) compared with the *o*-hydroxyphenylacetate (XLVI) is due to the presence in the latter of a strong intramolecular hydrogen bond ($\Delta\nu_{C=O}$ in carbon tetrachloride solutions is 30 cm^{-1}). The intramolecular hydrogen bond in *o*-carboxyphenyl-β-D-glucose (XLVII) explains why it is hydrolysed 10^4 times faster than the *p*-carboxyphenyl-derivative[105]:



(XLVI)

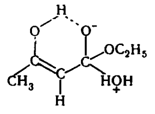


(XLVII)

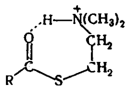
Table 7.

Compound	lgk_2
Phenyl acetate	0.22
o-Methoxyphenyl acetate	0.01
o-Hydroxyphenyl acetate	3.07
o-Phenylene diacetate	0.97

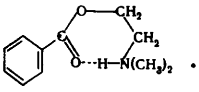
The stabilisation of the transition state (XLVIII) by the intramolecular hydrogen bond is the cause of the rapid hydrolysis of ethyl acetoacetate in water at 90°C:[106]



(XLVIII)



(XLIX)



(L)

Hansen[107] noted an appreciable effect of hydrogen bonds involving a nitrogen atom on the hydrolysis of esters. In the alkaline hydrolysis (pH 7–10) of two thioesters—2-(*NN*-dimethylamino)ethyl thioacetate $CH_3CH_2C(O)SCH_2CH_2NH(CH_3)_2$ (XLIX) and $CH_3CH_2C(O)SCH_2CH_2\overset{+}{N}(CH_3)_3$—it was found that the first ester is hydrolysed 240 times faster than the second. This may be due to a hydrogen bond in (XLIX). The same causes are responsible for the somewhat smaller increase (approximately by a factor of 20) of the rate of hydrolysis of the 2-(*NN*-dimethylamino)ethyl benzoate (L) compared with the 2-(*NNN*-trimethylamino)ethyl ester[108].

The enhanced (by a factor of 20–30) rate of hydrolysis of tertiary 2- and 3-dialkylaminoalkyl acetates compared with the corresponding quaternary compounds is also due to the existence of an intramolecular hydrogen bond in the former, as shown by spectroscopic data[109].

The kinetic data obtained in a comparative study[110] of the alkaline hydrolysis of esters with the general formula $C_6H_5COOCH_2R$ at a constant pH at 25°C in 50% ethanol are presented in Table 8, which shows that the esters capable of forming an intramolecular hydrogen bond with a carbonyl oxygen are hydrolysed many times faster than their analogues without such bonds. Thus compound (2) is hydrolysed 22 times faster than compound (1) and compound (6) is hydrolysed 1000 times faster than compound (5).

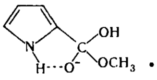
Many other examples of the effect of intramolecular hydrogen bonds on the rate of hydrolysis have been adduced[111,112]. In a spectrophotometric study of the acid hydrolysis of a number of aromatic Schiff bases in aqueous alcohol it was found that the rate constant for the hydrolysis of *o*-hydroxybenzylidene-*p*-toluidine (k_1 = 0.021) is 9.6 times lower than that of *p*-hydroxybenzylidene-*p*-toluidine (k_1 = 0.202).[111] On the other hand, *o*-methoxybenzylidene-*p*-toluidine (k_1 = 0.680) hydrolyses three times faster than *p*-methoxybenzylidene-*p*-toluidine (k_1 = 0.220). Clearly the markedly lower rate of hydrolysis of the *o*-hydroxy-isomer compared with the *p*-isomer is due to an intramolecular hydrogen bond in the former.

Table 8.

Substituent R	Presence of i.h.b.*	k, mole^{-1} min^{-1}
(1) $-C{\equiv}C-CH_2-N(C_2H_5)_2$	—	7.46
(2) $-C{\equiv}C-CH_2-NH-C_2H_5$	+	167
(3) $-C{\equiv}C-CH_2-\overset{+}{N}(C_2H_5)_2-CH_3$	—	32.1
(4) $-C{\equiv}C-$	—	12.8
(5) $-CH_2-N(C_2H_5)_2$	—	2.48
(6) $-CH_2-\overset{+}{N}H(C_2H_5)_2$	+	2500
(7) $-CH_2-\overset{+}{N}(C_2H_5)_3$	—	69.8

*A minus sign denotes the absence of a hydrogen bond and a plus sign denotes its presence.

This bond reduces the basicity of the imino-nitrogen and hinders its protonation:



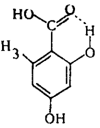
(LI)

The hydrogen bond has an accelerating effect on the alkaline hydrolysis of methyl pyrrole-2-carboxylate (LI) compared with the isomeric methyl pyrrole-3-carboxylate[64], the rate constants for their hydrolysis in aqueous acetone being 0.41 × 10^{-3} and 0.059 × 10^{-3} respectively. The explanation is that the transition state in the hydrolysis of compound (LI) is stabilised by an intramolecular hydrogen bond of the type >N–H. . . O<.

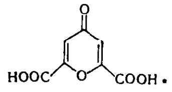
The ease of hydrolysis of 1-quinolinium derivatives to the corresponding quinolines is attributed[112] to the presence of an intramolecular hydrogen bond in 4-dialkylaminoalkylaminoquinolines[113].

7. DECARBOXYLATION REACTIONS

The decarboxylation reaction requires a weakening of the bond between the carboxyl carbon atom and the atom in the ring (or chain) to which it is linked. This happens to some extent on acid dissociation and the rate of reaction is determined mainly by the rate of decomposition of the anion[114–116]. Since acids with the carbonyl group involved in a hydrogen bond with *o*-hydroxy-groups are much stronger than their isomers, they should be decarboxylated much more readily than the latter. Thus, while benzoic acid is not decarboxylated up to 400°C and *p*-hydroxybenzoic acid is decarboxylated at about 300°C, salicylic acid splits off carbon dioxide on heating in water to 220–230°C,[49] 2-hydroxynaphthoic acid, which has a strong intramolecular hydrogen bond[117], is decarboxylated at 120°C,[49] and orsellinic acid (LII) decomposes into orcinol and carbon dioxide even on boiling in methanol[49]:



(LII)



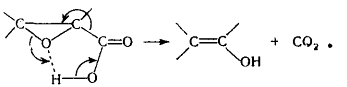
(LIII)

Similarly, meconic acid, the carboxy-group of which is chelated, splits off carbon dioxide above 120°C, while chelidonic acid (LIII) which does not have a hydrogen bond of this kind is decarboxylated only at 300°C.

Some of these acids, for example, phloroglucinoldicarboxylic and *o*-nitrosalicylic acids, are extremely unstable in a free form and therefore cannot be isolated[49]. On the other hand, isomers of *o*-nitrosalicylic acid are quite stable.

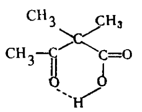
Pyridine-2-acetic[118,119] and quinoline-2-acetic[118] acids are decarboxylated very readily below 100°C. On the other hand, the isomeric 3-acetic acids are decarboxylated with considerable difficulty. This may appear strange if one remembers that the 2-isomers are weaker acids than the 3-isomers by virtue of an intramolecular hydrogen bond with the nitrogen atom[66]. One of the possible explanations of this finding is that the decarboxylation takes place in fact via the hydrogen-bonded cyclic form of the molecule. Thus the optically active methylethylpyridine-2-acetic acid is resistant to decarboxylation in acid and alkaline media and is readily decarboxylated in a neutral medium (maximum chelation) with formation of racemic 2-s-butylpyridine.

It has also been suggested[120] that the thermal decomposition of glycidic acid to carbonyl compounds is accompanied by the intermediate formation of the chelate compound (LIV):

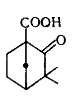


(LIV)

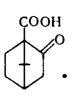
It has been established experimentally[121] that the non-catalysed decarboxylation of β-keto-acids, for example, dimethylacetoacetic acid (LV), is independent of the dielectric constant of the solvent. Therefore the rate-determining stage of the reaction cannot be the decomposition of strongly polar intermediate species. On this basis, and also because the primary product of the cleavage of compound (LV) is the enolic form of isopropyl methyl ketone, Westheimer and Jones[121] suggested that the reaction involves the intermediate formation of the chelate species (LV):



(LV)

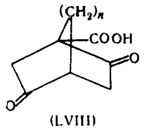


(LVI)

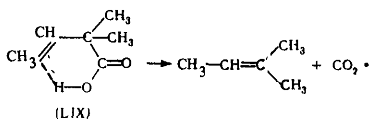


(LVII)

The validity of this hypothesis is indicated by the fact that β-keto-acids incapable of enolisation (because of the considerable steric strain on formation of the enol), for example, camphenic (LVI) and ketopinic (LVII) acids, are not decarboxylated above 300°C, while derivatives of bicyclo[3,3,1]nonane (LVIII) are not decarboxylated even on vacuum sublimation at 150°C.[122] According to Arnold et al., the decarboxylation of βγ-unsaturated acids, for example 2,2-dimethylbutane-3-carboxylic acid (LIX),[123] also proceeds via a cyclic chelate formed in which the double bond behaves as a proton acceptor:



(LVIII)



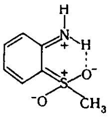
(LIX)

The unusual resistance to decarboxylation of styrylacetic acid and αα-dimethylstyrylacetic acid is explained by the fact that the loss of carbon dioxide with subsequent migration of the double bond leads to the breakdown of the conjugated system[123].

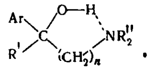
Similar mechanisms have been proposed for the decarboxylation of malonic acid and its half-esters and also the half-esters of 2,5-dimethylcyclopentanedicarboxylic acid[124].

8. INTRAMOLECULAR HYDROGEN BONDS AND BASICITY

Whereas fairly extensive data have accumulated on the effect of intramolecular hydrogen bonds on the acid properties of individual groups, the effect of the hydrogen bond on basicities has been investigated very much less. It may be supposed that the involvement of an atom or group of atoms with basic properties in a hydrogen bond should result in a weakening of the basic properties if the given group plays the role of a donor in the hydrogen bond. Thus *o*-aminophenyl methyl sulphone is a weaker base than the *p*-isomer although the steric effect of the methanesulphonyl group should increase and not decrease the strength of the *o*-base compared with the *p*-isomer. The reason for this is the flattening of the molecule as a result of the contribution of the resonance structure (LX) with an intramolecular hydrogen bond[125]:



(LX)



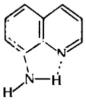
(LXI)

The less pronounced basic properties of 2-amino-4-trifluoromethylphenyl phenyl sulphone compared with the 4-amino-2-trifluoromethylphenyl isomer can be explained similarly[126].

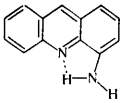
o-Hydroxybenzylidenepentylamine (pK_a = 12.15 in acetonitrile), which, like all *o*-hydroxybenzylidenealkylamines, has a strong intramolecular hydrogen bond[127], is a weaker base than *p*-hydroxybenzylidenepentylamine (pK_a = 14.80).[128]

In a study of amino-alcohols (LXI)[129,130] it was found that there is a reciprocal relation between the strength of the intramolecular hydrogen bond (displacement of the OH band in the infrared spectrum in carbon tetrachloride solution) and the basicity of amino-alcohols (in nitrobenzene)[130]: the stronger the hydrogen bond the lower is the basicity of the amino-group and, within the limits of each series, the frequency shift is fairly well correlated with the relative basicity of the amino-alcohol.

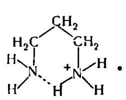
The intramolecular hydrogen bond has a considerable influence on the basicity of the ring nitrogen atoms in 8-aminoquinoline (LXII) and 1-aminoacridine (LXIII):[131,132]



(LXII)



(LXIII)



(LXIV)

Among all the aminoquinolines and aminoacridines, compounds (LXII) and (LXIII) are the weakest bases. The reason for this is the presence in them of intramolecular hydrogen bonds, demonstrated by spectroscopic data[133].

The reduced basicity of the amino-group in the monocation of trimethylenediamine (LXIV) compared with other diamines has also been attributed[134] to the presence of an intramolecular hydrogen bond.

9. REDUCTION REACTIONS

a. Reduction of the Carbonyl Group

The presence of a hydroxy-group in the *ortho*-position relative to a carbonyl group considerably alters the activity of the latter. In the polarographic reduction of a series of quinones in aprotic solvents it was noted[135] that electron-donating groups displace the half-wave reduction potential towards more negative values. At the same time hydroxy-groups linked to >C=O groups via an intramolecular hydrogen bond shift the potentials towards more positive values (Table 9).

Table 9.

Quinone	Substituent	Solvent	$E_{1/2}$, V
	H	CH_3CN	—0.71
		DMF*	—0.72
1,4-Naphthoquinone	2-CH_3	CH_3CN	—0.77
	2-NH_2	CH_3CN	—0.92
	2-OH	DMF	—0.64
		CH_3CN	—0.52
	5-OH	DMF	—0.51
	H		—0.98
9,10-Anthraquinone	2-C_2H_5	DMF	—1.12
	1-OH	DMF	—0.77
	1.8-$(OH)_2$	DMF	—0.64

*DMF = dimethylformamide

An analogous effect was noted[136] also in a series of aromatic ketones: the carbonyl group in *o*-hydroxyacetophenone is reduced appreciably more readily than in the *para*-isomer. Thus the intramolecular hydrogen bond greatly increases the electron affinity of the molecule.

b. Reduction of the Nitro-group

The presence of the hydrogen bond in *o*-nitro-compounds not only increases the ease of reduction of the nitro-group but is also the reason why the reduction products are not always amines. Thus *p*-nitrophenol and nitrocresols [(3) and (4) in Table 10], which have no intramolecular hydrogen bonds, are fully reduced to the amines at any pH, while the presence of intramolecular hydrogen bonds in the *ortho*-isomers [(1), (5), (6), and (7) in Table 10] stabilises the intermediate hydroxylamine derivative and inhibits further reduction at a dropping mercury electrode[137,138]. At the same time, dihydroxynitrobenzenes [(10)–(12) and (14) in Table 10], which have weaker hydrogen bonds than *o*-nitrophenol, are reduced to the amines at any pH.[139]

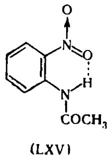
**Determination at pH 7.0
***Determination at pH 2.1.

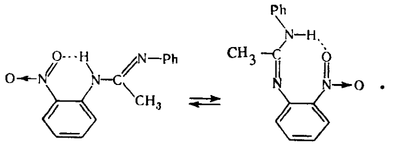
The half-wave potentials for the reduction of *o*-nitrophenol and its substituted derivatives and also dihydroxynitrobenzenes with intramolecular hydrogen bonds [(10)–(12) and (14) in Table 10] are much more positive than for the *para*-isomers and *o*-methoxynitrobenzenes in an acid medium, but are approximately the same in alkaline solutions where there is no intramolecular hydrogen bond. This is evidently due to the fact that the hydrogen bond is formed only with one oxygen atom of the nitro-group. This makes the oxygen atoms non-equivalent and facilitates the reduction of the oxygen atom not involved in chelation. The half-wave potentials for the reduction of different nitrophenols, nitrocresols, and dihydroxynitrobenzenes are listed in Table 10.

The kinetics of the reduction of substituted nitrobenzenes with titanium trichloride in aqueous alcohol were investigated by Newton et al.[140], who showed that the *p*-hydroxy-group lowers the rate of reduction of the nitro-group by a factor of 4 compared with nitrobenzene, while the *o*-hydroxy-group increases it by a factor of 16.5. At the same time, *o*- and *p*-methoxynitrobenzenes react at almost identical rates. It is therefore clear that the enhanced reactivity of *o*-nitrophenol is a consequence of the presence of an intramolecular hydrogen bond.

Chelation can also account for the greater ease of reduction of *o*-nitroacetanilides (LXV) compared with nitrobenzene and *m*- and *p*-nitroacetanilides[141]:



(LXV)



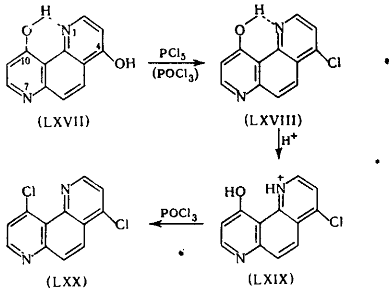
(LXVI)

The possibility of chelation of this type is demonstrated by the fact that *o*-nitroacetanilide is more volatile than the *meta*- and *para*-isomers, is less associated in naphthalene[142], and has a number of other properties typical for chelated systems[143]. At pH 8 and 12 the differences between the reduction potentials of the *ortho*- and *para*-isomers are +0.15 and +0.13 V respectively, while at pH 7 the half-wave potential for compound (LXV) is more negative by 0.04 V than for *p*-nitroacetanilide (in a highly alkaline medium there is no chelation). Similar results were obtained in a study of the polarographic and catalytic reduction of *o*-nitrophenylacetamidine (LXVI) and its isomers[144]. In the pH range between 2.2 and 7 the differences between the half-wave potentials for the reduction of the *meta*- and *para*-isomers are insignificant, while the value for (LXVI) is much less negative. The greater ease of reduction of (LXVI) compared with its isomers, due to the presence of an intramolecular hydrogen bond, was confirmed also by catalytic hydrogenation in methanol using Raney nickel as a catalyst. The times required for the complete reduction of the nitro-group in the *ortho*-, *meta*-, and *para*-isomers are in the ratios $o:m:p = 1:4:6$.

The greater ease of reduction of 4(7)-nitrobenzimidazole[145] and 4(7)-nitrobenzotriazole[146] compared with their isomeric 5(6)-nitroderivatives without intramolecular hydrogen bonds is explained by the chelation between the hydroxy- and nitro-groups in these compounds.

10. SUBSTITUTION REACTIONS

The intramolecular hydrogen bond has a considerable influence on certain substitution reactions. When 4,10-dihydroxy-1,7-phenanthroline (LXVII) is treated with phosphorus pentachloride or phosphorus oxychloride, the hydroxy-group in the 4-position is the first to be replaced by chlorine to give compound (LXVIII). Such preferential substitution of the hydroxyl can be accounted for by the "masking" of the hydroxy-group in the 10-position by the intramolecular hydrogen bond with the nitrogen atom in the 1-position[147]:



(LXVII) (LXVIII) (LXX) (LXIX)

The conversion of (LXVII) into (LXX) is achieved by prolonged heating of the former with $POCl_3$. The addition of a small amount of H_2O or HCl to the reaction mixture greatly increases the rate of reaction and the yield of the product, since under these conditions the intramolecular hydrogen bond breaks in consequence of the protonation of the ring nitrogen atoms. In a study of the reaction

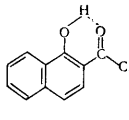
$$R{-}C_6H_4CH{=}N{-}C_6H_4R' + R''{-}C_6H_4{-}CHO \rightarrow R''{-}C_6H_4{-}CH{=}N{-}C_6H_4{-}R' + R{-}C_6H_4{-}CHO$$

it was found that among aromatic aldehydes the most reactive is salicylaldehyde[148], which may be attributed to the presence of an intramolecular bond.

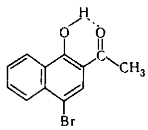
It is well known that *o*-halogenonitrobenzenes react with primary and secondary amines much more rapidly than their *para*-isomers. Thus *o*-chloronitrobenzene reacts with piperidine in xylene at 102°C 80 times faster[149,150] and in benzene 47–51 times faster[150,151] than the *para*-isomer. In polar solvents, for example, alcohols or aqueous dioxan, this ratio is much less, but always greater than unity[150]. The greater reactivity of *o*-halogenonitrobenzenes compared with the *para*-isomers is explained[152] by the fact that in the transition state of these reactions there is a hydrogen bond in the case of the *ortho*-isomers, which facilitates the process. Other explanations for this phenomenon have also been proposed[149].

An important argument in favour of the hypothesis of the decisive role of the intramolecular hydrogen bond is provided by the reaction of 1,4-diazabicyclo[2,2,2]octane with *o*-chloronitrobenzene in which there is no hydrogen bond in the transition state. This compound reacts with *p*-chloronitrobenzene in benzyl alcohol at 500°C hundreds of times faster than with the *ortho*-isomer. At the same time di-n-butylamine reacts with the *ortho*-isomer 16 times faster than with the *para*-isomer. These data support the hypothesis of the formation of a hydrogen bond in the transition state. Similarly the presence of a hydrogen bond between a hydrogen atom of the amino-group and the fluorine atom accounts also for the greater reactivity of *o*-fluoronitrobenzene compared with other *o*-halogenonitrobenzenes[154,155].

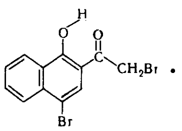
The presence of intramolecular hydrogen bonds explains the characteristics of certain electrophilic substitution reactions. Chang and Yang[156] found that 2-acetyl-1-naphthol (LXXI) is readily brominated at room temperature to 2-acetyl-4-bromo-1-naphthol (LXXII) and bromination with an excess of bromine gives 4-bromo-2-bromoacetyl-1-naphthol (LXXIII). However, 2-acetyl-4-bromo-1-naphthol does not react further with bromine if it is first isolated from the reaction mixture:



(LXXI)



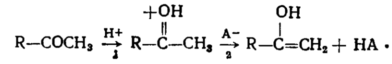
(LXXII)



(LXXIII)

This behaviour of (LXXI) becomes clear if one considers the formation of the dibromo-derivative (LXXIII): (LXXI) + $Br_2 \xrightarrow[1]{} (LXXII) + HBr \xrightarrow[2]{Br_2} (LXXIII) + HBr$. It follows from this mechanism that the formation of the dibromo-derivative (LXXIII) takes place only in the presence of hydrogen bromide formed in the first stage of the reaction. Indeed (LXXII) is brominated successfully when HBr is passed through its solution in acetic acid. This antagonistic effect on bromination is shown by both 4-bromo- and 4-nitro-derivatives of 2-acetyl-1-naphthol and is common to this group of compounds. It appears logical to attribute this behaviour to the interaction between the hydroxy- and oxo-groups.

The principal stages in the acid-catalysed bromination of ketones are as follows:



$$R{-}COCH_3 \underset{1}{\overset{H^+}{\rightarrow}} R{-}\overset{\overset{+OH}{\|}}{C}{-}CH_3 \underset{2}{\overset{A^-}{\rightarrow}} R{-}\overset{\overset{OH}{|}}{C}{=}CH_2 + HA\,.$$

Chelation should interfere with the formation of the intermediate ion and should lower the rate of bromination. The addition of a proton to the carbonyl oxygen breaks the hydrogen bond and permits further bromination. The behaviour on bromination of the methyl ether and acetate derived from (LXXI), in which there are no intramolecular hydrogen bonds, confirms this. None of these compounds requires the addition of acids for the bromination of the acetyl group.

11. REACTIONS OF *o*-HYDROXY-ALDEHYDES

One of the most thoroughly investigated reactions, the kinetics of which are significantly influenced by the presence of hydrogen bonds, is the reaction of aromatic *o*-hydroxy-aldehydes with reagents for carbonyl compounds. Studies of this kind were carried out for the first time by Vavon[157]. It was found that salicylaldehyde and *o*-vanillin, which have strong intramolecular hydrogen bonds, react with hydroxylamine hydrochloride 13 and 11 times faster respectively than the isomeric *p*-hydroxybenzaldehyde and *p*-vanillin[158]. This behaviour persists also in the interaction of other *o*-hydroxy-aldehydes with the hydrochlorides of hydroxylamine, phenylhydrazine, and semicarbazide,[158], and with melamine[159]. Thus 2-hydroxy-1-naphthaldehyde reacts with hydroxylamine hydrochloride 120 times faster and with phenylhydrazine hydrochloride 53 times faster than 4-hydroxy-1-naphthaldehyde which has no intramolecular hydrogen bond. It is interesting to note than *o*-methoxybenzaldehydes react with carbonyl reagents much faster than the *p*-methoxy-derivatives. For example, *o*-methoxybenzaldehyde reacts with hydroxylamine hydrochloride 150 times faster than anisaldehyde.

Table 11.

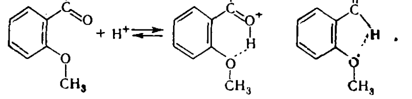
Substituent	$10^3 k_1$, s^{-1}	
	$NH_2OH \cdot HCl$	$C_6H_5NHNH_2 \cdot HCl$
o-OH	42.8	16.3
p-OH	5.9	0.8
m-OH	15.8	2

Knorre and Emanuel'[160] made a more rigorous kinetic study of this reaction. They investigated the kinetics of the interaction of hydroxy- and nitro-benzaldehydes with hydroxylamine and phenylhydrazine hydrochlorides in 95% methanol. The rate constants obtained for the reactions of hydroxybenzaldehydes are listed in Table 11, which shows that salicylaldehyde reacts with hydroxylamine hydrochloride 7.2 times faster and with phenylhydrazine hydrochloride 8.2 times faster than *p*-hydroxybenzaldehyde. On the other hand, the isomeric nitrobenzaldehydes react with these reagents for the carbonyl group at virtually identical rates (*o*-nitrobenzaldehyde even a little more slowly than the others).

The results of polarographic studies of the kinetics of the reactions of a large number of benzaldehydes with aniline in a buffer solution at pH 10.5 in 50% methanol[161] agree with those quoted above. Salicylaldehyde reacts with aniline 58 times faster than *p*-hydroxybenzaldehyde and *o*-chlorobenzaldehyde, in which there is no intramolecular hydrogen bond, reacts somewhat more slowly than *p*-chlorobenzaldehyde. It is surprising that *o*-aminophenol is very much more reactive in the reaction with benzaldehyde (by a factor of approximately 30) than *p*-aminophenol. This behaviour of *o*-aminophenol may be attributed to the greater stabilisation (by the intramolecular hydrogen bond) of benzylidine-*o*-aminophenol produced compared with the product formed by the *para*-isomer.

The data of Wolfenden and Jencks[162] on the formation of semicarbazones from aromatic aldehydes indicate a greater reactivity of *o*-aldehydes in general (*o*-Cl, *o*-OH, *o*-NO_2, *o*-CH_3) compared with the *para*-isomers. Thus the vast majority of data indicate that *o*-hydroxy- and *o*-methoxy-benzaldehydes are more reactive than their *para*-isomers, the ratio of the rate constants for the reactions of the *ortho*-isomers to those for the reactions of the *para*-isomers exceeding the analogous ratios for other substituents.

Knorre and Emanuel'[2] believe that the higher reactivity of the *o*-hydroxy- and *o*-methoxy-groups in an acid medium can be explained in the following way. The substituent in the *ortho*-position in relation to the aldehyde group affects its basicity by the stabilisation of the conjugate acid of the aldehyde as a result of the formation of a hydrogen-bonded bridge, as in compound (LXXIV):



(LXXIV) (LXXV)

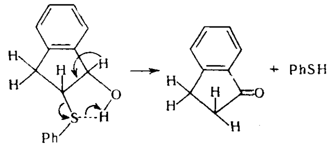
Such stabilisation depends in the first place on the capacity of the substituent for the formation of hydrogen bonds. Gordy's data[163] on the shift of the OD stretching vibration frequencies on dissolution of CH_3OD in solvents with different functional groups were used to obtain quantitative characteristics of this capacity. According to these results, $\Delta\nu$ is 200 cm^{-1} for hydroxy-compounds, 70 to 110 cm^{-1} for methoxy-compounds, and 30–50 cm^{-1} for nitro-compounds (for example). Consequently the enhancement of the basic properties of the carbonyl compound will be a maximum for the hydroxy-substituent and a minimum for the nitro-substituent.

A different explanation of the greater reactivity of *o*-hydroxy- and *o*-methoxy-benzaldehyde was put forward by Vavon and Montheard[157,158,164,165], who suggested that the rate of reaction is determined by the concentration of the conformers of compound (LXXV) with exceptionally high reactivity. The possibility of the existence of hydrogen bonds of this type has been indicated by Pinchas[166,167] on the basis of infrared spectroscopic measurements for a number of benzaldehydes. However, in later studies by Forbes[168] certain characteristics of the infrared spectra of *o*-nitrobenzaldehyde and related compounds were attributed not to intramolecular hydrogen bonds but to steric interactions. In general it is difficult to believe that such weak hydrogen bonds (if they exist at all) have so great an effect on the rate of reaction. Finally, Wolfenden and Jencks[162] suggested an explanation, based on a detailed study of the kinetics on the formation of semicarbazones, for the enhanced reactivity of *o*-substituted benzaldehydes in general and not only the hydroxy- and methoxy-derivatives, namely that the transmission of electronic effects by a resonance mechanism from the *para*-position is more effective than from the *ortho*-position.

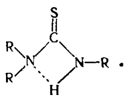
Evidently further data are required for a final choice between these hypotheses.

12. INTRAMOLECULAR HYDROGEN BONDS AND CERTAIN SPECIFIC REACTIONS

The intramolecular hydrogen bond influences also certain other types of chemical reactions, for example certain decomposition and condensation reactions. In particular, *cis*-2-phenylthioindanol (LXXVI) undergoes spontaneous decomposition. Since the *trans*-isomer is comparatively stable, such behaviour of (LXXVI) must be attributed to its intramolecular hydrogen bond, the presence of which has been demonstrated spectroscopically[169]:



(LXXVI)



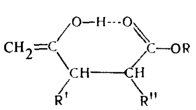
(LXXVII)

The fact that the product of the addition of sodium bisulphite to salicylaldehyde decomposes much more rapidly than the products of bisulphite additions to other *o*-aldehydes can be explained by "proton transfer" from the hydroxy-group to the sulphite group being eliminated, probably via a hydrogen-bond bridge[170].

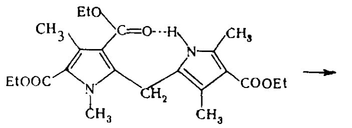
In a study of the kinetics of the decomposition of thiourea and its methyl derivatives in aqueous solution, Shaw and Walker[171,172] concluded that the reaction proceeds via a chelate cyclic species (LXXVII). This mechanism is confirmed by the finding that tetramethyl-thiourea, which is incapable of forming intramolecular hydrogen bonds, is not decomposed in aqueous solutions[173].

The effect of various types of intramolecular hydrogen bonds on the rate of cleavage of the –N=N–bond in azodyes under the influence of yeast has been noted[174].

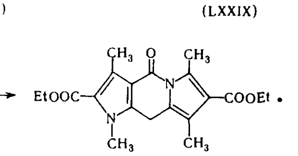
Since it has been established experimentally that the reactivity of the butyl ester of levulinic acid in the Claisen condensation is higher than that of the methyl ester[175], while in the hydrolysis of the esters the ratio of the reaction rates has the usual value (the rate for the butyl ester is higher), the ionic mechanism of the Claisen condensation has been rejected[176]. The authors suggest that the active form of levulinic acid in this condensation is the seven-membered chelate ring (LXXVIII):



(LXXVIII)



(LXXIX)

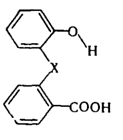


(LXXX)

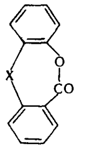
In consequence of the increasing +*I* effect in the series $CH_3 < C_2H_5 < C_3H_7 < C_4H_9$, the negative charge at the carbonyl oxygen also increases, which tends to increase the stability of the intramolecular hydrogen bond and accelerates the reaction.

The ready cyclisation of dipyrrolylmethanes (LXXIX) to cyclic amides with the dipyrrolopyridine structure (LXXX)[177] is probably due to the mutual approach of the reaction centres in compound (LXXIX) caused by the intramolecular hydrogen bond, the presence of which has been demonstrated by infrared spectroscopy[178].

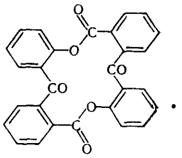
It is suggested that the intramolecular hydrogen bond is responsible also for the formation of various reaction products in the intramolecular cyclisation of compounds of type (LXXXI).[179,180] The dehydration of 2-carboxy-2′-hydroxybenzophenone (LXXXI, X = CO), 2-carboxy-2′-hydroxy-5′-methylbenzophenone, and 2-carboxyphenyl 2′-hydroxyphenyl ether (LXXXI, X = O) by acetic anhydride gives almost quantitative yields of the seven-membered lactones (LXXXII), while other dehydrating agents [P_4O_{10}, $POCl_3$, $(CF_3CO)_2O$] lead to the formation mainly of 14-membered lactides (LXXXIII):



(LXXXI)



(LXXXII)



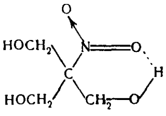
(LXXXIII)

This is explained by an intramolecular hydrogen bond in compound (LXXXI), which forces these molecules into a configuration which is unfavourable for lactone formation, favouring instead the formation of lactides. In fact 2-carboxy-2′-hydroxydiphenylmethane, in which an intramolecular hydrogen bond of this kind cannot exist, yields only a lactone under all conditions[180].

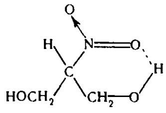
13. INHIBITION OF CHEMICAL REACTIONS BY INTRAMOLECULAR HYDROGEN BONDS

Numerous data showing that intramolecular hydrogen bonds can retard and sometimes prevent a number of chemical reactions have been published. The inhibition of alkylation and acetylation reactions by intramolecular hydrogen bonds has already been mentioned (Sections 2 and 4). In some cases the inhibition of chemical reactions by intramolecular hydrogen bonds can be explained by the fact that the latter stabilise conformations in which the reaction centres are separated and therefore the reaction cannot occur.

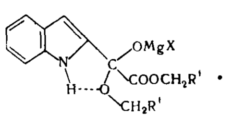
Thus the ability of nitro-groups to form strong hydrogen bonds is responsible for the ready formation of cyclic acetals and ketals from tri(hydroxymethyl)nitromethane (LXXXIV), which has free hydroxy-groups, while di(hydroxymethyl)nitromethane (LXXXV), where one of the hydroxy-groups is chelated, form these derivatives with great difficulty or not at all[181]:



(LXXXIV)

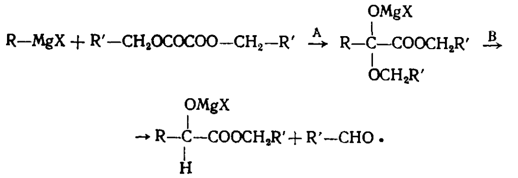


(LXXXV)



(LXXXVI)

Metal alkoxide halides formed in the reactions of oxalic esters with organomagnesium compounds [reaction (A)] and containing the α-indolyl group differ sharply in their thermal stability from compounds with any other substituents. The latter break down by reaction (B) in the range 40–110°C, while (LXXXVI) remains completely unchanged at these temperatures[182]. This is explained by the stabilising effect of the intramolecular hydrogen bond on the complex formed, as shown for compound (LXXXVI). The presence of a hydrogen bond of this type in the compound is confirmed by infrared spectra:



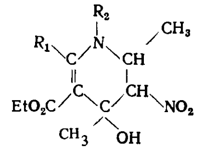
$$R{-}MgX + R'{-}CH_2OCOCOO{-}CH_2{-}R' \xrightarrow{A} R{-}\underset{OCH_2R'}{\overset{OMgX}{C}}{-}COOCH_2R' \xrightarrow{B}$$

$$\rightarrow R{-}\underset{H}{\overset{OMgX}{C}}{-}COOCH_2R' + R'{-}CHO.$$

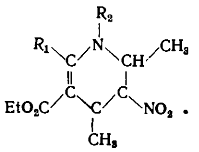
A very interesting case of the inhibition of chemical reactions by hydrogen bonds is the cyclisation of compounds of the type[183]

$$O_2N{-}\underset{}{\overset{CH_3}{CH}}{-}\overset{R_2}{N}{-}\overset{R_1}{C}{=}\overset{CO_2Et}{C}{-}COCH_3\ .$$

The compound with $R_1 = R_2 = H$ does not cyclise although the steric conditions should favour the formation of the cyclicaldol (LXXXVII) or its dehydration product (LXXXVIII):

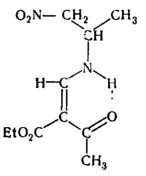


(LXXXVII)

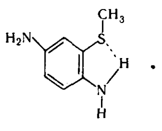


(LXXXVIII)

Evidently the aldol condensation may be hindered if the initial molecule contains an intramolecular hydrogen bond, as in compound (LXXXIX):



(LXXXIX)



(XC)

Indeed, when $R_1 = R_2 = H$ or $R_1 = CH_3$ and $R_2 = H$, the compounds are not cyclised under a wide variety of conditions, which suggests that their hydrogen-bond bridge is exceptionally stable, and as a result the molecule exists in the conformation unfavourable for cyclisation, since the reaction centres (the carbonyl and methylene groups) are distant from one another. This is confirmed by the behaviour of the compound with $R_1 = H$ and $R_2 = CH_3$ in which the formation of intramolecular hydrogen bonds is impossible and which therefore is instantly cyclised to 5-ethoxycarbonyl-4-hydroxy-1,2,4-trimethyl-3-nitro-1,2,3,4-tetrahydropyridine (LXXXVII).

Hydrogen bonds have a marked influence on the course and final products of condensation and substitution reactions. Thus 4-amino-3-methylthioazobenzene can be readily synthesised by the condensation of nitrosobenzene with 2-methylthio-1,4-phenylenediamine (XC). As a result of the presence of an intramolecular hydrogen bond in the initial compound, the condensation involves preferentially the free amino-group, so that the ratio of the condensation product involving the free and hydrogen-bonded amino-groups is 21 : 1.[184]

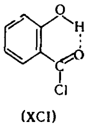
In a study of the condensation of aromatic aldehydes with benzyl carbamate[185], it was found that the reaction gives satisfactory yields with nitro- and methoxy-benzaldehydes but does not take place at all with salicylaldehyde and vanillin, owing to the presence of intramolecular hydrogen bonds in the molecule of the latter compounds. In contrast to these aldehydes, 3-nitrosalicylaldehyde, in which an analogous situation would appear to exist, gave *NN*-dibenzyloxycarbonyl-2-hydroxy-3-nitrobenzylidenediamine in high yield. However, one should not forget that in this compound the hydrogen bond is formed mainly between the hydroxy- and nitro-groups and therefore the reactive aldehyde group remains free.

The inhibiting effect of the *o*-hydroxy-group in the aldehyde component is observed also in the condensation of various aromatic aldehydes with phenylacetic acid[186].

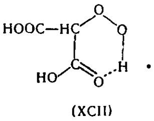
As already mentioned, the involvement of the hydroxyl in a hydrogen bond greatly reduces its tendency to enter into other reactions. The authors believe that the presence of a strong intramolecular hydrogen bond is the reason why *o*-nitrophenol does not form compounds with 8-hydroxyquinoline[187], acetamide[188], urea[189], acetone, and dimethyl sulphoxide[190].

14. THE ROLE OF INTRAMOLECULAR HYDROGEN BONDS IN THE STABILISATION OF ORGANIC MOLECULES

Intramolecular hydrogen bonds are known to be a factor stabilising molecules. In some cases the presence of intramolecular hydrogen bonds in molecules is the principal cause of their stability. Thus, owing to the presence in its molecule of a strong intramolecular hydrogen bond, salicyloyl chloride (XCI) can be isolated in a pure form[194,195], in contrast to its *meta*- and *para*-isomers which readily undergo polyesterification reactions. The existence of this type of hydrogen bond has been demonstrated spectroscopically[196]:



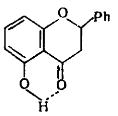
(XCI)



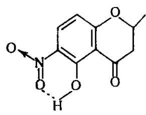
(XCII)

The impossibility of determining (with the aid of the usual reagents) of the hydroperoxy-group in hydroperoxymalonic acid obtained in the ozonolysis of acetylenedicarboxylic acid in concentrated formic acid is probably associated with the presence of a strong intramolecular hydrogen bond in compound (XCII).[197]

Hydrogen bonds have a marked influence also on the stability of certain *o*-hydroxychalcones and their cyclisation products—flavanones. While flavanone rings are usually readily opened by alkalies, 5-hydroxyflavanone (XCIII), in which there is a strong intramolecular hydrogen bond, is fairly stable[198]:



(XCIII)

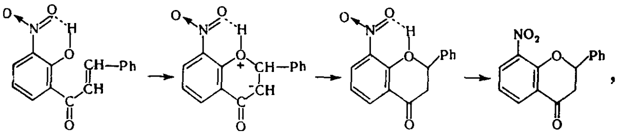


(XCIV)

At the same time 5-hydroxy-6-nitroflavanone (XCIV), where the hydroxy-group is hydrogen-bonded mainly on the nitro-group, readily undergoes ring opening under the action of alkalies[199].

The high stability of nitrochalcones of type (XCV) (low rate of cyclisation to flavanones) has been attributed to an intramolecular hydrogen bond between the hydroxy- and nitro-groups[199].

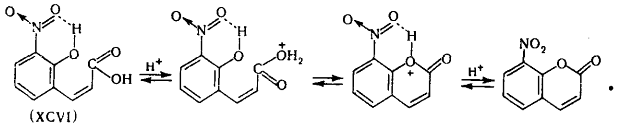
From the standpoint of the mechanism of the cyclisation of chalcones to flavanones adopted at the present time:



(XCV)

such behaviour of compound (XCV) is explained in the following way. The hydrogen bond between the nitro- and hydroxy-groups prevents the elimination of the proton in the last stage and stabilises the nitrosulphones in relation to the corresponding flavanones.

A similar stabilising effect of the nitro-group is observed with 3-nitro-*o*-coumaric acids[200]. This effect can be understood by considering the mechanism of the cyclisation of coumaric acids to coumarones:



(XCVI)

The formation of an intramolecular hydrogen bond, as in the case of hydroxynitrochalcones, prevents the loss of a proton in the last cyclisation stage. Therefore 3-nitro-*o*-coumaric acids are very stable in aqueous solutions. This explanation of the stability of compound (XCVI) is confirmed by the behaviour of 4-methyl-3-nitro-*o*-coumaric acid. The introduction of a methyl group breaks down the coplanarity of the ring and the nitro-group, as a result of which the hydrogen bond between the latter and the hydroxy-group is greatly weakened and the acid is relatively unstable in aqueous solution.

Intramolecular Coordination in Organic Derivatives of the Elements

A.K.Prokof'ev, V.I.Bregadze, and O.Yu.Okhlobystin

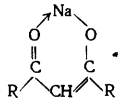
For the first time, the data on the problem of intramolecular coordination in organic derivatives of the elements have been compiled and a systematic and critical account has been given. A definition of intramolecular coordination in its various forms is proposed. It has been shown that intramolecular coordination may constitute the driving force of a number of reactions of such organic derivatives (α-, β-, and γ-elimination).
The bibliography comprises 210 references

CONTENTS

I. INTRODUCTION

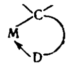
The concept of intramolecular coordination between a metal atom with vacant orbitals and an electron-donating atom in the same molecule has been recently put forward with increasing frequency to account for a number of physical anomalies associated with the structure of organometallic molecules and also in the interpretation of many of their reactions. Since the possibility of such coordination exists in principle, it is frequently postulated on the basis of purely intuitive considerations without more serious justification.

A typical example, dating back to as early as 1925, is the attribution of a chelate structure with covalent bonds to sodium enolates of β-dicarbonyl compounds on the basis of their relatively low melting points and appreciable solubility in aprotic solvents[1]:



Subsequently Brändström[2,3] attempted to use these concepts to explain the dual reactivity of alkali metal enolates.

The aim of the present review is to give a systematic account of the most important postulates put forward in connection with intramolecular coordination and to assess their possible role in organometallic reactions. It is scarcely useful to consider here also the numerous and well known cases of donor–acceptor interaction between two adjacent atoms (for instance, boron and nitrogen atoms in systems of the type of borazole, $d_\pi - p_\pi$ interaction in silylamines, etc.), although they can in fact be regarded as a special case of intramolecular coordination. Chelate compounds in which the electron-donating atom is in a side chain while the chain itself is separated from the metal by a heteroatom (acetylacetonates and related compounds) also will not be considered in detail if they are not truly organometallic compounds, i.e. do not contain at least one direct metal–carbon bond. Attention will be concentrated on compounds in which the carbon chain with the electron-donating atom is linked to the metal via a carbon atom:

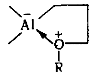


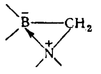
where D is the electron-donating atom.

Frequently in cases where intramolecular coordination in a non-reacting molecule is rejected for some reason, a hypothesis of this kind is suggested for the transition state. Cases of this kind will also be considered briefly.

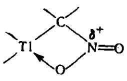
II. THE CONCEPT OF INTRAMOLECULAR COORDINATION

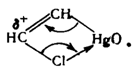
So far a serious theoretical basis for an intramolecular bond of this kind is lacking. Apparently the majority of investigators who postulated it agree that this is donor–acceptor interaction of the "hydrogen bond type". Nevertheless it is evident that in reality extreme cases are possible which could be regarded as qualitatively different. On the other hand, D → M interaction may be equivalent to almost complete charge transfer, i.e. the transfer of two electrons; we are then dealing with a stable intramolecular complex of the "reverse onium" type (ate-complex). In this class of intramolecular organometallic complexes, one may include, for example, the γ-alkoxy-derivatives of aluminium and certain amine complexes of boron, for example:



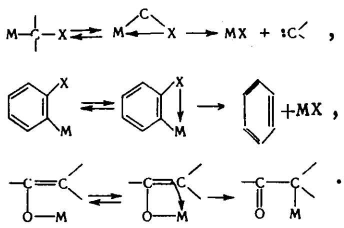


The charge transfer may not be quite so complete; such compounds resemble more the classical electron-deficient molecules (diborane, trimethylaluminium) containing three-centre bridge bonds, where the bond between the three nuclei is formed by two electrons. In this case a coordination-unsaturated metal atom and an atom with a considerable positive charge produced by its electronegative substituents serve as the electron-deficient centres. Such are, for example, the α-nitroalkyl derivatives of thallium and *cis*-β-chlorovinylmercury chloride:

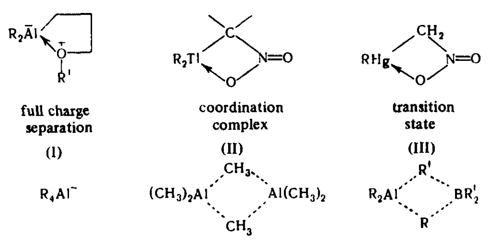




The similarity of these structures to the four-centre transition states in $S_E i$ reactions is not merely formal: there is finally a possibility of the case where a cyclic structure with a coordinate intramolecular bond is formed only as a transition state. These are the well known reactions involving the formation of carbenes and dehydrobenzene and O–C rearrangements of non-ionic enolates.



Thus it is possible to distinguish three different types of intramolecular coordination reactions in organometallic compounds. Firstly, coordination interaction with full charge separation, as in compounds such as the tetra-alkylaluminium salts, secondly, coordination complexes analogous to the trimethylaluminium dimer with bridge bonds, and, thirdly, intramolecular coordination occurring only in transition states, similar to the bridge type transition states in radical exchange reactions involving many organoaluminium and organoboron compounds:



However, it is important to remember that in all the above cases the driving force in the formation of bonds, possible rearrangements, or eliminations is the same: the coordination unsaturation of the metal atom which tends to make good its electron deficit at the expense of a donor in the same molecule, their interation (D → M) taking place through space in addition to a conjugation or induction chain.

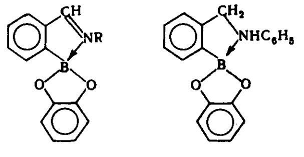
III. INTRAMOLECULAR COORDINATION AND PHYSICAL PROPERTIES OF THE MOLECULES

There is no doubt that the occurrence of intramolecular coordination may affect the physical properties of organometallic molecules. Indeed, in many cases the characteristic features of NMR and NQR spectra and dipole moments, the anomalous effects of *ortho*-substituents, etc. are attributed to such coordination interaction. Analysis of the literature data leads to the conclusion that in fact none of the usual methods can alone provide an answer as to the presence or absence of intramolecular coordination. Evidently such coordination can be reliably inferred only on the basis of consistent data derived by a number of methods. The situation is complicated also by the fact that factors such as intramolecular association (particularly in crystals), inductive and resonance effects, electrostatic attraction or attraction through space ("field effects"), etc. are superimposed on intramolecular coordination interaction.

Vibration Spectra

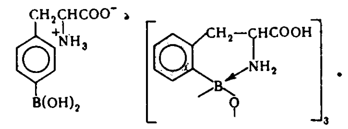
The presence of intramolecular coordination is frequently inferred from optical spectra of organic boron derivatives which show a distinct tendency towards the attainment of the tetrahedral sp^3 configuration.

B → N coordination interactions are therefore suggested for compounds of the type

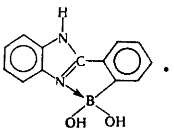


on the basis of a broad absorption band at 1220 cm^{-1}, which can be accounted for by B → N vibrations. The authors also postulate the possibility of intermolecular interaction.

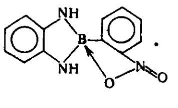
Comparison of the infrared spectra of boron-containing phenylalanines shows that the spectrum of the *ortho*-derivative exhibits, in contrast to the *para*-derivative, an intense broad band at 1710 cm^{-1}, which is characteristic of an unionised carboxylic acid:



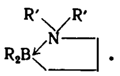
B → N intramolecular coordination has been proposed[6] for 2-(2-boronophenyl)benzimidazole on the basis of the high melting point (> 320°C) and the presence of $\lambda_{max} \simeq$ 310 nm in the ultraviolet spectrum (in 95% ethanol), while 2-(2′-methylphenyl)benzimidazole has $\lambda_{max} = 277$ nm. The absence of intense absorption in the region 7.2–7.8 μm is evidence that the boron atom is coordinated to four groups:



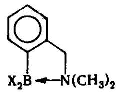
In view of the lower absorption intensity in the region of 350–400 nm of the ultraviolet spectra of 2-phenylbenzo-1,3,2-diazaborolines, compared with unsubstituted 2-(nitrophenyl)benzimidazoles, O → B intramolecular coordination, which is absent from the corresponding *meta*- and *para*-nitro-derivatives, is postulated[7]:



The dependence of the strength of the B → N coordinate bond on substitutents has been determined for γ-aminopropyl compounds[8,9]:

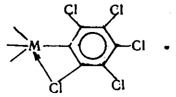


In the unsubstituted amine (R′ = H) coordination is postulated on the basis of the bathochromic shift of the NH_2 stretching vibration bands (3292 and 3350 cm^{-1}), which is characteristic of compounds with a B ← N coordinate bond. The occurrence of such interaction is supported also by the resistance to disproportionation (up to 200°C), which is high for asymmetric boron trialkyls, the relative stability in air, and high dipole moments (4.0–4.2 D). The substitution of a hydrogen atom at the nitrogen atom by dialkyl groups or the introduction of an alkoxy-group at the boron atom lowers the strength of the B ← N bond, while in the compound $(EtO)_2BCH_2CH_2CH_2NEt_2$ there is probably no coordination at all ($\mu = 1.44$ D). Similar coordination has been proposed[10] for compounds of the type

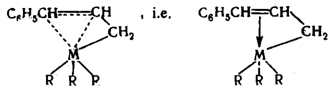


where X = OH or $N(CH_3)_2$. These compounds are relatively resistant to hydrolysis; furthermore, diamineboron distils in a vacuum (75–76°C/0.4 mmHg).

The ultraviolet spectra of pentachlorophenyl derivatives of silicon and tin show a much more intense absorption than the spectra of their hydrogen analogues; in view of this, intramolecular coordination was suggested as the explanation of many unusual properties of these compounds[11]:

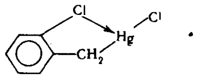


Substitution of the β-methyl proton in *trans*-β-methylstyrene by a $(C_2H_5)_3M$ group (where M = Si, Ge, or Sn) gives rise to a bathochromic shift, which has been explained[12] by an increase in the delocalisation of the π electrons of the allyl double bond through overlap with the vacant *d* orbitals of the metal



where M = Si, Ge, or Sn and R = C_2H_5.

A split Hg–Cl frequency (314, 364, and 251 cm^{-1}) in the infrared spectrum of *o*-chlorobenzylmercury chloride is accounted for by the existence of several rotational isomers[13]. The most intense band (314 cm^{-1}) is attributed to a conformation with possible intramolecular interaction:

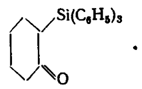


Recently, extensive experimental data have accumulated on the spectra of α-carbonyl organometallic compounds[14]. In the α-carbonyl derivatives of mercury and tin the carbonyl absorption in the infrared spectra is displaced towards lower frequencies (1686–1660 cm^{-1}) and in the ultraviolet spectra a slight displacement of the CO band towards longer wavelengths and a considerable increase of the intensity (by a factor of 200–300) compared with the carbon analogues has been observed, which suggests that these compounds have properties approaching those of conjugated systems. These data, together with the observed dual reactivity of α-metallated aldehydes and ketones, led to the conclusion that there is σ,π-conjugation in compounds of this kind[15,16]. However, Japanese investigators[17] believe that the considerable shift of the carbonyl frequency (ν_{CO} = 1645 cm^{-1}) in $Hg(CH_2CHO)_2$ and $ClHgCH_2CHO$ spectra can be explained by CO → Hg intramolecular coordination (the formation of a polymer is also possible), since in the spectra of acetaldehydemercury ν_{CH} = 2720 cm^{-1}, which corresponds to the normal vibrations in aldehydes; furthermore, this compound undergoes the usual reactions typical of the aldehyde group.

The lowering of ν_{CO} in the spectrum of $(C_6H_5)_3SiCH_2COC_6H_5$ (1667 cm^{-1}) compared with the carbon analogue (1698 cm^{-1}) has been explained by the inductive effect of silicon on the carbonyl group[18].

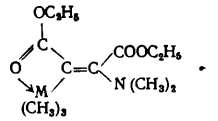
Thus the unusual spectroscopic properties of α-metallated ketones and aldehydes cannot be explained by any one effect. For this reason, attempts have been made in a number of investigations to discover the principal effect resposible for these anomalies. The significant difference between the observed and calculated frequencies of the carbonyl groups (the calculation was based on Thompson's equation $\nu_{CO} = 1720 + 15\Sigma\sigma^*$ cm^{-1}) [19] in $(CH_3)_3SiCH_2COCH_3$ (1698 and 1716 cm^{-1}) and $(CH_3)_3CCH_2COCH_3$ (1723 and 1717 cm^{-1}) suggested that intramolecular coordination in $(CH_3)_3SiCH_2COCH_3$ predominates over the inductive effect of silicon[20]. However, Thompson's relation was derived for compounds of the type CCl_3COCl, in which the field effect and other factors can be more important than inductive effects. Therefore this relation cannot be extended without modifications to the ketones considered above. The same workers later interpreted the higher intensity of the $n \rightarrow \pi^*$ transition (by a factor of 4–5) in α-silylketones relative to their carbon analogues as confirmation of the presence of intramolecular CO → Si coordination, since they believe that the intensity of this transition in related ketones cannot be accounted for by steric and inductive effects[21]. However, the study of β-substituted ketones shows that the exaltation of the $n \rightarrow \pi^*$ transition in these compounds can be explained by many factors and not necessarily the same ones which are responsible for the shift of the carbonyl frequency[22,23].

An attempt has been made to separate the inductive effects from other effects influencing the frequency of the carbonyl absorption in the spectrum of α-triphenylsilylcyclohexanone[24]:

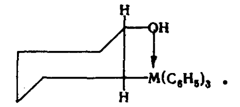


Since the frequency of the CO group in the spectrum of this compound in liquid paraffin is represented by a singlet at 1678 cm^{-1} and in the spectrum of the carbon analogue at 1709 cm^{-1}, it was concluded that Fermi resonance is unlikely. In carbon tetrachloride solution the singlet corresponding to the carbon compound is observed at 1720 cm^{-1}, while in the case of the silicon derivative it is split into two bands (1682 and 1692 cm^{-1}). The splitting is independent of concentration in the range 0.2–10%, which excludes intermolecular interaction. The splitting can be accounted for by a conformational equilibrium, since the relative intensities of the two peaks vary with temperature. The inductive effect of silicon should not depend on the conformation of the cyclohexane ring, whereas intramolecular coordination is possible only in the conformation where the silicon is equatorial. The results may be explained by the cooperative effect of the intramolecular CO → Si coordination and the inductive effect of silicon.

Intramolecular coordination has been proposed also for α-ethoxycarbonyl derivatives of Group IV elements, although it should be weaker than in the corresponding α-ketones. In organotin diazo-esters $R_{4-n}Sn[C(N_2)COOC_2H_5]_n$ (n = 1,2) it has been proposed on the basis that the dipole moment μ = 2.2 D (for n = 1 and R = CH_3) and also a considerable shift of the carbonyl (2070–2045 cm^{-1}) and diazo- (1675–1655 cm^{-1}) frequencies compared with the carbon analogues[25]. Intramolecular coordination is responsible for the splitting of the C=O bands (1735 and 1680 cm^{-1} for the silicon derivative, 1739 and 1698 cm^{-1} for the germanium derivative, and 1740 and 1705 cm^{-1} for the tin derivative) and the bands due to C=C vibrations (1570 and 1550 cm^{-1} for the silicon derivative, 1590 and 1555 cm^{-1} for the germanium derivative, and 1625 and 1590 cm^{-1} for the tin derivative) in the infrared spectra of compounds of the type[26]:



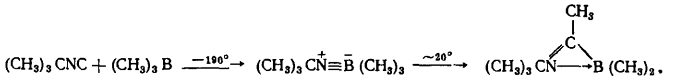
1,2-Disubstituted cyclohexanols of the type 2-$(C_6H_5)_3MC_6H_{10}OH$ (M = Si or Ge) have been found to have a higher acidity[24] than 1-triphenylmethyl-2-cyclohexanol in view of the greater changes in the vibration frequencies of the hydroxy-group on addition of dimethyl sulphoxide and tetrahydrofuran. Since the electropositive effect of silicon and germanium should reduce the acid strength, the above anomalous increase of acidity is explained by an intramolecular interaction between oxygen and the metal



A similar interaction is postulated on the basis of the changes under analogous conditions in the infrared spectra of the silicon and germanium analogues of 1,1,1-triphenylethanol[27].

Radio-frequency Spectroscopy

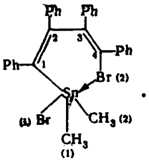
Attempts have often been made to demonstrate the presence of intramolecular coordination in organoboron compounds by proton resonance. The product of the addition of trimethylboron to t-butyl isocyanate isomerises at room temperature to a three-membered chelate complex which is resistant to the action of oxygen and moisture[28]:



The PMR spectrum of the complex in benzene consists of three peaks δ: 2.57 p.p.m. (very broad), 1.18 p.p.m. (sharp), and 0.20 p.p.m. (broad) in proportions of 1 : 3 : 2, which correspond to the groups $=\overset{|}{C}-CH_3$, $-\underset{|}{\overset{|}{C}}-CH_3$, and $>B-CH_3$. In the infrared spectrum there is no frequency due to the stretching vibrations of the $\overset{+}{N}\equiv\overset{-}{C}$ group (2247 cm^{-1}) but there is a $\nu_{N=C}$ frequency at 1548 cm^{-1}. The mass spectrum of the complex corresponds to a monomeric structure†. The formation of a three-membered ring is undoubtedly caused by a steric factor, since less hindered isonitriles dimerise with formation of 2,5-dibora-2,5-dihydropyrazines[29].

Intramolecular (and intermolecular) coordination[30] is postulated in the molecule of dimethylaminomethylboron $(CH_3)_2BCH_2NH_2$. This compound is a weak acid and a weaker base than the corresponding monofunctional derivative; in the PMR spectra δ_{CH_2} is displaced towards stronger fields—0.24 p.p.m. (60 MHz) (δ_{CH_2} for cyclopropane is 0.20 p.p.m.).

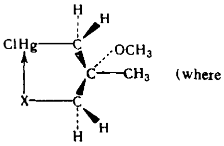
Intramolecular Sn ← Br interaction has been most convincingly demonstrated for 4-bromo-1,2,3,4-tetraphenyl-*cis*-*cis*-1,3-butadienyldimethyltin bromide[31]:



At 36°C the PMR spectra of this compound in carbon tetrachloride has a doublet with components of equal intensity due to the methyl protons (δ = 0.48 and 0.98 p.p.m.), which merges into a singlet at 87°C. There is a pronounced solvent effect: the addition of bases (pyridine, ethers, alcohols, etc.) to a solution of the compound in carbon tetrachloride gives rise to a singlet at δ = 0.73 p.p.m. At the same time in thionyl chloride (strongly ionising solvent) the temperature at which the doublet merges into a singlet is close to that for carbon tetrachloride. The non-equivalence of the methyl protons in the diene has been explained by intramolecular Sn ← Br interaction which stabilises the non-planar cisoid conformation and prevents rotation about the C(2)−C(3) bonds at low temperatures in non-basic solvents. The barrier to rotation about the C(2)−C(3) bonds, determined from the PMR spectra, is equivalent to 18.3 ± 0.23 kcal $mole^{-1}$. The hindered rotation of the diene and the non-equivalence of the methyl protons can be eliminated by breaking the weak coordinate bond Sn ← Br, which is observed experimentally on heating the specimen, the addition of a base competing with Br(2) in the coordination with Sn, and replacement of Br(2) by hydrogen. The suggested conformation of the diene has been confirmed by X-ray analysis[31].

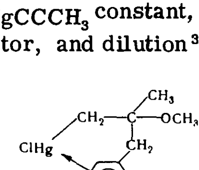
The formation of an intramolecular complex in the Reformatskii reagent derived from $BrCH_2COOC_2H_5$ is suggested on the basis of the shift to higher fields of the signal due to CH_2 protons in the NMR spectrum with increasing solvating power of the solvent[32].

The formation of a ring by an intramolecular donor–acceptor interaction between mercury and halogen atoms in γ-halogenopropyl derivatives of mercury is the cause of the non-equivalence of the methylene protons [Δν (CH_2Br) = 19.1 Hz, Δν (CH_2Hg) = 13.6 Hz]:[33]



(where X = Cl, Br) .

This non-equivalence diminishes sharply if a solvent such as pyridine, capable of breaking the coordinate bond, is employed. This entails also a decrease of the spin–spin coupling constant J_{HgCCCH_3} (36 Hz in deuterochloroform and 20 Hz in pyridine). The intromolecular π-coordination of the phenyl group with the mercury atom has been demonstrated for 2-methoxy-2-methyl-3-phenylpropylmercury chloride on the basis of the non-equivalence of the methylene protons, the J_{HgCCCH_3} constant, the effect of solvents, the temperature factor, and dilution[34]:



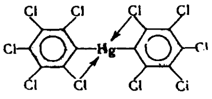
---

† On the basis of the mass spectra, the authors believe that a preferable structure is the resonance hybrid:

NMR spectroscopy has proved to be a powerful method for the investigation of intra- and inter-molecular coordination. The splitting of the lines due to the chlorine atoms in the CCl_3 group in the ^{35}Cl NMR spectra of the compounds Cl_3CHgBr (37.590, 37.893, 38.794, and 39.032 MHz), Cl_3CHgCl (37.604, 37.968, 39.032, and 39.172 MHz), and $(Cl_3C)_2Hg$ (37.037, 37.681, 38.675 MHz), which is considerable (> 2%), exceeding the limiting crystallographic splitting for molecular crystals with van der Waals interaction between molecules[35], has been explained by intramolecular interaction between one of the chlorine atoms of the CCl_3 group and the mercury atom[36,37]. However, this coordination, which has been confirmed by X-ray diffraction analysis[37], readily breaks down on formation of complexes of the above mercury compounds with dimethoxyethane (the appreciable line splitting vanishes from the ^{35}Cl NMR spectra)[38]. It is interesting that complexes are not formed with ethyl ether. Intramolecular coordination in Cl_3SnCH_2Cl has been proposed on the basis of spectroscopic data[39] and has been confirmed[40] by ^{35}Cl NMR spectra. The spectrum corresponding to the $SnCl_3$ group consists of two lines with intensity ratios of 1 : 2 and a splitting of 6% (23.072, 23.072, and 21.832 MHz), which is three times greater than the maximum possible crystallographic splitting. The non-equivalence of the chlorine atoms can be explained by the coordination interaction Cl → Sn in the $Cl{-}\underbracket{Sn{-}CH_2{-}Cl}$ plane. The cryoscopic determination of the molecular weight in benzene shows that there is no association. Furthermore, the possibility of coordination is not inconsistent with the results of studies of the ^{35}Cl NMR spectra of Cl_3SnCH_2Cl in benzene and ether (1 : 1 and 1 : 2).[41] For test compound : solvent molar ratios of 1 : 1 and 1 : 2, the spectra of Cl_3SnCH_2Cl proved to be identical and therefore only 1 : 1 complexes are formed.

The complex $SnCl_4.2(C_2H_5)_2O$ consists of a tetragonal bipyramid in which four chlorine atoms are located at the base and the ether group are at the vertices[42]. The number of lines and their splitting, assigned to the $SnCl_3$ group in the complexes of Cl_3SnCH_2Cl with benzene and ether, is very similar to that in the spectrum of $SnCl_4.2(C_2H_5)_2O$. Therefore one may suppose that these complexes too have the structure of a tetragonal bipyramid in which three chlorine atoms are located at the base. Probably one of the vertices of the bipyramid is occupied by the coordinated chlorine of the CH_2Cl group and the other by a ligand molecule (Fig. 1).

The intramolecular coordination of chlorine atoms in the 2,2′- or 6,6′-positions of di(pentachlorophenyl)mercury (38.220, 38.220, 38.094, 37.828, and 36.421 MHz), where the evidence for this type of coordination comes also from the crystallographic equivalence of the chlorine atoms in the 3,4,5- and 3′,4′,5′-positions, has been demonstrated by the same method. A similar conclusion was reached also for compounds of the series C_6Cl_5HgX (X = Cl, C_6H_5, or CH_3) in view of the anomalously high frequency shifts in the ^{35}Cl NMR spectra compared with the usual substituents, of the *o*-chlorides compared with the *m*- and *p*-chlorides[43].



On the basis of ^{35}Cl NMR data[44], dipole moments[45], and the relative capacities for complex formation[46] of *cis*- and *trans*-β-chlorovinylmercury chlorides, it has been suggested that there is powerful intramolecular coordination in the *cis*-chloride molecule. Crystals of the *cis*-chloride (m.p. 55°C) are amorphous to X-rays and their ^{35}Cl NMR spectrum shows a single C−Cl frequency (33.132 MHz), which excludes the possibility of intramolecular coordination of the type occurring in the *trans*-chloride crystals. While the dipole moment of the *trans*-chloride (1.82 D in benzene at 25°C) agrees satisfactorily with the value calculated for the ideal model (1.92 D), for the *cis*-chloride there is a considerable discrepancy between the observed and calculated moments (2.92 and 3.57 D respectively). This last finding can be probably accounted for only by a considerable decrease in the angles ClCC and CCHg in consequence of intramolecular coordination. In contrast to the *trans*-analogue, the *cis*-chloride does not form a complex with pyridine, which shows that the mercury atom is coordination-saturated; the capacity of the *cis*-isomer to eliminate acetylene under the action of nucleophilic reagents is also sharply reduced[45].

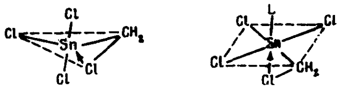


Figure 1. Structures proposed for Cl_3SnCH_2Cl and its ether and benzene complexes.

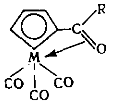
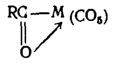
The conclusion that there is direct intramolecular interaction between the metal atom and the substituent is based[47] on the increase of the asymmetry parameter (η) in the ^{55}Mn, ^{187}Re, and ^{185}Re NMR spectra on introduction of a group COR (R = CH_3, CF_3, or C_6H_5) into the cyclopentadienyl ring of cyclopentadienylmetal tricarbonyls:



(M = Mn, Re) .

Interaction of the same type between the oxygen of the acyl group and the metal has been postulated for acyl derivatives of manganese and rhenium pentacarbonyls on the basis of the infrared spectra[48] in combination with X-ray structural data[49,50]:



Structures

X-Ray diffraction analysis is used comparatively rarely to determine the structures of organometallic compounds with intramolecular coordination.

It has been found[51] that phenylsilatrane $C_6H_5\underbracket{Si(OCH_2CH_2)_3N}$ consists of a distorted trigonal bipyramid with the nitrogen and carbon (from the phenyl group) atoms located at the vertices. The N−Si−C atoms lie almost on a straight line [deviation 0.016 Å (0.016°? Ed. of Translation)]. The silicon atom deviates from the plane of the oxygen atoms by 0.204 Å towards the phenyl carbon atom: ∠ C−Si−O (mean) = 97.1°; ∠ O−Si−O (mean) = 118.5°; l_{SiO} = 1.638−1.665 Å; l_{SiN} = 2.193 Å.

Ethylgermanatrane has a similar configuration[52]. The germanium atom deviates from the plane of the oxygen atoms by 0.23 Å towards the ethyl carbon atom: $\angle$N–Ge–C = 176°; l_{GeN} = 2.25 Å. In view of the experimentally established fact that the structures of the ethylgermanatrane and ethylsilatrane crystals are isomorphous, ethylsilatrane has a similar structure with corrections for the different covalent radius of silicon.

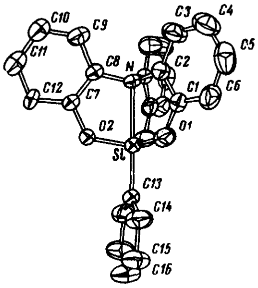


Figure 2. (2, 2′, 2″-Nitrilotriphenoxy)phenylsilane.

(2,2′,2″-Nitrilotriphenoxy)phenylsilane $C_6H_5Si(OC_6H_4)_3N$ also has the configuration of a distorted trigonal bipyramid[53]. The angle $\angle$C–Si–O (mean) = 100.0° is much greater than the analogous angle for the triethoxy-analogue (97.3°) and lies approximately halfway between 90° (for the ideal trigonal bipyramid) and 109.5° (in the tetrahedron). The angle $\angle$N–Si–C = 180° and the Si–N distance is 2.344 Å (2.179 Å in the triethoxy-analogue), which is 0.5 Å longer than the normal Si–N bond (Fig. 2).

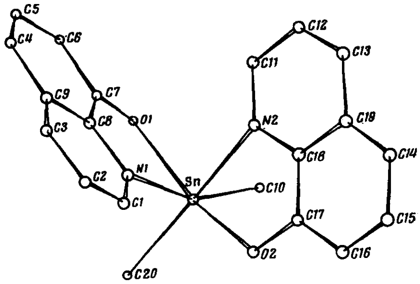

Figure 3. Di-(8-hydroxyquinolato)dimethyltin.

The configuration of di-(8-hydroxyquinolinato)dimethyltin $(CH_3)_2SnOx_2$ (Ox = 8-hydroxyquinoline) has also been determined[54] and found to be a highly distorted octahedron with the methyl groups in the *trans*-positions and the following bond lengths (Å): Sn–C 2.15 and 2.17, Sn–O 2.10 and 2.11, and Sn ← N 2.31 and 2.38; the angle $\angle$CSnC is almost tetrahedral (110.7° ± 0.80°) (Fig. 3).

The intramolecular Sn ← Cl coordination interaction has been found unexpectedly in bipy(OC)$_3$ClMoSnCH$_3$Cl$_2$.[55] Tin in the crystals of this compound may be regarded as having a distorted trigonal bipyramidal environment in which Cl(1) and Cl(3) are linked to tin and molybdenum respectively; Cl(1)SnCl(3) = 168°. The chlorine atom linked to molybdenum is at a distance of 2.81 Å from the tin atom and is clearly linked to both metals (Fig. 4).

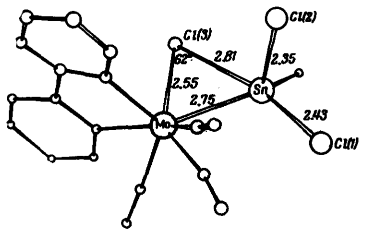

Figure 4. The structure of bipy(OC)$_3$ClMoSnCH$_3$Cl$_2$.

X-Ray diffraction analysis confirmed the occurrence of the intramolecular interaction Sn ← Br proposed for (4-bromo-1,2,3,4-tetraphenyl-*cis*-*cis*-buta-1,3-dienyl)dimethyltin bromide[31]. The presence of a weak coordinate Sn ← Br bond with a length of 3.769 ± 0.007 Å, which is shorter by 0.4 Å than the sum of the van der Waals radii of tin and bromine, has been demonstrated. For this interaction to be possible, the angle $\angle$ C(1)SnCH$_3$(1) has increased to 130.3° from the normal tetrahedral value of 109.5°.

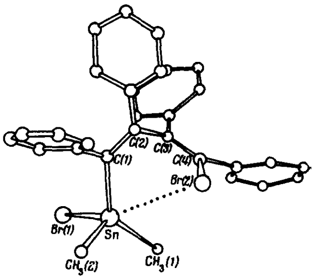

Figure 5. (4-Bromo-1,2,3,4-tetraphenyl-*cis*-*cis*-buta-1,3-dienyl)dimethyltin.

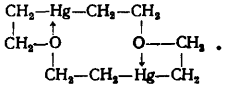
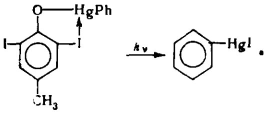
Furthermore, the lengths of the bonds involving Sn have increased from their normal values and also the bond C(4)–Br(2) has become appreciably longer. Normal bond lengths have also been observed (Å): Sn–Br(1) 2.507 ± 0.007 (2.46), Sn–C(1) 2.19 ± 0.04 (2.14); Sn–CH$_3$(1) = Sn–CH$_3$(2) 2.24 ± 0.04 (2.18), and C(4)–Br(2) 2.01 ± 0.04 (1.89) (see Fig. 5).

The crystal structures of α-substituted CCl_3HgBr, CCl_3HgCl,[37] $CBr_2ClHgBr$,[56] and CBr_3HgBr,[57] β-substituted (*trans*-ClCH=CHHgCl,[58] *trans*-ClCH=CHHgBr,[59] and $ClHgCH_2CHO$,[56] and γ-substituted $(CH_3)_2C(OC_2H_5)C(CH_3)_2\cdot CH_3HgSCN$,[60] $(CH_3)_2C(OCH_3)C(CH_3)_2CH_2HgI$, $(CH_3)_2C(OCH_3)C(CH_3)_2CH_2HgSCN$,[61] *o*-$ClC_6H_4CH_2HgCl$,[56] and *p*-$CH_3C_6H_2(I_2)OHgC_6H_5$ [62] derivatives of organomercury compounds have been investigated. It has been found that in compounds with chlorine and oxygen atoms in the α-, β-, and γ-positions the Hg...X interaction does not usually result in Hg...X distances markedly different from those normally observed when different molecules come into contact. An exception is the dimeric molecule of ββ'-oxidodiethylmercury[63], where the mercury atom is coordinated to an oxygen atom as well as two carbon atoms (Hg...O distance 2.21 Å):

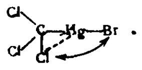


When the α-, β-, and γ-substituents are bromine, sulphur, and iodine atoms, intramolecular interaction in this case leads to a deviation of the Hg...X distances from the values corresponding to different molecules in contact: in CBr_3HgBr we have 3.00 Å for $Hg...Br_I$, 3.36 Å for $Hg...Br_{II}$, and 3.40 Å for $Hg...Br_{III}$; in derivatives of dithizone $Hg(C_{13}H_{12}N_4S)_2.2C_5H_5N$ the mercury atom has a nearly tetrahedral configuration: in the environment of the mercury atom there are two sulphur atoms at a distance of 2.4 Å and two sulphur atoms at a distance of 2.5–2.6 Å, with the valence angles SHgS = 155° and NHgN = 102°.

In the compound p-$CH_3C_6H_2(I)_2OHgC_6H_5$ the Hg...I intramolecular interaction leads to the photochemical decomposition of the crystals under the action of X-rays and the formation of phenylmercury iodide[62]:

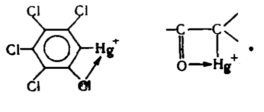


Under the action of X-rays, one of the chlorine atoms in the CCl_3 group in CCl_3HgBr crystals is replaced by bromine[37]:

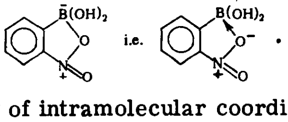


Other Methods

The low rate constants for the electrochemical reduction of β-carbonyl and pentachlorophenyl derivatives of mercury have been explained by the reduced positive charge at the mercury atom due to intramolecular coordination[64]:



The anomalously low acidity of *o*-nitrophenylboronic acid ($K_a = 0.56 \times 10^{-6}$) compared with the *meta*-isomer ($K_a = 6.9 \times 10^{-9}$) and the *para*-isomer ($K_a = 9.8 \times 10^{-9}$) has been explained[65] by the formation of the cyclic compound

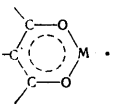


The possibility of intramolecular coordination, suggested in the compound $(C_2H_5)_3SnCH_2COCH_3$ in view of the appreciable quadrupole splitting in the GR spectrum (Moessbauer effect)[66–68], was investigated for different α- and β-carbonyl-containing stannanes[69]. Appreciable quadrupole splitting has been found for α-stannylcarbonyl compounds. It cannot be accounted for by the inductive effect of the halogenomethyl group, because it is absent even in the case of fluorine[70]. The enolate structure $R_3Sn{-}O{-}C\genfrac{}{}{0pt}{}{\diagup\!\!\diagup}{\diagdown}$ is excluded by spectroscopic data. In addition the GR (Moessbauer) spectra of alkoxystannanes are significantly different. The mass spectra are also consistent with intramolecular CO → Sn coordination. There is no quadrupole splitting in the case of β-carbonyl derivatives of tin, in good agreement with infrared spectroscopic data, which show that, in contrast to stannyl ketones, the carbonyl frequency (1718 cm^{-1}) is the same as for the carbon analogues.

"Atranes" and Related Compounds

Organic derivatives of the elements in which the chain with the electron-donating atom is linked to the metal via a non-carbon atom constitute a somewhat distinct group. It includes diketone, diazene, dithiocarbamate, etc. derivatives. Data on compounds of this kind touch upon the main subject of the present review and are briefly described below.

X-Ray diffraction studies on acetylacetonates[71,72] have shown that the acetylacetonate rings are planar and that the pairs of M–O, C–O, and C–C bonds are of equal length:



It has been shown that these systems undergo a wide variety of electrophilic substitution reactions characteristic of aromatic systems[73].

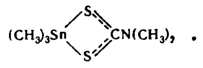
Intramolecular M ← N coordination interaction has been investigated in considerable detail for mono-, di-, and tri-ethanolamine derivatives of boron and silicon. Compounds of this kind were obtained for the first time in 1933[74] and in the course of 30 years boron compounds were investigated almost exclusively. The presence of the B ← N bond has been demonstrated on the basis of the monomeric structure[75], high dipole moments[76,77], high solubilities in water[78,79], and the absence of appreciable electron-donating properties of the nitrogen atom[80]. The presence of the Si ← N bond has been demonstrated using similar data[81] and also infrared[81,82] and PMR[81] spectroscopy and X-ray diffraction analysis[52,53]. The silicon compounds exhibit high biological activity: phenylsilatrane $C_6H_5\underline{Si(OCH_2CH_2)_3N}$ proved to be several times more toxic than hydrocyanic acid[81]. The existence of the Sn ← N bond in stannatranes has been demonstrated by PMR and GR (Moessbauer) spectroscopy[83]. Exhaustive data on all known compounds of this type are presented by Prokof'ev[41].

The chelate salts of nitrilotriacetic acid of the type $X_{n-3}\overline{M(OCOCH_2)_3N}$ should also be included in this class of compounds[84,85]. They have been found to have high biological activity[86].

The presence of the Sn ← N bond in the 8-hydroxyquinolinates $R_nSn(Ox)_{4-n}$, suggested because of the appearance of a yellow colour, the infrared, ultraviolet, and PMR spectrosopic data[87,88,89], and the monomeric nature of the compound[89], has been confirmed by X-ray diffraction analysis[54].

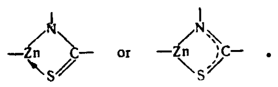
Organotin carboxylates of the type $R_2Sn(OCOR')_2$ exist in the fused and crystalline states as polymers with hexacoordinate tin atoms in which two carboxy-groups are located between adjacent tin atoms (according to infrared spectra)[90]. However, in non-polar solvents intermolecular coordination breaks down and the dicarboxylates form an asymmetric chelate structure with a non-linear skeleton (according to infrared and PMR spectra)[90,91]. Carboxylates of the type $R_3SnOCOR'$ also consist of polymers in crystalline and fused states[92-94]. However, in substituted carboxylates of the type $ClR_2SnOCOR'$ in solution intramolecular CO → Sn coordination is suggested (according to infrared spectroscopic data)[95].

A chelate structure has also been proposed for trimethyltin *NN*-dimethyldithiocarbamate on the basis of infrared spectroscopic studies in liquid paraffin and in solution and also in view of the monomeric form of the compound in benzene[96]:



It is surprising that its oxygen analogue has a polymeric structure.

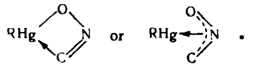
A similar difference between sulphur and oxygen in their capacity for forming an intramolecular coordinate bond was noted[97] in a comparison of the PMR spectra of *N*-(ethylzinc)acetanilide $C_2H_5ZnH(C_6H_5)COCH_3$ and its sulphur analogues. The considerably higher chemical shift of the methyl protons in *N*-(ethylzinc)thioacetanilide and its complexes with pyridine and *NNN'N'*-tetramethylethylenediamine constitutes, according to the authors, significant evidence in favour of the coordination of the thiocarbonyl groups to the zinc atom:



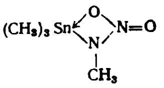
Similar coordination has also been proposed for other sulphur-containing compounds:

$C_2H_5ZnN(C_6H_5)\underset{\overset{\|}{S}}{C}-OCH_3$ and $C_2H_5ZnN(C_6H_5)\underset{\overset{\|}{S}}{C}-SCH_3$.

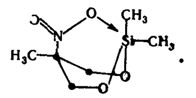
Interaction of this type has also been postulated for organomercury fulminates on the basis of preliminary structural data and characteristics of their chemical behaviour[98,99]:



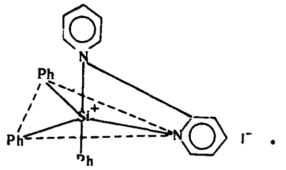
A transannular coordinate bond between one of the oxygen atoms of the nitro-group and the metal atom has been proposed for a number of organometallic nitro-compounds too. In organotin nitroamines $R_3SnN(NO_2)R'$ it is suggested in view of the pale brown colour, low melting points, stability in air, low conductivity in nitrobenzene, and infrared and Gr (Moessbauer) spectra[100]:



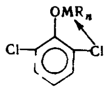
and in 2,2,5-trimethyl-5-nitro-2-sila-1,3-dioxan on the basis of the splitting of the signals due to the methylene protons in the PMR spectrum (in contrast to the analogous compounds without a nitro-group)[101]:



A chelate structure has been proposed for triphenyl(dipyridyl)siliconium iodide[102] and diphenyl(2,2'-dipyridyl)boronium perchlorate[103] but the proposed structures have not been adequately proved:



Intramolecular M ← Cl coordination interaction probably occurs also in organometallic derivatives of 2,6-dichlorophenol, since the ^{35}Cl NMR spectra showed two different signals for the chlorine atoms in the 2- and 6-positions in the aromatic ring and the splitting between these signals is 0.13 – 0.45 MHz for the tin and lead derivatives (i.e. is within the limits of the crystallographic effect), while for mercury it is 0.83 – 1.2 MHz (i.e. 2 – 3% of the measured quantity. If it is assumed that the splitting is proportional to the intensity of the coordination interaction, then it follows that in the above compound organotin groups exhibit a higher capacity for coordination[104]. However, the authors do not exclude completely the possibility of intermolecular interaction in these systems:



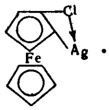
(M = Hg, Sn, Pb) .

Similar coordination has been proposed also for organometallic derivatives of 2,6-dibromo-4-fluorophenol[105] in view of the increase of the chemical shift of fluorine-19 under the influence of the groups Et_3SnO and PhHgO in the ^{19}F NMR spectra compared with the spectra of 4-fluorophenol derivatives without bromine. In these systems too the coordination is more intense for the organomercury group.

IV. CHEMICAL CONSEQUENCES OF INTRAMOLECULAR COORDINATION

The chemical effects of intramolecular coordination may be extremely varied. It is logical to expect that it will be reflected mainly in anomalous reactions because of a different distribution of electron density in the molecule compared with "normal" reactions of related compounds where intramolecular coordination is known to be absent.

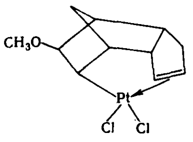
The first of the problems which arise here is the effect of intramolecular coordination on the strengths of metal–carbon bonds and hence the stability of the molecule as a whole. The views expressed in this connection reflect at least two, at first sight contradictory, trends. On the one hand, attempts are made to explain by intramolecular coordination the anomalous stability of many compounds which according to *a priori* estimates should not be so stable. The silver derivatives of chloroferrocene described by Nesmeyanov et al.[106] are typical examples of this kind; the authors explain their stability, unusual for organic silver σ-derivatives, by the Cl → Ag coordination:

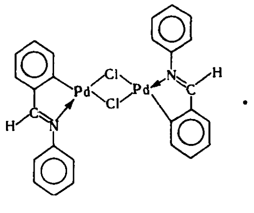


On the other hand, the hypothesis of intramolecular coordination is being increasingly put forward to account for the thermal instability of organometallic compounds with functional substituents, particularly to account for the elimination reactions and the mechanism of metallotropic rearrangements[107,108].

Apparently there is no contradiction between these two points of view. Among transition metals (or silver, copper, and gold which resemble them) intramolecular coordination, like intermolecular coordination, should indeed enhance the stability of the metal–carbon σ-bonds. The same bonds formed by a non-transition metal are polarised under the influence of coordination, which greatly increases their reactivity and hence makes the compound chemically more labile[109].

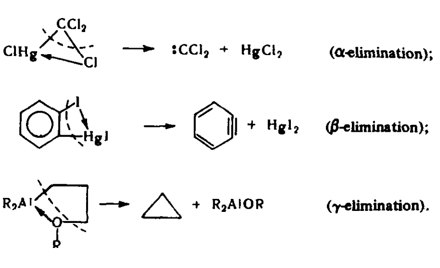
On the basis of X-ray diffraction[110] and infrared[111] and NMR[112] spectroscopic data, the stabilisation of the usually unstable σ-derivatives of transition metals as a result of intramolecular coordination interaction between the vacant orbitals of the metal atoms and the π-electron bonds or free electron pairs of other atoms is postulated, for example:





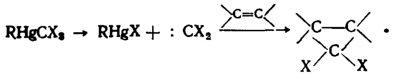
Similar intramolecular complexes or transition states corresponding to them are considered in Jones's review[113] and a number of later publications[114-117].

The presence of intramolecular coordination in the non-reacting molecule or its occurrence in the course of the incipient reaction may be regarded as a kind of "pre-existence" of the fragment to be eliminated:

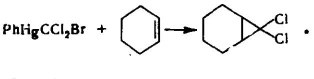


α-Elimination

As already mentioned (p. 200) the presence of intramolecular coordination in the trichloromethylmercury chloride molecules follows from X-ray diffraction analysis[37] and ³⁵Cl NMR spectra[38]. The capacity of compounds of this kind for α-elimination with the removal of a mercury halide and a dihalogenocarbene is not therefore surprising[118-138]:



Usually dihalogenocarbenes are readily formed in the thermolysis of trihalogenomethyl derivatives of mercury at 80°C in an inert solvent (benzene). However, some of them split off dihalogenocarbenes at a satisfactory rate even at room temperature. Thus the compounds $PhHgCCl_2Br$, $PhHgCClBr_2$, $PhHgCBr_3$, and $PhHgCCl_3$ decompose very slowly[132]:



The yields of 7,7-dichloronorcarane amount to 3, 12, and 66% after 3 h, 24 h, and 11 days respectively. Trihalogeno-derivatives of organomercury compounds, which are at least formally donors of dihalogenocarbenes, include also $PhHgCX_3$ (X = Cl or Br)[118-123], $Cl_3CHgCCl_3$, Cl_3CHgCl,[124] $PhHgCX_2Br$ (X = Cl or Br)[125], $PhHgCCl_2Br$,[120,121,126-136] $PhHgCClBr_2$,[121,127] $XC_6H_4HgCCl_2Br$,[137] and $Hg(CBr_3)_2$.[138]

Other α-halogenomethyl derivatives of organometallic compounds undergo the same type of thermal decomposition: ICH_2MgI,[139] $IZnCH_2I$,[140] $Zn(CH_2X)_2$ (X = Cl or I),[141,142] $Cd(CH_2I)_2$,[141] ICH_2HgI, $Hg(CH_2Br)_2$,[143] Et_2AlCH_2Cl,[144] and $In(CH_2I)_3$.[141] Monohalogenocarbenes CHX (X = Cl or Br) are eliminated in the decomposition of a number of organometallic compounds: $LiCHCl_2$,[145] $Zn(CHCl_2)$,[145] and $C_6H_5HgCHXBr$.[146,147]

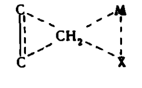
Under very mild conditions (−65°C), dichloronorcarane is formed from $LiCCl_3$ and cyclohexene[148-151] and at 80°C also from $(C_6H_5)_3PbCCl_3$.[143] The stability of organometallic compounds of this type depends on the metal. Dichlorocarbenes are formed in high yield on refluxing $(CH_3)_3SnCCl_3$ and $(CH_3)_3SnCCl_2Br$ in cyclo-octene[152], while trichloromethyltrichlorosilane gives rise to them only at 250°C.[153] Difluorocarbene is eliminated at 180–220°C from tris(trifluoromethyl)arsine and tris(trifluoromethyl)stibine[154] and at 100–200°C from trifluoromethyl derivatives of pentavalent phosphorus: $(CF_3)_nPF_{5-n}$ ($n = 1-3$).[155,156]

Dihalogenocarbenes may be formed as a result of the exchange of a halogen for a metal in tetrahalogenomethanes, for example in the reaction between methyl-lithium and trifluoroiodomethane[157] or in the reaction of n-butyl-lithium and dibromodifluoromethane[158]. However, there are no reliable data about the intermediate formation of organometallic compounds in such reactions and therefore they will not be considered here.

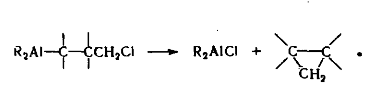
The interaction of the carbenes $:CZ_2$ (Z = H or halogen) with olefins, which leads to cyclopropanes, takes place stereospecifically and constitutes a *cis*-addition; this means that the carbenes entering into the reaction are in a singlet form.

Several different mechanisms have been proposed to account for the formation of cyclopropanes.

1. A bimolecular single-stage transfer of $:CZ_2$ in which the organometallic reagent reacts directly with the olefin via a five-centre transtion state[140,141]:



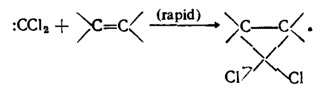
2. A bimolecular two-stage process via the addition of the organometallic reagent to the olefin with subsequent elimination of the metal halide[142]:



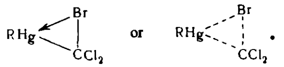
However, in this case it is difficult to reconcile the selectivity of the addition and elimination reactions and also the configurational stabilities of the intermediate organometallic compounds with the stereospecifity of the addition of carbenes to olefins.

3. A process in which the rate-determining stage (possibly reversible) is the decomposition of the organometallic compound to the carbene with subsequent rapid reaction of the latter with the olefin and formation of the cyclopropane. The carbene mechanism proposed by a number of investigators[153,156,159] and investigated in detail by Seyferth and coworkers[132,137] can be represented by the following equations:

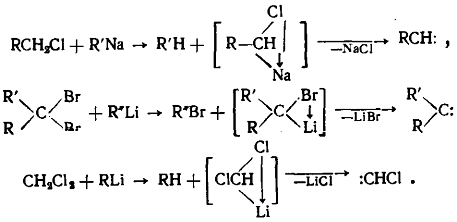
$$C_6H_5HgCCl_2Br \underset{\text{(rapid)}}{\overset{\text{(slow)}}{\rightleftarrows}} C_6H_5HgBr + :CCl_2,$$



The intermediate formation of carbenes has been demonstrated by kinetic experiments in a number of cases. Thus carbene is formed as a result of α-elimination, which requires an internal nucleophilic attack by the halogen atom on the metal via the following transition state:



The principal syntheses of alkyl(aryl)-, dialkyl(diaryl)-, and monohalogeno-carbenes are based on the α-elimination of intermediate organometallic compounds, for example:



For a detailed account of the chemistry of carbenes, see the monographs by Kirmse[160] and Hine[161].

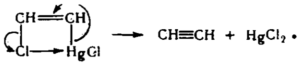
It is suggested that α-elimination from polyhalogenoalkyl compounds of various elements with expulsion of a carbene is a common reaction[153]. This is confirmed by the thermal instability of compounds of this kind. Trifluoromethylmagnesium iodide begins to decompose at a temperature as low as −60°C;[162] perfluoropropyl-lithium[157] and perfluoropropylmagnesium[163] and perfluoropropylzinc[164] iodides decompose at 40°, above 20°, and at 130−150°C respectively:

When any halogen except fluorine is in the α-position, the organometallic compounds of alkali and alkaline earth metals cannot be isolated at all[160,161,164]. Very slow decomposition of αα-dihalogenodialkyl compounds of mercury is observed even at room temperature, the process being sharply accelerated at 100°C:[165]

$$RR'CHCCl_2HgCHRR' \xrightarrow{100-140°} RR'C{=}CHCl + RR'CHHgCl.$$

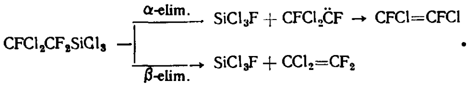
β-Elimination

The β-elimination reaction has been very thoroughly investigated among organomercury compounds[166]. If the reaction takes place under the influence of an extraneous reagent, β-elimination is usually explained by the Nesmeyanov mechanism[16] involving the transfer of the reaction centre along the σ, π- or σ,σ-conjugation chain. Until very recently, the possibility of coordination interaction through space, i.e. by-passing the conjugation chain, was not taken into account in such cases. Nevertheless the existence or formation of an intramolecular coordination bond is in some measure equivalent to nucleophilic attack on the metal atom, which results in a closed ring and the σ,σ- or σ,π-conjugation chain becomes "incorporated" as in the usual nucleophilic attack:

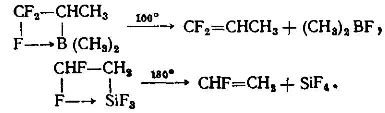


Evidently spontaneous and thermal β-elimination reactions should be treated in the same way. In those cases where coordination within the same molecule is impossible, a similar effect is achieved by intermolecular coordination, which occurs, for example, in the decomposition of *trans*-β-chlorovinylmercury chloride.

If the halogen in the polyhalogenoalkyl derivatives of silicon is present in both α- and β-positions, α-elimination is accompanied by simultaneous β-elimination, albeit to a much lesser extent, for example[153,167]:



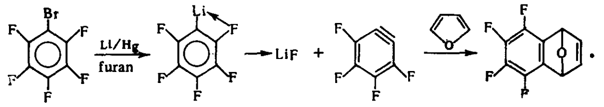
At 185°C the yields of CFCl=CFCl and CCl_2=CF_2 are 80 and 7% respectively. In the absence of a halogen in the α-position, β-elimination takes place, as shown for polyfluoroalkyl compounds of boron[168] and silicon[153]:



When the fluorine atom in polyfluoroalkylsilicones and polyfluoroalkylpolysiloxanes is present in both the α- and β-positions, thermal decomposition is accompanied by α- and β-elimination, both processes yielding an olefin[169]:

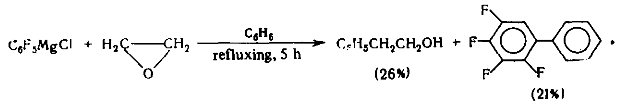
$$(CHF_2CF_2SiO_{1.5})_n \rightarrow n\,CHF{=}CF_2.$$

In contrast to the perfluoroalkyl organometallic compounds, the corresponding pentafluorophenyl derivatives are as a rule more stable. This applies particularly to lithium derivatives. Pentafluorophenyl-lithium[170] is an excellent starting material for the synthesis of other pentafluorophenyl metal derivatives. Being more stable than *o*-fluoro- and *o*-bromo-phenyl-lithium, pentafluorophenyl-lithium nevertheless decomposes with formation of tetrafluorodehydrobenzene, probably as a result of intramolecular coordination interaction between lithium and fluorine atoms. The intermediate formation of tetrafluorodehydrobenzene has been demonstrated by the reaction with bromine and chlorine and also by the isolation of a Diels–Alder adduct in the reaction with furan:



The formation of 2-bromononafluorobiphenyl from bromopentafluorobenzene and pentafluorophenyl-lithium has also been explained[171] by the intermediate formation of tetrafluorodehydrobenzene, since usually direct attack on compounds of the type C_6F_5X by nucleophilic reagents leads to *para*- and not *ortho*-substitution. The intermediate formation of tetrafluorodehydrobenzene in this reaction has been confirmed also by other investigators[172].

The study of the products of the reaction of pentafluorophenyl organomagnesium derivatives also indicates the intermediate formation of tetrafluorodehydrobenzene. The interaction of pentafluorophenylmagnesium chloride with epoxyethane in benzene yields 2,3,4,5-tetrafluorobiphenyl, which is probably formed as a result of the abstraction of hydrogen from benzene[173]:



When cyclohexane is used as a solvent in this reaction and furan is added to the reaction mixture, the furan adduct mentioned above is formed. Pentafluorophenylmagnesium bromide refluxed in toluene also yields tetrafluorodehydrobenzene[174].

In trifluoromethyl derivatives of tin the tendency of the metal atom to enter into coordination interaction with the fluorine atom is considerable and trimethyltrifluoromethyltin is thermally unstable due to the migration of the fluorine to the tin atom[159]. However, pentafluorophenyl compounds of this type are much more stable; thus trimethylpentafluorophenyltin is stable at 250°C and decomposes only at 350°C.[175]

The unusual decomposition of potassium pentafluorophenyltrifluoroborate can also be explained by the coordination interaction between fluorine and boron atoms[176]:

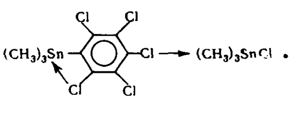
$$K^+[C_6F_5BF_3]^- \xrightarrow{300°} KBF_4 + \text{perfluoropolyphenylenes.}$$

Perfluoropolyphenylenes are probably obtained as a result of the intermediate formation of tetrafluorodehydrobenzenes.

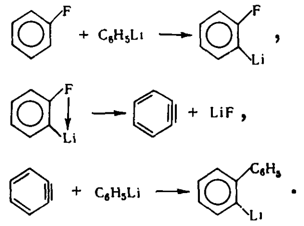
Prolonged pyrolysis of di-(π-cyclopentadienyl)di(pentafluorophenyl)titanium in a vacuum at 150°C leads to the migration of the fluorine atom to the titanium atom and partial decomposition of the substance:

$$(\pi\text{-}C_5H_5)_2\,Ti\,(C_6F_5)_2 \rightarrow (\pi\text{-}C_5H_5)_2\,Ti\,(C_6F_5)\,F\,.$$

Pentachlorophenyl organometallic compounds have not been investigated quite so widely as the pentafluorophenyl derivatives but here too results have been obtained which may be a consequence of the intramolecular coordination of the metal atom with the chlorine atom in the *ortho*-position. Thus pentachlorophenyltrimethyltin decomposes at 300°C with formation of trimethyltin chloride[177]:

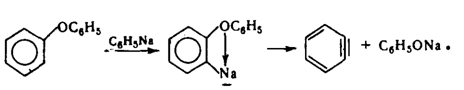


In all the above examples of coordination interaction between metal and halogen atoms the intermediate formation of dehydrobenzene derivatives has been demonstrated. Therefore such decomposition of pentafluoro- and pentachloro-phenyl derivatives of organometallic compounds may be regarded as a special case of a general tendency of aromatic compounds with metal and halogen atoms in the *ortho*-positions to decompose with formation of dehydrobenzenes. Wittig[178,179] was the first to postulate the formation of dehydrobenzene as an intermediate in the formation of 2-lithiumbiphenyl from fluorobenzene and phenyl-lithium:



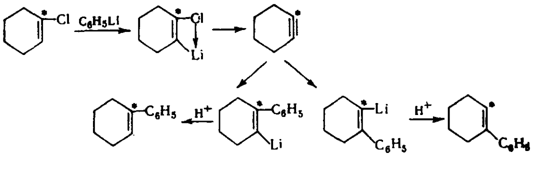
The rate-determining stage of the reaction is the elimination of lithium fluoride as a result of intramolecular coordination interaction leading to the formation of dehydrobenzene. The fact that, when labelled [^{14}C]-1-fluorobenzene is used, a mixture of almost equal amounts of the two isomeric biphenyls is obtained, suggests the intermediate formation of dehydrobenzene[180].

The existence of dehydrobenzene has also been demonstrated in the interaction of phenyl ether with phenylsodium[181,182]:



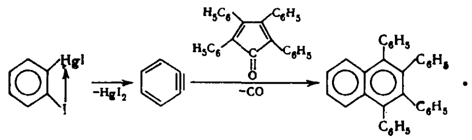
The elimination of sodium phenoxide in this reaction is probably caused by intramolecular coordination interaction of the ether oxygen with the sodium atom.

Similar elimination of MX fragments leading to analogues of dehydrobenzene is known also for the olefin series. Thus 1-phenylcyclohexene, which is obtained in the reaction between 1-chlorocyclohexene and phenyl-lithium in ether[183,184], and 1-phenylcyclopentene formed similarly from 1-chlorocyclopentene[185] are both probably produced via an intermediate cyclohexyne and cyclopentyne. This is confirmed by the finding that, when a labelled carbon atom in 1-chlorocyclohexene is employed, almost equal amounts of two phenylcyclohexenes, with substituents at both olefinic carbon atoms, are obtained[186]:

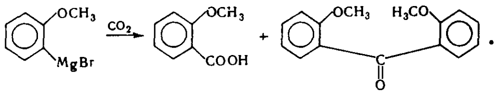


The coordination interaction between magnesium and bromine is probably responsible for the formation of cyclohexyne from the organomagnesium derivative of 1,2-dibromocyclohexene[187].

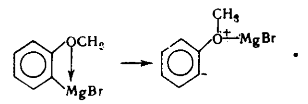
Irradiation with ultraviolet light leads to fairly intense coordination interaction between the mercury atom and the iodine atom in the *ortho*-position in 1-iodo-2-iodomercuribenzene. This results in the formation of mercury(II) iodide and dehydrobenzene, which was identified by the reaction with tetraphenylcyclopentadienone, giving a 25% yield of tetraphenylnaphthalene[188,189]:



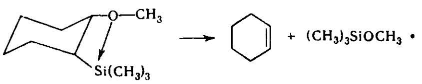
Reactions between carbon dioxide and Grignard reagents obtained from *o*-methoxybenzyl chloride, *o*-dimethylaminobromobenzene, and *o*-bromo(methylthio)benzene yielded both acids and ketones[190]. For example, *o*-methoxybenzoic acid and 2,2-dimethoxybenzophenone were obtained from *o*-methoxyphenylmagnesium bromide:



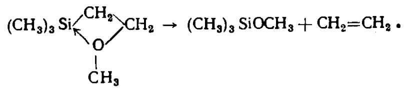
Under the same conditions, Grignard reagents obtained from *m*- or *p*-bromomethoxybenzene *β*-(*o*-methoxyphenyl)-ethyl chloride, *o*-bromomethylbenzene, and *γ*-methoxypropyl bromide give rise only to the corresponding acids. The anomalous reactions leading to the formation of ketones were accounted for by the formation of strained planar rings as a result of intramolecular coordination:



Thermal decomposition of the methyl ether derived from *cis*-2-trimethylsilylcyclohexanol (first-order reaction)[191] gives a quantitative yield of cyclohexene and methoxytrimethylsilane:



Ethylene is evolved in quantitative yield in the pyrolysis of ethylmethoxytrimethylsilane (first-order reaction)[191]:



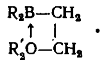
$$(CH_3)_3Si(CH_2CH_2)(OCH_3) \rightarrow (CH_3)_3SiOCH_3 + CH_2{=}CH_2.$$

2-Alkoxyethyl derivatives of boron are thermally unstable and readily eliminate olefins[192]. Thus tri-(2-ethoxyethyl)boron begins to evolve ethylene at a temperature as low as −10°C:

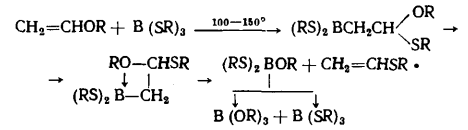
$$(C_2H_5OCH_2CH_2)_3B \rightarrow (C_2H_5OCH_2CH_2)_2BOC_2H_5 + CH_2{=}CH_2.$$

2-Ethoxyethyldiethoxyboron decomposes at a higher temperature (160–170°) than the butyl ester of di-(2-ethoxyethyl)boronic acid. Consequently thermal stability increases as 2-alkoxyethyl groups are replaced by alkoxy-groups.

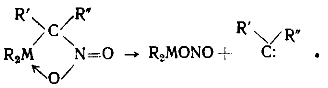
The reaction of dipropyldeuteroborane with *cis*-1-ethoxy-2-phenylethylene at 0°C gives a 40% yield of *trans*-*β*-deuterostyrene when the mixture is allowed to stand after the reaction at room temperature for 1 h. In this case *cis*-elimination takes place although the initial olefin does not isomerise on reaction with the normal borane[193]. It is interesting that, on replacing oxygen by sulphur in the initial olefin, the non-catalysed elimination reaction does not occur. The thermal instability of 2-alkoxyethyl derivatives of boron was explained by intramolecular coordination:



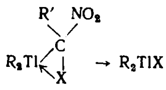
Similar coordination can account for the reaction of thioborates with vinyl ethers which yields alkyl vinyl sulphides and alkyl borates[194]:



Intramolecular coordination interaction is suggested for *α*-nitroalkyl derivatives of mercury and thallium, which decompose on heating with formation of nitrites and probably carbenes[195]:



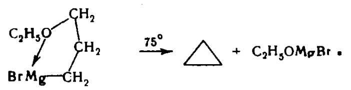
When halogen atoms are bonded to the *α*-carbon atoms of *α*-nitroalkyl derivatives of thallium, a competing intramolecular interaction takes place and in a number of cases the corresponding halide and not the nitrite is formed:



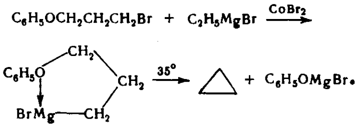
where X = F or Cl.

γ-Elimination

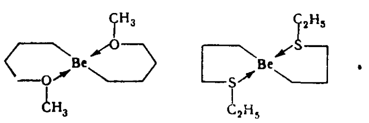
Intramolecular coordination can explain the thermal instability of 3-alkoxy-derivatives of Grignard reagents, as a result of which cyclopropane and its derivatives are readily formed[196,197]:



Cyclopropane is also formed in the double decomposition of Grignard reagents with 3-phenoxypropyl bromide in the presence of cobalt(II) salts (the Kharasch reaction)[198]:



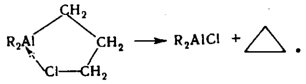
Di-(*δ*-methoxybutyl)beryllium and di-(*γ*-ethylthiopropyl)-beryllium[199] are probably chelate salts, since they can be distilled in a vacuum:



Convincing evidence has been adduced for intramolecular coordination in γ-amino-, γ-alkoxy-, γ-hydroxy-, γ-alkylthio-, γ-halogeno, and also δ-alkoxy-derivatives of aluminium[144,200,201]:

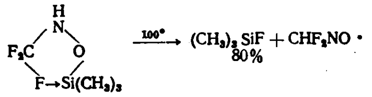
(n = 3, 4; A = RO, RS, R_2N, Hal).

γ-Halogenalkyl derivatives of aluminium readily eliminate cyclopropane[144]:

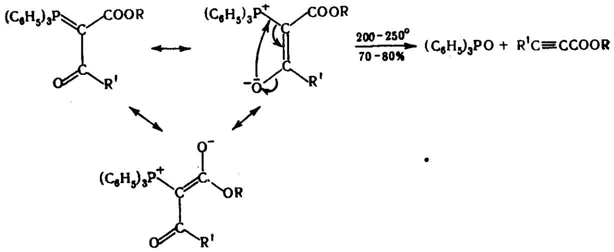


The evidence for coordination in the remaining compounds is based on their monomeric form in benzene and the absence of intermolecular coordination with ethyl ether; in the case of amines the evidence is based on the absence of electron-donating properties at the nitrogen atom (a quaternary compound is not formed with methyl iodide)[200,201]. When the fluorine atom is in the γ-position, the thermal and hydrolytic stability of the corresponding polysiloxanes is very high and $(CF_3CH_2CH_2SiO_{1.5})_n$ is not cleaved by alkalis at 20–80°C, while $(CF_3CH_2CH_2)_3B$ is stable at 100°C.[168]

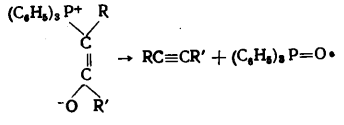
On the other hand, if the halogen atom is separated from the metal by a heteroatom (in *N*-trifluoromethyl-*O*-trimethylsilylhydroxylamine), γ-elimination can probably occur)[202]:



A surprising example of the effect of the possible intramolecular coordination on reactivity is provided by substituted phosphoranes[203]. Acylalkoxycarbonylmethylenetriphenylphosphoranes, the stability of which is explained by resonance, decompose at 220–250°C, yielding the corresponding propiolic esters and triphenylphosphine oxide:



On the basis of the resonance formulae, this reaction may be regarded as an intramolecular Wittig synthesis. In the reaction of betaines, in which R and R′ are not hydrogen atoms but any electron-accepting group, high yields of disubstituted acetylenes are obtained[204,205]:



On the other hand, when R = $-C{\equiv}C-R'$, diacetylenes may be obtained in this way.

Metallotropy

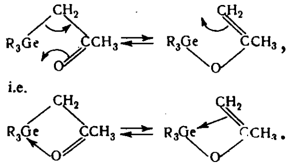
Intense studies on various metallotropic rearrangements, including metallotropic photomerism, were begun recently. In all these investigations the concepts of intra- and intermolecular coordination, usually postulated for the transition state, are always employed. There is scarcely any sharp qualitative distinction between a transition complex of a clearly coordination type and coordination (intra- or inter-molecular) interaction in a system which has not yet reacted. The occurrence of such interaction, leading, for example, to the preferential formation of the conformation required for the rearrangement, should undoubtedly facilitate the rearrangement itself, lowering the required activation energy.

Such metallotropic rearrangements include, for example, the rearrangement of α-silylketones to silylenolates on heating[107,108] or in the presence of mercury and zinc salts and chlorosilanes[108,206]. The thermal rearrangement must be molecular, since, in the first place, the rearrangement of $(C_6H_5)_3SiCH_2COC_6H_5$ is a first-order reaction[107] and, in the second place, on heating mixtures of $(C_2H_5)_3SiCH_2COCH_3$ with $(CH_3)_3SiCH_2COC_6H_5$ and of $(C_2H_5)_3SiO(CH_3O)C{=}CH_2$ with $(CH_3)_3SiCH_2COC_6H_5$, it proved impossible to isolated intermolecular rearrangement products[108]. It is believed that the rearrangement proceeds via a four-centre activated complex[107,108], which is of the intramolecular coordination type:

The rapid catalytic rearrangement of a number of similar tin compounds is of the equilibrium type[207]:

$$R_3SnCH_2COR' \xrightleftharpoons{R_3SnX} R_3SnOC(R'){=}CH_2 .$$

The corresponding trialkylgermane derivatives constitute a true metallotropic tautomeric system with a relatively low (about 1 month) rate of attainment of equilibrium. It may be supposed that here too the rearrangement proceeds via a four-membered coordination complex[208,209]:



The explanation of the recently discovered metallotropic tautomerism of organometallic derivatives of p-nitrosophenols[210] is similarly based on the concept of intermolecular coordination.

The above review shows that the concept of intramolecular coordination is employed to account for a wide range of phenomena associated with the structure and reactivity of organometallic compounds. Nevertheless the experimental proof of the occurrence of intramolecular coordination interaction is in many cases clearly inadequate and the concept itself is frequently merely a useful hypothesis. However, this new trend in the chemistry of organic derivatives of the elements promises to become extremely fruitful and consequently deserves extensive and impartial development.

Reactions of Epoxy-compounds by a Radical Mechanism

A.P.Meleshevich

Data on various methods for the initiation of radical reactions of epoxy-compounds, including their homopolymerisation, are reviewed systematically.
The bibliography comprises 134 references.

CONTENTS

I. INTRODUCTION

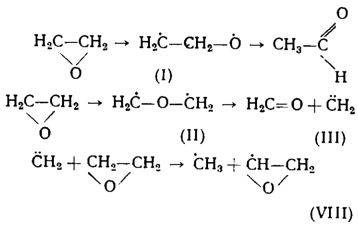
Much work has been done on the chemistry of epoxy-compounds. The reactions of these very simple heterocyclic compounds are treated from the standpoint of ionic mechanisms. With rare exceptions [5,13,14], no attention is devoted to radical reactions of epoxy-compounds in any of the monographs, reviews, and textbooks dealing with their chemistry [1-13]. Many investigators believe that such reactions are altogether impossible [15-18]. Similar views have been expressed by Staudinger and coworkers [15-17], who reported in the 1930's that radical type initiators, ultraviolet light, and sunlight do not influence epoxy-compounds and their reactions, in particular polymerisation, "occur only under the influence of appropriate catalysts". This situation did not alter in the course of the succeeding decade. Sorensen and Campbell [18] assert that only ionic catalysts are effective initiators of the polymerisation of epoxy-compounds. From time to time this view has been supported by new reports. Hopff and Zaner [second author not traced—name transcribed from Russian (Ed. of Translation)] [19] and also Oku et al. [20] did not observe the formation of acetophenone or a polymeric product from epoxyethylbenzene when azodi(isobutyronitrile) or benzoyl and lauroyl peroxides were used as initiators. The attempts to polymerise isoprene oxide [1,3-epoxy-2-methylbutane] by a radical mechanism in the presence of peroxides and azo-compounds were unsuccessful [21]. Epoxyethane does not react either with hydrogen peroxide (30%) or with lead dioxide, or with benzoyl peroxide [22]. In a recently published monograph dealing with the polymerisation of cyclic oxygen compounds [23] and also in the review by Frunze and Kurashev [14] the lack of reports on the homopolymerisation of epoxyalkanes initiated by radicals is pointed out.

Nevertheless, as early as 1918, Bodforss [24,25] obtained data which, in the light of modern concepts, may be explained as reactions of epoxy-compounds by a radical mechanism. The number of studies in which the reactions of epoxy-compounds are considered from the standpoint of radical processes has greatly increased in recent years. The investigation of chemical reactions of epoxy-compounds with participation of radicals is not only of theoretical but also of practical interest, since they have found application in many branches of the national economy.

The present review is a first attempt at a systematic account of reactions of epoxyalkanes involving a radical mechanism. Together with the description of the thermal, chemical, and photochemical initiation of the reactions, data are presented on the radiolysis of epoxy-compounds—a new branch of the radiation chemistry of heterocycles.

II. FORMATION OF RADICALS IN THE PYROLYSIS OF EPOXY-COMPOUNDS

Rice and Johnston [26] were some of the first investigators who noted the formation of radicals in the thermal decomposition of epoxy-compounds. Rice and Rice [27] detected free radicals in the pyrolysis of epoxyethane with the aid of a "metallic mirror". The rate of disappearance of the "metallic mirror" was higher than in the decomposition of other organic compounds, in particular acetaldehyde—a structural isomer of epoxyethane. Hence the authors concluded that a large number of radicals are formed in the decomposition of epoxyethane and proposed a mechanism of consecutive and parallel reactions [reactions (1)–(3)] in the pyrolysis of epoxyethane with participation of radicals of five types[†] (Table 1): ethylenoxy-radical [biradical (I)], hydroxydimethylene (II), carbene [methylene (III)], and methyl and epoxy-radicals (VIII).



$$\underset{\diagdown O \diagup}{H_2C{-}CH_2} \rightarrow \underset{(I)}{H_2\dot{C}{-}CH_2{-}\dot{O}} \rightarrow CH_3{-}C\overset{O}{\underset{H}{\lessdot}} , \tag{1}$$

$$\underset{\diagdown O \diagup}{H_2C{-}CH_2} \rightarrow \underset{(II)}{H_2\dot{C}{-}O{-}\dot{C}H_2} \rightarrow H_2C{=}O + \underset{(III)}{\ddot{C}H_2} , \tag{2}$$

$$\ddot{C}H_2 + \underset{\diagdown O \diagup}{CH_2{-}CH_2} \rightarrow \dot{C}H_3 + \underset{(VIII)}{\underset{\diagdown O \diagup}{\dot{C}H{-}CH_2}} . \tag{3}$$

There does not exist a unanimous view concerning the structure and reactions of pyrolytic free radicals. Rice

---

[†] There does not exist a single accepted terminology for the radicals arising in the cleavage of the epoxy-ring. In the present study an attempt is made to give a systematic account of such radicals and to name them on the basis of the nomenclature of organic compounds adopted by IUPAC [28,29]. In some cases the names of radicals adopted by individual authors were chosen and a number of trivial names have been proposed. Some of the radical names adopted in the original literature and not included in the Table have been retained in the text.

and Stalibaumer[30], Schumacher[31], Steacie[32], and Zimakov[13,33] give preference to radical (II). According to Zimakov[37], the biradicals (II), which are formed in the singlet state, influence the process only slightly since their lifetime is very short (about 10^{-13} s) and the metastable biradicals with a lifetime of 10^{-8} s make the main contribution to the pyrolytic reaction. To justify his view, Zimakov invoked Terenin's theory[38] of metastable biradicals produced as a result of the reversal of the spin of one of the two electrons and a transition of the biradical from the singlet to the triplet state, which in the case of epoxyethane can be represented as follows:

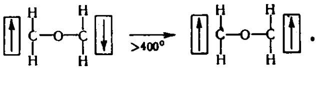


Table 1. Radicals formed from epoxy-compounds

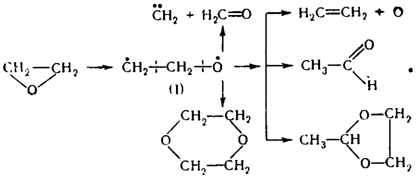
№	Formula	Radical	References
(I)	$\dot{C}R_1R_2-CR_3R_4-\dot{O}$	Alkyl(aryl)ethyleneoxy	—
	$\dot{C}H_2-CH_2-\dot{O}$	Ethyleneoxy (biradical)	29
(II)	$\dot{C}R_1R_2-O-\dot{C}R_3R_4$	Oxydi[alkyl(aryl)]methylene	—
	$\dot{C}H_2-O-\dot{C}H_2$	Oxydimethylene	29
(III)	$\ddot{C}R_1R_2$	Carbene	28,34
	$\ddot{C}H_2$	Methylene	28
(IV)	$\overset{\quad O}{\overset{/\!\!/}{\dot{C}}}-H$	Formyl	29
(V)	$O=\dot{C}-CH_3$	Acetyl	29
(VI)	$R-\dot{C}H-\overset{\quad O}{\overset{/\!\!/}{C}}-H$	Alkylformylmethyl	29
(VII)	$R-\underset{O}{\underset{\parallel}{C}}-\dot{C}H_2$	Keto-radical	20,35
		Acetonyl, R = CH_3	29
		Phenacyl, R = C_6H_5	29
(VIII)	$\underset{\diagdown O \diagup}{\dot{C}H-CH_2}$	Epoxy	36
		1,2-Epoxyethyl	29
(IX)	$\underset{\diagdown O \diagup}{\dot{C}H-CH}-CH_3$	1,2-Epoxy-1-propyl	—
(X)	$\underset{\diagdown O \diagup}{CH-\dot{C}}-CH_3$	1,2-Epoxy-2-propyl	—
(XI)	$\underset{\diagdown O \diagup}{CH_2-CH}-\dot{C}H_2$	Glycidyl (2,3-epoxypropyl)	—
(XII)	$\underset{\diagdown O \diagup}{CH_2-CH}-CH_2-\dot{O}$	Oxyglycidyl (2,3-Epoxypropyloxy)	—
		(2,3-Epoxypropoxyl)	—
(XIII)	$CH_3-\overset{OH}{\overset{\vert}{C}}H-\dot{C}H_2$	2-Hydroxypropyl	29
(XIV)	$\dot{C}H_2-CH_2-OH$	2-Hydroxyethyl	29
(XV)	$H-\underset{O}{\underset{\parallel}{C}}-\dot{C}H_2$	Formylmethyl	29

Zimakov frequently emphasised[33,37,39] that "the formation of the stable dimethylene oxide biradical (II) in the pyrolysis of epoxyethane should in fact account for *all the characteristic features* (my italics—A. M.) of the pyrolytic reactions" of epoxyethane and various substances in its presence.

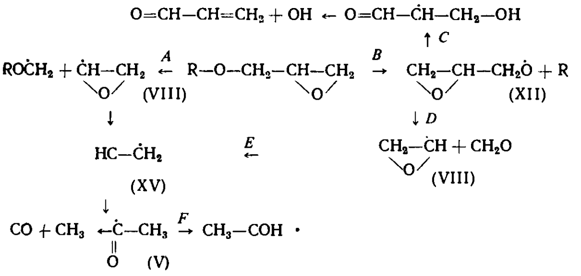
Malinovskii and Baranov demonstrated the inadequacy of the evidence for the decisive role of the biradical (II) in the pyrolysis of epoxyethane and epoxypropane in the presence of catalysts[40,41]. By adducing a number of pieces of evidence based mainly on the study of the composition of liquid-phase and gaseous decomposition products, Malinovskii and Baranov proposed other radical mechanisms for the pyrolysis of the above epoxy-compounds without the participation of oxydimethylene. Their mechanisms are based on the ethyleneoxy-biradical (I):



(4)

The authors note that the ethyleneoxy-biradical (I) is formed as an intermediate in the thermal decomposition of epoxyethane since "*only in this way* (my italics—A. M.) is it possible to explain" the presence of free oxygen and a large amount of ethylene and the formation of acetaldehyde and a cyclic acetal. The interpretation of the pyrolysis of epoxyethane and epoxypropane on the basis of the participation of ethyleneoxy-biradicals (I) provides a more convincing explanation of the formation of the final products, since the hypothesis of the oxydimethylene biradical (II) cannot account for the formation of all the reaction products.

In a series of studies by Neiman, Kovarskaya, Akutin, and coworkers[36,42–46] the thermal degradation of unhardened and hardened epoxy-resins was investigated. The composition of the gaseous pyrolysis products from the resins was the same for both hardened and unhardened resins regardless of the type of hardening agent employed (polyethylenepolyamine and maleic anhydride). According to the authors[36,42–46], the decomposition of the resin at 200–500°C is a free-radical process, which begins with the scission of the terminal part of the molecule and the formation of the epoxy-radical (VIII) (pathway *A*) and the oxyglycidyl radical (XII) (pathway *B*) according to the mechanism:



(5)

The radical (XII) can react in two ways: it can either isomerise via pathway *C* with formation of acrolein or it can decompose via pathway *D* into formaldehyde and the epoxy-radical (VIII). The latter isomerises via the formyl radical (XV) (pathway *E*) to the acetyl radical (V), which can in turn combine with hydrogen and form acetaldehyde or break down into carbon monoxide and a methyl radical. The suggested mechanism[36,42–46] does not postulate the cleavage of the three-membered ring at the C–C bond. The views of Neiman and coworkers on the isomerisation processes in the pyrolysis of epoxy-resins are shared by Anderson[47].

According to the literature, the mechanism of the thermal degradation or even the simplest epoxy-compound (epoxyethane) still remains controversial. This is indicated by (a) the difference between the radical and molecular pyrolysis products (furthermore, the complete set of products is not quoted in the reports of various workers), (b) the different interpretation of the formation of the same products, for example, carbon monoxide, methane, acetaldehyde, ethylene, acrolein, etc., and (c) the divergent views of investigators concerning the role of the methyl radical: some believe that it interacts with the epoxyethane molecule, while others reject this hypothesis, etc. The considerable qualitative and quantitative differences between the reaction products from which inferences concerning the processes occurring were in fact mainly drawn led to the situation where almost every investigator proposes his own mechanism for the pyrolysis of epoxyethane. Malinovskii[5] rightly remarked that this state of affairs arose because of failure to take into account completely the reaction products and frequently because the experiments were performed under non-comparable conditions (purity of the products, design of the reactor, static or dynamic process conditions, different temperatures and pressures, presence and type of catalyst, etc.).

Furthermore, because of serious practical difficulties, epoxy- and other radicals have not been identified and it is so far impossible to distinguish between the conceivable involvement of radicals (I) and (II) in the pyrolysis of epoxyethane, for example. One cannot exclude the possibility that they coexist in different proportions, which are determined either by the electronic and molecular structure of the epoxy-compound or by the experimental conditions.

Speaking of epoxy-radicals, attention must be drawn to the following factors. The considerations concerning the formation of the oxydimethylene biradical described earlier[33,37,39] are based on the fact that in the epoxyethane molecule the C–C bond is least stable and therefore, on raising the temperature, is the first to break:

C-H	87.3 kcal mole^{-1}
C-O	70.0 kcal mole^{-1}
C-C	58.6 kcal mole^{-1}.

Table 2. Dissociation energies of the C–O bond in oxygen-containing heterocycles

Compound	Biradical formed	Bond dissociation energy, kcal mole^{-1}	No. of atoms in ring
Tetrahydropyran	$\dot{C}H_2(CH_2)_4\dot{O}$	71.2	6
Tetrahydrofuran	$\dot{C}H_2(CH_2)_3\dot{O}$	68.6	5
Trimethylene oxide	$\dot{C}H_2(CH_2)_2\dot{O}$	—	4
Epoxypropane	$\dot{C}H_2CH(\dot{O})CH_3$	51.5	3
	$\dot{O}CH_2\dot{C}HCH_3$	50.5	
Epoxyethane	$\dot{C}H_2CH_2\dot{O}$	47.7	3

It is stated that the above estimates of bond strengths are consistent with the data of Gel'man[48] and Pauling[49]. However, more reliable studies[50] on the strength of the C–O bond in which account was taken of the ring size in cyclic ethers and epoxy-compounds yielded significantly different results. Table 2 shows that the maximum strength of the C–O bond is observed in six-membered cyclic ethers, where it reaches 71.2 kcal mole^{-1}. This value was in fact adopted[33,37,39] for the three-membered epoxy-ring. Actually, experiment shows[50] that, as the size of the ring of the heterocyclic oxygen-containing compound diminishes, the dissociation energy of the C–O bond falls sharply and for epoxy-compounds becomes approximately 50 kcal mole^{-1}. Thus the weakest bond in the epoxy-ring is C–O and not C–C as was believed[33,37,39]. In the vast majority of published reports and reports considered in the present review the preferential cleavage of the C–O bond in the epoxy-ring is noted, which agrees with the data of Gray and Williams[50].

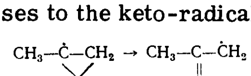
III. RADICAL REACTIONS OF EPOXY-COMPOUNDS INITIATED BY PEROXIDES

Probably the first communication where it was noted that the epoxy-ring may be opened with formation of a polymer by a radical mechanism in the presence of initiators was that of Conant and Peterson[51] published in 1932. Even under severe conditions (12 000 atm., 168 h, 2% of benzoyl peroxide), epoxycyclohexane polymerised with difficulty, yielding a viscous liquid. After degassing in a vacuum at 100°C, a solid polymer soluble in benzene, chloroform, and ethyl and allyl ethers and insoluble in ethyl alcohol, acetone, and acetic anhydride was obtained.

The work of Conant and Peterson remained unnoticed and it was not until 30 years later that the radical reaction between epoxypropane and oct-1-ene initiated by t-butyl peroxide at 150°C was described[52]. According to gas–liquid chromatographic data, the reaction product is a ~ 4 : 1 mixture of 2-undecanone and 5-hydroxy-2-hexanone. The t-butoxy-radical formed in the decomposition of the peroxide abstracts a hydrogen atom from the second carbon atom [of epoxypropane (Ed. of Translation)] with formation of a 1,2-epoxy-2-propyl radical (X):

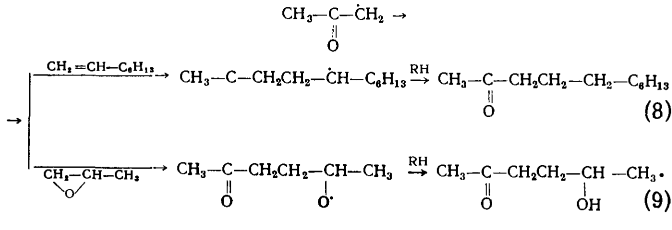
(6)

which then isomerises to the keto-radical (VII):



(7)

The radical (VII) attacks both the double bond of the olefin and the ring of the epoxy-compound, initiating the parallel competing reactions (8) and (9). 2-Undecanone is formed by reaction (8) from the keto-radical and oct-1-ene and 5-hydroxy-2-hexanone is formed by reaction (9) from the keto-radical and epoxypropane:



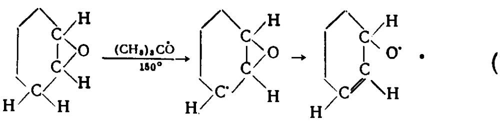
To test their hypothesis concerning the pathway followed in the formation of the hydroxy-ketone, Gritter and Wallace investigated the reactions of epoxypropane with t-butyl peroxide in the presence of compounds with active hydrogen atoms and butyl groups. Large fragments—the residues of radicals (VII) and (XIII)—appeared in the final reaction products. The addition of 1,2-epoxybutane, 1,2-epoxyoctane, and epoxyethylbenzene to oct-1-ene by reaction (8) has also been achieved[53]‡. Aldehydes are absent from the reaction products, ketones alone being detected. This suggests a preferential removal of the hydrogen atom from the methine group in the epoxy-radical and its subsequent isomerisation to radical (VII).

Free radicals may abstract hydrogen from epoxy-compounds not only at the α- but also at the β-carbon atoms in relation to the oxygen atom, i.e. atoms in the allyl position with respect to the three-membered ring. This type of radical attack was observed by Sabatino and Gritter[54] in the reaction of t-butyl peroxide with epoxycyclohexane. It was suggested that, in consequence of the decyclisation and

---

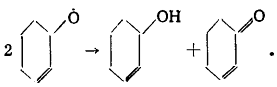
‡ The radical copolymerisation of epoxy-compounds is considered in the review of Frunze and Kurashev[14].

electronic isomerisation of the epoxy-ring, the initially formed radical isomerises to an unsaturated radical:



(10)

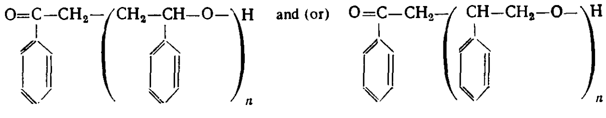
The authors explain the removal of a hydrogen atom from the β-carbon atom in the epoxycyclohexane molecule by postulating that the epoxy-ring behaves as a pseudo-olefin and the allyl position in olefins is known to be reactive with respect to radical attack[55,56]. Since cyclohex-2-en-1-one and cyclohex-2-en-1-ol are formed in small but approximately equal amounts, it may be supposed that the principal reaction undergone by the cyclohex-1-en-1-oxy-radical is disproportionation:



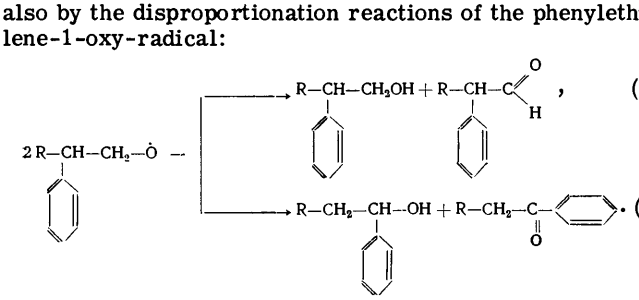
(11)

The main product of the reaction of t-butyl peroxide with epoxycyclohexane is cyclohexanone.

Using t-butyl and benzoyl peroxides as radical initiators, Oku et al.[20] achieved, in contradiction of the data of Hopff and Zaner[19], the polymerisation of epoxyethylbenzene and glycidyl phenyl ether. The only low-molecular-weight product isolated in the polymerisation of epoxyethylbenzene was acetophenone, which indicated the formation of the keto-radical (VII) as an intermediate. Polyepoxyethylbenzene had a molecular weight of 1500–2000. The infrared spectra of the polymer showed absorption bands at 3500 cm^{-1} (hydroxyl), 1720 and 1680 cm^{-1} (carbonyl), and 1030–1100 cm^{-1} (ether bond). These data suggest that the structure of the products formed by reaction (9) may be assigned to the polymer:



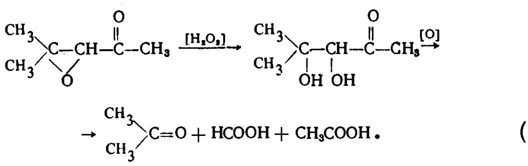
However, it has been established that there are about two hydroxy- and 1.5 carbonyl groups per polymer molecule. Probably these differences can be accounted for not only by the branching of the polyepoxyethylbenzene molecules but also by the disproportionation reactions of the phenylethylene-1-oxy-radical:



(12)
(13)

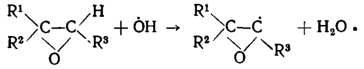
A similar mechanism of radical polymerisation in the presence of t-butyl peroxide has been suggested for glycidyl phenyl ether.

Razuvaev, Etlis, and coworkers investigated the interaction of hydroxy-radicals with a number of epoxyalkanes[57–60]. Since the carbonyl group lowers the reactivity of the oxygen atom of the epoxy-ring, t-butyl peroxide reacts with 3,4-epoxy-4-methylpentan-2-one with difficulty. However, the reaction of 3,4-epoxy-4-methylpentan-2-one with hydrogen peroxide takes place readily. A different reaction mechanism is proposed in this case: initially the epoxy-ring opens with formation of a keto-glycol, which is then oxidised to acetone and formic and acetic acids:



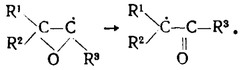
(14)

However, in most cases[57–59] the reactions of epoxy-compounds with hydrogen peroxide take place only on irradiation with ultraviolet light, which decomposes the peroxide into hydroxy-radicals. The hydroxy-radical formed abstracts a hydrogen atom with formation of a trialkylaryl-substituted epoxy-radical:



(15)

The latter may isomerise to a keto-radical. When an epoxyethane in which all the substituents were different was used, it was established[57] that the isomerisation is not accompanied by the migration of the R^1 or R^2 group to another carbon atom in the ring but takes place as a result of ring opening:



(16)

Unfortunately the authors do not consider the effect on the isomerisation process of the delocalisation of the unshared electron, which may alter to a considerable degree depending on the substituent. Thus the interaction of hydroxy-radicals with monosubstituted 1,2-epoxyalkanes also leads to the formation of epoxy-radicals but these isomerise to alkyl(aryl)formylmethyl radicals (VI) with migration of a hydrogen atom in the ring:

(17)

In contrast to trisubstituted epoxy-compounds, the products in this case are not ketones but aldehydes, which are probably formed by the reaction:

(18)

Furthermore, it is interesting to note that the products of the reactions of monosubstituted epoxy-compounds in which the substituents contain oxygen atoms (ether bond) include neither ketones nor aldehydes. Aldehydes may form in the isomerisation of epoxy-radicals but not the epoxy-compounds themselves, since the formation of propionaldehyde was not observed on irradiation of an aqueous solution of epoxypropane with ultraviolet light[59].

The oxidation of the aldehyde and (or) α-hydroxy-aldehyde formed as a result of the addition of a hydroxy-radical to radical (VI) probably leads to the formation of the corresponding acid, the reaction of which with the epoxyalkane yields an ester.

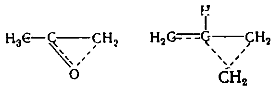
Photochemical liquid-phase chlorination of epoxyethane and epoxypropane with t-butyl hypochlorite was described by Walling and Fredricks[61] and that of epoxytrimethylethane and epichlorohydrin, by Razuvaev et al.[62] Epoxyethane, epoxypropane, and epoxytrimethylethane are converted under these conditions into monochloroepoxyethane, 2-chloroepoxypropane, and chloroepoxytrimethylethane

$$(CH_3)_3COCl \xrightarrow{h\nu} (CH_3)_3C\dot{O} + Cl\,, \qquad (19)$$

$$(CH_3)_3C\dot{O} + CH_2{-}CH{-}R \rightarrow CH_2{-}\dot{C}{-}R + (CH_3)_3COH, \quad (20)$$

$$(CH_3)_3COCl + CH_2{-}\dot{C}{-}R \rightarrow CH_2{-}CCl{-}R + (CH_3)_3C\dot{O}. \quad (21)$$

In the photochemical chlorination of the above epoxy-compounds with t-butyl hypochlorite there is preferential attack on the three-membered ring, the removal of a hydrogen atom from the ring, and the formation of α-chloro-epoxy-compounds, while in the chlorination of methylcyclopropane the chlorine atom enters the methyl group. It is suggested[61] that the attack on the epoxy-ring is due to the high electron availability adjacent to the ether oxygen. Furthermore, the epoxy-radical (1,2-epoxy-2-propyl) formed in this process is evidently more stable than the isomeric glycidyl radical:



However, in the photochemical chlorination of epichlorohydrin with t-butyl hypochlorite, the former behaves like methylcyclopropane, since in this case the main product was 3,3-dichloroepoxypropane[62], i.e. the glycidyl radical (XI) and not the epoxy-radical was formed.

Furthermore, in contrast to the observations of Gritter and Wallace[52], the radical (X) formed by reaction (20) did not isomerise to the keto-radical but reacted with t-butyl hypochlorite or its decomposition products to form α-chloroepoxy-compounds. These compounds then readily isomerised to carbonyl compounds with migration of the chlorine atoms to an adjacent carbon atom: chloroepoxyethane was converted into chloroacetaldehyde, and chloroepoxytrimethylethane into chloroisopropyl methyl ketone[62]:

$$(CH_3)_2{-}C{-}CCl{-}CH_3 \rightarrow (CH_3)_2CCl{-}\underset{\underset{O}{\|}}{C}{-}CH_3. \quad (22)$$

These data confirm yet again the view that the mechanism of the isomerisation of epoxy-compounds is determined primarily by their electronic structure.

The experimental data examined above show that the free-radical reactions of epoxy-compounds in the presence of initiators may be divided into three types: (1) reactions with ring opening as a result of attack by a free radical; (2) reactions involving the abstraction of a hydrogen atom from the α-carbon atom of the ring; (3) reactions involving the abstraction of hydrogen atoms in the allyl position with respect to the oxygen atom of the epoxy-ring, i.e. in the β-position with respect to the ring. The products contain hydroxy- and carbonyl-groups. The formation of carbonyl compounds from epoxy-compounds is due to the isomerisation of epoxy-radicals.

IV. PHOTOCHEMICAL REACTIONS OF EPOXY-COMPOUNDS BY A RADICAL MECHANISM

The photochemical decomposition of epoxyethane in the gaseous state was investigated by Phibbs et al.[63] Since epoxyethane has only one absorption band at 1713 Å,[64,65] its decomposition was sensitised by mercury vapour. The principal reaction products proved to be hydrogen, carbon monoxide, acetaldehyde, and a polymer; smaller amounts of methane, formaldehyde, and C_2 hydrocarbons were also detected. Bearing in mind the composition of the photolysis products and only slight dependence of their yield on pressure, the authors[63] believe that the isomerisation and decomposition processes are based on the reactions of excited epoxyethane molecules,

$$Hg(^3P_1) + CH_2{-}CH_2 \rightarrow CH_2{-}\dot{C}H + H + Hg(^1S_0), \quad (23)$$

and the polymerisation process has a free-radical mechanism. Homer and Noyes[66] carried out direct photochemical decomposition of epoxyethane at a wavelength < 2000 Å in the gas phase (10–100 mmHg, 27–250°C) and in a mixture with dimethylmercury. The reaction products were hydrogen, carbon monoxide, methane, ethane and smaller amounts of formaldehyde, acetaldehyde, and more complex aldehydes. The primary decomposition products are probably methyl and formyl radicals:

$$CH_2{-}CH_2 \xrightarrow{h\nu} \dot{C}H_3 + H\dot{C}O. \quad (24)$$

(IV)

Since the heat of dissociation of the formyl radical (IV) is close to zero and therefore its thermodynamic stability is almost independent of temperature, it should decompose as follows:

$$H\dot{C}O \rightarrow CO + \dot{H}. \quad (25)$$

The methyl radical mainly abstracts a hydrogen atom forming methane and to a lesser extent dimerises to ethane. With increase of the intensity of illumination and temperature, the methane : ethane ratio increases. The contribution of the reaction

$$H + CH_2{-}CH_2 \rightarrow H_2 + \dot{C}H{-}CH_2 \quad (27)§$$

(VIII)

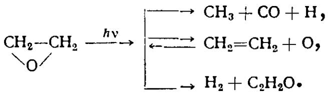
also increases with temperature. Part of the epoxy-radicals (VIII) decompose with elimination of carbon monoxide:

$$CH_2{-}\dot{C}H \rightarrow \dot{C}H_3 + CO \quad (28)$$

while others are stabilised by combining with other radicals and atoms.

The photochemical decomposition of epoxyethane sensitised by mercury[67] involves the formation of hydrogen, methane, ethane, propane, ethylene, carbon monoxide, acetaldehyde, higher homologues of acetaldehyde, and small amounts of a ketone. Cvetanovic[67] believes that the principal primary step is the decomposition of the excited epoxyethane molecule by reactions (23)–(25). He also postulates the molecular breakdown of epoxyethane into hydrogen and keten to a slight extent.

Evidently the mechanism of the photolysis of epoxyethane is complex and inadequately investigated. In order to avoid the effect of secondary reactions, Roquitte[68] subjected epoxyethane, tetradeuteroepoxyethane, and their mixtures to pulse photolysis at an effective wavelength of 1900 Å and energies of the light pulse up to 2160 J with the lifetime of a single pulse 44 ms. Hydrogen, methane, ethane, ethylene, carbon monoxide, and carbon dioxide were found among the photolysis products, but there were no aldehydes. The author believes that three parallel competing processes take place under these conditions:



$$CH_2{-}CH_2 \xrightarrow{h\nu} \begin{cases} \rightarrow CH_3 + CO + H, & (29) \\ \rightleftarrows CH_2{=}CH_2 + O, & (30) \\ \rightarrow H_2 + C_2H_2O. & (31) \end{cases}$$

---

§ Eqn. (26) is missing in the original Russian text (Ed. of Translation).

The principal stage of the process is reaction (29), since a high yield of carbon monoxide and its increase with light intensity are observed. Furthermore, 70% of hydrogen is also formed by reaction (29) and 30% as a result of the primary molecular reaction (31). The authors believe that the effect of reaction (30) is slight because of its reversibility. The relative quantitative contributions of reactions, (29), (30), and (31) to the pulse photolysis of epoxyethane are estimated as 2.3 : 1 : ≪ 1. Reaction (29) is analogous to the process described for photolysis with a low intensity of illumination[66] and reactions (30) and (31) were discussed by Cvetanovic[67,69]. In the photolysis of an equimolar mixture of C_2H_4O and C_2D_4O it was established[68] that 82% of the methane was formed from methyl radicals [reaction (29)] and 17.5% was formed with participation of methylene. The appearance of methylene can be explained by the decomposition of the excited keten molecule formed by reaction (31):

$$CH_2{=}C{=}O^* \rightarrow \dot{C}H_2 + CO. \qquad (32)$$

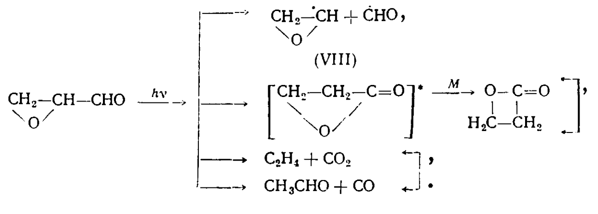
Carbonyl compounds, carbon monoxide, hydrogen, ethylene, and alkanes were the products of the photochemical decomposition of *trans*-2,3-epoxybutane in the gas phase[70]. When oxygen was added (about 0.5 mmHg), methanol was the principal photolysis product. An increase of pressure in the irradiation of pure *trans*-2,3-epoxybutane sharply reduces the yields of carbon monoxide, ethylene, propane, and particularly carbonyl compounds. It is believed that, with increase of pressure, the fragment C_3H_5O loses its excess energy in collisions and is stabilised by conversion into radical (IX), while at a low pressure it can isomerise to radicals (VI) and (VII) or decompose by the reaction

(33)

and further by reaction (25) or it can form $CH_3{-}C\substack{/\!\!/O \\ \backslash H}$ and $C_2H_5{-}C\substack{/\!\!/O \\ \backslash H}$ by reacting with $\dot{C}H_3$ and $\dot{C}_2H_5$.[67]

With increase of pressure, the quantum yield of the main photolysis product (isobutyraldehyde), formed at a low pressure [by the reaction of radicals (VI) with $\dot{C}H_3$] diminishes, since under these conditions the concentration of radicals (VI) falls. Cvetanovic and Doyle postulated the dissociation of the C–O bond in the epoxy-ring in the photolysis of *trans*-2,3-epoxybutane and the formation of "triplet biradicals" (I), similar to those which arose in the reaction between oxygen atoms and but-2-ene isomers $(CH_3{-}\underset{\dot{O}}{CH}{-}\dot{C}H{-}CH_3)$.[71] These radicals underwent intramolecular rearrangement and hardly decomposed. The dissociation of the C–H bond in the molecules of the epoxy-compound investigated was not observed during photolysis.

The gas-phase photolysis of glycidic aldehyde, one of the simplest of the bifunctional epoxy-compounds, was investigated by Goodspeed and Blacet[72] (irradiation at wavelengths of 3130 and 2654 Å, pressure 16–27 mmHg, 77–127°C). The decomposition of the aldehyde was represented by the following mechanism:

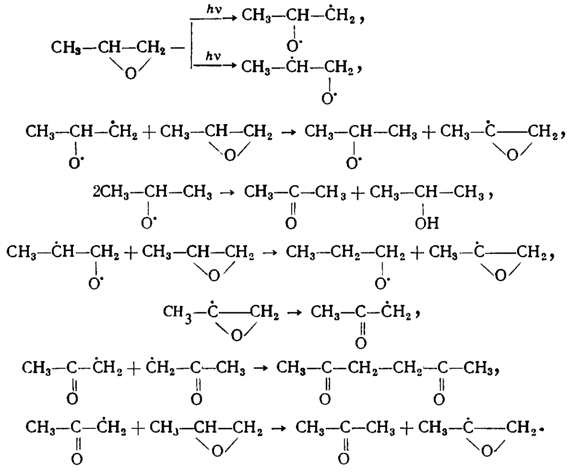


(34)
(35)
(36)
(37)

The radical (VIII) decomposes by reaction (28) and methyl and formyl radicals react with glycidic aldehyde giving rise to methane, carbon monoxide, $CH_3\dot{C}O$, and hydrogen and to carbon monoxide and $CH_3\dot{C}O$ respectively. It was established that at 3130 Å reactions (36), (37), and (34) consume 75%, 5%, and 10% of the energy absorbed respectively. Photochemical dissociation reactions (36) and (37) of the liquid propiolactone are also suggested.

In contrast to previous studies, where the epoxy-compounds were photolysed in the gaseous state, Sabatino and Gritter[54] initiated the free-radical reactions of a number of epoxy-compounds in the liquid phase at a wavelength of 2537 Å. The authors believe that pulse illumination and low conversions reduced the likelihood of secondary reactions. Epoxypropane was irradiated both in the presence and absence of oct-1-ene; epoxycyclohexane and epoxyethylbenzene were irradiated in a pure form. The reaction products suggested that the decomposition of all the epoxy-compounds was of the same type.

Like Cvetanovic[70], Gritter and Sabatino¶ believe that the most important factor is the primary homolytic cleavage of one or other C–O bond in the ring with formation of biradicals of type (I). To account for the radical mechanism of the photolysis of epoxypropane, for example, and the formation of a ketone, aldehydes, an alcohol, and a dimer, they suggest the following sequence of stages:



(38)
(39)
(40)
(41)
(42)
(7)
(43)
(44)

Referring to Walling[73], the authors state that the rearrangement of the initially formed biradicals into a ketone and an aldehyde, involving the migration of a hydrogen atom, is exceptionally fast. The acetonyl radical interacts with oct-1-ene by reaction (8). Although the authors attempted to exclude the occurrence of secondary reactions, Table 3 shows that in the photolysis of epoxypropane it was impossible to achieve this completely. The high content of acetone in the photolysis products (about 70% when acetonylacetone is allowed for) introduces additional difficulties into the interpretation of the mechanism of the photolysis, since acetone may be consumed in the photosynthesis of acetonylacetone[74,75]. Under the experimental conditions where the system was irradiated with light corresponding to the absorption band of ketones, acetone may also have served as a source of acetonyl radicals but this possibility was not taken into account; the effect of oxygen on various radicals and the process as a whole is obscure (the report does not state that the photolysis was carried out in a vacuum).

¶ J. Org. Chem., 29, 1965 (1964) (Ed. of Translation).

Although the suggested mechanism, as in very many other cases, is speculative and controversial and requires experimental confirmation, nevertheless the important role of acetonyl radicals in it and the preferential dissociation of C–O bonds are noteworthy. If 1-C–H and especially 2-C–H bonds were dissociated (which does not entail the isomerisation of the ring), it would be difficult to account for the formation of alcohols, while the dissociation of the C–C bond excludes the formation of even one of the observed reaction products.

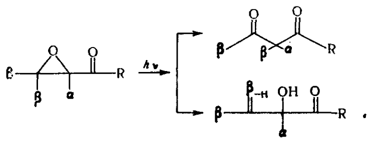
Table 3. Composition of the photolysis products of epoxypropane, epoxycyclohexane, and epoxyethylbenzene

Reactant	Reaction products	Site of dissociation	Conversion, %
Epoxypropane	acetone	C–1–O	0.28
	isopropyl alcohol	C–1–O	0.21
	acetonylacetone	C–1–O	0.22
	propionaldehyde	C–2–O	0.01
	propyl alcohol	C–2–O	0.01
Epoxycyclohexane	cyclohexanone	C–O	0.23
	cyclohexanol	C–O	0.14
Epoxyethylbenzene	acetophenone	C–1–O	0.03
	2-phenylethanol	C–1–O	0.14
	1-phenylethanol	C–2–O	0.13

Earlier it was noted that the absorption band of the epoxy-group in the electronic spectrum is in the far ultraviolet and the position of its absorption maximum does not differ markedly from that corresponding to the ethylene double bond. The conjugation of the ethylene double bond with the carbonyl group in the molecule of an $\alpha\beta$-unsaturated carbonyl compound results in a considerable shift of the absorption bands of both groups towards longer wavelengths[76]. A similar effect may be observed in $\alpha\beta$-epoxy-ketones where the ethylene double bond is replaced by an epoxy-group[72,77], which makes it possible to carry out the photolysis with ultraviolet light at longer wavelengths.

One of the first investigations of the photochemical reactions of $\alpha\beta$-epoxy-ketones was carried out by Bodforss[24,25].

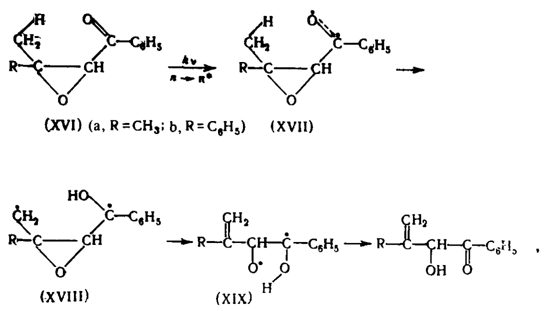
The photochemical rearrangement of $\alpha\beta$-epoxy-ketones may lead to the formation of a β-diketone [reaction (45)][24,78–81] or a keto-alcohol [reaction (46)][79]:



(45)

(46)

The formation of β-diketones entails the migration of the substituent from the β-carbon atom in relation to the carbonyl group to the α-carbon atom. The possibility of absorption of ultraviolet light by the epoxy-ring is disregarded and its cleavage is attributed to the effect of the carbonyl group[79,81]. The opening of the epoxy-ring in 1,2-epoxy-2-methylpropyl phenyl ketone (dimethylacrylophenone oxide) (XVIa) and 1,2-epoxy-2-phenylpropyl phenyl ketone (dypnone oxide) (XVIb) takes place as a result of the $n\rightarrow\pi^*$ excitation of the carbonyl group and subsequent rearrangement of the molecule by mechanism (47).[79] As a result of intramolecular photochemical dehydrogenation, in which the excited carbonyl group of compound (XVII) abstracts a hydrogen atom from the methyl group, the biradical (XVIII) is formed. The presence of an unpaired electron at the methylene group linked to the epoxy-ring favours the homolytic dissociation of the C–O bond, giving rise to the biradical (XIX) in which the semiquinone group $>\dot{C}{-}OH$ derived from the carbonyl group responsible for the photochemical dehydrogenation remains unchanged. In the last stage intramolecular disproportionation leads to the final reaction product:



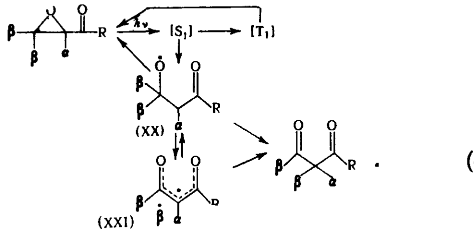
(47)

Together with the intermolecular photochemical dehydrogenation reactions known previously, reaction (47)[82] may be used for preparative intramolecular photochemical dehydrogenation of $\alpha\beta$-epoxy-ketones[79].

As a result of the photochemical reaction involving the excitation of the non-bonding electrons of the oxygen atom in the carbonyl group, 3,4-epoxy-4-phenyl-2-pentanone and 3,4-epoxy-4-methyl-2-pentanone rearrange to β-diketones [reaction (45)] with migration of the methyl group[78,79,83] in contrast to reaction (47). In a discussion of the reactivity of the carbonyl group in the excited $n\rightarrow\pi^*$ state it was noted[79,84,85] that the groups attached to the carbon atom adjoining the excited C=O group may undergo homolytic cleavage. Evidently reaction (45) does in fact begin with such cleavage. The cleavage of the C–O bond in the epoxy-ring, in contrast to the abstraction of a hydrogen atom from the γ-carbon atom in compound (XVI), is attributed[79] to an excited π^* electron which is more localised at the carbonyl group of 3,4-epoxy-4-methyl-2-pentanone and 3,4-epoxy-4-phenyl-2-pentanone and to the greater probability of C–O dissociation, since in compound (XVI) the excited electron is delocalised over both the carbonyl and phenyl groups and its effect is reduced.

In a study of the photochemical rearrangements of $\alpha\beta$-epoxy-ketones to β-diketones, an unusual sequence of various β-groups as regards their capacity for migration was observed[78,79,81,86,87]: diphenylmethyl and benzyl > hydrogen > methylene > methyl > phenyl.

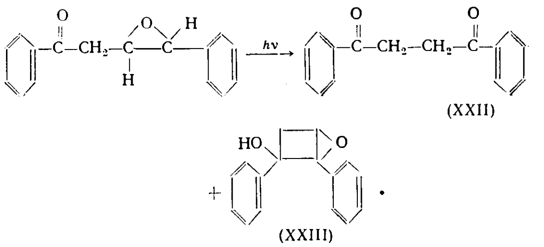
An important aspect of the mechanism of the photochemical rearrangement of epoxy-ketones was established by Markos and Reusch[81] [reaction (48)][81], who observed that the photochemical reactions of $\alpha\beta$-epoxy-ketones take place via the singlet excitation of the molecule [S] and the intermediate state (XX), bypassing the triplet state [T], since the rearrangement of epoxy-ketones proved to be insensitive to the presence of oxygen, a change of solvent, and the addition of reagents quenching triplet states.



(48)

To account for the anomalous capacity for migration and the formation of fragmentation products, it was assumed that the migrating group is a radical and that a radical pair is formed in the cage (XXI) from the intermediate state (XX). Unsaturated $\alpha\beta$-epoxy-ketones were much more stable in relation to the $n \rightarrow \pi^*$ excitation of the carbonyl groups than their saturated analogues[87].

The photochemical rearrangement of $\beta\gamma$-epoxy-ketones, for example *trans*-3,4-epoxy-1,4-diphenylbutan-1-one, leads to the formation of a γ-diketone (XXII) and an alcohol to which the structure (XXIII) is attributed:



(49)

It is suggested[88] that epoxycyclobutane may be formed by reaction (47) with the sole difference that the semiquinone reacts with the unshared electron of the γ-carbon atom, forming a new C–C bond.

Temnikova and coworkers[89–93] and a group of American investigators[94–100] obtained new, novel data on the radical mechanism of the photolysis of epoxy-compounds. They made the interesting observation of the intermediate formation of carbenes on irradiation with ultraviolet light of a number of epoxyethane derivatives (Table 4). The arrows indicate the chemical bonds in the three-membered ring which are preferentially cleaved during photolysis, i.e. the arrow separates the carbene formed. The remaining molecular fragment rearranges very rapidly to the corresponding carbonyl compound. As a rule, all the epoxy-compounds were irradiated in methanol or olefin solution. The type of solvent was probably dictated by the endeavour to demonstrate the existence of carbenes on the basis of the composition of the product formed by typical secondary reactions. Indeed, irradiation of epoxy-compounds 1 and 11 (Table 4) in methanol gave an almost quantitative yield of methoxydiphenylmethane[89,94], while irradiation of a solution of epoxy-compound 5 gave α-methoxyphenylacetonitrile[99]. In the presence of olefins the photolytic decomposition of epoxy-compounds takes place with formation of the corresponding cyclopropane derivatives, which is generally regarded as proof of the presence of carbenes. Thus the photolysis of the cyanoepoxy-compound 6 (Table 4) in tri- and tetra-methylethylene gave good yields (80%) of cyclopropane derivatives with the cyano-group attached to the three-membered ring. This process has been suggested as a preparative method for the synthesis of phenylcyanomethylene[92].

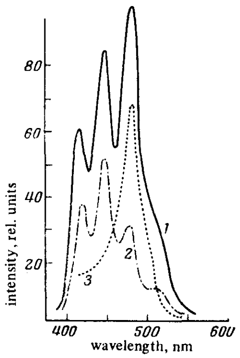
Convincing direct evidence for the formation of carbenes in the photolysis of epoxy-compounds was obtained recently. The carbenes were identified by a luminescence technique and by an ESR method in irradiated epoxy-compounds 10 and 11 (Table 4) at −196°C in methylcyclohexane solution. The Figure shows the luminescence spectrum of the irradiated epoxy-compound 11 (Table 4). The authors[100] showed that part of the total luminescence spectrum corresponds to the phosphorescence of benzophenone (the carbonyl-containing fragment of the molecule of compound 11 after its photochemical decomposition) and another part to the fluorescence of the diphenylcarbene biradical (III). The latter spectrum corresponded fully to the luminescence spectrum of diphenylcarbene obtained by a different method[101,102]. According to the ESR spectra of the irradiated solution of compound 11, diphenylcarbene has a triplet ground state (the spins of the free electrons are parallel), i.e. it may be regarded as a biradical.

Table 4. Epoxy-compounds yielding carbenes on photolysis

Formula	Epoxy-compound	Solvent, concn.	decomp. path way	References
1 	epoxy-1-methoxy-1,2,2-triphenylethane	methyl alcohol, trimethylethylene	*B*	89
2 	epoxy-1-methoxy-1,2-diphenylethane	trimethylethylene, tetramethylethylene	*B*	91
3 	epoxy-1-methoxy-2,2-dimethyl-1-phenylethane	trimethylethylene	*B*	89
4 	epoxy-1-methoxycarbonyl-1,2-diphenylethane	methyl alcohol, trimethylethylene	*A*	93,99
5 	1-cyanoepoxy-1,2-diphenylethane	trimethylethylene, tetramethylethylene, methyl alcohol (0.1 M), 2,3-dimethylbut-2-ene (0.5 M)	*A*	91,94 98,99
6 	1,2-dicyanoepoxy-1,2-diphenylethane	trimethylethylene, tetramethylethylene	*A*, *B*	92
7 	1-cyanoepoxy-1,2,2-triphenylethane	methyl alcohol (0.3 M), 2,3-dimethylbut-2-ene (0.3 M), 2-methylbut-2-ene	*A*	94,98 99
8 	1-cyanoepoxy-2,2-pentamethylene-1-phenylethane	methyl alcohol (0.3 M), 2,3-dimethylbut-2-ene (0.3 M)	*A*	99
9 	*trans*-epoxy-1,2-diphenylethane *trans*-(stilbene oxide)	2-methylbut-2-ene	*A*,*B*	94
10 	epoxytriphenylethane	methylcyclohexane (10^{-4} M), 2-methylbut-2-ene + benzene, 2-methylbut-2-ene	*A*	94,100
11 	epoxytetraphenylethane	methyl alcohol + benzene and methylcyclohexane (10^{-4} M)	*A*,*B*	94,100
12 	epoxy-1,2-dimethyl-1,2-diphenylethane		*A*,*B*	96

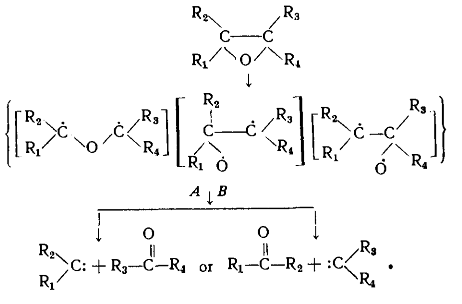
Thus, together with photolytic cleavage of diazo-compounds and ketones, a new source of biradicals with a wide variety of substituents has been found, namely epoxy-compounds. The photochemical method for the generation of carbenes from epoxy-compounds was discovered recently and is therefore not included in Kirmse's monograph[34].

The experimental data from the investigations considered[89-99] permit certain conclusions concerning the radical mechanism of the photolysis of epoxy-compounds. Although in all these investigations[89-99] without exception, starting with the first report by Kristinnsson and Griffin[94], the dissociation of the C–C bond is suggested as the primary step in the photolysis of the epoxy-rings, there is no convincing evidence for the reaction by this pathway. It appears desirable to represent the photolysis of epoxy-compounds by mechanism (50). We may also note that later Griffin and Kristinnsson changed their view on the primary stage of the process[100].



Luminescence spectra of the photolysis products of epoxytriphenylethane: *1*) overall luminescence spectrum; *2*) phosphorescence spectrum; *3*) fluorescence spectrum (the difference between the total luminescence and phosphorescence). Conditions of photolysis: 10^{-4} M solution of epoxytetraphenylethane in methylcyclohexane; temperature 77°K; duration of irradiation 20 s; wavelength 2537 Å.

The nature and number of substituents of the epoxy-ring are of decisive importance for the occurrence of reaction (50) by pathways *A* and *B* and for the very possibility of the formation of the carbene. Examination of data on the photochemical reactions of epoxy-compounds shows that carbenes are not formed from epoxyethane and its monosubstituted derivatives. On the other hand, methylene appearing in the photolysis of epoxyethane is not a product of the direct breakdown on the epoxy-compound [reaction (32)] but is formed in subsequent reactions[68]:



(50)

The determination of the sequence of the dissociation of the C–C or one of the C–O bonds in the epoxy-ring under the influence of ultraviolet light constitutes a very complex problem, which requires solution and a theoretical treatment. The mode of photochemical decomposition of the epoxy-ring is determined by the electromeric effect of the ring substituents[89-91,93] and the degree of weakening of the bonds in the ring. Furthermore, account must be taken of the isomeric structure of the molecules[90,94,99] and the effect of reactive solvents, for example, acetone[72] or methanol, both on the reaction and the polarisation of the C–O bonds in the three-membered ring, which has been scarcely investigated. Different views have been expressed about the effect of methanol on the epoxy-group. In one case[103] such an effect was noted (a shift of the band due to the hydrogen bond in the infrared spectrum of the same order of magnitude as for the methanol–acyclic ether pair, namely 80–99 cm^{-1}), while in another case[104] such an effect was denied (the infrared spectra of mixtures of epoxyalkanes and alcohols failed to reveal any interaction between them). In a third communication[105] it is stated that the interaction of the hydroxy-group with the ring involves the electrons of the C–O bond and that it occurs when the hydroxy group approaches not the apex of the ring but its plane. Account must also be taken of the effect of the size of the incident quanta, the duration of the irradiation, and the sensitisers used. Although compounds 10 and 11 (Table 4) do not absorb light at wavelengths higher than 3000 Å, their irradiation with light at a wavelength of 2537 Å for only 5 s is sufficient to cause further photolysis on irradiation with light at a wavelength of 3500 Å, which suggests a sensitising effect by the photochemical decomposition products[100]. The introduction into the reaction medium of photosensitisers, for example benzophenone (a decomposition product of compound 11, Table 4), leads to an increase of the yield of diphenylcarbene compared with non-sensitised photolysis. Possibly the photosensitiser arising in the photochemical decomposition of epoxy-compounds facilitates the transition of diphenylcarbene as well as other carbenes to a triplet state, as in the formation of triplet methylene in the presence of benzophenone[106], and thereby influences the reaction.

V. RADICAL PROCESSES IN EPOXY-COMPOUNDS INDUCED BY HIGH-ENERGY RADIATION

The radiation-chemical reactions of epoxy-compounds are the least investigated branch of the chemistry of three-membered heterocycles. The explanation is that the radiolysis of epoxy-compounds began to be investigated only in recent years and the radiation processes are extremely complex, since they involve the simultaneous occurrence of reactions with participation of radicals, radical-ions, ions, etc. These factors make it difficult to elucidate the mechanisms of the radiation-chemical reactions of epoxy-compounds.

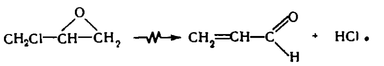
One of the first tasks undertaken in the study of radiation-induced reactions of epoxy-compounds consisted in the investigation of their polymerisation. For this purpose, epoxyethane was irradiated. However, it did not polymerise either in the liquid[107,108] or solid[109,110] phases or in methylene chloride solution[107]. A polymer was obtained in 0.22% yield by irradiating epoxyethane in the solid phase (dose 8 Mrad, dose rate 15.5 rad s^{-1}, −80°C, vacuum)[111]. By changing the irradiation conditions (41.6 Mrad, 50 rad s^{-1}, room temperature), the yield of the polymer was increased to 1.37%. The addition of inorganic oxides (ZnO, SiO_2, MgO, and As_2O_3) had little effect on the yield of the polymer.

Hoshino et al.[112] observed the formation of a polymer and acetaldehyde from epoxyethane and determined their yields. The gaseous products evolved were analysed. They concluded that the radiation-induced decomposition of epoxyethane involves both radical and molecular mechanisms, the polymerisation reaction predominating.

Frequent attempts to achieve the radiation-induced polymerisation of pure epoxypropane by a radical mechanism were unsuccessful[107,109,110,113-115]. Nevertheless the absence of a polymeric product in the irradiated epoxypropane cannot be regarded as proof that radical processes are impossible. An ESR study of the radiolysis of epoxypropane (between −140° and −170°C) established the formation of two types of radicals and their structure. Trofimov and Chkheidze[116] showed that the ESR spectrum of irradiated epoxypropane is produced by the superposition of a triplet with $\Delta H_T = 18$ Oe and the spectrum with a line width $\Delta H_{tot} = 82$ Oe. The glycidyl radical (XI) ($\Delta H_\alpha = 18.5$ Oe, $\Delta H_\beta = 0$) makes the main contribution with a small contribution by the epoxy-radical (VIII) (hyperfine structure splitting of 82 Oe). Radicals formed as a result of the opening of the three-membered ring were not detected.

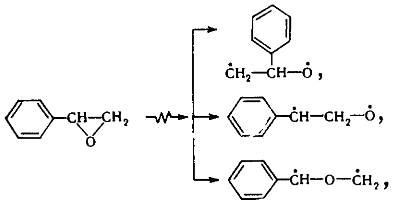
Tabata[114] and Tabata and Sobue[117,118] described the synthesis of a homopolymer of epoxypropane in the liquid and solid phases mixed with epoxyethylbenzene. Whereas previously the authors considered the radiation-induced polymerisation of epoxypropane in the presence of epoxyethylbenzene from the standpoint of a radical mechanism, in their latest publication[115] they concluded that the process has an ionic mechanism (low activation energy, the absence of an effect by radical inhibitors).

Radiation-induced polymerisation of epichlorohydrin (ECH) in the solid[110] and liquid states[119,120] was not observed. The infrared spectra of irradiated epichlorohydrin show new bands at 3450 cm^{-1} (hydroxy-groups) and 1720 cm^{-1} (carbonyl group) (cobalt-60 radiation, 400 Mrad). It has been noted[121] that the epoxy-ring is opened on radiolysis of epichlorohydrin with formation of carbonyl and hydroxy-groups and probably ether bonds (band with a maximum at 1065–1120 cm^{-1}). The viscosity of epichlorohydrin increases in the course of irradiation. Dichlorohydrin, acrolein and water (liquid phase) and hydrogen, methane, ethane, propane, and an unknown substance (gas phase) were detected among the radioysis products. One of the possible pathways in the formation of dichlorohydrin is as follows. H or Cl radicals are split off during the radiolysis and either recombine to HCl or abstract chlorine and hydrogen respectively from the epichlorohydrin molecule. Further reaction of hydrogen chloride with epichlorohydrin takes place by the familiar mechanism[122]. Acrolein may be formed from epichlorohydrin as a result of the elimination of hydrogen chloride:



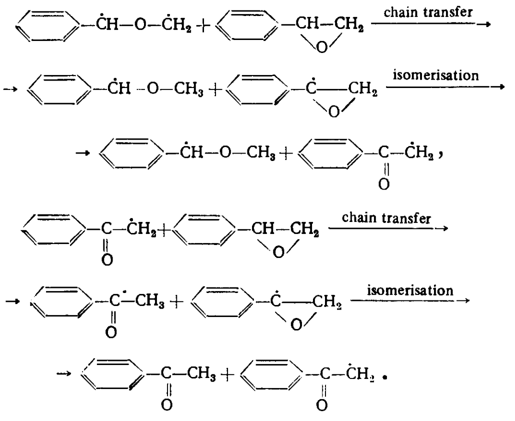
(51)

Epoxyethylbenzene polymerises on cobalt-60 irradiation (8–54 rad s^{-1}) or irradiation with accelerated electrons (8×10^4–2×10^5 rad s^{-1}) at temperatures between −196° and 140°C in the solid and liquid phases[114,115,117]. The rate of radiation-induced polymerisation of epoxyethylbenzene and its conversion increase with temperature. The radiation-chemical yield at 140°C is $G_{-M} = 1000$. The overall activation energy for the liquid-phase process is 6.25 kcal $mole^{-1}$. An increase of the dose increases the yield of the polymer and the degree of polymerisation. Benzoquinone (2%, 20°C, dose rate 23.8 rad s^{-1}) inhibits the reaction over a period of 150 h. All these data support a radical chain mechanism of the radiation-induced polymerisation of epoxyethylbenzene. In their discussion of the process mechanism, the authors postulate the formation of three types of biradicals arising on dissociation of the principal bonds of the epoxy-ring:



(52)
(53)
(54)

and suggest that the reaction takes place simultaneously by several pathways. In one of these the interaction of the primary radical with the monomer is represented by the following mechanism taking into account repeated chain transfer (abstraction of hydrogen atoms) and isomerisation:



(55)
(56)

The importance of the role of fast chain transfer and isomerisation reactions in this mechanism appears to be significantly responsible for the low rate of propagation and for the presence of stages in the reaction[118].

Colichman and Strong[123] did not observe any changes in an epoxy-resin after irradiation (cobalt-60, 100 Mrad, 55 rad s^{-1}, 38°C) and decided that radiation cannot promote the interaction in resins involving epoxy-groups. Nor was polymerisation observed after the irradiation of the pure diglycidyl ether of 2,2-di(*p*-hydroxyphenyl)propane[119].

On the other hand, it has been shown that epoxydian† resins (EDS) of types ED-5, ED-6, EDP, and EDL not only polymerise but are also cross-linked under the influence of high-energy radiation at room temperature without the use of hardening agents[124-128]. The study of the radiation-chemical reactions of these resins showed that the epoxy-group is the most sensitive unit in their molecule. The rate of decomposition of the epoxy-rings in the resins of all types was the same, being proportional to the dose both in a vacuum and in the presence of atmospheric oxygen. It is independent of the phase state (under the usual conditions, the ED-5 and ED-6 resins are liquid and EDP and EDL are solid) and the molecular weight of the resin in the range 370–1200, of the initial content of epoxy-groups in

---

† Dian = di(*p*-hydroxyphenyl)dimethylmethane (Ed. of Translation).

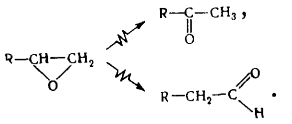
the resins (9–22%), and of the dose rate. The radiation-chemical yield of the reactions of the epoxy-groups proved to be 2.66 groups/100 eV. The rate of decomposition of epoxy-groups increases with temperature. The increase of the density, refractive index, and molecular weight varies linearly with the dose. These changes convincingly demonstrate the occurrence of radiation-induced polymerisation of unhardened epoxydian resins.

The nature of the radiation-chemical reactions of the epoxy-rings were inferred, in particular, from the changes in the infrared spectra. The intensity of the 915 cm^{-1} band (epoxy-groups) decreased, the band in the region of 3500 cm^{-1} became broader and more intense (hydroxy-groups and intermolecular hydrogen bonds), and a new band appeared at 1720 cm^{-1} (carbonyl groups). The formation of carbonyl groups and the increase of the concentration of hydroxy-groups cannot be attributed to radiation-induced oxidation reactions. There is a genetic relation between the decomposition of epoxy-groups and the formation of carbonyl groups and also the increase of the concentration of hydroxy-groups. Possibly it is revealed in the interaction of the epoxy-groups of two molecules of an epoxydian resin:

(57)

As already mentioned, the formation of carbonyl groups from epoxy-rings is evidence of the occurrence of radical processes.

One of the causes of the low rate of radiation-induced polymerisation of the resin is intramolecular rearrangements, which in fact lead to the consumption of epoxy-groups but do not give rise to an increase of the molecular weight. Depending on the site of the homolytic cleavage of the ring, ketones and aldehydes may be formed:



(58)

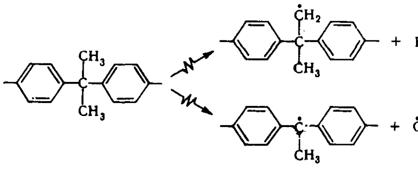
(59)

The formation of carbonyl groups, which is accompanied by the breakdown of epoxy-groups and a linear increase in the length of the resin molecules, can also occur as a result of the following reaction:

(60)

The radiation-chemical yield of the total gaseous product is smaller by a factor of almost 36 than the decomposition yield of the epoxy-groups and amounts to 0.074 mol./100 eV. The gaseous mixture consists mainly of hydrogen, but since $(G_{\text{-ep.gr.}}/2)/G_{\text{gas}} \ll 1$, reaction (60) occurs relatively rarely even if it is assumed that it is the sole source of hydrogen.

The molecular-structural changes in solid epoxydian resins were investigated by Bakaeva et al.[120] (cobalt-60, 1500 Mrad, 84–2100 rad s^{-1}).[120] In view of the similarity of the ESR spectra of irradiated 2,2-di(*p*-hydroxyphenyl)-propane and the resin, the authors believe that the primary radiation-chemical steps in the resins are the following radical reactions:

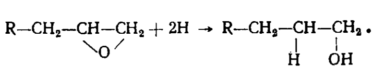


(61)

(62)

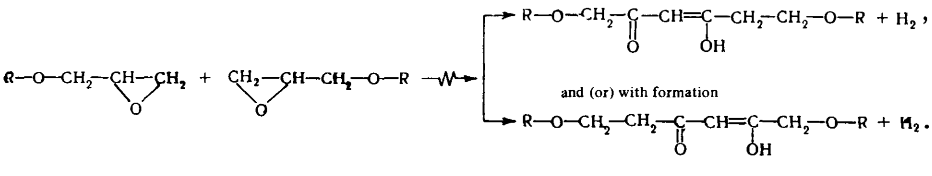
As assumed by Bakaeva et al.[120], the formation of bonds between resin molecules occurs only as a result of the interaction between radicals formed by reactions (61) and (62). However, such a reaction is complicated by the rigidity of the *p*-phenylene unit[129,130] and of the entire resin molecule[126], i.e. a sharp decrease in mobility and greater inhibition of the rotation of all the units of the molecular chain, when the resin solidifies[131]. Furthermore, a change in the type of substituent or an increase in the length of the side chain at the central dian atom might lead to a change in the ultraviolet spectrum of the compound when the concentration of new bonds is sufficiently high[132]. However, after irradiation with a dose of 500 Mrad the ultraviolet spectra of the resins proved to be identical with those of the non-irradiated resins. This indicates, firstly, a low probability of the reactions of the above radicals with one another, secondly, the absence of reactions involving addition to the benzene ring in the *o*- and *m*-positions, and, thirdly, the high radiation stability of the bond between the quaternary carbon atom and the phenyl rings in the resin molecules[128].

Like Colichman and Strong[123], Bakaeva et al.[120] do not postulate a linear growth of the resin molecules and the participation of the epoxy-groups in this process. They believe[120] that the epoxy-groups decompose by reaction (58) or form a primary alcohol as a result of hydrogenation:



(63)

The radiation-chemical reactions of the diglycidyl ether of ethylene glycol (DEG) obey very largely the same relations as the reactions of epoxydian resins[125,127,128]. The absence of aromatic rings from DEG favours more vigorous gas evolution ($G_{\text{gas}} = 0.95$ mol./100 eV) and decomposition of epoxy-groups ($G_{\text{-ep.gr.}} = 5.66$ groups/100 eV). On the basis of chemical analyses and ultraviolet and infrared spectra, it has been suggested that, on irradiation of DEG, the enol of a β-diketone is formed apart from the occurrence of reaction (57):



(64)

(65)

Polyfunctional epoxy-compounds the molecules of which contain, in addition to epoxy-rings, various other reactive groups, for example, double bonds are of definite interest. Glycidyl methacrylate (GMA) polymerise in the solid state (cobalt-60, 0.4 Mrad, 3–600 rad s^{-1}) by a radical chain reaction with bimolecular chain termination[133]. After 10–15% conversion, a gel fraction is formed. The appearance of a three-dimensional structure is regarded as proof of the involvement in the reaction of both functional groups, since it is well known that monofunctional monomers, for example, methyl methacrylate and butyl methacrylate (the closest analogues of GMA) are degraded and not cross-linked by radiation. In the initial stage of the process the polymerisation of GMA involves mainly the double bonds. But even in this stage the epoxy-groups are involved also.

The data presented show that, under the action of high-energy radiation, radical processes occur in epoxy-compounds as a result of which they can polymerise via the epoxy-groups, isomerise to carbonyl compounds, and give rise to ethers and hydroxy-groups. Despite some analogy with the double bond[134], the three-membered epoxy-ring is much less reactive.

---o0o---

The data presented show that under certain conditions epoxy-compounds may react by a radical mechanism. Despite the various methods of initiation of the radical reactions of epoxy-compounds, the results are the same in most cases—cleavage of the C–O bond of the ring. The site of the dissociation of the bond is little affected by the form of activation: nuclear vibrations (pyrolysis), electron excitation (photochemistry), radical attack (chemical initiation), and radiation-induced reactions. The electronic structure of their molecules plays a decisive role in the mode and rate of the reactions of epoxy-compounds. It is reasonable to expect that the epoxy-ring may be cleaved at different sites, since the strength of the bonds in it depends on the substituents. Consequently one of the most important tasks in the study of the mechanism of the radical processes involving epoxy-compounds is the identification of the intermediate products in order to establish the site of the dissociation of the chemical bonds in the epoxy-ring and the effect on the cleavage of the number and nature of the substituents at the ring carbon atoms.

Aromatic Polyethers

V.V.Kopylov

Aromatic polyethers which have found industrial application are surveyed. The formation, structure, and properties of poly(phenylene oxides) are described. A list of 361 references is included.

CONTENTS

I. INTRODUCTION AND CLASSIFICATION

Aromatic rings and ether bonds are among the chemical groupings which possess great resistance to heat and to thermal oxidation. It is not surprising, therefore, that aromatic polyethers—poly(arylene oxides)—have found wide application as high-temperature materials. Furthermore, the benzene rings in phenyl ethers are not coplanar, but are inclined at an angle to one another[1]. Such arrangement results in absence of resonance conjugation between these rings, so that they can easily rotate relative to one another through a solid angle of 120°.[2] Because of this combination of stability and mobility the arylene oxide unit is very frequently used to confer flexibility on the macromolecules of thermostable polymers. The introduction of such units into macromolecules usually results in an improvement in the solubility and the elasticity of the polymer, while its mechanical and thermal stability are maintained, as has been confirmed experimentally on series of such polymers as the polybenzimidazoles, polybenzothiazoles, polybenzoxazoles[3], polypyromellitimides[4-7], polythiazoles[8], polycarbonates[9-12], polyamides[13], poly-1,3,5-triazines[14], polyester–amides[15], polyquinoxalines[16], polysulphones[17-20], polysulphonamides[21], polybenzylenes[22,23], polyperfluorobenzylenes[24], polyphenylenes[25,26], poly(phenylene borates)[27], etc.

The Dowtherm high-temperature heat-transfer agents—eutectic mixtures of diphenyl ether with biphenyl and naphthalene—which have been known since the 1930s, may be regarded as the first industrial materials of this type[28,29]. The principal subsequent developments on these lines have been due mainly to chemists working for the Dow and Monsanto firms, and in recent years the General Electric Company.

Poly(arylene oxides) are met in Nature only in the form of poly(phenylene oxide) resins having molecular weights up to 5000, in which the ether bonds are oriented in the *meta*-position relative to one another. These resins can be isolated from certain petroleums by repeated reprecipitation with petroleum ether from oxolan solution[30]. No such results are yet available for the *para*-isomers. The possibility of the existence of poly-(*o*-phenylene oxides) is doubtful because of steric hindrance, although they are mentioned in some patents.

With few exceptions the aromatic polyethers which have hitherto been synthesised and investigated have been benzene derivatives. In the literature they are denoted by several different terms. In the present Review we shall use the name *phenylene oxides*. The reason for this choice is that, although all the terms equally reflect the chemical structure of the compounds, only the above name corresponds to those adopted in the chemistry of macromolecular compounds, such as poly(phenylene sulphides), poly(phenylene sulphoxides), polyphenyleneimines, etc.

Phenylene oxides of low and of high molecular weight differ substantially in methods of preparation, properties, and fields of application, and merit separate consideration. In the present Review, therefore, all phenylene oxides are divided into three classes—(*a*) oligomeric phenylene oxides, containing up to 10 benzene rings in the molecule, (*b*) meso(phenylene oxides), containing 10—100 benzene rings, and (*c*) poly(phenylene oxides), containing more than 100 benzene rings, and exhibiting all the properties of high polymers.

II. OLIGO(PHENYLENE OXIDES)

Oligo(phenylene oxides) can in turn be provisionally divided into two groups—neutral, consisting only of ether bridges and benzene rings having alkyl or halogen substituents; and functional derivatives, containing such groups as hydroxyl, carboxyl, amino, sulpho, etc. in the framework.

1. Synthesis of Neutral Oligo(phenylene Oxides)

The chief method of synthesis consists in building up the chain step by step by the Ullmann condensation of alkali-metal phenoxides or phenoxyphenoxides with aryl halides in the presence of catalytic quantities of copper powder[31-33]. A mechanism of heterolytic substitution had been suggested earlier for this process, but evidence has recently been obtained that the reaction involves the formation of free radicals of phenoxyl type[34,35]. A search for optimum conditions for the synthesis of oligo(phenylene oxides) has shown that, in order to increase the purity and the yield of the required product, the process must be conducted in solution or in suspension in a highly polar organic solvent having a high boiling point, especially in one which is a single-electron carrier, whether in the form of a solvated electron (ether)[36,37] or in the form of a radical-anion (ketone)[38,39]. In several cases copper salts and their complexes are used instead of metallic copper as catalyst. It is sometimes useful to activate the reaction with ultraviolet radiation, iodine, or a free-radical catalyst[40].

The structure of the oligomers is determined by that of the initial compounds: isomerisation has not been observed during synthesis. The initial phenoxyphenols are usually obtained also by Ullmann condensation. A promising method of preparing phenoxyphenols is the "radical acidolysis" of poly(phenylene oxides)[41],[42]:

The aryl halides are prepared by the usual methods, and if necessary are isomerised by means of aluminium chloride[43]. The greatest influence on the reactivity of phenoxyphenols in the Ullmann condensation is exerted by substituents located *ortho* and *para* to the hydroxy-group, the reactivity being diminished by electron-acceptor substituents, and increased by electron-donor substituents. The halogen in the aryl halide and the process conditions have a considerably greater effect. It has been found that the activity sequence of the halogens is $I \simeq Br > Cl \gg F$ [44]; in the synthesis of the polyethers $I > Br > Cl$ and *para* > *ortho* ≫ *meta*.

It has been noted several times that the synthesis of oligo(phenylene oxides) is accompanied by several side-reactions. The effect of oxygen is especially injurious, quinones and biphenylquinones being formed in its presence. Since these impurities catalyse decomposition of the oligomers, purification of the final product becomes particularly important. Ordinary fractional distillation and recrystallisation are usually ineffective. The best results are obtained by treatment with silica and alumina in a flow system (chromatography) or in solution with subsequent filtration and fractional distillation, by zone melting, or by treatment with ion-exchange resins or alkali metals[45-50].

2. Synthesis of Oligo(phenylene Oxides) containing Functional Groups

Functional groups are introduced into oligo(phenylene oxides) either by the choice of appropriate initial compounds containing protected functional groups, e.g. alkoxylated aromatic compounds, the protection being removed after condensation, or by appropriate chemical treatment of the neutral oligomers. Since an aromatic ether bond possesses great chemical stability, both methods are quite effective. Thus dihydroxylated oligo(phenylene oxides) have been obtained[10],[51] by hydrolysing the dimethoxy-compounds, diepoxy-derivatives[52], and sulpho-derivatives, by treating neutral oligomers with oleum[53], etc. A mixture of mono- and di-hydroxylated oligomers is formed by the action of aqueous alkali on a monochlorodiphenoxide in the presence of copper at 250–350°C.[54] An interesting and evidently promising method for the synthesis of the monohydroxylated oligomers is the oxidative polycoupling of phenols terminated in its early stages. It has been shown experimentally[55-57] that oligomers containing 2–7 benzene rings and one terminal hydroxyl can be obtained in this way. The decomposition of poly(phenylene oxides) of high molecular weight may also yield oligomers containing one or two terminal hydroxy-groups[58],[59].

3. Physical Properties of Oligo(phenylene Oxides)

Almost all known oligo(phenylene oxides) are clearly identified chemical compounds. The series of *para*-isomers are crystalline solids, and the *meta*-isomers are viscous liquids at room temperature. The characteristics of some of these compounds are listed in Table 1.

X-Ray examination of a series of oligo-(*p*-phenylene oxides) has shown that the parameters of the unit cell are independent of the length of the molecular chain. All these compounds give the same indices of type *h*, *k*, 0, corresponding to interplanar spacings of 6.79, 5.05, 4.58, 4.22, 3.94, 3.42, 3.67, 2.88, 2.71, 2.56, 2.32, 2.12, 1.89, 1.82, 1.66, 1.60, and 1.50 Å, which represent a crystal lattice having the parameters $a = 9.6$ Å, $b = 6.45$ Å, and $\gamma = 90°$.[60]

Table 1. Characteristics of oligo(phenylene oxides) of general formula $C_6H_5.[OC_6H_4]_n.H$.

n	M.p., °C	B.p., °C	Ref.

All neutral oligo(phenylene oxides) are excellent dielectrics, having volume resistivities of the order of 10^{11}–10^{12} ohm cm. The electrical conductivity of the series of *meta*-oligomers over this range can be explained by convection currents[67]. A more interesting rule has been observed in the series of *para*-oligomers, whose conductivity at room temperature diminished with increase in the length of the molecular chain; it varied exponentially with rise in temperature, the activation energy being 5.2–7.2 eV, and near the melting points reached a value of the order of 10^{-9} ohm^{-1} cm^{-1}, which was approximately the same for all the compounds investigated[60].

The viscosity of the oligomers diminishes with rise in temperature, but nevertheless remains sufficiently high for them to be used as high-temperature lubricants. In order to obtain oligo(phenylene oxide) lubricants which do not thicken at low temperatures, halogen atoms[68],[69] or alkyl groups[70],[71] are introduced around the phenylene oxide chain, or else ester or carbonyl groups are included in the chain itself[72-74].

The dielectric properties of the oligomers are preserved over wide ranges of frequency and temperature. Thus *p*-*p*′-chlorophenoxyphenyl phenyl ether has a dielectric constant of 4.57–5.98, a dielectric loss angle of $\tan^{-1} 0.001-0.0071$, and a volume resistivity of 3.1×10^{10} to 3×10^{12} ohm cm.[75]

The infrared spectra of oligo(phenylene oxides) contain all the typical absorption bands of aromatic compounds having the given type of substitution. The characteristic bands due to an aromatic ether bond lie in the range 1210–1230 cm^{-1} and in the region of 1270 cm^{-1} in the cases of the *para*- and *meta*-oligomers respectively. The mass spectra of several of the oligomers have also been investigated[78].

The high radiation stability of the oligomers is especially interesting. According to various workers oligo(phenylene oxides) withstand, without appreciable change in viscosity, irradiation with γ-rays and neutrons of total dosages up to 10^8 rad at temperatures up to 140°C.[79-81] The addition of 1–10% of an acylate, dialkyldithiocarbamate, or a dialkyl phosphorodithioate of an alkaline-earth metal, mercaptobenzothiazole, or a dithiol enables the stability of the oligomers to be raised to 10^9–10^{10} rad.[81-85]

The mechanical properties of the oligomers have been discussed in a review[86].

4. Chemical Properties of Oligo(phenylene Oxides)

As has been stated above, the ether bond in oligo(phenylene oxides) is very inert chemically. It is cleaved only by the action of alkali-metal amides in liquid ammonia[87] or (by a radical-anion mechanism) by interaction with alkali metals in an aprotic solvent in an inert atmosphere[88-90]. In the former case a phenol and an amine are formed, and in the latter case a phenol and biphenyl.

Substitutions in the benzene ring of the oligomers are almost identical with the corresponding reactions in the aromatic series. The ether bridges in the oligomers are able to form complexes with aluminium bromide and several other electron acceptors; the heat of formation of the complex depends on the structure of the oligomer[91,92].

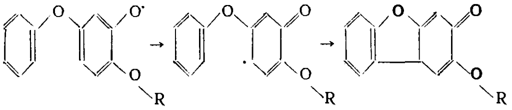
The great resistance of the oligomers to the action of oxidising agents at high temperatures is especially interesting. In air oxidation begins only above 300°C. This stability is responsible for several special applications of oligo(phenylene oxides) (see below). The standard method for testing the oligomers for thermo-oxidative degradation consists[93-95] in bubbling air or oxygen at different rates through a portion of the molten oligomer at a constant temperature, preferably 315°C, for 24 and 48 h. This method is used to determine the relative stability of different oligo(phenylene oxides), the stabilising effect of additives, the influence of contact with various metals on the course of the process and on the corrosive power of the oligomers under these conditions.

Results obtained by different workers indicate that oligo(phenylene oxides) are thermally stable up to 300–450°C and withstand oxidation up to 200–300°C. Wilson and Smith[96] investigated the thermo-oxidative degradation of the oligomers labelled with deuterium and tritium, and found the process to be accompanied by the detachment of hydrogen atoms, predominantly from terminal groups, with the participation of phenyl and hydroxyl radicals, the formation of new C–C bonds, and in the later stages new C–O–C bonds, as a consequence of which macromolecular compounds of phenylene oxide structure are observed among the products of oxidative degradation.

The thermal and thermo-oxidative degradation of unsubstituted, neutral oligo(phenylene oxides) has been investigated systematically by Archer and Bozer[97]. They found the *meta*-oligomers to be considerably less stable than the corresponding *para*-isomers: the latter exhibit self-stabilisation, evidently as a consequence of the formation of dibenzofuran structures in the early stages of oxidation. The tetrameric and pentameric oligo(*m*-phenylene oxides) are thermally stable up to 420°C; after 336 h in air at 315°C the *para*-isomers have absorbed one-tenth of the oxygen absorbed by the *meta*-isomers during 150 h under the same conditions. Mass-spectroscopic and chromatographic examination of the products of thermo-oxidative degradation has shown them to include a bisphenoxyphenyl ether (in the case of the pentamers), a diphenoxybenzene, *o*- and *p*-phenoxyphenol, diphenoxide, phenol, benzoquinone, benzofuran, dibenzofuran, 2-phenoxybenzofuran, and traces of benzenediols, carbon dioxide, and water. Monomeric products constituted 34–48% of the total organic products; the yields of carbon dioxide and water were respectively 0.0003 and 0.0006 mole per gramme of the initial oligomer.

The authors suggested a mechanism of oxidative degradation of oligo(phenylene oxides) initiated by the oxidation by oxygen of an *ortho*- or *para*-position in a terminal benzene ring to a hydroperoxide, which then breaks down into hydroxyl and aryloxyl radicals. The former radical abstracts a hydrogen atom from the next molecule, and the resulting phenyl radical undergoes recombination or adds oxygen; the peroxy-radical thus formed detaches a hydrogen atom from another molecule, and then breaks down into a hydroxy-radical and a new aryloxy-radical, which results in branching of the kinetic chain. Termination of this chain by the coupling of phenyl and hydroxyl radicals will give phenols containing a hydroxyl end-group.

Initial attack by oxygen on an inner benzene ring in the oligo(phenylene oxide) by a somewhat different mechanism yields the same final situation: the initial ether is converted into a number of phenoxyl radicals and substituted phenols. Thus the role of oxygen in this process reduces to the formation of phenoxy-radicals. According to the authors the subsequent course of degradation is determined solely by these radicals. In the case of the *para*-isomers there are two possibilities: if the initial attack takes place *ortho* to the ether bond, the molecule undergoes a quinonoid rearrangement, and then a dibenzofuran structure is formed which stabilises the system:



when the initial attack occurs at the *para*-position, elimination of *p*-benzoquinone followed by chain growth is more probable. Furthermore, the authors accept the possibility of the formation of *o*-benzoquinone, without detailing the mechanism.

Much attention has been paid to the problem of improving the thermo-oxidative stability of oligo(phenylene oxides) by means of various additives or special treatments. As noted above, the stability of the oligomers is substantially influenced by their purity. Further treatment of the oligomers with alkali[98] or alkaline-earth[99] metals, or their oxides or hydroxides[100,101], lengthens the period of service of the oligomers at 300–350°C. A favourable effect is produced by the addition of aryltin halides, trifluoroacetates, or thiocyanates[102-109], arylhalogenoplumbanes and lead acylates[110,111], or triphenylphosphine oxide and tri-*p*-chlorophenylphosphine oxide[112,113]. Among organic compounds the best stabilisers for the oligomers were compounds containing at least one sulphur or halogen atom in the molecule[114], including halogenophenols[115,116], and also phthalimide, anthraquinone, phenyl benzoate, diphenyl phthalate, benzanilide, acenaphtho[1,2-*a*]acenaphthylene, or Schiff bases from 3-aminorhodamine[117-123]. However, organic salts and complexes of metals have proved to be more effective, such as the benzoates and naphthenates[112,124], dithiocarbamates[125], acetylacetonates[108,126,127], and bis-2-*N*-phenylformimidoyl-5-nitrophenoxides[128] of nickel and cobalt, tricarbonyltristriphenylphosphinyliron[129], and aryl-ferrocenes or -titanocenes[130,131]. The standard mixture of oligo(phenylene oxides) for testing the stabilising action of additives comprised 65% of *mm′m″*-, 30% of *mm′p″*-, and 5% of *pm′p″*-pentaphenylene tetroxide. The same mixture is most widely employed in industry when oligo(phenylene oxides) are used as hydraulic liquids, heat-transfer agents, coolants in atomic reactors, high-temperature lubricants, etc.

5. Uses of Oligo(phenylene Oxides)

Oligo(phenylene oxides) are used either alone or with various additives in many fields besides those mentioned above. Oligomers containing 4 – 6 benzene rings enable heat transfer to be effected by direct contact between a gas stream and the heat-transfer agent[132]. A study has been made[133] of the dependence of heat transfer on the composition of the oligomer, the character of the surface, the properties of the flow, etc.

In No. 102 diffusion pumps the *meta*-pentamer ensures that a vacuum down to 10^{-9} torr can be obtained[134,135].

Oligo(phenylene oxides) can be used as operating liquids in hydraulic systems at 400°C for up to 600 h, and at 480°C for 80 min[136,137], withstanding loads up to 30 kbar[138]. This has enabled them to be used as fireproof hydraulic liquids for submarines[139].

Elastodynamic film lubricants, greases for gas turbines, and other lubricants based on the oligomers are able to function at 315°C for more than 100 h. Partial fluorination of the oligomers, or the addition of polyphenylenes or chloroperfluoroacylates of heavy metals, enhances the fire-resistance and the oxidative stability of these lubricants, and also improves their properties at high pressures[140–148].

Lubricating greases based on the oligomers, suitable for operating at speeds up to 20 000 rev/min and temperatures up to 300°C, are obtained by introducing into the oligo(phenylene oxide) 5 – 40% of an acylate of an alkali or an alkaline-earth metal[149,150], 1 – 2% of a polymethacryate containing C_{22-24} alkyl groups[151], a mixture of 30% of silica gel with 0.5% of asbestos[152,153], 25 – 50% of esters of polyols with higher fatty acids[154], or a mixture of oligomeric poly(phenylene sulphides)[155].

Oligo(phenylene oxides) are used as lubricants in the machining of thin aluminium sheet and foil at 350 – 450°C.[156] In several cases their application is determined by their specific chemical properties. It has been noted earlier that sulphonic acids based on the oligomers are surface-active agents[53]. Hydroxy-derivatives of the oligomers are used as strong antiseptics and herbicides[157], and alkylthio-derivatives as pesticides[158]. In combination with substituted phenols and compounds of Group IVa metals oligo(phenylene oxides) stabilise polypropylene to the action of ultraviolet rays[159]. An oligomer can be used as cocatalyst for the Ziegler polymerisation of alkenes[160]. Functional derivatives of the oligomers have been used to obtain polymers of enhanced thermal stability[161].

III. MESO(PHENYLENE OXIDES)

Meso(phenylene oxides) have acquired hardly any intrinsic value in technology. However, considerable experience has been gained in the course of studying their synthesis and properties, and this has subsequently led to the successful synthesis of poly(phenylene oxides).

1. Syntheses from Halogenated Phenols

The first person to obtain a synthetic meso(phenylene oxide) was probably Benedict, who in 1879 investigated the decomposition of 2,4,6-tribromophenol at 130°C, and obtained an amorphous powder whose composition corresponded to the formula $C_6H_2Br_2O$.[162] As Hunter showed later, this was undoubtedly a polymeric product of not very high molecular weight. A similar result was obtained by Castle[163].

The polycondensation of halogenated phenoxides was investigated later by a group of chemists under the direction of Hunter[164]. They found that britle amorphous polymers were formed when suspensions of the 2,3,6-trichloro-, 2,4,6-tribromo-, and 2,4,6-tri-iodophenoxides, 2,4,6-tribromo-3-methoxyphenoxide, and other halogenated phenoxides of silver were heated in benzene or in ethyl iodide at 60°C or in the form of the dry powders. Silver 2,4,6-tribromophenoxide reacted with ethyl iodide to form a dark blue solution, which gradually became brownish yellow, and then deposited silver bromide; alcohol precipitated from the solution an amorphous product of molecular weight 6600 and empirical formula $C_6H_2Br_2O$. A systematic study of the process revealed the following rules: (*a*) in the case of the trihalogenated compounds the reaction took place predominantly in the *para*-position; (*b*) the activity of the halogens diminished in the sequence iodine – bromine – chlorine; and (*c*) only those halogen atoms which were attached directly to a hydroxylated benzene ring reacted under the conditions investigated.

Conclusions (*b*) and (*c*) are confirmed by the dehalogenation by mercury of 2,6-dibromo-4-(4-chloro-2, 6-di-iodophenoxy)phenol and 4-(4-chloro-2, 6-di-iodophenoxy) phenol: only bromine is abstracted from the former compound, whereas the latter does not react at all. The colour of the meso(phenylene oxides) obtained is probably due to the formation of biphenylquinonoid units in the chain, for it disappears on reduction of the polymer. Additional confirmation has been obtained by means of infrared spectroscopy.

"Mesomeric" phenylene oxides of the same type are formed also by (i) the action of mercury on 2,4,4,6-tetrabromocyclohexa-2, 5-dienone, (ii) the action of iodine on potassium trichlorophenoxide in aqueous or benzene medium, and (iii) the electrolysis of silver halogenophenoxides.

Golden[165] has prepared several meso(phenylene oxides) of this type using a modification of Hunter's method. The properties of the products are listed in Table 2. From solutions they all yield only brittle films, as was to be expected for polymers of low molecular weight. The possibility of the formation of dibenzodioxan was also noted in the course of this work; with pentachlorophenol the reaction could be controlled to give mainly polymers in which the unit was either C_6Cl_4O or 2,3,4,5,7,8,9,10-octachlorodibenzodioxan.

Rainford and LeRosen[166] obtained a dark blue meso(phenylene oxide) of molecular weight 1800 by heating sodium 2,4,6-tribromo-3-fluorophenoxide. Blanchard and his coworkers[167] developed Hunter's work further, and found that 2,4,6-tribromo-3-methoxyphenol in the presence of iodine in benzene, and 2,4,4,6-tetrabromocyclohexa-2,5-dienone in the presence of metallic mercury, give initially a green polymer, which when subsequently dissolved in benzene and allowed to stand became decolourised. At the same time the molecular weight of the polymer doubled, probably as a result of coupling and the formation of dienone structures.

Table 2. Meso(phenylene oxides) synthesised by Golden[165].

Phenoxide		Polymer		
substituents	metal	yield, %	softening point, °C	mol. wt.
p-Chloro-	K	4	356—260	2800
2,4-Dichloro-	Na	45	270—273	—
2,4-Dibromo-	Na	81	240—245	—
2,4,5-Trichloro-	Na	37	215—220	—
2,4,6-Trichloro-	Na	90	185—186	4800
2,4,6-Trichloro-	Ag	79	185—188	9600
2,4,6-Tribromo-	K	60	244—246	3200
2,3,4,6-Tetrachloro-	Na	78	219—222	—
2,3,4,6-Tetrachloro-	Ag	80	213—235	—
Pentachloro-	Ag	73	192—194	1500
Pentabromo-	Na	63	300—310	—

The free-radical mechanism of the condensation of halogenated phenols to meso(phenylene oxides) has been proved by work on the oxidation of these phenols by aryloxy-radicals[168], benzoyl peroxide[169-171], lead tetraacetate or dioxide[172], or copper(II) acylates[173], in which trichloro-, tribromo-, tri-iodo-, and pentabromo-phenols gave meso(phenylene oxides) having molecular weights of 2000–5000, melting points from 165° to 265°C, and cyclohexadienone terminal groups; potassium pentafluorophenoxide in the presence of copper(II) oxide yielded the corresponding polymer of molecular weight 1700–4300.[174]

The formation of meso(phenylene oxides) from *m*-halogenophenols has been investigated by Brown and his coworkers[175-180]. They find that the Ullmann polycondensation of *m*-bromophenol takes place at 150–220°C to give the corresponding meso(phenylene oxide). Catalysis by copper salts results in branched products. In the presence of polar solvents secondary reactions involving C–C coupling predominate. The exothermic character of the reaction results in cross-linked products when the process is accomplished in the mass. Optimum results are obtained in a system formally analogous to suspension polymerisation, with high-boiling aliphatic hydrocarbons used as reaction medium. With appropriate preparation and purification of the catalyst (metallic copper) it is possible to obtain by this method meso(phenylene oxides) having molecular weights from 4000 to 10 000 in the form of solid powders suitable for the production of filled plastics which are thermostable up to 500°C.[175,176].

2. Synthesis of Meso(phenylene Oxides) by the Decomposition of 4-Diazocyclohexadienones

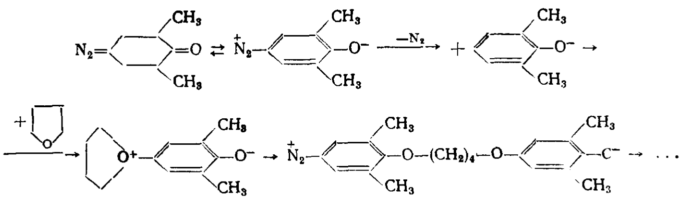
The second general method used in attempts to synthesise meso(phenylene oxides) was the decomposition of "*p*-benzenediazo-oxides" [4-diazocyclohexadienones]. It was assumed that such decomposition would involve the intermediate formation of a biradical , which would probably polymerise to a poly(phenylene oxide). Süs and his coworkers[181] studied the decomposition of 4-diazocyclohexadienone in various solvents under the influence of ultraviolet radiation. In all cases products containing solvent molecules were obtained. Similar results have been found by Wang[182]. In methanolic solution the main product was *p*-methoxyphenol. In boiling benzene *p*-phenylphenol was formed in almost theoretical yield. At room temperature a small quantity of a phenolic resin melting at 300°C could be isolated together with a phenylphenol from benzene solution.

An elastomer having good thermal stability could be obtained by decomposing a fluorinated "diazo-oxide"[183].

Dewar[184] investigated the thermal decomposition of 2,6-dibromo-4-diazocyclohexadienone in chlorobenzene. He hoped that blocking the oxygen by means of adjacent bromine atoms would diminish secondary reactions, including those in the *ortho*-position relative to the oxygen. This method yielded only polymers of low molecular weight (1600–6600) soluble in chloroform, with softening points of 200–220°C. Elementary analysis showed that the polymer contained chlorine as well as bromine, indicating that the solvent had taken part in the reaction. Conducting the same reaction in chlorobenzene containing 1% of methanol or water diminishes the yield of polymer, several benzene derivatives of low molecular weight being formed. The author regards these results as confirming the intermediate formation of a biradical similar to the above.

Kunitake and Price[185] studied the decomposition of 4-diazo-2,6-dimethylcyclohexadienone in a series of solvents under the influence of heating and ultraviolet irradiation. The diazonium salt, prepared by the usual method, was extracted from aqueous solution in an organic solvent, in which it was then decomposed. In benzene solution only 2,6-dimethyl-4-phenylphenol is formed by the action of light and heat. From chlorobenzene solution unchanged diazonium salt and *o*- and *p*-chlorohydroxybiphenyls were isolated, which was taken as evidence that an intermediate biradical was involved in the reaction.

The heating or ultraviolet irradiation of 4-diazocyclohexadienone in oxolan or dioxan yields semi-solid products of molecular weight 1400 or a powder of melting point 60–70°C. The ratio of the areas of the peaks for aliphatic and aromatic protons in the nuclear magnetic resonance spectrum of these products indicates a structure in which the ratio of tetramethylene oxide and phenylene oxide units is about 1 : 1. This is supported by elementary analysis. The facts that the polymers have the same composition independently of the conditions of this reaction and that some of the polymers are shown by X-ray diffraction to be crystalline indicate a structure with a regular alternation of aliphatic and aromatic units. The mechanism suggested for the reaction is



It is interesting that the "diazo-oxide" reacts to form either a biradical or an ionic intermediate compound depending on the solvent.

A similar formation of alternant copolymers has been observed by Stille et al.[186] when diazocyclohexadienone reacts with 1,4-epoxycyclohexane or with 2,2-bischloromethyloxetan. No copolymer could be obtained with methyloxiran[187].

Dimerisation and ring-closure have also been observed in several experiments on the decomposition of 4-diazocyclohexadienones.

With the exception of the work of Wall[183], in which the intermediate biradical may have been stabilised by the electron-acceptor effect of fluorine, and work by Price and Stille on copolymers, the use of diazo-compounds to prepare poly(phenylene oxides) has proved to be on the whole unsuccessful.

3. Other Methods for the Synthesis of Meso(phenylene Oxides)

Several other routes to the synthesis of meso(phenylene oxides) have been tried by various workers. Golden[165] and Briner[188] were unsuccessful in attempting to synthesise poly(phenylene oxides) by the dehydration of polyhydric phenols. Paushkin and his coworkers[189,190] conducted this reaction in the presence of zinc chloride at 200°C, but obtained only oligomers of molecular weight exceeding 1000 and softening points of 310–330°C. Treatment of phenols with iron(III) chloride gave similar results[191]. Although a polyphenylene structure was attributed to the products, their properties, especially the infrared spectra, were closer to those of known meso(phenylene oxides), not those of polyphenylenes.

Price[192] prepared a cross-linked polymer, in the form of a powder containing 12% of a soluble oligomeric fraction, by the decomposition of 4-acetoxymercuri-2,6-dimethylphenol.

An interesting method for synthesising a polymer containing alternating poly-*p*-phenylene and poly-(*p*-phenylene oxide) units was found by Stille and his coworkers[25], who accomplished a Diels–Alder polycondensation between 3,3-(oxydi-*p*-phenylene)-2,4-bistriphenylcyclopentadienone and *m*- and *p*-diethynylbenzene in toluene solution at 200°C.

A series of meso(phenylene oxides) were synthesised as insoluble, infusible powders of molecular weight 4000–7000 (from end-group analysis) or soluble resins of molecular weight 1000–2000 by Cox et al.[193], who subjected alkali-metal halogenophenoxides to thermal decomposition in the absence of a catalyst.

Meso(phenylene oxides) have been prepared also by the radiolysis of diphenyl ether[81] and by the Williamson polycondensation of dihydric phenols with bis-*p*-chloromethylphenyl ether[23,194,195]. In neither case was the structure of the products proved, and the molecular weight did not exceed 2000. Molecular weights up to 2300 have been obtained[196] by the condensation of oligo(phenylene oxides) with arenedisulphonyl chlorides. Several meso(phenylene oxides) have been synthesised by the oxidative polycoupling of phenols. Since this reaction is discussed in the following Section, information on these compounds will be given there.

Almost all meso(phenylene oxides) are dark coloured, friable powders which, although exhibiting certain properties characteristic of polymers, have not yet found practical application.

IV. POLY(PHENYLENE OXIDES)

As has been indicated in the preceding Section, the history of the synthesis of poly(phenylene oxides) of high molecular weight has been characterised by perennial unsuccessful attempts. The best results were obtained when the intermediate formation of radicals of phenoxyl type was possible under the conditions of polycondensation of halogenated phenols. The approach to catalysts for the process was therefore reviewed: metallic copper was replaced by oxides and complex salts of the metal, as a result of which polymers of high molecular weight could be obtained in good yield not only from halogenated phenols but also from phenols containing no *ortho*- or *para*-substituents.

The early failures are explained by the inadequate mobility of the halogen in these monomers, as is confirmed by the relatively easy preparation of polymers containing arylene oxide units by the polycondensation of diphenoxides with aromatic dihalides activated by a strongly electron-acceptor nuclear substituent, such as sulphonyl, nitro, or fluorine. For example, a polymer prepared from the disodium salt of bisphenol A and bis-*p*-chlorophenyl sulphone has already become available commercially[19,197,198]. This reaction is accomplished in a dipolar aprotic solvent by heating in the absence of oxygen and moisture at 130–140°C for 4–5 h. Several polymers of this type are listed in Table 3.

Table 3. Poly(arylene oxides) synthesised by nucleophilic substitution of halogen.

* Softening point 310°C.

A similar result is obtained by treating pentafluorophenol with caustic soda in pyridine[199]:

$$C_6F_6 + NaOH \rightarrow C_6F_5ONa \rightarrow [-C_6F_4O-]_n \ .$$

Heterolytic nucleophilic substitution is usually difficult in the aromatic series. Poly(phenylene oxides) can be successfully synthesised probably only by homolytic substitution of halogen, as is confirmed both by the coloration noted by Hunter and by Blanchard and by the sequence of activity of the halogens—I > Br > Cl—observed by Hunter, for the opposite sequence—F > Cl > Br > I—is found with heterolytic substitution[200].

An unexpected result has been found by Bolton and his coworkers[201,202], who have obtained insoluble films of poly(phenylene oxides) by the prolonged heating of *p*-phenoxyphenols in air at 330°C. This method of synthesis is an example of oxidative coupling.

During the past 10–15 years, in the course of work on the oxidation of phenols under various conditions, in particular in the synthesis of biphenylquinones by this method, formation of a certain amount of an amorphous polymeric byproduct has been observed[203-207]. More careful study and development of this line of research led Hay[208] and Price[192] to the almost simultaneous discovery in 1959–1960 of a new method of synthesising poly(phenylene oxides) of high molecular weight by the oxidative polycoupling of phenols and halogenated phenols. Poly-(2,6-dimethyl-1,4-phenylene oxide) was synthesised from 2,6-xylenol by the action of oxygen in the presence of a copper–pyridine catalyst or interfacially from 4-bromo-2,6-xylenol in the presence of potassium hexacyanoferrate(III) in the benzene–aqueous alkali system. Poly(phenylene oxides) have since been obtained by the same and similar methods from several dozen other phenols.

Table 4. Poly(phenylene oxides) obtained by oxidative coupling of phenols of the type.

The results are summarised in Tables 4–6. An emulsion method of synthesis has been patented[209]. Complex compounds of almost all metals of variable valency were used as catalysts. Electrochemical synthesis has also been tried[210-212]. Replacement of pyridine by its derivatives and the introduction of platinum black into the system have enabled the poly(phenylene oxides) to be obtained from phenols which do not polymerise under ordinary conditions (Table 5).

Only the two original methods of synthesising poly(phenylene oxides)—the hexacyanoferrate(III) and copper—amine processes—have been investigated in any detail. Though sharing many common features, they have several individual characteristics, and will therefore be discussed separately.

Table 5. Synthesis of poly(phenylene oxides), on an activated copper–amine catalyst, from phenols of the type.

1. Polymerisation initiated by Potassium Hexacyanoferrate(III)

Staffin and Price[192] found that poly(phenylene oxides) of molecular weight 4000–7000 are formed from 4-bromo-2,6-dimethylphenol in the presence of oxidants of the type potassium hexacyanoferrate(III), lead dioxide, etc. The reaction is initiated by ultraviolet irradiation, iodine, and phenoxy-radicals. The correctness of the 1,4-chain structure was confirmed by the nuclear magnetic resonance, infrared, and ultraviolet spectra. When polymerisation is initiated by phenoxy-radicals, excess of alkali is required: otherwise the polymerisation slows down[231,232]. This suggests that initiation consists in oxidation of the phenoxide anion to the phenoxy-radical.

Since the bromide ion is quantitatively precipitated during the process, chain growth may be supposed to occur by replacement of the *para*-bromine atom, probably with the formation of some intermediate state, i.e. that on the whole the process is a classic case of oxidative coupling. In an inert atmosphere polymerisation ceases soon after introduction of the catalyst, and the "frozen" process is revived by a fresh portion of catalyst; the molecular weight of the poly(phenylene oxide) does not exceed 10 000.[233] In air polymerisation continues until the monomer is completely converted, and the molecular weight reaches 40 000–50 000. In neither case is a direct relation between molecular weight and degree of conversion observed. The authors therefore regard this process as similar to the free-radical polymerisation of vinyl monomers. The mechanism of the action of oxygen consists in chain transfer by means of the hydroperoxy-radical.

End-group analysis combined with osmometry showed that 0.1 phenolic hydroxyl and 4 bromine atoms were associated with each macromolecule. This was explained either by the formation of ethers of quinol similar to those obtained by Dimroth[234] or by branching of the polymer chain resulting from attack by a phenoxylic macroradical at the middle of a neighbouring chain.

Considerable attention has been paid to the effect of substituents in the phenols. In the view of Staffin and Price[192] 4-bromodurenol and pentabromophenol do not polymerise because of steric hindrance to the approach of a phenoxy-radical to a bromine atom. Poly(phenylene oxides) from 2,6-disubstituted 4-bromophenols are listed in Table 6.[235,236]

Table 6. Effect of substituents on the polymerisation of 2,6-disubstituted 4-bromophenols[235,236].

R_2	R_6	Intrinsic viscosity	Product
$-CH_3$	n-C_3H_7	0.15	polymer
$-CH_3$	$-CH_2CH=CH_2$	0.17	polymer
$-CH_2CH=CH_2$	$-CH_2CH=CH_2$	0.15	polymer
n-C_3H_7	$-CH_2CH=CH_2$	0.11	polymer
n-C_3H_7	$-C_6H_5$	0.10	polymer
$-CH_2CH=CH_2$	$-C_6H_5$	0.11	polymer
$-H$	$-H$	—	biphenylquinone and oligomers
$-CH_3$	$-COOCH_3$	—	polymer
$-CH_3$	F	—	minute amounts of semi-solid products
t-C_4H_9	t-C_4H_9	—	no polymer

Table 6 shows that introducing a phenyl, allyl, or n-propyl group into an *ortho*-position yields poly(phenylene oxides) of low molecular weight. The allylic double bond is then inactive towards the growing radical and the catalyst: such great liability of phenolic hydroxyl to oxidation in comparison with an ethylenic double bond has been observed previously[237]. An attempt to polymerise 4-bromo-2-vinylphenol by this method resulted in an amorphous powder containing 80–90% of bromine based on the amount calculated for the monomer, probably as a consequence of a complicated growth reaction involving the double bond.

Polymerisation does not take place with bulky substituents such as t-butyl or strong electron acceptors such as $COOCH_3$ or fluorine.

A polymer containing reactive groups in its framework is interesting as a basis for several polymerlike reactions. Allylphenols themselves do not polymerise readily, but with xylenol they give various copolymers having molecular weights up to 50 000.[238–241]

2. Polymerisation initiated by Amine Complexes of Copper Salts

Although the interfacial polycondensation of halogenated phenols does enable copolymers to be obtained, the low molecular weight of the poly(phenylene oxides), the complicated technology, and the use of expensive monomers restrict its application. The homogeneous oxidative coupling of phenols is free from these defects and permits delicate control of the activity of the catalyst (Table 5). The use of a copper–amine catalyst for synthesising poly(phenylene oxides) from *p*-halogenophenols in the absence of oxygen revealed the necessity of using stoichiometric or even greater quantities of catalyst relative to the monomer[219], which is consistent with results for the catalytic activity of basic copper salts alone[242,243]. 4-Bromo-2,6-dinitrophenol and 4-bromo-2,6-dichlorophenol did not yield polymers by this method, and only an oil of low molecular weight was obtained from a 2-aryl-4-bromo-6-methylphenol.

The secondary formation of biphenylquinones during the synthesis of poly(phenylene oxides) had already been noticed in Hay's early work[213]. Further investigations established that polymerisation (C–O coupling) and the formation of the quinones (C–C coupling) are competitive reactions, depending on the substituents and the amine : copper (N/Cu) ratio. The larger the substituent the more readily is a biphenylquinone formed (Table 7).

Table 7. Formation of biphenylquinones.

R_2	R_6	Yield, %	M.p., °C
$-CH_3$	t-C_4H_9	45	217
t-C_4H_9	t-C_4H_9	97	246
n-C_3H_7	n-C_3H_7	53	255
$-OCH_3$	$-OCH_3$	74	>300

Interesting results have been obtained for the oxidation of 2,6-xylenol. The highest rate of absorption of oxygen by the reaction mixture was observed at a ratio $N/Cu \simeq 100$, whereas formation of biphenylquinones was noted only at $N/Cu < 10$.[244] The specific rates of C–O and C–C coupling were calculated by means of the equations

$$R_{C-O} = f_P \cdot R; \quad R_{C-C} = f_Q \cdot \frac{R}{2}$$

where f_P and f_Q are the yields of poly(phenylene oxides) and biphenylquinones respectively, while R is the actual rate of absorption of oxygen. Table 8 shows that both R_{C-O} and R_{C-C} increase with increase in N/Cu, with the former increasing more rapidly, so that polymerisation predominates.

Table 8. Specific rates of C–C and C–O coupling of 2,6-dimethylphenol under the influence of oxygen on a copper–pyridine catalyst.

N/Cu	$10^3 \cdot R_{C-O}$	$10^3 \cdot R_{C-C}$
0.67	0.0065	0.0256
1.0	0.0338	0.0505
2.0	0.267	0.112
3.0	0.639	0.162
10.0	3.90	0.270

Later Blanchard et al.[245,246] have shown that the polymers and the quinones are formed on catalysts differing in structure, which are present together in the reaction system.

A study of the relation between degree of conversion (from the absorption of oxygen) and the molecular weight of the poly(phenylene oxide) established[244] that the latter was not very high up to 80–90% of the theoretical absorption of oxygen, but increased rapidly as the stoichiometric quantity was approached. In view of this it was at first assumed that this was a process of step-by-step increase in molecular weight, akin to polycondensation, as was supported indirectly by the ability of dimers and trimers to give a polymer identical with that obtained from the monomer. Since neutral oligo(phenylene oxides) are inert solvents for the process [247,248], a mechanism was suggested in which oxidation of an oligomeric phenoxide anion to the phenoxy-radical is followed by migration of the unpaired electron along the polymer chain from its "tail" to its "head", so that the "head" again becomes anionic, and the "tail" a radical-ion. Addition of the radical "head" of a monomer or an oligomer to such a "tail" makes the number of electrons in the system even, after which the process is repeated [249]. An alternative mechanism was proposed by Cooper, who used trimethylchlorosilane to terminate the polymerisation of dimers at an early stage, and observed considerable quantities of monomer and trimer among the products [55-57]. On the basis of these results a new scheme—of quinol ether equilibrium disproportionation—was set up. The use of labelled atoms [250,251] revealed that exchange of protons in *meta*- and *para*-positions occurred during polymerisation, which was explained by a fresh scheme involving a phenonium intermediate compound (Scheme 2). It was suggested that the hexacyanoferrate(III) and copper–amine methods of synthesising poly(phenylene oxides) occurred by different mechanisms. It was found, however, that the dimeric 4-(4-bromo-2,6-dimethylphenoxy)-2,6-dimethylphenol polymerised in the same way by both methods [252], which could be explained only by the same mechanism—quinol ether equilibrium disproportionation—operating in both cases.

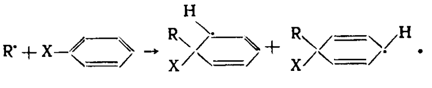
Taking this into account, McNelis [268] represented his own and published experimental results by a fundamentally different general scheme of oxidative polycoupling of phenols to form poly(phenylene oxides) and biphenylquinones (Scheme 1). Analysis of this scheme reveals several defects:

1. The formation of biphenyldiols (VIII) and biphenylquinones (IX) is in no way related to the composition or the structure of the catalyst.

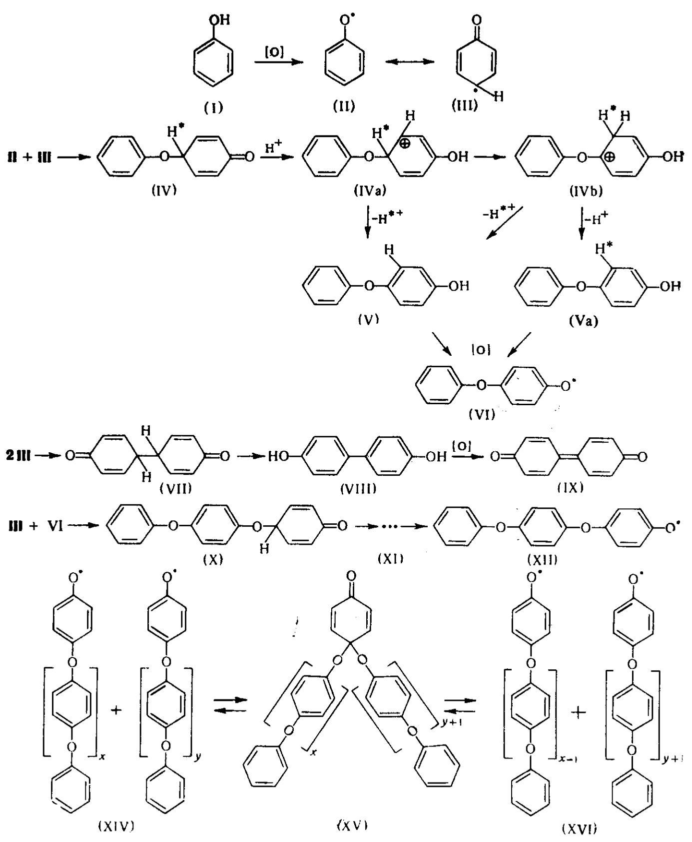
2. The scheme is applicable only to phenols in which the *para*-position is unsubstituted.

3. The stage of conversion of quinol ether (IV) into aryloxyphenol (V) and aryloxyphenoxyl (VI) involves hydrogen ions and should depend on the pH of the medium. In practice, however, replacement of pyridine by trihexylamine and other amines has hardly any effect on the results [24], and the acceleration of the reaction in the presence of caustic alkalis [269-271] is inconsistent with such a mechanism.

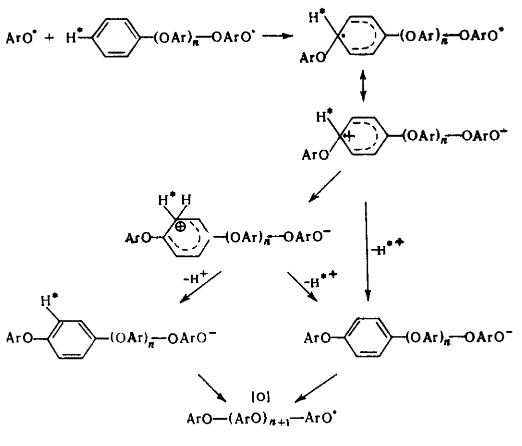
4. Coupling of the isomeric radicals (II) and (III) was presented as probability processes. According to this scheme no biphenylquinone is formed if the system contains very little or no radical (III), but in such case nor could a polymer be formed. Moreover, this scheme takes no account of the work of Milyutinskaya [272], de Tar [273], or Grashey [274], who showed that the addition of free radicals to a benzene ring resembles their addition at a C=C bond:



Scheme 1 (Ref.268)



Scheme 2

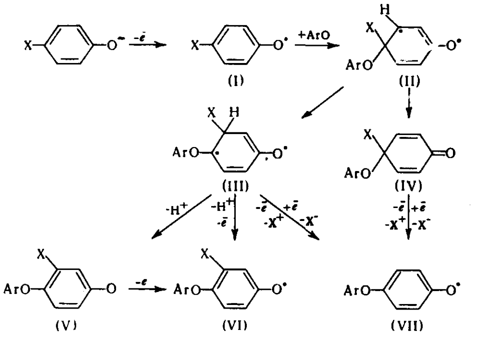


(where H* = H, D, T).

Kopylov and Pravednikov [275] were the first to show experimentally that the synthesis of poly(phenylene oxides) by this method involves free radicals of phenoxyl type, and this was soon confirmed by Waters [276]. Conversion of the monomer, formation of the polymer, and the variation in content of e.p.r. detectable species in the reaction system were used to investigate the kinetics of the process, and a new generalised scheme was suggested [277] in which the process consisted of a series of consecutive reactions of the first order with respect to the monomer and having activation energies of 16–17 kcal mole^{-1} (Scheme 3). On the whole the mechanism of the oxidative polycoupling of phenols to poly(phenylene oxides) is ambiguous, being determined by the oxidisability of the phenol and the nature of the *para*-substituents and also by the oxidant used. The former group of factors can be assessed quantitatively from the distribution of electron density in the phenoxyl radical, which can be estimated from the critical oxidation potentials, the pK of the phenols, or the Hammett constants.

Only certain empirical rules can be derived for the latter group of factors. The catalysts used for the synthesis of poly(phenylene oxides) have been various salts and complex compounds of silver[268,278], cupric and cuprous copper[252-267], and lead[208,214-216], oxides, chelates, and halides of cobalt and manganese[279-285], manganese dioxide[217,221], potassium permanganate[286], nickel peroxide[287,288], iron complexes[192], persulphates[289], organic and inorganic peroxides[169-171], compounds of mercury[290], chromium, iodine, and many compounds of Groups IV – VI elements[291,292], and tri-t-butylphenoxyl radicals[293]. It has also been shown that poly(phenylene oxides) are formed by the oxidation of *p*-phenoxyphenols by air in the absence of a catalyst[201], by their oxidation with chlorine in the presence of copper salts[294], and by the electrolytic oxidation of phenols[211].

Scheme 3



and then as XIV-XV-XVI in Scheme 1, where X = H, D, T, Hal, etc.

It was found here that phenols of low pK yield a polymer only when catalysts of high oxidation potential are used, and conversely. Furthermore, it was definitely established that the activity of the catalyst could be controlled by varying the coordinated ligands. Thus poly(phenylene oxides) of high molecular weights are obtained by the polycondensation of sodium *p*-halogenophenoxides in the presence of complexes of copper(I) chloride with organic compounds containing a tertiary nitrogen atom. The yield and the molecular weight of the polymer vary with the ligand used[295,296]. A similar rule has been noted in the oxidative coupling of amines to give azo-polymers[297].

3. Secondary Processes

Besides the formation of biphenylquinones, several other secondary processes, especially oxidation of the skeleton, complicate the oxidative polycoupling of phenols to form poly(phenylene oxides). Many workers have noted that the resulting polymer is yellowish or reddish, the colour not being removed or even weakened by repeated reprecipitation or purification by Soxhlet extraction. The presence of an absorption band in the region of 1660 cm^{-1} in the infrared spectra of such polymers and the weakening of the colour under the influence of reducing agents indicate that the colour is due to quinonoid groups entering the polymer chain[298]. Peroxy- and hydroperoxy-groups are probably present in poly(phenylene oxides)[192,299-301]. Up to one carboxyl per twenty chain units has been found in the polymer[219,298], its formation being explained by the presence of peroxides in the reaction system. In several cases cross-linked, insoluble, or thermosetting polymers are formed during the synthesis, which can be explained by the production and interaction of functional groups in the skeleton of the polymer chain. The occurrence of such "defects" is due to replacement of the catalyst—of copper halides by acylates—or to a rise in the temperature of the synthesis above a critical value.

When 2,6-xylenol is polymerised in a mixture of chlorobenzene and methanol, the molecular weight of the resulting poly(phenylene oxide) is inversely proportional to the mole fraction of methanol, this being due to precipitation of the polymer when it reaches a certain molecular weight[302].

4. Properties of Poly(phenylene Oxides)

Published information on the properties of poly(phenylene oxides) is extensive and varied—from advertising matter to special reviews and references in textbooks and monographs[303-310]. Only general technical and working properties will be discussed here: questions of the mechanism of synthesis and thermal degradation are discussed elsewhere.

At the present time only poly-(2,6-dimethyl-1,4-phenylene oxide) (2,6-p.ph.o.) is produced on an industrial scale, being manufactured by the General Electric Company in the USA, by A. K. U. in Holland, and by Hodgson-Thomson [*sic*] in France. It is a thermoplastic, non-crystalline linear polyether. The material can be welded by means of ultrasonic vibrations and cemented with organic solvents. Injection moulding and extrusion are effected in standard equipment at 288 – 343°C, the duration of the casting cycle being 15 – 30 s and the pressure employed 850 – 1400 atm. The mould should first have been heated to 120 – 150°C to improve filling; the mould is emptied at 190°C. Preliminary mastication on worm machines is recommended to shorten the casting cycle. This process is used to make tubes, profiled articles, rods, insulation for wire, parts for mechanical and electrical equipment, wood screws, etc. The resistance to heat and moisture and their great chemical stability enable 2,6-p.ph.o. to compete with alloy steel and fluorinated plastics for operation in corrosive media at high temperatures. The high resistance to arcing and the low dielectric loss angle of 2,6-p.ph.o. enable it to be used for the manufacture of parts for electronic equipment. The good dielectric properties permit the employment of this polymer for the electrical insulation of high-voltage lines.

Two brands of 2,6-p.ph.o. —C-1001 pure polymer and Noryl modified polymer—are manufactured on an industrial scale. Furthermore, foam plastics are also obtained from C-1001.[311,312].

The chief characteristics of these materials are listed in Table 9. Goods made of C-1001 withstand 200 treatments in a sterilisation autoclave without change in appearance or mechanical properties. The polymer resists the action of mineral acids and alkalis, salt solutions, organic acids, and aliphatic hydrocarbons and alcohols, swells slightly in ketones, and dissolves in aromatic hydrocarbons, halogenated hydrocarbons, and certain cyclic ethers. Although 2,6-p.ph.o. is usually amorphous, it crystallises on the prolonged heating of a 2-pinene solution[313]. The parameters of the unit cell are $a = 8.45$ Å, $b = 6.02$ Å, and $\gamma = 91°1'$. The dielectric characteristics of the polymer do not vary by more than 20% over the temperature range from −80° to +160°C and the frequency range 10–10^8 c/s.[314] The dependence of certain properties of 2,6-p.ph.o. on molecular weight is given in Table 10.

Such almost unique combination of properties with simplicity of production and processing ensure for 2,6-p.ph.o. wide practical applications—from high-frequency insulation to parts of chemical equipment, from surgical instruments to units in the construction of sputniks. Information is available on the production from it of films and fibres by spinning from solutions and melts[315-317].

The characteristics of poly(phenylene oxides) obtained by other methods or having a different structure from 2,6-p.ph.o. can be briefly summarised as follows: (1) all poly(phenylene oxides) possess high thermal stability (this will be discussed in greater detail in the following subsection); (2) all poly(phenylene oxides) possess good hydrolytic and chemical stability and good electrical properties; and (3) various polymers having specific properties can be prepared from poly(phenylene oxides) by various polymerlike transformations.

A base for high-temperature adhesives has been obtained by the epoxidation of copolymers of 2,6-xylenol and 2-allyl-6-methylphenol[240].

A series of papers has been published on the preparation of ion-exchange resins having a poly(phenylene oxide) matrix. An anion-exchange resin has been prepared by the dimethylamination of chloromethylated 2,6-p.ph.o. [318-321]. Treatment of 2,6-p.ph.o. or chlorinated 2,6-p.ph.o. with chlorosulphuric acid, oleum, trialkyl phosphites, potassium cyanide, and other reagents followed by hydrolysis or reduction gives cation exchangers and anion exchangers based on poly(phenylene oxides) and having exchange capacities up to 4.0 m-equiv. g^{-1}.[322-339] Most of these ion exchangers are soluble in organic solvents, and from the solutions yield durable elastic films of electrical resistance 4 ohm cm and above, which can be used as membranes in fuel cells and for other purposes. The conductivity of these membranes is determined by the degree of sulphonation, which depends on the reaction conditions[335]. Electron-exchange resins and semiconductors have been based on poly(phenylene oxides)[324]. The ion-exchange resins are used for the coagulation of photographic emulsions[339], for the production of antistatic coatings[329,331], etc. The action of *N*-bromosuccinimide on 2,6-p. ph.o. in the presence of benzoyl peroxide results in bromination of the methyl groups. By choosing different catalysts it is possible to control the chlorination of 2,6-p.ph.o. to produce substitution in the benzene ring or in the methyl groups[319,321]. As analogue of benzyl halides the products are highly reactive, are easily hydrolysed, form quaternary ammonium salts with amines[318,329], and can be reduced to the original polymer[340].

Table 10. Properties of poly-(2,6-dimethylphenylene oxides) of different molecular weights.

Property	Units	Specimens		
		No. 1	No. 2	No. 3
Intrinsic viscosity $[\eta]$	dl g^{-1}	0.635	0.780	0.920
Dispersion factor tan δ	–	0.00245	0.00200	0.00146

Dinstat impact resistance	–	—	7.7	—

Under mild conditions poly-(2,6-diallylphenylene oxide) is oxidised to the corresponding carboxylic acid, with incidental degradation of the polymer chain and considerable decrease in the molecular weight[235].

The infrared spectra of poly-(2,6-dimethylphenylene oxides) have been investigated in some detail. All authors agree in asigning the absorption bands at 835 and 855 cm^{-1} to a tetrasubstituted benzene ring, at 1180–1190 cm^{-1} to an ether bond, at 1232 cm^{-1} to a *para*-substituted benzene ring, at 1300 and 1380 cm^{-1} to aliphatic C–H bonds, and at 1490 and 1600 cm^{-1} to C=C bonds in the benzene ring. Some divergence appears in the asignment of bands at 3400–3500 cm^{-1}, in the region of vibrations of the hydroxy-group. Hay[213] considers this band as due to the presence of traces of water. Endres[244] explains it as originating in terminal phenolic hydroxyls, the content of which per macromolecule is calculated as 1.5 group. Laborie-Gardaix[223] also attributes this band to hydroxy-groups in the polymer, without specifying their position. Kopylov and Pravednikov regard this band as due to the presence of carboxy-groups in the polymer[298]. The most debatable are the bands at 1660, 1690, and 1720 cm^{-1}, which have been ascribed to residual catalyst[213], overtones of out-of-plane C–H vibrations[213], a C=O group of undefined position[135], a tetrasubstituted benzene ring[224], and a carboxylic or quinonoid C=O group[219,220,298].

The molecular weight of the poly(phenylene oxides) also proved to be a quite complicated problem, since large discrepancies were observed depending on the method of determination. From an analysis of end-groups Price[192] derived for 2,6-p.ph.o. the equation

$$[\eta] = 8.7 \cdot 10^{-8} M^{0.876}$$

linking the intrinsic viscosity in benzene at 30°C with the molecular weight. Tsou[238] compared viscometric and osmometric data in benzene at 25°C, and suggested the equation

$$[\eta] = 1.5 \cdot 10^{-7} M^{1.44} \quad .$$

Hay and his coworkers[341,342] determined the molecular weights of a series of poly(phenylene oxides) by osmometry and light scattering, and obtained the values given in Table 11. A systematic investigation of the viscosity, osmotic pressure, and light scattering of dilute solutions of fractionally precipitated 2,6-p.ph.o. led Pepper et al.[343,344] to establish the following formulae at 25°C:

$$\text{in toluene} \quad [\eta] = 2.85 \cdot 10^{-4} M^{0.68 \pm 0.02} \quad ,$$
$$\text{in chlorobenzene} \quad [\eta] = 3.78 \cdot 10^{-4} M^{0.66 \pm 0.02} \quad ,$$
$$\text{in chloroform} \quad [\eta] = 4.83 \cdot 10^{-4} M^{0.64 \pm 0.02} \quad .$$

Table 11. Viscosity and molecular weight of some poly(phenylene oxides) obtained by the oxidative polycoupling of phenols.

Monomer	$[\eta]$ in $CHCl_3$ at 25°C, dl g^{-1}	Mol. wt. of polymer from	
		osmometry	light scattering
Phenol	0.070	18500	66000

The size of the undisturbed molecular tangle in the same solvents was calculated as (883 ± 10), (830 ± 5), and (845 ± 20) $\times 10^{-11}$ cm mole$^{0.5}$ g$^{-0.5}$ respectively.

5. Thermal Properties of Poly(phenylene Oxides)

Two aspects of the thermal degradation of aromatic polyethers must be distinguished. The degradation of the phenylene oxide chain itself has been studied in sufficient detail on oligo(phenylene oxides). This case is hardly ever met in poly(phenylene oxides) of high molecular weight, since these polyethers begin to break down at lower temperatures under the influence of end-groups, chain defects, and functional groups in the framework. The phenylene oxide chain itself is stable in an inert atmosphere and in air at least up to 500°C, as Stille and his coworkers[25] showed, for example for poly(penta-*p*-phenylene oxide) prepared by Diels–Alder condensation. It was also shown that the thermal stability of polymers containing aromatic hydrocarbon or heterocyclic rings joined by carbonyl, sulphonyl, and/or oxygen bridges equals or exceeds that of polyphenylenes[345]. It was found that, in the case of poly-(*p*-phenyleneethylene-*p*′-phenylene oxide) in air for 2 h, loss in weight, beginning at 375°, reaches 50% by 425° and 80% at 450°C, the activation energy of this process being 40 kcal mole^{-1}. The polymer specimen investigated had a molecular weight of 5000 and a softening point of 150°C, and was soluble in chloroform. Neither the mechanism of degradation nor the composition of the products was examined.

Cox and his coworkers[193] made a kinetic study of the thermal degradation of a large number of poly(arylene oxides) prepared by the polycondensation of halogenated phenols and containing 3–70 monomer units in the polymer chain. The structure of these units and the properties of some of the polymers are given in Table 12.

Table 12. Properties of some poly(phenylene oxides) obtained by polycondensation[193].

Polymeric	Mol. wt.	Solubility	Softening temp.	$T_{50\%}$*
m-Phenylene oxide	1800/A	—	465	610 (40%)
o-Chloro-*p*-phenyl oxide	—	+	270	590
p-Phenylene oxide (I)	7700/A	—	315	515 (31%)
p-Bromo-*o*-phenylene oxide–*p*′-phenylene oxide	4000	—	500	550
2,6-Dichloro-1,4-phenylene oxide	9600/B	+	190	480

2,3,5,6-Tetrabromo-1,4-phenylene oxide	—	+	300	380
2,3,5,6-Tetrachloro-1,4-phenylene oxide	1450/B	+	195	370
2,5-Dichloro-1,4-phenylene oxide	—	+	215	135

Notes: A = analysis of end-groups; B = cryoscopic measurements. Solubility in organic solvents in the cold and on heating.

* Temperature at which 50% loss in weight is achieved in 2 h. In the second column a minus sign means insoluble, and a plus sign soluble.

It was established that degradation of most of the polymers investigated took place in two stages. There was a considerable loss in weight during the first stage. After this, the losses diminished sharply, owing to stabilisation of the polymer probably caused by the formation of a system of fused aromatic rings after the loss of substituents, X-ray examination showed that, at a pyrolysis temperature of 400°C, the non-volatile residue was almost identical with the initial polymer. With a pyrolysis temperature of 600°C the rings were randomly arranged in the residue, and after 1000°C the residue contained structures comprising 3–4 fused rings. After degradation at 400°C the elementary composition of the residue was close to that of the original polymer, but at higher temperatures the carbon content of the residue increased, and the hydrogen content decreased.

The relative stability of the polymers investigated was expressed in terms of the temperature at which heating the polymer for 2 h results in half-decomposition (50% loss in weight). These values are also included in Table 12. With increase in the number of substituents in the aromatic ring the thermal stability diminishes. The anomaly observed with poly-(2,5-dichlorophenylene oxide) is probably due to 2,3,7,8-tetrachlorodibenzo-*p*-dioxan structures, either present in the specimen or formed during degradation. With the exception of the tetra-substituted poly(phenylene oxides), the chlorinated polymers are more stable than the brominated derivatives. Polymers in which rotation about the oxygen atom is difficult are the least stable. Poly(phenylene oxides) having the same structure but obtained by different methods differ in thermal stability. The rate constants of the initial stage of degradation can be represented by the equations $k = 10^{12} \exp(-52\,000/RT)$ and $k = 10^{10} \exp(-43\,000/RT)$ for poly-(2,3,6-trichloro-1,4-phenylene oxide) and poly-(2,3,5,6-tetrabromo-1,4-phenylene oxide) respectively.

Most of the degradation products of poly(phenylene oxides) consisted of compounds which were volatile at the pyrolysis temperature but not volatile at room temperature. Compounds volatile at room temperature constituted not more than 4% of the total products. An attempt at a mass-spectroscopic analysis of the composition of the thermal degradation products was unsuccessful because of the complexity of the mass spectra, and therefore the authors refrained from expressing any ideas on the mechanism of degradation.

Thermogravimetric data indicate that the degradation of 2,6-p.ph.o of molecular weight ~10 000 begins in an atmosphere of nitrogen at 350°, goes most rapidly at about 400°, reaching 65% in extent, and then slows down markedly, the loss in weight reaching 70% by 900°C.[240] Other results indicate weight losses of 1%, 13%, and 69% at 320°, 370°, and 420°C.[192] After degradation at 320° and 370°C no products which condense out in a liquid nitrogen trap are observed, and after degradation at 420°C most of the products condense out at room temperature.

Heating 2,6-p.ph.o. with an equimolecular amount of phenol in the presence of a free-radical type of catalyst at 150–250°C results in the formation of 4-aryloxy-2,6-dimethylphenols and the corresponding trimers[42]. In the electrolytic oxidation of 2,6-p.ph.o. of molecular weight 20 000 at potentials up to 1.6 V only a portion of the polymer is converted into 2,6-dimethylbenzoquinone and 3,3′,5,5′-tetramethylbiphenylquinone; the unoxidised residue was not investigated[346].

Investigation of the thermal properties of 2,6-p.ph.o. of molecular weight about 40 000 in a differential adiabatic calorimeter showed[347] that its melting point was 267°C (540°K), its glass point 221°C (498°K), and its specific heat of fusion 16.4 J g^{-1}. The abnormally high T_{gl}/T_m ratio was attributed to the residual entropy of the amorphous polymer. Degradation of the polymer in an atmosphere of nitrogen began at about 460°C with a strongly exothermic process. The discrepancy in the temperature at which degradation begins, in comparison with the results of other workers, was explained by differences in the molecular weight and the method of preparation of the polymer.

Petris used a thermomechanical method and obtained different values for the glass point[348]. He found temperatures of 600°, 480°, and 400°K respectively for poly-(1,4-phenylene oxide), poly-(2,6-dimethylphenylene oxide), and poly(diphenylenepropane–diphenylene sulphone oxide).

The thermo-oxidative degradation of poly-(2,6-dimethylphenylene oxide) of molecular weight 40 000 and of the corresponding 2-isopropyl-6-methyl polymer of molecular weight 10 000 was investigated at temperatures up to 500°C by Conley and Alvino[349]. In an inert atmosphere thermogravimetric results were consistent with those of other investigators, but in air loss in weight began at 150°C with the dimethyl polymer, some increase was then observed at about 250°C, after which degradation rapidly reached 100% by 400°C. In argon the isopropyl methyl polymer behaved in the same way as the dimethyl polymer, but this behaviour did not change in air. Differential thermal analysis of the dimethyl polymer showed a strong exothermic effect at 210°C, overlapped by a still stronger endothermic effect in the range 250–270°C. Infrared spectroscopy indicated the appearance and increase in intensity of absorption bands in the range 1660–1720 cm^{-1}, which were attributed to a carboxy-group and to quinonoid structures. The mass spectra of the volatile degradation products were too complicated to be deciphered; with the dimethyl polymer the mass spectra were almost identical for degradation in inert and oxidising atmospheres. In both cases chromatography showed the presence of sixteen products, three of which, constituting up to 40% of the total quantity, could be identified as substituted phenols and quinones. With the isopropyl polymer the main products were water and acetone. No viscometric results could be obtained for the residues because of gel formation.

The scheme suggested for degradation of the isopropyl polymer involves attack on a tertiary hydrogen atom by oxygen followed by the cumene hydroperoxide type of decomposition into acetone and phenol with further cross-linking of the polymer of the ether, dioxan, or biphenyl type.

Oxidation of the methyl group is assumed to involve the successive formation of CH_2OOH, CH_2OH, CHO, and COOH groups with decarboxylation of this last group and parallel processes of cross-linking of the polymer by interaction of the groups. In both cases cleavage of the polymer chain was probably due to attack by aryloxy-radicals, but the mechanism was not specified. Kelleher and his coworkers[299-301] have studied the oxidative degradation, initiated by heat and by light, of poly-(2,6-dimethylphenylene oxide) at 100° and 125°C. The experiments were made on films of the polymer 0.025 and 0.15 mm thick, of intrinsic viscosity 0.32. The films were heated in air in the dark or in ultraviolet radiation for up to 10 000 h. Elementary analysis of the initial polymer indicated excess of oxygen—13.51% in comparison with 13.32% calculated for the formula C_8H_8O—and traces (0.14%) of nitrogen, which was regarded as indicating some oxidation of the polymer even during preparation and contamination by the catalyst. However, an alternative interpretation can be given for this fact, for the experiment was made on industrial specimens of the polymer which had been carefully purified, so that the retention of traces of catalyst in the polymer was doubtful. On the other hand, picric acid is a good initiator for synthesis of this polymer[341], and calculation based on Pepper's formula[343] gives a value of 55 000 for the molecular weight of the polymer. Accepting a bimolecular mechanism of termination during polymerisation, i.e. assuming the macromolecule to contain two $C_6H_2(NO_2)_3O$ end-groups, we obtain calculated oxygen and nitrogen contents of 13.67% and 0.153%.

As the polymer specimens aged under the above conditions their oxygen content increased from 13.51% to 17.95%. At the same time the intensity of absorption increased in the region of the hydroxy-group and at 1695 cm^{-1} (carboxyl C=O group), while a weak absorption band appeared at 1660 cm^{-1}. The mass spectrum of the volatile degradation products shows the formation of carbon dioxide and traces of hydrogen. Losses in weight reached 2% during the first 200–500 h, and increased to 4% by 10 000 h. Up to 10% of a gel fraction was formed on ultraviolet irradiation, and up to 80% in the dark. The intrinsic viscosity of the soluble fraction fell to 0.49, compared with an initial value of 0.52. The authors regard this as indicating that the molecular weight of the polymer does not change, which can hardly be correct, for the appearance of a large quantity of functional groups in the framework should result in a change in the rigidity of the macromolecule and a decrease in the viscosity of the solution. The maintenance of the viscosity in this case indicates an increase in the molecular weight of the polymer, i.e. the first stage of cross-linking. The 0.15-mm film after exposure in air to ultraviolet radiation for 2 min gives an electron spin resonance signal with $g = 2.0065$, probably due to radicals of phenoxyl type; exposure in a vacuum doubles the intensity of the signal.

The mechanism suggested for the process involves formation of phenoxy-radicals in the polymer as the first stage. There are three sources—decomposition of hydroperoxides present in the initial polymer, photolysis of an Ar–O–Ar bond, or breakdown of hydroperoxides formed during the experiment—for such radicals. The radical chain grows by the attack of an aryloxy-radical on the methyl groups, formation of phenol and a benzyl radical following addition of oxygen, etc. by a branching kinetic chain, terminated by cross-linking of the polymer or the formation of hydroxymethyl, oxomethyl, carboxyl, and other groups in the framework.

A systematic study of the thermal degradation of a series of poly(phenylene oxides) made by Kopylov and Pravednikov[350,351] established the following generalisations:

1. At 175–300°C quinol ether groups in the polymer dissociate by a first-order reaction having an activation energy of 22–23 kcal $mole^{-1}$, with the formation of terminal radicals of phenoxyl type.
2. At 350–450°C these radicals initiate degradation of the polymer chain, which under their influence undergoes random breakdown into a mixture of fragments, mainly hexamers of phenylene oxide structure containing hydroxy- and oxo-groups.
3. Increasing the molecular weight of the poly(phenylene oxide) and blocking the end-groups tends to improve the thermal stability of the polymer and increase the activation energy of degradation from 15–20 to 30–40 kcal $mole^{-1}$.

These authors suggested a general scheme for the thermal degradation of alkylated poly(phenylene oxides) involving radicals of phenyl, phenoxyl, and benzyl types as well as quinone methides. The conclusions reached in this work are confirmed by the effective stabilisation of poly(phenylene oxides) by blocking their end-groups by arylation, alkylation, alkoxylation, acylation, or the action of isocyanates, thiols[352-359], phosphites, or borates[360,361].

---oOo---

Oligo-, meso-, and poly-(phenylene oxides) constitute a separate class of organic compounds. They exhibit several identical chemical properties—high resistance to acid and alkaline hydrolysis, stability towards oxidants, ability to form complexes, and readiness to undergo substitution rather than addition and cleavage—besides having the same chemical structure. On the other hand, all these compounds are equally inclined to interact with free-radical species, which results in breakdown of the phenylene oxide chain, except in rare cases of self-stabilisation. With regard to practical application phenylene oxides are of greatest value as materials stable to heat and radiation and as a durable basis for several polymerlike transformations.

Recent Advances in Ion-exchange Catalysis

N.G.Polyanskii

Since the last review article on this topic was published by the writer seven years ago, a great deal of experimental information on the use of ion-exchange resins as organic reaction catalysts has become available, the range of techniques for ion-exchange catalysis has been extended, new types of resin have been examined, and some important theoretical generalisations have been formulated. Reviews by Andreas[2], Sugihara[3], Kaldor[4], and Mulder[5] have dealt with various aspects of the problem: the most extensive of these[3] gives 136 references, mainly up to 1960. The present article discusses some theoretical problems in ion-exchange catalysis, and the use of ion-exchange resins as catalysts in the hydration, dehydration, hydrolysis, esterification, alkylation, polymerisation, isomerisation, and condensation of organic compounds. 254 references.

CONTENTS

I. THEORETICAL PROBLEMS IN ION-EXCHANGE CATALYSIS

Helfferich[6] has defined the effectiveness q^1 of an ion-exchange resin, and has related it to the distribution coefficient λ of the reactants between the catalyst phase and the solution phase. He treats the liquid surrounding the resin particles as an inert medium whose only function is to contain and supply the reactants. This outer solution is in equilibrium with an immobile liquid phase in contact with the resin, which is considered to be the true seat of the reaction. Since the immobile liquid is not separated from the active centres of the resin by an interface, Helfferich[6] treats ion-exchange catalysis as a special case of homogeneous catalysis, whilst recognising that (as in the case of heterogeneous catalysis) rate limitation may be associated with inner diffusion effects.

Combining the concept of resin effectiveness with the hypothesis of a quasi-homogeneous reaction, Helfferich[6] examined the relationship between the former quantity and the distribution coefficient of the reactants between the phases.

Defining the distribution coefficient as the ratio of the molalities of the reactant in the resin phase ($\bar{m}_{AB}$) and in the solution phase (m_{AB}), we have

$$\bar{m}_{AB}/m_{AB} = \lambda. \tag{1}$$

Hence, the reaction rate in the presence of the resin can be written

$$v_r = k_r\bar{m}_{AB} = k_r m_{AB}\lambda , \tag{2}$$

whereas under homogeneous conditions the rate is

$$v_h = k_h m_{AB}. \tag{3}$$

Assuming that both rate constants are proportional to the concentration of catalytically active ions (m_{cat}), which are present in equivalent numbers, we have

$$k_r = k'_r m_{cat} \tag{4}$$

$$k_h = k'_h m_{cat}. \tag{5}$$

Substituting the values of k_r and k_h from (4) and (5) into (2) and (3), we finally arrive at

$$q = (k'_r/k'_h)\lambda. \tag{6}$$

Eqn. (6) describes the main specific feature of ion-exchange catalysis, and underlines the possibility of differences in the composition of the reacting system as between the resin phase and the bulk of the solution.

The experimental determination of the distribution coefficient presents some difficulties[7], which were ingeniously overcome by Tartarelli in his work on the application of Eqn. (6) to the hydrolysis of a series of aliphatic carbonate esters[7]. Relatively little work of this type has been published so far, but it has already made a significant contribution to our understanding of the influence upon ion-exchange catalysis of the factors which control the distribution coefficient (nature of the solvent, size of the reactant molecules, structure of the resin network).

The stability of the resin in operation is of the utmost importance to the theory and practice of ion-exchange catalysis. The commonly observed loss of catalytic activity of the resin during a reaction is frequently due to a gradual decrease in the number of catalytically active ions. The detailed mechanism of structural changes of this type within cation- and anion-exchange resins has been studied by the writer and his coworkers. A relationship has been established[8,9] between the thermal stability and the catalytic activity of ion-exchange media towards the polymerisation of tertiary pentenes, and the correctness of this approach has been confirmed in a study[10] of the racemisation kinetics of $d(+)$-α-isobutyldesoxybenzoin.

However, it would be wrong to ascribe all changes in activity to desulphonation, deamination, or degradation effects. In some reactions which take place under particularly mild conditions, such as the hydration of propylene oxide[11] and the decomposition of ethyl diazoacetate[12,13], the activity of sulphonated resins is found to decrease quite rapidly although desulphonation under the experimental conditions seems unlikely. It was found that in these systems the pores of the resin particles are blocked by reaction products, and reactant molecules are therefore unable to reach the active sites. The steric hindrance opposing access to some of the counterions present in the resin has been shown[12] to be high enough to prevent alkalimetric titration[14] of these ions at room temperature. The number of hydrogen ions corresponding to the initial exchange capacity can be set free only by boiling the treated resin with an aqueous solution of sodium sulphate. Gaseous nitrogen (produced by the decomposition of the diazoacetate and responsible for the loss of catalytic activity) is released at the same time.

As a result of this blocking effect, the rate constant for the reaction falls quite quickly to some limiting value, whose level is lower, the greater the degree of cross-linking of the resin catalyst. The changes in catalytic activity can be accompanied by changes in the kinetic order of the reaction[13].

In the present case, the change in catalytic activity is described by the equation

$$H=(H_A-H_R)e^{-\frac{\alpha u}{H_0}}+H_R, \qquad (7)$$

where H is the activity at the instant when the extent of reaction is u, H_A and H_R are the initial and the final residual activity respectively, H_0 is the ideal activity of the catalyst in the absence of diffusional limitations, α is the activity decrease coefficient (a measure of the probability of retention of gaseous nitrogen in the resin), and e is the base of natural logarithms. Eqn. (7) can be treated as a general equation for the change in activity of a resin under the influence of blocking by any reaction product.

Frisch[15] has discussed the mechanism of the loss of activity of macroporous resins and some special aspects of the kinetics of catalytic reactions in the presence of these resins. A useful attempt is made in that work to identify the optimum catalyst porosity (corresponding to maximum activity).

Saito[16] has produced a mathematical theory of the reaction rate in ion-exchange catalysis, with allowance for the influence of particle size, the degree of cross-linking, and the distribution coefficient of the reactants.

Thus, some attempts at generalising the results of experiments on ion-exchange catalysis have been made during the period covered by the present review. The ultimate objective of the present stage is the development of a full, quantitative theory of reactions proceeding in the presence of ion-exchange resins.

II. ION-EXCHANGE CATALYSIS IN ORGANIC SYNTHESIS

1. Hydrolytic Reactions

Because hydrolytic reactions are reversible, they are seldom carried out (at least for preparative purposes) as batchwise processes[17,18]. The reactor is usually a three-necked flask fitted with stirrer, reflux condenser, and thermometer, held in a thermostat bath. The catalyst is added to the reaction mixture when the desired temperature has been reached. A nitrogen atmosphere is used when the reactants are sensitive to atmospheric oxygen[17].

The static method is useful for determining the distribution coefficient of the reactants and solvents between the resin and the solution phase. The measurement is made rapidly, without allowing the reactant concentrations in the bulk of the solution and in the resin to change[6]. If the cation exchange resin is used in the sodium rather than in the hydrogen forms[7], the risk of hydrolysis during analysis is eliminated.

The static method has occasionally been used to study the kinetics of hydrolysis[19] by keeping the reaction mixture and the catalyst for a known time in sealed tubes in a temperature-controlled centrifuge, quenching the reaction by cooling, and analysing the mixture.

Dynamic methods require more complicated apparatus, but they have been widely used in preparative work[20-22] as well as in kinetic studies of hydrolysis[7,23-25]. The reactor usually consists of a column, packed with a layer of the resin, and carrying a continuous flow of the reaction mixture. The equilibrium can be strongly displaced towards hydrolysis by distilling off the volatile reaction products[20] or by extraction[21]. In this way the efficiency of the apparatus and the yield of the desired product can be made very high[27], and energy losses can be minimised[21]. Some reactions (e.g. the hydrolysis of pentaerythritol trichlorohydrin monobutyrate[22]) can only be exploited under dynamic conditions. Spes[21] has described a rational continuous process which offers quantitative hydrolysis yields with minimum consumption of energy.

The best hydrodynamic flow conditions are obtained with a column packing of sulphonated polystyrene catalyst rings[22] or of ion-exchange resins mixed with porous polyethylene[21].

The following compounds have been hydrolysed with ion-exchange catalysts†: ethyl acetate[27] (KU-1), methyl acetate[28], methyl lactate[29] (Duolite-C25), allyl acetate[30] (Amberlite-IR 120), ethyl malonate[31] (Dowex-50 W), esters of dicarboxylic acids[32] (KU-2), simple vinyl esters of aliphatic and aromatic alcohols[20] (KU-2 and SG-50), saccharose (Amberlite-IR 120 + Amberlite-IRA 410)[33], starch[34] (sulphonated coal), protein fractions of molecular weight 600–2000[35] (KMT), phenylalanine peptides[17] (Amberlite-IR 113), and ethyl iodide[19] (various anion exchange resins). In the latter case the resin plays the part of a reactant, by taking up acidic products and thus displacing the equilibrium in the desired sense.

The most typical saponification catalysts for esters are cation exchange resins in the hydrogen form, occasionally promoted by Ag ions[30,36] or by Group IVB and VB elements of the Periodic Table[29]. In all reactions so far examined, sulphonated resins have been more effective than carboxylic acid resins. Some reactions (e.g. the hydrolytic cleavage of vinyl phenyl ether) occur only on sulphonated resins.

The efficiency of cation exchange resins towards hydrolytic reactions depends not only on the nature of the active groups but also on the structure of the polymer network. Thus, the hydrolysis of Sarin [isopropylmethylphosphonofluoridate (Ed. of Translation)] is hardly catalysed by a sulphonated phenol–formaldehyde cation exchange resin, but it is quite fast in the presence of the sulphonated styrene–divinylbenzene copolymer[37].

Hydrolytic reactions are usually carried out at relatively low temperatures, where the stability of cation exchange resins is fairly high. Hence there is no reason to doubt the good operating lives of cation-exchange catalysts reported in the literature. According to a group of Soviet workers[22], a granular sulphonated styrene–divinylbenzene copolymer, operated intermittently during 3 years for hydrolysis and esterification reactions, has retained its activity for 500 h without regeneration. Mixed resins, containing 50 wt.% of Amberlite-IR 120 in a matrix of polyethylene, showed no detectable change after 5000 h operation[21]. On the other hand, Dowex-50w X 8 cation exchange resin suffered blocking effects, particularly at elevated temperatures, when used as an inversion catalyst for concentrated saccharose solutions[38].

The kinetic aspects of ion exchange catalysis have been investigated in the fullest detail for the case of hydrolytic reactions.

As in homogeneous acid-base catalysis, the rate of hydrolysis in the presence of resins increases (other things being equal) with the number of catalytically active ions. In some reactions (e.g. the hydrolysis of Sarin in aqueous solutions with a sulphonated resin catalyst)[37] the reaction rate is a linear function of the quantity of catalyst added. The specific rate constant of these reactions, referred to 1 g of resin or to 1 mg-equiv. of sulphonic acid groups, is independent of the amount of catalyst. However, these

---

† Throughout this paper the grade of resin is shown in brackets.

relationships become more complicated when diffusional limitations are involved. The specific rate constant for the inversion of saccharose in aqueous solution[39] decreases continuously from 4.63×10^{-6} to 3.96×10^{-6} s^{-1} mg-equiv.$^{-1}$ on increasing the amount of KPS-200 resin catalyst from 1.16 to 6.87 g. The specific rate constants for the hydrolysis of the diesters of dicarboxylic acids in water–dioxan solutions remain constant as the proportion of KU-2 resin is increased up to 25%,[40] but they begin to fall off at higher concentrations, which the authors ascribe to diffusion-limited access to some of the H^+ ions in the sulphonic acid groups.

As in the case of homogeneous acid–base catalysis, the rate of hydrolysis in the presence of ion-exchange resins is influenced by the strength of the bond being attacked (i.e. by the chemical nature of the compound). However, and in contrast to homogeneous catalysis, the steric factor (defined as the ratio of the size of the reactant molecules to the distance between the counterions of the nearest active groups in the catalyst) plays an important role in ion-exchange catalysis. This effect accounts for the often reported influence of molecular size on reaction rate. Ordyan and coworkers[41] found that methyl acetate is hydrolysed 5 times faster than butyl acetate, and the latter only 1.2 times faster than methyl valerate. The ratio of the rate constants for the esters of the C_5 acids (valeric, trimethylacetic, and isovaleric) is 3.29 : 1.31 : 1, indicating that the reaction is retarded by branched chains: similar effects have also been observed[7] with n- and isopropyl acetate.

It is important, however, not to overestimate steric conditions as a kinetic factor in ion-exchange catalysis. Thus, disaccharides show widely different rates of hydrolysis despite the fact that the geometrical conditions of the reaction are practically identical in all cases. Saccharose, in which the C–O–C bond joining the monosaccharide residues is less stable than in its isomers, is hydrolysed 100 times faster than maltose and cellobiose on KPS-200 resin[13].

Inert solvents can have a profound effect on the rate of hydrolysis. The rate constants for the hydrolysis of ethyl acetate[27] and acetanilide[42] in aqueous acetone solutions decrease as the mole fraction of acetone increases. We must assume that the inhibition of the reaction by increased concentration of organic solvent is due not only to the lowering in dielectric constant but also to the different distribution of reactant molecules between the solid and the liquid phase. As the concentration of acetone increases, the relative amount of water absorbed by the resin also increases, and this effect hinders the penetration of relatively insoluble compounds into the resin. Bolton and Henshall[42] conclude, from their experimental results, that sparingly soluble compounds are most efficiently hydrolysed in the presence of the minimum amount of organic solvent required for their dissolution. The relationship between the reaction rate and the dielectric properties of the medium is not always unequivocal. For example, the rate of hydrolysis of dimethyl sebacate in water–dioxan and water–acetone solutions in the presence of KU-2 cation exchange resin goes through a maximum on varying the ratio of water to organic solvent[32].

The influence of the organic solvent on the efficiency (as defined by Hammett) of the resin catalyst was discussed at length in our previous review[1]. In aqueous solutions the efficiency of resins with an intermediate degree of cross-linking towards the hydrolysis of acetates[7] and of ethyl acetoacetate[31] is in excess of unity. The efficiency of a strongly cross-linked cation exchange resin[22] towards the hydrolysis of methyl acetate is well below unity, probably as a result of diffusional limitations.

Reactants having large molecules are particularly sensitive to changes in the content of bridging component. The hydrolysis of Sarin[37] was used to demonstrate the rapid increase in rate constant accompanying a decrease in the divinylbenzene content of the resin from 8 to 1%. It was shown that the catalytic activity of the weakly cross-linked cation exchange resin is comparable to that of soluble acids.

Many workers have examined the influence of the resin particle size on the reaction kinetics in order to throw light on the role of diffusional limitation. The hydrolysis rate constants of ethyl acetate[25] and acetamide[43] are practically independent of particle size over quite a wide range: the rate-limiting step in these reactions is the chemical act itself.

Kinetic effects arising from inner diffusion are very clearly observed when the reactant molecules are very large or branched. Hydrolysis of saccharose under static[18] or dynamic[23,38] conditions is much faster when smaller resin particles are used: Reed and Dranoff[23] have observed a linear relationship between the rate constant and the catalyst particle size. In the hydrolysis of Sarin[37] the kinetic curves become steeper as the diameter of the catalyst particles decreases and as the temperature increases.

The calculated activation energy for the hydrolysis of Sarin on Amberlite-IR 100 is relatively low (5500 cal mole^{-1}). This is additional evidence in favour of rate limitation by inner diffusion. However, the same reaction in the presence of Dowex-50, which has a more open three-dimensional network, gave an activation energy of 11200 cal mole^{-1}, and closely similar values were obtained for the hydrolysis of ethyl acetate[27] and dimethyl sebacate[32].

The rate of hydrolysis of Sarin[37] on Dowex-50 cation exchange resin is insensitive to stirring rate. On the other hand, with a more active catalyst (Amberlite-IRA 400) the rate constant at 20° was 5.3, 7.5, and 8.5 h^{-1} at 60, 800, and 1000 revolutions min^{-1} respectively, suggesting that film diffusion was the rate-limiting step.

Thus, the mechanism of the rate-limiting step depends on the nature of the catalyst.

2. Hydration Reactions

The hydration of organic compounds has been investigated, like their hydrolysis, under static conditions[44] or in a flow system[45].

The hydration of unsaturated hydrocarbons, which gives rise to a system of immiscible liquids, presents some practical difficulties. Effective contact between the reactants and the catalyst is obtained by specially pretreating the cation exchange resin[54] or by homogenising the liquid phase with a suitable solvent or emulsifier[46-48]. Much better yields are obtained in the conversion of hydrocarbons into alcohols by using mixed gas–liquid processes, in which the reaction takes place in a thin layer of water surrounding the resin particles, whilst the reaction products are continuously removed by an excess of water[45].

The writer and Kozlova[44] have increased the equilibrium conversion of tertiary pentenes in the hydration of the pentane–pentene fraction by using a large excess of water and keeping the catalyst (KU-2 cation exchange resin) at the boundary between the liquid phases in a hydrophobic state, obtained by replacing part of the hydrogen counterions by trioctylamine[49]. The reactor was of stainless steel, and fitted with a stirrer. It is interesting to note that the achievement of equilibrium was accelerated by the addition of anion exchangers: the mechanism was probably analogous to that of the hydrolysis of saccharose[33]. The use of a hydrophobic cation exchanger raised the conversion of tertiary pentenes from 2.7 to 13% (as compared with the previously recommended method[50]).

In the development of apparatus for the continuous production of tertiary butanol by the conversion of isobutene in high yields it has been necessary to abandon the countercurrent principle[51]. It is stated that the best contact between the reactants and the most complete conversion are obtained by a downward flow of water and isobutene through a layer of resin.

Ion exchange resins have been used for the hydration of the following compounds: tertiary pentenes[44,46] (KU-1, KU-2), 2-methylpent-1-ene[46] (KU-1), 2-dioxymethylnorbornene-5[52] (Dowex-50), acetylene[53] (KU-2), hydrocarbons with double and triple bonds[54] (Allasion CS), propene oxide[11] (KU-2. phosphate resins), and hydrocarbons with lactone rings[55] (Amberlite-IRA 400).

Hydration in the presence of a cation exchanger in the hydrogen form is believed to involve the formation of an intermediate carbonium ion[1]. Sulphonated resins are almost invariably chosen, but phosphate and even carboxylate resins can be used for the hydration of reactive materials[11] such as propene oxide. Cation exchange resins in the Hg form are used as catalysts for the Kucherov reaction[53,54]. In view of the conditions used in their preparation, these catalysts are likely to contain H^+ counterions; hence, it is interesting to examine the effect of various counterions on the catalytic activity of the resin. A group of Roumanian workers has shown that in the presence of CS-1 resin in the Cu, Zn, or Cd form acetylene undergoes polymerisation rather than hydration[56].

Cation exchange resins suffer changes of various types when used in practice as hydration catalysts. Firstly, changes in the degree of swelling under the influence of the reactants or of the heat of reaction can lead to disintegration of the particles[1]. An interesting way of guarding against these effects is to use coarsely granular[57] or two-phase[21] cation exchange resins. Secondly, blocking of the active groups in the resin may occur as a result of the incorporation of reactant[58] or product[11] molecules. Thirdly, irreversible chemical reactions (e.g. desulphonation) can proceed within the resin at high temperatures. The writer and Tulupov have shown[58-60] that this reaction can be vigorous in aqueous, alcoholic, and other media, particularly at high temperatures and when the heat of reaction is large. Thermal desulphonation and other forms of ageing of the resin lower the yield of hydration products[45].

The thermal stability and catalytic activity of sulphonated cation exchange resins in hydration reactions depend on the structure of the polymer network. In many reactions the presence of sulphonic acid groups is a necessary but not always sufficient condition for catalytic activity. For example, the hydration of acetylene proceeds smoothly in the presence of the sulphonated cation exchange resin KU-2, but it is not catalysed by the sulphonated phenol–formaldehyde KU-1 resin[53]. Sulphonated asphaltene deposited on silica gel does not catalyse the hydration of tertiary pentenes[61].

The water uptake of the catalyst plays an important role in determining the effectiveness of the catalyst, and sometimes even the course of the main reaction. It has been shown[8] that a KU-2 resin containing $<$ 24% of water catalyses only the polymerisation of tertiary pentenes. At higher water concentrations the strength of the bond between water molecules and the sulphonic acid groups decreases, and addition of water to the double bond of the hydrocarbon becomes easier. In the presence of a large excess of water the hydration of pentenes is practically quantitative, with a negligible amount of polymerisation[44].

Tertiary pentenes form carbonium ions more readily than other C_5 alkenes: in practice, therefore, they alone can add on water in the presence of KU-2. Normal pentenes, and 3-methylbut-1-ene, remain unchanged[62] even after lengthy treatment at high temperature (75°) with hydrated KU-2 resin. A process for the selective removal of tertiary pentenes from complex mixtures[62] can be based on these properties.

The rate of hydration of alkenes and other sparingly water-soluble compounds can be increased by adding indifferent organic solvents to improve the contact between catalyst and reactants. This principle has been successfully applied in practice[46], but a quantitative relationship between the reaction rate and the nature of the solvent has not yet been derived.

The hydration of alkenes is often accompanied by polymerisation and isomerisation side reactions, also involving a carbonium ion mechanism. Polymer formation has been observed in the hydration of propene[45], isobutene[51], and tertiary pentenes. These side reactions can become predominant under the appropriate experimental conditions[63].

3. Dehydration Reactions

For preparative purposes, dehydration is often carried out as a batch process. When an azeotrope-forming solvent[64] is used, the reactor includes a reflux condenser fitted with a water-separation trap, and the reaction is allowed to continue until the stoichiometric amount of water has been collected. In some cases the organic dehydration product is steam-distilled, thus ensuring that the water content of the resin remains constant and providing relatively mild conditions[65].

Under industrial conditions, dehydration is usually carried out as a continuous process. Soviet workers[66,67] have described a rational pilot-scale process for the production of isobutene which relies on a reactor without heat exchangers in order to minimise energy consumption. Free transport of the materials and a high throughput (1300–1400 kg h^{-1}) were achieved by locating the KU-1 cation exchange resin in the upper part of the reactor[68].

A flow apparatus for studying dehydration kinetics has been described[69]. It includes a continuous sampling facility (a microsyringe for removing samples of the product through a silicone rubber cap).

Resins have been used to dehydrate the following compounds: pentan-1-ol[64] (KU-2), cyclohexanol[70] (KU-2), cyclohexylethanol[71] (KU-2), menthol[72] (sulphonated polyphenyl resin), terpin hydrate[65] (KU-2), dimethylvinylethynyl carbinol[74] (KU-1), methylphenylethanol[73] (KU-2, phosphate exchangers), symmetric alkyne glycols[75] (KU-1), and castor oil[76]. All the cation exchangers were used in their hydrogen form.

There can be no doubt that the use of cheap sulphonated phenol–formaldehyde resins is fully justified, since these materials can extract water from alcohols at temperatures $<$ 100°. Under these conditions the exchange capacity and other physicochemical properties of the resin do not change appreciably[60]. At higher temperatures, on the other hand, the loss of capacity of these resins in aqueous[60], alcoholic[60], and hydrocarbon[8] media can be serious.

Thus, the claim by some French workers[77] that sulphonated phenol–formaldehyde resins can be used up to 210° is unacceptable. The KU-2 resin is appreciably more stable[60]: it can be used as a dehydration catalyst up to 150°, or up to 200° if used once only. If the experimental conditions require a reaction temperature in excess of 200°, the recently developed[72] sulphonated polyphenyl cation exchange resins, which have a high thermal stability, should be tried.

Since the catalytically active form of the cation exchange resins is the hydrogen form, the effectiveness of these catalysts is determined primarily by their acidic properties. The writer has shown[78] that the carboxylic acid resin SG-1 does not catalyse the dehydration of t-pentanol. The more acidic, phosphorus-containing RF cation exchanger accelerates this reaction, but the achievement of equilibrium is even faster in the presence of the KU-2 cation exchange resin. The relative activity of the sulphonate and phosphate exchanger was later confirmed[73], and it was shown that in the latter the kinetics of methylphenylethanol dehydration are affected by the structure of the polymer network. Zirconium phosphate was found to be the least active of the phosphorus-containing exchangers.

Water content has a large effect on the activity of cation exchangers. It would appear from the available experimental data that water absorption lowers the catalytic activity of cation exchangers towards the dehydration of compounds with a relatively low molecular weight (e.g. ethanol[69] and t-butanol[79]). In the dehydration of compounds with large or branched molecules, such as terpene alcohols[80], trapped water loosens the three-dimensional network of the cation exchanger and decreases the steric barriers to the formation of carbonium ions, thus leading to faster reaction.

An important controlling factor in dehydration reactions at cation exchangers, which allows control over the nature and yield of the products, is the composition of the medium and in particular the addition of indifferent solvents. Karpov and coworkers[81], who published the only noteworthy data on this subject, stress the importance of careful choice of solvent. Thus, addition of high-boiling hydrocarbon solvents in the preparation of dipentyl ether affects neither the yield nor the rate of the reaction, but if the reaction is carried out in a *p*-xylene medium the yield of ether drops by 17% owing to alkylation of the solvent by the alcohol. For the same reason, addition of xylene is undesirable in the preparation of di-n-octyl ether. On the other hand, addition of n-nonane prevents the complete dehydration of octanol on KU-2 and raises the yield of octyl ether by 29%.

The reaction temperature has a profound effect on the nature of the dehydration products. Shuikin and coworkers[82] have shown, in their study of the dehydration of primary alcohols, that the reaction on KU-2 gives mainly ethers at 135° in 5 h. On raising the temperature and the contact time, the proportion of alkenes in the reaction products increases.

As in the case of homogeneous acid–base catalysis, the rate of dehydration on ion exchangers increases with the concentration of catalytically active ions. The dehydration of t-butanol is faster in the presence of KU-1 resin[83] than in the presence of an equivalent amount of sulphuric acid. According to Helfferich's theory[6], the greater efficiency of the ion exchanger is due to selective absorption of alcohol molecules by the cation exchanger rather than to any difference in catalytic activity between hydrogen ions under homogeneous catalysis and ion-exchange catalysis conditions respectively. Unfortunately, no data are given[83] on the distribution of the alcohol between the liquid phase and the catalyst.

Soviet workers have shown that the catalytic activity of sulphuric acid and of sulphonated polystyrene resin towards the dehydration of tetracycline is determined only by value of the Hammett acidity function and is independent (within the range explored) of the concentration of water, divinylbenzene, and third component (Na^+ ions) in the resin[84]. As Fig. 1 shows, all the points in the experimental plot of the logarithm of the rate constant for this reaction against the acidity function lie on the same straight line. This is evidence that the catalytic activity of the H^+ ions is the same in the resin and in the acid phase. It would be interesting to extend these results[84] to reactions whose kinetics depend on the distribution of reactants between the liquid phase and the cation exchanger.

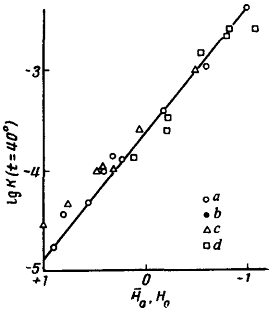

Figure 1. Logarithm of the rate constant for the dehydration of tetracycline plotted against the acidity function in the presence of: *a*) H_2SO_4; *b*) ion exchanger in the mixed Na–H–T form; *c*) ion exchanger in the T–H form; *d*) ion exchanger in the T–H form, dried to a known water content (T = tetracycline)

Detailed kinetic studies of the dehydration of tetracycline[85], ethanol[69], and dimethylethanol[79,83] have been published.

4. Synthesis of Esters

Esters are prepared mostly by esterification and ester interchange (transesterification) reactions. In order to avoid the formation of water and thus to raise the yield of esters, anhydrides are sometimes added with the alcohol[86,87], and alkenes[88], ethylene oxide[89], or ethylene carbonate[90] with the acid.

Like the reactions discussed above, esterification can be carried out as a batch process or as a continuous process. A simple version of the laboratory apparatus for the continuous production of ethyl octanoate[91] is shown in Fig. 2. The mixture of reactants in a known molar ratio, and containing hydroquinone as a polymerisation inhibitor, is supplied by the metering pump *2* to the bottom of a temperature-controlled glass reactor *4* of the "double tube" type, packed with KU-1 resin swelled in the reaction mixture. The vapours of ethyl octanoate, ethanol, and water, formed in the reactor at the boiling point of the reaction mixture, are continuously condensed (*6*) and collected in the receiver *7*.

Trofimov and Isagulyants[92] have described a relatively simple, high-capacity reactor for the continuous production on an industrial scale of n-nonyl methacrylate by the transesterification of methyl methacrylate.

Ion exchangers have been used to esterify formic acid with ethanol[93] (KU-2), acetic acid with ethanol[94] (KU-2), butanol[95] (KU-2), isobutanol[95] (KU-2), and pentanol[96] (KU-2), acrylic acid with ethanol[91], methacrylic acid with C_5–C_{10} aliphatic alcohols (KU-2) and ethanediol[98] (SBS, SDV-3), naphthenic acids with ethanediol[99] (KU-2), adipic acid with methanol[100] (KU-2) and higher aliphatic alcohols[101] (KU-2) as well as ethanediol[86] (silicone cation exchange resin), sebacic acid with allyl alcohol[102] (KU-2), benzoic acid with ethanediol[103] (KU-1), salicylic acid with aliphatic alcohols[104] (KU-2), maleic acid with allyl alcohol[102] (KU-2), terephthalic acid with methanol[105] (Wofatit KPS-200), and sorbic acid with aliphatic alcohols[106] (KU-2). Furthermore, esters have been prepared by the reaction between maleic anhydride and butanol[107] (KU-2), phthalic anhydride and glycerol[86] (silicone cation exchange resin), and methyl methacrylate and n-nonanol[92] (KU-2).

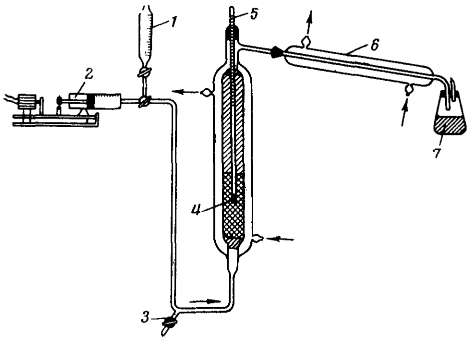

Figure 2. Laboratory apparatus for the continuous esterification of acrylic acid with ethanol

Since many of these esters are produced on an industrial scale, the use of ion-exchange catalysis should now be regarded not merely as an elegant preparative technique but also as a potential method in modern chemical technology, combining simplicity in the design and operation of the plant with high yields of valuable products.

In addition to the traditional hydrogen form, salt forms of sulphonated cation exchangers[108,109], which behave as Lewis acids, are used in the catalytic synthesis of esters. Because of their high thermal stability in the salt form[110], these resins can be used to accelerate reactions taking place at temperatures of 200° or higher. Sulphonated cation exchangers in the hydrogen form on a silicone substrate are also interesting in this respect[86]. Macroporous cation exchangers—about whose catalytic activity very little is yet known—offer the prospect of accelerating esterification reactions involving large molecules.

It should be noted that the nature of the polymer network of the resin has practically no effect on the yield of the ester[107] or on the kinetics of the reaction between low-molecular-weight acids and alcohols[16]. However, if one of the reactants has a high molecular weight the structure of the three-dimensional network becomes an important kinetic factor: some interesting comparisons have been reported[111,112] of various sulphonated cation exchangers as catalysts for the synthesis of butyl oleate and polyesters. Cation exchangers containing carboxyl groups are said[111] to have little effect on the rate of these esterifications.

On increasing the amount of cation exchanger the yield of ester, as a rule, increases to a limiting value and thereafter remains constant[96,104,113]. However, in the esterification of methacrylic acid with higher alcohols[114] the yield of ester goes through a maximum at 10 wt.% of catalyst. Unfortunately, the results of different authors are often difficult to compare because different units are used to define the amount of catalyst added. The writer suggests the adoption of mg-equiv. of active groups per g-equiv. of acid or alcohol as a universal scale: these units are particularly useful in kinetic studies.

Rate constants referred to 1 mg-equiv. of active groups give a clear indication of the specific features of the catalyst and are to be preferred to the traditional quantities used in formal kinetics. The rate constants for the esterification of glycerol by acetic acid, referred to 1 g of KU-1 and KU-2 resins, have been reported[115] as 1.65×10^{-4} and 4.29×10^{-4} min^{-1} respectively. When referred to 1 mg-equiv. of active groups these constants become practically indistinguishable (4.0×10^{-4} and 3.9×10^{-4} min^{-1}), which is consistent with the lack of a specific effect of the network structure under these particular conditions.

Table 1. Influence of particle size and cross-linking of KU-2 ion exchanger on the rate of esterification of acetic acid by ethanol

Particle size, mm	Reaction rate, $\frac{g\ CH_3COOH}{s \cdot g\ KU\text{-}2} \times 10^4$			
	1% devinylbenzene		20% divinylbenzene	
	liquid-phase reaction	vapour-phase reaction	liquid-phase reaction	vapour-phase reaction
0.5—1.0	53	16.2	11	9.8
0.1—0.25	58	34.5	—	13.7
0.01—0.10	67	85.8	18	20.5

If the rate of esterification is limited only by the reaction itself, and diffusional limitations are negligible, the reaction rate is independent of the stirring rate[116,117] and of the size of the resin particles[116–118]. As inner diffusion effects become predominant, the size of the catalyst particles begins to influence the rate of esterification. Table 1 shows the effect of this factor and of the degree of cross-linking of the KU-2 exchanger on the rate of esterification of acetic acid by ethanol in the liquid[94] and the vapour[119] phase (for 15–20% conversion).

It is evident from Table 1 that the influence of particle size on the rate of esterification of acetic acid by ethanol is appreciable even in the liquid phase. In the vapour phase the effect is more marked because the swelling of the catalyst is minimal. As expected, the reaction is faster on the strongly swelled KU-2 cation exchanger containing 1% of divinylbenzene than on the resin with 20% of cross-linking agent. Very large reactant molecules can interact by topochemical reactions: in this case the effect of particle size is even more marked[1]. In a very few cases (e.g. the esterification of glycerol by phthalic anhydride and talloleic acid[86]) the cation exchanger does not accelerate the reaction, evidently because of inactivation of the exchanger by alkyd resins.

The rate of esterification decreases substantially when the chain length of the aliphatic radical in the alcohol[104] or the acid[120] is increased: the analogous relationship for homogeneous acid–base catalysis was established by Menshutkin[121] at the end of the last century. The influence of this factor on the esterification kinetics is less marked at elevated temperatures[122].

The yield of esters is a function of the structure of the reactants. Normal alcohols give esters in higher yields than their isomers. The accurate correlation between the yield of ester and the molecular weight of the alcohol, which had been established[123] for homogeneous reactions at equilibrium, does not hold in the presence of ion exchange catalysts[97]. On raising the molecular weight of aliphatic acids up to C_5 the yield of isopentyl esters remains constant[120], but with still larger acid molecules the yield begins to decrease. This effect is probably associated with side reactions, or with the preparative difficulty of isolating the esters of higher acids, rather than with any thermodynamic feature of the esterification reaction.

Some workers[96] lower the temperature of the reaction mixture by adding low-boiling solvents in order to minimise side reactions. However, this expedient also lowers the rate of the main reaction, and it is necessary to reach a compromise and accept solvents of relatively high boiling point. In particular, the esterification of ethanediol by naphthenic acids and of pentanol by salicylic acid gives higher yields[99,104] in boiling xylene than if toluene is used to remove the water azeotropically.

The yield of esters[124] and the reaction kinetics[120,122] are very sensitive to the molar ratio of alcohol to acid. Esterification in the presence of an excess of alcohol produces conditions leading to resin swelling, which accelerate the reaction[120,122]. On the other hand, in the presence of an excess of carboxylic acids the resins do not swell appreciably and the reaction is slower than when the reactants are taken in equimolecular proportions.

It does not follow, however, that a chemical reaction is invariably accelerated by increasing the degree of swelling of the resin. The water evolved in the liquid-phase esterification of acetic acid by ethanol accentuates the swelling of the cation exchanger, but the rate constant of the reaction falls off[94]. In the esterification of salicylic acid by methanol, increased water concentration in the reaction mixture tends to inhibit the reaction[117]: the author[117] correctly ascribes this effect to partial deactivation of the protons in the sulphonic acid groups by hydration, as a result of which the formation of active intermediate complexes is sterically hindered.

Esterification is often accompanied by side reactions which (like the main reaction) involve the participation of a carbonium ion: dehydration of the alcohol[104,120] and polymerisation of the resulting alkenes[120], alkylation of the solvent[104], and dehydration of the ester[122].

The adoption of ion-exchange catalysis in industrial synthesis is economically justified[96]. According to Chashchin and coworkers[124], a saving of 10–20 roubles per tonne of butyl acetate could be made by replacing the soluble catalysts by ion exchangers.

5. Alkylation

Like the reactions already discussed, alkylation can be carried out as a batch process or as a continuous process. The use of a fluidised bed of catalyst by Belov and Isagulyants[125] is particularly interesting.

Ion exchangers have been used as catalysts for the alkylation of *p*-xylene by propene[126], *o*-xylene by isobutanol[127] (KU-2), phenol by propene[128] (KU-2), isobutene[129], and pentenes[130] (Ku-2), and by 2-ethylhex-1-ene[131] (SDV-3), propene trimer[132] (Amberlist-15), isoprene[133] (KU-2), monoarylacetylenes[134] (sulphonated cation exchanger), α-pinene[135] (KU-2), isobutanol[136], higher aliphatic alcohols[137] (KU-2), and benzyl alcohol[138] (KU-2); also for the alkylation of *p*-cresol by isobutene[139] (KU-2), cyclohexene[140] (KU-2), styrene[141] (KU-2), octanol[142] (KU-2), and cyclohexanol[140] (KU-2), for the alkylation of *o*-xylenol by hex-2-ene[143] (KU-2), cyclohexene[143] (KU-2), and styrene[144] (KU-2) of β-naphthol by isobutanol and butanol[145] (KU-2), of pyrocatechol by but-1-ene[146] «Allasion CS» and isobutene[147] (KU-2), of hydroquinone by isobutene[148] (KU-2), of guaiacol by hex-1-ene[149] (KU-2), and of *p*-methoxyphenol by alkenes[150] (KU-2).

The main reaction in the alkylation of phenols is direct replacement of hydrogen in the benzene nucleus, leading in most cases to the formation of monoalkylphenols: the substitution occurs mostly in the *p*-position to the phenolic hydroxyl, or (if this position is occupied) in the *o*-position[142]. Dialkyl phenols are sometimes formed in addition to the monosubstituted phenols. In the presence of a large excess of alkylating agent the disubstituted phenol may account for most of the yield[143,144]. Some workers have observed the formation of alkyl phenyl ethers, which usually[140,151] but not invariably[140] undergo regrouping into alkylphenols. Some reactions are complicated by the disproportionation of the alkylphenols[152], the replacement of one alkyl radical by another[152], the degradation of branching side-chains[153], and polymerisation of the hydrocarbons[144,152]. The yield of dialkyl substituted phenols decreases as the molar ratio of phenol to alkylating agent increases[125,138,148,154,155] and also if the reaction time is extended[155]. Other conditions being the same, the yield of dialkylphenols on cation exchangers is less than in the presence of soluble acids[155], which suggests selective sorption of the phenols from the reaction mixture[154].

The nature of the reactants has a considerable influence on the total yield of alkylation products. Increasing the number of substituents in the nucleus of the compound to be alkylated, and branching of the hydrocarbon chain of the alkylating agent, produce a lower yield of alkylphenols[153]. Soviet workers[153] have convincingly demonstrated, by studying the alkylation of the cresol and xylenol isomers, steric hindrance to the entry of a tertiary radical in the *o*-position to the methyl or hydroxyl group of a phenol. This *ortho*-effect is most marked in symm.*o*-xylenol, which is not alkylated by di-isobutene: the t-octyl radical (6.18 Å in diameter) cannot be located between two methyl groups or between a methyl and a hydroxyl group, whose separation is 5.24 and 5.17 Å respectively[157].

Information on the influence of the cation exchanger on alkylation reactions is mostly qualitative[141], and is so scanty that useful generalisations cannot be made.

More definite conclusions are possible on the effect of water content of the catalyst on the yield of alkylation products. The yield of alkylphenol on KU-1 resin containing 20–30% of water is 50% lower than on the same resin dried to constant weight[158]. Alkylation of phenol on SDMS resin prepared by sulphonation of shredded rubber[159] and having a water content of 20% gave a 69% yield of octylphenol. On decreasing the water content to 9% the yield rose to 75%, and on a dry resin the yield reached 80%. The highest yield of bis-phenols by the reaction of phenol with diarylalkynes[134] was obtained at 2% water content of the cation exchanger. From these results, pre-drying of ion-exchange alkylation catalysts in an air oven at 110–120° is recommended. Alternatively, the resin may be dried in a vacuum or by refluxing with an azeotropic solvent (e.g. benzene).

If the alkylation involves not only the surface but also the bulk of the resin particles, smaller particle size raises the yield of dialkyl derivatives. Soviet workers have given a convincing explanation of this effect[154] by pointing out that the molar ratio of phenol to alkylating agent is greater in the cation exchanger than in the bulk of the solution: this favours the formation of monoalkyl derivatives. When the particle size of the resin is decreased the relative importance of the reaction taking place at the surface (and therefore at the same molar ratio of components as in the reaction mixture) increases, and so also does the yield of dialkylphenol.

In some cases it is useful (or even necessary) to operate at elevated temperatures in order to increase the rate of diffusion of reactants within the resin particles and the mobility of the counterions of the active groups as well as accelerating the reaction itself. However, an excessive rise in temperature may cause dealkylation and favour side reactions as well as irreversible changes in the catalyst. Thus, on raising the temperature of the alkylation of phenol by di-isobutene in the presence of the cation exchanger SDMS the yield of alkylphenol increases up to 100°, remains constant in the range 100–115°, and falls off above 120° due to the onset of dealkylation[159]. When phenol is alkylated with high-molecular-weight alkenes, the total yield of alkylphenol rises from 64 to 81% as the temperature is increased from 150 to 160°. [160]However, whereas at 130° only monoalkylphenols are formed, the product obtained at 150° appears to contain (judging by its boiling range) di- and even polyalkylphenols.

Special caution is necessary when using sulphonated phenol–formaldehyde cation exchangers at high temperatures. The KU-1 resin is so unstable towards heat that the yield of useful product decreases by a factor of two[141] when the resin has been used three times as a catalyst for the aryl-alkylation of *p*-cresol at 110°. Under the same conditions the KU-2 resin retains its catalytic properties unchanged for at least 12 consecutive operations, and has been used for 500–600 h without regeneration[153] in the continuous alkylation of phenols at 120°. Under the more stringent conditions of the alkylation of asymm.*o*-xylenol by alkenes[143], the exchange capacity of KU-2 fell from 4.9 to 2.3 mg-equiv. g^{-1} after 13 reaction cycles.

The catalytic properties and technological potential of cation exchangers in alkylation reactions are affected not only by changes in exchange capacity but also by the extent of swelling in the reaction medium[161], resinification of the surface[161,162], and breaking up of the particles[163]. Resinification of the surface can be avoided by adding indifferent solvents, and its effects can be cured by regenerating the cation exchanger. Regeneration can be achieved in the cold or by refluxing with resin solvents such as acetone[143], ethanol[154], benzene[161], or an alcohol–benzene mixture[153]. Some authors recommend successive treatment of the resin in alkali and hydrochloric acid[143] (or 10% sulphuric acid[135]) after the treatment with organic solvents.

The mechanism of the reaction is generally considered to be a nucleophilic addition through a reactive intermediate state (π-complex or carbonium ion[136,164,165]).

This mechanism has recently been confirmed by Soviet workers[153] by measurements of the electrical conductivity of mixtures of phenol, KU-2 resin, and the trimer of propene.

6. Polymerisation and Isomerisation Reactions

These reactions can be carried out as batch processes at high pressure in stirred autoclaves[166], but semi-continuous[167] or continuous[168] methods are usually employed. The continuous method sometimes offers higher yields[167] as well as the other advantages of continuous operation.

Ion-exchange resins have been used as catalysts for the dimerisation and trimerisation of alkenes[166,168] and acetaldehyde[167] (KU-2), and also for the polymerisation of vinylbenzene[169], isobutyl vinyl ether[170], and acetaldehyde[171] (various sulphonated resins). Ion exchangers have also been used as catalysts for the isomerisation of alkenes[62,72,172,173] (sulphonated cation exchangers), unsaturated alcohols[54] ("Allasion CS"), hydrocarbons (Wofatit L-150)[174], phenol esters[175] (KU-2), cyclohexanoneoxime[176] and phenylhydrazones[3] (resins of the KU-2 type).

Often polymerisation, isomerisation, and cracking occur together, and the reaction product is complex and variable in composition. In most cases these reactions are accelerated by cation exchangers in the H form, but a resin containing mercury counterions has been used[54] for the isomerisation of propynols. The isomerisation of glucose is accelerated by anion exchangers in the OH form[174].

In the low-temperature polymerisation of oxygen-containing compounds the main factor leading to loss of catalytic activity is the blocking of reactive sites by the reaction products, which hinders the contact between the counterions and reactant molecules[170]. Impurities in the monomer contribute to the deactivation of the catalyst: hence, special attention must be devoted to the purification of the raw materials.

If the isomerisation can proceed at temperatures up to 80–90°, sulphonated phenol–formaldehyde cation exchangers can be used without serious loss of catalytic activity. Thus, after 99, 477, and 1600 h operation at 75–80°, samples of KU-1 gave 83, 78, and 76% conversion of 2-methylpent-1-ene and 2-methylpent-2-ene, the selectivity remaining constant[168]. A cation exchanger of higher thermal stability (e.g. KU-2) must be used for the di- and trimerisation of alkenes, which usually require temperatures in excess of 100°.

The effect of temperature on the yield of polymerisation and isomerisation products depends on the nature of the reactants, on the reversibility of the reaction, on the reaction time, and on the moisture content of the resin[177–180].

The possibility of a reaction is often determined by the nature of the active groups and by the geometry of the three-dimensional network of the resin. For example, it is well known that carboxylate and phosphate cation exchangers do not catalyse the polymerisation of isobutene[177]. Sulphonated polyphenyl cation exchangers[72] are efficient catalysts for the isomerisation of but-1-ene to but-2-ene, and for the same reason a phosphoric acid polyelectrolyte has a negligible effect on the rate of this reaction. The KU-2 resin is a more effective catalyst than hydrochloric acid for the pinacoline rearrangement[181], and the polymeric carboxylate cation exchanger KB-4P-2 does not affect the rate of isomerisation.

However, these reactions are not accelerated by any sulphonated cation exchanger in any physical state. For example, a technical mixture of KU-1 and another sulphonated phenol–formaldehyde cation exchanger does not catalyse the polymerisation of tertiary pentenes[182] and isobutene[177]. Within limits, the activity of a cation exchanger can be altered by modifying the state of the resin. Thus, by finely dividing the dried KU-1 resin or by loosening its network with water or methanol it is possible to bring about a very significant increase in its catalytic activity towards the polymerisation of tertiary pentenes. However, if the finely divided exchanger is heated in the air or in nitrogen atmosphere it ceases to be a catalyst for this reaction[182]. The more ordered network of the polymeric KU-2 catalyst is sufficiently open even under dry conditions to permit diffusion of low-molecular-weight alkenes such as isobutene[170], tertiary pentenes[178], and α-methylstyrene[73]. In this case the polymerisation proceeds faster on the dried than on the hydrated resin. The KU-2 catalyst is more active towards the formation of high polymers when in the hydrated state[80], since a very open three-dimensional network is needed to allow the interlinking of a large number of monomer units.

The step which controls the reaction kinetics depends on the water content of the cation exchanger. In the pinacoline rearrangement, carried out in the presence of KU-2 resin swelled to the limit, the rate-limiting step is the chemical reaction itself[181], because the diffusion of pinacone is unhindered when the resin particle is swelled by water. Diffusional limitation begins to be appreciable in the polymerisation of t-pentenes on dried KU-2 resin, and therefore the rate of this reaction decreases as the size of the catalyst particles increases. Fang[10] obtained a similar somewhat unexpected result in his work on the kinetics of isomerisation of (*d*+)-α-isobutyldesoxybenzoin on a macroporous cation exchanger in which practically all the sulphonic acid groups of its enormous internal surface were available for the formation of carbonium ions.

Fang[10] used the change in the rate constant for the racemisation of (*d*+)-α-isobutyldesoxybenzoin as a measure of the stability of the catalyst (Amberlist-15) towards heating in an inert medium at 100–165°. This is the first example of the use of a kinetic quantity to characterise the thermal stability of a resin. These results are shown in Table 2 as rate constants referred to 1 g of catalyst (k_1) or 1 mg-equiv. of active groups (k_2).

Table 2. Influence of heat treatment on the catalytic activity of Amberlist-15

Temp. of heat treatment, °C	Exchange capacity of resin, mg-equiv. g^{-1}	Rate constants, min^{-1}	
		$k_1 \times 10^4$	$k_2 \times 10^4$
100	4.61	5.33	1.16
110	4.55	5.07	1.11
120	4.55	5.00	1.10
130	4.48	5.09	1.14
140	4.30	4.81	1.12
150	4.07	3.53	0.87
165	4.36	3.42	1.02

It can be seen from Table 2 that heat treatment of the cation exchanger at temperatures up to 140° leads to partial desulphonation with a corresponding decrease in k_1, whilst k_2 remains approximately constant. At still higher temperatures both rate constants decrease, since the access of ketone molecules to the active centres is hindered by the shrinkage of the three-dimensional network of the resin. These views have long been held by the present writer in connection with the thermal stability of ion exchangers[183]: their relevance to ion-exchange catalysis is now beginning to be appreciated.

As in the case of other Brønsted acids[184], polymerisation in the presence of ion exchangers occurs by a cationic mechanism[185]. Intermediate formation of a carbonium ion is suggested during the isomerisation of *l*-menthene[72], and this mechanism has been proved beyond doubt for the transformation of but-1-ene into but-2-ene (which was investigated by the isotope exchange method[24]).

7. Condensation Reactions

Additional evidence of the advantages of ion exchange catalysis over the classical methods relying on soluble acids or alkalis has become available as a result of the current interest in condensation reactions brought about by ion-exchange resins.

Many reactions take place under milder conditions in the presence of ion exchangers, giving a higher grade of product[186,187] in better yields[188]. Because of the improved quality of the technical products obtained by ion-exchange catalysis, some purification stages can be omitted (for example, extraction in the preparation of polyhydric alcohols[187] or neutralisation in the preparation of diacetone alcohol[189]), and therefore the process can be speeded up on the industrial as well as on the laboratory scale. Thus, the preparation of diacetone alcohol by the condensation of acetone in the presence of barium hydroxide requires 120 h as compared with 8–10 h if an anion exchanger is used[189].

In some cases the use of ion exchangers offers new possibilities in organic synthesis. A striking example of this is the cyanoethylation of water in the presence of AV-16 anion exchanger, achieved by Mekhtiev and coworkers[190], which is impossible under homogeneous acid–base catalysis conditions.

The advantages of ion-exchange catalysis have led many authors[187,191–193] to suggest the use of ion exchangers as condensation catalysts on a pilot-plant scale and even on a full industrial scale.

Like the reactions already discussed, condensation can be carried out as a batch process or a continuous process. However, a combined approach is used for the synthesis of trimethoxypropane because the reaction mixture tends to separate into layers in the continuous reactor, causing low yield[187].

Most of the recent work in this field has been concerned with the use of ion exchangers as catalysts for cyanoethylation[4,194–197] (anion exchangers), aldol condensation[103,187,189,198,199] (anion exchangers, and occasionally cation exchangers), the Prince reaction[192,200–203] (cation exchangers), and the reaction between aldehydes and alcohols[103,204–208]. Some papers have dealt with the Knoevenagel condensation[209] (Dowex-3) and the reactions of phenol with acetone[191] and acetylene[210] (cation exchangers), the reactions of nitromethane with furfural[211] and paraformaldehyde[212] (anion exchangers), of acetic anhydride with hydrogen sulphide[193] and sugars[213], of cyclohexene with hydrogen peroxide[214] (KU-2), of various phenols with 1,3-cyclohexadiene[215] (Dowex-50), of oleic acid with diethylenetriamine[216]. Among the areas where further research is needed we could mention hydroxylation reactions[214], the synthesis of nitro derivatives[217,218] and the hitherto unpromising condensation of ketones with alcohols to give the corresponding acetals[206].

Although ion-exchange catalysts in general offer a higher selectivity than soluble acids and alkalis, this feature should not be overstated[187,195,219,220]. Very careful selection of the optimum conditions is necessary to minimise side reactions. Parameters such as reaction temperature, contact time, and molar ratios of components must be varied, as well as the water content, amount, and nature of the resin (ionic strength of the active groups, structure of polymer network, degree of cross-linking). As an illustration, the effect of various parameters on the yield of the cyanoethylation of ethanethiol[221] is shown in Fig. 3. It is evident that the yield of β-(ethylmercapto)propionitrile, calculated on the basis of acrylonitrile consumed, is not a sensitive function of the reaction conditions. On the other hand, the yield calculated on the basis of added acrylonitrile varies widely with the conditions of the reaction, and this behaviour must be taken into account in optimising the process.

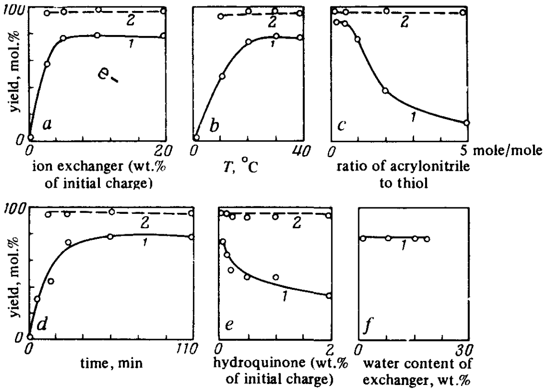

Figure 3. Effect of various parameters on the yield of the cyanoethylation of ethanethiol, expressed in terms of acrylonitrile (AN) added (*1*) and consumed (*2*): *a*) amount of AV-16 anion exchanger; *b*) temperature; *c*) AN : thiol molar ratio; *d*) time of experiment; *e*) amount of hydroquinone added; *f*) water content of resin

With the exception of the condensation of phenol with acetylene[210], catalysed by a resin in the Hg form, cation exchangers are commonly used as catalysts in the H form, and anion exchangers in the OH form, though an anion exchanger in the acetate form has been used[209] in the Knoevenagel condensation. The activity of the cation exchangers towards the condensation of phenol with acetone[191,222] can be increased by the addition of promoters: thioglycollic acid, ethanethiol, and others. A very ingenious method has been devised[222] to improve the quality of the diphenylolpropane obtained catalytically: 3–20% of the sulphonate groups in the cation exchanger are esterified with thiols instead of adding promoters to the reaction mixture.

The effectiveness of anion exchangers increases with their basicity, and improved yields can sometimes be obtained in this way. In some cases, however, weakly basic anion exchangers give better results (e.g. in the synthesis of thioglycollic acid[193]), and in some reactions (aldol condensation of acetaldehyde[1]) their use is mandatory.

Sulphonated cation exchangers are most frequently used in reactions which occur through the formation of an intermediate complex cation. In some reactions[197], adequate activity is obtained with phosphate or carboxylate resins, the latter being the more active.

Several examples have been reported[191,208,223] of the superiority of sulphonated polystyrene cation exchangers as compared with various sulphonated phenol–formaldehyde resins, all of which have a more compact three-dimensional network. Some compounds, such as diphenylolpropane, are formed only on KU-2 cation exchanger: the KU-1 resin merely absorbs phenol and acetone in molar proportions without inducing condensation.

In the presence of water, the activity of the catalyst can remain unchanged[198], it can increase[205], or it can even decrease[191]. Hence, the exchanger may have to be hydrated, or it may have to be dried, before the reaction.

Dehydration, like other forms of heat treatment, is relatively safe with cation exchangers of the sulphonated polystyrene type. Thus, KU-2 cation exchanger can be used for 1200 h without regeneration[222] in the synthesis of diphenylolpropane at 75°. Its analogue (Dowex-50) remained active for several years[206] under milder conditions in the condensation of acetone with alcohols.

Strongly basic anion exchangers in the OH form are sensitive to heat, and their exchange capacity rapidly decreases[224] on drying the resins even at ordinary temperature. Hence, the deactivation of the AV-17 anion exchanger towards condensation reactions reported by Isagulyants and coworkers[217,225] is not surprising. The relationship between the thermal stability and the catalytic activity of anion exchangers has not so far been investigated.

Published work on the condensation kinetics has dealt with the effect on the reaction rate of indifferent solvents[226], of the particle size[227], and degree of cross-linking of the resin[191], and of the nature of the active groups[228]. The activation energy[195,221,227,229] and the kinetic order of some condensation reactions have been reported[195,200,209,221,230]. An anomalously low activation energy has been observed[229] in the aldol condensation of acetone (4.5 kcal mole^{-1}), pointing to inner diffusion as the rate-limiting step. The kinetic order of the reaction on ion exchangers may not be the same as in homogeneous acid–base catalysis[200]; in the condensation of chloroacetaldehyde with polyhydric alcohols[230] the kinetic order depends on the amount of KU-1 present and on the molar ratio of the reactants. This fact underlines the specific features of ion-exchange catalysis, which goes beyond the simple idea of "a homogeneous phase in which the reaction can take place".[6]

---o0o---

The period in the development of ion-exchange catalysis which we have discussed is qualitatively different from the previous stage. Between 1961 and 1968, satisfactory theoretical foundations were developed and new ideas were put forward (for example, on the blocking of ion exchangers) in the form of precise quantitative relationships. Kinetic studies have attracted much more attention than during the previous stage, and have helped to reveal the specific features of ion-exchange catalysis. Considerable progress has been made in the synthesis and exploitation of new (thermally stable, macroporous, and mixed) ion-exchange catalysts which enable many of the defects of the older ion-exchange materials to be overcome or at least mitigated. The relationship between thermal stability and catalytic activity has been formulated in principle; these basic ideas are of the utmost importance for the optimisation of the reaction condition in ion-exchange catalysis.

Future work on ion-exchange catalysis should aim to remedy the shortcomings of some of the researches of the current period. Firstly, the criteria for the choice of catalyst should be further refined, making allowance for the electrochemical properties of the active groups, the exchange capacity, the degree of cross-linking, the structure of the polymer network, the pore characteristics (for macroporous exchangers), and the thermal stability, using mathematical expressions for these properties. Secondly, our understanding of the role of indifferent solvents in ion-exchange catalysis must be extended in breadth and in depth, taking account of their influence on the distribution of reactants between the catalyst and the reaction medium. Thirdly, it is important to intensify the study of reaction kinetics and mechanisms, with special emphasis on the exact kinetic description of the properties of the catalysts. Fourthly, the thermal stability of the catalysts must be investigated, and means must be found to prevent ageing of the catalysts under practical conditions. Lastly, work on the synthesis of new ion exchangers with desirable thermal and mechanical properties must continue. Advances in all these directions will help to shorten the gap between the theoretical studies of the methods of ion-exchange catalysis and their general exploitation in the chemical industry.

While this article was in press, new papers have been published on the hydrolysis[231], hydration[232], dehydration[233–235], decomposition[236,237], esterification[238–243], ester interchange[244], alkylation[245–248], isomerisation[249], and condensation[250–252] of organic compounds in the presence of ion-exchange resins as catalysts. A special review of the dehydration of various compounds (mainly alcohols) has appeared[253]. The writer's thesis[254] presents a general discussion of ion-exchange catalysis.

Vladimir Il'yich Lenin

U.D.C. 62.09

Fulfilling V.I.Lenin's outline for the development of Soviet chemistry

V.I.Spitsyn

All progressive mankind marks the centenary of the birth of Vladimir Il'yich Lenin, founder of the Communist Party of the Soviet Union and of the first Socialist State, and one of the greatest scientists of our time.

Lenin was the first political figure of world calibre to consider science to be enormously important and to base his concepts of Party and State on thoroughly scientific foundations. It is well known that Lenin's philosophical works—"Materialism and Empirical Criticism", "Philosophical Notebooks" and others—played a very important part in the period between the two Russian revolutions. In these works Lenin also touched on questions of modern science—among them the depth of our knowledge of the outside world, the inter-relation of matter and energy, the transformation of chemical elements.

Lenin paid much attention to the problems of chemistry. Whilst writing his "Materialism and Empirical Criticism", he studied the work of the chemists Ostwald and Liebig, and those philosophers and physicists who had exerted much influence on the development of chemistry—Falaise, Democritus, Gassendi, Newton, Faraday, Helmholtz, and Thomson. In the Sorbonne and Berne libraries Lenin studied the works of Abderhalden, the organic chemist, and Meyer. He was interested in radioactivity, agricultural chemistry, coal chemistry, petrochemistry and geochemistry. He read carefully the works of the gifted agricultural chemist and publicist, Engelhardt, as well as those of Vernadskii, who was one of the founders of geochemistry; he read Planck's "The Principle of the Conservation of Energy", and Boltzmann's papers in the "Vienna Scientific Treatises". The V. I. Lenin Library in the Kremlin contains, besides works on philosophy, history, the law, and economics, many special works dealing with various problems of chemistry and other related sciences: works by Lomonosov, Timiryazev, Vernadskii, Fersman and others.

Lenin also made a study in depth of the problems of the development of the chemical industry. In his work "The Development of Capitalism in Russia" he noted that "chemical production is of the utmost importance for economic development and the growth of the country's productive power" (Complete Works, Vol. 3, p. 476). Subterranean gasification of coal, suggested by Mendeleev and then by the English chemist Ramsey, constituted, in Lenin's view, a gigantic technological revolution which, under Socialism, would help in electrifying factories and railways (Vol. 23, p. 93).

After the October victory Lenin embarked on a scientific plan for the building of a new society. He believed that the country had sufficient natural resources and manpower, and the necessary scope was given to "the national endeavour by the great Revolution—in order to create a truly mighty and prosperous Russia" (Vol. 36, p. 80). Lenin gave an important role to the chemical industry in creating the material and technological basis for Socialism. He wrote: "Increased efficiency of labour requires first of all a proper material basis for heavy industry: increased production of fuel and steel, growth of mechanical engineering and the chemical industry" (Vol. 36, p. 188). Lenin considered Karabugaz, a bay in the Caspian Sea, as the richest source of raw materials for the chemical industry.

On Lenin's initiative, the Supreme Economic Council created a Department of Chemical Industry as early as December 1917. In 1918 Lenin signed the decree prepared by this Department concerning the transfer of a number of chemical and chemico-pharmaceutical enterprises to the ownership of the Russian Republic. Several months later the Council of People's Commissars adopted the decree which nationalised all chemical enterprises. Despite the great hardships besetting the young Republic, considerable sums were assigned in that year for completing the building of the "Provodnik" rubber goods factory in Moscow, for prospecting for phosphorites in the Volga-Kama region and near Aktyubinsk, and for the rebuilding of a number of chemical plants. The Supreme Economic Council did much to assist the Department of Chemical Industry in acquiring raw materials and equipment for chemical laboratories.

In the second half of April 1918 Lenin composed his famous outline plan for scientific and technological progess. This arose as the result of an approach made to the Soviet Government by the Academy of Sciences in March 1918, suggesting that scientists should be drawn into a survey of the country's natural resources. This proposal by the Academy was discussed at a meeting of the Council of People's Commissars on 12 April 1918. The resolution adopted stressed the aim of a "systematic solution of the problems of proper distribution of industry in the country and the most effective utilisation of its economic forces".

In his outline scientific and technological plan, Lenin recommended that the Academy of Sciences be asked to form a series of Commissions of experts in order to work out with all possible speed a plan for reorganising industry and bringing about economic recovery and progress in Russia. This plan had to include a rational siting of industry in relation to accessibility of raw materials and minimising the labour involved in their processing; provision of all the main types of raw materials and industries for the Soviet Russian Republic; special emphasis on the electrification of industry, transport and agriculture; utilisation of inferior types of fuel for producing electric power; and the use of water power and wind-driven motors generally and in agriculture.

Scientists and highly qualified engineers were needed to solve these problems. There were eminent individual scientists in pre-Revolutionary Russia who were working chiefly in academic institutions. Among the chemists there were N. S. Kurnakov, L. A. Chugaev, and I. A. Kablukov (Inorganic Chemistry), D. P. Konovalov, V. A. Kistyakovskii, and E. I. Shpital'skii (Physical Chemistry), N. D. Zelinskii, A. E. Favorskii, and A. E. Chichibabin (Organic Chemistry), N. A. Tananaev, and K. A. Nenadkevich (Analytical Chemistry), V. I. Vernadskii and A. E. Fersman (Geochemistry), D. N. Pryanishnikov (Agricultural Chemistry), V. S. Gulevich (Biochemistry), V. E. Tishchenko and A. A. Yakovkin (Chemical Technology), and V. G. Khlopin (Radiochemistry). These scientists had only a few colleagues, teaching in the various Departments. The material and technological basis for developing research inherited from Tsarist Russia was totally inadequate and became still worse as the result of wartime destruction. This, and the poorly developed network of centres of higher learning prevented the development of large schools of scientific research in pre-Revolutionary Russia at a time when these were already flourishing abroad.

On Lenin's initiative, and with the active participation of leading Russian scientists, specialised research Institutes, including chemical ones, began to be created from the first months of Soviet power. Among the first ones to be created in 1918 in Petrograd were the Institute of Platinum and Other Noble Metals (Director—L. A. Chugaev) and the Institute of Physico-Chemical Analysis (Director—N. S. Kurnakov) In Moscow the Central Chemical Laboratory was organised under the aegis of the Supreme Economic Council; it subsequently became the L. Ya. Karpov Physico-Chemical Institute. A number of other Institutes followed, including the State Institute of Applied Chemistry, the State Institute of High Pressures, the Scientific-Research Institute of Pure Chemical Reagents, the Institute of Fertilisers.

The VIII Congress of the Russian Communist Party which took place in Moscow in March 1919, included the following in the Party programme: "The Soviet Government has already taken a number of measures designed to advance science and strengthen its links with industry by creating a network of new Institutes of Applied Science, laboratories, experimental stations, pilot plants for testing new technological methods, improvements and inventions, and by registering and organising all available scientific manpower and resources. The Russian Communist Party supports all these measures and aims at their further development and the creation of the most favourable conditions for scientific work relevant to improving the productive forces of the country".

The plan of the State Commission on the Electrification of the Republic was based on Lenin's ideas concerning the material and technological foundations of a Socialist society; this was the first long-term plan for the economic development of the Soviet Republic put forward in 1920 and calculated for 10—15 years. It was devoted mainly to the problem of electrification of Soviet Russia, but it also dealt with the means of developing the principal branches of the country's economy. In particular, it outlined an accelerated growth of the chemical industry. Its production was to show a 2.5-fold increase compared with 1913. At that time it was a gigantic task.

It is well known that before the Revolution the Russian chemical industry was technologically backward, despite the eminence of individual Russian chemists. It was characterised by small-scale production, factories limited to several areas in the European part of the country, absence of a well developed base for raw materials, and shortage of qualified personnel. The chemical industry was immensely dependent on foreign capital. Tsarist Russia, possessing vast deposits of mineral raw material was forced to import pyrites, phosphorites, sulphur, potassium salts and saltpetre. One-third of valuable chemical products and 80% of mineral fertilisers were also imported from abroad. The country had no chemical engineering and not a single college specialising in chemical technology. Suffice it to say that in 1913 there was one graduate chemist per 340,000 population!

The Communist Party and the Soviet Government began in the first years of Soviet power to carry out Lenin's indications for the extensive use of chemistry in the national economy. With the liberation of territories captured by the Whites, measures were taken to restart and reconstruct the oil industry in Baku and the coal chemistry industry in the Donbass, as well as to restore and reorganise the existing basic chemical works.

Besides being concerned about the preservation and utilisation of already existing chemical plants, Lenin gave much attention to new lines of technological development. In 1918 he ordered the evacuation of uranium ore stocks from Petrograd to the Urals. In July 1918 the Council of People's Commissars adopted a resolution on starting a pilot radium plant. The telegram sent to the Urals Economic Council, signed by Lenin, read: "Work on the radium plant must begin forthwith". The first preparation of Soviet radium was obtained in 1921, under the direction of V.G. Khlopin and I. Ya. Bashilov. The problem which had baffled the shareholders of the "Ferganskii Rare Metals Company" before the Revolution was solved. The isolation of radium and the training of highly qualified specialists able to handle highly radioactive substances played an important part twenty years later in organising the atomic industry in the USSR.

In that early period the Council of People's Commissars was much concerned with the production of synthetic materials. It initiated a competition for developing a method of preparation of synthetic rubber. This problem was solved in 1932, when the technique of synthetic rubber production, developed under the direction of S. V. Lebedev, was adopted.

Research into the use of oil shales as chemical raw material for the production of primary shale tar and the preparation of valuable chemicals from it was begun in 1918 on Lenin's personal instigation.

At the same time, on Lenin's instructions, new centres for tertiary education were being established. In the three years from 1918 to 1920 the following institutions came into being: Universities in Tbilissi, the Urals (Sverdlovsk), Erevan and Central Asia (Tashkent), and the Moscow Mining Academy, with increased admissions to already existing tertiary schools. Chemical specialties were extended and chemical Faculties created at the Moscow, Petrograd and other Universities. The training of qualified chemists was extended in Technical Colleges (the Moscow Technical College and the Technological Institute in Petrograd, among others). In 1920 the first specialised Chemical Technological College—the D. I. Mendeleev Institute of Chemical Technology—was opened in Moscow.

These measures made it possible to train in a few years many researchers and chemical engineers for research Institutes, laboratories and industrial concerns. Whereas in early 1925 there were 2750 engineers working in the chemical industries, two years later their number had risen to 4000.

The establishment of new scientific Institutes continued throughout the Civil War and after its end. These included the Radium Institute, the Institute of Applied Mineralogy and Non-Ferrous Metallurgy, the State Institute of Rare Metals, and many other chemically-oriented Institutes. There was considerable expansion of research in the Chemistry Departments of Colleges. A start was made on the organisation of Applied Research and Designing Institutes geared to various branches of industry. Among the first of these were the Urals Chemical Research Institute, the Mining Chemical Institute, the Scientific-Research Institute of Basic Chemical Industry in Kharkov, the Glass Institute, the State Institute of the Nitrogen Industry, the GIPROKHIM Design Institute, and others.

In the not quite seven years during which Lenin led the Soviet State the development of science in our country, and chemistry in particular, received a great stimulus. Lenin's genius and creative initiative played a vital role in this respect. As N. P. Gorbunov, Secretary of the

Council of People's Commissars, wrote subsequently in his memoirs, there is hardly a scientific or technological undertaking in the Soviet Union which has not been associated with Lenin's name.

After Lenin's death, science and industry in the USSR continued to advance along the lines laid down by him. An important step in the advance of science in our country was the transfer in 1934 of the Academy of Sciences of the USSR from Leningrad to Moscow, which led to an expansion of a network of new academic Institutes. The Institute of General and Inorganic Chemistry came into being through the merging of the Institute of Platinum and other Noble Metals with the Institute of Physico-Chemical Analysis and the Chemical Laboratory of the Academy of Sciences. The Institute was subsequently named after N.S.Kurnakov. It became an important centre for advances in Soviet inorganic chemistry. Other Institutes which were created included the Institute of Organic Chemistry, and the Institute of Colloidal and Electro-Chemistry which subsequently became the Institute of Physical Chemistry from which, in turn, the Institute of Electrochemistry split off later. The Institute of Chemical Physics came into the structure of the Academy. Academy bases and branches were being organised; many of these became, in time, Academies of Science of the Republics. At the same time stronger links were being forged between the work of the Academy and practical needs, in accordance with Lenin's testament. In 1938 the Council of the People's Commissars of the USSR proposed that the Academy of Sciences concentrate its attention on the main scientific problems dictated by the development of the Socialist economy and culture.

The development of Soviet chemistry had leaned on the continuously growing might of our chemical industry, mechanical engineering and the national economy as a whole. The State Plan for the Electrification of the Republic was fulfilled ahead of schedule. By 1926 chemical production had reached again the 1913 level. New workshops and factories began to be built for the production of synthetic ammonia, various acids and salts, artifical fertilisers, intermediate products of aniline dye-stuffs industry, etc.

In 1929 the Central Committee of the All-Union Communist Party published its resolution concerning the work of the Northern Chemical Trust, which stressed the importance of further acceleration in the development of the chemical industry. During the First Five-Year Plan (1929-1932) chemical production increased 3.2-fold, outstripping other industries in growth. The development of Soviet chemistry during that period was greatly helped by a national movement in support of a chemical orientation of the national economy which was headed by a number of eminent scientists and resulted in the appointment by the Government of a Committee for promoting this orientation at the Council of People's Commissars of the USSR (1928).

The resolution of the XVII Congress of the All-Union Communist Party put forward the following aim for the Second Five-Year Plan (1933-1937): "To achieve decisive advances in the development of the chemical industry, ensuring an extensive chemical basis for all branches of the national economy and strengthening the country's defences". The resolution urged the adoption by the chemical industry of the newest technological methods (electrolysis, electrothermy, gaseous phase reactions), the use of new raw materials, the creation of a series of new enterprises and further steps in combining the chemical industry with other branches of the national economy. The Second Five-Year Plan achieved a 3-fold increase in chemical production compared with 1932.

A still more extensive programme for the growth of the chemical industry was envisaged in the Third Five-Year Plan, which was interrupted by the treacherous invasion of the Soviet Union by Fascist Germany. Nevertheless, our country had achieved considerable success in the development of the chemical industry during the pre-war Five-Year Plans. Over one hundred large chemical plants were built to produce synthetic ammonia, nitric acid and nitrogeneous fertilisers, sulphuric acid, synthetic rubber, synthetic fibres, potassium and phosphorus fertilisers, aluminium and magnesium compounds for smelting appropriate metals, rare element compounds and many rare metals. The creation of an organic chemical industry was a great achievement. By 1941 the chemical production output had exceeded the 1931 level by a factor of over 20. This proved to be one of the decisive factors in ensuring that the Army and the rear were supplied with all the necessary chemical materials. Soviet chemistry made an important contribution towards the defeat of Germany Fascism and the victory in the Great Patriotic War.

The chemical industry, like other branches of our national economy, suffered greatly from Hitler's invasion. The heroic efforts of the Soviet people during the post-war period made it possible rapidly to restore destroyed factories and build new plants. By 1948 the industry as a whole had returned to the 1940 level and continued to advance. The establishment of new Institutes and research centres continued. In 1957 the Siberian Branch of the Academy of Sciences of the USSR was organised, together with a number of Chemical Institutes. Later, a Research Centre of the Ukrainian Academy of Sciences was created in Donetsk.

As a result of the successful fulfilment and over-fulfilment of four Five-Year Plans (the Fourth, 1946-1950; Fifth, 1951-1955; Sixth, 1956-1960 and Seventh, 1961-1965) the level of chemical production in 1965 had risen 300-fold compared to 1913. The Eighth Five-Year Plan (1966-1970) will see at least a further 1.5-fold increase in chemical production.

Against this background of rapid growth of the chemical industry and allied branches of the national economy there has been an intense development of Soviet chemical science in all directions, many of which had been indicated by Lenin in his time. In a short article one can only mention the most important achievements.

Important discoveries have been made in the field of organic catalysis by N.D. Zelinskii and other outstanding scientists. It became possible to effect various previously unknown transformations of hydrocarbons with the help of specially selected catalysts. Many of these reactions found practical applications in the production of high-quality liquid fuels from oil (catalytic cracking), and served to advance petrochemistry. The multiplet theory of catalysis, put forward by A.A. Balandin, has thrown light on the mechanism of catalytic processes, especially for complex organic reactions.

The growing amount of work on petrochemistry and the processes of oil refining has been accompanied by the establishment of special Research Institutes—the Institute of Petrochemical Synthesis of the Academy of Sciences of the USSR, The Institute of Petrochemical Processes of the Academy of Sciences of the Azerbaidzhan SSR, and others. The achievements of petrochemistry have justified in full the help which Lenin extended to the oil industry in the early period of Soviet power.

A. E. Favorskii and his students, who investigated isomerisation and polymerisation of unsaturated hydrocarbons, did much to fulfill the demands for new synthetic materials made by Lenin and the Council of People's Commissars. This school of scientists developed methods of producing synthetic rubber from divinyl and acetylene, and plastics and adhesives from vinyl acetylene, vinyl esters and other acetylene derivatives. Our chemistry of organic polymers has continued to advance further; its achievements and targets were discussed at the May Plenary Session of the Central Committee of the Communist Party of the Soviet Union in 1957.

The stimulus given to the development of Soviet Organic chemistry after the Great October Socialist Revolution has led to the appearance of new branches of this science. Among these one must mention the chemistry of organoelemental compounds, based on the work of P. P. Shorygin, A. E. Arbuzov and other outstanding Soviet chemists. Organic silicon compounds found extensive application in the preparation of new polymers, lubricating substances and other products. Organic compounds containing atoms of tin, lead, antimony and other metallic elements are used as antiseptics, catalysts and other valuable materials. They have also played an important part in evolving a theory of the structure of organic substances.

In his outline plan for science and technology, Lenin stressed that the young Soviet Republic must aim at being able to provide its own most important raw materials. This aim was pursued on a wide front by large groups of researchers over a period of years. Geological prospecting for the necessary mineral raw materials was associated with experimental work on their technology.

One must mention the work associated with the preparation of aluminium oxide from Tikhvin bauxites which made it possible to organise the production of aluminium by the first Soviet aluminium enterprises—the Volkhovskii and the Dneprov plants. The studies carried out by A. A. Yakovkin on the technology of the production of alumina and by P. F. Antipin on its electrolysis played a very important part in this. Similar work was done on the production of magnesium from carnallite.

In 1922 V. I. Spitsyn and colleagues, working in the Laboratory of Inorganic Chemistry of the Moscow State University, began the study of the chemistry of high-melting rare metals—molybdenum and tungsten. The technology of these metals was studied on samples of native ores and these processes were then translated to an industrial scale at the Baskakov Cable Works in Moscow. In 1925, under the direction of T. M. Aleksenko-Serbin, the country obtained home-produced molybdenum and tungsten wire for the manufacture of electric bulbs and other electrical equipment.

In order to coordinate research into the geology, mineralogy, chemical technology and metallurgy of rare elements, as well as the economic problems associated with these, the Scientific and Technological Section of the Supreme Economic Council established, in 1922, a Bureau to deal with the study and industrial application of rare elements. This Bureau organised the first studies of the chemistry and technology of beryllium, tantalum and the rare earth elements. Later all these resulted in the establishment of industries which had not previously existed in our country. The Bureau's supervisory work passed to the State Institute of Rare Metals when it was established in 1931. Within the latter's walls were developed the scientific foundations for many rare element industries. Among these were the studies directed by M. N. Sobolev on the extraction of vanadium from wastes obtained in the processing of the Urals titanium-magnetite ores. The production of ferrovanadium, established before the start of the Great Patriotic War, ensured the production of high-quality steel alloys for the war effort.

The Institute of Rare Metals organised the production of metallic beryllium, lithium, many rare earth elements, very pure antimony, titanium, germanium and other rare metals. Research into the chemistry of rare elements was also carried out in many scientific Institutes with other designations and in Academic departments. N. P. Sazhin deserves special mention for his contribution to the development of research into the technology of many rare elements.

Platinum metals occupy a special place among the rare elements. Before the Revolution crude platinum was mined in large amounts in Russia, but methods of its refining were not known and it was exported abroad. From there pure platinum and other platinum metals were reimported at great cost. As already mentioned, one of the first Soviet Institutes to be established in 1918 was that for the development of research into the chemistry and technology of platinum and other precious metals. The Institute carried out successfully the targets set by the Soviet Government. Here, under the direction of L. A. Chugaev and I. I. Chernyaev, were begun the investigations which subsequently formed the basis for an original method of platinum refining, which was finally developed at the Institute of General and Inorganic Chemistry of the Academy of Sciences of the USSR. Our country obtained all the platinum metals separately, and in a very pure state.

Rare elements present a particularly good example of the way in which the problem of satisfying all the requirements of our Socialist country in terms of raw materials and manufactured products was taken up by Soviet scientists as a patriotic duty and solved by them. At present the Soviet Union has all the chemical elements which have a practical application.

The Institute of Physico-Chemical Analysis, created under Lenin, carried out under N. S. Kurnakov's direction, an immense task of national importance in studying the salt deposits of our country and the methods of utilising these. Solikamsk, Kara-Bogaz-gol, the soda lakes of Siberia—these are but a few of the subjects studied by researchers at the Institute and later in the Institute of General and Inorganic Chemistry. One must also mention a different line of physico-chemical analysis followed by G. G. Urazov and other colleagues at the Institute. This was the study of metallic systems, which formed the basis for producing high-quality Soviet alloys for aviation and other technological needs. Furthermore, the creative development of methods of physico-chemical analysis which took place in our country after 1917 made an immense contribution to world science.

The part played by Lenin in establishing radium production in Soviet Russia has already been mentioned. The outstanding work directed by V. G. Khlopin put the separation of radium and barium by fractional crystallisation on a scientific basis. The Law of co-crystallisation of micro-admixtures and carriers, discovered by them, threw a new light on the phenomena of isomorphism, and made it possible to use co-precipitation for determining the valency states of elements in unstable compounds and for determining the composition of substances present in minute amounts. At the same time the country was also being provided with radium for medical and research purposes.

The accumulated experience of working with radioactive substances proved later to be extremely important when the problem of organising an atomic industry and preparing pure fissile materials arose in the early Forties. Now the Soviet Union is fully provided with all radioactive elements. Methods have been devised for isolating individual fragment elements used as sources of energy particles (conversion of the heat of radioactive decomposition into electrical energy by means of thermoelectric transducer), in electric charge neutralisers for the textile industry (for neutralising the charges which arise on the thread during spinning) and in other spheres. Industrial production of radioactive isotopes for use in technology and in research has been going on in the Soviet Union for over 20 years.

It would not, of course, be proper to limit this review only to those lines of development in Soviet chemical science which had been directly initiated or supported by Lenin. The Great October Socialist Revolution which took place under Lenin's inspired leadership, brought out new ranks of scientists and engineers from the people and opened before them a wide path of creative activity. They responded to all the new challenges presented by the rapid developments in science and technology. They shared the will to realise Lenin's vision of close ties between science and the practical demands of the national economy.

It has not therefore been an accident that our country became, under the Soviet Government, one of the most important centres of research into the chemistry of complex compounds (I. I. Chernyaev, A. A. Grinberg, and others). Some of the achievements of Soviet chemists include: detailed unravelling of the theory of chain reactions which makes it possible to control the kinetics of chemical processes; creation of an important new aspect of physical chemistry—physico-chemical mechanics with its numerous practical applications; elaboration of the theory of surface phenomena in electrode processes, which is of the utmost importance in clarifying the mechanism of reactions occurring in chemical sources of current; the work of V. A. Kistyakovskii, G. V. Akimov and their students which laid the foundations for the theory of corrosion processes in metals and developed effective anti-corrosion measures; study of adsorption, begun during the First World War by N. D. Zelinskii and N. A. Shilov which led to the discovery of important laws recently used in the synthesis and rational application of new types of sorbents, which have become very important in modern technology (molecular sieves).

The scientific and technological revolution in our country has followed Lenin's outline and brought about a rapid growth in culture and technical education of the population unmatched elsewhere. In 1917 the Russian Physico-Chemical Society had 565 members. At present the D. I. Mendeleev All-Union Chemical Society has a membership of 180 000, and the total number of scientsts and chemical engineers far exceeds this number. Before the Revolution the number of scientists in Russia, Doctors and Masters of Chemical Science did not exceed a few score. Now the Soviet Union has over 1100 Doctors and about 11,000 Candidates of Chemical Science.

It can be said without exaggeration that at present Soviet scientists and engineers, workers and technicians in our chemical industry are able to solve the most complicated problems that the Soviet State may place before them. Our people have achieved these successes by their persistent endeavours under the guidance of the Communist Party. But we shall never forget that it was Lenin who set the course for the development of science and technology in the first Socialist State.

Cyclisation Reactions with Participation of Epoxy-compounds

V.N.Yandovskii, V.S.Karavan, and T.I.Temnikova

The review deals with reactions of epoxy-compounds in which they are involved in the formation of cyclic structures. Intramolecular rearrangements with participation of epoxy-compounds can lead to alicyclic and heterocyclic compounds. Intermolecular condensations of epoxy-compounds with various reagents give rise to heterocyclic structures.
The bibliography comprises 307 references.

CONTENTS

I. INTRODUCTION

The continuing interest of chemists in epoxy-compounds is due to unusual reactions undergone by compounds of this class. The interest in them increased especially when their significant role in biological processes, where epoxy-compounds are involved as intermediates in the fixation of oxygen by the ethylene bond yielding numerous derivatives in subsequent reactions, became recognised. Many natural products containing the epoxy-ring have been isolated and their number is continually increasing[1].

In recent years a number of reviews dealing with reactions of epoxy-compounds have been published[2-4]. However, the treatment of processes in which epoxy-compounds take part in the formation of cyclic products has been clearly inadequate.

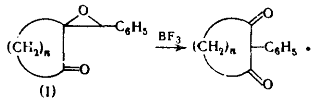
The primary aim of the present review has been to give a systematic account of reactions of this type and to classify them in accordance with common cyclisation mechanisms.

II. INTRAMOLECULAR CYCLISATIONS

1. SYNTHESIS OF CARBOCYCLIC COMPOUNDS

a. Rearrangement on Displacement of an sp^3-hybridised atom

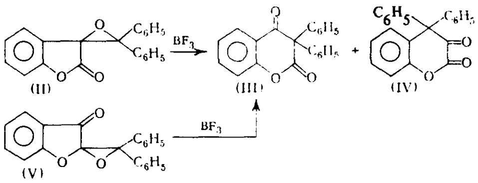
Rearrangements with participation of a carbonium ion. Epoxy-compounds are known to isomerise to the corresponding carbonyl compounds in the presence of acids. The process is accompanied by the migration of the group adjacent to the electron-deficient carbon atom, produced on opening of the ring. In the special case where the epoxy-derivatives of cycloalkenes with an *endo*- or *exo*-double bond are isomerised, the migration of an alkyl group leads to the contraction or expansion of the ring respectively. For example, the epoxy-derivatives obtained from methylenecyclopropane and methylenecyclobutane isomerise to cyclobutanone[5] and cyclopentanone[6] respectively, while the epoxy-derivative of methoxybenzylidenecyclohexane gives 2-anisylcycloheptanone[7]. House and Wasson converted the epoxy-compounds (I) into β-diketones under the action of boron trifluoride in benzene[8]:



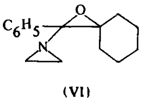
(I)

(n = 3 4,5)

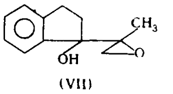
Schönberg and Junghans[9] also observed cases of ring expansion in the isomerisation of epoxy-compounds: the epoxy-compound (II) gave a mixture of products (III) and (IV), the former being obtained also in the isomerisation of the epoxy-compound (V):



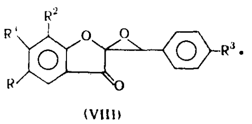
Another example is the conversion of epoxyamines (VI) into cycloheptanone derivatives[10], the conversion of *threo*- and *erythro*-1-(2-hydroxyindolyl)-1-methyloxirans (VII) into a mixture of α- and β-tetralones[11] and also the conversion of the epoxy-compound (VIII) into 4-hydroxycoumarin derivatives[12]:



(VI)

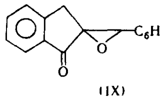


(VII)

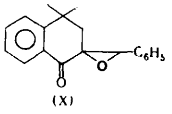


(VIII)

Certain other spirocyclic epoxy-compounds, for example (IX) and (X), undergo similar isomerisation with ring expansion under the action of boron trifluoride[13,14]:



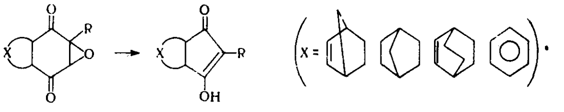
(IX)



(X)

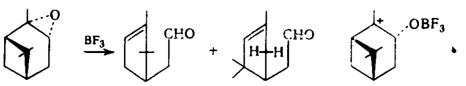
The isomerisation of alicyclic epoxy-compounds with ring contraction is observed much more frequently. Thus magnesium bromide causes the rearrangement of epoxycyclohexane to formylcyclopentane[15-18], of 1,2-epoxycyclohex-3-ene and 1,2-epoxycyclohex-4-ene to 2- and 3-formylcyclopentenes respectively[19], and of 1,2-epoxy-1-methylcyclohexane to acetylcyclopentane[18]. Under analogous conditions, 4-acetoxy-1,2-epoxy-1-methylcyclohexane rearranges to 1-acetoxy-3-formyl-3-methylcyclopentane[20] and the epoxy-derivative of dihydronaphthalene rearranges to 2-formylindane[21]. The isomerisation of 2,3-epoxycyclohexanone catalysed by boron trifluoride-ether yields 2-formylcyclopentanone[22], and 2-formyl-2-phenylcyclopentanone was obtained by the isomerisation of 2,3-epoxy-3-phenylcyclohexanone[22].

The reaction of epoxycyclohexane with methyl-[23,24], ethyl-[24], cyclohexyl-[25], β-phenylethyl-[26], and phenylmagnesium bromides[27,28] gives alkylcyclopentylmethanols, since the formylcyclopentane formed initially reacts further with the Grignard reagent. Similarly the reduction of 1-methylepoxycyclohexane with the mixed aluminium hydride $AlH_3.2AlCl_3$ yields 1-hydroxymethyl-1-methylcyclopentane[29]. The epoxy-compounds (XI) are isomerised by acid catalysts (BF_3, H_2SO_4) to compounds (XII) as a result of ring contraction and subsequent deformylation[30]:



(XI) (XII)

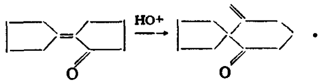
The reactions of epoxy-compounds under acid conditions may be accompanied sometimes by very pronounced changes in the carbon skeleton. Thus the epoxy-derivative of *trans*-cyclo-octene is isomerised by formic acid to hexahydro-*o*-toluic aldehyde[31] and the epoxy-derivative of α-pinene forms campholenic aldehyde under the action of Lewis acids[32-35]. Moreover, apart from campholenic aldehyde (XIII), the mixture contained a certain amount of the aldehyde (XIV), the formation of which can be understood only as a result of non-concerted C-7 and C-2 migration in the carbonium ion (XV)[34]:



(XIII) (XIV) (XV)

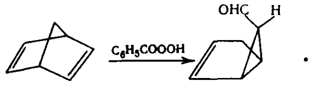
The reactions of the epoxy-derivatives of α- and β-pinenes has been reviewed[36]. The isomerisation of the 3,4-epoxycarane system also provides examples of profound changes in the carbon skeleton[37-39]; the reactions of certain sesquiterpenes[40] and also rearrangements in the steroid series[41-45] catalysed by boron trifluoride-ether have been described.

The oxonium ion formed on co-ordination of the oxygen atom of the epoxy-ring to acids resembles in many respects the structures formed on halogenation and protonation of the ethylene bond; the subsequent rearrangements of this ion with migration of the adjacent group resemble the isomerisation reactions which accompany, for example, the halogenation of a double bond at a quaternary carbon atom[46]. The conversion of a double bond into an epoxy-derivative also includes the formation of an oxonium complex as one of the stages; there are examples of 1,2-alkyl migration in the oxidation of olefins by peracids. In special cases this can cause the contraction or expansion of the carbon ring. The conversion of an exocyclic double bond into an epoxy-group leads to ring expansion[7,47], for example the reaction of a mixture of trifluoroperacetic acid and boron trifluoride with (XVI) yields (XVII):



(XVI) (XVII)

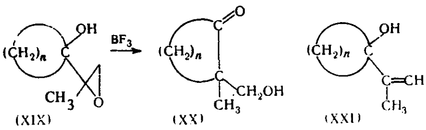
The conversion of an endocyclic double bond into an epoxy-group results in ring contractions: oxidation of norbornadiene with perbenzoic acid gives the aldehyde (XVIII)[48]:



(XVIII)

Certain other examples concerning steroids have been quoted[49].

In the halogenation of a double bond and its conversion into an epoxy-group and in the co-ordination of epoxy-compounds to acids the positive charges at the carbon atoms in the transition states are in general different. This can lead to different final products when account is taken of the possibility of the following competing reactions: (1) internal nucleophilic (in the limit) attack by the oxygen atom in the conversion to an epoxy-group leads to the closure of the epoxy-ring; (2) the migration of the adjacent group yields isomerisation products; (3) the anchimeric assistance of an adjacent group with electron-donating properties (when such is present) can result in the formation of cyclic structures; (4) external nucleophilic attack leads to addition products. In connection with the above, we may note that the epoxy-compounds (XIX) are isomerised by boron trifluoride to the ketones (XX) with ring expansion[50], the reaction of the hydrocarbons (XXI) with hypohalous acids also gives the ketones (XX) while their conversion into epoxy-derivatives yields only compounds (XIX):



(XIX) (XX) (XXI)

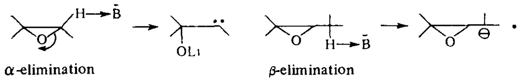
All the cases quoted so far included the formation of a new C–C bond as a result of the migration of an alkyl group to a carbonium ion generated on opening of the epoxy-ring or on its formation. Considerably much less attention has so far been devoted to the reactions of epoxy-compounds with bases. Most of the examples studied included an investigation of the addition of various basic reagents in proton-donating solvents (alcohol, water, dilute acids). However, the latest studies of Cope, Crandall, and Temnikova and coworkers led to the discovery of new interesting reactions of epoxy-compounds in the presence of strong bases.

Anionoid rearrangements. Crandall and coworkers[5] reported certain reactions of epoxy-compounds in the presence of strong bases (R_2NLi, BuLi). A proton may be eliminated from the α- or β-position in the epoxy-compound molecule.† Elimination from the α-position yields a carbene, which can be subsequently inserted intramolecularly in a C–H bond or can add to a C=C bond.

---

† Here and henceforth Crandall's terminology is used[51].

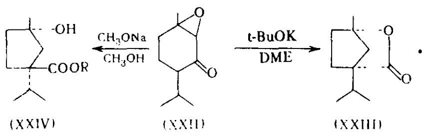
β-Elimination yields a carbanion, the rearrangement of which leads to the isomerisation of the epoxy-compound to an allyl alcohol[51-55]:



The contributions of α- and β-elimination are determined by the presence of a proton in the appropriate positions and the ease of its elimination[51].

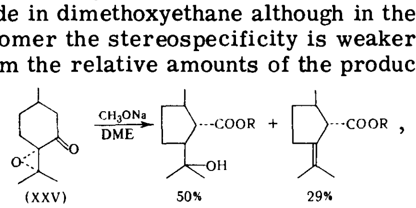
Evidently Crandall's mechanism can be supplemented by certain specific cases. Thus, when the molecule of the epoxy-compound contains a powerful electron-accepting group (for example a carbonyl group), elimination of a proton from other positions in the substrate becomes possible and therefore one can speak of γ-elimination, δ-elimination, etc. The most interesting examples of γ-elimination are the rearrangements of αβ-epoxy- and γδ-epoxy-ketones into cyclopropane derivatives:

The close analogy between αβ-epoxyketones and α-halogenoketones is quite evident; it is confirmed also by the very similar behaviour of these bifunctional substrates in the Favorskii rearrangement. The intermediate formation of cyclopropanone as a result of a co-ordinated S_Ni attack by the carbanion on the α-carbon atom takes place similarly in both cases. The subsequent cleavage of cyclopropanone under the reaction conditions takes place stereospecifically in non-polar solvents (for example dimethoxyethane) or non-stereospecifically‡ (water, alcohol) and leads to hydroxyacids or lactones. The isomerisation of the epoxy-derivative of piperitone (XXII) yields (XXIII) as a result of a stereospecific Favorskii rearrangement in dimethoxyethane (DME), while in methanol (XXIV) is formed non-stereospecifically[56]:

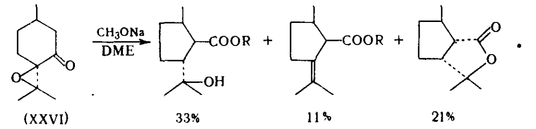


(XXIV) (XXII) (XXIII)

The *cis*-epoxy-derivative (XXV) and *trans*-epoxy-derivative (XXVI) of pulegone undergo preferential stereospecific rearrangement in the presence of sodium methoxide in dimethoxyethane although in the case of the *trans*-isomer the stereospecificity is weaker[57], as can be seen from the relative amounts of the products:



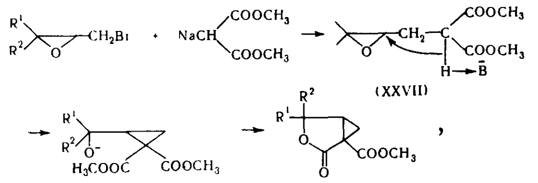
(XXV) 50% 29%



(XXVI) 33% 11% 21%

The study of the reactions of the same epoxy-compounds with sodium methoxide in ethanol or with sodium hydroxide in aqueous ethanol and water showed that in such cases the reaction is stereospecific[61,62]. The Favorskii rearrangement of the epoxy-derivative of isophorone[56] and of αβ-epoxyketones of the steroid series[57] also involves the contraction of a six- to a five-membered ring.

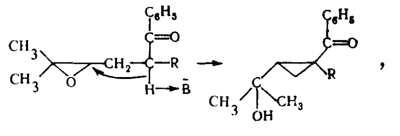
Other interesting examples involving the formation of the cyclopropane ring are provided by the rearrangement of γδ-epoxyketones. Thus the alkylation of dimethyl sodiomalonate with α-bromo-derivatives of epoxypropane, 1,2-epoxy-2-methylpropane, 1,2-epoxybutane, 2,3-epoxybutane, and 2,3-epoxy-2-methylbutane gave the γ-lactone of 1-hydroxymethyl-2-methoxycarbonylcyclopropane-2-carboxylic acid and its homologues according to the following mechanism[63,64]:



(XXVII) (XXVIII)

where R¹ = H and R² = H or CH_3 or R¹ = CH_3 and R² = CH_3.

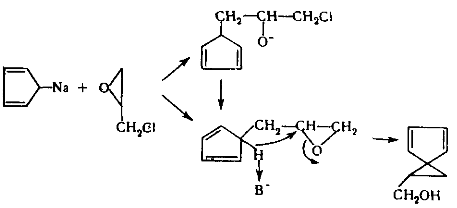
The mechanism is confirmed by the finding that the epoxy-compound (XXVII) obtained in a different way isomerises to (XXVIII)[64]. The products of the alkylation of the sodio-derivatives of acetophenone and benzyl methyl ketone with 1-bromo-2,3-epoxy-3-methylbutane in toluene undergo a similar rearrangement[65,66]. The epoxyketones formed in the first stage isomerise in an alkaline medium to cyclopropane structures via the intramolecular attack by the nucleophilic carbon atom of the epoxy-ring according to the mechanism[66]



where R = H or C_6H_5. We may note that the epoxy-compound (XXIX) (synthesised by an independent method), the chain of which contains one carbon atom more than in (XXVII), is not converted into the corresponding cyclobutane[67]:

(XXIX)

The interaction of epichlorohydrin with cyclopentadienylsodium leads to the formation of cyclopropane as a result of the attack by the carbanion on the epoxy-ring according to the mechanism[68]



The authors do not state which pathway is actually followed. For information about the preparation of cyclopropane by the rearrangement of 1,2-dicyano-oxiran, see Ershov et al.[69]

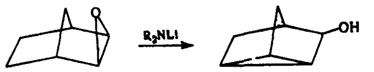
b. Reactions with Participations of a Carbene

The elimination by strong bases of a proton from epoxy-compounds without electron-accepting functional

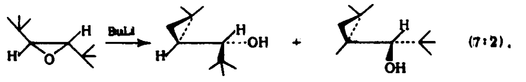
---

‡ For a discussion of this problem, see Refs. 56–60.

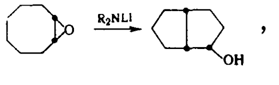
groups involves, as already stated, competition between α- and β-elimination. In the vast majority of cases β-elimination is observed[51]. There are, however, cases, where the formation of a carbene predominates or constitutes the sole reaction of epoxy-compounds in the presence of bases. For instance, epoxynorbornane rearranges to a nortricyclanol via the intermediate formation of a carbene, because the elimination of a proton from the β-position is impossible[70]:

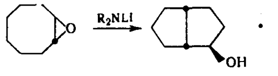


1,2-Di-t-butylepoxyethane yields two products of the insertion of a carbene in the C–H bond[71]:

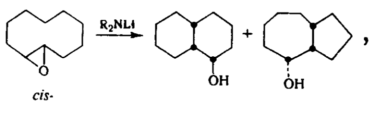


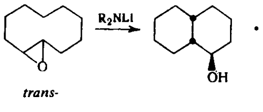
The formation of a considerable amount of the second isomer is evidence of the incomplete stereospecificity of the insertion reaction and can probably be accounted for by the existence of the carbene as a discrete entity. On the other hand, the configurational mobility of the carbon chain leads to a mixture of products. In contrast to aliphatic epoxy-compounds, the epoxy-derivatives of cycloalkanes (n = 7, 8, or 10) undergo stereospecific *trans*-annular insertion of the carbene. The closeness of the atoms in medium rings leads to the preferential interaction of the carbenes with the C–H bond at the opposite end of the molecule. The epoxy-compounds derived from *cis*- and *trans*-cyclo-octenes undergo a stereospecific rearrangement to the corresponding bicyclo-octanols[72,73]:



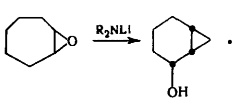


The epoxy-compounds derived from *cis*- and *trans*-cyclodecenes are converted into bicyclodecanols also as a result of a stereospecific *trans*-annular insertion of the carbene in a C–H bond[73,74]:

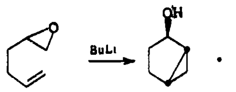




The rearrangement of epoxy-cycloheptane takes place similarly[51]:

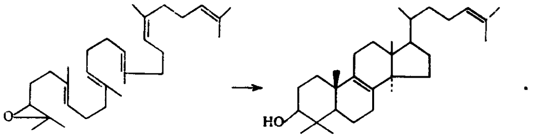


The stereospecificity of reactions involving the *trans*-annular insertion of carbenes into medium rings and also the predominance of α-elimination in such cases have been explained[51,71,75]. We shall only note an interesting example of intramolecular addition of a carbene to a double bond in the rearrangement of the monoepoxy-compound derived from diallyl[71]:

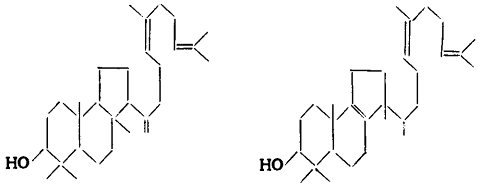


c. Nucleophilic Participation of the C=C bond in the Rearrangement of Epoxy-Compounds

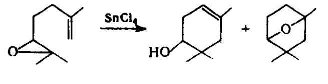
A study of the rearrangement of the electron-deficient carbon atom in the opening of the epoxy-ring gives rise to the following natural question: whether the alkyl group migrates synchronously as the charge of the carbon atom in the oxonium complex increases or whether the coordination of the epoxy-compound molecule to acids with subsequent ring opening involves a discrete carbonium ion. Probably this question can be solved in a concrete form as a function of the reaction conditions and the object investigated[76,77]. In particular, there are a number of examples where the rupture of the C–O bond in the epoxy-ring takes place synchronously with formation of the new bond, with the adjacent group playing the role of a donor. This leads ultimately to cyclic products. This process can be aided by the nucleophilic effect of a hetero-atom (O, N, etc) or groups with a relatively high electron content, for example, a multiple bond. The nucleophilic involvement of the C=C bond in enzyme- and acid-catalysed reactions of epoxyolefin systems attracted very considerable attention in recent years as a model of the biosynthesis of natural products (terpenes, steroids). The most interesting example of this kind is the conversion of squalene-2,3-oxide into lanosterol steroids, which has been achieved enzymically under laboratory conditions[78-81]:



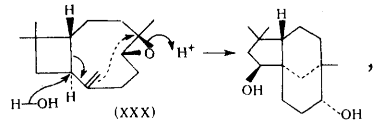
Certain homologues of squalene-2,3-oxide and its derivatives have also been converted into lanosterols[82-86]; by varying the enzymes, it proved possible to obtain under laboratory conditions fusidic acid[87] and pentacyclic products: β-amyrin[88] and cycloartenol[89]. Non-enzymic cyclisation of 2,3-oxidosqualene with stannic chloride yielded only tricyclic products[90]:



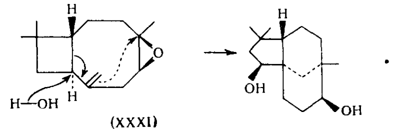
One of the first studies in this series involved an investigation of the cyclisation of the monoepoxy-derivative of geraniolene as a model compound in the synthesis of 3-hydroxy-derivatives of polycyclic systems (steroids, terpenes)[91]:



The yield of these cyclic products in the presence of boron trifluoride as a catalyst (both in benzene and in ether)[92] was smaller than in the presence of $SnCl_4$. Pyrethrosin undergoes a cyclisation of a similar type yielding a tricyclic product[93]. The epoxy-compounds derived from caryophyllene (XXX) and isocaryophyllene (XXXI) cyclise[94,95] to the corresponding glycols by the mechanisms

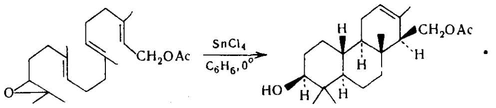


(XXX)

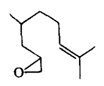


(XXXI)

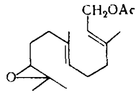
A similar process takes place when geranylgeranyl acetate is treated with stannic chloride[96]:



Goldsmith et al.[97] studied the reaction of stereoisomeric epoxy-derivatives of citronellal (XXXII), and the stereochemistry of the cyclisation of the epoxy-derivatives of farnesyl acetate (XXXIII) has been discussed by van Tamelen and coworkers[98,99]:



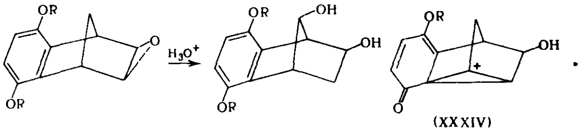
(XXXII)



(XXXIII)

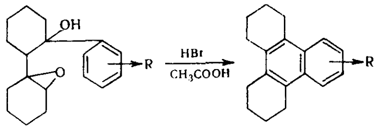
The conversion of certain epoxyolefins into carbocyclic compounds has also been described[100-102].

The involvement of a double bond, formerly included in a benzene ring, in the acid-catalysed hydrolysis of epoxy-groups in the benzonorbornene series yields anomalous water addition products. The formation of a new C–C bond in the intermediate structure (XXXIV) is postulated, as shown in the mechanism below[103-105]:



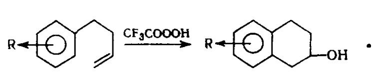
(XXXIV)

The epoxy-compound (XXXV) reacts similarly; under these conditions, the cyclic product is dehydrated[106]:



(XXXV)

An unusual example of the involvement of the C=C bond is quoted by Davidson and Norman[76]. The conversion of butenylbenzenes (XXXVI) into epoxy-derivatives with trifluoroperacetic acid leads to 1,2,3,4-tetrahydronaphthols in yields of 7% (R = H) and 25% (R = OCH_3):



(XXXVI)

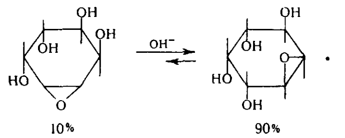
It is surprising that in the presence of boron trifluoride epoxy-compounds derived from unsaturated hydrocarbons do not yield naphthols.

2. SYNTHESIS OF HETEROCYCLIC COMPOUNDS

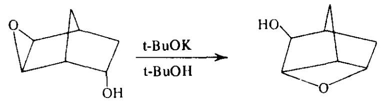
The previous section quoted certain examples of the reactions of epoxyolefins with the nucleophilic participation of the carbon–carbon double bond and formation of carbocyclic products. In this section we shall discuss cases of the formation of heterocyclic compounds such as the intramolecular nucleophilic involvement of the heteroatom in the base- and acid-catalysed rearrangements of epoxy-compounds with functional groups.

a. Attack by the Heteroatom on the Epoxy-ring without Incorporation of the Oxygen Atom into the Cyclic System

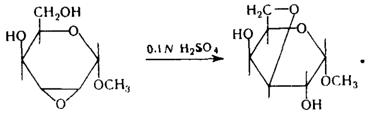
The simplest example of processes of this kind is the so called migration of the epoxy-group, which in the case of sugars, for example, can lead to an equilibrium mixture of isomers[107]:



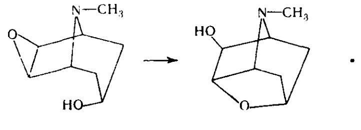
Some examples of reactions of this type have been reviewed by Newth[108] and Lemieux[109]. Similar cases of migration of the epoxy-group have been observed by Payne[110] for epoxyalcohols[110] and Akhrem and coworkers for steroids[111,112]. All these reactions take place under mild alkaline conditions involving the formation of an oxy-anion. The participation of such anions can lead to a strained oxacyclobutane system[113]:



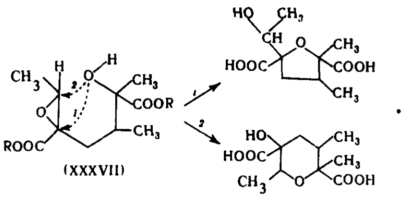
If, owing to steric factors, the participation of an O^- or OH group is impossible, then furans and pyrans are readily formed when the epoxy-ring is opened. The acid hydrolysis of methyl-2,3-anhydro-D-hexopyranosides leads to 3,6-anhydropyranosides[114]:



This cyclisation, which takes place most readily under mild alkaline conditions, has been described in the literature for 2,3-anhydro-derivatives[114-118] and 5,6-anhydro-derivatives[119]. Reactions of a similar kind are encountered among alkaloids: for example, scopine is converted into scopoline[120]:



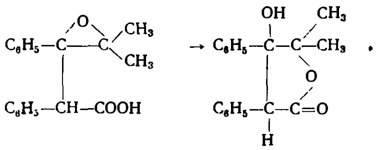
The alkaloid jacobine (XXXVII) is converted into a mixture of substituted tetrahydrofuran and tetrahydropyran derivatives[121] (in the formulae below R = R = H or R = R = retronecine residue):



(XXXVII)

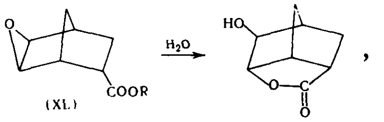
Many other examples of O-5 and O-6-involvement of the hydroxy-group in acid- and base-catalysed reactions of epoxy-derivatives of the terpene series, leading to the formation of furan and pyran derivatives, have been found in recent years[122-126].

Examples of the nucleophilic involvement of the carboxy-group in the isomerisation of epoxyacids are rarely encountered in a pure form. In particular, we may note that the $\beta\gamma$-epoxyacid (XXXVIII) is readily converted into the lactone (XXXIX) in the presence of *p*-toluenesulphonic acid[127]:



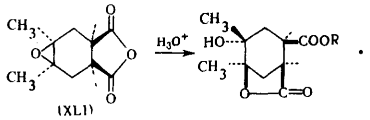
(XXXVIII) (XXXIX)

In most cases it is difficult to decide, because of a deficiency of data, whether the epoxy-ring opens with participation of the adjacent group or whether the epoxy-group is first hydrolysed to a glycol and the lactone is formed as a result of the interaction between the hydroxy- and carboxy-groups. This is illustrated by the conversion of the epoxyester (XL) into a hydroxylactone[113]:



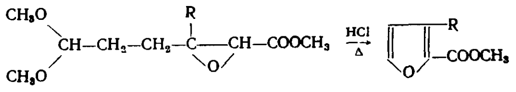
(XL)

or the conversion of the epoxyanhydride (XLI) into a hydroxylactone on hydrolysis[128]:

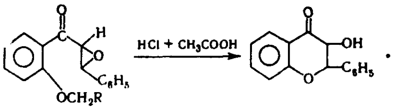


(XLI)

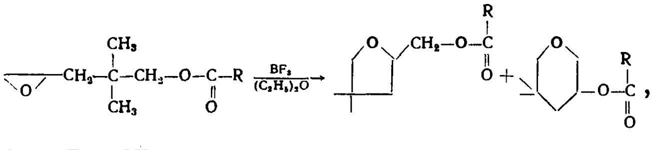
Excellent examples of translactonisation occurring on opening of the epoxy-ring in epoxylactones subjected to hydrolysis or reduction with lithium aluminium hydride have been given by Conroy[129,130] and Nazarov et al.[131] Cases of the participation of the oxygen atom in ether, ester, and epoxy-groups following the opening of the epoxy-ring in the corresponding epoxy-compounds under acid conditions are very numerous. In particular, the cyclisation of δ-acetals of glycidic esters leads to 3-substituted furans[132]:



and epoxy-derivatives of 2′-hydroxychalcone yield 3-hydroxyflavanone[133]:



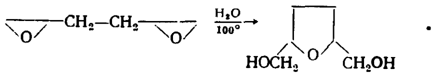
The rearrangement of 4,5-epoxy-2,2-dimethylpentyl acetate catalysed by boron trifluoride gave a mixture of furan and pyran derivatives[134]:



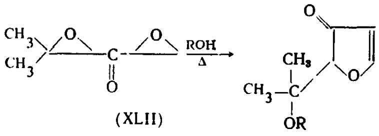
where R = CH_3.

Only the furan derivative was isolated after the reaction of 4,5-epoxy-2,2,4-trimethylpentyl isobutyrate[134].

The nucleophilic co-operation with the epoxy-oxygen atom in the opening of the second epoxy-ring in diepoxy-compounds is also well known. For example, the diepoxy-compound derived from hexa-1,5-diene forms a tetrahydrofuran derivative in the presence of acids[135]:

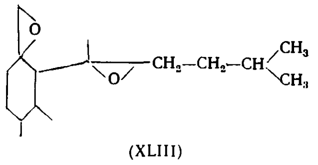


On heating in the presence of alcohol, the epoxy-compound (XLII) isomerises to dihydrofuranone[136]:



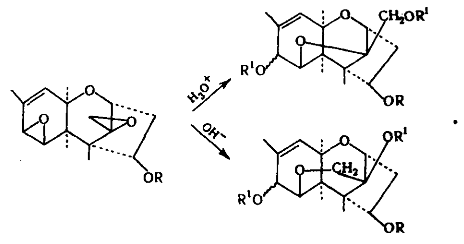
(XLII)

Klein and coworkers[137,138] described the conversion of diepoxy-derivatives of geraniol, nerol, and linalo-ol into furan and pyran derivatives under mild alkaline conditions. In the course of experiments designed to elucidate the structure of fumagillin (XLIII), Tarbell[139] observed various reactions of this compound due to the presence of two epoxy-groups:



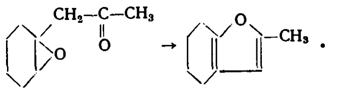
(XLIII)

Crotocin, an antimildew antibiotic, also contains two epoxy-groups, the interaction of which is different under acid and alkaline conditions[140], leading to furan or pyran derivatives:



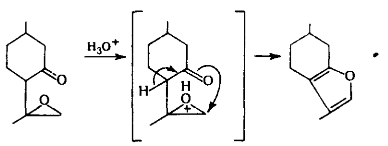
Similar reactions have been described also for certain other diepoxy-compounds[126,141].

The intramolecular interaction of carbonyl and epoxy-groups can take place in two different ways. Under alkaline conditions, there is a possibility of the formation of a mesomeric enolate anion, the intramolecular interaction of which with the epoxy-ring leads to carbocyclic products (cyclopropanes, cyclobutanes, etc) in the case of C-alkylation or to oxiran (oxetan, tetrahydrofuran, etc.) derivatives in the case of O-alkylation. In an acid medium the epoxy-group activated by co-ordination to the catalyst can cause a displacement via a field effect of the electrons from the carbonyl group (or the hydroxy-group of the enol if such is formed), which leads to the formation of cyclic products, as in O-alkylation in an alkaline medium. For example, the ketoepoxy-compound (XLIV) is cyclised by dilute sulphuric acid to furan[142]:

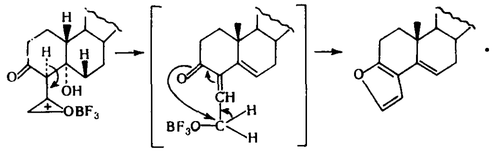


(XLIV)

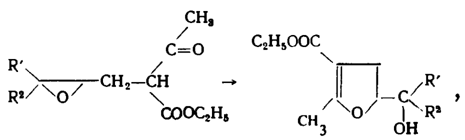
The epoxy-derivative of isopulegone undergoes a similar reaction, menthofuran being formed under very mild conditions, close to those obtaining in biological systems[143]:



Epoxyketols of the cholestane series also tend to undergo similar reactions; the reaction is catalysed by boron trifluoride which behaves at the same time as a dehydrating agent[144,145]:



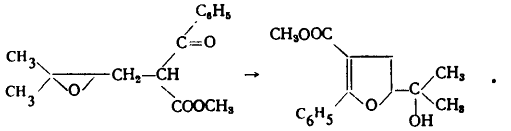
Much attention has been devoted to the problem of the biosynthesis of furans from natural products, in particular from epoxy-derivatives[144,146]. Interesting results were obtained in the alkylation of metal derivatives of carbonyl compounds by α- and β-bromoepoxy-compounds. In most cases the alkylation products formed initially undergo a rearrangement as a result of attack by the enolate anion on the epoxy-ring. In the interaction of sodioacetoacetic ester with 1-bromo-2,3-epoxybutane and 1-bromo-2,3-epoxy-3-methylbutane, compound (XLV), formed as an intermediate, rearranges to dihydrofuran[147,148]:



(XLV)

where $R^1 = R^2 = CH_3$ or $R^1 = H$ and $R^2 = CH_3$.

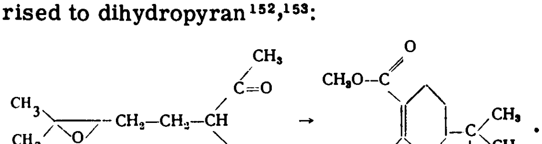
Similarly, compound (XLVI), formed as an intermediate in the reaction of methyl benzoylacetate with 1-bromo-2,3-epoxy-3-methylbutane in methanol also yields a dihydrofuran[149]:



(XLVI)

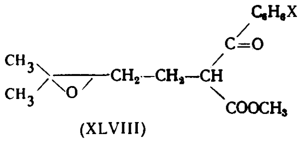
Dihydrofurans have also been obtained in the alkylation of the sodio-derivatives of benzyl phenyl ketone, benzoylacetone, and acetylacetone with 1-bromo-2,3-epoxybutane as a result of rearrangement under the reaction conditions of the γδ-epoxyketones formed[150,151].

In the alkylation of methyl acetoacetate with 1-bromo-3,4-epoxy-4-methylpentane the intermediate (LVII) isomerised to dihydropyran[152,153]:



(XLVII)

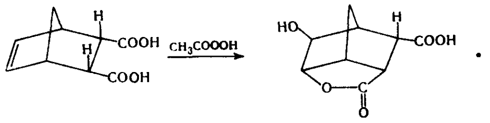
The epoxy-compounds (XLVIII) synthesised by an independent procedure are also converted into dihydropyran in the presence of bases[154]:



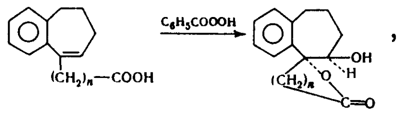
(XLVIII)

where $X = p\text{-}CH_3O$, $p\text{-}CH_3$, H, or $p\text{-}NO_2$.

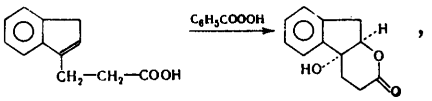
The nucleophilic involvement of an oxygen atom may be reflected not only in the opening of the epoxy-ring but also in its formation. Thus in the conversion into epoxy-derivatives of unsaturated compounds containing hydroxy-, carboxy-, ester, ether, or epoxy-groups the reaction is anomalous. The reaction of peracetic acid with 2,3-di-*endo*-carboxybicyclo[2,2,1]hept-5-ene gives a lactone[155]:



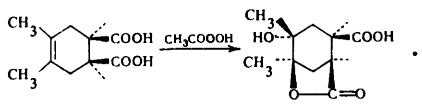
Lactones are formed similarly from the derivatives of benzocycloheptene[156]:



indene[157]:

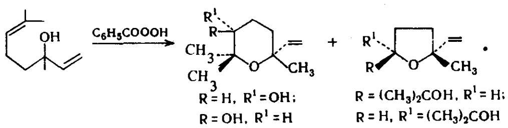


and 4,5-dimethyl-Δ^4-cyclohexene-*cis*-1,2-dicarboxylic acid[128]:



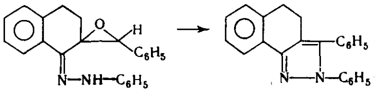
Interesting examples of the formation of a mixture of γ- and δ-lactones in the oxidation of *trans*- and *cis*-*o*-carboxystilbenes with perbenzoic acid have been quoted by Berti and Bottari[158-160] (see also Nazarov et al.[131] and Mousseron et al.[161]).

The most numerous examples of the participation of the hydroxy-group have been found in the Prilezhaev oxidation of hydroxyolefins with formation of furans and pyrans. For example, the conversion of 2-allylphenols into epoxy-derivatives leads to benzofurans[162,163]. Benzofurans have also been obtained by the oxidation of 2-propenylcresols[164]. The conversion of linalo-ol into an epoxy-derivative over phthalic acid yields a mixture of stereoisomeric tetrahydropyrans[165,166]:

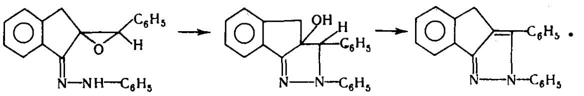


More detailed studies showed that the mixture contained also stereoisomeric tetrahydrofurans[125,167]. The formation of furan and pyran derivatives in the conversion to epoxy-derivatives of diallyl[168], octadeca-9,10-trienecarboxylic, octadeca-11,12-trienecarboxylic, and octadeca-13,14-trienecarboxylic acids[169], and other compounds[170,171] has been described.

Few data have been published on the intramolecular cyclisation of epoxy-compounds with participation of a nitrogen atom, probably owing to the difficulty of the synthesis of such bifunctional compounds. Cromwell showed that epoxyphenylhydrazones of type (XLIX) and (L), which are formed in the reaction between the corresponding $\alpha\beta$-epoxyketones with phenylhydrazine, are readily converted into pyrazoles[13,172]:

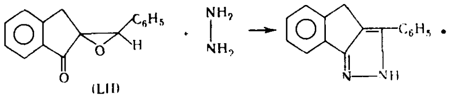


(XLIX)



(L) (LI)

Since the rates of cyclisation of epoxyphenylhydrazone (L) into pyrazoline (LI) and its subsequent dehydration are comparable, it proved possible to isolate all three products. The interaction of the epoxy-compound (LII) with hydrazine leads directly to a pyrazole[13]:

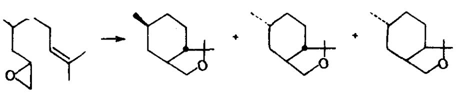


(LII)

Certain other examples of the formation of pyrazoles in the interaction of $\alpha\beta$-epoxyketones with hydrazine have been described[173-176].

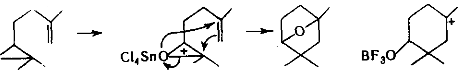
b. Cyclisation with Incorporation of the Oxygen Atom of the Epoxy-compound into the Cyclic System

Most of the examples considered above involved an intramolecular nucleophilic attack on the epoxy-ring with inversion at the carbon atom attacked. In reactions in an alkaline medium the group eliminated (the oxy-anion) was stabilised by abstracting a proton from the medium. In acid-catalysed processes the oxygen atom of the epoxy-group was bound to a proton or a Lewis acid. The molecule was then stabilised either by splitting off the catalyst and forming a carbonyl compound or by the fixation of the oxygen atom as a hydroxy-group as a result of hydrolysis by the reaction medium. It is quite evident that this mechanism is oversimplified. Indeed, if the molecule is fairly complex, in the rearrangement in the presence of bases the liberated oxy-anion may attack any other electrophilic centre in the same molecule (if allowed by the geometry). Such a case has already been mentioned (p. 267). Another example is provided by acid-catalysed rearrangements of epoxyolefins. The isomerisation of the epoxy-derivative obtained from citronellal leads to bicyclic products[97]:



The cyclisation of the mono-epoxyderivative obtained from geraniolene (p. 268) and the epoxy-derivative from geranylgeranyl acetate takes place similarly[96]:

The fact that the yield of the cyclic products was higher in the catalysis by $SnCl_4$ than in the catalysis by BF_3 is striking[91,92]. As a catalyst, $SnCl_4$ is a weaker Lewis acid than BF_3 and the rupture of the C–O bond of the epoxy-ring requires a higher degree of nucleophilic co-operation by an adjacent (geometrically suitable) C=C bond. Consequently in this case the cyclisation process is more synchronous. As the C–O bond is broken, the interaction of the π electrons of the double bond with the positive charge generated at one of the carbon atoms of the epoxy-ring becomes intensified simultaneously with the intensification of the nucleophilic interaction between the oxygen atom and the carbon of the multiple bond. The entire process may be represented by the following mechanism:-

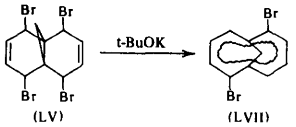


(LIII) (LIV)

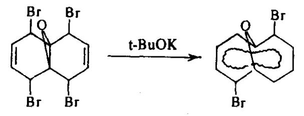
In the presence of boron trifluoride the carbonium cation structure of the transition state in the opening of the epoxy-ring is more pronounced and therefore the process is less synchronous and the yield of the cyclohexane derivative is lower. The bicyclic product (LIII) is also formed in a small amount, because the significant weakening of the nucleophilicity of the oxygen atom increases the probability of a competing process—the stabilisation of (LIV) by the elimination of a proton. We believe that the greater resemblance to a carbonium cation of the transition state in the BF_3-catalysed reaction of epoxy-compounds is indicated by the formation of fluorohydrins in this reaction, which has been known for a long time. On the other hand, in the reaction catalysed by $SnCl_4$ the formation of chlorohydrins has not been observed.

c. Valence Tautomerism of Epoxy-compounds

The valence tautomerism of acyclic and alicyclic dienes and their cyclopropyl analogues, involving 1,5-dienyl or homodienyl migration of hydrogen, has been described fairly adequately[177]. A certain similarity in the state of the bonds in the cyclopropane and oxiran rings is reflected in a number of rearrangements of vinyl-substituted cyclopropanes and oxirans. For example, dehydrobromination of (LV) and (LVI) with potassium t-butoxide in ether at 10°C leads to (LVII) and (LVIII) respectively[178]:

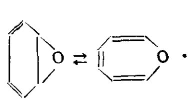


(LV) (LVII)

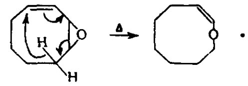


(LVI) (LVIII)

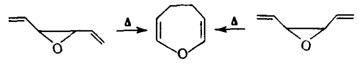
The monoepoxy-derivative of benzene is in equilibrium with its monocyclic tautomer—oxepin; in iso-octane their ratio is 3 : 7, while in aqueous methanol epoxycyclohexadiene predominates[179]:



Crandall and Watkins reported 1,5-migration of hydrogen in epoxycycloalkenes[180]:



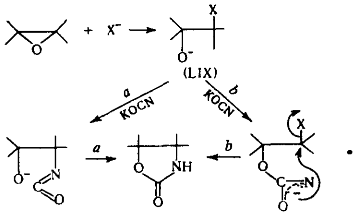
This rearrangement has also been observed in the acyclic series. When the epoxy-derivatives obtained from *cis*- and *trans*-1,2-divinylethylenes are heated, 4,5-dihydro-oxepin is formed. The *trans*-isomer of the epoxy-compound reacts under more severe conditions and is usually present in a mixture with 4,5-dihydro-oxepin[181,182]:



Certain other examples have also been described[183-185].

III. INTERMOLECULAR CYCLISATIONS

All the cases of the formation of cyclic products in the condensation of epoxy-compounds with various reagents described below involve the formation of five-membered rings. Huisgen[186] suggested that these reactions of epoxy-compounds can be classified as 1,3-dipolar addition processes in which the molecule of the epoxy-compound in the transition state is regarded as a 1,3-dipole, (i.e. $^{-}O-C-C^{+}$). The expansion of the oxiran ring in the presence of bases evidently does not include such a dipolar structure, since in the first stage the nucleophilic agent attacks the least substituted carbon atom with formation of an intermediate oxy-anion, the existence of which has been demonstrated in many cases[187]. The interaction of the oxy-anion with the electrophilic agent completes the cyclisation when the electrophilic centre is also part of the attacking agent. Epoxy-compounds react in this way with carbanions. The reactions of epoxy-compounds with molecules having multiple bonds (cyanates, isocyanates, isothiocyanates, etc.) probably involve a different mechanism. As will be shown below, in all cases a catalyst must be present (metal and ammonium halides and certain others). The role of the catalyst reduces to the formation of the oxy-anion (LIX), the interaction of which with the condensing agent can occur via two pathways:



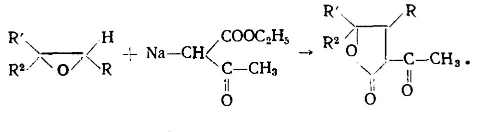
The kinetic data for reactions of epoxyalkanes with carbon dioxide catalysed by potassium, sodium, and ammonium halides support pathway *b*[188,189]; the alternative pathway *a* has been considered by Dyen and Swern[190]. The acid-catalysed condensation of epoxy-compounds with compounds having multiple bonds has been investigated purely empirically. Here the role of the acid probably reduces to the activation of the epoxy-ring (the formation of an oxonium complex) and, on the other hand, to the activation of the multiple bond, which becomes polarised as a result of co-ordination to the catalyst.

For a number of reasons, it is difficult to classify the intermolecular reactions. For example, pyridine, tribenzylamine, $ZnCl_2$, $FeCl_3$, LiCl, alkalis, etc. have been suggested as catalysts for the reactions of epoxy-compounds with isocyanates[191-193]. The site of the opening of the epoxy-ring is known to depend also on the presence of even traces of acids and therefore it is evident that pyridine and zinc chloride catalysts will lead to different reaction products. Moreover, the primary condensation products sometimes undergo pronounced changes under the reaction conditions, which also hinders the classification. Nevertheless, we believe it useful to consider separately reactions occurring in the presence of acids and bases. To simplify the task, the interaction of epoxy-compounds with the simplest inorganic molecules (CO_2, CS_2, COS, SO_2) will not be considered; this problem is discussed in detail in a recent review[4].

1. CONDENSATIONS IN THE PRESENCE OF BASES

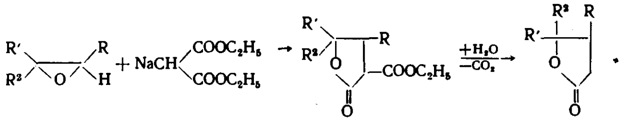
a. Attack of the Epoxy-ring by Carbanions

The most numerous examples of this type of interaction are the reactions of epoxy-compounds with *α*-dicarbonyl compounds, which lead to *γ*-lactones. The latter are formed, for example, in the reaction of sodioacetoacetic ester with epoxyethane[194], epoxypropane, epoxyethylbenzene[195], epichlorohydrin[196,197], the propyl, isopropyl[198], ethyl, and phenyl[199] ethers of glycidol, and *ββ*-dimethyl- and *α*-phenyl-glycidic esters[200], the epoxy-ring being opened on the side of the least substituted carbon atom in all the cases enumerated:



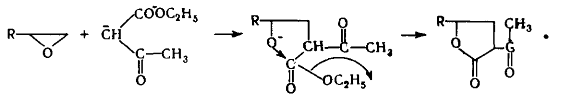
1,2-Epoxybut-3-ene[195], 2,3-epoxypent-4-ene[201], and 1,2-epoxypent-3-ene[201] form a mixture of lactones, the products obtained as a result of the attack by the nucleophilic agent on the unsubstituted carbon atom predominating. Two lactones were isolated also in the interaction of sodioacetoacetic ester with 3-chloro-1,2-epoxybutene[202], the product ratio (4 : 1) illustrating the preferential ring opening in accordance with Krasusskii's rule. The reaction of epoxyethane[203] and epichlorohydrin[196,203] with methylsodioacetoacetic ester also leads to the corresponding lactones; epoxyethane reacts similarly also with benzoylacetic ester[204].

The least substituted carbon atom is also attacked in the reaction between sodiomalonic ester and epichlorohydrin[205], epoxyethylbenzene[206-208], 2,3-epoxybutene[206], epoxycyclohexane[209,210], epoxymethylcyclohexane, the epoxy-derivative from menthene[209], *ββ*-dimethyl-[200,211], *ββ*-dialkyl-[212], and *β*-phenyl-glycidic esters[213], the ethyl and phenyl ethers of glycidol[199], and 3-dialkylamino-1,2-epoxypropanes[214], as a result of which γ-lactones are again formed:



It has been shown recently that sodiomalonic ester reacts with epoxyethylbenzene attacking the rings at two different carbon atoms[215] and not exclusively at the primary carbon atom, as was claimed in early investigations[206,207]. Cristol and Osman[216] also confirmed that epoxyethylbenzene is attacked preferentially and *p*-(epoxyethyl)nitrobenzene entirely at the secondary carbon atom. Similar results were obtained by de Puy et al.[217], who established that epoxyethylbenzene is attacked to the extent of 60% at the secondary carbon atom and to the extent of 40% at the primary carbon atom.

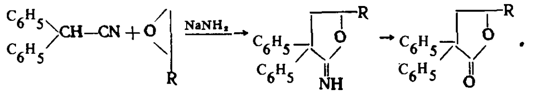
Lactones were also obtained in the reaction of sodiomalonic ester with the epoxy-derivative of dihydronaphthalene[209] and in the reactions of sodioethylmalonic ester with the ethyl and phenyl ethers of glycidol[199] and of methylsodiomalonic ester with 1,2-epoxy-3,4-dihydronaphthalene[218]. The mechanism of the above condensations was examined in the reaction with sodioacetoacetic ester by Adams and Vander-Werf[195] (see also Chelintsev[219]):



The condensation of epoxy-compounds with sodioacetoacetic and sodiomalonic esters takes place with high yields and can be used for preparative purposes[3,220].

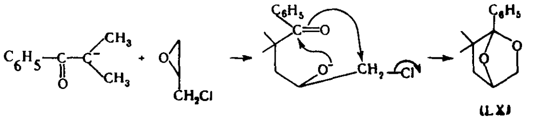
γ-Lactones are formed also in the reaction of epoxy-compounds with sodiocyanoacetic ester. In the presence of sodamide epoxyethylbenzene and 2,3-epoxybutene[221] give rise to stereoisomers of α-cyano-γ-lactones; under these conditions, as in the interaction between sodiocyanoacetic ester with ethyl and phenyl ethers of glycidol[199], the unsubstituted carbon atom of the epoxy-compound is attacked. Glickman and Cope[222] showed that epoxyethane reacts similarly, forming α-cyano-γ-butyrolactone[222].

Imidolactones, which are subsequently readily hydrolysed to γ-lactones, were obtained in the reaction of diphenylacetonitrile with a number of epoxy-compounds in the presence of sodamide[223,224]:



Under these conditions too, the carbanion attacks the primary carbon atom (see also Temnikova and Kovalevskaya[225]).

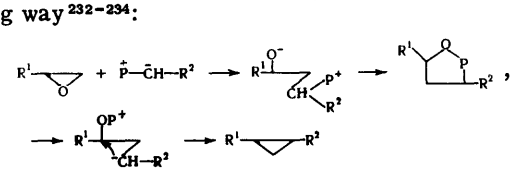
The interaction of epoxy-compounds with Ivanov's reagent also leads to γ-lactones[226-228]. The reaction of the sodio-derivative of isobutyrophenone with epichlorohydrin takes place in an interesting way[229]:



(LX)

The bicyclic product (LX) had been isolated earlier but its structure had not been demonstrated[230].

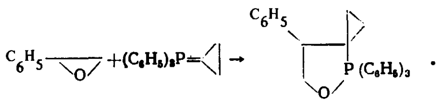
The interaction of epoxy-compounds with phosphorus ylides takes place in an unusual manner[231]. The reaction mechanism probably involves substitution in the epoxy-ring with subsequent rotation about the C–C bond and the closure of a five-membered ring, the subsequent rupture of which leads to the formation of cyclopropane in the following way[232-234]:



(LXI)

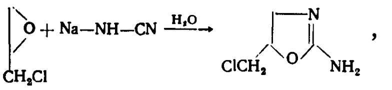
where R^1 = H or alkyl, P = Ph_3P, $(RO)_2PO$, or R_2PO, and R^2 = CN or COOR.

The formation of cyclopropanes by the above mechanism takes place only with reagents of the type $P^+-C^-H-R^2$, where R^2 is an electronegative group (CN, $COOC_2H_5$). The stabilisation of the carbanion (LXI) by these reagents favours the rupture of the intermediate five-membered ring[232-236]. The interaction of cyclopropylidenetriphenylphosphorane with certain epoxy-compounds gives rise to stable ring compounds[237], for example:

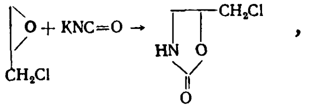


b. Attack of the Epoxy-ring by a Nitrogen Atom

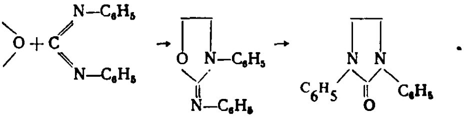
Epichlorohydrin and sodiocyanamide react in the cold in aqueous solution to form 2-amino-5-chloromethyloxazoline[238-239]:



while potassium isocyanate and epichlorohydrin give 5-chloromethyl-2-oxazolidinone[240]:

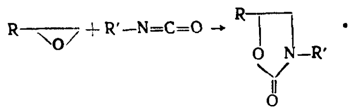


i.e. in such cases the primary carbon atom of the epoxy-ring is attacked. Pyridine, triethylamine, and lithium chloride catalyse the reaction of epoxyethane with carbodi-imides. The imino-oxazolidine formed initially rearranges under reaction conditions to 1,3-diphenyl-2-imidazolidinone[223]:

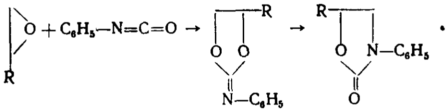


The interaction of epoxyethane, epoxypropane, epoxydodecane with phenyl and ethyl isocyanates in dioxan, dimethylformamide, and acetonitrile at 160–200°C [catalyst $(C_2H_5)_4NBr$ and KBr] leads to 2-oxazolidinones.

In this case the reaction involves the unsubstituted carbon atom[241]:



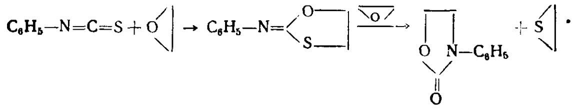
Dimethylbenzylamine catalyses the condensation of benzylepoxyethane and the phenyl ether of glycidol with phenyl isocyanate to the corresponding 2-oxazolidinones in yields up to 45%[242]. Pyridine, tribenzylamine, metal (zinc, lithium, and iron) chlorides, alkalis, etc. were used as catalysts for the reaction of aliphatic, aliphatic-aromatic, and alicyclic epoxy-compounds with phenyl isocyanate[191-193]. 2-Oxazolidinones were also obtained in the absence of a solvent at 180–200°C. Gulbins and Hamann[223,243] suggested that the initial products of this reaction are 2-phenylimino-1,3-dioxolans which isomerise to 2-oxazolidinones under the reaction conditions:



The occurrence of such isomerisation has been demonstrated by the conversion of 2-imino-1,3-dioxolans into 2-oxazolidinones at 200°C in the presence of lithium chloride (under conditions identical to those indicated above). However, this does not mean that dioxolans must necessarily be the primary products in all cases. Their formation is more evident under conditions of acid catalysis when the secondary carbon atom of the epoxy-ring in the oxonium complex is attacked and the nucleophilic centre in the phenyl isocyanate molecule is the oxygen atom. In the presence of basic catalysts, normal ring opening takes place and 2-oxazolidinones may be formed directly. Numerous examples of the synthesis of 2-oxazolidinones by the condensation of epoxy-compounds with cyanates, cyanuric acid, organic isocyanates, and urea and its derivatives, have been discussed in detail by Dyer and Swern[190,244].

c. Cyclisation with Participation of a Sulphur Atom

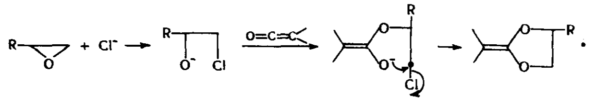
The interaction of epoxy-compounds with isothiocyanates takes place in a more complex manner than with isocyanates and is accompanied by various side processes: for example, epoxyethane and phenyl isothiocyanate give 2-oxazolidinone according to the mechanism[245]



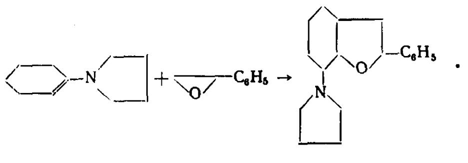
The reaction with alkyl isothiocyanates is even more complex. Without considering this process in detail, which is analysed in the review by Grobov et al.[4], we shall only mention that the epoxy-ring is attacked by the more highly polarised sulphur atom with subsequent S → O migrations[246].

d. Certain Other Cases

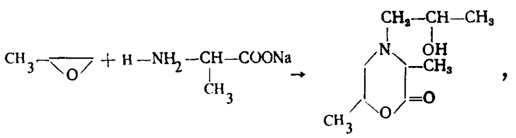
There are no data on the base-catalysed condensations of epoxy-compounds with carbonyl components. The formation of ketals in the interaction between epoxy-compounds and diphenylketen is noteworthy[223] and may be explained by the following mechanism:



The interaction of epoxyethylbenzene with enamines leads to cyclic products[247]:



Morpholone derivatives are obtained in the interaction between epoxypropane and certain aminoacids[248]:

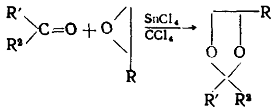


2. CONDENSATIONS IN THE PRESENCE OF ACIDS

The interaction of the epoxy-ring with polar groups having multiple bonds (carbonyl, cyano-, azomethine, etc.) might constitute a good method for the synthesis of new heterocyclic compounds. However, the small number of experimental data and almost total absence of any attempt to discover the laws governing these processes preclude for the moment the use of this method on an adequate scale.

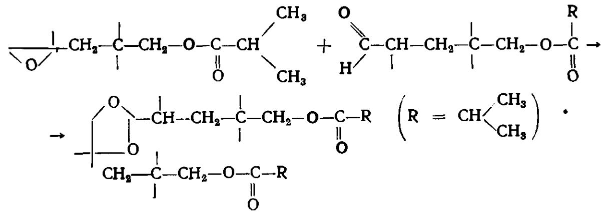
a. Synthesis of 1,3-Dioxolans

In 1861 Wurtz attempted for the first time to prepare 1,3-dioxolan by the direct condensation of epoxyethane with acetaldehyde[249]. The formation of 1,3-dioxolan as a side product was observed in 1906 in the catalytic synthesis of dioxan from epoxyethane[250]. It was suggested that the acetal is formed from epoxyethane and acetaldehyde formed by the isomerisation of the epoxy-compound. This was confirmed by the work of Bogert and Roblin[251], who obtained 1,3-dioxolans by the condensation of epoxyethane and epoxypropane with a number of aldehydes and ketones (benzaldehyde, hexanal, hexyl ethyl ketone, acetophenone):



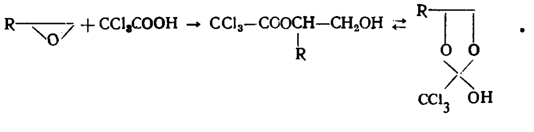
$SnCl_4$, $SnCl_4.4H_2O$, $ZnCl_2$, $FeCl_3$, $SbCl_3$, $AlCl_3$, and $CaCl_2$, as well as HCl, H_2SO_4, and $POCl_3$ were chosen as catalysts. Best results were obtained with $SnCl_4$. In recent years the reaction of carbonyl compounds with epoxy-compounds has been applied to some extent in the synthesis of new 1,3-dioxolans. The interaction of epichlorohydrin and epibromohydrin with aliphatic aldehydes (acetaldehyde, propionaldehyde, butyraldehyde, crotonaldehyde, chloral) and also with ketones (diethyl ketones, cyclopentadecanone, bromoacetophenone, benzophenone[252,253]), of epoxyethane, epoxypropane, epoxybutane, and epoxy-derivatives obtained from pseudo- and iso-butenes with a wide variety of aldehydes and ketones[254,255], and of glycidol ethers, 2,3-epoxybutene, and epoxyethylbenzene with acetone[256,257] has been investigated. Certain 1,3-dioxolans have been obtained as intermediates in the synthesis of antispasmodic compounds by the condensation of epichlorohydrin and epibromohydrin with various aromatic ketones[258,259]. The interaction of acetylenic epoxy-compounds with acetone, ethyl methyl ketone[260], cyclopentanone, and cyclohexanone[261] has been described.

1,3-Dioxolans may be formed also as side products in the intramolecular reactions of epoxy-compounds. House observed their formation in a study of the isomerisation of *cis*- and *trans*-2,3-epoxybutanes in the presence of $MgBr_2$ and BF_3.[262] The isomerisation of 4,5-epoxy-2,2,4-trimethylpentyl isobutyrate to a tetrahydrofuran derivative under the influence of boron trifluoride-ether is accompanied by the formation of dioxolan, which is probably obtained as a result of the interaction between the initial epoxy-compound and an aldehyde[134]; the formation of the latter under the reaction conditions has been demonstrated:



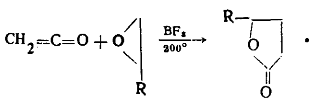
In the presence of inorganic acids (HCl, H_2SO_4) benzoin reacts with epichlorohydrin, and epoxyethane and epoxypropane react with formaldehyde, yielding 1,3-dioxolans[263,264]. The preparation of certain ketals containing a silicon atom or a triple bond in the 4-position of the ring has been described[265-267].

Aldehydes and ketones are usually employed as the carbonyl components in the synthesis of acetals and ketals, but Hibbert[268,269] and Meerwein[270,271] attempted to extend the applications of this reaction. In Meerwein's report on the preparation of 2-hydroxy-1,3-dioxolans by the condensation of di- and tri-chloroacetic acids with epoxyethane, epichlorohydrin, and glycidic ester at room temperature, it is stated that the reaction product can exist as a tautomeric mixture of cyclic and linear compounds. The cyclic structure is indicated by the stability of the product in the presence of alkalis and the ease with which it is hydrolysed by acids, which is typical for a ketal:

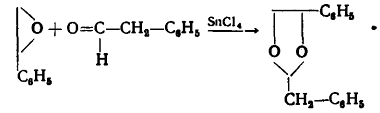


Under the same conditions, monochloroacetic and acetic acids yield the half-esters, e.g. $CH_2Cl-COOCH_2CH_2OH$.

The possibility of using ketens for the synthesis of 2-methylene-1,3-dioxolans appears to be attractive but only one such example is described in the literature. Diphenylketen was allowed to react in a sealed tube with epoxyethane at 200°C for 4–5 h, forming a dioxolan (catalyst LiCl).[223] The interaction of keten with epoxyethane, epoxypropane, and epichlorohydrin under acid conditions (BF_3) leads to the corresponding γ-lactones[272]:

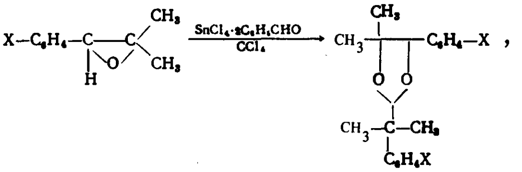


The behaviour of epoxy-derivatives obtained from substituted styrenes is striking. The attempt to condense epoxyethylbenzene with acetophenone did not give the desired results even in the presence of a large excess of epoxy-compound: the main reaction product was 2-benzyl-4-phenyl-1,3-dioxolan[273,274], probably formed as a result of the interaction between the epoxy-compound and phenylacetaldehyde (an isomerisation product of the epoxy-compound):



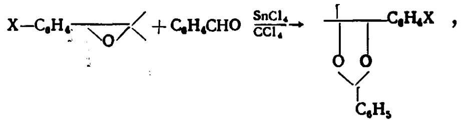
2-Benzyl-4-phenyl-1,3-dioxolan formally corresponds to the dimer of epoxyethylbenzene; previously the structure of 1,4-dioxan was attributed to the dimer, which is formed from the epoxy-compound[275] or the corresponding glycol[276,277] under acid conditions.

The behaviour of the epoxy-derivatives obtained from *para*-substituted ββ-dimethylstyrenes in the condensation with benzaldehyde in the presence of $SnCl_4$ was investigated[278]. It was found that, for epoxy-compound : benzaldehyde : catalyst ratios of 2 : 2 : 1 (under these conditions, the benzaldehyde is fully bound in a complex with $SnCl_4$), only the so called "dimers" of epoxy-compounds—2-benzyl-1,3-dioxolans—are formed:



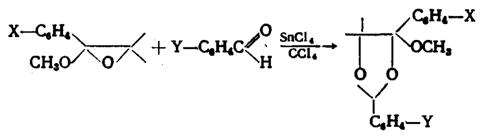
where X = Cl, H, or CH_3.

In the presence of an excess of the carbonyl compound (aromatic aldehyde) normal products are formed:



where X = Cl, H, or CH_3.

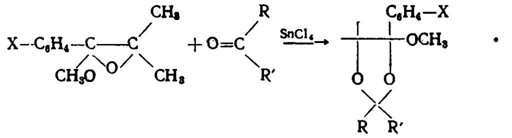
However, the epoxy-derivatives obtained from α-methoxy-ββ-dimethylstyrenes condense with aromatic aldehydes regardless of whether the aldehyde is bound in a complex with $SnCl_4$ or not[279]:



where X = Cl, H, CH_3, or CH_3O and Y = Cl, H, or CH_3.

The very sharp difference between the behaviour of the epoxy-compounds can be accounted for by the different stabilities of the carbonium ions generated on opening of the ring.

Temnikova and Gontarev obtained a large amount of 4-methoxy-1,3-dioxolans by the condensation of methoxy-derivatives of epoxy-compounds with various aldehydes and ketones[280-283]:

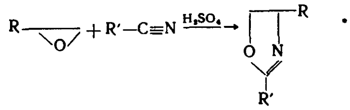


The presence in the products obtained of a system of acetal bonds may prove to be of significant interest.

An adequate mechanism has not been proposed[251,252,278] for the condensation of epoxy-compounds with carbonyl compounds.

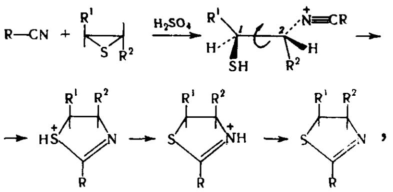
b. Synthesis of 2-Oxazolines and 2-Oxazolidines

Oda et al.[284] were the first to isolate 2-oxazolines by condensing epoxyethane, epoxypropane, and epichlorohydrin with acetonitrile, phenylacetonitrile, benzonitrile, and isobutyronitrile in concentrated sulphuric acid:



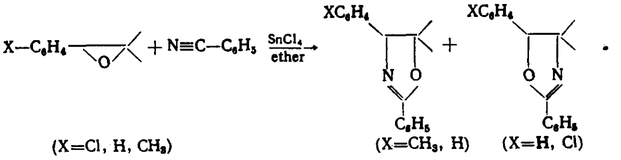
After the interaction of epoxypropane and acetonitrile, they succeeded in isolating two oxazolines: 2,2-dimethyl- and 2,5-dimethyl-Δ^2-oxazolines in proportions of 7 : 3, i.e. the opening of the epoxy-ring at the secondary carbon atom predominates. Unfortunately, the systems investigated do not allow an interpretation of the stereochemistry of the reaction.

The interaction of episulphides, which are very close in their properties to epoxy-compounds, with nitrile in concentrated sulphuric acid takes place according to the mechanism[285,286]



i.e. involves nucleophilic attack from the rear with formation of a nitrilium salt and subsequent rotation of the C^1-C^2 bond and ring closure. The validity of extending this mechanism to epoxy-compounds has not yet been proved.

Temnikova and Zhesko were the first to isolate a 4-methoxy-Δ^2-oxazoline by the reaction of 1,2-epoxy-1-methoxy-2-methyl-1-phenylpropane with benzonitrile in the presence of $SnCl_4$ in carbon tetrachloride[287]. They suggested the structure of 4-methoxy-Δ^2-oxazoline for this product in accordance with the usual rule governing the rupture of the epoxy-ring in methoxy-derivatives of epoxy-compounds under acid conditions. The epoxy-derivatives obtained from *para*-substituted $\beta\beta$-dimethylstyrenes did not yield appreciable amounts of oxazolines in the condensation with benzonitrile under these conditions[288]. When carbon tetrachloride was replaced by butyl ether, the desired products were obtained, the *para*-substituents in the molecule of the epoxy-compound having a decisive influence on the mode of attack on the epoxy-ring by the nitrile. The mechanism below shows that, with X = Cl, benzonitrile attacks the tertiary carbon atom and, with X = CH_3, the secondary carbon atom:

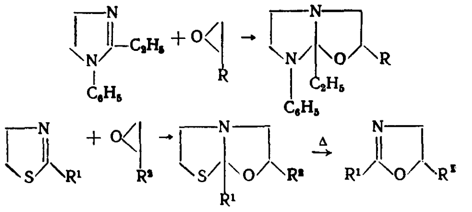


The unsubstituted epoxy-compound gives two products.

The condensation of Schiff bases with epoxyethane, epoxypropane, and epichlorohydrin in the presence of $SnCl_4$ leads to oxazolidines[289]. The reaction is carried out in carbon tetrachloride at 10–20°C. The yield of the final product greatly depends on the structure of the substrate and as a rule decreases when BF_3 is employed instead of $SnCl_4$:

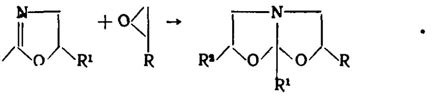
The interaction with t-butylazomethine does not require a catalyst, the introduction of which only reduces the yield.

The condensation of epoxy-compounds with certain imidazolines and thiazolines with C=N bonds in the ring gives rise to bicyclic products[290,291]:

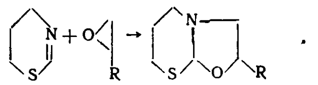


(LXII)

In the case of thiazolines the product (LXII) is unstable under the reaction conditions and is converted into oxazoline, which reacts with a further molecule of the epoxy-compound:

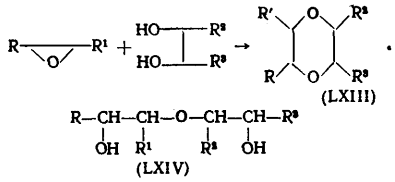


This mechanism is confirmed by the isolation of stable bicyclic products in the condensation of epoxy-compounds with thiazines[290]:



c. Certain Special Cases

The interaction of epoxyalkanes with glycols[292-294] yields dioxans (LXIII). The reaction proceeds via the intermediate formation of (LXIV), further reaction of which giving rise to dioxan:

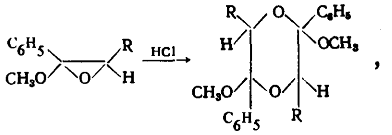


(LXIII)

(LXIV)

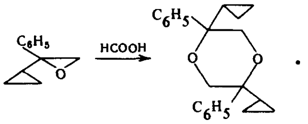
3. DIMERISATION AND n-CYCLOMERISATION OF EPOXY-COMPOUNDS

Numerous data have been published on the formation from epoxy-compounds of dimeric products to which the structure of 1,4-dioxans has been attributed. The industrial manufacture of 1,4-dioxan from epoxyethane is generally known; epoxypropane gives dimethyldioxan[295]. More detailed studies of the polymerisation products of epoxypropane, 1,2-epoxybutane, and epichlorohydrin initiated by BF_3, $SnCl_4$, and triethyloxonium fluoroborate showed that the low-molecular-weight products obtained from epoxy-propane, for example, consist of a mixture of dimers (*cis-* and *trans-*isomers of 2,5- and 2,6-dimethyl-1,4-dioxans), tetramers, pentamers, and hexamers[296,297]. It appears likely that the dimers are formed from methoxy-derivatives of the epoxy-compounds in acid media by the mechanism[298-300]:

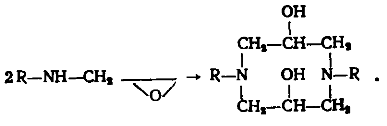


where R = CH_3, C_2H_5, or C_6H_5.

The reactions of epoxyethylbenzene in the presence of acids are usually accompanied by the formation of a high-boiling product to which the structure of 1,4-dioxan was attributed initially[275]. Summerbell and coworkers[273,274] showed that the main product of the reaction of epoxyethylbenzene in the presence of $SnCl_4$ is 2-benzyl-4-phenyl-1,3-dioxolan with only a slight admixture (up to 5%) of the isomeric 2,5-diphenyl-1,4-dioxans (see also Pasika[301]). Tiffeneau and Levy[302,303] proposed the 1,4-dioxan structure also for the dimerisation product of epoxy-$\beta\beta$-dimethylethylbenzene, but the latter proved to be in fact a derivative of 2-benzyl-1,3-dioxolan[278]. Of the other examples available, mention may be made of the dimerisation of epoxy-α-methylethylbenzene to 2,5-dimethyl-2,5-diphenyl-1,4-dioxan[304] and of the work of Oda and coworkers on the synthesis of 1,4-dioxan by the cleavage of 1-cyclopropyl-1,2-epoxyethylbenzene with formic acid[305]:



Alkyl-2,3-epoxypropylamines are converted into cyclic dimers—1,5-dialkyl-1,5-diazacyclo-octane-3,7-diols[306,307]:



Mixed condensation of two glycidylamines is also known to occur.

The Current State of the Problem of the Structure and Reactivity of Aromatic Diazo-compounds

B.A.Porai-Koshits (deceased)

The author, one of the leading investigators of the chemistry of diazo-compounds, describes in this article his views on the structure and reactivity of aromatic diazo-compounds. In the usual sense of the of the word, this is not a complete review of studies on diazo-compounds; it does not reflect all the numerous data published recently and does not contain a critical analysis of new results obtained in the last decade. The review describes the author's views based on the experimental data from his laboratory. The bibliography comprises 32 references.

The Editors

CONTENTS

1. THE DIAZOTISATION REACTION

The study of the detailed structure of aromatic diazo-compounds is at present impossible without establishing the relations governing their formation. Therefore, before considering the structure, it is necessary to describe at least briefly the modern views on the preparation of aromatic diazo-compounds.

Without exaggeration one can say that the diazotisation reaction, as well as the structure of the diazo-compounds formed, is one of the most interesting and at the same time the most complex problems of organic chemistry. The experimental difficulty consists in the extreme instability and variability of diazo-compounds, which makes it difficult to isolate the individual substances.

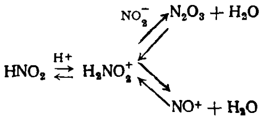
The simplest and the most widely used method for diazotisation consists in treating the amine dissolved in an aqueous inorganic acid, with alkali metal nitrites. An acid medium during the diazotisation reaction is essential, on the one hand in order to prevent the shift of the ammonium ion ⇌ amine equilibrium to the right (although, as we shall see below, the free amine is in fact diazotised and not its salt), which makes the amine insoluble, and, on the other hand in order to form the most active species participating in the reaction with the amine during its diazotisation. Finally a distinctly acid medium in the diazotisation process prevents the formation of certain side products.

Alkali metal nitrites are used in strictly stoichiometric amounts. An excess as well as a deficiency have an unfavourable effect on the stability of the diazo-compound formed. With decrease of the basicity of the amine diazotised, it is difficult to carry out the reaction in dilute aqueous solutions. In such cases concentrated acids (usually sulphuric) are used as solvents together with dry alkali metal nitrites[1]. Apart from these main diazotisation methods, there exist also certain others, the discussion of which would not throw any fundamentally new light on the problem.

The occurrence of the diazotisation reaction in an acid medium is as it were evidence that not the free amine but the salt is diazotised. However, if we remember that in a fairly concentrated acid there is always an equilibrium between the arylammonium ion and the free amine base and also that aromatic amines are fairly weak bases, the hypothesis that even in a strong acid medium the free amine is converted into the nitroso-derivative is not unexpected. Various workers arrived at this conclusion independently[2-6] and its validity was proved in 1958 by Hughes et al using kinetic methods[7]. However. recently publications have appeared where the possibility of diazotisation of certain arylammonium salts, probably by a synchronous mechanism, is postulated[8]. In either case, the first stage in the diazotisation process is the introduction of a nitroso-group into the amino-group. In principle, this reaction does not differ from the nitrosation of secondary aliphatic aromatic amines and is one of the amine acylation reactions.

In accordance with the electrophilic mechanism of the substitution of a hydrogen atom in acylation, it was to be expected that the nitrosating species would carry a positive charge or would exhibit a strong tendency to acquire such a charge.

The nitrous acid formed in the first instant of the reaction between alkali metal nitrites and the inorganic acid also reacts with the inorganic acid, giving rise to a number of equilibria which can be represented as follows:

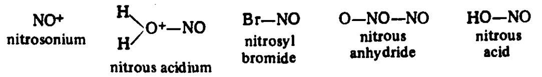


,

and in the presence of hydrogen halides:

$$HNO_2 \rightleftarrows H_2NO_2^+ \xrightleftharpoons{Hal^-} HalNO + H_2O.$$

These mechanisms show that in sulphuric acid a powerful nitrosating species is formed and readily gives rise to the nitrosonium cation, which is the essential electrophilic agent. In the presence of hydrogen halides nitrosyl halide with a highly polarised nitrogen–oxygen bond is formed, which also leads to the presence in the medium of an electrophilic species. Bearing in mind the above equilibria in the nitrous acid–inorganic acid system, all possible nitrosating agents can be arranged in the following sequence with respect to their effectiveness:



Nitrosyl halide HalN=O, which adjoins nitrous acidium as regards its activity but is formed only in hydrogen halide solutions, stands somewhat in isolation in the above series. Experimental proof of the validity of this sequence of nitrosating species in terms of their activity was found by Hammett, Ingold, and others[9,10].

It appeared that the interaction of the nitrosonium ion with the free base of an aromatic amine should give rise to a nitrosammonium ion. Therefore the nitrosamine should be at least slightly basic. In one of the present author's studies[11] it was shown that the basic properties of nitrosamine are extremely weak. Thus even if the nitrosammonium ion is formed (this is the view of, for example, Zollinger[12]), it must be rapidly hydrolysed under the reaction conditions. Consequently its formation should be regarded as a quasi-steady-state intermediate reaction stage. Another mechanism of the nitrosation reaction, in which the interaction of the nitrosonium ion with the amine and the elimination of a proton take place synchronously, is extremely probable. The difference between the both mechanisms is minimal.

In diazotisation in hydrogen halide solutions the first reaction product is a complex formed by the addition of the amine to nitrosyl halide, which is subsequently converted into a diazonium salt:

$$\mathrm{Ar{-}NH_2 + HalNO} \rightleftarrows [\mathrm{Ar}{-}\underset{\mathrm{H}}{\mathrm{N}}{-}\underset{\mathrm{Hal}}{\mathrm{N}}{-}\mathrm{OH}] \rightleftarrows \mathrm{Ar{-}N{=}N{-}OH} \underset{\mathrm{OH^-}}{\overset{\mathrm{H^+}}{\rightleftarrows}} \mathrm{ArN_2^+}\,.$$

The conversion of nitrosamine into a diazonium salt is fairly clear in broad outline. Since the nitrosamine is in tautomeric equilibrium with the amphoteric diazohydroxide, in an acid medium the latter reacts instantaneously with the inorganic acid and is converted into the diazonium salt:

$$\mathrm{Ar{-}NH{-}NO} \rightleftarrows \mathrm{Ar{-}N{=}N{-}OH} \xrightarrow[-\mathrm{H_2O}]{+\mathrm{H^+}} \mathrm{Ar{-}N_2^+}$$

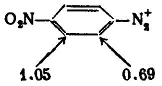
2. THE STRUCTURE AND REACTIVITY OF DIAZO-COMPOUNDS

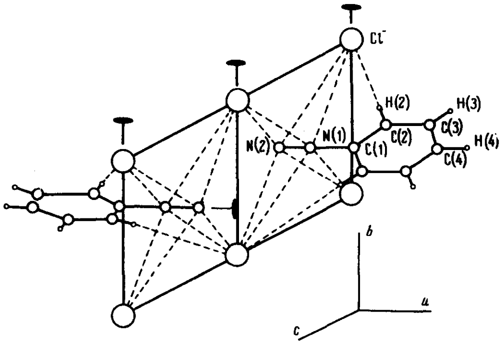
X-Ray diffraction analysis of diazonium salt crystals showed[13] that the anion is at a distance of 3.5 Å from the diazonium group and slightly closer to the extreme nitrogen atom. This is evidence that both nitrogen atoms have positive charges, which is extremely important for the understanding of the structure and reactivity of the diazonium cation.

The effective radii of the anion and the nitrogen atoms overlap, albeit to only a slight extent, but probably enough for the bond between the anion and cation to vary somewhat in type, while remaining ionic, depending on the properties of the anion. This is probably the cause of the differences between the properties of various salts of the same diazonium cation.

The above X-ray diffraction analysis shows that the diazonium cation is a planar system with nitrogen atoms linearly distributed in the plane of the aromatic ring; the the nitrogen atoms are thus *sp*-hybridised. The anion is located on one side of the plane of the organic ion. The Figure gives a clear representation of the steric structure of benzenediazonium chloride.

As a substituent of the aromatic ring, the diazonium group is strongly electronegative. Its electronegativity is approximately twice as pronounced as that of the nitro-group[14-16], which means that, in relation to the diazonium group, the aromatic ring is an electron donor even when it includes an electron-accepting substituent such as the nitro-group. This is demonstrated by the degrees of electron shielding characterising the depletion of the electron cloud and determined by NMR method, resulting from the electron-withdrawing effect of the nitro- and diazonium groups in the *para*-positions relative to one another: they are 1.05 and 0.69. This can be illustrated by the following scheme:





Schematic representation of a benzenediazonium chloride crystal according to X-ray diffraction data.

In the unsubstituted benzene ring the above numbers are 2.72.

It has been firmly established that the bond between the nitrogen atoms approaches the triple bond type[17,18]. This is illustrated in the Table, where the first column lists the substituents in the phenyldiazonium ring and the remaining columns give the absorption frequencies of the triple bond in liquid paraffin and in water together with the multiplicities of the bond between the nitrogen atoms.

It is clear from the Table that the bond multiplicity varies between 2.645 and 2.850. Calculation of electron density by the MO method in the Hückel approximation carried out by Schuster and Polansky[19,20] led to similar conclusions. The triple bond character of the link between the nitrogen atoms contradicts to some extent the X-ray diffraction data, according to which a greater part of the positive charge is concentrated on the outer nitrogen atom, since a triple bond implies the presence of only one positively charged nitrogen atom (linked directly to the ring).

The following considerations may be adduced to eliminate these conditions. Of the three bonds between the *sp*-hybridised nitrogen atoms only one π bond, the plane of the electronic vibrations of which coincides with the π-electron plane of the aromatic ring, is capable of transmitting conjugation. As a result of the presence of this bond, the aromatic ring is conjugated with all its substituents and the extreme nitrogen atom. Infrared spectroscopic data show that this conuugation may influence to some extent the link between the two nitrogen atoms causing its approach to or departure from the "pure" triple bond.

Frequencies and multiplicities of the nitrogen–nitrogen bonds in various benzenediazonium compounds.

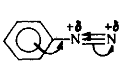
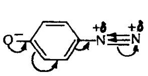
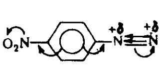
The second π bond, which is not in the plane of the π-electron cloud over the aromatic ring, and the third σ bond can transmit only the inductive effect of the positively charged nitrogen atom to the extreme nitrogen atom, which also carries in consequence a permanent positive charge, this being confirmed by X-ray diffraction data. It appears that the following formulae of the most typical diazonium cations reflect to some extent all that has been said about their structure:







The Reactivity of Diazonium Salts

The most important reaction of which aromatic diazo-compounds are capable is azo-coupling. Therefore, when speaking of the reactivity of diazo-compounds, one usually has in mind their reactivity in the azo-coupling reaction. Since various investigators have established rigorously that only the diazonium cation enters into the azo-coupling reaction, the reactivity in this reaction is usually attributed to the diazonium cation.

Since within the framework of a short article it is impossible to consider all the reactions of which aromatic diazo-compounds are capable, here too only the azo-coupling reaction, interpreted, however, in a somewhat extended sense, will be dealt with.

From the above considerations, it follows inevitably that the reactivity of the diazonium cation is linked to the electrophilic properties of the extreme nitrogen atom or, in a more restricted sense, the Lewis acid strength of the diazonium cation.

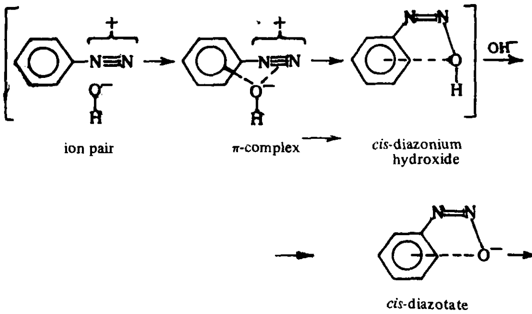
Bearing in mind that the aromatic ring with any of the usual substituents is always an electron donor in relation to the diazonium group and therefore always neutralises to a greater or lesser extent the positive charge of the extreme nitrogen atom, the problem of the reactivity reduces to the degree of neutralisation of the charge by various substituents. From this point of view, *p*-nitrobenzene diazonium for example, should be much more reactive than *p*-dimethylaminobenzenediazonium.

At the same time the first of the above substances is a stronger Lewis acid than the second. Evidently the strength of the Lewis acid and its reactivity in the azo-coupling reaction should be correlated, since acidity constitutes a special case of electrophilicity. Therefore the reactivity of the diazonium cation is initially most conveniently investigated in its reaction with a hydroxide ion. As will be shown below, despite its apparent simplicity, this reaction has certain features which permit it to be treated as a model for more complex cases.

The reaction between a hydroxide ion and a diazonium cation begins with the formation of an ion pair. The ion pair should be fairly stable, since the hydroxide ion is oriented by the π-electron system of the aromatic ring and the diazonium group. The gradual conversion of this ion pair into a π complex takes place in such a way that the bond between the hydroxyl and the π-electron system of the ring is maintained, which predetermines the steric configuration of the diazohydroxide formed subsequently. In the π complex the nitrogen atom linked to the ring is in a state of *sp*-hybridisation and therefore the structure of this complex is still linear.

In the next, slowest reaction stage the π complex is converted into diazohydroxide in which both nitrogen atoms are now in a state of sp^2-hybridisation as a result of which the molecule becomes bent. Since the hydroxyl probably remains linked to the aromatic ring, both residues must occupy *cis*-positions in relation to the double bond of diazohydroxide. Suhr and coworkers[21] found on the basis of a study of PMR spectra of aromatic diazotates that not all the ring hydrogen atoms are equivalent. From this, he concluded that there is a bond between the oxygen of the diazotate ion and the carbon atom in the *ortho*-position, which is also evidence in favour of the *cis*-configuration.

The reaction of the diazonium cation with the hydroxide ion is shown schematically below:



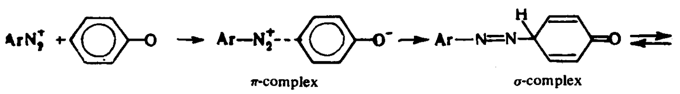
Usually diazohydroxide is not regarded as the final reaction product, since no representative of this series has so far been isolated. It is regarded either as "an intermediate product in a quasi-steady state" or as a σ complex. The present author believes it more logical to regard the *cis*-(or *syn*-) diazohydroxide as the final compound which has, however, unusual properties enabling it to undergo further reactions under the given conditions. One of the most important properties of diazohydroxide is its amphoteric nature which leads to its rapid acid or base ionisation. The diazotate ion in which the multiplicity of the bond between the nitrogen atoms is 1.4 according to calculations[22], formed on acid ionisation of diazohydroxide, is also capable of *cis–trans* isomerism and in an alkaline medium comparatively readily undergoes a stereochemical transformation, forming the *trans*-(*anti*-) isomer, which is extremely stable.

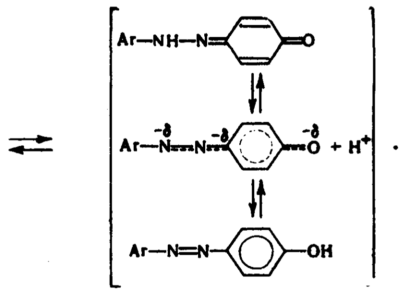
However, the reactions which follow the formation of the *cis*-diazohydroxide should not be included, according to the present author, with the nucleophilic attack proper by the hydroxide ion on the diazonium cation.

Thus one may assume that the reaction between the diazonium cation and the hydroxide anion has an S_N2 mechanism. The substrate (diazonium cation) undergoes the most pronounced changes in this process: the state of hybridisation of the nitrogen atoms changes, the previously non-existent capacity for stereoisomerism appears, etc. It is scarcely possible to regard the hydroxide anion as the substrate in this reaction and the diazonium cation as the reagent. It would then be necessary to assume that the hydrogen atom in the hydroxide ion is substituted. The azo-coupling reaction, which takes place in exactly the same way, is then assumed to have an S_E2 mechanism with a quasi-steady-state intermediate stage. The diazonium cation is regarded as an electrophilic reagent, similar, for example, to the nitronium cation, the chlorine cation, the carbonium cation, and other positive species. "The quasi-steady-state intermediate product" (or σ complex) differs from the final compound by the position of the proton, which is removed from the molecule by any base present in the medium during the second, faster reaction stage.

The present author believes that there is no fundamental difference between the interaction of the diazonium cation with the hydroxide anion and with the azo-component. In both cases the diazonium cation undergoes the same, much more significant changes than the reagent—the hydroxide anion or the azo-component. Also in both cases a covalent bond is formed between the extreme nitrogen atom and the atom of the attacking species. In the first case this atom is the oxygen of the hydroxide anion and consequently one may speak of the acidity of the diazonium cation. In the second case it is a carbon atom, the electrophilic properties of which may be assessed.

On the other hand, analysis of the structure of the so called σ complex ("the quasi-steady-state intermediate product"), formed in the azo-coupling reaction shows that it is none other than the final product in one of its possible tautomeric forms. Its further conversion into another tautomeric form, the azo- or quinohydrazo-form, usually does occur but under certain conditions may not. Therefore in the scheme representing the stages in the azo-coupling reaction—the ion pair, the complex, and one of the possible steric isomers of the azo-compound—the stage in which the tautomer formed is converted into another form, which may involve the inversion of the configuration, is separate from the azo-coupling reaction proper:





Indirect confirmation of the validity of the separation of further reactions of the product from the azo-coupling reaction proper is provided by the wide variety of views concerning the presence or absence of a kinetic isotope effect in the azo-doupling reaction[23]. In some cases it is absent, while in others it is observed. This is probably associated with the different rates of tautomeric transformations of the so called σ complex. The changes in the hybridisation of the carbon atom linked to the extreme nitrogen atom of the diazonium cation are of the usual type accompanying any tautomeric transformation.

Thus it is possible to postulate that the azo-coupling reaction also has an S_N2 mechanism, i.e. the reagent (the azo-component) adds to the triple bond of the substrate (the diazonium cation).

This new approach to the azo-coupling reaction will make it possible to treat from the same standpoint reactions which are at first sight quite different and to combine them in a single system.

The present author has in mind (apart from the azo-coupling proper) the reactions of the diazonium cation with amines leading to the formation of diazoamino-compounds, with alcohols leading to ethers, and with nucleophilic reagents such as the sulphite ion, the nitrilium ion, etc. — in other words all the reactions of the diazonium cation resulting in the formation of a covalent bond between the terminal nitrogen atom and any other atom in a nucleophilic species (base). There is a possibility now of determining the causes of the stereoisomerism, the reactivities of various nucleophilic agents, etc.

It must be emphasised yet again that the properties of the product of the addition of the nucleophilic agent to the triple bond determine its subsequent fate. If this is a product resulting from the attack by an azo-component, then, as stated above, it may undergo tautomeric transformations; if it is a result of reaction with amines, there is a possibility of a rearrangement of the diazoamino-compound formed into an aminoazo-compound; if it is a product of the addition of a hydroxide ion, it undergoes acid ionisation with further stereochemical transformations; if it is a product of the reaction of hydrocyanic acid with the diazonium cation, it undergoes only stereochemical changes; finally, if it is a compound formed as a result of nucleophilic attack on the diazonium cation by any alkoxide, the reaction terminates at this point, etc.

It is interesting to note that in all these cases the sequence of cations arranged in order of increasing or decreasing reactivity is maintained. It is possible to estimate the reactivities of various nucleophilic agents as a function of their structure, and the possibility of further reactions of the primary product of addition to the triple bond.

The capacity of certain diazo-compounds for decomposition on irradiation with ultraviolet light is widely used in engineering. Diazo-compounds with electron-donating hydroxy-, dialkylamino-, arylamino-, sulphide, etc. groups in the *para-* or *ortho*-positions in relation to the diazonium-group are particularly light sensitive. As a result of the presence of these groups, the neutralisation of the positive charge of the extreme nitrogen atom is considerable. However, infrared spectrophotometric data and calculations by the molecular orbital method in the Hückel approximation suggest that the bond between the nitrogen atoms is much closer to a triple than to a double bond. This is true also in those cases where the *para-* (or *ortho-*) position in relation to the diazonium group contains a readily ionisable hydroxy- or acid imino-group. Therefore the "quinodiazide" structure proposed for these compounds, like the name itself, is hardly accurate. The "quinodiazide" formula must be regarded only as one of the extreme resonance structures, invariably associated with another formula, whereby these substances are represented as inner salts and which makes a much greater contribution.

In accordance with the above considerations, the electrophilic reactivity of diazonium salts with powerful electron-donating substituents in the *para-*(or *ortho*)-position in relation to the diazonium group is reduced, although they, including the so called "quinodiazides", retain their capacity for azo-coupling. On the other hand, their light sensitivity and thermal stability are enhanced[24-26]. The latter is important for applications in engineering.

3. DIAZOHYDROXIDES AND NITROSAMINES

When diazonium salts are treated with alkalis one might expect that the neutralisation of one equivalent of acid would convert the substance into diazohydroxide (as shown above, *syn*-diazohydroxide). However, because of the amphoteric properties of diazonium hydroxide and the high rate of its reaction with the second equivalent of hydroxide ions leading to the formation of the final product (*syn*-diazotate), diazohydroxide is not formed. As shown by Bryuske[27], the theoretical explanation of this is that in an aqueous medium the diazohydroxide is fully ionised. Therefore the attempt to isolate representatives of this class of compound were in vain. The interaction of alkali with diazonium salts leads to the formation of a mixture of diazonium cations and diazotate anions and not diazohydroxide. The amphoteric properties of the latter and the fact that the reaction with the second equivalent of hydroxide ions is faster than with the first constitutes the foundations of all modern hypotheses concerning the structure of aromatic diazo-compounds. These properties of diazohydroxides suggest that, if they are ever isolated, it will be from non-aqueous solutions and even then under non-equilibrium conditions. However, there is no doubt about the existence of diazohydroxides as a necessary logical and chemical stage in the neutralisation of diazonium cations by alkalis. The well known curves obtained by the potentiometric titration of various diazonium cations with alkalis confirm this[28]. As regards *anti*-diazohydroxides, we may note that this structure has been sometimes attributed to the product of the acidification of *anti*-diazotates. However, in a recent study Eiges[29] showed by infrared spectrophotometry, dipole moment measurements, and molecular orbital calculations that in those cases where the product of the acidification of the *anti*-diazotate can be isolated from solutions (and this has been achieved for diazo-compounds with electron-accepting groups in the *para*-position with respect to the diazo-group) it has the structure of a primary nitrosamine. At one time Hantzsch suggested that the nitrosamine and *anti*-diazohydroxide are in equilibrium. This view should evidently be accepted but in a modern sense: the two compounds are in tautomeric equilibrium and the *anti*-diazohydroxide does not exist in aqueous solutions because of its amphoteric properties.

4. DIAZOTATES

Syn- (or *cis-*) diazotates, obtained by the interaction of alkalis with diazonium salts, can be isolated as precipitates, although this operation requires a considerable skill of the experimenter. On heating in concentrated alkalis, these diazotates are converted into stable readily isolated *anti-*(*trans-*)diazotates, which, in contrast to *syn*-isomers capable of undergoing instantaneous coupling with the azo-component, are capable of this reaction only after relatively prolonged treatment with inorganic acids. It will be seen later that this is because the equilibrium in aqueous solutions between the *syn*-diazotate and the diazonium cation is established instantaneously, while that between the *anti*-diazotate and the diazonium cation is attained slowly. There is at present no doubt that both diazotates are stereoisomers. However, it must be emphasised that the modern view differs somewhat from the Hantzsch hypothesis which postulates the stereoisomerism of covalent diazo-compounds (for example, diazohydroxides assuming them to be unionised), while modern chemists postulate the stereoisomerism of the ions (diazotates).

The present author and Shaburov[30] not only succeeded in demonstrating this but also showed the presence of the *syn*-diazotate in solution for the *p*-nitrobenzenediazo-compound, the existence of the *syn*-diazotate of which had not been proved previously. The converse transition of the *anti*-diazotate into the *syn*-diazotate has been demonstated in only a few cases. It occurs when the *anti*-diazotate is irradiated with solar ultraviolet light.

5. EQUILIBRIUM BETWEEN DIFFERENT FORMS OF DIAZO-COMPOUNDS

Various forms of diazo-compounds were mentioned above. We have seen that these include diazonium salts, diazohydroxides, nitrosamines, and diazotates. A mechanism for the interconversions of these forms of diazo-compounds was put forward for the first time by Hantzsch but this now requires some modernisation, revision, and correction. All the forms are present in equilibrium in aqueous solution. The position of this equilibrium depends on the pH of the medium and in some cases may be displaced to a limit where a particular form of the diazo-compound can be isolated and investigated in detail. There are protolytic and tautomeric equilibria. The stereoisomeric transformations do not give rise to equilibria and are rarely reversible.

We shall first attempt to examine special equilibrium systems, included in the general reaction mechanism; purely protolytic equilibria will be artificially separated from tautomeric and stereochemical transformations.

The behaviour of the diazonium cation is typical for dibasic Lewis acid. When acted upon by alkali, it reacts in succession first with one and then with another hydroxide ion and is converted into a diazotate anion. To some extent this occurs also in the absence of alkali: one can then speak of the hydrolysis of the Lewis acid. This acid–base equilibrium has been well investigated. It is established extremely rapidly and has many characteristic features.

The first stage in the interaction of the diazonium cation with the hydroxide ion is, as stated above, the formation of a covalent *cis*-diazohydroxide, while the second, faster stage is the ionisation of the diazohydroxide and the formation of *cis*-(*syn*-) diazotate:

$$\mathrm{Ar{-}N_2^+} \underset{\mathrm{H^+}}{\overset{\mathrm{OH^-}}{\rightleftharpoons}} \mathrm{Ar{-}N{=}N{-}OH} \underset{\mathrm{H^+}}{\overset{\mathrm{OH^-}}{\rightleftharpoons}} \mathrm{Ar{-}N{=}N{-}O^-}(syn)\,.$$

The neutralisation curves obtained by potentiometric titration do not show a jump in potential after the addition of the first equivalent of alkali as happens in the titration of the usual dibasic acids. This form of neutralisation curve implies that the equilibrium constant for the first reaction stage is much lower than for the second stage[31]:

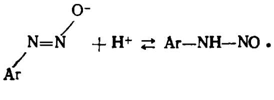
$$K_1 = \frac{[\mathrm{Ar{-}N_2OH}][\mathrm{H^+}]}{[\mathrm{Ar{-}N_2^+}]}\,;\quad K_2 = \frac{[\mathrm{Ar{-}N_2O^-}][\mathrm{H^+}]}{[\mathrm{Ar{-}N_2OH}]}\,;\quad K_2 \gg K_1\,.$$

The condition $K_2 \gg K_1$ means that, when exactly one equivalent of alkali is added to the solution of the diazonium salt, the product is not diazohydroxide as indicated in the above equation, but a 1 : 1 mixture of diazotate anions and diazonium cations. Thus a kind of salt—diazonium diazotate—is formed. This interesting phenomenon is based on the amphoteric properties of diazohydroxide mentioned above. The high rate of equilibration between the diazonium cation and *syn*-diazotate, to which Littler first drew attention[32], gives rise to the apparent capacity of the diazotate for azo-coupling. After a time, the *syn*-diazotate rearranges to the *anti*-isomer under the action of alkalis or heat. Since the basicity of the *anti*-diazotate is lower, this rearrangement involves a spontaneous decrease of the pH of the medium. The stronger is the Lewis acid (diazonium cation) from which the *syn*-diazotate has been obtained the easier is the stereoisomeric rearrangement.

The rearrangement of the diazo-compound from *p*-nitroaniline is so fast that the intermediate formation of the *syn*-diazotate can be observed only by special methods[30]. On the other hand, the more basic the amine from which the diazo-compound has been prepared the more severe conditions are required for the rearrangement: for example, the rearrangement of the diazo-compound obtained from aniline requires treatment with concentrated alkali at 130–150°C.

The converse transformation of the *anti*-diazotate to the *syn*-isomer takes place, as stated above, only in certain cases on irradiation with ultraviolet light[33]. Therefore the stereoisomeric transformation cannot be regarded as reversible. The acidification of *anti* -diazotate solutions never regenerates the *syn*-isomers, other reactions taking place.

When a proton adds to the *anti*-diazotate, an acid is formed, which, as stated above, in those cases where it could be isolated proved to have the structure of a nitrosamine:



$$\mathrm{Ar{-}N{=}N{-}O^-} + \mathrm{H^+} \rightleftarrows \mathrm{Ar{-}NH{-}NO}\,.$$

The interaction of the nitrosamine with an acid medium leads to a gradual formation of the diazonium cation.

We may recall that an obligatory stage involving the formation of a nitrosamine with its subsequent conversion into the diazonium cation is also postulated for diazotisation, which is carried out in an acid medium. The mechanism of the transformation in an acid medium of the nitrosamine (which had acid properties) into the diazonium cation has not as yet been investigated, but kinetic methods will probably assist in its determination. However, one can now postulate that it consists in a tautomeric rearrangement of the nitrosamine into diazohydroxide, which instantaneously ionises to form the diazonium cation. We may recall that Hantzsch adhered to exactly the opposite view. He suggested that the acidification of the *anti*-diazotate yields the *anti*-diazohydroxide, which is in equilibrium with the nitrosamine. The latter rearranges via an unknown mechanism to the diazonium salt. On the other hand, one cannot postulate the preliminary formation of the *anti*-diazohydroxide in diazotisation, since the formation of the nitrosamine constitutes the first diazotisation stage.

Conversely the transformation of the nitrosamine into the diazonium cation cannot be logically imagined without the diazonium hydroxide stage, of whatever steric configuration, since on formation it should instantaneously (particularly in an acid medium) decompose into the diazonium cation.

The transformation of the nitrosamine into diazohydroxide takes place under the influence of protons. The tautomeric rearrangement presupposes the formation of an ion common to both tautomers. Thus, as stated previously, one must either postulate that the nitrosamine has minimal basic properties or that its transformation into diazohydroxide takes place by a push-pull (synchronous) mechanism. Then attack by the proton is directed to the most nucleophilic oxygen atom. The mechanism of the transformation of the nitrosamine into diazohydroxide can be represented as follows under these conditions:

$$\mathrm{Ar{-}NH{-}NO} + \mathrm{H^+} \rightleftharpoons [\mathrm{Ar{-}NH{-}N{=}\overset{+}{O}{-}H} \leftrightarrow \mathrm{Ar{-}\overset{+}{N}H{=}N{-}O{-}H}] \rightleftharpoons \mathrm{Ar{-}N{=}N{-}OH} + \mathrm{H^+}$$

or

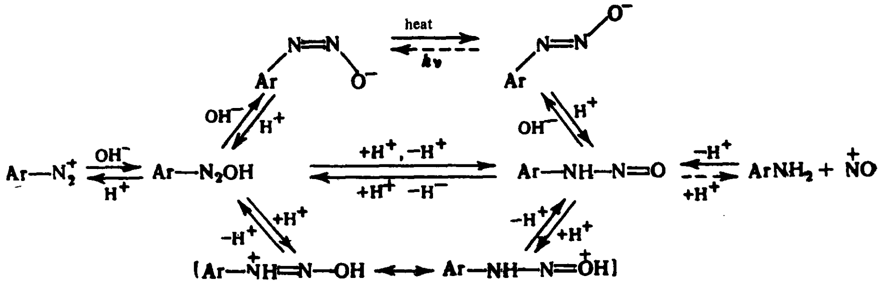
$$\mathrm{Ar{-}N(H){-}N{=}O\ H^+} \rightleftharpoons \mathrm{H^+} + \mathrm{Ar{-}N{=}N{-}O{-}H}\,.$$

Regardless of its steric structure, the diazohydroxide form is instantaneously converted into the diazonium cation:

$$\mathrm{Ar{-}N{=}N{-}OH} + \mathrm{H^+} \rightarrow \mathrm{H_2O} + \mathrm{Ar{-}N_2^+}\,.$$

Summarising all the above considerations, one may postulate the following "cycle of transformations" of the diazo-compounds in the equilibrium systems formed in aqueous solutions of diazonium salts and by the action of alkalis on diazonium salts followed by treatment with acids.

The suggested mechanism involves protolytic, tautomeric, and stereochemical transformations, i.e. transformations of the type investigated and discussed in modern theoretical organic chemistry. It is not therefore surprising that the data collected in the study of aromatic diazo-compounds are frequently extended to other classes of organic compounds and the conclusions drawn from them are of great importance for theoretical organic chemistry.



In conclusion the author would like to deal with a minor terminological problem. Above, diazo-compounds, including in this term diazonium salts, diazohydroxides, diazotates, and nitrosamines, were considered. At the same time all these compounds differ markedly from one another in their structure: diazonium salts are indeed "diazo-compounds" since in them two nitrogen atoms replace a hydrogen atom of the aromatic ring; nitrosamines and diazohydroxide contain, in addition to the two nitrogen atoms replacing hydrogen, also an oxygen and a hydrogen atom. Diazotates contain an additional oxygen atom. Many investigators include among diazo-compounds substances in which there is a covalent bond between the terminal nitrogen atom and occasionally a very complex residue (for example diazonium sulphonates, diazonium cyanides, etc.) but do not include among them diazoamino-compounds or azo-dyes.

To eliminate these logical contradictions, the present author believes it correct to name as diazo-compounds only substances which in aqueous or other media are involved in simple or complex equilibria with diazonium cations.

Fluorine-containing Aminoacids

F.Weygand (deceased) and W.Oettmeier

CONTENTS

I. INTRODUCTION

Organofluorine compounds are important not only because they have unusual chemical properties and applications in engineering but also because some of them prove to be physiologically active. The fluorides of dialkylphosphoric acids and derivatives of monofluoroacetic acid are highly toxic, 5-fluorouracil and fluoro-orotic acid are tumour inhibitors, and the replacement of hydrogen by fluorine in certain steroid hormones greatly increases their biological activity.

The reason for the physiological activity of fluorine compounds probably consists in the fact that the cell cannot distinguish fluorinated and non-fluorinated compounds and makes use of them equally because the dimensions of the hydrogen and fluorine atoms are similar (covalent radii: H 0.35 Å, F 0.64 Å; van der Waals radii: H 1.20 Å, F 1.55 Å). However, the replacement of hydrogen by very electronegative fluorine creates a centre with an enhanced electron density and the powerful hydrogen bonds formed by this component of the molecule with enzymes can prevent the formation of normal enzyme–substrate complexes[1,2].

Since aminoacids play an important role in metabolism, the effects of fluorinated aminoacids on the organism is particularly interesting. This review deals with the synthesis and properties of fluorinated aminoacids and also their biological activity (in those cases where it is has been investigated). The review is restricted mainly to carboxylic 2-aminoacids (apart from fluorinated 3-aminopropionic acids).

II. THE SCOPE OF THE SYNTHESIS OF FLUORINE-CONTAINING AMINOACIDS

The syntheses of fluorinated aminoacids achieved hitherto can be divided into three general groups.

1. It is possible to use the classical syntheses for aminoacids from fluorinated starting materials, for example Erlenmeyer's azlactone synthesis, syntheses with acylmalonic esters, ammonolysis of carboxylic 2-halogenoacids, and Strecker's cyanohydrin synthesis. However, the replacement of hydrogen by fluorine in the starting compound can lead to complications. Because of the powerful *I*-effects of the fluoroalkyl and fluoroaryl groups, the substitution and addition reactions in the course of the synthesis may be hindered, facilitated, or take place in a different way. Finally, decomposition reactions, in particular the elimination of fluorine, may occur.

2. Another possibility is to introduce fluorine into existing aminoacids, their derivatives, or intermediate products by exchanging hydrogen, another halogen, or a hydroxyl for fluorine.

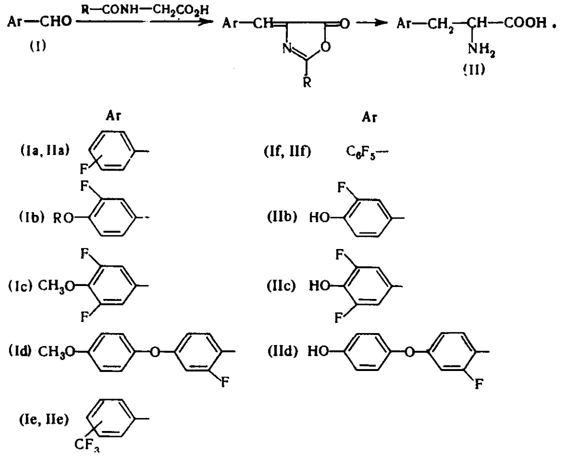
3. Special methods have also been developed (particularly for the synthesis of polyfluorinated aminoacids), which have no analogy in the chemistry of non-fluorinated aminoacids.

III. PREPARATION OF FLUORINE-CONTAINING AMINOACIDS BY CLASSICAL METHODS FOR AMINOACID SYNTHESIS

1. Fluorinated Aromatic Aminoacids

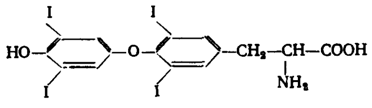
Fluorine-substituted aromatic compounds are readily obtained by the decomposition of aromatic diazonium fluoroborates and can be used for the synthesis of fluorinated aromatic aminoacids. Thus as early as 1932 Schiemann and Roselius succeeded in obtaining three isomeric fluorinated derivatives of phenylalanine (IIa) by the condensation of *o*-, *m*-, or *p*-fluorobenzaldehyde (Ia) with hippuric acid and subsequent hydrolysis and reduction[3] (see Scheme 1).

Scheme 1



It proved possible to obtain 3-fluorotyrosine (IIb) by this method using as starting materials 3-fluoro-4-methoxy- or 4-ethoxy-3-fluoro-benzaldehyde (Ib, R = CH_3 or C_2H_5) as starting materials. This compound can be also synthesised from *m*-fluorophenylalanine by nitration, reduction, and decomposition of the corresponding diazo-compounds on refluxing[4,5]. 3,5-Difluorotyrosine (IIc) was obtained similarly[6].

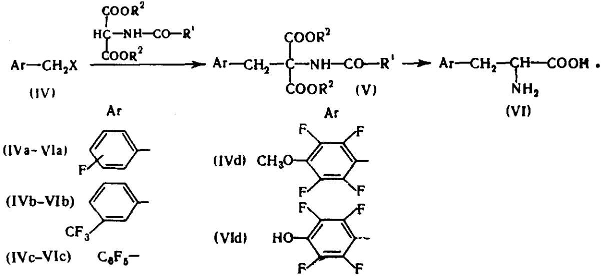
Thyronine, a compound related to tyrosine, is the non-iodinated analogue of the thyroid hormone—thyroxine (III):



Schiemann and coworkers succeeded in synthesising 2-fluorothyronine (IId) using a fluoroaldehyde (Id)[4,5]. In connection with their possible application in therapy, subsequently a series of similar fluoro-derivatives of thyronine were obtained: 3′-fluorothyronine, 3′-fluoro-3,5-di-iodothyronine, 3′-fluoro-3,5,5′-tri-iodothyronine, 3′,5′-difluorothyronine, and 3′,5′-difluoro-3,5-di-iodothyronine[7,8].

Three isomeric fluorophenylalanines were obtained in high yields by the condensation of the corresponding fluorine-substituted benzyl chlorides (IVa, X = Cl) with acetamidomalonic ester and subsequent hydrolysis of the acylamino esters formed (V, $R^1 = CH_3$, $R^2 = C_2H_5$) (see Scheme 2).

Scheme 2



The racemate produced can be separated into optical isomers by synthesising enzymically in the presence of papain the phenylhydrazides of the *N*-acylaminoacids, only the L-aminoacids reacting[9]. Similar resolution of racemates is possible also for 3-fluorotyrosine[10].

All the above aminoacids proved to be biologically active. Thus a number of studies have been published on the biological activity of fluorotyrosine and *p*-fluorophenylalanine. Only a few examples illustrating the importance of these antimetabolites were selected arbitrarily and are described below.

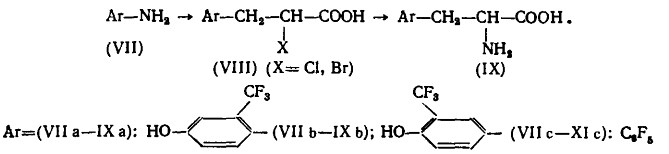
3-Fluorotyrosine is much more toxic than sodium fluoride: the lethal dose is about 12 mg kg^{-1} (for white mice)[11]. The lethal dose is independent of whether the D-isomer, the L-isomer, or the racemate is employed (experiments on rats)[10]. The Gudernatsch test on tadpoles (their growth is greatly accelerated by the addition of thyroxine) showed that fluorotyrosine may counteract the effect of thyroxine[12]. For this reason, fluorotyrosine is used in medicine in the treatment of goitre ("Pardinon") produced by the Bayer Company)[13]. It also inhibits the growth of tumours in rats and mice[14].

Fluorophenylalanines also inhibit the growth of *Neurospora crassa*[15] and are toxic to rats[16]. The addition of *p*-fluorophenylalanine to cultures of *E. coli* retards their growth, but at a certain phase in the development of *p*-fluorophenylalanine is incorporated in the proteins[17-19]. It is also possible to grow strains which are stable in relation to *p*-fluorophenylalanine[20]. These stable strains contain a phenylalanine-RNA synthetase, which no longer activates *p*-fluorophenylalanine[21,22].

A number of trifluoromethylphenylalanines and trifluoromethyltyrosines were obtained by Filler and coworkers. While *m*-trifluoromethylphenylalanine (VIb) is readily obtained from *m*-trifluoromethylbenzyl bromide (VIb, X = Br) and dibenzyl *N*-benzylyxycarbonylaminomalonate ($R^1 = C_6H_5CH_2O$, $R^2 = C_6H_5CH_2$; Scheme 2), the synthesis is unsuitable for the *o*- and *p*-isomers. However, all three isomers of trifluoromethylphenylalanine (IIe) can be readily obtained by azlactone synthesis (Scheme 1) from trifluoromethyl-substituted benzaldehydes (Ie) and aceturic acid (R = CH_3) (the benzamido-group is eliminated only with difficulty after the synthesis)[23].

Meerwein arylation was chosen for the synthesis of 2- and 3-trifluoromethyltyrosines (IXa, b):

Scheme 3



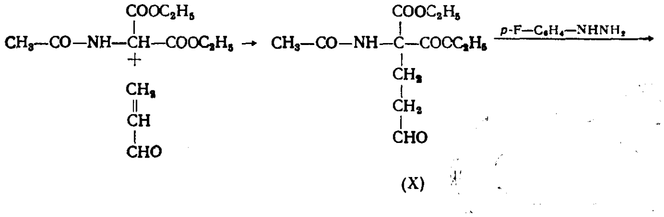
The diazonium chloride obtained from the aromatic amine (VII) is converted under the action of copper(I) chloride and acrylic acid into 3-aryl-2-chloropropionic acid (VIII), which yields the aminoacid after ammonolysis[24,25].

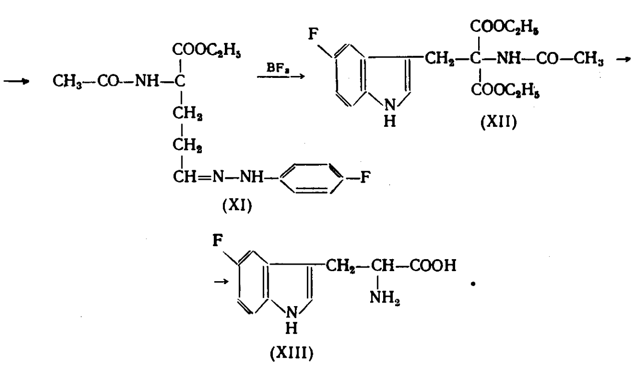
The corresponding aminoacids were obtained from the available polyfluorinated aromatic compounds. Pentafluorophenylalanine was synthesised by all three methods: azlactone synthesis (Scheme 1) with pentafluorobenzaldehyde (If)[26,27,30], synthesis with acetamidomalonic ester (Scheme 2) using pentafluorobenzyl bromide (IVc, X = Br)[28,30], and finally Meerwein arylation (Scheme 3) starting with pentafluoroaniline (VIIc) via 3-aryl-2-halogenopropionic acid (VIIIc)[28,30]. In this case it is impossible to obtain the aminoacid (IXc) by treating the chloride or bromide (VIIIc) with ammonia, since elimination and substitution reactions result in the formation of *trans*-4-amino-2,3,5,6-tetrafluorocinnamic acid. It is necessary to employ the azide and hydrogenate it catalytically. Pentafluorophenylalanine proved to be biologically inactive[28,30].

Finally, tetrafluorotyrosine (VId) was also obtained according to Scheme 2.[29,30]

The next aromatic acid for which fluoro-derivatives are known is tryptophan. Rinderkneche and Niemann[31] synthesised a fluoro-derivative using the method for the synthesis of tryptophan developed by Warner and Moe[32,33].

The addition of acetamidomalonic ester to acrolein by the Michael reaction gives 4-acetamido-4,4-diethoxycarbonylbutyraldehyde (X), the *p*-fluorophenylhydrazone (XI) of which can be cyclised by the Fischer method to an indole derivative (XII) and 5-fluorotryptophan (XIII) may be obtained by subsequent hydrolysis:





Hoffmann et al. prepared the same compound by the usual method of synthesis via gramine starting with 5-fluoroindole[34]. 5- and 6-Fluorotryptophans proved to be just as interesting key compounds for biochemical studies as fluorophenylalanine and fluorotyrosine. Only a few examples will be quoted: fluorotryptophan is toxic to mice[35], inhibits the tryptophan hydroxylase of rat brain[36], and inhibits the growth of a wild strain of *E. coli*. However, a mutant of *E. coli* incapable of synthesising tryptophan incorporates fluorotryptophan in its proteins[37].

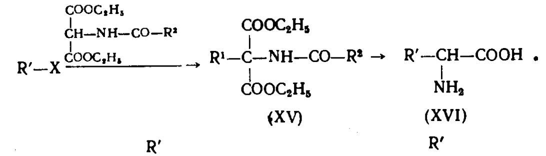
2. Fluorinated Aliphatic Monoaminoacids

After the reason for the toxicity of monofluoroacetic acid became known, the attention of biochemists was drawn to other aliphatic monofluoro-compounds. Monofluoroacetic acid takes part in the citric acid cycle, like acetic acid. The condensation of fluoroacetate with oxalylacetate is irreversible and aconitase cannot propagate the cycle in the usual way.

It was found that unbranched carboxylic ω-fluoroacids with an even number of carbon atoms are just as toxic as monofluoroacetic acid, since on β-oxidation in the living organisms they are converted into monofluoroacetic acid.

Aliphatic monofluoro-substituted aminoacids were synthesised for further investigation. Using an acylaminomalonic ester, Raasch and Lontz obtained 2-amino-4-fluorobutyric acid (XVIa), 5-fluoronorvaline (XVIb), and 6-fluoronorleucine (XVIc).

Scheme 4



$$R'{-}X \xrightarrow{CH(COOC_2H_5)_2{-}NH{-}CO{-}R^2} R^1{-}C(COOC_2H_5)_2{-}NH{-}CO{-}R^2 \rightarrow R'{-}CH(NH_2){-}COOH\,.$$

(XV) (XVI)

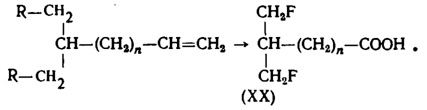
R′
(XIV a — XVI a) $F(CH_2)_2—$
(XIV b — XVI b) $F(CH_2)_3—$
(XIV c — XVI c) $F(CH_2)_4—$

R′
(XIV d — XVI d) $CH_3—CHF—(CH_2)_2—$
(XIV e — XVI e) $CF_3—(CH_2)_3—$
(XIV f — XVI f) $CF_3—CH(CH_3)—(CH_2)_2—$

The fluorine atom in the ω-position is very sensitive to hydrolysis; for example, the hydrolysis of the derivative (XVa) of acetamidomalonic ester with dilute sulphuric acid yields, together with the fluorine-containing aminoacid, an equal amount of 2-amino-4-hydroxybutyric acid. Therefore compounds (XVb) and (XVc) were hydrolysed with 48% hydrofluoric acid to prevent this exchange reaction[38,39]. Hudlický obtained by the same method 5-fluoronorleucine (XVId) from 4-bromo-2-fluorobutane (XIVd). In this case too the fluorine atom is readily substituted; more prolonged heating with dilute inorganic acids yields almost exclusively 5-hydroxynorleucine[40,41].

As was to be expected from the above, 5-fluoronorvaline proved to be very toxic (actually 10 times more toxic than sodium monofluoroacetate), while 6-fluoronorleucine is almost non-toxic. In this connection it is interesting to note that 3-fluoropyruvic acid (the product of the transamination of 3-fluoroalanine, the synthesis of which will be discussed below) is non-toxic and is not converted into monofluoroacetic acid in the rat organism[39].

Lettré and Wolcke[42] obtained a number of mono- and di-fluoro-substituted aminoacids starting with carboxylic fluoroacids[42]. When the latter were not known, the authors developed a new method of synthesis. Toluene-*p*-sulphonates (XVIII) obtained from the unsaturated diols (XVII) were converted by the action of potassium fluoride in diethylene glycol into fluoro-olefins (XIX), the ozonolysis and oxidation of which gave the carboxylic acids (XX):



$$(R{-}CH_2)_2CH{-}(CH_2)_n{-}CH{=}CH_2 \rightarrow (CH_2F)_2CH{-}(CH_2)_n{-}COOH\,.$$

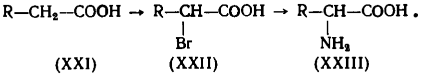
(XX)

(XVII) R=OH
(XVIII) R = OTs
(XIX) R=F

(n = 1 and 2)

The bromides of the fluoroacids (XXI) were brominated in the α-position and subsequently converted into aminoacids by the action of ammonia:

Scheme 5



$$R{-}CH_2{-}COOH \rightarrow R{-}CH(Br){-}COOH \rightarrow R{-}CH(NH_2){-}COOH\,.$$

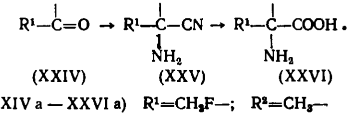
(XXI) (XXII) (XXIII)

(XXI a — XXIII a) $FCH_2—$
(XXI b — XXIII b) $F(CH_2)_2—$
(XXI c — XXIII c) $(FH_2C)_2CH—$
(XXI d — XXIII d) $(FH_2C)_2CH—CH_2—$
(XXI e — XXIII e) $CF_3—CF_2—CF_2—(CH_2)_2—$
(XXI f — XXIII f) $CF_3—CF_2—CF_2—(CH_2)_3—$

This method improved the synthesis of 3-fluoroalanine (XXIIIa) and 2-amino-4-fluorobutyric acid (XXIIIb) and made it possible to obtain for the first time 4,4′-difluorovaline (XXIIIc) and 5,5′-difluoroleucine (XXIIId). Attempts to prepare 4-fluoroleucine by this method had to be abandoned, because even the intermediate 3-fluoro-5-methylhex-1-ene splits off hydrogen fluoride at room temperature. The dipeptide DL-3-fluoroalanyl-L-leucine can be obtained from *N*-benzyloxycarbonyl-3-fluoroalanine and the trimethylsilyl ester of *N*-trimethylsilyl-L-leucine.

The Strecker method for the synthesis of aminoacids was also successfully employed to prepare mono- and di-fluoro-substituted aminoacids:

Scheme 6



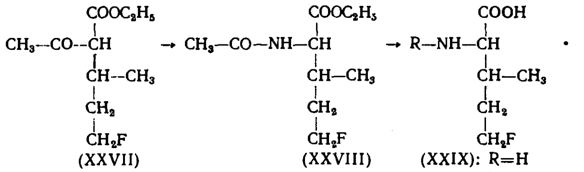
$$R^1{-}C(R^2){=}O \rightarrow R^1{-}C(R^2)(NH_2){-}CN \rightarrow R^1{-}C(R^2)(NH_2){-}COOH\,.$$

(XXIV) (XXV) (XXVI)

(XXIV a — XXVI a) $R^1=CH_2F—$; $R^2=CH_3—$
(XXIV b — XXVI b) $R^1=R^2=CH_2F—$
(XXIV c — XXVI c) $R^1=CF_3—CH_2—CH_2—$; $R^2=H—$
(XXIV d — XXVI d) $R^1=CF_3—$; $R^2=CH_3—$

However, here too side reactions play an appreciable role. Thus a mixture of 3-fluoro-2-hydroxyisobutyronitrile and 2-amino-3-fluoroisobutyronitrile (XXVa) was obtained by the reaction of fluoroacetone (XXIVa) with sodium cyanide and ammonium chloride; similarly, hydrolysis gives a mixture of 3-fluoro-2-hydroxyisobutyric acid and 2-amino-3-fluoroisobutyric acid (XXVIa)[43,44]. In the reaction of 1,6-difluoroacetone (XXIVb) 3,3′-difluoro-2-hydroxyisobutyronitrile formed as an intermediate is converted by the action of gaseous ammonia into 2-amino-3,3′-difluoroisobutyronitrile (XXVb), the hydrolysis of which gives 2-amino-3,3′-difluoroisobutyric acid (XXVIb)[43].

Hudlický chose a completely new method for the synthesis of monofluoro-derivatives of isoleucine[45]. Alkylation of acetoacetic ester with 3-bromo-1-fluorobutane gives the ethyl ester of 2-acetyl-5-fluoro-3-methylvaleric acid (XXVII). This acetyl derivative is converted by the Schmidt rearrangement into ethyl 2-acetamido-5-fluoro-3-methylvalerate (XXVIII):

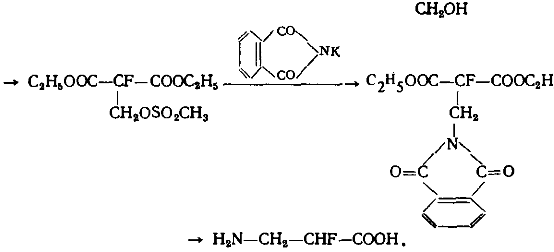


$$\underset{\text{(XXVII)}}{\begin{array}{c}\mathrm{COOC_2H_5}\\ |\\ \mathrm{CH_3{-}CO{-}CH}\\ |\\ \mathrm{CH{-}CH_3}\\ |\\ \mathrm{CH_2}\\ |\\ \mathrm{CH_2F}\end{array}} \rightarrow \underset{\text{(XXVIII)}}{\begin{array}{c}\mathrm{COOC_2H_5}\\ |\\ \mathrm{CH_3{-}CO{-}NH{-}CH}\\ |\\ \mathrm{CH{-}CH_3}\\ |\\ \mathrm{CH_2}\\ |\\ \mathrm{CH_2F}\end{array}} \rightarrow \begin{array}{c}\mathrm{COOH}\\ |\\ \mathrm{R{-}NH{-}CH}\\ |\\ \mathrm{CH{-}CH_3}\\ |\\ \mathrm{CH_2}\\ |\\ \mathrm{CH_2F}\end{array}\;.$$

(XXVII) (XXVIII) (XXIX): R=H
(XXX): R=CH₃—CO—

While acid hydrolysis gives DL-2-amino-5-fluoro-3-methylvaleric acid (XXIX), alkaline hydrolysis under mild conditions gives an *N*-acetyl derivative (XXX). To separate it into its optical isomers, this compound was acted upon by pig kidney acylase. However, instead of the expected L-aminoacid, its cyclisation product—*cis*-3-methyl-L-proline—was obtained together with D-2-acetamido-5-fluoro-3-methylvaleric acid. These results provide a key to the solution of the problem of the stereochemistry of the compounds. Since the *cis*-compound is obtained by the cyclisation of *threo*-2-amino-5-fluoro-3-methylvaleric acid, the product of the synthesis is evidently DL-5-fluoroalloisoleucine (XXIX). The *N*-acetyl derivative obtained by enzymic hydrolysis is thus (2S : 3R)-2-acetamido-5-fluoro-3-methylvaleric acid (XXX).

Here we should also mention the fluoro-derivative of 3-aminopropionic acid (β-alanine), although this is not an α-aminoacid. β-Alanine is one of the few β-aminoacids occurring in nature; it is a component of pantothenic acid. 3-Amino-2-fluoropropionic acid (XXXI) may be isolated as a decomposition product of 5-fluorouracil from the urine of mice, cats, or man after internal administration of 5-fluorouracil[46]. Bergmann and Cohen obtained α-fluoro-β-alanine (XXXI) in the following way[47]:



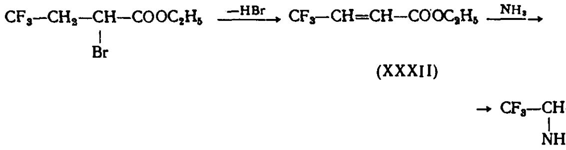
(XXXI)

A similar synthesis was developed by Tolman and Vereš on the basis of 2-fluoro-3-hydroxypropionic acid[48].

Bearing in mind the ease with which mono- and di-fluoro-substituted aminoacids lose fluorine, it is evident that the problem of whether the observed cytotoxic effect of the compound is determined by its properties as an antimetabolic or whether it is caused by the formation of fluoride ions remains open[42].

The stability of fluorine-containing aminoacids should increase following the introduction of a complete trifluoromethyl group or other perfluoroalkyl group at once instead of replacing one or two hydrogen atoms by fluorine.

Walborsky et al. synthesised 2-amino-4,4,4-trifluorobutyric acid (XXXVIa) from 4,4,4-trifluorobutyric acid. It is readily brominated in the α-position and is converted into ethyl 2-bromo-4,4,4-trifluorobutyrate. However, instead of the expected 2-amino-4,4,4-trifluorobutyramide ammonolysis yields the isomeric 3-amino-4,4,4-trifluorobutyramide (XXXIII)[49]:

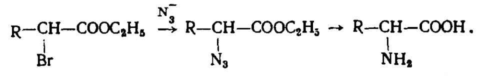


$$\mathrm{CF_3{-}CH_2{-}\underset{\underset{\mathrm{Br}}{|}}{CH}{-}COOC_2H_5} \xrightarrow{-\mathrm{HBr}} \underset{\text{(XXXII)}}{\mathrm{CF_3{-}CH{=}CH{-}COOC_2H_5}} \xrightarrow{\mathrm{NH_3}} \underset{\text{(XXXIII)}}{\mathrm{CF_3{-}\underset{\underset{\mathrm{NH_2}}{|}}{CH}{-}CH_2{-}CONH_2}}.$$

(XXXII)

(XXXIII)

As a result of the elimination of hydrogen bromide, ethyl trifluorocrotonate (XXXII) is formed initially, since the inductive effect of the trifluoromethyl group facilitates the elimination of a proton from the β-position. Subsequently ammonia adds in the usual way to the β-carbon atom. A less basic but more nucleophilic reagent (for example the azide ion) should drive the reaction towards normal substitution. Indeed, when the α-bromoester (XXXIVa) was treated with an azide with subsequent catalytic hydrogenation, 2-amino-4,4,4-trifluorobutyric acid (XXXVIa) was obtained[50]; 4,4,4-trifluorovaline (XXXVIb)[51] and 5,5,5,5′,5′,5′-hexafluoroleucine (XXXVIc)[52] were obtained similarly:



$$\underset{\text{(XXXIV)}}{\mathrm{R{-}\underset{\underset{\mathrm{Br}}{|}}{CH}{-}COOC_2H_5}} \xrightarrow{\mathrm{N_3^-}} \underset{\text{(XXXV)}}{\mathrm{R{-}\underset{\underset{\mathrm{N_3}}{|}}{CH}{-}COOC_2H_5}} \rightarrow \underset{\text{(XXXVI)}}{\mathrm{R{-}\underset{\underset{\mathrm{NH_2}}{|}}{CH}{-}COOH}}.$$

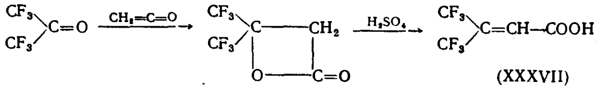
(XXXIV) (XXXV) (XXXVI)

(XXXIV a — XXXVI a) $\mathrm{CF_3{-}CH_2}$

(XXXIV b — XXXVI b) $\mathrm{CF_3{-}\underset{\underset{\mathrm{CH_3}}{|}}{CH}{-}}$

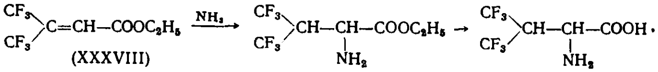
(XXXIV c — XXXVI c) $\mathrm{CF_3{-}\underset{\underset{\mathrm{CF_3}}{|}}{CH}{-}CH_2}$

Knunyants and Cheburkov showed that 3,3-bis(trifluoromethyl)acrylic acid (XXXVII), obtained from hexafluoroacetone and keten via a β-lactone[53],



(XXXVII)

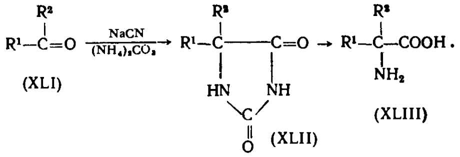
and also the ethyl ester of this acid (XXXVIII) do not behave like ethyl 4,4,4-trifluorocrotonate (XXXII). In the case of the ester (XXXII) the attack by ammonia is directed to the β-carbon atom and 3-amino-4,4,4-trifluorobutyramide (XXXIII) is formed; on the other hand, the ester (XXXVIII) combines with ammonia at the α-position. Free 4,4,4,4′,4′,4′-hexafluorovaline (XL) is then obtained from the aminoacid ester thus produced[54]:



(XXXVIII) (XXXIX) (XL)

A number of trifluoromethyl-substituted aminoacids have also been obtained in other ways. 6,6,6-Trifluoronorleucine (XVIe) and 6,6,6-trifluoro-5-methylnorleucine (XVIf) were synthesised with the aid of formamidomalonic ester (Scheme 4, $R^2 = H$)[49]; the starting materials were respectively 4,4,4-trifluorobutyl iodide (XIVe) or 4,4,4-trifluoro-2-methylbutyl iodide (XIVf), which may be obtained in several stages from 1,1,1-trifluoroacetone.

The Strecker synthesis (Scheme 6) was used successfully to prepare 5,5,5-trifluoronorvaline (XXVIc)[49] and 2-amino-3,3,3-trifluoroisobutyric acid (XXVId)[44]. However, while the yield of 5,5,5-trifluoronorvaline [(XXVIc) or (XLIIIa)] synthesised by the Strecker method is only 4.6%, synthesis via the hydantoin makes it possible to increase the yield to 30%:[49]

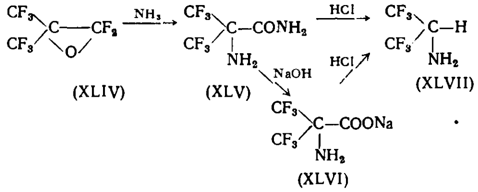


(XLI a — XLIII a) $R^1=CF_3-CH_2-CH_2-$; $R^2=H$

(XLI b — XLIII b) $R^1=CF_3-$; $R^2=CH_3-$

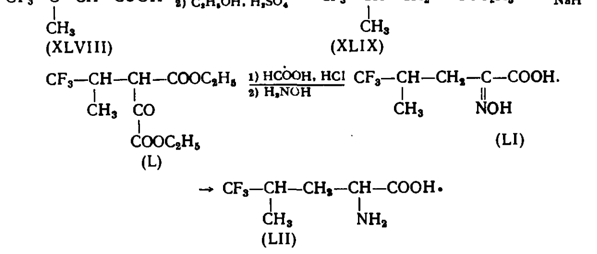
2-Amino-3,3,3-trifluorobutyric acid (XLIIIb) was also obtained via hydantoin[38].

In this connection it is interesting to note an observation by Knunyants and coworkers: it was found that the corresponding aminoacid derivative of hexafluoroacetone—2-amino-3,3,3,3′,3′,3′-hexafluoroisobutyric acid—is unstable. The interaction of epoxyperfluoroisobutane (XLIV) with ammonia at −10°C yields the amide of 2-amino-3,3,3,3′,3′,3′-hexafluoroisobutyric acid (XLV)[55]. Hydrolysis of this amide with dilute hydrochloric acid is accompanied by decarboxylation and gives hexafluoroisopropylamine (XLVII); although the sodium salt of the aminoacid (XLVI) can be obtained by alkaline hydrolysis, on acidification it too decarboxylates spontaneously[56]:



Yet another synthesis of 5,5,5-trifluoronorvaline and 4,4,4-trifluorovaline has so far been mentioned only in conference abstracts[57].

The synthesis of 5,5,5-trifluoroleucine (LII) should also be described. Rennert and Anker employed 4,4,4-trifluoro-3-methylcrotonic acid (XLVIII) as the starting material. Catalytic hydrogenation, esterification, and condensation with oxalate ester leads to compound (L). After hydrolysis and decarboxylation, the resulting 2-ketoacid is converted into the oxime (LI). Its catalytic hydrogenation yields the aminoacid (LII)[58]:



$$\underset{\substack{|\\CH_3\\(XLVIII)}}{CF_3-C}=CH-COOH \xrightarrow[2)\,C_2H_5OH,\,H_2SO_4]{1)\,H_2(Pt)} CF_3-\underset{\substack{|\\CH_3\\(XLIX)}}{CH}-CH_2-COOC_2H_5 \xrightarrow[NaH]{(COOC_2H_5)_2}$$

$$CF_3-\underset{\substack{|\\CH_3}}{CH}-\underset{\substack{|\\CO\\|\\COOC_2H_5\\(L)}}{CH}-COOC_2H_5 \xrightarrow[2)\,H_2NOH]{1)\,HCOOH,\,HCl} CF_3-\underset{\substack{|\\CH_3}}{CH}-CH_2-\underset{\substack{\|\\NOH\\(LI)}}{C}-COOH.$$

$$\rightarrow CF_3-\underset{\substack{|\\CH_3\\(LII)}}{CH}-CH_2-\underset{\substack{|\\NH_2}}{CH}-COOH.$$

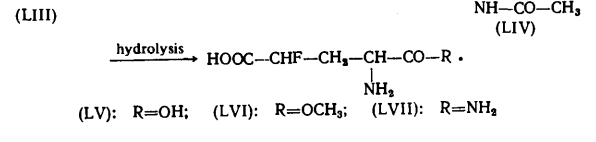
In view of their possible biochemical importance, Walborsky and Lang determined the pK's of a number of trifluoromethyl-substituted aminoacids and compared them with those of the corresponding non-fluorinated compounds[59]. As expected, pK_{COOH} and pK_{NH_2} decrease under the influence of electronegative trifluoromethyl groups and to a greater extent the closer the latter are to the dissociating groups. However, in biological tests the aminoacids obtained did not fulfil the expectations. 6,6,6-Trifluoronorleucine, 6,6,6-trifluoro-5-methylnorleucine, 4,4,4,4′,4′,4′-hexafluorovaline, 4,4,4-trifluorovaline, and 5,5,5,5′,5′,5′-hexafluoroleucine proved to be inactive in relation to *Saccharomyces cerevisiae* and *E. coli*; only 5,5,5-trifluoronorvaline inhibits the growth of *E. coli*[49,51,52]. On the other hand, the growth of HeLa cells ceases almost completely at a hexafluorovaline concentration as low as 7.2×10^{-4} M.[60]

An interesting effect was observed with 5,5,5-trifluoroleucine. Leucine dependent *E. coli* mutants continue to grow exponentially when trifluoroleucine is added to the nutrient medium. Inhibition is not observed until the concentration of trifluoroleucine exceeds by severalfold the concentration of leucine. When the trifluoroleucine : leucine ratio is 2, at least half of the leucine in the bacterial protein is replaced by trifluoroleucine. *E. coli* can actually become adapted to grow in a nutrient medium containing solely trifluoroleucine and the leucine in the protein is entirely replaced by trifluoroleucine. On the other hand, a wild strain of *E. coli* does not incorporate trifluoroleucine added to the nutrient medium[58].

Two perfluoroalkyl-substituted long-chain aminoacids, obtained by Brace[61] according to Scheme 4 from fluoroacids (XXIe) and (XXIf), namely 2-amino-5,5,6,6,7,7,7-heptafluoroheptanoic acid (XXIIIe) and 2-amino-6,6,7,7,8,8,8-heptafluorocaprylic acids (XXIIIf)[61], are not analogues of natural aminoacids.

3. Fluorinated Monofunctional Aliphatic Aminoacids

A monofluoro-derivative of glutamic acid has been obtained by several methods. 4-Fluoroglutamic acid (LV) was obtained for the first time by Hudlický[62,63] from ethyl α-fluoroacrylate (LIII). The Michael condensation of acetamidomalonic ester and subsequent hydrolysis of the addition product led to the aminoacid (LV):



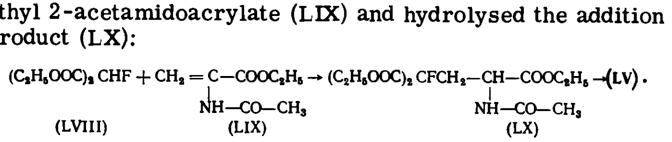
$$\underset{(LIII)}{C_2H_5OOC-CF=CH_2} \xrightarrow{CH_3CONHCH(COOC_2H_5)_2} C_2H_5OOC-CHF-CH_2-\underset{\substack{|\\NH-CO-CH_3\\(LIV)}}{C}(COOC_2H_5)_2 \rightarrow$$

$$\xrightarrow{hydrolysis} HOOC-CHF-CH_2-\underset{\substack{|\\NH_2}}{CH}-CO-R.$$

(LV): $R=OH$; (LVI): $R=OCH_3$; (LVII): $R=NH_2$

Tolman and Vereš[64] obtained 5-fluoroglutamine (LVII) by treating the γ-methyl ester of 4-fluoroglutamic acid (LVI) with ammonia; the amino-group was protected with carbon disulphide as the dithiocarbamate.

Independently of Hudlický, Buchanan et al. obtained 4-fluoroglutamic acid by this method. However, they described a second method as well, which is also based on the Michael addition but is otherwise the converse of the Hudlický method. They added diethyl fluoromalonate (LVIII) to ethyl 2-acetamidoacrylate (LIX) and hydrolysed the addition product (LX):



$$\underset{(LVIII)}{(C_2H_5OOC)_2CHF} + CH_2=\underset{\substack{|\\NH-CO-CH_3\\(LIX)}}{C}-COOC_2H_5 \rightarrow (C_2H_5OOC)_2CFCH_2-\underset{\substack{|\\NH-CO-CH_3\\(LX)}}{CH}-COOC_2H_5 \rightarrow (LV).$$

The yield was almost twice as high as in the previous synthesis. Biological tests showed that fluoroglutamic acid has virtually no activity.

Attempts to synthesise 3-fluoroaspartic acid proved to be unsuccessful[42,63].

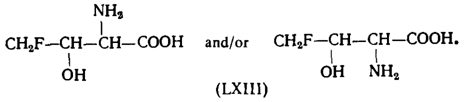
2,6-Diaminopimelic acid is present in bacterial cell walls. Together with other aminoacids, it gives rise to the formation of cross-links between polysaccharide chains thereby imparting stability to the cell walls.

Cavalleri et al. synthesised as possible antimetabolites 2-amino-6-fluoropimelic acid (LXI) and 2,6-diamino-4-fluoropimelic acid (LXII) from the fluoropimelic acids by bromination in the α-position and replacement of bromine by the action of ammonia or potassium phthalimide[66]:

$$\mathrm{HOOC{-}\underset{F}{CH}{-}CH_2{-}CH_2{-}CH_2{-}\underset{NH_2}{CH}{-}COOH}\qquad \mathrm{HOOC{-}\underset{NH_2}{CH}{-}CH_2{-}\underset{F}{CH}{-}CH_2{-}\underset{NH_2}{CH}{-}COOH.}$$

(LXI) (LXII)

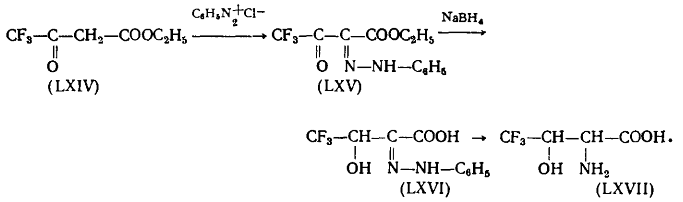
Furthermore, mention should also be made of 4-fluorothreonine (LXIII), a monofluorinated polyfunctional aminoacid. It was obtained by the addition of hypobromite to 4-fluorocrotonic acid with subsequent ammonolysis in liquid ammonia. So far it has not been determined whether this leads to the formation of DL-4-fluorothreonine or DL-4-fluoroallothreonine[42]:



$$\mathrm{CH_2F{-}\underset{OH}{CH}{-}\overset{NH_2}{CH}{-}COOH}\quad \text{and/or}\quad \mathrm{CH_2F{-}\underset{OH}{CH}{-}\underset{NH_2}{CH}{-}COOH.}$$

(LXIII)

Walborsky and Baum[67] proposed a synthesis of 4,4,4-trifluorothreonine (LXVII):



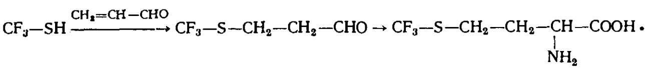
$$\mathrm{CF_3{-}\underset{\underset{O}{\|}}{C}{-}CH_2{-}COOC_2H_5}\xrightarrow{C_6H_5N_2^+Cl^-}\mathrm{CF_3{-}\underset{\underset{O}{\|}}{C}{-}\underset{\underset{N-NH-C_6H_5}{\|}}{C}{-}COOC_2H_5}\xrightarrow{NaBH_4}$$

$$\mathrm{CF_3{-}\underset{OH}{CH}{-}\underset{\underset{N-NH-C_6H_5}{\|}}{C}{-}COOH}\rightarrow\mathrm{CF_3{-}\underset{OH}{CH}{-}\underset{NH_2}{CH}{-}COOH.}$$

(LXIV) (LXV) (LXVI) (LXVII)

For this purpose, 4,4,4-trifluoroacetoacetic ester (LXIV) is treated with phenyldiazonium chloride (the Japp–Klingemann reaction), the keto-group is reduced to an alcoholic group with sodium borohydride, and the ester is hydrolysed. Finally, the phenylhydrazone (LXVI) is hydrogenated catalytically with formation of the aminoacid. Here too a mixture of trifluorothreonine and trifluoroallothreonine is probably formed. The attempts by the same authors to achieve the asymmetric synthesis of 4,4,4-trifluorothreonine will be described in Section V (subsection 1).

S-Adenosylmethionine is a transferring agent for the methyl group in biological methylation. Interesting results might have been expected on replacement of the methyl group by a trifluoromethyl group. Trifluoromethionine (or S-trifluoromethylhomocysteine) (LXX) was synthesised by Dannley and Taborsky[68] starting with trifluoromethanethiol (LXVIII), obtained by the fluorination of carbon disulphide with mercury fluoride. The mercaptan was added to acrolein and 3-trifluoromethylthiopropionaldehyde (LXIX) obtained in this way was converted into trifluoromethionine (LXX) by hydantoin synthesis:



$$\mathrm{CF_3{-}SH}\xrightarrow{CH_2=CH-CHO}\mathrm{CF_3{-}S{-}CH_2{-}CH_2{-}CHO}\rightarrow\mathrm{CF_3{-}S{-}CH_2{-}CH_2{-}\underset{NH_2}{CH}{-}COOH.}$$

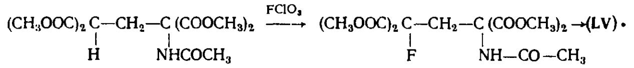
(LXVIII) (LXIX) (LXX)

The hopes concerning trifluoromethionine were indeed realised. It inhibits the growth of many micro-organisms[69] and forms an *S*-adenosyl derivative both *in vitro* and *in vivo*, competing thereby with methionine and preventing the demethylation of *S*-adenosylmethionine[70].

IV. SYNTHESES OF FLUORINE-CONTAINING AMINOACIDS BY THE INTRODUCTION OF FLUORINE INTO AMINOACIDS OR THEIR DERIVATIVES

1. Replacement of Hydrogen by Fluorine

4-Fluoroglutamic acid (LV) is not obtained solely by the two methods mentioned above. It is also possible to replace the hydrogen atom in the γ-position of the tetramethylester of 2-acetamido-2,4-dicarboxyglutaric acid (LXXI) by fluorine with the aid of perchloryl fluoride and then hydrolyse the fluorinated ester (LXXII)[71–73]:



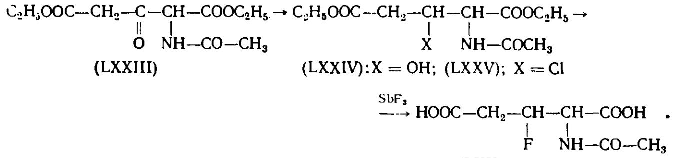
$$\mathrm{(CH_3OOC)_2\underset{H}{C}{-}CH_2{-}\underset{NHCOCH_3}{C}(COOCH_3)_2}\xrightarrow{FClO_3}\mathrm{(CH_3OOC)_2\underset{F}{C}{-}CH_2{-}\underset{NH-CO-CH_3}{C}(COOCH_3)_2}\rightarrow\mathrm{(LV)}.$$

(LXXI) (LXXII)

The diastereoisomers obtained could be separated[74].

2. Replacement of a Halogen by Fluorine

3-Fluoroglutamic acid, isomeric with 4-fluoroglutamic acid can be synthesised [as the *N*-acyl derivative of compound (LXXVI)] from the diethyl ester of 2-acetamidoacetonedicarboxylic acid (LXXIII)[75]. This ester is hydrogenated catalytically and the hydroxy-group in compound (LXXIV) thus formed is replaced by chlorine. The chlorine in the resulting chloro-derivative (LXXV) is replaced by fluorine by the action of antimony trifluoride and the ethoxycarbonyl group is then hydrolysed, which yields the *N*-acyl derivative of (LXXVI):



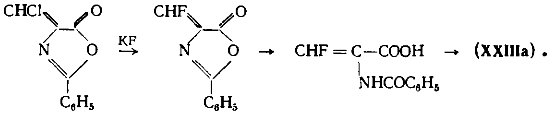
$$\mathrm{C_2H_5OOC{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}\underset{NH-CO-CH_3}{CH}{-}COOC_2H_5}\rightarrow\mathrm{C_2H_5OOC{-}CH_2{-}\underset{X}{CH}{-}\underset{NH-COCH_3}{CH}{-}COOC_2H_5}\rightarrow$$

(LXXIII) (LXXIV): X = OH; (LXXV); X = Cl

$$\xrightarrow{SbF_3}\mathrm{HOOC{-}CH_2{-}\underset{F}{CH}{-}\underset{NH-CO-CH_3}{CH}{-}COOH}\ .$$

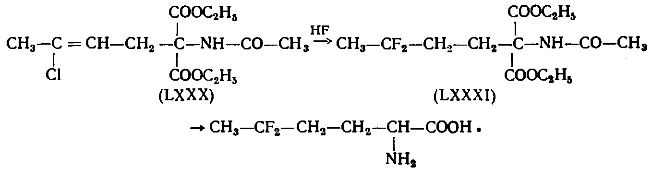
(LXXVI)

3-Fluoroalanine (XXIIIa) was obtained for the first time by a similar replacement of a halogen. 4-Chloromethylene-2-phenyl-5-oxazolone (LXXVII) is converted into the fluoro-derivative (LXXVIII) by the action of potassium fluoride in acetylacetone; the unsaturated *N*-benzamido-acid (LXXIX) obtained by hydrolysis is hydrogenated catalytically and finally the benzoyl group is eliminated[76]:



(LXXVII) (LXXVIII) (LXXIX)

In an attempt to replace chlorine by fluorine in a derivative of acetamidomalonic ester (LXXX) Hudlický[77] obtained immediately a difluoro-product (LXXXI), since hydrofluoric acid added simultaneously to the double bond. Hydrolysis gave 5,5-difluoronorleucine (LXXXII):

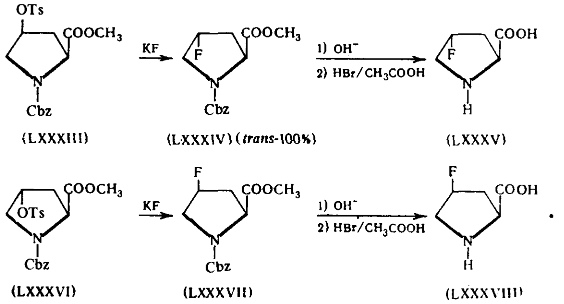


$$CH_3{-}\underset{Cl}{C}{=}CH{-}CH_2{-}\overset{COOC_2H_5}{\underset{COOC_2H_5}{C}}{-}NH{-}CO{-}CH_3 \xrightarrow{HF} CH_3{-}CF_2{-}CH_2{-}CH_2{-}\overset{COOC_2H_5}{\underset{COOC_2H_5}{C}}{-}NH{-}CO{-}CH_3 \rightarrow CH_3{-}CF_2{-}CH_2{-}CH_2{-}\underset{NH_2}{CH}{-}COOH.$$

(LXXX) (LXXXI) (LXXXII)

3. Replacement of a Hydroxy-group by Fluorine

Aminoacids containing hydroxy-groups are used in such syntheses. Witkop and coworkers achieved the stereospecific synthesis of *cis*- and *trans*-4-fluoro-L-proline (LXXXVIII) and (LXXXV) from L-hydroxyproline and L-hydroxyalloproline[78]:

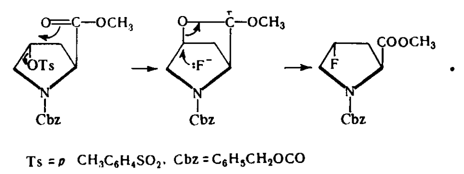


(LXXXIII) (LXXXIV) (*trans*-100%) (LXXXV)

(LXXXVI) (LXXXVII) (LXXXVIII)

OTs = p-$CH_3C_6H_4SO_2$
Cbz = $C_6H_5CH_2OCO$

When the methyl ester of *N*-benzyloxycarbonyl-*O*-tosyloxy-L-alloproline (LXXXIII) is heated with potassium fluoride in diethylene glycol, the *trans*-compound (LXXXIV) is obtained as a result of a stereospecific S_N2 reaction. Hydrolysis and elimination of the benzyloxycarbonyl group give *trans*-4-fluoro-L-proline (LXXXV). However, the fluorination of the methyl ester of *N*-benzyloxycarbonyl-*O*-tosyloxy-L-proline (LXXXVI) gives rise to a mixture of 83% of the *cis*-compound and 17% of the *trans*-compound. This can be explained by the intramolecular involvement of the ester carbonyl group in the substitution reaction:

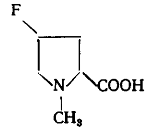


Ts = p $CH_3C_6H_4SO_2$, Cbz = $C_6H_5CH_2OCO$

A somewhat modified synthesis was described by another group of investigators[79].

In tests on *E. coli* it was found that both isomers are incorporated in the protein but the *trans*-isomer is incorporated to a much greater extent. In contrast to the *cis*-isomer, *trans*-fluoroproline does not inhibit the growth of mice. On the other hand, in the presence of *cis*-fluoroproline the weight of mice is smaller approximately by one-quarter compared with the control experiment. When the animals were cut open, pathological changes were found, particularly in the liver. Therefore it is suggested that in the experiments with *E. coli* too *cis*-fluoroproline inhibits the biosynthesis of proteins[78,79]. In the case of collagens, which contain particularly large amounts of proline and hydroxyproline, the latter is obtained as a result of the replacement in the finished protein of a *trans*-hydrogen atom in the 4-position of proline by a hydroxy-group; hydroxyproline is not incorporated in proteins. Experiments with *trans*-fluoroproline labelled with tritium showed that fluorine can also be replaced enzymically by a hydroxy-group[78].

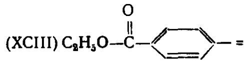
Cohen and Bergmann[80] attempted to use 2-chloro-1,1,2-trifluoroethyldiethylamine as a fluorinating agent for the replacement of a hydroxy-group by fluorine in the synthesis of monofluoro-substituted aminoacids from hydroxy-aminoacids. However, this method proved to be suitable only for aminoacids with alkylated amino- and carboxy-groups. 4-Fluoro-*N*-methylproline (LXXXIX) (from hydroxyproline), 3-fluoro-*NN*-dimethylalanine (XC) (from serine), 2-amino-3-fluoro-*NN*-dimethylbutyric acid (XCI) (from threonine), 3-fluoro-*NN*-dimethylphenylalanine (XCII) (from phenylserine), and *O*-ethoxycarbonyl-3-fluoro-*NN*-dimethyltyrosine (XCIII) (from hydroxyphenylserine) were obtained in this way; the last two compounds were prepared only as the methyl esters:



(LXXXIX)

$R{-}\underset{F}{CH}{-}\underset{N(R)_2}{CH}{-}COOH$

(XC) H— = R
(XCI) CH_3— = R
(XCII) C_6H_5— = R



(XCIII) $C_2H_5O{-}\overset{O}{\overset{\|}{C}}{-}C_6H_4{-}$ = R

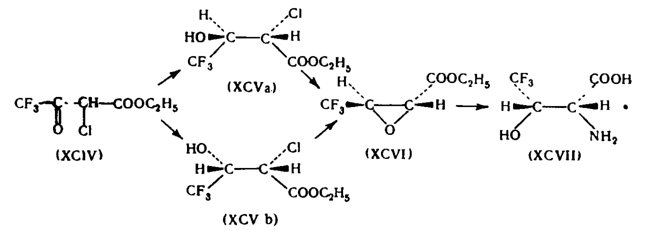
V. SPECIAL METHODS FOR THE SYNTHESIS OF FLUORINE-CONTAINING AMINOACIDS

This section deals mainly with the syntheses of highly fluorinated aminoacids, which are possible only due to the electronic influence of perfluoroalkyl groups. These syntheses are unsuitable for non-fluorinated compounds or they give rise to different products.

1. Opening of the Ring in Glycidic Esters

Apart from the synthesis of 4,4,4-trifluorothreonine already described, Walborsky and Baum attempted an asymmetric synthesis, which would not result in a mixture of 4,4,4-trifluorothreonine and 4,4,4-trifluoroallothreonine[67].

In the reduction with sodium borohydride of the ethyl ester of 2-chloro-4,4,4-trifluoro-3-oxobutyric acid (XCIV), which is readily obtained by the chlorination of 4,4,4-trifluoroacetoacetic ester, a mixture of both stereoisomers of ethyl 2-chloro-4,4,4-trifluoro-3-oxobutyrate [(XCVa) and (XCVb)] is formed:

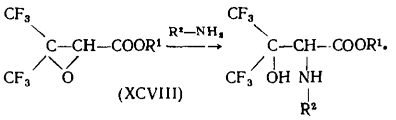


(XCIV) (XCVa) (XCV b) (XCVI) (XCVII)

The isomers may be separated by distillation; they are obtained in proportions of 7 : 4. According to Cram's rule, more of the *erythro*-compound (XCVb) than of the threo-isomer (XCVa) should be formed, so that the ester formed in a greater amount should be the *erythro*-isomer. However, ring closure in both isomers gave the same epoxy-compound (XCVI), to which Walborsky and Baum attributed the *trans*-configuration.

It was of interest to elucidate how the glycidic ester (XCVI) behaves when its ring is cleaved with ammonia; whether the attack is directed to the α-carbon atom with formation of a 2-amino-3-hydroxyacid or whether a 3-amino-2-hydroxy acid is formed as a result of attack on the β-carbon atom. Experiments showed that the ring is opened exclusively at the α-carbon atom, i.e. 4,4,4-trifluorothreonine or its amide is formed, depending on the conditions. Since ring opening is also a *trans*-reaction, the *erythro*-compound, i.e. 4,4,4-trifluoroallothreonine (XCVII), should be produced.

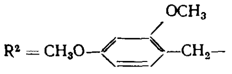
Knunyants and coworkers showed that diazoacetic ester reacts with hexafluoroacetone in an unusual manner with formation of bis(trifluoromethyl)glycidic ester (XCVIII)[81]. In this case too reaction with amines, for example, benzylamine or aniline, gives 2-amino-3-hydroxy-compounds (XCIX) or (C)[82]. When the amine employed is 2,4-dimethoxybenzylamine, the 2,4-dimethoxybenzyl group can be very readily eliminated from the resulting ethyl ester of 4,4,4,4′,4′,4′-hexafluoro-2-[*N*-(2,4-dimethoxybenzyl)-amino]-3-hydroxyisovaleric acid (CI) by means of a mixture of trifluoroacetic acid and its anhydride[83]. After hydrolysis, 2-amino-4,4,4,4′,4′,4′-hexafluoro-3-hydroxyisovaleric acid (CII) is obtained[84]:



(XCIX) $R^1 = C_2H_5—$; $R^2 = C_6H_5—CH_2—$

(C) $R^1 = C_2H_5—$; $R^2 = C_6H_5—$

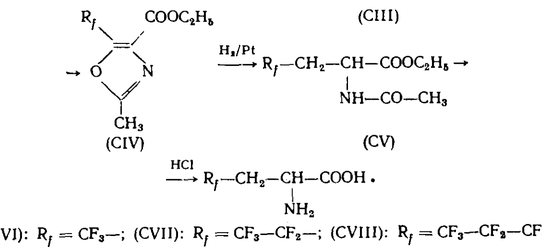
(CI) $R^1 = C_2H_5—$; $R^2 =$



(CII) R^1, $R^2 = H$

2. Opening of the Ring in Esters of 5-Perfluoroalkyl-2-methyloxazole-4-carboxylic Acids

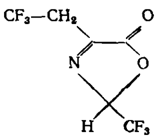
Steglich et al.[85] developed a general method for the synthesis of alanines with perfluoroalkyl substituents in the β-position. The starting materials were perfluoroacyldiazoacetic esters (CIII), which are readily obtained from the anhydrides of perfluoroacids and diazoacetic ester:



(CVI): $R_f = CF_3—$; (CVII): $R_f = CF_3—CF_2—$; (CVIII): $R_f = CF_3—CF_2—CF_2—$

When compounds CIII) are irradiated in acetonitrile, esters of 5-perfluoroalkyl-2-methyloxazole-4-carboxylic acids (CIV) are formed. Catalytic hydrogenation of the latter is accompanied by hydrogenolysis, which leads to the ethyl esters of *N*-acetyl-3-perfluoroalkylalanines (CV). Hydrolysis with concentrated hydrochloric acid gives, depending on the perfluoroalkyl group, 2-amino-4,4,4-trifluorobutyric acid (CVI), 4,4,5,5,5-pentafluoronorvaline (CVII), or 4,4,5,5,6,6,6-heptafluoronorleucine (CVIII). Measurements of the pK′s showed that, as expected, they are again lower compared with the non-fluorinated aminoacids[86].

DL-2-Amino-4,4,4-trifluorobutyric acid (CVI) can be converted into the L-form. The aminoacid is trifluoroacetylated and then cyclised by reaction with dicyclohexylcarbodi-imide to 4-(2,2,2-trifluoroethyl)-2-trifluoromethyl-Δ³-5-oxazolinone (CIX):

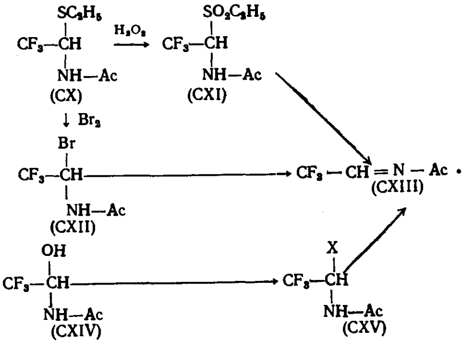


(CIX).

When the ring of this optically inactive Δ³-oxazoline derivative is opened by the action of the dimethyl ester of L-glutamic acid, the product is the dimethyl ester of *N*-trifluoroacetyl-(2-amino-4,4,4-trifluorobutyryl)-L-glutamic acid, which, as a result of optical induction, consists of 83% of the LL- and 17% of the DL-diastereoisomer (determined by gas–liquid chromatography). Repeated recrystallisation, hydrolysis, and elimination of L-glutamic acid gave pure L-2-amino-4,4,4-trifluorobutyric acid (CVI)[85]. L-4,4,5,5,5-pentafluoronorvaline (CVII) was obtained similarly[86].

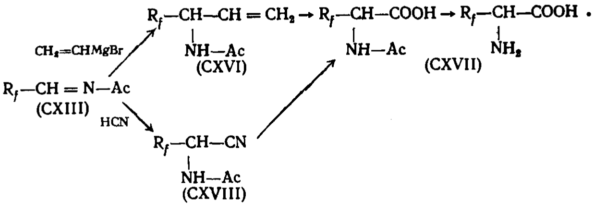
3. Reactions involving Addition to *N*-Acylimines of Perfluoroaldehydes and Perfluoroketones

Weygand, Steglich, and coworkers observed that the *N*-acylimines of trifluoroacetaldehyde (CXIII) are extremely reactive. *N*-Acyl-1-ethylthio-2,2,2-trifluoroethylamines (CX, Ac = CH_3CO, CF_3CO, C_6H_5CO, or $C_6H_5CH_2OCO$) are readily oxidised to sulphones (CXI) with hydrogen peroxide in glacial acetic acid[87]. It has been shown that the mechanism of reactions of the sulphones (CXI) with nucleophilic reagents involves elimination and addition; initially the sulphones are converted by bases into *N*-acyltrifluoroacetaldimines (CXIII), to which the nucleophilic agents were then added[87]. The bromination of the thioesters (CX) yields *N*-acyl-1-bromo-2,2,2-trifluoroethylamines (CXII) from which highly moisture-sensitive aldimines (CXIII) can be isolated in a pure form[88]. A simpler pathway to the aldimines (CXIII) involves the condensation of trifluoroacetaldehyde, trifluoroacetaldehyde hydrate, or hemiacetals of trifluoroacetaldehyde with acid amides; this results in the formation of *N*-acyl-2,2,2-trifluoro-1-hydroxyethylamines (CXIV), which can be readily converted into the chloro-derivatives (CXV, X = Cl) by the action of phosphorus pentachloride[88]; in the presence of acid-sensitive acyl groups such as the p-methoxybenzyloxycarbonyl or t-butoxycarbonyl groups, the hemiaminals (CXIV) can be converted into acyloxy-compounds (CXV, X = CR_3COO or CH_3COO)[89,90]:



As already stated, *N*-acyltrifluoroacetaldimines (CXIII) react with many nucleophilic reagents; there is then no necessity to isolate them in a pure form—one can start with their precursors[87–91].

The possibility of using these aldimines in the synthesis of fluorinated aminoacids is self-evident. For this purpose vinylmagnesium bromide was added to them initially[87]. The resulting 3-acylamino-4,4,4-trifluorobut-1-ene (CXVI) was oxidised with potassium permangate to 2-acylamino-3,3,3-trifluoropropionic acid (CXVII), Ac = C_6H_5CO or $C_6H_5CH_2OCO$)[87,92] and then the acyl residue was eliminated. 3,3,3-Trifluoroalanine (CXIX) was obtained in this way[92]:



(CXIX): $R_f = CF_3-$; (CXX) CF_3-CF_2-; (CXXI) $CF_3-CF_2-CF_2-$

This sequence of reactions is also applicable to other perfluoroalkyl residues and has led to the synthesis of 2-amino-3,3,4,4,4-pentafluorobutyric acid (CXX) and 3,3,4,4,5,5,5-heptafluoronorvaline (CXXI)[93].

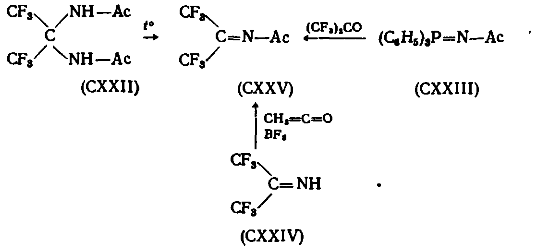
An attempt to use another method for the preparation of fluorinated aminoacids—by the interaction of the sulphone (CXI) with a cyanide—led only to the ethylene derivative as a result of the elimination of the fluoride ion[87].

However, the addition of anhydrous hydrocyanic acid to aldimines (CXIII) made it possible to develop yet another method for the synthesis of 3,3,3-trifluoroalanine. The resulting nitrile (CXVIII) is readily hydrolysed and the subsequent elimination of the acyl group gives the aminoacid (CXIX)[94].

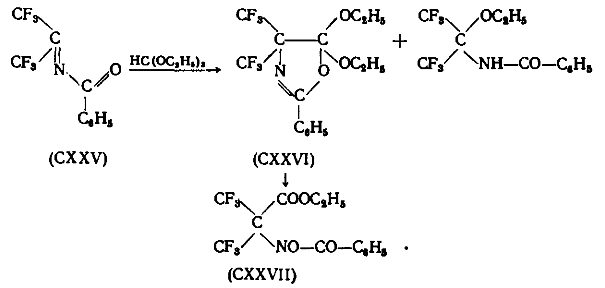
However, this synthesis is not suitable for higher α-perfluoroalkylglycines.

α-Perfluoroalkylglycines (CXIX–CXXI) have pronounced acid properties. pK_{NH_2} for trifluoroalanine (5.61) is much lower than for alanine itself (9.69). In contrast to the usual monocarboxylic 2-monoaminoacids, trifluoroalanine forms a crystalline dicyclohexylammonium salt. It may be acylated at the nitrogen atom and converted to the methyl ester with diazomethane[92,93].

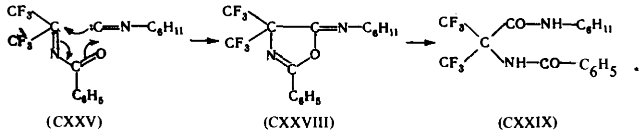
N-Acyl-1,1,1,3,3,3-hexafluoroisopropylideneimines (CXXV) are also very reactive in relation to nucleophilic agents. The acylimino-derivatives of hexafluoroacetone (CXXV) are obtained by the pyrolysis of bisbenzamido-compounds (CXXII, Ac = C_6H_5CO), by the reaction of hexafluoroacetone with triphenylphosphine-*N*-benzoylimine (CXXIII, Ac = C_6H_5CO)[95], and also by the acylation of the imino-derivative of hexafluoroacetone by the action of keten in the presence of boron trifluoride[96]:



The benzoylimino-derivative of hexafluoroacetone (CXXV, Ac = C_6H_5CO) enters into a 1,4-addition reaction with orthoformic ester, yielding 5,5-diethoxy-4,4,-di(trifluoromethyl)-2-phenyl-Δ^2-oxazoline (CXXVI), the hydrolysis of which gives the ethyl ester of 2-benzamido-3,3,3,3′,3′,3′-hexafluoroisobutyric acid (CXXVII)[97]. However, as stated above, the free acid is unstable[56]:

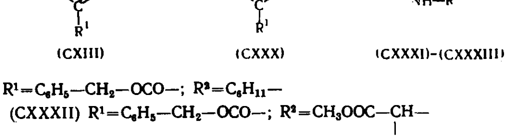


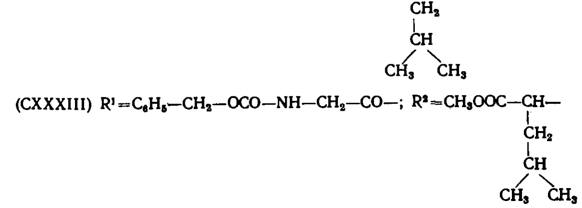
The addition of isonitriles to *N*-acylketimines (CXXV) is of great importance:



The resulting 5-cyclohexyl-4,4,-di(trifluoromethyl)-2-phenyl-Δ^2-oxazoline(CXXVIII) may be hydrolysed to the cyclohexylamide of 2-benzamido-3,3,3,3′,3′,3′-hexafluoroisobutyric acid (CXXIX)[98].

The application of this reaction to *N*-acyltrifluoroacetaldimines (CXIII) makes it possible to synthesise the cyclohexylamide of *N*-benzyloxycarbonyl-3,3,3-trifluoroalanine (CXXXI):





(CXXXI) $R^1=C_6H_5-CH_2-OCO-$; $R^2=C_6H_{11}-$

(CXXXII) $R^1=C_6H_5-CH_2-OCO-$; $R^2=CH_3OOC-CH(CH_2-CH(CH_3)_2)-$

(CXXXIII) $R^1=C_6H_5-CH_2-OCO-NH-CH_2-CO-$; $R^2=CH_3OOC-CH(CH_2-CH(CH_3)_2)-$

Trifluoroalanyl peptides can be obtained directly in this way by introducing into the reaction the isonitriles obtained from esters of *N*-formylaminoacids. The methyl ester of *N*-benzyloxycarbonyl-3,3,3-trifluoroalanyl-L-leucine (CXXXII) was obtained by this procedure. Additional possibilities are provided by the application of *N*-(*N*-benzyloxycarbonylaminoacyl)trifluoroacetaldimines. This results in the ester of the *N*-benzyloxycarbonyltripeptide with trifluoroalanine in the centre of the chain, for example the methyl ester of *N*-benzyloxycarbonylglycyl-3,3,3-trifluoroalanyl-L-leucine (CXXXIII)[92].

Peptides containing trifluoroalanine may be obtained also from *N*-benzyloxycarbonyl-3,3,3-trifluoroalanine by allowing it to react in the usual way with aminoacid esters in the presence of dicyclohexylcarbodi-imide. Trifluoroalanine can also be used in the form of the methyl or t-butyl ester as the ester component in peptide synthesis. However, while the benzyloxycarbonyl group is readily eliminated, it is impossible to hydrolyse the ester group by alkalis. It has been shown for the methyl ester of *N*-benzyloxycarbonyl-3,3,3-trifluoroalanine that the trifluoromethyl group is first hydrolysed to a carboxy-group[93]. Another possibility of synthesising peptides is provided by the sequence of reactions of compounds (CXIII)–(CXVII) using as the acyl residue an aminoacid residue with a protected amino-group[93].

According to the data on the biological activity obtained hitherto, the addition of trifluoroalanine inhibits many micro-organisms, albeit at relatively high concentrations[93]. L-Aminoacid oxidase does not act upon trifluoroalanine, but the addition of trifluoroalanine can prevent it from acting on other L-aminoacids[93].

Steroids with a Heteroatom in the Nucleus or the Side Chain of the Molecule

G.I.Zhungietu, G.N.Dorofeenko, and B.M.Savin

CONTENTS

Methods for the synthesis of steroid compounds with N, O, and S atoms in the molecular side chain and steroid compounds containing an oxygen atom in the main steroid nucleus, obtained by the reaction of unsaturated steroids with ozone, are discussed. Methods for the preparation of steroids containing a nitrogen atom in the nucleus, synthesised by the reaction with ozone of unsaturated $\alpha\beta$-steroid ketones with subsequent heterocyclisation of the reaction products, are analysed. Methods are described for the total synthesis of steroid heteroanalogues from precursors of comparatively simple structure. Data are presented on the biological activity of the compounds.

The bibliography comprises 79 references.

I. INTRODUCTION

Compounds containing heterocyclic systems condensed with the main steroid nucleus have aroused considerable interest recently[1,2]. Several preparations isolated from them have found wide application in medical practice as anabolic agents[3].

In connection with the study of the physiological activity of modified steroid compounds and the problem of the regulation of cholesterol in the organism, studies have been made recently on the methods for the synthesis of heteroanalogues of steroid systems containing heteroatoms (oxygen, nitrogen, sulphur) in the cyclopentanoperhydrophenanthrene skeleton or in the molecular side chain.

One cannot exclude the possibility that these compounds will prove useful in the fight against various forms of neoplasms of a hormone-dependent type. They may also prove interesting as antihormonal preparations capable of reacting with the same receptor systems as steroids, and behave as antagonists of the latter.

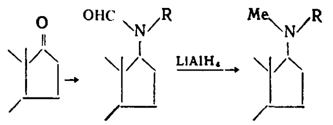
In the fight against the accumulation of cholesterol in the organism as the cause of the development of atherosclerosis, the idea of finding compounds which would be completely or at least partially free of oestrogenic properties appeared attractive. On the other hand, it was found that, when cholesterol is fed to animals, the rate of its synthesis in the liver diminishes[4,5]. The elucidation of the nature of this process might be of undoubted interest for the solution of the problem of cholesterol metabolism in the organism. With this aim in view, work has begun on the chemistry and pharmacology of heteroanalogues of natural steroids.

Although the number of such compounds increases every year, insufficient attention has been devoted to them in the literature, which makes it difficult to become familiar with the results achieved in this field.

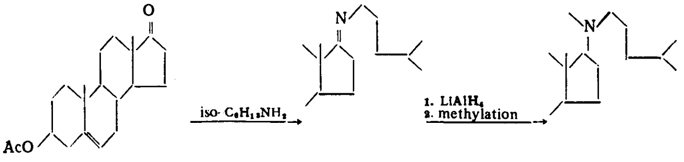
The desire to fill this gap to some extent led the authors to write this review. However, it must be remembered that this review deals very briefly only with compounds which are close analogues of steroids and does not include data on numerous heterocyclic homosteroids containing expanded rings A, B, C, and D.

II. COMPOUNDS WITH HETEROATOMS IN THE SIDE CHAIN

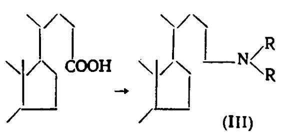
This group includes aza- and oxa-derivatives of steroids containing heteroatoms in the side chain and also compounds of type I with secondary amino-groups in rings A, B, and D and obtained by the Leuckart reaction[6]:



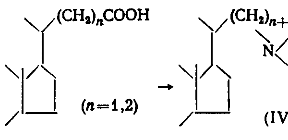
(I)



Lettré et al.[7] obtained 25-azacholesteryl acetate from the acetate of Δ^5-cholenic acid with subsequent reduction of its dimethylamide with $LiAlH_4$. This carefully developed method for the conversion of carboxylic acids via their chlorides and amides and the reduction of the latter with metal hydrides gives as a rule high yields of products and has been widely used by other investigators, in particular for the synthesis of a number of azacholestane derivatives of type (III)–(V)[8-10]:



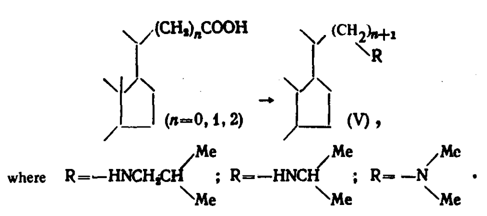
(III)



(n=1,2)

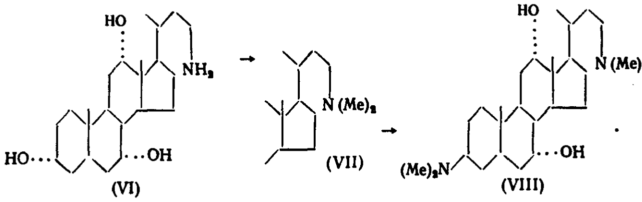
(R=H, Me, Et)

(IV)



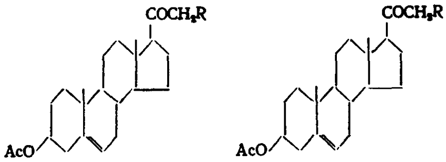
25-Azacoprostane was obtained in the same way from the corresponding cholane derivative[7].

Bisdimethylaminocholane (VIII) was synthesised from cholic acid azide, which was reduced to aminotrihydroxycholane and the amine was then methylated further to give (VII). Subsequent Oppenauer oxidation of (VII), reduction to the oxime, reduction of the oxime, and methylation of the resulting amine gave (VIII):



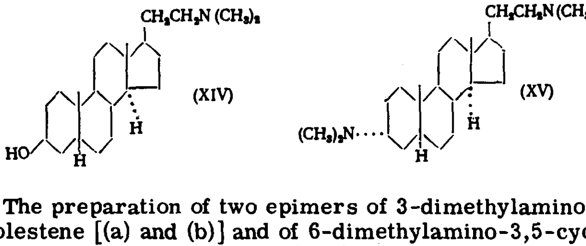
7α,12α-Dihydroxy-3-oxocholanic acid was converted in the same way into 3,17-bisdimethylaminoandrostane[7,11].

A series of 21-aminosteroids, obtained by the interaction of 21-iodo-derivatives (IX)[12] and (X)[13] with various secondary amines proved to be very interesting physiologically[14]:

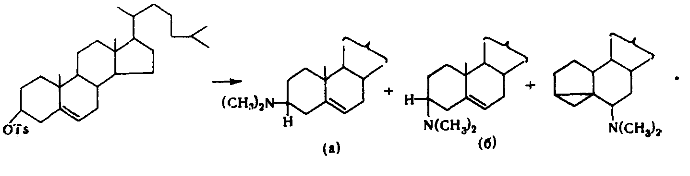


(X) R=I(Ref.13)
(XII) R=N(Me)$_2$ · HCl
(XIII) R=N-morpholino-HCl
(IX) R=I(Ref.12)
(XI) R=$\overset{+}{\text{N}}$(Me)$_3$I$^-$

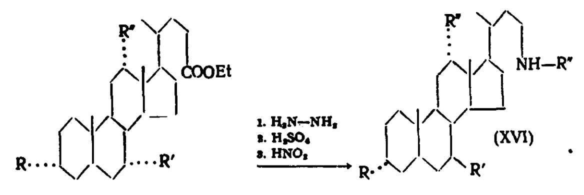
In the search for antibacterial agents 21-dimethylaminoallopregnan-3β-ol (XIV) and 3α,21-dimethylaminoallopregnane (XV) were synthesised[15]:



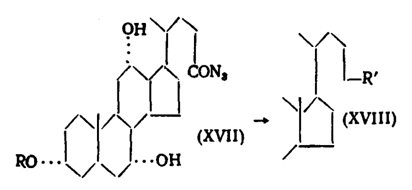
The preparation of two epimers of 3-dimethylaminocholestene [(a) and (b)] and of 6-dimethylamino-3,5-cyclocholest-5-ene by the action of $(CH_3)_2NH$ on 3β-tosyloxycholest-5-ene has also been described[16]. Hydrogenation of compounds (a) and (b) in acetic acid gave 3-dimethylaminocholestane, which was identified by synthesis—by the action of dimethylamine on 3α-tosyloxycholestane:



Certain 23-amino-derivatives (XVI) have been obtained by the Schmidt reaction from derivatives of cholanoic acid[17,18]:



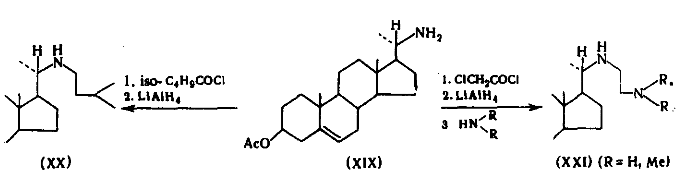
Certain amines (XVIII) were synthesised from cholic acid azide (XVII)[19]. The condensation of compound (XVII) with secondary amines gave the corresponding amides, which were then reduced to the tertiary amines (XVIII)[20]:



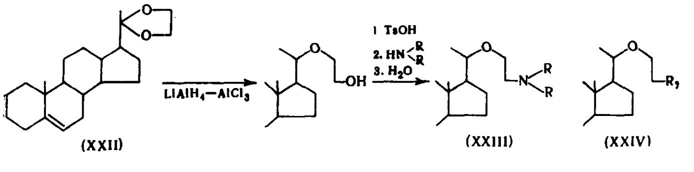
[R′ = piperidino, N-morpholino, N(Me)$_2$, N(Et)$_2$].

(R = Ac, COEt, or veratroyl)

The preparation of 22-azacholesterol (XX)[9] and 22,25-diazacholesterol (XXI)[22] from 20-amino-Δ^5-pregnen-3β-yl acetate (XIX) has been described[21]:

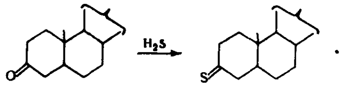


Crabbe and coworkers[23] obtained 25-aza-22-oxacholesterol (XXIII) and a number of its analogues (XXIV) from the ethyleneketal (XXII) by the following mechanism:



where R = CH_2-N-piperidine or CH_2I(F).

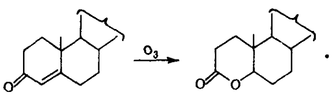
Of other studies in this field, mention should be made of the synthesis of steroids containing a sulphur atom. Thus Djerassi and coworkers synthesised[24] 21-thiolacetates—analogues of deoxycorticosterone, Reichstein's substance "S", and cortisone. These syntheses were achieved by the action of CH_3COSH on the corresponding diazoketones or by treating 21-hydroxy-20-ketones with p-toluenesulphonyl chloride and subsequent interaction with NaI and CH_3COSK. Thio-derivatives were obtained by the reaction of hydrogen sulphide with oxosteroids in the presence of $ZnCl_2$:[25]



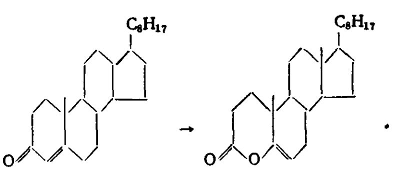
III. COMPOUNDS WITH HETEROATOMS IN THE STEROID NUCLEUS

1. Syntheses Based on Natural Compounds

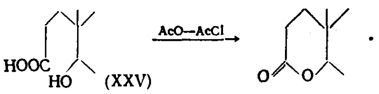
A large group of steroid oxygen-containing heterocyclic compounds were synthesised by the oxidation of Δ^4-3-oxosteroids with persulphuric acid or hydrogen peroxide[26]. However, best results were obtained by the reaction of oxosteroids with ozone in chloroform or acetic acid[27]:



The cleavage of ring A in steroids by the reverse Michael reaction has been described for cholest-4-en-3-one with the isolation of an enol lactone as an intermediate[28]:

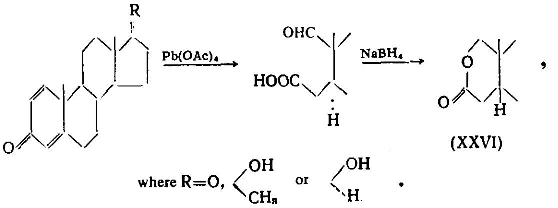


A number of 4-oxasteroids have been obtained[29] by the cyclisation of hydroxyacids (XXV):



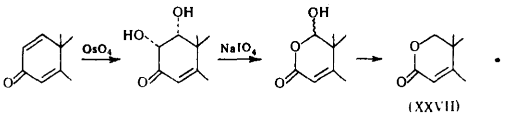
(XXV)

Interesting compounds were synthesised by replacing C_2 of the steroid ring by oxygen[30]:



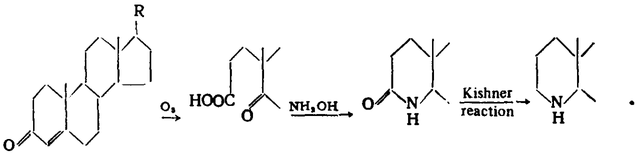
(XXVI)

The corresponding Δ^4-analogues are obtained with much greater difficulty and with much lower yields[30,31]:



(XXVII)

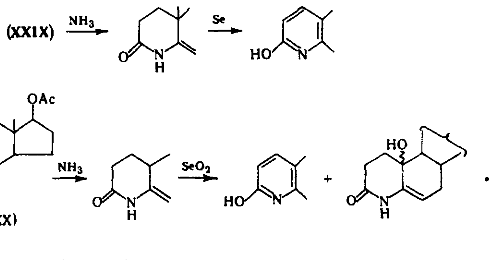
The main method for synthesising compounds containing a nitrogen atom in rings A and B consist in the reaction of ozone with $\alpha\beta$-unsaturated ketones and subsequent cyclisation of the oxidation products. This method was employed for the first time by Bolt as early as 1938[32]:



(XXVIII) (XXIX)

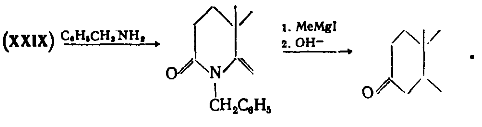
R = iso-C_8H_{17} or OAc.

For a long time this work was ignored until a more profound investigation of the synthetic heteroanalogues of steroids was begun. In 1959 a large series of 4-azasteroids was obtained by the reaction of the ketoacids (XXIX) and lactones of type (XXX) with ammonia in benzene according to the mechanism[33,34]:



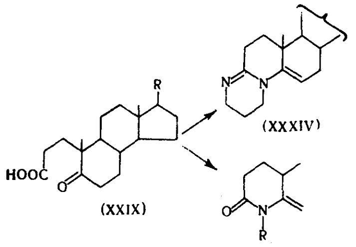
(XXX)

The reaction of (XXIX) with benzylamine gave a good yield of (XXXI), the α-piperidine ring of which is readily converted into ring A of the steroid to be synthesised[35]:



(XXXI) (XXXII)

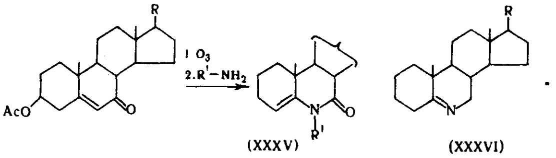
Many N-substituted natural compounds (XXXIII) were obtained by the reaction of the acid (XXIX) with various amines[27,36-39]. Treatment of (XXIX) with 1,3-diaminopropane gives the 4-aza-derivative (XXXIV):



(XXXIV) (XXIX) (XXXIII)

where R = methyl, benzyl, NH_2, OH, or CH_2CH_2OH.

6-Azasteroids containing a nitrogen atom in ring B [(XXXV) and (XXXVI)] were also obtained by reaction with ozone followed by heterocyclisation[30,31,40-44]:

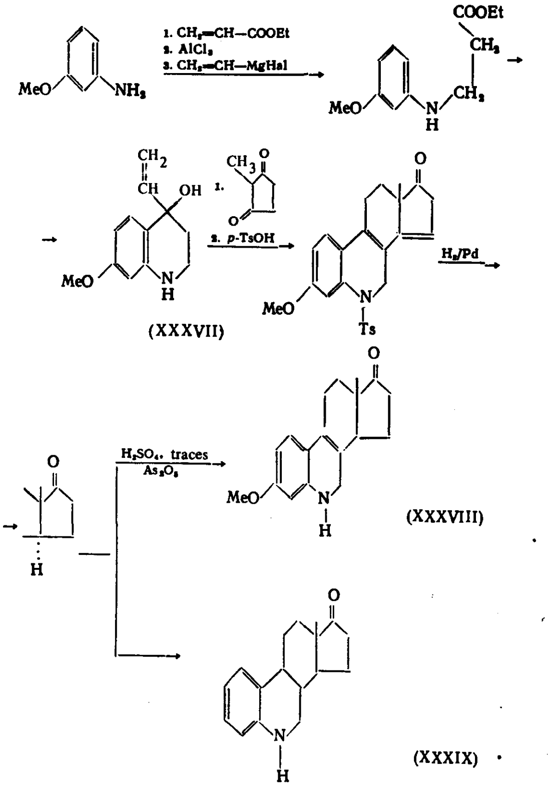


(XXXV) (XXXVI)

2. Total Synthesis of Steroid Heteroanalogues

The method of synthesis of oestrogens by the condensation of 6-methoxy-1-vinyl-1-tetralol with methylcyclopentanedione, extensively developed by Torgov in the Laboratory of Steroid Chemistry at the Institute of the Chemistry of Natural Compounds (IKhPS) of the USSR Academy of Sciences[45], proved to be suitable for the preparation of a wide variety of steroid heteroanalogues.

The tetrahydroquinolinone derivative (XXXVII)[46], obtained from m-anisidine, was used to synthesise the methyl esters of 1-azaequilenin (XXXVIII) and 6-azaoestrone (XXXIX)[46-53]:

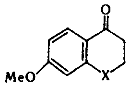


(XXXVII)

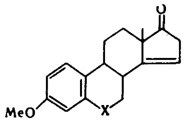
(XXXVIII)

(XXXIX)

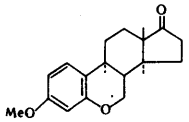
Chromanone (XL)[54] was converted by a similar mechanism into 6-oxaoestrone (XLI) and (XLIII) was obtained from 7-methoxythiachroman-4-one (XLII)[55]:



(XL) X=O
(XLII) X=S

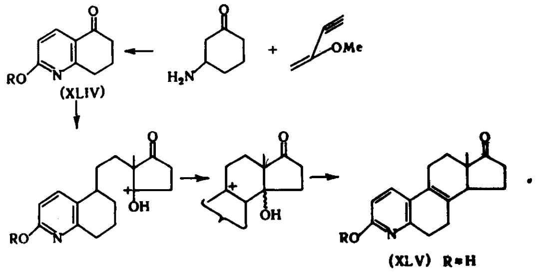


(XLIII)



(XLI)

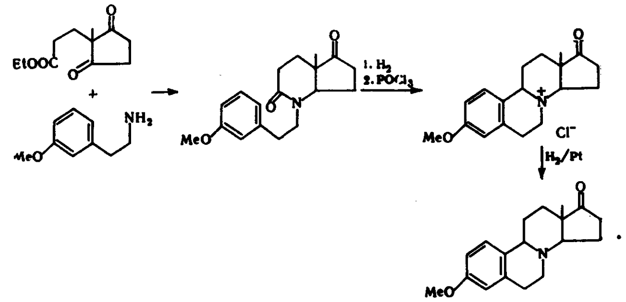
Meyers and coworkers described a three-stage synthesis of the methyl ether of *dl*-8-azaoestrone and its 14β-isomer from 1-(2-hydroxy ethyl)-2-methoxy-1,2,3,4-tetrahydroisoquinoline by condensation with 2-methylcyclopenta-1,3-dione[56]. 4-Aza-8,14-bisdehydrooestrone (XLV) was obtained similarly from pyridine (XLIV). The much greater difficulty of the reaction when R = H compared with the case where R = Et can be explained, according to the authors, by the preliminary rearrangement of the exocyclic double bond to an endocyclic double bond[57,58]:



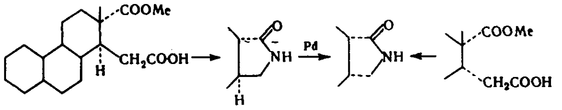
(XLIV)

(XLV) R=H
(XLVI) R=Et

Analogues of oestrone and D-homo-oestrone containing a nitrogen atom in the 8-position were obtained by the following mechanism[59,60]:

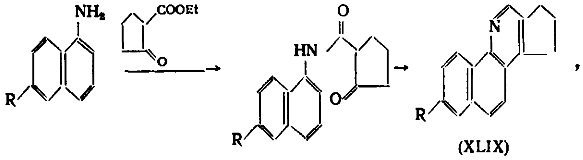


As early as 1950, in experiments designed to determine the configuration of the C–D junction in deoxy- and isodeoxy-equilenine, their 16-aza-analogues (XLVII) and (XLVIII) were obtained[61]:



(XLVII) (XLVIII)

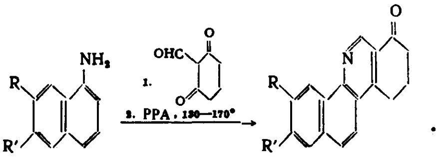
Other heterocyclic steroid analogues have also been described: 1-azachrysene[62] and 6-azachrysene, 1-azapyrene, and 3,4-benzo-5-azaphenanthrene[63], as well as the 11-aza-derivative (XLIX)[64]:



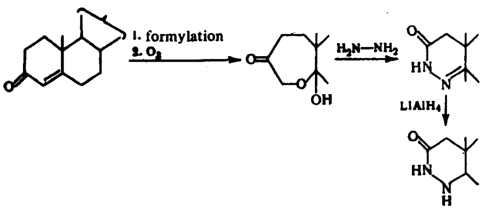
(XLIX)

where R = H or OMe.

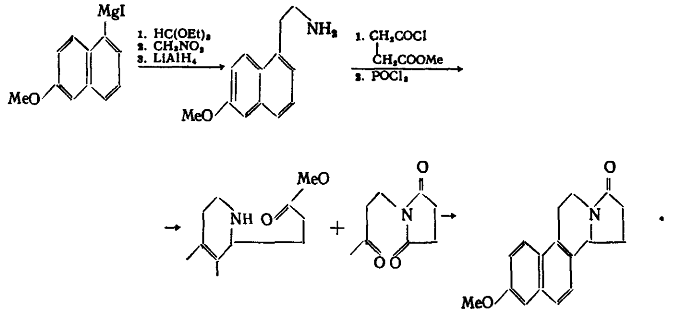
The attempts to introduce an oxo-group into (XLIX) by oxidation with SeO$_2$ and CrO$_3$ were unsuccessful. A compound of this type was obtained somewhat later in a different way[65]:



Tetrahydropyridazinone derivatives of steroids containing two nitrogen atoms in ring A have been described[66]:

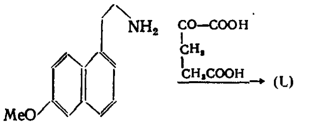


Recently the synthesis of a 13-aza-steroid analogue has been reported: the methyl ether of 13-aza-18-norequilenin (L) was obtained by the following mechanism[67]:



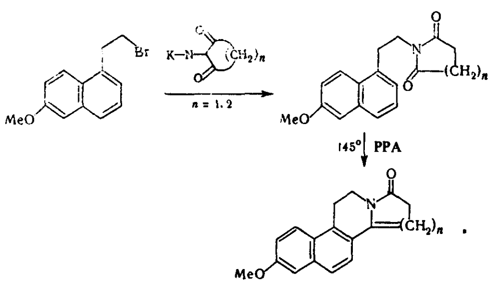
(L)

The same compound can also be prepared by the single-stage condensation of (LI) with α-oxoglutaric acid in boiling acetic acid but the yield is then much lower[68]:

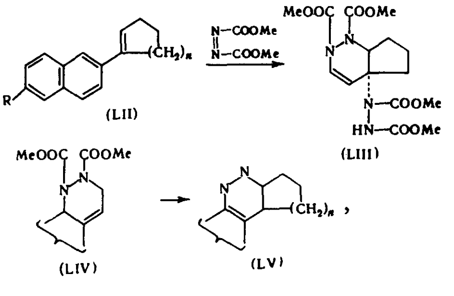


(LI)

A different synthesis has also been proposed for analogues of (L)[69]:

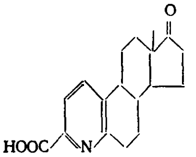


The addition of pseudodienes of type (LII)[70] [wrong reference (Ed. of Translation)] to the dimethyl azodicarboxylate leads to the formation of the adducts (LIII) and (LIV) which are converted by hydrolytic decarboxylation with hydrazine hydrate and oxidation with mercury(II) oxide into the 11,12-diaza-derivative (LV)[71]:



where R = H or MeO and n = 1 or 2. 7,8,9,10-Tetrahydronaphtho[1,2-*c*]cinnoline (LV, R = H) was obtained even earlier[72].

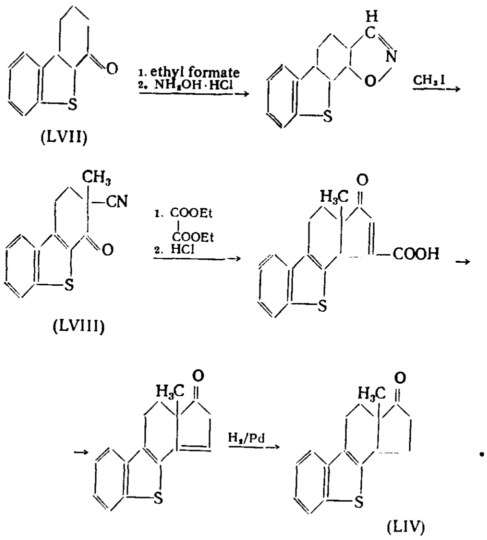
It is noteworthy that 17-oxo-4-azaoestrane-3-carboxylic acid (LVI) has been found among the products of the microbiological conversion of oestrone by *Nocardia sp.*[73]:



(LVI)

Steroid heteroanalogues containing a sulphur atom in their skeleton are of undoubted interest.

Collins and coworkers[74] obtained a thiophen analogue of 3-deoxyequilenin from 4-oxo-1,2,3,4-tetrahydrobenzothiophen (LVII), which is in turn obtained by succinylation of thianaphthene, the reduction of the resulting ketoacid, and its cyclisation to the ketone (LVII). The hydroxymethylation of (LVII) and cyclisation with hydroxylamine hydrochloride give rise to an isoxazole derivative, the reaction of which with CH$_3$I yields the methylketonitrile (LVIII). The latter reacts with ethyl succinate and after hydrolysis is converted into a ketoacid. The decarboxylation of this acid in pyridine and the reduction of the product with hydrogen over metallic palladium gave 3-deoxythiaequilenin (LIV):



In an assessment of the scope of the synthesis of steroids containing a heteroatom in the nucleus preference should probably be given to methods of total synthesis, taking into account the availability of the starting materials.

IV. BIOLOGICAL ACTIVITY

1. Steroids with a Heteroatom in the Side Chain

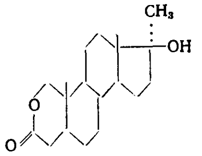
Among compounds containing an amino-group in the side chain, 21-aminosteroids proved to be physiologically active. Biological tests showed that some of them [(XI) and (XII)] fully inhibit the growth of *B. subtilis* and (XIII) inhibits the growth of *Aspergillus niger*. The hydrochlorides of 23-amino-3α-hydroxy- and 23-amino-3-oxocholanoic acids proved to be active against Gram-positive micro-organisms[17].

Certain oxa- and aza-derivatives of steroids were found to have marked cholesterolemic activity. Thus 20,25-diazacholesterol reduces the cholesterol content in blood by 30%[75]. Possibly it also acts on one of the receptors as a cholesterolmimetic agent[76]. 25-Aza-22-oxacholesterol reduces the cholesterol content in blood by 38% and 25-aza-21-nor-20-oxacholesterol reduces the cholesterol level by 47%[77].

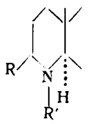
It is noteworthy that all these preparations interrupt the biosynthesis of cholesterol at the stage of its formation from desmosterol (24-dihydrocholesterol) and lead to the accumulation of the latter in the blood. As a result, the total amount of sterols is maintained at an approximately constant level[78,79].

2. Steroids with a Heteroatom in the Nucleus

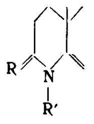
In general the biological activity of steroids containing an oxygen atom in ring A is comparable to that of the usual steroids[30]. Nevertheless (LV) proved to be a more effective anabolic agent than 17β-hydroxymethyl-17α-methylandrostan-3-one[3]:



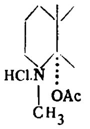
Of the compounds containing a nitrogen atom in ring A of the steroid skeleton, the following should be mentioned:



(LVI) $R=R'=CH_3$
(LVII) $R=Bz$, $R'=CH_3$
(LXI) $R=H$, $R'=Et$



(LVIII) $R=O$, $R'=\overset{+}{N}(CH_3)_3Et\ I^-$
(LX) $R=O$, $R'=Ph$.



(LXI)

Compounds (LVI)–(LIX) block the conversion of desmosterol into cholesterol, (LX) intensifies the synthesis of cholesterol, (LXI) has an antimicrobial activity, and (LXII) causes the expansion of coronary vessels.

Derivatives of 6-azasteroids containing a nitrogen atom in ring B also exhibit a physiological activity. Tests with 6-azacholesterol and 6-azacholestane revealed their intense cytotoxic activity[42]. The same compounds containing an acetate group at the 17-carbon atom have androgenic properties. They stimulate the activity of the hypophysis and exhibit antioestrogenic and antiprogestational activity[43]. Among compounds containing a sulphur atom in the nucleus, none have so far been found with appreciable physiological activity.

The data discussed show that many steroids containing heteroatoms in the nucleus or in the side chain exhibit physiological activity. There is no doubt that further progress in this very interesting branch of steroid chemistry will yield new important results and discoveries.

Advances in the Polycondensation Methods for the Synthesis of Thermostable Polymers

S.V.Vinogradova and V.V.Korshak

The review deals with the properties and the methods of synthesis by non-equilibrium condensation of heat resistant and thermostable polymers which have found considerable practical application in various branches of engineering.
The bibliography includes 42 references.

The growing requirements for polymeric materials by many branches of modern engineering have, in the last decade, attracted much attention to polymers with enhanced heat resistant and thermostable properties. Heat resistance will be understood as the limiting temperature at which the polymer can retain a particular mechanical strength and thermal stability is defined as the limiting temperature which a given polymer can withstand without chemical change, mainly decomposition.

Classical examples of thermostable polymers known for a long time are, for example, polytetrafluoroethylene and organosilicon polymers of the polydimethylsiloxane type. However, despite their high thermal stability, they cannot be used successfully in many cases.

Recently it has become necessary to obtain new types of heat resistant materials which retain high strengths under load at elevated temperatures. Promising materials of this kind are polymers the macromolecules of which consist of aromatic or heterocyclic units. However, since the chains of such a structure are very rigid, many of these polymers cannot be used as starting materials for the preparation of films, fibres, and other articles for which a certain elasticity is needed. Therefore a natural solution of the problem was to synthesise polymers the macromolecules of which contain, in addition to the rigid phenylene and heterocyclic rings, more flexible bonds for example, esters and ether bonds.

The principal method for the synthesis of the majority of the known heat resistant and thermostable polymers is polycondensation, primarily non-equilibrium polycondensation. Until recently polycondensation methods, unlike polymerisation techniques, were not subdivided into various types. When fairly extensive experimental data on various polymerisation processes were accumulated and treated from a general standpoint, various types of the process became distinguishable, such as radical, cationic, anionic, and ionic–coordination polymerisation, each of which became established in polymer chemistry and occupies an honourable place among its techniques.

A similar development is being undergone by polycondensation reactions too. A general treatment of extensive experimental data on polycondensation makes it possible to subdivide polycondensation processes into at least two different types, namely equilibrium and non-equilibrium polycondensation processes which differ in the types of reaction occurring[1,2].

A principal feature of non-equilibrium polycondensation is the absence of degradation of the polymer by a low-molecular-weight polycondensation product and in most cases the absence from the polycondensation process also of other degradative exchange reactions.

Since the equilibrium constant for the process

$$A+B\underset{k_2}{\overset{k_1}{\rightleftarrows}}C+D$$

is defined by the equation

$$K=\frac{k_1}{k_2}=\frac{[C][D]}{[A][B]},$$

it follows that high equilibrium constants should be characteristic of irreversible processes and hence also of non-equilibrium polycondensation, i.e. $k_1 \ll k_2$, or $k_1 \to \infty$, or an infinitesimal value of k_2.

The absence from the polycondensation process of degradative exchange reactions, which is responsible for the irreversibility of the process, may be due to various causes: (a) owing to the occurrence of the process at fairly low temperatures where exchange reactions do not take place at all and the starting materials are sufficiently reactive to form the polymer under such conditions; (b) owing to the formation in the polycondensation process of a polymer with a chemical structure such that it is incapable of degradative reactions with a low-molecular-weight polycondensation product, with the starting materials, or with the growing or completed macromolecules.

In contrast to equilibrium polycondensation, which has been investigated fairly thoroughly, non-equilibrium polycondensation is a little known process. Reactions of this type have been investigated only in recent years. So far comparatively few cases of non-equilibrium polycondensation have been studied in detail and the main features of these processes are still not altogether clear, although a fairly large number of cases of non-equilibrium polycondensation are known. Table 1 presents a far from complete list of such reactions, many of which have been used successfully for the synthesis of heat resistant polymers. It is not possible to examine them all in detail in this review, but some of them will be considered.

One of the classes of heat resistant and thermostable polymers to which much attention has been drawn in the last decade are heterochain esters of dihydric phenols—polyarylates. Polyarylates of dicarboxylic aromatic acids have the most interesting properties[3]. Table 2 presents data on the softening temperatures and the thermal stability of some of these polymers, which show that these are highly heat resistant and thermostable macromolecular compounds[4-7].

Since in the synthesis of polyarylates one of the reaction components is a dihydric phenol the hydroxy-groups of which are less reactive to acids than those of aliphatic polyhydric alcohols, it proved useful to employ the chlorides of dicarboxylic acids as the acid reagents in the synthesis of polyarylates[3]. The use of acid reagents of this type made possible successful polycondensation in solution and at interfaces. In general the availability of these two methods of polycondensation is important for the synthesis of heat resistant high-melting polymers, since polycondensation can be continued to a high degree of completion of the process without decomposition of the polymer formed: because of the high melting point of many heat resistant polymers, including polyarylates, polycondensation in the melt would have to be carried out at 300–500°C and sometimes at even higher temperatures.

Thus the main method for the synthesis of heat resistant polyarylates is the reaction of dicarboxylic acid chlorides with dihydric phenols, which can be achieved in three versions.

(a) By the interaction of the dicarboxylic acid with the dihydric phenol in solution at an elevated temperature:

$$x\,ClOCRCOCl + x\,HOArOH \rightarrow [-OCRCOOArO-]_x + 2x\,HCl.$$

(b) By the interaction of the dicarboxylic acid with the dihydric phenol in solution at room or a relatively low temperature in the presence of a tertiary amine:

$$x\,ClOCRCOCl + x\,HOArOH \xrightarrow{NR'_3} [-OCRCOOArO-]_x + 2x\,NR'_3 \cdot HCl.$$

(c) By the interfacial polycondensation of the dicarboxylic acid chloride with the dihydric phenol:

$$x\,ClOCRCOCl + x\,HOArOH + 2x\,NaOH \rightarrow [-OCRCOOArO-]_x + 2x\,NaCl.$$

Until recently the polycondensation of dicarboxylic acid chlorides with dihydric phenols, carried out at high temperatures, was automatically classified as an equilibrium polycondensation process. However, studies in recent years at the Institute of Organic Derivatives of the Elements of the USSR Academy of Sciences in collaboration with the Laboratory of the Kinetics of Polymerisation Processes at the Institute of Chemical Physics of the USSR Academy of Sciences showed that this is not so.

The equilibrium in the reaction

$$-\overset{\overset{O}{\|}}{C}-O- + HCl \rightarrow -\overset{\overset{O}{\|}}{C}-Cl + HO-$$

was studied using as an example the interaction of hydrogen chloride with the polyarylate of terephthalic acid and 9,9-di-(4-hydroxyphenyl)fluorene and with model compounds such as 9,9-di-(4-benzoxyphenyl)fluorene and phenyl benzoate[8]. The reactions were carried out at 220°C in ditolylmethane in a stream of dry hydrogen chloride and also under pressure, which ensured the presence in the reaction mixture of a definite amount of hydrogen chloride.

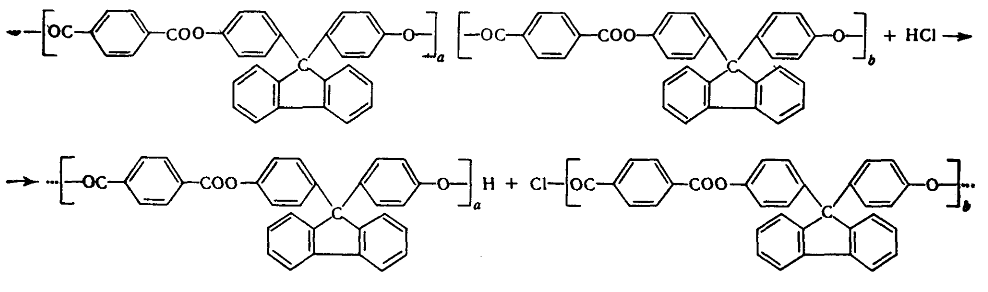
Table 1. Examples of starting materials employed in non-equilibrium polycondensations and the types of polymers thus obtained

First component	Second component	Type of compound formed
$ClOCRCOCl$	$HOArOH$	polyarylate
ClO_2SRSO_2Cl	$HOArOH$	polysulphonate
$RPOCl_2$	$HOArOH$	polyphosphonate
$ClOCRCOCl$	$H_2NR'NH_2$	polyamide
ClO_2SRSO_2Cl	$H_2NR'NH_2$	polysulphonamide
$ClOCOROCOCl$	$H_2NR'NH_2$	polyurethane
$ClOCRCOCl$	$HOOCR'COOH$	polyanhydride
ClO_2SRSO_2Cl	$HArH$	poly(arylene sulphone)
$NaOArONa$	$XArX$	polyether
		polyether
$NaOArONa$		polyethersulphone
$HArH$	$ClRCl$	polyarylenealkane
C_6H_6	C_6H_6	polyphenylene
$HOOCRCOOH$	H_2NNH_2	polyaminotriazole
$HC{\equiv}CH$	$HC{\equiv}CH$	poly-yne (carbyne)
CH_2O	$HArOH$	polyphenol
		polybenzimidazole
	$ClOCR'COCl$	polybenzoxazole

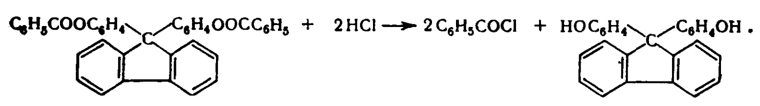
Table 2. Polyarylates

Repeating unit	Softening temp., °C (from thermomechanical curve)	Temp. of onset of decomposition, °C (inert medium)
	340	350—360
	350	350—360
	360	350—360

It was found that, on heating 1 M solutions of the polymer in an open system in a stream of dry hydrogen chloride for 5 h at 220°C, the molecular weight of the polymer remained unchanged. When phenyl benzoate and 9,9-di-(4-benzoxyphenyl)fluorene were heated under the same conditions, neither phenol nor benzoyl chloride were detected in the reaction mixture. This showed that the following reactions do not occur:



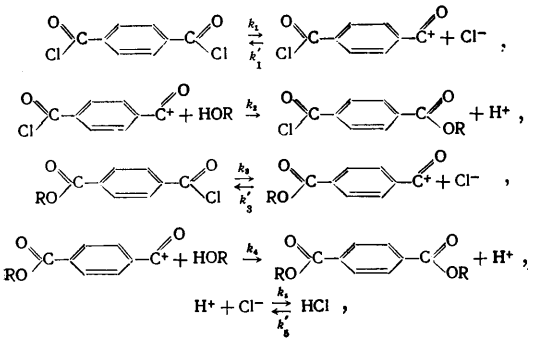
$$C_6H_5COOC_6H_5 + HCl \rightarrow C_6H_5COCl + C_6H_5OH;$$



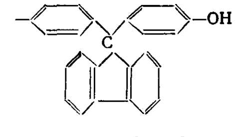
On the other hand, measurement of the equilibrium constant for the reaction of phenyl benzoate with hydrogen chloride in a closed system showed that at 40°C it is 2.35×10^{-4} and at 220°C 4.48×10^{-3}. Values of the same order of magnitude were also found by Polish investigators in a study of the equilibrium in the reaction of 2,2-di-(4-hydroxyphenyl)propane and its dichloroformate derivative in nitrobenzene at 60°, 80°, and 100°C.[9]

The equilibrium constants for equilibrium polycondensation processes are known to amount usually to several units. Thus the above data show that the equilibrium in the interaction of dicarboxylic acid chlorides with dihydric phenols is strongly displaced to the right. This suggests that the interaction is largely a non-equilibrium process for the low-molecular-weight polycondensation product.

More detailed studies were also made at the Institute of Organic Derivatives of the Elements and the Institute of Chemical Physics of the kinetics of the interaction of terephthalic acid chloride with 9,9-di-(4-hydroxyphenyl)fluorene under conditions typical for the synthesis of polyarylates by high-temperature condensation, namely in the temperature range 150–200°C using ditolylmethane, dowtherm†, and nitrobenzene as solvent[10]. It was found that the order of the reaction based on initial rates is 1.5: the reaction is first order with respect to the dihydric phenol and of order 0.5 with respect to the acid chloride. Analysis of the kinetic data and measurements of the conductivity of the system showed that the interaction has the following ionic mechanism:



where R =

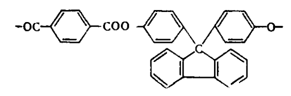


or the residue of the macromolecule.

The first reaction stage is equilibrium ionisation of one of the acid chloride groups. The resulting acylium ion interacts with the phenol or recombines with a chloride anion. The second stage is the equilibrium ionisation of the acid chloride group in a mixed ester–acid chloride species and its further interaction with the phenol.

Despite the fact that the polycondensation of dicarboxylic acid chlorides with dihydric phenols is, as mentioned above, an irreversible process for the low-molecular-weight polycondensation product (hydrogen chloride), the chain propagation reaction is nevertheless accompanied also by various degradative exchange reactions between the polymer molecule formed and the starting materials and also between the macromolecules themselves, because the process is carried out at an elevated temperature. Owing to the higher stability of polyarylates to chemical processes as compared with other types of polyesters, these reactions take place to a lesser extent in the above series of polyesters but they do occur and must be taken into account in an examination of the general features of the formation of polyarylates by high-temperature polycondensation.

Table 3. Degradation of the polyarylate



by various reagents

Duration of degradation, h	η_{intr} in tricresol before and after degradation					
	hydroxyphenylfluorene				isophthalic acid

0	0.80	0.8	0.80	0.80	0.80	0.80
2	0.74	0.60	0.77	0.74	0.80	0.72
4	0.71	0.50	0.75	0.65	0.73	0.67
10	0.58	0.40	0.69	0.46	0.65	0.59
20	0.49	—	0.63	—	0.64	—

* The degradation was carried out in a 10% solution of the polymer in ditolylmethane at 220°C.

Table 3 presents the results obtained for the degradation of poly[9,9-di-(4-hydroxyphenyl)fluorene terephthalate] by various chemical agents, from which it is clear that polyarylates do undergo exchange reactions[11]. It is interesting that the low-molecular-weight polycondensation product (hydrogen chloride) catalyses all types of degradative exchange processes in the synthesis of polyarylates by high-temperature polycondensation. It is also noteworthy that a tendency has been found for a narrowing of the molecular weight distribution of polyarylates (Table 4) as a result of degradative exchange reactions during polycondensation on heating[12].

Table 4. Variation of the coefficient of polydispersity (M_w/M_n) of the polyarylate as a result of degradation at 220°C

Degrading agent	Duration of reaction, h	Gas stream	M_ω/M_n
None	0		2.09
Hydroxyphenylfluorene	10	HCl	1.22
Hydroxyphenylfluorene	10	Ar	1.68
Hydroxyphenylfluorene	20	Ar	1.48
	20	Ar	1.45

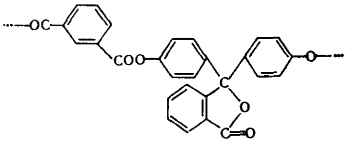
Very interesting results were obtained at the Institute of Organic Derivatives of the Elements of the USSR Academy of Sciences in studies on the effect of the reaction medium on the synthesis of heat resistant polyarylates. In particular, it was established that the physicomechanical

---

† A eutectic mixture of phenyl ether and biphenyl (Ed. of Translation).

properties of the polyarylate of isophthalic acid and phenolphthalein, the so called polyarylate F-1, depend appreciably on the solvent in which the polycondensation is carried out[13].

The chemical structure of the polyarylates of phenolphthalein and aromatic dicarboxylic acids is responsible for the high rigidity of the macromolecules:



Therefore in the synthesis of phenolphthalein polyarylate in ditolylmethane, which does not dissolve the polymer formed, the free energy of formation of coiled macromolecules should be lower than the free energy of formation of extended macromolecules (there are fewer points of contact between the coiled macromolecule and the insoluble polymer). This leads to preferential synthesis of the globular forms of the macromolecule, which is responsible for the globular type of the supermolecular structure of the phenolphthalein polyarylate synthesised in ditolylmethane. On the other hand, in the synthesis of phenolphthalein polyarylate in good solvents, for example, in 1-chloronaphthalene or nitrobenzene, extended macromolecules are formed preferentially. As a result packets of macromolecules and other fibrillar supermolecular structures arise. Polymers with this structure naturally possess better physicomechanical properties than the corresponding polymer with a globular supermolecular structure, as can be seen from the data presented in Table 5.[13]

Table 5. Properties of polyarylate F-1

Property	Medium in which polymer was obtained		
	ditolylmethane	1-chloronaphthalene	
Supermolecular structure	globular	fibrillar	
Molecular weight	28 000	28 000	48 000
Softening temperature, °C	270	290	300
Tensile strength, kgf cm^{-2}	640	740	780
Elongation on rupture, %	10—20	80	100
Specific impact strength, kg cm cm^{-2}	2—3	10	20

Thus in the synthesis of polymers with rigid macromolecular chains, which are, incidentally, typical for many heat resistant polymers, it is necessary to choose the correct reaction medium bearing in mind its effect on the selection of particular macromolecular conformations during the synthesis itself. In the synthesis of heat resistant polymers capable of crystallisation, the polycondensation conditions are sometimes very important. This will be illustrated by the synthesis of the crystallisable polyarylate of 9,9-di-(4-hydroxyphenyl)-10-anthrone and terephthalic acid[14]. Table 6 shows that, by varying the reaction temperature, it is possible to obtain either a crystalline or an amorphous polymer, which in turn affects its properties[14]. In the synthesis of crystallisable polymers it is necessary to take into account also other factors in the reaction conditions, such as the rate of heating and cooling of the reaction mass, the concentration of the reaction mixture, and methods for the isolation and purification of the polymer.

For polyarylate as an example, we considered one of the cases of non-equilibrium polycondensation which leads to heat resistant and thermostable polymers, the process involving heating in an organic solvent. Below we shall return to several cases of the synthesis of heat resistant polymers under such conditions.

In the last decade the synthesis of heat resistant polymers by non-equilibrium polycondensation under mild temperature conditions, virtually without heating, has attracted much attention. This process became possible owing to the discovery of methods for the synthesis of polymers such as interfacial polycondensation and low-temperature polycondensation in solution.

Table 6. Effect of the conditions of synthesis of the polyarylate obtained from hydroxyphenylanthrone and terephthalic acid on its properties and structure

Polycondensation conditions			η_{intr}, dl g^{-1} (Ph-TCE)*	Softening temp., °C (in a capillary)	Organic liquid dissolving the polymer	Structure
°C	duration, h	medium				
220	11—12	Sovol	0.42	does not melt, darkens at 450°	mixture of phenol and TCE	crystalline
220	10	1-chloronaphthalene	0.90	ditto	ditto	ditto
250	5	" "	1.70	380—400	tricresol, TCE, dichloroethane, $CHCl_3$, CH_2Cl_2, dioxan, cyclohexanone, etc.	amorphous structure predominates
320	1	Sovol	0.68	350—380	ditto	amorphous

* Ph = phenol and TCE = tetrachloroethane.

We shall not consider in detail interfacial polycondensation as a non-equilibrium polycondensation method since this has been extensively discussed in recent years[15,16]. We shall only note that its essential feature involves reaction between the starting materials when the solution of one of the active initial components (for example the dicarboxylic acid chloride) in an organic solvent is brought into contact with an aqueous (usually alkaline) solution of the second component (for example a diamine or a dihydric phenol). The reaction takes place at atmospheric pressure, at a low, usually room temperature and is very rapid. Under optimum conditions, the yield of polymers synthesised by this method is a rule high and so is the molecular weight. The range of heat resistant polymers synthesised by this method is fairly wide. These are heat resistant polyamides, polyarylates, polyanhydrides, polysulphonamides, polyamidoarylates, etc., based mainly on compounds with aromatic rings in the molecules:

$$x\,\mathrm{ClOCRCOCl} + x\,\mathrm{H_2NR'NH_2} \xrightarrow{\mathrm{NaCH}} [-\mathrm{OCRCONHR'NH}-]_x + 2x\,\mathrm{NaCl},$$

$$x\,\mathrm{ClSO_2RSO_2Cl} + x\,\mathrm{H_2NR'NH_2} \xrightarrow{\mathrm{NaOH}} [-\mathrm{SO_2RSO_2NHR'NH}-]_x + 2x\,\mathrm{NaCl},$$

$$x\,\mathrm{ClOCRCOCl} + x\,\mathrm{HOArOH} \xrightarrow{\mathrm{NaOH}} [-\mathrm{OCRCOOArO}-]_x + 2x\,\mathrm{NaCl},$$

$$x\,\mathrm{ClOCROOCl} + x\,\mathrm{HOOCRCOOH} \xrightarrow{\mathrm{NaOH}} [-\mathrm{OCRCOOOCRCOO}-]_x + 2x\,\mathrm{NaCl}.$$

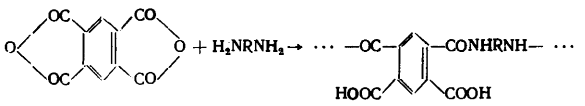
The method of the so called low-temperature polycondensation in solution is extremely interesting. One must stipulate immediately that, when non-equilibrium polycondensation including low-temperature polycondensation is carried out in an organic solvent, different versions are possible: (a) both the starting materials and the resulting polymer are readily soluble in the reaction medium and the polycondensation really takes place in solution; (b) the starting materials are soluble in the reaction medium, while the polymer is only partially soluble or altogether insoluble; (c) the starting materials are only partially soluble or completely insoluble in the reaction medium, while the polymer is soluble.

Despite the fact that in the last two cases the process takes place under heterogeneous conditions, nevertheless these methods are also known in the literature as polycondensation in solution, although it will of course be more correct to regard them as simply polycondensation in an organic solvent. The most favourable conditions for the synthesis of heat resistant high-melting polymers are, of course, usually those where the polymer is formed and is readily soluble in the reaction medium, since this makes it possible to manufacture articles from the polymer (films, fibres) directly from the reaction solution, omitting the preliminary isolation of the polymer itself.

Polycondensation in solution at low temperature (room temperature or slightly above) of the order of 50°C proved to be possible owing to the use of reactive starting materials—such as acid chlorides and anhydrides—and special reaction media of activators. Thus low-temperature polycondensation of dicarboxylic acid chlorides with dihydric phenols at room temperature or with slight heating to about 50°C has been achieved by carrying out the reaction in the presence of a tertiary amine[15,17-49]:

$$x\,\mathrm{ClOCRCOCl} + x\,\mathrm{HOArOH} \xrightarrow{2x\,\mathrm{NR}'_3} [\mathrm{-OCRCOOArO-}]_x + 2x\,\mathrm{NR}'_3\cdot\mathrm{HCl}.$$

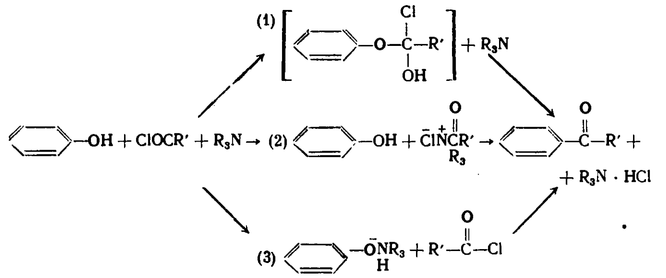
The conversion of dicarboxylic acid chlorides into polyamides by reaction with diamines can be successfully carried out in an amide solvent, for example dimethylacetamide[20-22]. In two-stage syntheses of heat resistant and thermostable polymers such as polyimides, the first stage, involving the formation of a high-molecular-weight polyamidoacid, has been successfully achieved in solvents such as dimethylacetamide, dimethylformamide, and dimethylsulphoxide[23,24]:



In a two-stage synthesis of polyoxadiazoles good results are obtained when the first reaction stage, involving the formation of a polyhydrazide, is carried out under conditions of low-temperature polycondensation in hexamethylphosphoramide (HMPA)[25]:

$$\mathrm{ClOCRCOCl} + \mathrm{H_2NHNOCR'CONHNH_2} \xrightarrow{\mathrm{HMPA}} \cdots\mathrm{-OC\dot{R}CONHNHCOR'CONHNH-}\cdots$$

We shall consider briefly certain features of the formation of polymers by low-temperature polycondensation in solution. Despite the fact that the acylation of phenols by carboxylic acid chlorides in the presence of tertiary amines is widely used in practical organic chemistry, the problem of the role of the base in this process has still not been solved. In principle, several hypotheses concerning the role of the base in the acylation of phenols are possible[15]: (1) the first reaction step is the formation of a complex of the acid chloride and phenol which breaks down under the action of the base to form an ester bond; (2) the base forms a reactive complex with the carboxylic acid chloride the reaction of which with phenol yields an ester bond; (3) a reactive complex of the base and phenol is formed and then readily reacts with the carboxylic acid chloride:



At present it is still impossible to state a preference for a particular mechanism. However, studies aimed at solving this problem are being carried out, in particular at the Institute of Organic Derivatives of the Elements of the USSR Academy of Sciences. At the present stage of the investigation we believe that the first reaction stage most probably takes place via mechanism (2), but this is still a very arbitrary assumption and the elucidation of the problem requires further study.

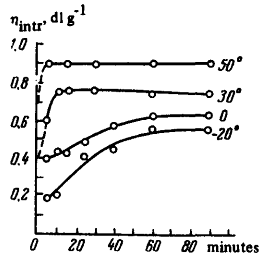


Figure 1. Variation of the intrinsic viscosity of polyarylate F-2 solution in tetrachloroethane with time for different polycondensation temperatures

Very few data have been published on the rate of low-temperature polyesterification in solution. However, there is no doubt that it is fairly high, since in most cases the reaction reaches completion in a very short time.

Fig. 1 presents data on the variation of the molecular weight of polyarylate F-2 in the polycondensation of terephthalic acid chloride with phenolphthalein in dichloroethane solution in the presence of triethylamine at various temperatures (concentration of acid chloride 0.2 M, molar ratio acid chloride : phenolphthalein : triethylamine = 1 : 1 : 2).[17] They indicate a high rate of this reaction. Indeed at 50°C the increase in the molecular weight and the formation of the polymer cease roughly five minutes from the start of the reaction. Even when the polyesterification is carried out at −20°C, the formation of the polymer is virtually complete after 1 h.

The low-temperature polycondensation of terephthalic acid chloride with phenolphthalein takes place in a very interesting way in the presence of a tertiary amine in acetone, which does not dissolve the resulting polymer[18]. Here after the first minute of polycondensation the yield of the polyarylate (the polymer is precipitated as it is formed) is already 95%. At the same time the molecular weight of the polymer increases considerably when the reaction is continued. It goes on increasing to almost the same extent when the precipitated polymer is separated after the first minute of the process, washed free of the starting materials with acetone, and treated with a fresh portion of pure acetone.

This is undoubtedly evidence that in the synthesis of the polyarylate in acetone the molecular weight of the polymer may increase as a result of reactions of the terminal groups of the polymer chains even after the precipitation of the polymer. Probably this is favoured by the high polarity of the acetone and its consequent high solvating power, which facilitates the interaction between the terminal groups of the polymer chains.

Successful low-temperature polyesterification is also dependent on the purity of the starting materials and the tertiary amine, the relative amounts of the starting materials, their concentration in solution, and other factors[26]. Polymers with highest molecular weights are obtained when carefully purified starting materials are introduced into the reaction in equimolar proportions.

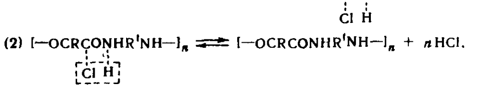
Low-temperature polyamide formation, used successfully in particular for the synthesis of heat resistant aromatic polyamides such as, for example, polyphenyleneisophthalamide[21,22], polyamides based on anilinephthalein, anilinofluorene, etc. has also been developed in recent years[27]. Table 7 lists certain examples of these polyamides obtained at the Institute of Organic Derivatives of the Elements of the USSR Academy of Sciences by Sokolov and coworkers[28].

Table 7. Aromatic polyamides

Polymer	Softening temp.*,°C	Temp. of onset of weight loss in air, °C
	390	450
 (phenylone)	280	—
 (polysulphonamide)	278	—

* Determined from thermomechanical curves

The polycondensation of dicarboxylic acid chlorides with diamines in solution may involve several competing reactions[15,20]:



$$(1)\ n\mathrm{ClOCRCOCl} + n\mathrm{H_2NR'NH_2} \longrightarrow [\mathrm{-OCR-}\underset{\mathrm{Cl}}{\mathrm{C}}\mathrm{O}\underset{\mathrm{H}}{\mathrm{N}}\mathrm{HR'NH-}]_n,$$

$$(2)\ [\mathrm{-OCR}\underset{\boxed{\mathrm{Cl}}}{\mathrm{C}}\mathrm{O}\underset{\boxed{\mathrm{H}}}{\mathrm{N}}\mathrm{HR'NH-}]_n \rightleftharpoons [\mathrm{-OCRCONHR'NH-}]_n + n\mathrm{HCl}.$$

(3) acceptor + HCl ⇌ acceptor salt,

$$(4)\ \mathrm{H_2NR'NH_2} + \mathrm{HCl} \rightleftharpoons \mathrm{HCl\cdot H_2NR'NH_2},$$

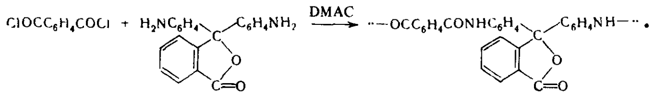
$$(5)\ \mathrm{HCl\cdot H_2NR'NH_2} + \mathrm{HCl} \rightleftharpoons \mathrm{HCl\cdot H_2NR'NH_2\cdot HCl},$$

(6) ClOCRCOCl + acceptor ⇌ saltlike product.

The first three reactions favour the formation of the polymer, while the last three lead to the breakdown of the equimolar proportions of the starting materials and stimulate the termination of the growing polymer chain, i.e. reduce the molecular weight of the polyamide. The ease of their occurrence is determined both by the chemical nature of the starting materials employed and the process conditions.

The role of the substance binding the hydrogen chloride evolved in low-temperature polyamide formation may be fulfilled by tertiary and secondary amines, the initial diamines themselves, and weakly basic organic solvents.

Low-temperature polyamide formation in solution is rapid. This can be inferred if only from the fact that the polycondensation of isophthalic acid chloride with anilinephthalein[20] at −30°C is terminated after several minutes:



The rate of low-temperature polycondensation is of course determined largely by the chemical nature of the starting materials. For example, according to the data of Sokolov and coworkers[28], the time required for the formation of a polyamide from isophthalic acid and di(aminophenyl)sulphone by low-temperature polycondensation is about 30 min, while in the case of poly-*m*-phenyleneisophthalamide it is about 1 h.

Table 8. Low-temperature polyamide formations

"	"	DMF	0.08	solid acid chloride used in reaction

* DMAC = dimethylacetamide.
** DMF = dimethylformamide.

The products of low-temperature polyamide formation are greatly influenced by the order and method of the introduction of the starting materials into the reaction. When the process is carried out in dimethylacetamide, best results are obtained by adding the solid acid chloride (Table 8) to a solution of the diamine in dimethylacetamide, since it is then probably possible to avoid or weaken many undesirable side processes, which are stimulated by the amide solvent[20,22,24].

NN-Diethylacetamide, hexamethylphosphoramide, and *N*-methylpyrrolidinone can also be used as solvents for low-temperature polyamide formation. On the other hand, when the process is carried out in diethylformamide, high-molecular-weight polyamides are not as a rule obtained. Sokolov and coworkers explained this by the fact that in dimethylformamide side reactions predominate over the main process[29].

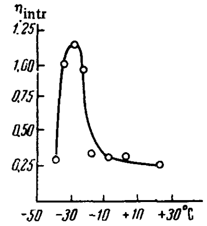

Figure 2. Variation of the viscosity of the polyamide obtained from isophthalic acid chloride and anilinephthalein with polycondensation temperature

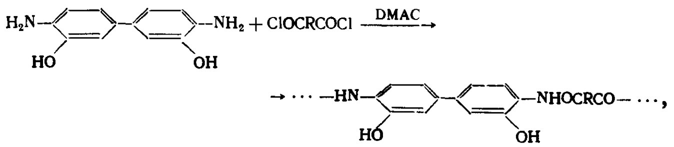
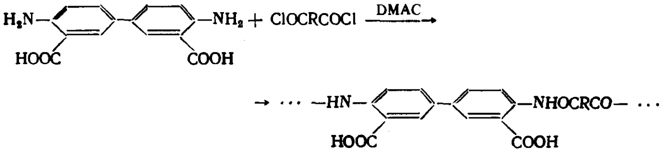
The molecular weight of the polyamide synthesised by low-temperature polycondensation is significantly influenced by the reaction temperature. Fig. 2 shows that in the polycondensation of isophthalic acid chloride with anilinephthalein in dimethylacetamide a polymer with the highest molecular weight is formed at -30°C.[20] According to the data of Savinov and Sokolov[22], poly-*m*-phenyleneisophthalamide with the highest molecular weight is produced when the reaction is performed in dimethylacetamide at 0°C. According to Morgan's data[15], highest molecular weights are achieved in the polycondensation of terephthalic acid chloride and *trans*-2,5-dimethylpiperazine in chloroform at or below room temperature.

Other low-temperature polycondensations in solution are not unaffected by temperature either. Thus the optimum temperature for the polycondensation of the acid chloride of di-(4-carboxyphenyl) ether with the dihydrazide of the same acid in hexamethylphosphoramide is 0–5°C.[25] Polyhydroxyamides have been synthesised at somewhat higher temperatures, approximately between 17° and 40°C, from 3,3′-dihydroxybenzidine and the chlorides of various dicarboxylic acids in dimethylacetamide[30,31]:



and also by the condensation of 4,4′-diaminobiphenyl-3,3′-dicarboxylic acid and an acid chloride:



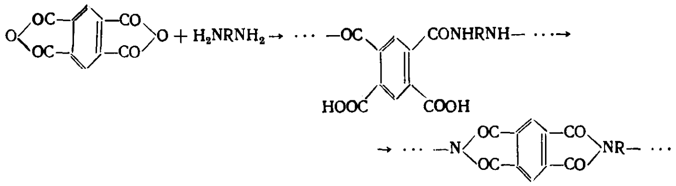
Probably an increase of reaction temperature, leading to an increase of the rate of the main reaction, is desirable in the case of less reactive diamines such as dihydroxy- and dicarboxy-diamines. On the other hand, in the polycondensation of still less reactive di-(4-bromoacetylphenyl) ether with 4,4′-dimercaptobiphenyl in hexamethylphosphoramide, it is desirable to increase the reaction temperature at a certain stage from 20°C to as much as 100°C in order to obtain a polymer with a higher molecular weight[32].

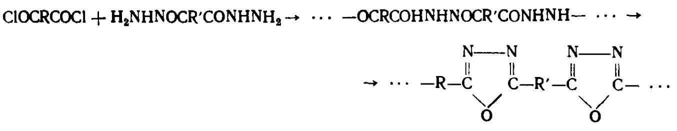
$$x\,\mathrm{BrCH_2COC_6H_4OC_6H_4COCH_2Br} + x\,\mathrm{HSC_6H_4C_6H_4SH} \xrightarrow{\mathrm{HMPA}}$$

$$\rightarrow \cdots -\mathrm{CH_2COC_6H_4OC_6H_4COCH_2SC_6H_4C_6H_4S}- \cdots + 2x\,\mathrm{HBr}$$

The rule of the equivalence of functional groups, which consists in the fact that polymers of high molecular weight are obtained when the starting materials are reacted in stoichiometric proportions, operates in most cases of low-temperature polycondensation.

Among heat resistant and thermostable polymers, cyclochain polymers have attracted much attention recently. Because of their infusibility and insolubility, the only reasonable and useful method of synthesis of many of them was until recently two-stage polycyclisation with formation in the first reaction stage of a high-molecular-weight intermediate which is soluble and therefore can be processed, for example a polyamidoacid in the case of polyimides and polyhydrazides in the case of polyoctadiazoles, which after the formation of the appropriate article are cyclodehydrated to give polymers with a cyclochain structure:



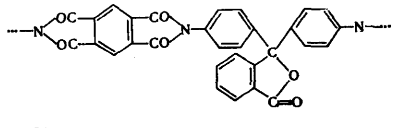


$$\mathrm{ClOCRCOCl} + \mathrm{H_2NHNOCR'CONHNH_2} \rightarrow \cdots -\mathrm{OCRCOHNHNOCR'CONHNH}- \cdots \rightarrow$$

$$\rightarrow \cdots -\mathrm{R}-\overset{\displaystyle \mathrm{N}\!-\!-\!\mathrm{N}}{\underset{\displaystyle \mathrm{O}}{\mathrm{C}\quad\mathrm{C}}}-\mathrm{R'}-\overset{\displaystyle \mathrm{N}\!-\!-\!\mathrm{N}}{\underset{\displaystyle \mathrm{O}}{\mathrm{C}\quad\mathrm{C}}}- \cdots$$

Apart from the evident advantages of this method—for example, articles can be manufactured from infusible and insoluble polyimides—in many cases the final stage of polymerisation has certain disadvantages also, namely (1) the difficulty of obtaining high-molecular-weight polymers in a block or in a thick sheet because of the vigorous hydrolysis of the polyamidoacid by the water evolved in its cyclisation, (2) the degradation of polyimides by the solvents remaining in the polymer even after heat treatment at elevated temperatures, and (3) the necessity to employ high temperatures (frequently of the order of 300°C) and a high vacuum to obtain polyimide articles with satisfactory physical properties.

Recently methods have been found at the Institute of Organic Derivatives of the Elements of the USSR Academy of Sciences for the preparation of heat resistant soluble polyimides, their synthesis involving the use of starting materials containing a central carbon atom in a bulky cyclic group[32-35]. The solubility of such polyimides, in particular anilinephthalein polyimides,



and their stability at high temperatures in many solvents led to a different method for their synthesis—single-stage high-temperature polycondensation in solution[31,34].

Table 9. Synthesis of polyimides by single-stage polycondensation in solution

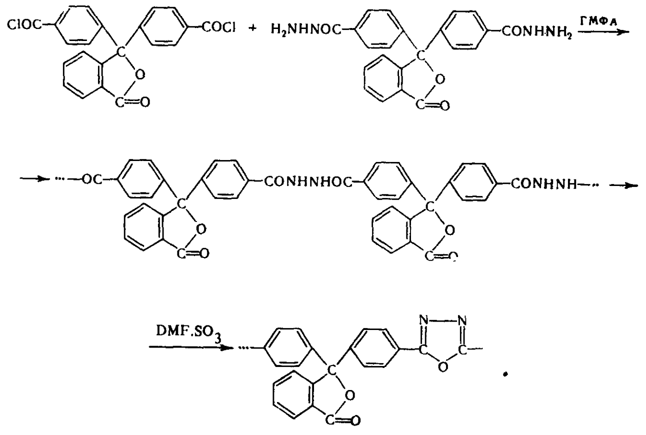
Table 10. Poly-1,3,4-oxadiazoles

Structure of elementary unit	Softening temp., °C	Temp. of onset of decomp. in air, °C
	390	400 (3 deg min^{-1})
	390	450 (3 deg min^{-1})
	370	420 (10 deg min^{-1})
	does not soften before decomp.	450 (10 deg min^{-1})

In the synthesis of such a polyimide by high-temperature polycyclisation in nitrobenzene the initial product is an amidoacid, which, being insoluble in the reaction medium, is precipitated. The subsequent polymerisation (polycyclisation) reaction takes place at 160–210°C and is accompanied by quantitative conversion of the insoluble amidoacid into soluble polyimide. In this method of synthesis of polyimides the difficulties associated with the degradation of the polyamidoacids and polyimides are eliminated and it is no longer necessary to subject the polyimide articles to high-temperature vacuum treatment.

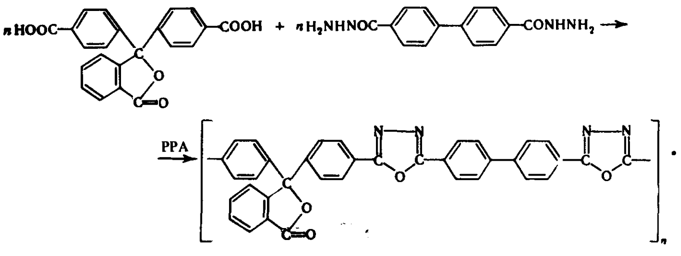
The single-stage method for the separation of soluble polyimides based on anilinephthalein was also extended successfully to the synthesis of high-molecular-weight polyimides based on various tetracarboxylic acid and diamines (Table 9).

We shall consider briefly yet another class of heat resistant and thermostable polymers with a cyclochain structure—polyoxadiazoles. Table 10 lists as an illustration the softening temperatures and the temperatures corresponding to the onset of decomposition of certain polyoxadiazoles[36,37]. They can be synthesised by two-stage methods and also in one stage. Using the two-stage method of synthesising polyoxadiazole, particularly from di-(4-carboxyphenyl) ether, Korshak et al.[25] obtained good results when the first stage, involving the polycondensation of the acid chloride of di-(4-carboxyphenyl) ether with its dihydrazide, was carried out in hexamethylphosphoramide. In the second stage, involving the conversion of the polyhydrazide into polyoxadiazoles, the polymer is usually heated in a vacuum under very severe conditions (about 300°C, 25–30 h). However, it has recently been shown, for polyoxadiazoles obtained from diphenylphthalide-4,4′-dicarboxylic acid as an example, that polyhydrazides can be cyclodehydrated successfully at atmospheric pressure under milder conditions, namely by heat treatment at 100°C for 5 h, when the complex of an amide solvent, for example dimethylformamide (DMF) or dimethylacetamide with sulphur dioxide, is to be used as the cyclodehydrating agent[36,38]:



It was noted that polyoxadiazoles may be synthesised also in one stage. Here the process is carried out in polyphosphoric acid (PPA). In a study of the synthesis of soluble polyoxadiazoles based on diphenylphthalide-4,4′-dicarboxylic acid very good results were obtained using this method.

In this case the acid and the hydrazide are allowed to react in equimolar proportions. For example, :



The reaction is carried out gradually by heating the reaction mixture to 140°C and maintaining it at this temperature for several hours.

	0.58	0.70	1.90
	0.89	0.80	4.75

* PPA = polyphosphoric acid (Ed. of Translation).

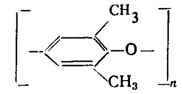
Table 11 presents the results obtained in the synthesis of polyoxadiazoles from diphenylphthalide-4,4'-dicarboxylic acid by various methods. They show that polycondensation in polyphosphoric acid yields high-molecular-weight polymers[36].

In recent years considerable progress has been achieved also in the synthesis of aromatic polyethers and polysulphones. Despite the fact that these materials are less heat resistant than aromatic polyamides, polyesters, and particularly polymers with a cyclochain structure, they nevertheless have valuable properties; they are heterochain polymers with reasonably good heat resistant properties. Therefore we shall consider briefly their synthesis.

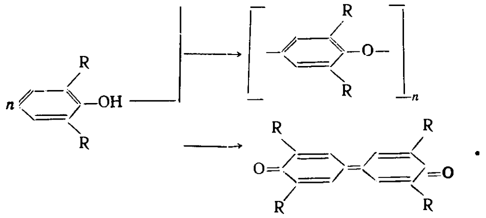
For a long time considerable difficulties were encountered in the synthesis of aromatic polyethers. It was impossible to obtain polymers with a high molecular weight. Recently, various methods have been employed in their synthesis. Thus, a method has been described for the preparation of a polyether with a 1,4-phenyl structure from sodium *p*-bromophenoxide by a modified Ullman condensation:

Copper(I) chloride combined with various organic bases (pyridine, *NN*-dimethylformamide, *NN*-dimethylacetamide) is employed as a catalyst. The reaction is carried out at 200°C in dimethoxybenzene, nitrobenzene, or benzophenone with careful exclusion of oxygen and moisture. Since the polymer obtained has the capacity to form fibres, its molecular weight is fairly high. It is also fairly heat resistant: it can be moulded at 300–350°C.[39]

A new variety of non-equilibrium condensation, namely oxidative dehydropolycondensation, proved to be a very interesting procedure for the preparation of aromatic polyethers. The General Electric Company manufactures by this method on an industrial scale a polyether with the following structure:



Its glass point is 205°C and the crystals melt at 267°C. According to thermogravimetric data, the degradation of the polymer in an inert atmosphere begins at about 400°C. Its synthesis became possible when it was established that certain 2,6-disubstituted phenols react by the following mechanism in the presence of oxygen with an amide complex of copper as catalyst:



With 2,6-dimethylphenol, the process takes place readily giving a polymer with a high molecular weight, while the yield of side products is very low. In general the formation of polymers of this type by oxidative dehydropolycondensation is successful when the dimensions of the constituents in the *ortho*-position are small.

On the other hand, if one of the substituents is, for example, a t-butyl group or both substituents are isopropyl groups, the corresponding diphenoquinone is formed preferentially and not the polymer. Substituents which increase the oxidative potential of the phenol retard the polycondensation. Thus, whereas 2,6-dimethylphenol readily undergoes polycondensation at room temperature, the polycondensation of 2-chloro-6-methylphenol requires a temperature of 60°C and for comparable rates of the process with 2,6-dichlorophenol a still higher temperature is needed[39].

Copper chloride in pyridine is usually employed as a catalyst for the oxidative dehydropolycondensation of 2,6-disubstituted phenols; other primary, secondary, or tertiary amines may be used instead of pyridine.

An interesting case of non-equilibrium polycondensation developed in recent years is the polycondensation of the phenoxides of dihydric phenols with aromatic dihalogeno-derivatives in which the halogens are labile because of the presence of electronegative substituents in the molecule[40–42].

An example of this type of reaction is that of the phenoxide derived from dian‡ with di-(4-chlorophenyl) sulphone in dimethyl sulphoxide, which leads to the formation of the so called "polysulphone" (this product was developed and is manufactured by the Union Carbide Company):

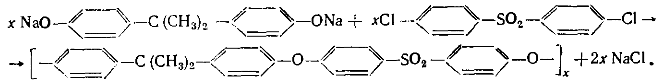


Table 12. Synthesis of polysulphone from di-(4-chlorophenyl) sulphone

Dian salt	Solvent	Duration of reaction, h	Reaction temp., °C	η_{intr} of soln. with 0.2 g/100 ml $CHCl_3$	Yield, %
Na	dimethyl sulphoxide	1	160—165	1.0	>99
K	dimethyl sulphoxide	4	195—200	0.65	>99
Na	sulpholane	3	200—210	0.75	>99
Na	diphenyl sulphone	11	230—250	0.40	—
Na	di-n-propyl sulphoxide	3.5	200—210	0.08	98
Na	benzophenone	8.5	220—230	—	53

The glass point of this polymer, which is fairly thermostable, is 195°C. On heating in an inert atmosphere for 30 min at 400°C, it remains unchanged. The heat resistance of polymers of this type can be varied by altering their chemical structure. For example, the glass point of the corresponding polymer obtained from di-(4-hydroxyphenyl) sulphone is 245°C. In general polycondensation of this type is carried out at elevated temperatures in anhydrous dipolar aprotic solvents, among which dimethyl sulphoxide and sulpholane (1,1-dihydroxytetrahydrothiophen) proved to be the most effective. Probably highly polar solvents of this type not only dissolve the polymer formed but also promote a higher rate of reaction, as it were catalysing the process. On the other hand, Table 12 shows that less polar organic solvents do not facilitate the reaction[40]. Johnson et al.[40], who made a detailed study of the interaction of the phenoxides derived from dihydric phenols with dihalogeno-compounds, noted that the reaction is sensitive to admixtures of water and other nucleophilic substances, because these interfere with the synthesis of a polymer having a high molecular weight. Polymers with the highest molecular weight are obtained when the starting materials enter into the reaction in equimolar proportions. The rate of this reaction depends on the basicity of the phenoxide obtained from the dihydric phenol and the electronegativity of the substituent in the dihalogeno-derivative. The reactivity of dihydric phenols evidently varies in inverse proportion to their acidity.

Thus alkali metal phenoxides derived from di(hydroxyphenyl) sulphone, which is a comparatively acid dihydric phenol, reacts much more slowly with di-(4-chlorophenyl) sulphone than the corresponding phenoxides obtained from dian. The reactivity of aromatic dihalogeno-derivatives (Table 13) is determined both by the nature of the activating group and the halogen: difluoro-compounds are more reactive than dichloro-compounds[40]. Sodium and potassium phenoxides may be employed in the reaction. The phenoxides of other metals (lithium, calcium, or magnesium) derived from dian are not suitable because of their insolubility in dimethyl sulphoxide[40].

It is clear from the foregoing that many types of heat resistant and thermostable polymers are successfully obtained by the polycondensation method. Non-equilibrium polycondensation processes are the most important. Most of these are reactions discovered and investigated in recent years. There is no doubt that a more profound study of such reactions and the discovery of their mechanisms constitute the tasks of the immediate future.

Outer-sphere Complexes of Tervalent Cobalt

V.E.Mironov

Certain theoretical postulates concerning the formation of outer-sphere complexes have been described. Various approaches to the investigation of these compounds have been considered. Data are presented showing the necessity to take into account the packing term in unitary cratic thermodynamic functions of outer-sphere complexes. Methods for and the results of investigations of various classes of cobalt(III) outer-sphere complexes have been discussed. It is suggested that the formation of transition metal outer-sphere complexes takes place in steps as a result of directional forces. Like inner-sphere interactions, this process takes place in accordance with limiting and characteristic co-ordination numbers. The types of bonds involved in the formation of outer-sphere complexes have been examined.
The bibliography includes 232 references.

CONTENTS

1. INTRODUCTION

Interest in the study of outer-sphere complexes (OSC) increased sharply in the last ten years because outer-sphere coordination processes determine the mechanisms and the rates of many reactions, provide a more profound understanding of catalysis [1], yield a partial model of the transition state, and lead to the discovery of new methods for the isolation, purification, and detection of many metals [2,3], and also have a marked effect on inner-sphere interaction. Many types of complex compounds exist in aqueous solutions solely because of outer-sphere association [4,5]. Recently a number of theoretical postulates have been formulated [6] concerning the formation of such complexes. The data on the thermodynamics and structure of cobalt(III) outer-sphere complexes have played an important role in the formulation of these postulates but the complexes have not so far been reviewed.

This paper constitutes an attempt to review and examine critically the published data and also the results obtained by the author of the review and his coworkers for cobalt(III) outer-sphere complexes.

Complexes of di- and ter-valent cobalt are most frequently encountered [3]. A characteristic feature of most of the cobalt(III) complexes is a low rate of inner-sphere electrolytic dissociation and a constant coordination number of six [7,8]. The compounds have an octahedral configuration. Almost all cobalt(II) complexes are labile and their coordination number is four or six [9].

At present cobalt(III) outer-sphere complexes have been investigated in greatest detail compared with analogous compounds of other metals. This situation arose partly because of the inertness of the inner sphere of cobalt(III) and the lability of the outer-sphere complexes. The low rate of dissociation of the inner-sphere complex made it possible to investigate the cobalt(III) outer-sphere complexes by many methods used for the study of labile inner-sphere coordination [10] and it also permitted the application of the most effective modern methods, such as, for example, circular dichroism spectroscopy [11]. The outer sphere complexes of other metals such as chromium, platinum, rhodium, iridium, etc. frequently have advantages, which are indicated in the description of the properties of the cobalt(III) complexes, but for various reasons [5] these complexes have not been investigated systematically.

The study of cobalt(II) outer sphere complexes is difficult because of the high lability of the inner sphere of this ion, but infrared [12,13], Raman [14], and electronic spectroscopy [15-18] permits the study of outer-sphere complexes in these and other systems with similar properties. The most promising approach for the investigation of cobalt(II) outer-sphere complexes is a combination of thermodynamic and electronic spectroscopic methods [15-17]. The methods proposed for the study of outer-sphere complexes in the present author's earlier investigations [4,5,19-27] are also suitable for the study of the analogous cobalt(II) complexes.

2. SOME GENERAL DATA ON OUTER SPHERE COORDINATION

According to Werner's theory, all saturated complex compounds are capable of outer-sphere interaction. However, the theoretical postulates formulated at present concerning the formation of outer sphere complexes[6] are valid only for transition metal, lanthanide, and probably actinide compounds. Ions of other metals are capable of outer-sphere association but the occurrence of outer-sphere coordination has not been demonstrated for them. In fact the study of the outer-sphere interaction of ions with filled *d* orbitals indicates the absence of stepwise outer-sphere coordination[28].

Numerous literature data show[5,6,29-47] that the capacity of transition metals for interaction is determined by the main and subsidiary valences and also by additional specific forces, the effect of which is directed to fixed positions in space. The nature of these forces is determined by the nature of the Werner complexes functioning as the central groups of the outer sphere complexes. The directional effect of the additional forces determines the stereochemistry of the second coordination sphere.

Like inner-sphere interaction, outer-sphere complex formation processes take place in stages and involve a decrease in the strength of the bond between the outer-sphere ligands and the inner sphere on going from the *n*th to the $(n+1)$th outer-sphere ligand. Sometimes deviations from this rule are observed[4,5]. This happens when inner-sphere coordination is superimposed on the outer-sphere interaction or when the activity coefficients of the interacting and product ions are altered. Similar deviations may be attributed also to the geometrical characteristics of the outer coordination sphere.

Outer-sphere interaction, like inner-sphere complex formation, is characterised by limiting and characteristic coordination numbers[6]. Inner-sphere complexes with octahedral configuration have limiting outer-sphere coordination numbers of 8 and 12 and characteristic numbers of 2 and 4. An especially large number of octahedral inner-sphere cobalt(III) complexes coordinate four outer sphere ligands[30,38-42,45,46]. There are few data on outer-sphere complexes the central ions of which are Werner complexes with tetrahedral and square configurations. According to theoretical considerations[6], one may assume that tetrahedral complexes have limiting outer-sphere coordination numbers of 4 and 6 and a characteristic number of 4. The outer-sphere coordination numbers of complexes with a square configuration are probably 2 and 4.

The charge, dimensions, geometrical configuration, and type of inner-sphere ligand, the electronic state of the Werner complex, and also the nature of the medium, temperature, and pressure determine the stability, structure, and number of ligands combined in the outer-sphere complex. However, the charge and dimensions of inner-sphere complexes do not influence the coordination numbers of the outer-sphere complexes. These characteristics have a major effect on the thermodynamic functions of outer-sphere coordination[4]. A decrease of the dielectric constant of the medium and an increase of the electron-accepting properties of the inner-sphere complex usually increase the stability of the outer-sphere complex.

The sites of contact between the outer-sphere ligands and the inner-sphere complex are points with the most effective charges of the interacting species. The centres of the edges or faces of the octahedral and tetrahedral complexes and the reactive atoms of the inner-sphere ligands[31,43,44,47] not involved in inner-sphere interaction frequently form the closest bond in the outer sphere complex.

Comparison of data on the stability of typical ion pairs and triplets with the stability typical of outer-sphere coordination complexes shows[5] appreciable differences between these two groups of association complexes. The difference consists in the characteristic coordination number. The latter is unity for typical ion pairs and triplets. Saturated complex cations (in the sense of Werner's theory) show a much higher capacity for outer-sphere coordination than complex anions[5]. The latter rarely form stable-outer sphere complexes in which they behave as the central group. Both complex and simple anions have a pronounced capacity for addition to central groups as ligands. The explanation is that all anions tend to exhibit electron-donating properties and do not have appreciable electron-accepting properties.

The interaction between ions and molecules of water or another highly polar solvent leads to the formation around the ions of three concentric shells[48-50] and therefore the overall concentration (C_M) of a conventionally free ion M can be expressed[51] by the equation

$$C_M = \sum_{n=0}^{N} \sum_{n_1=0}^{N_1} \sum_{n_2=0}^{N_2} ([MS_n]S_{n_1}S_{n_2}), \tag{1}$$

where N, N_1, and N_2 are the maximum numbers of solvent molecules S in the first, second, and third solvation shells of the ion M. The square brackets in this equation define the first solvation shell and the symbols of the substances in round brackets denote their equilibrium concentrations. The ionic charges have been omitted for simplicity.

The first solvation shell of the association complexes is identical in many ions with the Werner coordination sphere[52-58]. The second solvation shell of the association complex is characterised by a lower degree of order in the solvent structure than in the pure solvent. The bond between the solvent molecules in the second shell and the ion M is usually formed via the molecules of the first shell but $N_1 > N$.[59] The state of the solvent molecules in the third solvation shell does not differ fundamentally from that in the pure solvent and $N_2 \gg N_1$.

Inner-sphere complex formation in solutions is a process in which the solvent molecules in the Werner coordination sphere of the central ion are displaced by any ligand other than the solvent molecule[60]. Such a process is always accompanied by the formation of a direct bond between the central atom and the ligand.

It is suggested that outer-sphere complex formation be regarded[61,62] as a process in which solvent molecules in the second shell of the association complex, with the composition defined by formula (1), are substituted. Such a process is accompanied by the formation of bonds between the central ion M and the outer sphere ligand A via an inner sphere ligand L and by secondary interaction between M and A as a result of charge transfer from A to the antibonding orbitals of ML_n.[35]

The formation of a successive series of outer-sphere complexes of the central group $[ML_nS_{N-n}]$ may be represented by the equilibrium

$$[ML_nS_{N-n}]S_{N_1} + q[AS_P] \rightleftarrows [ML_nS_{N-n}]A_qS_x + (qP + N_1 - x)S, \tag{2}$$

where $q = 1, 2, 3, \ldots$ The above formulation of reaction (2) is valid if the addition of each outer-sphere ligand is accompanied by the elimination from $[ML_nS_{N-n}]S_{N_1}$ of an arbitrary number of solvent molecules.

When outer-sphere complex formation occurs in solution with a high concentration of inert salts, then one or several ions of the inert salt are detached from the central group together with solvent molecules in the course of reaction (2). This postulate has been found to hold in practice[30].

The equilibrium constant for reaction (2) ($^P\omega_{nq}$) is related to the stability constant ω_{nq} of the outer-sphere complex $[ML_nS_{N-n}]A_qS_x$ formed by the equation

$$\omega_{nq} = {}^P\omega_{nq} \cdot (S)^{x-N_1-qP} \tag{3}$$

when the activity coefficients of all three components of equilibrium (2) are constant and arbitrarily set equal to unity.

The equilibrium constants for reaction (2) and similar processes, expressed on the molal and molar scales consist of a unitary component, characterising the nature of the interacting species, and a packing or cratic component, defined by the number of interacting species[63]. The packing term in equilibrium (2) is $(S)^{x-N_1-qP}$.

Some time ago Bjerrum pointed out[64] the necessity to correct the equilibrium constants for the packing term. This has also been noted in other investigations[65,66].

Gurney[63] examined the problem of the standard state in the study of solutions starting with the concept of the separation of the overall entropy of the process into unitary and cratic components. The difference between the standard states of the solvent (pure solvent) and the solute (hypothetical or real solutions) makes it necessary to take into account two components of the equilibrium constant—the free energy and entropy terms. Only the use of the mole fraction scale eliminates the asymmetry in the choice of the standard state for the solvent and solution, but this method of expressing concentrations is inconvenient in practice[67].

It is interesting to note that the correction of the formation constants of outer-sphere complexes for the cratic terms eliminates many contradictions in data on the stability of these compounds[30]. Unfortunately there are very few literature data necessary for such correction of the thermodynamic functions of both inner-sphere and even more so outer-sphere complexes.

The enthalpy of complex formation in solutions is a unitary constant when it is determined from thermochemical measurements. The cratic term varies with temperature and therefore the process enthalpies calculated from the temperature variation of the equilibrium constants can differ fundamentally from the values obtained from thermochemical measurements.

3. FIRST STUDIES ON OUTER-SPHERE COMPLEXES OF TERVALENT COBALT

The first studies on cobalt(III) outer sphere complexes in solution were made by Brintzinger as early as 1935.[38,39,68] The author notes[38] the necessity to distinguish two types of complex: comparatively simple complexes such as hexamminecobalt(III) chloride, aquopentamminecobalt(III) bromide, etc. and more complicated compounds where saturated complexes (in the sense of Werner's theory) play the role of the central ion or ligand. According to Brintzinger[33], the central ion in the latter type of complex may be any complex cation and anion and therefore there are many more of the complicated complexes than of the simple complexes. The above postulates put forward by Brintzinger are valid also in the light of modern investigations. It is necessary to make only one modification namely that complex anions show little tendency to behave as coordination centres in outer-sphere complexes compared with complex cations.

Brintzinger demonstrated[38,39,68] the formation of a large number of outer-sphere complexes by dialysis and also by transport measurements.

The molecular weight data for outer-sphere complexes found by dialysis have been criticised[7,29] on account of the error involved. Indeed this method is unsuitable for the accurate determination of the number of molecules of water or another solvent in various solvation shells of an association complex the composition of which is represented by formula (1),[29] but it frequently makes it possible to determine the molecular weight of complex ions[69] and outer-sphere association complexes[39] with adequate reliability[70]. Moreover, the validity of Brintzinger's data showing that hexamminecobalt(III) ions move towards the anode in the presence of an excess of outer-sphere anionic ligand species is unequivocal[70] and the critics of Brintzingers investigations unfortunately did not take this into account.

The first studies of cobalt(III) outer-sphere complexes showed that in 2 M solutions of sodium nitrate hexaammine, trisethylenediamine-, and various acidopentammine-, and acidotetrammine-complexes of cobalt(III) do not interact appreciably with nitrate ions[69]. However, in 2 M ammonium sulphate solutions, in 1.5 M potassium oxalate solutions[38], in 0.5 M potassium hexacyanoferrate(II) solutions[68], and in 1.5 M potassium pyrophosphate solutions[39] all the above and a number of other simple and mixed cobalt(III) complexes form outer-sphere complexes with a coordination number of 4 when the outer sphere ligands behave as monodentate species. Immediately after their preparation, cobalt in these solutions migrates to the anode under the influence of an electric field. Thus the first studies on cobalt(III) outer-sphere complexes already demonstrated unambiguously the addition of several anionic ligands in the outer sphere.

The addition to CoL_N^{3+} complexes of even one hexacyanoferrate(II) ion leads to the formation of a negatively charged association complex. Consequently further addition of outer-sphere ligands cannot occur because of electrostatic forces. Similar situations are encountered also in other systems. However, many investigators still believe that the interaction between complex and outer-sphere ions in aqueous solutions is virtually non-existent[29] or can be accounted for[7,8,67,71] within the framework of the theory of electrostatic interaction. The results of Brintzinger's work and other early investigations of cobalt(III) complexes have been discussed in detail in a number of monographs[7,72,73].

4. TWO APPROACHES TO THE STUDY OF COBALT(III) OUTER SPHERE COMPLEXES

The present author's work showed[4,5,74-77] that the association of any ions in any solvent can be characterised quantitatively on the basis of the law of mass action (LMA). A knowledge of the true composition of the interacting and product species is necessary for such description of the process. Hence it follows that the association of saturated complexes (in Werner's sense) with outer sphere ions is also a process obeying the law of mass action. The validity of this postulate is confirmed by numerous investigations[5].

Many workers believe[78-82] that the dissociation of complexes in aqueous solutions into complex and outer-sphere ions should be characterised by formal activity coefficients. There exists a view that large complex ions show less tendency towards association than simple ions. A number of objections have also been made[83-86] to the use of the law of mass action to characterise quantitatively association interactions with participation of complex ions. However, recent measurements of osmotic coefficients and activity coefficients of hexammine- and acidopentamminecobalt(III) complexes disprove [87-91] the view that outer-sphere interaction can be usefully characterised with the aid of the activity coefficients of complex salts. These data confirm the view expressed by the author of this review more than ten years ago [92] and constitutes the second approach to the study of outer-sphere complexes with calculation of the law of mass action constants on the basis of measured activity coefficients. The first approach to the study of such complexes consists in a direct determination of the changes in thermodynamic functions in the course of outer-sphere interaction.

A pronounced dependence of the outer-sphere complex formation constants on the concentration of complex salts was observed [81] in early measurements of activity coefficients. New studies have shown [87-90] that, with a correct approach to the calculation of the outer-sphere association constants from the activity coefficients, the association constants remain invariant over a wide range of the concentrations of various salts. Moreover, it has been observed that the activity coefficients of numerous acidopentamminecobalt(III) salts are much lower than those of simple electrolytes of a similar type and do not pass through a minimum even in solutions at concentrations of about 2.5 M.

Very convenient methods have now been developed [87-91] for the calculation of the thermodynamic functions of outer-sphere complexes with one ligand from osmotic and activity coefficients. These methods have been used to investigate cobalt(III) outer-sphere complexes.

5. ALLOWANCE FOR THE PACKING TERM OF THE UNITARY CRATIC FUNCTIONS OF COBALT(III) OUTER-SPHERE COMPLEXES

The principal standard state used in the study of stepwise outer-sphere coordination is a solution with a high and constant ionic strength maintained by means of inert salts. Studies on solutions with variable ionic strengths cannot yield accurate thermodynamic characteristics of outer-sphere complexes, since there is no way of finding the activity coefficients of individual ions (particularly complex ions) in solutions with high concentrations of ligand ions, where the majority of outer-sphere complexes are formed.

The thermodynamic functions of outer-sphere complexes referred to solutions with various constant ionic strengths as standards can be adjusted to zero ionic strength [93-97] but various complications frequently arise in such recalculations [98,99]. For example [30], in aqueous solutions with perchlorate ion concentrations of about 0.1 M, hexamminecobalt(III) ions form association complexes with perchlorate ions in which the latter are probably separated from the complex ion by water molecules. The location of perchlorate ions in the third coordination shell of the association complex, the composition of which is represented by formula (1), is confirmed by the absence of an appreciable effect of perchlorate ions on the electronic spectra of hexamminecobalt(III) and the circular dichroism spectra of (+)-trisethylenediaminecobalt(III). [32] The formation of cobalt(III) outer-sphere complexes in aqueous lithium or sodium perchlorate solutions is accompanied by the partial dissociation from the conventionally free central group of one or several perchlorate ions [30,100], which requires the introduction into the unitary-cratic values of the thermodynamic functions of outer sphere complexes of a correction for the packing effect. Recently the present author developed [30] an approximate method for applying such a correction. It is interesting to note that an increase of temperature from 25° to 45°C reduced sharply the cratic terms of the thermodynamic functions for formation of hexamminecobalt(III) halide complexes.

The need to apply a correction for the packing effect follows from numerous data [41,101-104]. For example, it has been shown [102] that the chloropentamminecobalt(III) ion forms with perchlorate ions, usually regarded as inert, more stable association complexes than with nitrate, chloride, azide, and acetate ions. Electrophoretic studies have shown [103,104] that cobalt complexes with three molecules of ethylenediamine, 2,2′-dipyridyl, and 1,10-phenanthroline also interact with perchlorate ions more strongly than with many other singly-charged ions.

A particularly striking example of the necessity to take into account the packing term follows from the work of Larsson [41], who investigated the association of *trans*-dithiocyanatobisethylenediaminecobalt(III) with thiocyanate ions in 3 M aqueous solutions of a mixture of sodium perchlorate and thiocyanate at 20°C by an ion-exchange method. The calculations without a correction for the packing term led to the detection of only the complex with a single ligand having a stability constant of 0.30. This constant could not account for various properties of the system investigated. The use of an extraction method enabled Larsson to investigate the perchlorate association complexes of *trans*-dithiocyanatobisethylenediaminecobalt(III) and to introduce a correction for the packing term. After applying the correction, it was found that three thiocyanate complexes are formed in the system, with overall stability constants of 1.42, 0.88, and 0.30.

6. METHODS FOR THE INVESTIGATION AND CERTAIN GENERAL FEATURES OF COBALT(III) OUTER-SPHERE COMPLEXES

It can now be regarded as proved that all coordination-saturated complex cobalt(III) cations are capable of stepwise coordination in the outer sphere of various anions [30,32] and also molecules [93,105-108] with electron-donating properties. The outer-sphere coordination of ligands by inner-sphere cobalt(III) complexes involves an increase of the intensity of the charge-transfer bands in electronic spectra [109,110] and is equally reflected in the results of thermodynamic studies of outer-sphere complexes [30].

The study of the addition of a seventh ammonia molecule [107,108], of outer-sphere ethylenediamine molecules [93,105], and a number of other ligands [30,44,47] made a considerable contribution to the proof of the occurrence of outer-sphere coordination by cobalt(III) complexes. These investigations showed that the stepwise outer-sphere interaction constants are independent of the methods of determination and the ratios of their logarithms yield reasonable values for the statistical and ligand effects [29] when the correct limiting coordination numbers for the second shell are employed [6].

Interesting data on the stepwise formation of cobalt(III) outer-sphere complexes were obtained in studies on circular dichroism spectra [30-32,35,36,45,46,111-113], since this method is free from the many disadvantages characteristic of customary electronic spectroscopy and measurements of optical rotatory dispersion [11]. The high sensitivity of circular dichroism spectra and different signs of the dichroic molar absorption coefficients in successive stages of outer-sphere coordination made it possible to investigate accurately the stepwise outer-sphere interaction.

The circular dichroism spectra of the selenite complexes of (+)-trisethylenediaminecobalt(III) were investigated with particular care. The results obtained by Larsson[31] agreed well with the present author's data[45] but the stability constants calculated in these investigations[31,45] were inexplicably high[30,114]. This finding can be accounted for by the presence of several conformations of (+)-trisethylenediaminecobalt(III).[114] Moreover, it is now clear[30] that data on dichroic absorption cannot always be used for the simultaneous determination of the stability constants and molar dichroic absorption coefficients, because the latter may be zero, which greatly distorts the stability constants. Despite these limitations, the study of circular dichroism spectra in combination with data from thermodynamic methods gives a clear idea about the stereochemistry and bonds in the outer-sphere complexes of cobalt(III) and a number of other metals[111,115].

The stability of a large series of cobalt(III) outer-sphere acido-complexes in dilute aqueous and non-aqueous solutions with variable ionic strengths was investigated conductimetrically[10,116-119]. The stability constants calculated from the data obtained by this method are usually referred to solutions at zero ionic strengths as standards. Conductimetric measurements were used to determine the thermodynamic functions of outer-sphere complexes with one ligand only.

Electronic spectroscopy has been most frequently used to investigate cobalt(III) outer-sphere complexes[120-131], the data thus obtained permitting the calculation of the stability constants (the first and more rarely the second stability constants) and to solve approximately the problem of the nature of the outer-sphere coordination bonds.

A number of studies on the thermodynamics of cobalt(III) outer-sphere complexes were made by the solubility method[30,97-100,132-136]. Measurements were made of the solubility of sparingly soluble iodates[133-135], perchlorates[97-100], hexacyanoferrates(III),[136] and other hexa- or pent-amminecobalt(III) salts in solutions with different concentrations of outer-sphere ligands. In a number of other studies[133] the solubility of sparingly soluble salts containing outer-sphere ligands was investigated as a function of the concentration of inner-sphere cobalt(III) complexes.

Studies on the kinetics of complex formation[61,62,102,137-142] and various versions of the potentiometric method[30,135,143,144] made a considerable contribution to the thermodynamics of cobalt(III). Outer-sphere complexes with the anions of weak acids were investigated[120,135,144] by pH titration. The study of the redox potentials of the cobalt(III)–cobalt(II) system proved very useful and promising in the investigation of cobalt(III) outer-sphere complexes[30,143]. The use of electrodes reversible with respect to the outer-sphere anionic ligands is less suitable because the stability of the majority of outer-sphere complexes is comparatively low and therefore the equilibrium and overall concentrations of the ligands are almost equal.

In studies on the outer-sphere complexes of various metals the e.m.f.'s of cells with ion transport were usually measured. The conventional diffusion potentials of such cells were determined experimentally in accurate investigations[28,30,145] but normally they were calculated from the Henderson equation. The latter method of finding the diffusion potentials is unreliable[28,30] in studies on unstable complexes. Cells without transport have not so far been used to investigate outer-sphere complexes although this approach may prove to be very useful[146].

Isolated studies have been made on cobalt(III) outer-sphere complexes by extraction[34,41], ion-exchange[40,41], and electrophoretic[103,104] methods.

Interesting data on chromium(III)[147,148] and iron(III)[149] outer-sphere complexes were obtained by nuclear magnetic resonance. Recently this method was applied also in the study of cobalt(II) outer-sphere complexes[44,150].

Several systems with stepwise cobalt(III) outer-sphere complex formation were investigated polarimetrically[33,35,42,136]. Trisdiaminecobalt(III) compounds were studied. The investigations led to the determination of the composition and the calculation of the stepwise outer-sphere coordination constants and also the demonstration that there is no difference in the tendency towards the formation of outer-sphere complexes by the racemate and the dextro- and leavo-rotatory isomers[30]. However, the stability constants found from the polarimetric measurements are frequently inaccurate[114] and optically active outer-sphere ligands interact in different ways with dextro- and leavo-rotatory isomers[151].

Infrared spectroscopic studies led to a number of conclusions concerning the nature of the chemical bond in cobalt(III) outer-sphere complexes and to the solution of the problem of the stability of these complexes[152-154]. However, it should be noted that the applicability of the infrared spectroscopic method in the study of outer-sphere complexes is limited and the method is altogether inapplicable to dilute solutions. This is also true of Raman spectra.

The polarographic[155-163] and amperometric[164] methods proved to be useful in the study of cobalt(III) outer-sphere complexes. The shift of the half-wave potential or the changes in diffusion current[159] following the addition of the outer-sphere ligands to cobalt(III) complexes were measured by these methods.

The possibility of using the chronopotentiometric transition to study cobalt(III) outer-sphere complexes has been justified theoretically[165] and confirmed experimentally.

This isopiestic[87-91] and thermochemical[30,93,105,166,167] methods have been shown to be promising.

So far there are no literature data on the thermodynamic functions of cobalt(III) outer-sphere complexes with an outer-sphere coordination number greater than unity referred to solutions at zero ionic strength as standards. Possibly modern methods for the conversion of the thermodynamic functions from one standard state to another will help fill this gap[168-170].

7. HEXAMMINE COBALT(III) COMPLEXES

Numerous data have been published[10,41,71,95-100,103,104,106,116,123,171-177] on the stability of single-ligand outer-sphere complexes where the central group is the hexamminecobalt(III) ion, but the enthalpies and entropies of formation of these compounds have not been determined with adequate reliability; on the other hand the formation of polyligand complexes has been studied only in isolated cases[34,41,100,104].

An advance in the study of hexamminecobalt(III) complexes has been the demonstration of the formation of an outer-sphere chelate ring. This has been shown[175] by investigating the ultraviolet and circular dichroism spectra of a solution of hexamminecobalt(III) perchlorate in the presence of an excess of diethyl-(+)-tartrate ions. The appearance of a new absorption band in the spectrum of this system at about 3000 Å was attributed to charge transfer from the outer-sphere ligand to the complex ion and to a *d–d* electronic transition.

The contradictory nature of the literature data on the stability of single ligand (particularly chloride and bromide) complexes of hexamminecobalt(III) has been the subject of several controversies[4,5,40,100,126]. The reason for these controversies were examined in earlier publications[4,40,98].

Certain thermodynamic functions for a number of hexamminecobalt(III) complexes with various anions have been determined with sufficient reliability to allow their comparison. These data show that the stability of single-ligand association complexes of this cation increases in the following series of anions: lactate[134] < thiocyanate[134] < hydroxide[137] < iodide[97] < azide[97] < bromide[97] < chloride[97] < < tartrate[134] < malonate[134] < sulphate[95] < sulphite[124] < < thiosulphate[174] < fluoride[30] < oxalate[10] < triphosphate[119] < tetraphosphate[119]. The logarithm of the stability constant increases in this series from 0.68 to 4.44 at 25°C and zero ionic strength of the aqueous solution. This series suggests that an increase of the charge and a decrease of the dimensions of the outer-sphere ligands almost always entail an increase of the stability of the outer-sphere complex. There are only a few deviations from this rule—for example, the position in the series of the hydroxide ion. The charge and dimensions of this ion suggest a higher stability of the hydroxo-complex than is indicated by the literature data[137]. The reason for this discrepancy may be the specific features of the hydration or the association of the OH^- ion or it may be due to experimental error. The results of quantitative studies on the stability of sulphate, sulphite, and thiosulphate complexes of hexamminecobalt(III) are extremely contradictory[10].

Deviations from the expected position in the stability series of single-ligand hexamminecobalt(III) association complexes may be caused by hydrogen bonds between the outer-sphere ligands and the inner-sphere ammonia molecules, the effect of which is superimposed on that of the charge and ligand radius. However, the study of infrared spectra and in particular the vibration frequencies of the N–H bond indicates[177] the absence of an appreciable contribution of hydrogen bonding even in the formation of the fluoride complexes of hexamminecobalt(III). This finding may be related to the non-linearity of the Co–N–H group. A strong hydrogen bond formed in the presence of a linear N–M–A structure, where A is an outer-sphere ligand leads[178,179] to the maximum distance between A and cobalt and is clearly reflected in the N–H frequency, but the latter may not in fact change when a non-linear N–H–A group is formed. Consequently the conclusion[177] that there is no hydrogen bond in hexamminecobalt(III) complexes requires further confirmation, particularly since in outer-sphere trisethylenediamine-, diamminebisethylenediamine-, and dichlorobisethylenediaminecobalt(III) complexes a hydrogen bond has been detected[44] by proton magnetic resonance.

A steady decrease of the enthalpy and entropy is observed in the interaction of the following series of outer-sphere ligands with the hexamminecobalt(III) cation: chloride > bromide > iodide > azide.

The formation of chloride[97] and probably fluoride[30] complexes of hexamminecobalt(III) complexes involve an increase of entropy. The enthalpy change prevents the formation of monohalide complexes of this cation in solutions at low ionic strengths. The magnitude of the hindering enthalpy effect diminishes with increase in the size of the halide ion, but the entropy contribution diminishes still further. This results in a decrease of the stability of the outer-sphere complexes in the ligand series fluoride > chloride > bromide > iodide and the logarithms of the stability constants vary in inverse proportion to the crystallographic radii of the halide ions[180]. In contrast to the monohalide complexes, the monoazide complex of hexamminecobalt(III) is formed by virtue of the decrease of the enthalpy with an insignificant effect of the entropy factor[97]. The sulphate and thiosulphate complexes are formed because of the increase of entropy in the presence of only a slightly unfavourable enthalpy effect[95,174].

Far-reaching conclusions concerning the enthalpies and entropies of formation of hexamminecobalt(III) complexes are impossible at present, since these quantities are not accurate, having been determined from the association constants found at only two or three temperatures. Direct thermochemical studies[30,100] confirm this.

The errors in the determination of the stability constants of the outer-sphere complexes of hexamminecobalt(III) and related ions may be estimated on the basis of nine investigations[95,119,125,134,157,159,165,181,182] carried out during the period between 1930 and 1967. The constant for the association of $Co(NH_3)_6^{3+}$ with sulphate ions in aqueous solutions at zero ionic strengths and 25°C was calculated in these investigations. The average value of the logarithm of the constant is 3.30 and the error in its determination amounts to approximately 6%. However, a decrease in the association constant usually entails an increase in the error of its determination.

The formation of polyligand complexes of hexamminecobalt(III) has been demonstrated by Brintzinger[38,39,68] and has been confirmed in recent years for sulphate[40], halide[40,100], thiocyanate[110], thiosulphate[40], carbonate[110], salicylate[40], ammine[108], and aquo-compounds[173]. The majority of the data on the polyligand complexes have been obtained by ion-exchange[40], extraction[34], solubility[100,108], and spectrophotometric[110] methods and by studying the adiabatic compressibility of solutions with the aid of an ultrasonic interferometer[173]. Almost all these data are qualitative or semi-quantitative. Rigorously quantitative studies have not so far been made on the polyligand complexes. However, one may note that hexamminecobalt(III) forms complex anions with an outer-sphere coordination number of 3.[38,39] Judging from anion-exchange data, the stability of these complexes decreases[40] in the following series of outer-sphere ligands: iodide > bromide > > chloride > fluoride thiosulphate > sulphate. This series is the reverse of the series corresponding to the variation of the stability of the single-ligand association complexes[10]. The reversal of the stability series of the cobalt(III) association complexes for high degrees of coordination is a consequence of the large contribution of the entropy term to the addition of the first outer-sphere ligand[95]. It is reasonable to suppose that the enthalpy term varies little with the number of the successive outer-sphere ligands, while the entropy term may decrease. Hence the reversal of the stability series for higher cobalt(III) outer-sphere complexes may be understood.

The inverse stability series of the outer-sphere complexes is also the opposite of that expected from a purely electrostatic interaction. The extent of the formation of higher outer-sphere complexes increases with the polarisibility of the ligands, which has been attributed[35] to charge transfer from the complex ion to the outer-sphere ligand. This is in good agreement with electronic spectroscopic data[110].

Experimental determination of the limiting coordination number of outer-sphere complexes is difficult because of their low stability, although extraction with non-aqueous solvents helps solve this problem. Thus in the study of extraction by cyclohexanone it was shown[41] that hexamminecobalt(III) probably coordinates eight salicylate ions. This finding is consistent with theoretical postulates concerning outer-sphere coordination[6].

It has been established[183] that the fourth chloride ion adds to hexamminecobalt(III) in 7 M aqueous hydrogen chloride solutions because under these conditions the solubility curve for hexamminecobalt(III) chloride passes through a minimum. Hence the constant for the addition of the fourth chloride ion is about 0.1.

It is interesting to note that the hexamminecobalt(III) ion combines in aqueous solutions with as many water molecules as CoL_3^{3+} ions, where L is ethylenediamine, propylenediamine, trimethylenediamine, and diethylenetriamine. Consequently all the above complexes have an outer sphere of the same composition.

The determination of the change in the volume of the solution on association of hexamminecobalt(III) with the first sulphate ion[184] showed that the volume change is almost the same as in the conversion of aquopentamminecobalt(III) into sulphatopentamminecobalt(III). Hence it follows that it is not always possible to distinguish inner- and outer-sphere complexes by dilatometric measurements.

Several studies have been devoted to the effect of pressure on the formation of chloride and sulphate complexes of hexamminecobalt(III).[117,118] The investigations were carried out conductimetrically. It has been found for the chloride complexes that the formation constant of the complex with one ligand passes through a minimum at a pressure of about 400 kg cm^{-2} and 25°C. Calculations by the van't Hoff equation showed that at pressures of 300 and 500 kg cm^{-2} the volume changes are 17 and 13 cm^3 $mole^{-1}$. These values consist of the volume change of the ions themselves and of the solvating solvent. The first type of change predominates at low pressures and the second at high pressures, where the dielectric constant of water increases with pressure.

The association of hexamminecobalt(III) has been investigated[118] in sulphate solutions at 25–40°C and pressures in the range 1–600 atm. It was found that the association is accompanied by a small positive enthalpy change at pressures below 200 atm and an enthalpy effect of the opposite sign at pressures in excess of 400 atm. The interaction is accompanied by an increase in the volume and entropy of the system, an increase of pressure and temperature reducing appreciably the contribution of the entropy component to the free energy. This has been attributed[118] to the decrease in the dielectric constant of water.

The study of the infrared spectra of freshly prepared aqueous solutions of hexamminecobalt(III) salts in the presence of an excess of sodium sulphate showed[12] the occurrence of slight outer-sphere interaction: the sulphate ion is probably coordinated as a monodentate ligand.

Interesting data on outer-sphere interactions were obtained[172] by comparing the results of conductimetric and ultraviolet spectroscopic measurements. It was found that the formation constants of single-ligand hexamminecobalt(III) complexes with chloride, bromide, iodide, and sulphate ions calculated from conductimetric data are much higher than the values obtained by ultraviolet spectroscopy. The constants were calculated on the assumption that association complexes with one ligand species only are formed. The neglect of the formation of complexes with two ligands or association complexes involving the third solvation shell of the species represented by formula (1) accounts for the observed difference. The involvement of the third shell is indicated by the virtual equality of the constants for the addition of hexammine cobalt(III) of perchlorate, chloride, and iodide ions[172], although perchlorate ions do not affect the ultraviolet spectra.

Solubility measurements led to the conclusion[108] that the hexamminecobalt(III) ion forms complexes with acetone in aqueous solutions. These compounds are probably similar to the ketone complexes of actinides[185]. It is not known whether such complexes can be regarded as products of outer-sphere coordination, because it is difficult to distinguish typical outer-sphere complex formation and solvation leading to the formation of the second solvation shell. Additional studies on the interaction between cobalt(III) complexes and various molecules are necessary.

8. TRISETHYLENEDIAMINECOBALT(III) COMPLEXES

The results of studies on the outer-sphere interaction of the trisethylenediaminecobalt(III) ion with various anions by potentiometric[30], calorimetric[30], and spectroscopic[31-36,40-46] methods constitute the main bulk of the experimental data on trisdiaminecobalt(III) outer-sphere complexes.

The circular dichroism spectra of (+)-trisethylenediaminecobalt(III) hardly change in the presence of perchlorate, chlorate, nitrite, nitrate, borate, and tetraborate ions[32,43,113]. This fact indicates the absence of measureable amounts of outer-sphere complexes. The ions enumerated above interact with trisethylenediaminecobalt(III), occupying the third coordination sphere.

Halide, pseudohalide, sulphate, sulphite, thiosulphate, selenite, tellurite, phosphate, phosphite, hypophosphite, arsenate, arsenite, hexafluoroarsenate, hexacyanoferrate(II), carbonate, oxalate, malonate, succinate, maleate, fumarate, tartrate, lactate, formate, acetate, propionate, diethyldithiocarbamate, and benzenehexacarboxylate ions have a significant influence on the circular dichroism spectrum of an aqueous solution of (+)-trisethylenediaminecobalt(III) perchlorate. Their effect is reflected[32,45] in a change in the rotatory powers *R* determined from the area of the corresponding circular dichroism bands—E_a at 4900 Å and A_2 at 4300 Å. All the ions which influence the circular dichroism spectrum form typical outer-sphere complexes.

The rotatory power of the low-frequency component E_a decreases and that of the high-frequency component A_2 increases at low concentrations of the anion. At high concentrations the opposite changes are observed, which suggests[31,32,35-37,45,46] that outer-sphere complexes of different compositions with different circular dichroisms spectra are formed when the concentration of the outer-sphere ligands is varied. The validity of this hypothesis is confirmed by careful potentiometric and thermochemical studies[30]. The e.m.f. of cobalt(III)–cobalt(II) electrodes was measured in the potentiometric experiments. The diffusion potentials of the cells were determined experimentally[28,30]. Some experiments were performed by the familiar method[4,5,186-188] for the determination of the changes in activity coefficients due to the replacement of the inert ClO_4^- ions by anionic ligands in solutions with high and constant ionic strengths maintained with lithium or sodium perchlorate. The corrections for the observed changes in activity coefficients were applied to the experimental data. The heats of formation were calculated from the thermochemical measurements and the stability constants found potentiometrically and from the solubility of trisethylenediaminecobalt(III) perchlorate. Part of the results of these investigations are compiled in Table 1, which shows that sulphate, carbonate, thiosulphate, sulphite, selenite, and tellurite ions form a series of outer-sphere complexes in which the trisethylenediaminecobalt(III) cation behaves as the central ion. The formation constants for the outer sphere complexes found by solubility, potentiometric, and calorimetric methods agree with one another for all degrees of outer-sphere coordination. The errors in the determination of the constants listed in Table 1 increase with increasing *n*, as for inner-sphere complexes.

Table 1. Stepwise thermodynamic functions of formation of outer-sphere complexes of the type $[Coen_3]A_n^{3-2n}$ in 3 *N* solutions of $Na(ClO_4, A)$ at 25°C.

Ionic ligand	*n*	κ_n	ΔH_n, kcal g-ion^{-1}	ΔS_n, e.u.
Sulphate	1	3.6	1.7	8.5
	2	1.4	0.80	3.5
	3	0.40	0.40	−0.5
Carbonate	1	2.9	1.2	6.0
	2	1.4	0.30	2.0
	3	0.40	0	−2.0
Thiosulphate	1	5.3	0.80	6.0
	2	1.7	0.40	2.5
	3	1.0	0.20	1.0
	4	0.50	0	−1.5
Sulphite	1	4.1	1.9	9.0
	2	1.5	1.0	4.0
	3	0.85	0.50	2.0
	4	0.40	0	−2.0
Selenite	1	3.6	1.4	7.0
	2	1.4	0.40	2.0
	3	0.70	−0.20	0
	4	0.30	0	−2.0
Tellurite	1	2.0	1.1	5.0
	2	1.1	0.50	1.0
	3	0.50	0	−2.0

The systems which were investigated up to high concentrations of the anionic ligands may be characterised, to within the experimental error, by four outer-sphere complexes. This agrees well with the data examined earlier in this review and also indicates a characteristic coordination number of four. The stepwise stability constants, and the enthalpy and entropy changes at all stages of outer-sphere coordination for all the complexes investigated decrease steadily with increasing coordination number or, more precisely, with increasing number of the successive ligands added to the complex (Table 1).

The substitution of outer-sphere ligands in the series sulphate, sulphite, and thiosulphate and tellurite, selenite, and sulphite increases the stability of the outer-sphere complexes at all coordination stages (Table 1). The enthalpies and entropies of formation in the first of the above two series change less regularly than the stability constants but in the second series the components of the free energy vary almost as regularly as the stability constants. The existence of these series indicates an important role of electrostatic interactions in the formation of outer-sphere complexes.

Sulphate ions exhibit a lower capacity for outer-sphere association than sulphite ions. This fact is associated with the presence of lone-pair electrons in sulphite ions[32]. Similar relative stabilities have been observed for selenate and selenite complexes of trisethylenediaminecobalt(III).[32]

The majority of outer-sphere complexes are formed by virtue of the increase of entropy, while the enthalpy change hinders their formation (Table 1). An increase of the number of the successive ligand combined reduces the entropy component. The addition of a third doubly charged ligand to trisethylenediaminecobalt(III) involves a negative or a small positive entropy change. The fourth ligand always adds a negative entropy change. This finding can be explained by the absence from the third coordination sphere of the association complex, the composition of which is represented by formula (1), of perchlorate anions when the outer sphere contains two anionic ligands of the type listed in Table 1.

For the outer-sphere complex series with the (+)-trisethylenediaminecobalt(III) central ion as an example, it has been established[30,35,45] that the circular dichroism spectra are characterised by changes in rotatory powers of alternating sign at even and odd stages of outer sphere coordination. Relative to the rotatory powers of the free complex ion, $R[A_2]$ increased and $R[E_a]$ decreased on formation of outer-sphere complexes with odd *n*. On the other hand, these changes were of the opposite sign at even stages of outer-sphere coordination. Thus for $n = 2$, $R[A_2]$ and $R[E_a]$ did not differ from the analogous characteristic for the free (+)-trisethylenediaminecobalt(III) ion. The facts considered show that symmetry elements are lost at odd stages of outer-sphere coordination and are fully (for $n = 2$) or partially (for $n = 4$) recovered in outer-sphere complexes with an even value of *n*. This finding constitutes unambiguous evidence that outer-sphere complexes are formed as a result of forces directed to fixed positions in space.

Electronic transitions of the *d*–*d* type in octahedral cobalt(III) complexes are forbidden by the selection rule. Deviations from this rule are shown[31] by (+)-trisdiaminecobalt(III) complexes as a result of the loss of a centre of symmetry. The deviations increase on formation of an asymmetric outer coordination sphere.

Electrostatic forces favour a centrosymmetric linear environment of the inner-sphere complexes on formation of outer-sphere complexes with two ligands. A tetrahedral configuration of outer-sphere complexes with four ligands is more favourable from the electrostatic standpoint than a planar square outer-sphere ligand environment of the inner sphere. An increase of the polaribility of the ions may also influence the structure of the outer sphere. Further studies are necessary to solve the problem of the geometrical configuration of the outer sphere.

The much smaller frequency shifts in the circular dichroism spectra of trisdiaminecobalt(III) as a result of the formation of outer-sphere complexes than the shifts caused by inner-sphere interaction suggest that outer-sphere coordination has only a slight direct effect on the *d* orbitals of cobalt(III). This effect is not shown at all in the visible part of the usual spectra[189].

The appearance of bands in the circular dichroism spectra as a result of an interionic electronic transition from an outer sphere ligand to the complex ion confirmed that the ions forming the outer-sphere complex exhibit mutual orientation. The closest and most probable approach of the outer sphere ligands to their coordination centre is determined by many factors, including steric factors[32,43]. The problem of the configuration of the monophosphate complex of trisethylenediaminecobalt(III) was examined from these standpoints. Interesting conclusions were arrived at also from a study of the interaction between this central ion in outer-sphere complexes with polyanions[112]. The latter have a very strong effect on the circular dichroism spectra of trisethylenediaminecobalt(III).

Numerous data have been published[96,116,120,161,190,191] on the stability of single-ligand complexes of trisethylenediamine- and, more rarely, trispropylenediamine-cobalt(III). The majority of them refer to highly dilute aqueous solutions. Under such conditions, an increase in the size of the trisdiaminecobalt(III) and outer sphere ions and a decrease of the charge of the latter reduces the stability of the outer-sphere complexes. The variation of the stability is largely consistent with the series quoted in Section 7 of this review for hexamminecobalt(III) association complexes[30,192].

It has been shown[191] that the addition of dioxan to water sharply increases the stability of trisdiaminecobalt complexes with OH^- ions, while the addition of heavy water does not have a significant effect.

Proton magnetic resonance data[44] unambiguously indicate the formation of a second coordination sphere around trisethylenediaminecobalt(III) in various solvents. Outer-sphere coordination sharply increases the activation energy for conformational transformations in the inner sphere.

The problem of the stability of CoL_3^{3+} complexes, where L = 2,2′-dipyridyl and 1,10-phenanthroline, with various ligands can be solved only qualitatively on the basis of data at present available. The study of these outer-sphere complexes by electrophoretic[103,104] and potentiometric[193] methods suggests that the replacement of 2,2′-dipyridyl by 1,10-phenanthroline reduces the stability of the cobalt(III) outer-sphere complexes.

Thermochemical study of trisethylenediaminecobalt(III) association complexes with halide ions shows that for the series of the outer-sphere ligands fluoride, chloride, bromide, and iodide the formation of outer-sphere complexes entails a sharp decrease of the entropy contribution and a decrease of the enthalpy term hindering complex formation. Since the enthalpy changes less and the formation of the outer-sphere complexes involves an increase of entropy, the stability of the association complexes with one ligand species diminishes in the above series[30].

9. ACIDO- AND AQUO-PENTAMMINECOBALT(III) COMPLEXES

The interaction of acido- and aquo-pentamminecobalt(III) complexes with various anions has been investigated by solubility[102,194], spectrophotometric[95,123,127,195], pH titration[135,195], kinetic[102], and isopiestic methods[87-91]. The formation of chloropentamminecobalt(III) complexes has been investigated most thoroughly. The association constants were determined from the solubility of the iodate of this complex, by pH titration, and by kinetic methods[102,135], the result agreeing to within 5–30%. The stability of the single-ligand complexes of chloropentamminecobalt(III) increases for the following series of outer-sphere anions: acetate < chloride < nitrate < azide < perchlorate < < glycolate < succinate < malate < tartrate < malonate < < sulphate < maleate < phthalate. This series is not consistent with the electrostatic characteristics of the outer-sphere ligands, but the available data show[102,135] that the stability of outer-sphere complexes with doubly-charged anions is higher than that of the complexes with singly-charged anions. The constants for the addition of sulphate and succinate ions to chloropentamminecobalt(III) agree with the analogous characteristics of the divalent nickel, zinc, cobalt, manganese, cadmium, and copper complexes[196]. All the above metals probably form with these ligand complexes which are largely of the outer-sphere type. This has been confirmed by other investigations[17,18].

The data in Table 2 shows that the stability of the monosulphate complexes of the acidopentamminecobalt(III) ion falls with decrease of the charge, but the stability of the outer-sphere complex remains high when L = F^-, the fluoride ion being small. The nature of ligands with the same charge also has an appreciable influence on the stability of the outer-sphere complexes. This problem should be the subject of a detailed investigation.

Table 2. Logarithms of the stability constants of outer-sphere complexes of the type $[Co(NH_3)_5L]SO_4^{Z-2}$ at 25°C in 0.1 M $NaClO_4$ solutions according to polarographic data[157].

L	lg ω_1	L	lg ω_1	L	lg ω_1	L	lg ω_1
NH_3	2.1	NO_2^-	1.7	N_3^-	1.2	F^-	1.85
H_2O	1.9	CH_3COO^-	1.65	SO_4^{2-}	1.0	—	—

Measurements have shown[87-91] that the activity coefficients of acidopentamminecobalt(III) nitrates, halides, and perchlorates are almost equal in solutions at concentrations less than 0.1 M but at higher concentrations decrease for the following series of outer-sphere ligands: chloride > bromide > iodide > nitrate and change little when the inner-sphere anions are substituted. It has been suggested[88] that, judging from the activity coefficients, the stability of the outer-sphere complexes cannot be accounted for by Coloumbic interaction.

The stability constants of single-ligand complexes of acidopentamminecobalt(III) complexes were calculated from the activity coefficients of their various salts[88,90]. The constants remained invariant when the salt concentrations were altered by a factor of 10–20. The stabilities of the outer-sphere complexes were compared on the basis of the constants referred to solutions at an ionic strength of 0.1 as standards. This comparison showed that the stability of the nitrate, iodide, and bromide complexes of acidopentamminecobalt III) increases with the size of the complex ion, while the stability of the chloride complexes varies in the opposite sense. The replacement of the *trans*-isomer of bisethylenediaminenitroamminecobalt(III) by the *cis*-isomer resulted in an increase of the stability of the halide outer-sphere complexes. This is because the *cis*-isomer has a higher dipole moment than the symmetrical *trans*-isomer. Nitrate ions, which show little tendency towards polarisation, interact to an equal degree with the *cis*- and *trans*-isomers.

The substitution in acidopentamminecobalt(III) of four ammonia molecules by two ethylenediamine molecules reduced appreciably the stability of the outer-sphere complexes. This is probably due to the contribution of dispersion forces to outer-sphere interaction[92].

A spectrophotometric method has been used to investigate the aquation of pentamminecobalt(III) containing the sulphate ion in the inner sphere and the formation of the monosulphate complex of aquopentamminecobalt(III).[95, 122,123] It was established that the aquation equilibrium involving the formation of an outer-sphere complex is displaced towards the latter. This is favoured by the enthalpy change with a small antagonistic entropy effect. Similar equilibrium with phosphate ions is strongly displaced towards the inner-sphere complex[197].

Equations have been derived for the effect of ionic strength on the stability of monosulphate complexes of aquopentammine- and hexammine-cobalt(III) complexes[95]. The form of these equations shows that the cratic contribution to the stability constants is probably represented by the coefficient of the square root of the ionic strength of the test solution in the denominator.

The chromate complex of aquopentamminecobalt(III) was studied spectrophotometrically and by pH titration[198]. Both enthalpy and entropy changes favour the formation of this outer-sphere complex, which results in a high formation constant (3.07×10^5).

10. DIACIDOTETRAMMINECOBALT(III) COMPLEXES

Diacidotetramminecobalt(III) complexes have been the subject of a large number of studies[41,93,105,128,129,131,150, 198–211]. The halide, thiocyanate, and sulphate association complexes of dichloro-, bromochloro-, and dithiocyanatobisethylenediaminecobalt were mainly investigated. A considerable proportion of these studies on outer-sphere complexes were performed in non-aqueous solvents. Stepwise outer-sphere coordination by diacidotetramminecobalt(III) ions has been demonstrated in only a few studies[41,140], but recently its occurrence has been unambiguously proved[47].

Combination of anion-exchange and extraction data led to the suggestion that three thiocyanate complexes are formed by the dithiocyanatobisethylenediaminecobalt(III) cation in 3.0 M aqueous solutions of a mixture of sodium perchlorate and thiocyanate. The results of a study of the kinetics of the substitution of the inner-sphere ions in diacidobisethylenediaminecobalt(III) complexes, could be explained only by stepwise outer-sphere coordination[47].

A spectrophotometric study[198,199] of the interaction of *cis*- and *trans*-dichlorobisethylenediaminecobalt(III) complexes with chloride and acetate ions in methanol solutions led the authors to the conclusion[71] that only the *cis*-isomer forms outer-sphere association complexes. Recent work[203] demonstrated that this is erroneous. It proved possible to show that the *trans*-isomer also forms outer-sphere complexes, but less stable than the *cis*-compound which has a high dipole moment. The low association constant for the *trans*-isomer calculated from the experimental data is also due to the neglect of the association of the chloride ion and the cation with which the ligand was introduced into the solution[207].

Thermochemical[93,105] and spectrophotometric[128,137,202] methods have been used to investigate the association of *cis*- and *trans*-dichloro-, bromochloro-, and chlorodimethylformamidecobalt(III) complexes with halide ions in *NN*-dimethylformamide (DMF), dimethyl sulphoxide (DMSO) and *NN*-dimethylacetamide (DMA). Earlier, such association was investigated by a semiquantitative kinetic method[138,140]. It was found that an increase of the size of the halide ions usually reduces the formation constant of the outer-sphere complex, but the constant is not a linear function of the crystallographic radius of the halide ion. Thus the constants for the addition of bromide and iodide ions to *cis*-dichlorobisethylenediaminecobalt(III) are almost equal. This indicates a considerable contribution to the formation of the outer-sphere complex by charge transfer from the ligand to the central group[199].

The enthalpy change in outer-sphere association is due to the formation of the outer-sphere complex and the desolvation of the interacting species. The small enthalpy of formation of chlorodimethylformamidebisethylenediaminecobalt(III) chloride shows[202] that the desolvation energy is a little higher than the association energy.

Bromide ions are solvated by dimethylformamide to a greater extent than chloride ions[212] and therefore the formation of outer-sphere complexes with bromide ions entails a greater increase of entropy than the formation of the chloride complexes[202].

The addition of the second chloride ion to *cis*-dichlorobisethylene diaminecobalt(III) takes place owing to the decrease of enthalpy and is accompanied by a decrease of entropy[202], in contrast to the addition of the first chloride ion.

An increase of the charge, a decrease of the dimensions, and conversion of the *trans*- into the *cis*-isomers of the complexes under consideration almost always increases the stability of the outer-sphere complex. A change of solvent reduces the stability of the majority of the outer-sphere complexes in the following series: DMF > DMA > DMSO. This lowering is correlated with the dielectric constants of the solvents[213,214].

The distances of average approach of the ions in outer-sphere complexes were calculated[93,199] from the stability constants in DMA, DMF, and DMSO, and were found to be smaller than the dimensions of the free complex ion. This has been explained[93,105] by postulating that the outer-sphere complexes are not formed solely by electrostatic forces. The absence of a contribution by the Coloumbic interaction to the formation of outer-sphere complexes of diacidotetramminecobalt(III) with two ligands is confirmed also by the stepwise thermodynamic functions[202] of formation of the complexes[215]. The presence of hydrogen bonds between the Werner complex and the outer-sphere ions or molecules has been confirmed by studies on proton magnetic resonance in systems containing dichlorobisethylenediaminecobalt(III) ions[44,150].

Outer-sphere complexes with a cation of the diacidotetrammine type have been assigned (on the basis of kinetic studies) a tetragonal-pyramidal structure[204], but this hypothesis requires confirmation.

11. OUTER-SPHERE INTERACTION OF COBALT(III) ACIDO-COMPLEXES

Cobalt(III) acido-complexes usually behave as ligands like any simple or complex anions. The species produced by the outer-sphere association of acido-complexes of cobalt(III) with cations showing a tendency towards the formation of covalent bonds are frequently converted into heteromononuclear complexes[164,216] or are intermediate between the latter and ion pairs. Only the interactions of the hexacyanocobalt(III) ion with alkali metals[217], lanthanides[219], cadmium[218], and hexammine- and trisethylenediaminecobalt(III)[218] cations have so far been investigated in detail in aqueous[217], mixed[219], and non-aqueous solvents.

A detailed examination of outer-sphere association complexes of cobalt(III) acido-complexes does not come within the scope of the present review, since the formation of such compounds does not characterise the capacity of cobalt(III) to form an outer coordination sphere.

12. SOME HYPOTHESES CONCERNING THE BOND IN COBALT(III) OUTER-SPHERE COMPLEXES

The numerous literature data examined in this review show that the formation of cobalt(III) outer-sphere complexes, like that of the outer-sphere complexes of other transition metals, cannot be accounted for solely by electrostatic forces. The contribution of hydrogen bonds[44] is hardly ever sufficient to prevent the mutual repulsion of the complex and outer-sphere ions bearing similar and high charges.

The type of bond in cobalt(III) outer-sphere complexes frequently depends on the structure of the inner sphere[32,220]. The presence of charge-transfer bands in the ultraviolet spectra of cobalt(III) outer-sphere complexes indicates[109-110] the occurrence of donor–acceptor electronic interaction as in the molecular complexes of benzene with iodine and other similar compounds[221,222]. It has been shown[223] that the electron is transferred from the readily oxidisable outer-sphere ligand to the central cobalt(III) ion in the complex converting it into an almost typical divalent state. This is evidence of possible formation of a dative bond in which the electron from the outer-sphere ligand is transferred to a lower free orbital of the inner-sphere complex. This mechanism of addition of outer sphere ions is denoted by the symbol *a* and is represented by the formula $M + A = M^{\delta-}A^{\delta+}$, where the symbol M denotes an inner-sphere complex with any charge, A denotes an outer-sphere ligand and the charge symbols $\delta-$ and $\delta+$ of the reaction products characterise the redistribution of electrons in the course of the formation of the outer-sphere complex. A typical example of mechanism *a* is the formation of hexamminecobalt monoiodide[109].

The stability of the bond linking the fourth (and succeeding) outer-sphere halide ions to the hexamminecobalt(III) cation increases with the dimensions of the outer-sphere ligand[5]. This phenomenon is attributed to the "hardness" (in Pearson's terminology[224]) of the central group of the outer-sphere complex and is interpreted[225] as evidence for $d\pi$–$d\pi$ interaction. It may be supposed that in this type of bond the electrons are displaced from the filled orbitals of hexamminecobalt(III) to the large halide ions or other outer-sphere ligands. This type of bond in outer-sphere complexes is denoted by the symbol *b* and is represented by the formula $M + A = M^{\delta+}A^{\delta-}$.

Mechanism *a* increases the number of electrons in the antibonding orbitals of the inner-sphere complexes and makes the inner-sphere bonds more labile[226], which is reflected in an enhanced reactivity of cobalt(III) complexes.

The outer-sphere bond types represented by mechanisms *a* and *b* are extreme. There is no doubt about the existence of intermediate bond types. This is confirmed by data on the solubility of non-electrolytic cobalt(III) complexes in aqueous salt solutions[227]. These data were explained within the framework of the formation of outer-sphere complexes[30]. In addition, the stability of the solvation shells of the reactant and product ions and molecules may play a decisive role in the formation of outer-sphere complexes.

Aquo-complexes of cobalt(III) and chromium(III) are known[4,228] to show a smaller tendency towards outer-sphere interaction with small singly-charged anions than the analogous compounds with ammonia and ethylenediamine. This difference has been explained[71] by the high positive charge on the periphery of the inner-sphere complexes the ligands of which have a large number of protons. However, one should remember[88] that hydrated cations may enter into the structure formed by water molecules. Such incorporation hinders a close contact with the anions. Ammine complexes of cobalt(III) combine with water in the second coordination sphere more slowly and less strongly, which facilitates their outer-sphere interaction with other ligands. Moreover, large complex ions enter into the structure of the solvent, forming cavities[229], the dimensions of which are sufficient to accomodate small outer-sphere ligands. Large and highly charged ligands form more stable associated species with aquo-complexes than with ammine compounds because the bonds between the water protons and the oxygen atoms of the oxy-anions are stronger than the analogous bonds with the ammine protons[230].

Dispersion forces may play a definite role in the formation of outer-sphere complexes. Forces of this type in fact lead[88] to enhanced stability of hexamminecobalt(III) complexes when ethylenediamine is gradually replaced by ammonia.

Hydrogen bonds are also important for the formation of outer-sphere complexes[44]. As a result of these forces, inner-sphere ligands combine with hydrogen and many metal ions[231] and sometimes also anions and solvent molecules.

Further expansion of work on cobalt(III) outer-sphere complexes constitutes an important task. The concept of additional specific forces must be developed or rejected. The necessity for a thorough investigation of outer-sphere complexes was pointed out also in one of the latest papers by Bjerrum[232].

Nuclear Quadrupole Resonance in Studies on Molecular Compounds

Yu.K.Maksyutin, E.N.Gur'yanova, and G.K.Semin

The review describes and gives a systematic account of data on the application of the nuclear quadrupole resonance method in studies on donor-acceptor complexes. Particular attention is paid to factors responsible for the changes in the principal parameters of nuclear quadrupole resonance spectra.
The bibliography includes 87 references.

CONTENTS

I. INTRODUCTION

The formation of a donor–acceptor bond between two valence-saturated molecules can be regarded as the result of charge transfer from the donor to the acceptor molecule[1]. The transfer of an electron from a higher, as regards energy, occupied molecular orbital (MO) of the donor to a lower vacant molecular orbital of the acceptor is accompanied by a change in electron distribution and a corresponding change in the electric field gradient at a particular atomic nucleus of the complex. Therefore the nuclear quadrupole resonance (NQR) method is very effective in studies on molecular compounds. Its application is interesting also because the field gradient is significantly influenced by various steric factors, in addition to the charge distribution in the molecule. Starting in 1953, when the first two NQR spectra of donor–acceptor complexes were published[2], the number of publications on charge-transfer complexes has steadily increased every year. However, very frequently quadrupole resonance data are non-systematic and their interpretation very contradictory.

Since in the vast majority of studies the effect of complex formation on the quadrupole spectrum of the acceptor was investigated, the type of the acceptor served as a basis for the subdivision of the available data into different sections. The type of the acceptor is determined by the type of the orbital to which the electron is transferred: for π-acceptors it is the π-electron system of aromatic and unsaturated compounds, for σ-acceptors (I_2, ICl, RX, etc.) it is a σ-molecular orbital (usually antibonding), and for v-acceptors (metal halides, organometallic compounds) it is a vacant orbital of the central atom. In the discussion of the experimental data much attention has been devoted to the analysis of those spectra which had not been fully analysed from the standpoint of chemical structure in the original papers.

The review is not concerned with problems of self-association and intramolecular coordination since the same molecule then behaves simultaneously as the donor and the acceptor. Nor are data included on the quadrupole splittings of the NMR spectra of deuterium in hydrogen bonds. A review on this topic has been recently published[3].

2. THE NUCLEAR QUADRUPOLE RESONANCE METHOD

Nuclei with spin $I \geqslant 1$ typically have a non-spherical distribution of the positive nuclear charge. A measure of the deviation from the spherical distribution is the nuclear quadrupole moment Q. The quadrupole moment is positive when the charge ellipsoid is extended in the direction of the spin and negative when the ellipsoid is compressed in this direction. In the interaction between the quadrupolar nucleus and an inhomogeneous electric field due to the electrons surrounding it, there arise energy levels associated with definite orientations of the nucleus relative to the principal axes of the tensor of the electric field gradient. Thus the difference between the levels and hence the frequency of the transition depend on the quadrupole moment of the nucleus and the electric field gradient q. The frequencies of the transitions between the levels corresponding to different orientations of the nuclear spin lie in the radiofrequency range.

These transition frequencies are a source of information about the electronic structure of the molecules. With a suitable choice of the system of coordinates, the field gradient tensor q is defined by three components:

$$q_{xx}=\frac{\partial^2 V}{\partial x^2},\quad q_{yy}=\frac{\partial^2 V}{\partial y^2},\quad q_{zz}=\frac{\partial^2 V}{\partial z^2}.$$

It is assumed that q_{zz} is the largest component and q_{xx} the smallest. All three components are related by the Laplace equation

$$q_{xx}+q_{yy}+q_{zz}=0. \qquad (1)$$

For an axially symetrical field ($q_{xx} = q_{yy}$), the energy levels are given by the simple expression

$$E_m=\frac{eQq_{zz}}{4I(2I-1)}[3m^2-I(I+1)], \qquad (2)$$

where $m = I, I-1, \ldots, -I+1, -I$ is the magnetic quantum number of the nucleus and characterises the orientation of the spin in the external field. Since the square of m appears in the equation, the energy levels (with the exception of $m = 0$ for integral spins) are doubly degenerate. The selection rule for transitions between levels is of the type $\Delta m = \pm 1$ and the transition frequency is given by

$$\nu_{m+1,m} = \frac{3eQq_{zz}}{4I(2I-1)} \frac{2|m|+1}{h}. \tag{3}$$

The quantity eQq_{zz}/h (or eQq_{zz} in frequency units, usually MHz) is called the quadrupole interaction constant.

On the other hand, when there is no axial symetry, i.e. $q_{xx} \neq q_{yy}$, the expressions for the energies become more complex and include an asymmetry parameter $\eta = |q_{zz} - q_{yy}|/q_{zz}$. For example, for nuclei with $I = 3/2$,

$$E_{\pm 1/2} = \frac{eQq_{zz}}{4}\left(1 + \frac{\eta^2}{3}\right)^{1/2}, \tag{4}$$

$$E_{\pm 3/2} = -\frac{eQq_{zz}}{4}\left(1 + \frac{\eta^2}{3}\right)^{1/2}. \tag{5}$$

The frequency of the corresponding transition,

$$\nu = \frac{eQq_{zz}}{2}\left(1 + \frac{\eta^2}{3}\right)^{1/2} \tag{6}$$

depends simultaneously on two parameters: eQq_{zz} and η. When η has not been determined by the Zeeman effect, a certain indeterminacy appears in the interpretation of data on the quadrupole resonance of the nuclei. For halogen atoms $\eta < 0.2$, which gives rise to only slight changes in frequency. For this reason, it is assumed that η for halogens is either zero or has a definite value, adopted on the basis of structural data. For the majority of other quadrupole nuclei, at least two frequencies are observed in the spectra, from which it is possible to calculate both eQq_{zz} and η. Evidently there must be a fully defined relation between these two parameters and the electronic structure of the molecule.

The charge e at a distance r from the nucleus gives rise to a field gradient at the latter:

$$q_{zz} = e\frac{3\cos^2\theta - 1}{r^3}, \tag{7}$$

where θ is the angle between the direction of the radius vector $\bar{r}$ and the z axis. For an electron in an atom, the field gradient depends on the symmetry of its orbital ψ:

$$q_{zz} = e\int \psi^2 \frac{3\cos^2\theta - 1}{r^3} dv, \tag{8}$$

where dv is a volume element.

Since the s orbital is spherically symetrical, its electrons do not contribute to the field gradient at the nucleus. For the same reason, the field gradient due to filled electron shells is zero. The contributions to the gradient by d and f electrons are insignificant for transition elements, and are in most cases neglected. The principal contribution to the field gradients comes from the p electrons of the valence shells. If the gradient due to one p_z electron is denoted by q_0 (or q_{at}), then, according to Eqn. (1), we have for an axially symetrical field

$$q_{xx} = q_{yy} = -\frac{1}{2}q_{at}, \tag{9}$$

i.e. the contribution to the field gradient by p_x and p_y electrons is smaller by a factor of 2 than the contribution by p_z electrons.

In an examination of the changes in the field gradient of an atom in a chemical bond, it is extremely convenient to estimate the gradient in terms of the population N of the p states (here the z axis coincides with the direction of the σ bond):

$$q_{zz} = \left(\frac{N_x + N_y}{2} - N_z\right) q_{at} = U_p q_{at} \tag{10}$$

The quantity U_p denotes "the number of non-balanced p electrons". The quantity q_{at} is usually determined from atomic spectra or by the atomic beam method. When the gradients are replaced by quadrupole interaction constants, Eqn. (10) can be written in the form

$$eQq_{zz} = U_p (eQq)_{at}. \tag{11}$$

Examination of the free chlorine atom as an example shows that two unshared pairs of its p electrons yield $N_x = N_y = 2$ and the valence electron gives $N_z = 1$. Then, according to Eqns. (10) and (11), $eQq_{zz} = eQq_{at}$. The chlorine atom in chemical compounds, usually the more electronegative species, attracts an additional charge. Then $N_z = 1 + i$ (i is the degree of ionic character of the bond) and $eQq_{zz} = (1 - i)eQq_{at}$. In sp-hybridisation the contribution to the field gradient by the electron in the p_z orbital diminishes $(1 + i)s$ owing to its partial s character. However, $3s^2$ electrons acquire a certain porportion of p_z character and make a contribution $2s$ to the field gradient. As a result, the gradient diminishes and

$$eQq_{zz} = (1 - i)(1 - s)\, eQq_{at}. \tag{12}$$

In aromatic and unsaturated compounds the participation of one of the unshared pairs of p electrons in the conjugation system entails a decrease of the p_x or p_y electron density at the chlorine atom and a corresponding decrease of the quadrupole interaction constant:

$$eQq_{zz} = [(1 - i)(1 - s) - \pi]\, eQq_{at}. \tag{13}$$

Eqn. (13) shows that the field gradient in the molecule depends on three parameters: i, s, and π. This gives rise to some indeterminacy in the interpretation of the NQR spectra. In many cases a knowledge of the asymmetry parameter may help significantly. By definition, $\eta = |q_{xx} - q_{yy}|/q_{zz}$ is a direct measure of the difference between the populations of the p_x and p_y orbitals. Therefore the asymmetry parameter may provide information about the double bond character. Quite often it is possible to estimate some of these three parameters from structural considerations or results obtained by other methods. Usually however, as with many other techniques, the relevant information is obtained by comparing the data within the limits of a single series or several series of compounds.

Measurements of quadrupole spectra are possible only for substances in the solid state, since in the gas or liquid molecular rotation averages out the field gradient and there is no splitting of quadrupole levels. Therefore the interpretation of the data may be somewhat complicated by the influence of the crystal lattice. However, similar difficulties are usually encountered also in studies by other methods (the solvent effect, etc.). It has been shown[4] that the effect of the crystal lattice does not as a rule exceed 2% of the measured frequency, while for a series of compounds with similar structures the standard deviation is about 0.3%.

In a description of the method as a whole one must emphasise particularly its high sensitivity to changes in the structural parameters of the molecules. A more detailed description of the essential features of the method and its applications can be found in a number of monographs and reviews[5-9].

3. FREQUENCY SHIFTS AND THE SPLITTING OF THE NUCLEAR QUADRUPOLE RESONANCE SPECTRA OF CHARGE-TRANSFER COMPLEXES

As mentioned above, the formation of a donor–acceptor type of complex is due to a partial charge transfer from the donor to the acceptor molecule. The charge transferred, the distribution corresponding to it, and the accompanying changes in the electronic structure of the interacting molecules, give rise to fairly significant changes in the field gradient at each atom of the complex.

Furthermore, new steric interactions may arise and those existing previously may change on complex formation, which naturally entails additional changes in the field gradient. The indeterminacy introduced by the crystal field is of course still present. The combination of all these factors can give rise to a very complicated pattern of NQR spectroscopic effects associated with complex formation. Therefore it is useful to carry out a preliminary analysis of the effects of the individual factors and to determine under what conditions each of them operates and what role it plays.

We shall examine the role of charge transfer or the electronic factor. The wave function of the ground state of the complex D.A can be represented as follows[1,10]:

$$\psi_N = a\psi_0(D\cdot A) + b_1\psi_1(D^+A^-)\,. \qquad (14)$$

Using this approximation, relations have been obtained[11] between the changes in the field gradient Δq_{ZZ}, on the one hand, and the degree of charge transfer b^2 and its density c^2 at the given atom, on the other:

$$\Delta q_A = \frac{b^2}{1+S^2}\sum_t c_{At}^2 q_t \text{ for the acceptor} \qquad (15)$$

$$\Delta q_D = -\left(1 - a^2 + \frac{b^2S^2}{1+S^2}\right)\sum_r c_{Dr}^2 q_r \text{ for the donor} \qquad (16)$$

where S is the overlap integral of the interacting molecular orbitals and t the atomic orbital of the atom investigated, participating in the formation of the donor–acceptor bond. We may recall that $q_s = 0$, $q_{p_z} = q_{at}$, $q_{p_x} = q_{p_y} = -q_{at}/2$ and the quantities q_d and q_f may be neglected. We shall now consider the application of Eqn. (15) to acceptors of various types (σ, π, v). For simplicity, we shall for the moment confine ourselves to halogen-containing molecules. In the first place, Eqn. (15) shows that the change in the gradient as a result of charge transfer is directly proportional to the degree of charge transfer b^2. The direction of the shift may be predicted beforehand even without calculating the electron distribution. For σ acceptors (I_2, ICl, CCl_4, $CHCl_3$, etc.), an increase of the σ-electron density of the molecule is accompanied by an increase of the population of the p_z orbital of the halogen and consequently a decrease of the field gradient. In the simplest case of a diatomic σ acceptor (I_2, ICl, IBr, etc.) Eqn. (15) yields a simple expression for the relative change in the field gradient or, putting $\eta = 0$ in Eqn. (6), the relative frequency shift:

$$\frac{\Delta q_{zz}}{q_{zz}} = \frac{\Delta\nu}{\nu} = -\frac{b^2}{2(1+S^2)}\,. \qquad (17)$$

For π acceptors (chloranil, picryl chloride, etc.) charge transfer to the π orbital increases the population of the p_x orbital of the halogen atom, which increases its field gradient. Since $q_{p_x} = -q_{at}/2$, we find, after substituting Eqn. (15) in Eqn. (13), that the field gradient at the halogen atom of the acceptor molecule increases as a result of charge transfer by an amount

$$\Delta q_{zz} = \frac{b^2}{2}c_A^2 q_{at}\,. \qquad (18)$$

The subscript t may be omitted, since the p_x orbital is non-hybridised.

As already stated, the p-electron density is closely linked to the asymmetry parameter η. Then the degree of charge transfer can be related, to an adequate degree of approximation, to the change in the asymmetry parameter $\Delta\eta$ by the expression[12]:

$$\Delta\eta = -b^2c_A^2\,. \qquad (19)$$

Eqns. (18) and (19) yield a direct relation between the changes in the characteristics of the NQR spectra and the degree of charge transfer for π acceptors. The corresponding relations for σ and π donors have been given by one of the present authors[12].

The analysis of the shifts is more complex for v acceptors. The formation of complexes by v acceptors involves in the vast majority of cases a complete rearrangement of the entire electron system of the molecule and the appearance of one or several additional vacant orbitals. The rearrangement of molecular geometry naturally involves changes in the M–X bond parameters (amount of ionic character, double bond character, etc.). Therefore, exception in certain cases, a detailed analysis of the change in the field gradient is possible only on the basis of a detailed calculation for each specific complex. The entire process may be represented approximately as consisting of two stages: direct rearrangement of the acceptor molecule MX_n and charge transfer to the vacant orbital produced, in accordance with the distribution of the charge. One can assume with reasonable certainty that, within the limits of a restricted range of complexes of the same acceptor with different donors, the change in electron distribution solely due to the rearrangement of the electron system will be approximately the same for all the complexes. Then the variation from complex to complex within the limits of this series can be fully attributed to the differences in the degree of charge transfer. An increase in the degree of charge transfer will favour an increase in electron density in the σ system of the acceptor and hence a decrease of the field gradient at the atoms X. This is the qualitative aspect of the problem. On the other hand, as already stated, the quantitative relation between the quadrupole shift and charge transfer can be revealed only by detailed calculations. However, one may suppose that this relation is fairly complicated. Sometimes, the valence bond method may be used to analyse the NQR spectra of complexes having similar compositions and structures, particularly when there is a possibility of observing the NQR spectra not only due to X atoms but also due to the central atom.

In the molecule of an n donor the coordination due to the unshared electron pair causes a shift of electron density towards the atom involved in the formation of the dative bond. When the group R contains a halogen atom X, this shift is accompanied by decrease of the ionic character of the C–X bond, which in turn leads to a high-frequency shift of the NQR spectrum of the halogen.

Thus in the general case the direction of the NQR frequency shift due to the electronic factor for both donors and acceptors is determined by the orbital involved in complex formation. On the other hand, the magnitude of the shift depends on the degree of charge transfer and the nature of charge distribution.

We shall consider how steric factors affect NQR spectra. On formation of a complex, the coordinating centres of the interacting molecules can approach one another to within distances ranging from the sum of the van der Waals radii (weak complexes) to the sum of the covalent radii (stable complexes). Both the structure of the interacting molecules themselves and their relative positions in the complex play a major role in the spectroscopic effects of complex formation[12,13]. The effect of steric factors can be ultimately divided into three types. Firstly, steric factors can prevent the mutual approach of the donor and acceptor molecules, restricting the possibility of charge transfer. Then, even when the donor has pronounced dative properties, the degree of charge transfer may be slight. This means that in this case steric factors affect electronic factors, whose relation to the field gradient has already been examined. Secondly, steric interactions can distort the geometrical structure of the molecules: they may cause changes in bond length, distort the valence angles, etc. There will be corresponding changes also in the field gradient of the atoms. Thirdly, steric effects can lead to the deformation of the electron shells of the atoms investigated due to polarisation. The last two factors are not related to the degree of charge transfer and are of independent importance. The combination of all three factors can alter significantly from complex to complex even within the limits of the same series. For this reason, their effect on the field gradient is specific for each concrete case.

Thus the change in field gradient as a result of complex formation is determined by two principal factors: electronic effects and steric interactions. On the other hand, both factors affect one another and, on the other, they compete with one another. It may be supposed that, depending on the intensity of the donor–acceptor interaction, the electronic factor will predominate in the NQR spectra of the stable complexes and the geometrical factor will predominate in those of weak complexes. The influence of the combination of the two factors leads to a very complex pattern of spectroscopic shifts which must be duly taken into account in the analysis of the NQR data.

Apart from the frequency shift, an important characteristic of the NQR spectra is their multiplicity. When the molecule contains several identical atoms with quadrupole nuclei, their frequencies may be expected to be different. Such splitting of the spectrum can be caused by differences in the electronic state of the atoms (chemical non-equivalence), steric effects, and the effect of the crystal field. The splitting due to crystal field effects is as a rule within the limits of the usual 2% range, while the splitting due to the chemical non-equivalence can be very considerable, depending on the type of electron distribution in the molecule.

This makes it possible, on the one hand, to predict the nature of the splitting in the spectrum of a complex from its electron distribution and, on the other hand, to draw conclusions from the type of splitting concerning the geometrical and electronic structure of the complex. An approximate analysis of this type has been made[12,14] for the octahedral *cis*- and *trans*-complexes $MX_4.2D$ (where X = halogen) (Fig. 1). Using molecular orbitals of symmetry O_h, the authors showed that in the *trans*-complexes all four halogen atoms have the same σ-electron density and are chemically equivalent. Therefore the splitting in the NQR spectra of the octahedral *trans*-complexes is possible only owing to the crystal field effects. Fig. 1*a* shows the hypothetical form of the spectrum of such a complex. Analogous calculation for the *cis*-complex shows that the σ-electron density for the two positions of the halogen atom (equatorial and axial) is different. Therefore considerable splitting, due to the chemical non-equivalence of these positions, should be observed in the NQR spectra of such complexes (Fig. 1*b*). Yet another interesting consequence of this calculation is noteworthy, namely that, for the same degree of charge transfer, the average shift of the NQR spectrum of the halogen in the *cis*- and *trans*-complexes is different. This must be taken into account in a comparison of the properties of donors (treated as bases) in complexes of different structures. In the simplest case the type of splitting in the spectra due to chemical non-equivalence can be determined with the aid of the symmetry properties of the complex. In symmetry operations the molecular orbitals of the complex are transformed in accordance with the irreducible representations of its point group. Therefore in symmetry operations chemically equivalent atoms will be interchanged. Hence it is not difficult to determine the number of non-equivalent positions of the halogen atom.

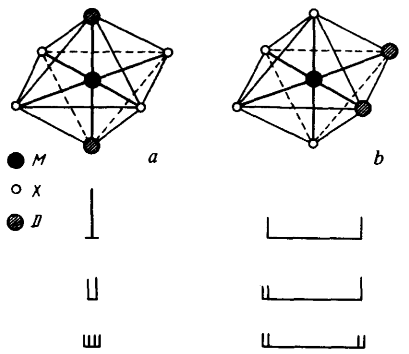

Figure 1. Schematic representation of the splitting in the NQR spectra of the octahedral complexes $MX_4.2D$: *a*) *trans*-structure; *b*) *cis*-structure.

In an analysis of the splitting in the spectra particular attention must be paid to the effect of steric factors. The role of the deformation of the angles and bonds in spectral splitting can be so marked that its importance in some cases can approach or even exceed that of chemical non-equivalence. However, as for the frequency shifts, the effect of steric factors on the splitting is highly specific for each concrete case.

4. π-ACCEPTOR COMPLEXES

Among π acceptors, the NQR method was used to study the complexes of polyhalogenobenzenes[13,15], chloranil[15,16], and picryl chloride[12,17,18]. The studies were based only on chlorine-35 frequencies.

Charge transfer in complexes of this type increases the electron density in the π system of the acceptor and consequently the spectroscopic shift should occur at high frequencies. The degree of charge transfer in the π complexes is slight and usually lies in the range 1–6%.[19] For this reason, even under conditions of complete localisation of the transferred charge at the halogen atom the quadrupole frequency shift will not exceed 5%. Hence it is easily seen that in the complexes of these acceptors steric interactions will have a dominant effect on the NQR spectra.

The effect of the geometrical structure of the molecules (or the geometrical factor) on the shift of the quadrupole spectra on complex formation was first demonstrated for the complexes of halogenobenzenes[13]. Calculation by Hückel's method[20] showed that halogenobenzenes have almost identical and very weak acceptor properties. According to X-ray diffraction analysis[21], the distance between the components of the complex is not reduced as compared with the sum of the van der Waals radii of the components. Both these findings indicate that in this case the usual intermolecular interactions predominate. This view is confirmed also by a series of physicochemical experiments[22,23].

Table 1. ^{35}Cl NQR spectra of the complexes $C_6F_5Cl.D$.

Donor	$\nu_{^{35}Cl}$, MHz
——	39.410
Benzene	38.717
Mesitylene	38.68
Chlorobenzene	39.36
Aniline	38.64
Triethylamine	39.284
Toluene	39.16

Table 1 shows that in five chloropentafluorobenzene complexes with various bases[13] the chlorine-35 frequency shifts are independent of the dative properties of the donors, a measure of which is provided by the ionisation potentials, and are determined mainly by the geometrical structure of the molecules. Thus the ionisation potentials of mesitylene and benzene (8.39 eV[24] and 9.25 eV[25]) are significantly different, but the symmetry types of both molecules are similar and the chlorine-35 frequency shift is virtually identical in both cases. In all the remaining complexes the molecular structure of the donors is extremely varied and the frequency shifts show significant differences. This suggests, in the first place, that in the complexes of chloropentafluorobenzene the degree of charge transfer is small and, in the second place, that molecular geometry plays a dominant role in the spectroscopic effects.

The nature of a slight low-frequency shift is still obscure. One can only note that the extremely short spin–lattice relaxation times for these complexes indicate that their benzene rings rotate (although at frequencies lower than those observed by NQR). Such rotation may lead to the averaging of the field gradient and hence to a lowering of the frequency.

The complexes of chloranil with mesitylene and hexamethylbenzene are more stable. The distance between the components of the complex is somewhat smaller than the sum of the van der Waals radii[26] and the degree of charge transfer is approximately 3%.[19] The observed shifts of the quadrupole spectra of these complexes occur at high frequencies, as was to be expected, but are very small (0.075 MHz[15] and 0.107 MHz[16] respectively). However, the available experimental data are too few to arrive at any definite conclusions.

A more systematic investigation of the effect of the electronic and geometrical factors on the quadrupole frequency shift has been made[12,18] for complexes of picryl chloride with aromatic donors (Table 2).

Picryl chloride can be very conveniently investigated by the NQR method. The two nitro-groups in the *ortho*-positions relative to the chlorine atom are displaced from the plane of the ring and make an angle of 80–90° with it[27]. The chlorine atom is to some extent protected from the direct steric effect of the donor molecule. When account was taken of the corresponding donor symmetry, this made possible a number of interesting conclusions concerning the effect of various factors on the NQR frequency shift.

Table 2. ^{35}Cl NQR spectra of picryl chloride complexes with aromatic donors.

No.	Donor	ν, MHz	$\Delta\nu$, MHz	Remarks
1	——	39.385	+0.193

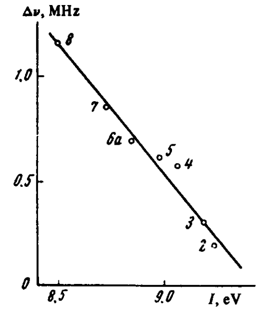

Figure 2. Variation of the ^{35}Cl NQR frequency shift for picryl chloride in complexes with monosubstituted benzene derivatives as a function of the ionisation potential of the donor (the points are numbered in accordance with Table 2).

In complexes with monosubstituted benzenes the symmetry of the donor molecules is identical and therefore one may assume that the steric interactions are also approximately the same. It has been shown for such complexes that the shift of the chlorine-35 quadrupole frequency of the acceptor varies linearly with the ionisation potential of the donor (Fig. 2). Since the degree of charge transfer in a series of complexes of the same acceptor is linearly related to the ionisation potential of the donor[28], the nature of this correlation confirms the linearly of Eqn. (15), i.e. the linearity of the relation between the quadrupole frequency shift and the degree of charge transfer.

In complexes with *para*-substituted toluenes the symmetry of the donors can also be regarded as identical. However, the presence of the *para*-substituent intensifies the effect of the steric interaction. There are two most probable positions of the *donor* molecule in the complex depending on the orientation of the CH_3 group in relation to the bulky picryl chloride group (*syn*- or *anti*-).

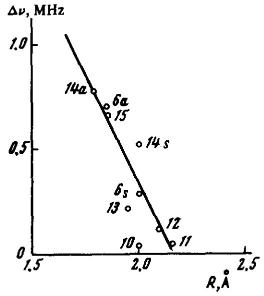

Figure 3. Variation of the ^{35}Cl NQR frequency shift for picryl chloride as a function of the van der Waals radius of the *para*-substituent in complexes with *para*-derivatives of toluene [the points are numbered according to Table 2; *a*—anti-conformation; *s*—syn-conformation].

Table 2 shows that in the majority of complexes there is only one conformation, believed[18] to be the *anti*-conformation. The doublet structure of the spectrum in many cases indicates the existence of both conformations.

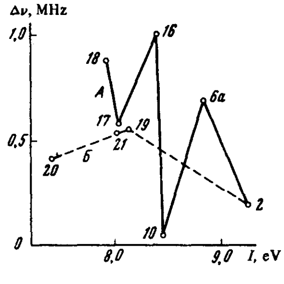

Figure 4. Variation of the ^{35}Cl NQR frequency shift for picryl chloride as a function of the ionisation potential of the donor in complexes with polymethylbenzenes (A) and condensed aromatic systems (B) (the points are numbered according to Table 2).

Furthermore, with increase of the bulk of the *para*-substituent, the distance between the components of the complex also increases, which reduces the degree of charge transfer. Therefore an increase of the bulk of the *para*-substituent in the donor molecule should cause a fall of the quadrupole frequency shift. Fig. 3 shows the variation of the quadrupole frequency shift with the van der Waals radius of the *para*-substituent. Evidently the relation is fairly well approximated by a straight line.

The effect of the molecular structure of the donor on the shift is well illustrated by the spectra of the complexes of picryl chloride with polymethylbenzenes and condensed aromatic systems (Fig. 4). With increase in the number of methyl groups in the donor molecule, the ionisation potentials of the donor decreases, but the effect of its molecular symmetry is so great that the shift does not show a definite variation from complex to complex, although its general direction is maintained. The same tendency is observed also in the spectra of the complexes of picryl chloride with polycyclic aromatic systems.

Thus the investigations show that (1) after exclusion of the effect of the geometrical factor the linearity of the relation between the quadrupole frequency shift and the degree of charge transfer is confirmed and that (2) in the presence of the combined effect of the electronic and geometrical factors the role of the latter may be very significant.

5. σ-ACCEPTOR COMPLEXES

As already stated, charge transfer to an antibonding σ orbital of the acceptor leads to a low-frequency shift in the quadrupole spectrum of the halogen. The magnitude of this shift is determined by the distribution of the transferred charge. Since in the majority of complexes of this type the degree of charge transfer is small, the frequency shift should depend significantly on the geometrical factor.

Table 3. ^{81}Br NQR spectra of the complexes $Br_2.D$.

Donor	$\nu_{^{81}Br}$, MHz	Δν, MHz
—	319.509	—
Benzene	319.616	+0.107
Fluorobenzene	319.469	−0.040
Chlorobenzene	319.483	−0.026
Bromobenzene	317.803	−1.704
	215.92*	−8.69
Dioxan	314.77	−4.74
Acetone	318.336	−1.173
Ethyl ether	320.499	+0.990

*Bromine-81 in bound C_6H_5Br.

Among complexes of σ acceptors, those of Br_2 with various *n* and π donors have been most thoroughly investigated[29-32]. Table 3 shows that, with the exception of the bromine complexes with benzene and ethyl ether, the observed low-frequency shifts are usually small and lie in the range 0.01–4%. In the spectra of the complexes $Br_2.C_6H_6$ and $Br_2.O(C_2H_5)_2$ small high-frequency shifts were observed. Comparison of the data shows that the shifts are not determined by the dative properties of the donors. As for the complexes of π acceptors, steric interactions play a dominant role in the spectroscopic effects. An attempt was made[32] to compare the dative properties of the donors with the quadrupole interaction constants of bromine atoms calculated by Eqn. (6) from the experimental frequencies for various arbitrarily specified asymmetry parameters. However, the attempt was unsuccessful because of the specificity of the steric factors.

For the complex $Br_2.C_6H_5Br$, observations were also made of the ^{81}Br NQR frequencies for the bromine atom in the aromatic system. The low-frequency direction of the shift agrees with expectation and the magnitude of the shift is 4%. In this case complex formation involves the unshared pair of electrons of the bromine atom and not the π-electron system of the ring[33]. The magnitude of the shift determines directly the decrease of electron density at the p_x orbital of the bromine atom as a result of the charge transfer. The charge transfer was estimated[32] as 8% from the relative change of the field gradient $\Delta q_{zz}/q_{zz(obs)}$. However, according to Eqn. (18), in such an estimate it is more valid to employ q_{at} instead of $q_{zz(obs)}$, since the population of the $3p_x$ orbital is influenced neither by the degree of s-hybridisation nor the amount of ionic character of the C–Br bond, on which q_{zz} depends. Generally speaking, this inaccuracy is of secondary importance in a rough estimate but may be significant in more accurate calculations. The use of q_{at} yields an estimate of about 5% for the degree of charge transfer. On the other hand, the degree of charge transfer determined from the shift of the spectrum of the Br_2 acceptor is 2%. The discrepancy between the fractions of charge transferred found for the donor and the acceptor may be accounted for by the involvement in complex formation of the vacant d orbitals of the bromine atoms in the Br_2 molecule. A similar hypothesis was also made for the complex of carbon tetrabromide with p-xylene[34,35]. The involvement of d orbitals favours a decrease of the p_z-electron density and consequently a high-frequency shift of the quadrupole spectrum of the bromine atom.

A remarkable feature of the spectra, characteristic of all bromine complexes, has also been noted[32]: the frequencies of both bromine atoms in the acceptor molecules fully coincide, without any signs of a broadening of the band. This type of phenomenon implies that their chemical and crystallographic environments are fully equivalent. X-Ray diffraction studies showed[36–39] that the complexes of bromine with benzene, acetone, and dioxan have a chain structure. It may be supposed that a chain structure obtains also in all other cases, since otherwise signs of crystallographic splitting should be observed.

The complexes of I_2, ICl, and IBr with various donors are widely known and have been fairly thoroughly investigated by other methods. X-Ray diffraction analysis has shown[40] that the length of the I–X bond in the complexes is much greater than in the initial compound, while the I... D distances are smaller than the sum of the van der Waals radii of the coordinating atoms. For a large series of complexes with amines, the degree of charge transfer has been estimated by various methods[41,42] as 20–50%. According to these data, a decrease of the frequencies in the NQR spectra by about 10–25% was to be expected. However, contrary to expectation, experiments showed[43,44] that eQq_{zz} for ^{127}I in complexes of this kind increases.

The suggested low degree of charge transfer[43,44] is inconsistent with the above results from other methods. It is also difficult to accept that, with the observed increase of eQq_{zz} (from 2156 MHz for I_2 to 3000–3100 MHz for $I_2.D$, where D = pyridine), a charge transfer of 20–50% plays an insignificant role. It is more realistic to suppose that in these complexes charge transfer is accompanied by sp^3d-hybridisation of the iodine atom[42]. We shall consider the effect of sp^3d-hybridisation and charge transfer on eQq_{zz} in greater detail. For simplicity, we shall confine ourselves to the complex $I_2.D$, where the ionic character of the I–X bond may be neglected. Five sp^3d-hybrid wave functions of the iodine atom are of the following form[45]:

$$\begin{aligned}
\sigma_1 &= \frac{1}{\sqrt{6}}(s - d_{z^2} + 2p_x),\\
\sigma_2 &= \frac{1}{\sqrt{6}}(s - d_{z^2} - p_x + \sqrt{3}\,p_y),\\
\sigma_3 &= \frac{1}{\sqrt{6}}(s - d_{z^2} - p_x - \sqrt{3}\,p_y), \qquad (20)\\
\sigma_4 &= \frac{1}{2}(s + d_{z^2} + \sqrt{2}\,p_z),\\
\sigma_5 &= \frac{1}{2}(s + d_{z^2} - \sqrt{2}\,p_z).
\end{aligned}$$

The σ_1, σ_2, and σ_3 orbitals are occupied by unshared electron pairs, the σ_4 orbital is involved in the formation of a covalent bond, and σ_5 is an acceptor orbital. After the summation of the electron densities of the p_x, p_y, and p_z orbitals, it is readily seen [Eqn. (10)] that the field gradient due to the sp^3d-hybrid valence shells of iodine is $\frac{3}{2}q_{at}$ and charge transfer leads to its decrease. Hence the degree of charge transfer in the complexes investigated is about 40–50%, which agrees fairly well with the previous results based on the dipole moments and infrared spectra.

In the complexes of carbon tetrachloride and carbon tetrabromide with various donors electrons are transferred to an antibonding σ orbital of the acceptor molecule. As already stated, this should be accompanied by a low-frequency shift of the halogen spectra. The available data for the complexes $CCl_4.D$[15,29,46,47] are non-systematic and contradictory and therefore will not be discussed. The spectra of CBr_4 complexes with a number of π donors[29,48] consist of 2–3 lines located in most cases in the same frequency range as the spectra of the initial compounds. Using X-ray diffraction data, the low-frequency lines in the spectra of the complexes were assigned[49] to the bromine atoms in the immediate vicinity of the aromatic system. The attempts to compare their frequencies with the ionisation potentials of the donors were unsuccessful. It is believed that this may be caused by intermolecular reorientation of the donor in the complex and by the difference between the Ar... Br distances.

In the complexes $AsI_3.3S_8$, $SbI_3.3S_8$, $SnI_4.2S_8$, and $SnI_4.4S_8$[50–53] coordination also involves the iodine atoms and not the central metal atom[54–56]. They too can be classified as complexes with acceptors of the σ type.

The large changes in the quadrupole interaction constants of iodine-127, antimony-121, and antimony-123 and in the arsenic-75 frequencies in the complexes $AsI_3.3S_8$ and $SbI_3.3S_8$ originate not from charge transfer but from a rearrangement of the crystal lattice when the individual compound is converted into the complex. Thus the crystals of pure AsI_3 have a layer structure with six adjacent I atoms surrounding one ^{75}As atom. On the other hand, in the complex the AsI_3 molecule has a pyramidal structure. The changes in the gradient following such rearrangement are of course appreciable. The changes in the iodine-127 quadrupole interaction constants in the remaining complexes are very slight and their interpretation is difficult.

Thus the investigation of the NQR spectroscopic effects of complex formation by σ acceptors suggests that (1), since the degree of charge transfer in these complexes is low, the geometrical factor plays the principal role in the spectroscopic effect and (2) there is a general tendency towards a low-frequency shift as a result of charge transfer.

6. THE HYDROGEN BOND

The hydrogen bond is also of the donor–acceptor type [1]. Protic acids usually behave as proton donors in the hydrogen bond. Thus they can be regarded as electron acceptors of the σ type. Using the generally adopted hypotheses concerning the nature of the hydrogen bond, this makes it possible to maintain a common approach to the analysis of the quadrupole shifts. Among systems with hydrogen bonds, complexes of certain halogen-containing acids (CCl_3COOH, $CHCl_3$, HCl, HBr) with various donors have been investigated by the NQR method [15,17,46,47,58].

The transmission of the effect of complex formation to the halogen atoms of the acceptors, which are usually remote from the coordinating centre, is achieved by an inductive mechanism and leads to an increase of the ionic character of the R–X bond. For this reason, the quadrupole spectra of the halogen-containing acids should exhibit a low-frequency shift.

The hydrogen bonds in dilute solutions are frequently investigated using acids capable of self-association. In the solid state such acids form polymeric structures when the same molecule behaves simultaneously as a donor and an acceptor. On addition of a base to such an acid (in studies by the NQR method the pure components are usually mixed), a dynamic equilibrium is established in the liquid between the self-associated species and the complex. On crystallisation both forms of associated species are maintained and the NQR spectrum shows simultaneously the frequencies of the self-associated species as well as the complex, altered by the steric and crystal field effects. It is very difficult to analyse in detail and assign the frequencies in such spectra. For this reason, it is more convenient to employ an average frequency shift in the analysis of the results. The average frequency shift will be greater, the more basic is the donor. Although this approach is very approximate, the results may be of definite interest.

A large number of molecular compounds of trichloroacetic acid with oxygen-containing substances have been investigated [59]. The multiplicity of the NQR spectra of trichloroacetic acid in these compounds is higher than in the spectrum of the initial acid and the limits of the frequency range are greatly extended. These changes were fully attributed [59] to crystal effects ignoring the possibility of charge transfer. However, trichloroacetic acid is a fairly powerful acceptor and therefore the role of hydrogen bonds may be significant. As a rule, the second component added to trichloroacetic acid was either another acid or a base. Since in the mixtures there is a possibility of the formation of associated species with a wide variety of compositions, it is interesting to examine in the light of the above considerations the distribution of the mean frequencies along the frequency scale for mixtures of both types. Fig. 5 shows such a distribution as a function of $N(\nu_{av})$. As was to be expected, the average frequencies of the complexes with bases are displaced to the low-frequency region, while those with acids remain the same as the mean frequency of the initial trichloroacetic acid (40.010 MHz).

A similar behaviour is possible also for weak acids incapable of self-association (for example, chloroform). In this case, the wek acidity favours a greater degree of dissociation of the complexes and therefore the spectrum may show together with the frequencies of the complex those of the initial acid. However, with increasing basicity of the donor, the low-frequency shift of the average frequency should increase. This tendency is observed in the spectra of the complexes of chloroform with various donors [15,46,47,58]. The chlorine-35 shifts of bound chloroform in all the complexes investigated are of the low-frequency type and are usually in the range 1 to 2.5%. A more detailed analysis is difficult, since the donors investigated have various frequencies and it is difficult to estimate the role of the geometrical factor. One can only note that on going from aromatic to oxygen-containing donors and from the latter to amines, the average low-frequency shift increases.

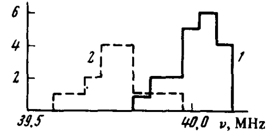

Figure 5. Frequency distribution for [^{35}Cl]trichloroacetic acid in molecular compounds with acids (1) and bases (2).

Interesting results were obtained from the NQR spectra of complexes of HCl with chlorine-containing amines [60–64]. Hydrogen chloride is close to the ionic state in such complexes and therefore the frequencies of its chlorine atoms should be close to zero, the possibility of their observation being limited in consequence. The frequencies of the chlorine present in the donors were observed in the spectra. In complexes of HCl with aliphatic amines there are high-frequency shifts in accordance with the decrease of the ionic character of the C–X bond, their magnitude reaching about 10%.

Table 4. NQR spectra of the hydrochlorides of *p*-halogenoanilines $(p\text{-}XC_6H_5NH_3)^+Cl^-$.

Compound	ν_X, MHz	$\Delta\nu/\nu$, %
$p\text{-}IC_6H_4NH_2$	261.14 521.15	
$(p\text{-}IC_6H_4NH_3)^+Cl^-$	288.28 572.15	+10.1
$p\text{-}BrC_6H_4NH_2$	221.862	
$(p\text{-}BrC_6H_4NH_3)^+Cl^-$	232.043	+4.6
$p\text{-}ClC_6H_4NH_2$	34.146	
$(p\text{-}ClC_6H_4NH_3{}^+Cl^-$	35.448	+3.8
$(p\text{-}ClC_6H_4NH_3)^+Br^-$	34.572	+1.8

In HCl complexes with *p*-halogenoanilines the effect of complex formation is transmitted to the halogen atoms in two ways. The ionic character of the C–X bond decreases via an inductive mechanism and a high-frequency shift should be observed. However, in complex formation the conjugation between the *p*-electrons of the ring and the unshared pair of the nitrogen atom is broken and the unshared pair now participates in complex formation. As a result, the conjugation between the halogen and the ring increases. The enhanced double bond character is indicated by the increase of the asymmetry parameter of the iodine atom to 7% in p-iodoanilinium chloride compared with pure p-iodoaniline ($\eta = 3\%$).[64] The increase of the conjugation between the halogen and the ring reduces the p_X electron density at the halogen, which should favour a low-frequency shift in the spectrum.

It has been shown[62-64] (Table 4) that the inductive effect prevails and the relative high-frequency shifts increase in the sequence $Cl < Br < I$. Comparison of the chlorine frequencies of p-chloroaniline in complexes with HCl and HBr shows that their H–Cl and H–Br bonds retain a certain amount of covalent character.

Thus the data quoted demonstrate that all the factors which operate in σ-acceptor complexes apply to hydrogen bonds. On the one hand, the self-association and dissociation phenomena hinder the interpretation of the NQR data and on the other serve as an additional source of information concerning the role of hydrogen bonds in solids.

7. v-ACCEPTOR COMPLEXES

The complexes of metal halides have been most completely investigated by the NQR method. In the vast majority of cases the frequencies of the halogen atoms bound to the central atom were studied. As a rule they show low-frequency shifts which are interpreted as due to an increase of the ionic character of the M–X bond. When the central atom has a quadrupolar nucleus, there is a possibility of a more complete study of the changes in the electronic structure of the acceptor molecule as a result of complex formation. Since the third section of this review dealt with a preliminary examination of the nature of the shifts and splittings in the spectra of v-acceptor complexes, we can proceed directly to a discussion of the experimental results. These can be conveniently arranged in order of the increasing Periodic Group number of the central atom.

Among Group II metal halides, 1 : 1 complexes of mercury chloride and bromide with various n-donors have been investigated by the NQR method[65,66] (Table 5). The relative low-frequency shifts of $HgCl_2$ chlorine-35 in the complexes are quite considerable, amounting to 7–15%. The complexes $HgCl_2.D$ in the solid state consist of polymeric structures comprising trigonal bipyramids linked via the edges, with the Hg atom in the centre and the donor molecule in the equatorial phase[67]. The same chlorine atom is equatorial relative to one bipyramid and axial relative to another. Therefore the splitting in the NQR spectra of complexes of this kind may be due only to crystal field effects. If one assumes that the change in the parameters of the Hg–X bonds following the change in the hybridisation of the mercury atom is the same for all complexes, the quadrupole frequency shift should be proportional to the degree of charge transfer. Indeed Table 5 shows that a decrease of the ionisation potential of the donor entails an increase of the average shift of the $HgCl_2$ chlorine-35 quadrupole frequency. It is difficult to expect a rigorously linear relation, since the geometrical factor plays a very significant role, but the general tendency is maintained.

For the complexes $HgBr_2.D$, both low-frequency and high-frequency shifts are observed. It is difficult to expect that only the geometrical factor is responsible for the 8% high-frequency shift in the spectra of the $HgBr_2$. dimethoxyethane complex. The change in the double bond character of the Hg–Br bond may also play a very significant role.

Table 5. ^{35}Cl and ^{81}Br NQR spectra of the complexes $HgX_2.D$.

No.	Complex	ν_X, MHz
1	$HgCl_2$	22.522 22.874
2	Dimethylformamide.$HgCl_2$	20.208 20.456
3	Dimethoxyethane.$HgCl_2$	21.326
4	Dimethylsulphoxide.$HgCl_2$	19.878 19.494
5	Dioxan.$HgCl_2$	21.196
6	Tetrahydrofuran.$HgCl_2$	20.584 19.272
7	$HgBr_2$	122.90 130.93
8	Dimethyl sulphoxide.$HgBr_2$ (2 : 1)	128.08 134.78 141.45 141.84
9	Dimethoxyethane.$HgBr_2$	141.23 140.40
10	Dimethylformamide.$HgBr_2$	122.87 134.60 136.00

Among compounds in Group III elements, the NQR spectra of complexes of aluminium chloride and bromide and also gallium chloride with n-donors have been investigated[2,12,68,70,71]. The only available spectrum, of the complex of $AlCl_3$ with ethyl ether[2], does not yield any definite conclusions concerning the structure, since so far the ^{35}Cl NQR spectrum of pure aluminium chloride has not been obtained. In all the aluminium bromide spectra investigated[68] appreciable low-frequency shifts of the quadrupole frequencies of the bromine atoms were observed (Table 6). Comparison of the spectra shows that in the spectrum of the complex $AlBr_3$.pyridine, which is more stable than the complexes $AlBr_3.OR'R''$ and therefore gives rise to a higher degree of charge transfer[60], there is a more pronounced low-frequency shift. Complexes of aluminium bromide with ether are of interest also from another point of view. The splitting in the NQR spectra of $AlBr_3$ in complexes with ethers of various structures indicates the occurrence of significant steric interactions between the hydrocarbon groups of the ether and the bromine atoms of the $AlBr_3$ molecule. The type of this interaction is such that, an increase in the bulk of the group increases the quadrupole frequency of the adjacent bromine atom compared with that of the bromine atom adjacent to a smaller group.
