Among the halide complexes of Group III elements, those of gallium chloride with a number of n-donors have been investigated in greatest detail[70,71]. Both chlorine-35 and gallium-69 (central atom) frequencies were found in the NQR spectraof these complexes. The variation of the NQR frequencies within the limits of a series of complexes investigated are very considerable: 16–18.5 MHz for chlorine-35 and 0–25 MHz for gallium-69. Unfortunately, the main paper on the subject[70] does not give the numerical results of the measurements and all data are presented as plots of ν_{Cl} against ν_{Ga}, ν_{Cl} against $-\Delta H$, and ν_{Ga} against $-\Delta H$, where $-\Delta H$ is the heat of complex formation in the gas phase. Nor are the relations obtained discussed from the standpoint of the chemical structure. Although lack of concrete data restricts the interpretation of the NQR spectra obtained, the observed correlations permit a number of interesting conclusions.

Table 6. ^{81}Br NQR spectra of the complexes $AlBr_3.D$.

Donor	ν_{av}, MHz
	92.00
Ethyl ether	83.49
Phenetole	85.73
Phenyl ether	86.33
Dimethyl sulphide	81.62
Pyridine	82.22

The relations between ν_{Cl} and $-\Delta H$ and between ν_{Ga} and $-\Delta H$ obtained by the author (Fig. 6) show that an increase in the strength of the donor–acceptor bond, i.e. an increase in the degree of charge transfer, entails a low-frequency shift of the frequencies of both the halogen and the central atom. Furthermore, the presence of such relations confirms directly the earlier conclusion that the effect of charge transfer on the NQR spectroscopic shift predominates over the effect of steric factors in complexes of v acceptors.

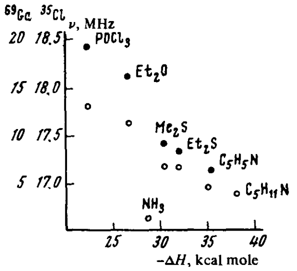

Figure 6. Variation of the average ^{35}Cl (o) and ^{69}Ga (o) NQR frequencies with the energy of the donor–acceptor bond in the complexes $GaCl_3.D$ (Figure taken from Tong[70]).

The correlation between the chlorine-35 and gallium-69 frequencies, presented by the author in a graphical form and in the form of the equation

$$\nu_{Cl} = 16.326 + 0.826\,\nu_{Ga},$$

is of considerable interest. The equation permits the estimation of the type of distribution of the transferred charge in the $GaCl_3$ acceptor molecule. Assuming that the sp^3-hybridisation of the gallium atom remains unchanged, the equation can be reformulated as follows:

$$\Delta e_{3Cl} = 2.5\,\Delta e_{Ga},$$

where Δe_{3Cl} is the overall change in electron density at all three chlorine atoms as a result of charge transfer and Δe_{Ga} is the analogous change at the gallium atom. This equation characterises the distribution of the transferred charge in the $GaCl_3$ acceptor molecule, i.e. 2/7 of the charge is localised at the central Ga atom and 5/7 is distributed among the three chlorine atoms. These results are notable because they refer to one of the first experimental estimates of the distribution of the transferred charge.

Above it was shown (Section 2) that the multiplicity of the spectra of the complexes may be used to investigate their geometrical structures. In addition to a theoretical examination of this problem, Babushkina et al.[4] made an experimental study of a number of hexaco-ordinated tin tetrachloride complexes. By comparing the experimental splitting of the chlorine-35 spectra with the theoretical scheme for the complexes $MX_4.2D$ with various geometrical structures, the structures of a number of octahedral $SnCl_4.2D$ complexes were established. Some of these complexes were investigated also by other workers[2, 46, 65, 72].

Table 7. ^{35}Cl NQR spectra of the complexes $SnCl_4.2D$.

Complex	ν, MHz	Structure
$SnCl_4\cdot 2\,(C_2H_5)_2O$	19.438 19.473	*trans-*
$SnCl_4\cdot CH_3O\,(CH_2)_2OCH_3$	19.620	*trans-*
$SnCl_4\cdot CH_3O\,(CH_2)_4OCH_3$	19.428 20.160	*trans-*
$SnCl_4\cdot 2POCl_3$	19.035 19.807 21.146	*cis-*
$SnCl_4\cdot 2C_2H_5OH$	17.498 17.750 20.120 20.568	*cis-*
$SnCl_4\cdot C_6H_5NO_2$	20.832 20.952 23.152 23.208 23.336	*cis-*

The complexes $SnCl_4.2C_2H_5OH$, $SnCl_4.2POCl_3$, and $SnCl_4.C_6H_5NO_2$ have been assigned the *cis*-structure (Table 7). On the basis of the average low-frequency shift, the dative properties of the donors can be arranged in the series $C_2H_5OH > POCl_3 > C_6H_5NO_2$. The complexes $SnCl_4.2(C_2H_5)_2O$, $SnCl_4.CH_3OCH_2CH_2OCH_3$, and $SnCl_4.CH_3O(CH_2)_4OCH_3$ have the *trans*-configuration and the last two complexes have a chain structure in the solid state (Fig. 7). Since the complexes $SnCl_4.RO(CH_2)_2OR$ have the *cis*-structure in solution, it was concluded that the *cis*-form isomerises to the *trans*-form when the complexes are crystallised from solutions.

The literature data[73-75] on the structures of certain complexes confirm these results. High-frequency shifts of the $POCl_3$ chlorine-35 transition have been found for the complex $SnCl_4.2POCl_3$. On average they amount to 4%. The shifts indicate that, on formation of the complex with $SnCl_4$, the ionic character of the P–Cl bond diminishes by 2.1%.

The structure of the octahedral complexes of antimony pentachloride of type $SbCl_5.D$ is very close to that of the octahedral complexes of tin tetrachloride. Their symmetry belongs to the point group C_{4v}. Consequently 4 of the 5 chlorine atoms should be equivalent (equatorial atoms). The non-equivalent (axial) atom is in the *trans*-position in relation to the donor molecule. Accordingly,

when steric factors and the crystal field effects are disregarded, the ^{35}Cl NQR spectra of the complexes $SbCl_5.D$ should consist of 2 lines with an intensity ratio of 4 : 1.

The spectra of two antimony pentachloride complexes ($SbCl_5.CH_3CN$ and $SbCl_5.POCl_3$) have been obtained[72,76]. As was to be expected, the ^{35}Cl NQR spectrum of the $SbCl_5$ molecule in the complex with acetonitrile consists of two lines with an intensity ratio of 4 : 1 and a splitting of 1.5 MHz. The frequency assignment gives rise to no doubt in this case. The steric effect of the donor molecules in the complex $SbCl_5.POCl_3$ on the quadrupole frequencies of the equatorial chlorine atoms in $SbCl_5$ is so great that the resulting splitting exceeds the frequency difference caused by the chemical non-equivalence. For this reason, in order to assign the frequencies, it was necessary to investigate[76] their temperature variation.

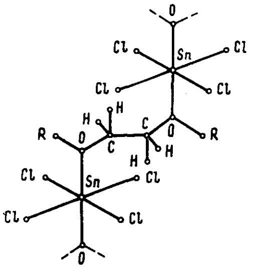

Figure 7. Structure of the complex $SnCl_4.RO(CH_2)_2OR$.

The chlorine-35 frequency shifts together with the quadrupole interaction constants of antimony-121 and antimony-123 (spins of 5/2 and 7/2 respectively) make it possible to estimate the degree of charge transfer and the type of its distribution in the acceptor molecule. For simplicity we shall assume that, when the sp^3d-hybridisation of the antimony atom changes to sp^3d^2-hybridisation, the amount of ionic character of the Sb–Cl bond is unaltered. Then the increase of electron density at the chlorine atoms can be fully attributed to charge transfer. The overall charge transfer is about 35%. Using the hybrid orbitals, it is possible to calculate that the increase of the charge at the antimony atom as a result of complex formation is approximately 5 and 10% respectively for $SbCl_5.CH_3CN$ and $SbCl_5.POCl_3$. Thus the overall degree of charge transfer is about 40–45% for both complexes. It is interesting to note that the charge transferred is preferentially localised at the chlorine atoms, probably due to their high electronegativity.

As for the complexes of antimony pentachloride, the presence of two isotopes (antimony-121 and antimony-123) permits the determination of eQq_{zz} and η for antimony trichloride and tribromide in complexes with various aromatic bases[47,65,76–85]. Extensive experimental data have revealed the following trends in the changes of quadrupole spectra on formation of the complexes $SbX_3.D$ and $2SbX_3.D$: (1) the shift of eQq_{zz} for antimony is in most cases towards higher frequencies; (2) for 2 : 1 complexes, eQq_{zz} is usually higher than for 1 : 1 complexes; (3) for 1 : 1 complexes, some parallelism in the increase of eQq_{zz} with increase of the ionisation potential of the donor is observed; (4) the average $SbCl_3$ chlorine-35 frequencies in the complexes are slightly displaced to the low-frequency region relative to the frequency of the initial $SbCl_3$; in antimony tribromide complexes such shifts are hardly ever observed; (5) in most of the $2SbX_3.D$ complexes the two acceptor molecules are non-equivalent.

The interpretation of the changes in eQq_{zz} in these complexes is very complicated, since on complex formation the partially sp^3-hybridised atomic orbitals of antimony become in addition partially d-hybridised. Neglecting the d-hybridisation, the authors[79–84] interpret the decrease of eQq_{zz} by electron transfer to the p_x or p_y atomic orbitals of antimony and the increase by transfer to the p_z orbital. However, this interpretation is not unique. In the first place, direct transfer of electrons to the p_x, p_y, or p_z orbitals is impossible, since three of the sp^3-hybrid orbitals participate in the formation of Sb=Cl bonds and the fourth is occupied by an unshared electron pair. Moreover, sp^3d-hybridisation leads to a change in the distribution of electron density between the s, p, and d orbitals. For a sufficiently high degree of d-hybridisation, the contribution to eQq_{zz} due to such redistribution may be very considerable. Therefore neglect of d-hybridisation can lead to an incorrect interpretation of the experimental data.

The overall change in eQq_{zz} on complex formation can probably be regarded as a result of the operation of two principal effects (excluding the steric and crystallographic effects): sp^3d-hybridisation with a corresponding change in the populations of the p orbitals and charge transfer to the vacant orbital.

It has been shown by infrared spectroscopy[86] that the complex $2SbCl_3.C_6H_6$ has C_{2v} symmetry. From this point of view, and also taking into account the maximum repulsion between the "ligands" and the unshared pair of the antimony atom, sp^3d_{xy}-hybridisation is most appropriate[45]. Then an increase of the degree of d-hybridisation hardly alters the p_z character of the unshared electron pair and reduces significantly the populations of the p_x and p_y orbitals. Consequently a change in hybridisation leads to an increase of eQq_{zz} [see Eqn. (10), remembering that the sign of q_{at} for antimony is the opposite of that for the halogen]. Charge transfer to the vacant hybrid orbital corresponds to an increase of p_x- and p_y-electron density and leads to a decrease of eQq_{zz}. This view appears to be more appropriate for the explanation of the available experimental data. One may assume that in complexes of the same acceptor, for example $SbCl_3$, the degree of d-hybridisation is approximately the same and leads to the same increase of eQq_{zz}. Then, following an increase in the degree of charge transfer, eQq_{zz} in this series of complexes will diminish. Such a tendency is observed very distinctly in the complexes $SbCl_3.D$; when the ionisation potential of the donor falls, the degree of charge transfer increases and eQq_{zz} diminishes. In a complex $2SbX_3.D$ the degree of charge transfer to one of the acceptor molecules will of course be smaller than in a complex $SbX_3.D$ and therefore eQq_{zz} for D will, of course, be greater. The increase of the antimony field gradient in most of the complexes and the slight low-frequency shifts in the quadrupole spectra of the halogens suggests a low degree of charge transfer in these complexes. Steric factors would then, of course, play a very significant role. Despite the large number of experimental data, a more detailed analysis of the effects of the electronic and steric factors in these complexes is still difficult.

An attempt has been made[86] to establish the steric structure of the complex $2SbCl_3.C_6H_6$ by the Zeeman analysis of the quadrupole spectra. It was shown that the geometry of both $SbCl_3$ molecules is distorted only slightly. The relative positions of all three molecules in the complex can probably be elucidated in detail by X-ray diffraction analysis.

As for the antimony trichloride complexes, only slight chlorine-35 frequency shifts were observed in the complexes $AsCl_3.Ar$.[65,85] By analogy with the splitting of the chlorine-35 frequencies and the splitting of the spectra of antimony trichloride complexes, the authors established that the structure of the $2AsCl_3.D$ complexes investigated is analogous to that of the corresponding complexes $2SbCl_3.D$.

While in the above investigations the spectroscopic shifts of the acceptors for various dative properties of the donors were mainly compared, Rogers and Ryan[72] attempted to use the frequency shifts of the donors to compare the acceptor properties of certain metal halides. According to the $POCl_3$ chlorine-35 shift in the complexes $MX_n.POCl_3$, the acceptor properties of the metal chlorides vary in the sequence $SbCl_5 > FeCl_3 > SnCl_4 > TiCl_4$. After appropriate development, it will probably be possible to use this method for the determination of the electron affinities of acceptors.

Thus the effect of complex formation by *v* acceptors on NQR spectra is as follows.

1. The change in the field gradient at the central atom is determined mainly by two factors—the change in the hybridisation of the valence shell and in the degree of charge transfer. In most cases the effect of electronic factors is considerable, while steric factors play a secondary role.
2. The frequencies of the quadrupole spectra of the halogens are displaced towards lower values as a result of an increase of the ionic character of the M–X bond. This shift is higher, the greater is the degree of charge transfer. An appreciable effect of steric factors is characteristic of weak complexes.
3. The type of splitting in the spectra is largely determined by the symmetry of the complex formed. This splitting is caused by the chemical non-equivalence of the halogen atoms in the complex. The magnitude and nature of the splitting can serve as an additional source of information about the electronic and steric effects in the complexes investigated.

---o0o---

The results of the investigations demonstrate in the first place that the shift of the NQR frequencies for the complexes is closely related to the degree of charge transfer. Although there is as yet no direct experimental proof of this relation, theoretical studies and many indirect experimental data suggest that this relation should be of the type of direct proportionality. The type of splitting in the spectrum is determined by the distribution of electron density in the molecule and the symmetry of the complex. Steric effects can, on the one hand, obscure the effects of electronic factors and, on the other hand, they can serve as an additional source of information about the steric structure of the complexes in the crystal.

Summarising the results of the investigations, we should note that, despite the small number of studies, NQR has proved useful as a very effective method for the investigation of molecular compounds. It is effective because NQR is directly related to the distribution of electron density among the bonds in the molecule. Even slight changes, as regards energy, in electron distribution are reflected in NQR spectroscopic parameters. From this point of view, the NQR method is very promising for chemical structure analysis.

The temperature variation of the frequencies and the asymmetry parameters is of great interest for the investigation of charge-transfer complexes. Recent studies have shown that these relations can yield information about the intra- and inter-molecular motions in crystals.

The review does not deal at all with the problem of the effects of complex formation on the spin–lattice (T_1) and spin–spin (T_2) relaxation times. The number of studies in this field is so far small. This branch of NQR spectroscopy has been scarcely applied in the study of molecular compounds.

Investigation of the Association of Alcohols and Phenols by the NMR Method

A.I.Brodskii (deceased), V.D.Pokhodenko, and V.S.Kuts

The review discusses and analyses the literature on the study of the association of alcohols and phenols by the NMR method. The methods for the determination of the equilibrium constants and heats and entropies of formation of the association complexes of the above substances in both inert and basic solvents are described for equilibria of different types.

The polar and steric effects of the substituents in alcohols and phenols on the thermodynamic functions for the formation of self-association complexes and also of association complexes with polar molecules has been analysed.

The bibliography comprises 151 references.

CONTENTS

I. INTRODUCTION

In recent years the nuclear magnetic resonance (NMR) method has been widely used in structural investigations and also in the study of problems such as isomerism, tautomeric equilibria, reaction rates, and others[1-3]. An important application of the method is also the study of intermolecular interaction and in particular association processes in hydrogen-bonded systems. The wide use of NMR for this purpose is due to its many advantages compared with the traditional procedures for the investigation of hydrogen bonds, for examples infrared spectroscopy. The advantages include primarily the relative simplicity of the NMR spectra and a fairly high sensitivity of the method, which allows the observation of shifts due to the formation of hydrogen bonds even in the case of relatively weak interactions. The availability of a frequency scale for NMR measurements permits the determination of the lifetime of the association complex formed by hydrogen bonding or the limits of existence of the complex. When strong intramolecular hydrogen bonds are formed, the band due to the OH group in infrared spectra is frequently so diffuse that it is very difficult to observe. In contrast, the detection of such bonds by NMR spectroscopy does not present difficulties, since the NMR signals in liquid specimens and in solutions are as a rule fairly narrow. The NMR method permits the investigation of aqueous solutions, the study of which by infrared spectroscopy is difficult due to the opacity of water as a solvent in the relevant regions of the infrared spectrum.

Numerous studies on association processes using NMR undertaken after the initial investigations[4,5] showed that a general property of systems with intermolecular hydrogen bonds is a parallel shift of the proton signal of the OH group with temperature and with dilution. Studies on the concentration and temperature dependence of the NMR signal yielded extensive data on the characteristics of hydrogen bonds, led to the determination of the degree of association in various systems, and made it possible to establish the effects of polar and steric factors in molecules on the thermodynamic characteristics of the formation of association complexes.

The problems associated with the application of the NMR method in the study of hydrogen-bonded systems are discussed in a number of monographs and reviews[1-3,6-12]. However, most of them do not deal with the many studies carried out in recent years.

This review presents a discussion of the results obtained in studies by NMR of the association of alcohols and phenols. In this connection the methods for the determination of the equilibrium constants and other thermodynamic properties of the formation of association complexes are briefly described. The self-association processes of alcohols and phenols in inert solvents and their association with bases are discussed.

The review is not concerned with problems of the hydrogen bond theory, which are discussed at a contemporary level in a number of publications[13-16] or with the nature of and methods for the calculation of chemical shifts accompanying hydrogen bond formation[13,17-24].

II. SELF-ASSOCIATION

1. Self-association Equilibrium Constants

In pure liquids and also in solutions of many substances in an inert solvent, there is a possibility of the formation of association complexes of molecules of one kind. In contrast to other spectroscopic methods[1], in the NMR spectrum the proton involved in the hydrogen bond gives rise to one averaged signal, the chemical shift of which corresponds to a mean screening for all the existing states when account is taken of their statistical weight. This is because the frequency with which hydrogen bonds are formed and dissociated exceeds by several powers of ten the frequency at which resonance absorption by protons is usually observed[25,26]. This property is responsible for certain unusual features in the method used to find the association parameters—equilibrium constants and thermodynamic functions—from NMR data.

Consider the monomer—n-mer equilibrium[2,27,28]:

$$nA \rightleftarrows (A)n \,. \qquad (I.1)$$

We shall denote by A_0, C and S the initial concentration of substance A, the equilibrium concentration of the association complex, and the initial concentration of the inert solvent (with $A_0 + S = 1$), and by n the number of monomeric molecules entering into the composition of the self-association complexes. Then the equilibrium constant expressed in mole fractions is

$$K = \frac{c\,[1-(n-1)\,c]^{n-1}}{(A_0 - n\,c)^n}\,. \qquad (I.2)$$

The chemical shift of the average signal τ in cyclic association is defined by the expression

$$\tau = \frac{n\,c}{A_0}\,\tau_n + \frac{(A_0 - n\,c)}{A_0}\,\tau_m = n\,\alpha\,\Delta\tau + \tau_m, \qquad (I.3)$$

and in linear association by the expression

$$\tau = \frac{(n-1)\,c}{A_0}\,\tau_n + \frac{A_0 - (n-1)\,c}{A_0}\,\tau_m = \alpha\,(n-1)\cdot\Delta\tau + \tau_m, \qquad (I.3^a)$$

where τ_m and τ_n are the chemical shifts of the proton in the free and hydrogen-bonded states, τ is the observed chemical shift of the proton, $\alpha = C/A_0$ the degree of self-association, and $\Delta\tau = \tau_n - \tau_m$.

It is clear from Eqns. (I.2), I.3), and (I.3^a) that, when τ_m, τ_n, and the initial concentration A_0 are known, it is possible to find the degree of association α and the equilibrium constant K for the formation of the association complexes. However, the determination of exact values of τ_m and τ_n is a complex problem. The difficulties in the determination of the first chemical shift are associated with the inadequate sensitivity of modern NMR apparatus, which precludes measurements at very low concentrations where the existence of the solute in the monomeric state is most likely. Moreover, even at the lowest concentration there is no certainty that the given substance is entirely present as the monomer (this applies, for example, to carboxylic acids). The chemical shift τ_n cannot be determined accurately because of the presence in concentrated solutions of association complexes of species with a degree of polymerisation different than that of n-meric molecules and also because of the possible presence of unassociated molecules. Therefore various approximations are usually employed in the determination of association parameters from NMR data.

Let us consider the variation of the chemical shift at low concentrations of the solute ($A_0 \to 0$). At the point $A_0 = 0$ the slope of the extrapolated chemical shift–concentration curve is defined by the following expressions: for a cyclic association complex,

$$\left(\frac{d\tau}{dA_0}\right)_{A_0\to 0} = n\,\Delta\tau\left(\frac{d\alpha}{dA_0}\right)_{A_0\to 0}, \qquad (I.4)$$

and for a linear association complex,

$$\left(\frac{d\tau}{dA_0}\right)_{A_0\to 0} = (n-1)\,\Delta\tau\left(\frac{d\alpha}{dA_0}\right)_{A_0\to 0} \qquad (I.4^a)$$

The quantity $(d\alpha/dA_0)_{A_0\to 0}$ is found by differentiating Eqn. (I.2) with respect to A_0. It has been shown[27-29] that only for monomer–dimer equilibrium ($n = 2$) is $(d\alpha/dA_0)_{A_0\to 0}$ and hence the slope of the chemical shift–concentration curve non-zero. Then

$$\left(\frac{d\alpha}{dA_0}\right)_{A_0\to 0} = K_2\,.$$

Examination of the variation of the chemical shift at very low concentrations ($A_0 \to 0$) does not eliminate the difficulty in the determination of the equilibrium constant because of the complexity of the accurate measurement of $\Delta\tau$,[29] although it does make it possible to establish the type of association. However, it should be noted that a non-zero slope of the concentration variation of the chemical shift at low concentrations is observed also for the monomer + (n −1)-mer ⇌ n-mer association[28].

At moderate and high concentrations of the solute, in contrast to the region of low concentrations, the concentration variation of the chemical shift deviates from linearity even in the monomer–dimer equilibrium, as follows from the simultaneous solution of Eqns. (I.2) and (I.3) or (I.2) and (I.3^a). Moreover, the deviation of the relation from linearity also occurs due to the presence in solution of association complexes of higher orders than at low concentrations.

For simplicity, it is usually assumed that even at high concentrations only one type of association occurs in solution. In this approximation simultaneous solution of Eqns. (I.2) and (I.3) with $|\tau_m| > |\tau_n|$ leads to the expression[12]

$$\frac{\tau_m - \tau}{\tau_m - \tau_n} = n\,K\,A_0^{n-1}\left(\frac{\tau - \tau_n}{\tau_m - \tau_n}\right)^n. \qquad (I.5)$$

Since

$$\frac{\tau_m-\tau}{\tau_m-\tau_n}+\frac{\tau-\tau_n}{\tau_m-\tau_n}=1,$$

Eqn. (I.5) can be reduced to the form

$$\sqrt[n]{\frac{\tau_m-\tau}{A_0^{n-1}}}=\sqrt[n]{n\ \ K\ \ (\tau_m-\tau_n)}-\sqrt[n]{n\ \ K\ \ (\tau_m-\tau_n)^{1-n}}\ \ (\tau_m-\tau) \tag{I.6}$$

or

$$(\tau-\tau_n)^n A_0^{n-1}=(\tau_m-\tau_n)^n/n\ \ K-(\tau_m-\tau_n)^{n-1}\ \ (\tau-\tau_n)/n\ \ K\,. \tag{I.6a}$$

Eqns. (I.6) and (I.6^a) permit the graphical determination of the association order n, $\Delta\tau$, and the equilibrium constant. The accuracy of the determination of the last two quantities by this method depends entirely on the accuracy of the determination of the chemical shift of the monomer τ_m or the chemical shift of the n-mer τ_n.

The dependence of the chemical shift on the logarithm of the solute concentration usually has a point of inflection[12,30–32], the position of which is determined by the degree of association. Indeed, knowing the approximate values of τ_m and τ_n and taking the second derivative of the logarithmic form of Eqn. (I.5) with respect to the logarithm of the concentration, we find that at the point of inflection

$$n=\left(\frac{\tau_p-\tau_n}{\tau_m-\tau_p}\right)^2$$

where n is the integral value of the association order and τ_p the chemical shift at the point of inflection. Combination of Eqn. (I.5) with its logarithmic form and the derivative of the latter with respect to the logarithm of the concentrations yields

$$\tau_m=\tau_p+\frac{1}{\sqrt{n}-1}\left(\frac{d\tau}{d\ln A_0}\right)_p,$$

$$\tau_n=\tau_p-\frac{\sqrt{n}}{\sqrt{n}-1}\left(\frac{d\tau}{d\ln A_0}\right)_p, \tag{I.7}$$

$$\ln K=(n-1)(-\ln A_0)_p-\frac{n+2}{2}\ln n.$$

The method described permits the determination of the association order from approximate values of τ_m and τ_n and also the calculation of the equilibrium constant and more accurate values of τ_m and τ_n.

If the point of inflection in the relation between the chemical shift and the logarithm of the concentration is outside the limits of measured values of τ, the association parameters are usually determined by comparing the experimental variation of the chemical shift τ with that calculated from the modified Eqn. (I.5) for different n.[30,32] It is noteworthy that this method is far from accurate and frequently yields markedly different results for the same systems[33].

The above methods for the determination of association parameters make it possible to find fairly reliably only the association order n, while the accuracy of the calculated equilibrium constant is lower. The reliability of the calculated equilibrium constants may be significantly enhanced using, for example, the linearity of the dependence of the chemical shift on the degree of association α. By determining α from Eqn. (I.2) and substituting it in Eqn. (I.3), we find that

$$\tau=n\,\alpha(K,A_0)\,\Delta\tau+\tau_m\,. \tag{I.8}$$

By varying K successively in the function $\alpha(K, A_0)$, we find its value which gives the maximum correlation coefficient of the linear equation (I.8). This method has the advantage that it is not necessary to know τ_m and $\Delta\tau$ in order to find K. It was used in our determination[34] of the monomer–dimer equilibrium constants in the study of the association of dihydric and trihydric phenols.

In a number of investigations it has been shown[35–37] that the quantities τ_m and $\Delta\tau$ are almost independent of temperature. This made it possible to determine the heat of formation of the dimeric association complexes (ΔH) from the variation of the slope of the chemical shift–concentration curve with temperature using Eqn. (I.4):

$$\ln\left(\frac{d\tau}{dA_0}\right)_{A_0\to 0}=-\frac{\Delta H}{RT}+\text{const.} \tag{I.9}$$

In the monomer–n-mer equilibrium the heat of formation of the association complexes is determined either from the temperature variation of the point of inflection in the relation between the chemical shift and the logarithm of the concentration [Eqn. (I.7)] or from the temperature variation of the chemical shift at a given concentration[33]. In this case combination of Eqns. (I.2) and (I.3) with the equation $RT\ln K = -\Delta H + \Delta S T$ leads to the expression

$$\ln\left(\frac{\tau_m-\tau}{(\tau-\tau_n)^n}\right)=-\frac{\Delta H}{RT}+\text{const.} \tag{I.10}$$

In the approximation discussed ΔH is determined by varying n in such a way that the maximum correlation coefficient of the linear equation (I.10) is obtained for the given τ_m and τ_n.

A significant disadvantate of the method described is the need for accurate values of τ_m and τ_n, which are almost impossible to determine from the temperature variation alone. There is more justification for the use of these quantities found from the concentration variation in combination with data on the temperature variation of the chemical shift at a given concentration in order to determine the effect of temperature on the equilibrium constant.

2. Alcohols

In the study of the self-association of aliphatic alcohols (methyl, ethyl, isopropyl, and t-butyl), it was found that the difference between the chemical shifts of the monomeric species and species associated to the maximum extent (the self-association shift $\Delta\tau$) is approximately constant and of the order of 5 p.p.m.[35,38] This shift is so large that, on maximum dilution, the signal of the OH proton is displaced towards stronger fields than those in which the signal of the CH_3 is located. However, despite the approximately equal values of $\Delta\tau$ for these alcohols, the degree of their self-association decreases appreciably on going from methyl to t-butyl alcohol[39,40].

The composition of the multimers formed in the self-association of aliphatic alcohols has been investigated in a number of studies. Thus, by comparing the results of the measurements of the concentration dependence of τ^{OH} for methyl and t-butyl alcohol with calculated data for the monomer–dimer, monomer–trimer, and monomer–tetramer equilibria, it was found[30,41] that methanol is present in solution mainly as tetrameric association complexes and t-butyl alcohol mainly as trimeric complexes. In contrast, the study of the concentration variation of τ^{OH} for ethanol in carbon tetrachloride at very high dilutions showed[42] that the association complexes of this alcohol are predominantly dimeric. This finding agrees with the results of an infrared spectroscopic study by the same investigators[43]. Assuming that aliphatic alcohols are present in solution as dimers, the heats of formation of the association complex ΔH were determined[35] and were found to be very close to the values obtained by the infrared spectroscopic method[43]. The dimeric association of aliphatic alcohols is also indicated by other results[44].

A detailed study of the composition of the association complexes of the alcohols and their thermodynamic characteristics was made by Feeney and Walker[33]. Since the values of ΔH for the bond O–H...O are usually in the range between 3 and 6 kcal mole^{-1},[1] they calculated from the temperature variation of τ^{OH} for methyl, ethyl, and t-butyl alcohols the heats of formation of the linear and cyclic dimers, trimers, and tetramers. From the ΔH values thus obtained, only those in the range 3–6 kcal mole^{-1} were selected. The results led to the conclusion that methyl alcohol forms in solution both linear and cyclic tetramers. In ethanol both linear and cyclic trimers and tetramers are possible, while for t-butyl alcohol ΔH indicates the presence in the solution predominantly of cyclic trimers. In their investigation a number of critical remarks were made concerning the results obtained in earlier studies. Thus Feeney and Walker[33] believe that the method involving the comparison of experimental and calculated concentration variation for *n*-mers[30] cannot be used for an accurate determination of either the type or the parameters of association. This method can indicate the order of association predominating only at a particular concentration, which makes it difficult to compare the results obtained in different investigations. On the other hand, the conclusion arrived at by Becker et al.[42] that monomer–dimer equilibrium occurs in alcoholic solutions is doubtful, since their investigation was made at a very high dilution. At higher concentrations the existence of other types of *n*-mers is quite possible.

The formation of cyclic t-butyl alcohol trimers is explained[33–45] by steric hindrance of the t-butyl groups which prevents the linear association of the molecule. Moreover, the specific stability of the six-membered ring formed makes some contribution to this form of association. It is noteowrthy that Huyskens et al.[46] suggest also the existence of non-cyclic chains of associated molecules, in addition to the cyclic species, in t-butyl alcohol solutions.

The data examined show that the problem of the composition of the association complexes of aliphatic alcohols in solution is far from being finally resolved. One may suppose that the formation of hydrogen bonds in solution produces varying extents of intermolecular association. This is indicated by a number of data. Thus Vanthiel et al.[47] observed in the infrared spectrum of pure methyl alcohol at low temperatures a number of distinct bands, which they believe can be accounted for by the presence of different types of association complexes: dimeric, trimeric, tetrameric, and polymeric. Studies on dilute solutions of methyl alcohol at room temperature led to the same conclusion[48]. X-ray diffraction analysis of alcoholic solutions[49] showed that at low concentrations monomer–dimer equilibrium occurs, higher association complexes being formed on increasing the concentration.

The effect of the introduction of a halogen atom into the alkyl group of the alcohol on its self-association has been investigated in a number of studies. It has been shown that the degree of self-association diminishes in the series ethanol > monochloroethanol > dichloroethanol > trichloroethanol[50–52]. These data are confirmed by the results of the investigation of chlorinated ethanols by the infrared spectroscopic method[53]. A comparative study of ethanol and trifluoroethanol led to a similar conclusion[54]. The chemical shift of the OH proton in monomeric trifluoroethanol obtained by extrapolation to infinite dilution occurs in the region of lower fields than for ethanol itself, which is due to the greater electronegativity of the CF_3 group compared with CH_3. The lower slope of the concentration variation of τ^{OH} at infinite dilution of trifluoroethanol compared with ethanol indicates that the latter has the higher degree of association in solution.

Comparison of propyl, allyl, and propargyl alcohols showed that the presence of the double bond and even more so a triple bond increases the degree of self-association of the alcohol[39]. It is believed that the effect is due to the increased acidity of the OH proton and the decrease of steric hindrance in the series of alcohols propyl > allyl > propargyl.

There are some NMR data, mostly qualitative, on the degree of association and the nature of the multimers formed in different alcohols[55,56]. Since the slope of the concentration variation of τ^{OH} for 2-methoxyethanol is not zero, it was concluded that the monomer–linear dimer equilibrium occurs in the solution of this alcohol[33]. Similar association is proposed also for 3-ethylpentan-3-ol,[57] a number of but-3-en-1-ol derivatives, and phenylethyl alcohol[58].

As the concentration of diacetone alcohol in carbon tetrachloride or cyclohexane decreases, the OH proton is displaced towards stronger fields, i.e. the self-association complexes break down, but intramolecular hydrogen bonds between the hydroxyl proton and the carbonyl oxygen are maintained[54]. The presence of both inter- and intramolecular hydrogen bonds has also been noted for a number of diols[59–61] and substituted ethylene glycols[62], the formation of hydrogen bonds in the latter being strongly influenced by the steric properties of the adjacent groups.

The chemical shift of the OH proton in a number of substituted 2-hydroxybenzophenones is relatively insensitive to changes in concentration but is altered approximately by 10 Hz when the temperature is raised from −25° to +80°C.[63] This is evidence of the presence in the compounds investigated of strong intramolecular hydrogen bonds the formation of which has been suggested also for diastereoisomeric α- and β-aminoalcohols[64]. An unusual intramolecular hydrogen bond between the hydroxyl proton and the oxygen of the methoxy-group has been observed in the study of solutions of substituted benzyl alcohols[65].

An interesting effect of hydrogen bonds was observed by Oki and Iwamura[66], who showed that an intramolecular hydrogen bond exists between the hydroxyl proton and the ring π electrons in aryldimethylmethanol, this being confirmed also by infrared spectroscopic data[67]. The signal due to the OH proton in aryldimethylmethanol shifts towards stronger fields on dilution[66], which is evidence of self-association of this compound in solution, the monomer-dimer equilibrium constant of the ring-substituted aryldimethylmethanols varying linearly with Hammett's σ constants for the substituents. A similar intramolecular interaction between the OH proton and π electrons has also been observed[68] in allyldimethyl- and benzyldimethylmethanol; in addition, intermolecular association complexes exist in solutions of the above alcohols.

Comparison of the chemical shifts of the OH and SH protons in methanol and methanethiol in gaseous, liquid, and solid phases indicates a much higher stability of the association complexes of methanol compared with its thioanalogue.[69]. In view of the linear variation of τ^{SH} for ethanethiol[70], n-propanethiol, and phenylmethanethiol[71] with concentration in carbon tetrachloride, it was concluded that monomer–dimer equilibrium occurs in their solutions. The degree of self-association of aliphatic mercaptans decreases from methanethiol to t-butanethiol[72,73], in accordance with the known polar and steric properties of the alkyl group. The slope of the linear relation between τ^{SH} and temperature decreases in the same sequence[74].

Magnetic screening of the OH proton in aliphatic hydroperoxides (from n-propyl to n-octyl peroxide) is lower than for the OH proton in alcohols; its magnitude is similar to the screening of the proton in the carboxy-group of aliphatic acids[75,76]. When hydroperoxides are dissolved in carbon tetrachloride, the signal of the OOH proton shifts towards stronger fields, which indicates the breakdown of the self-association complexes.

3. Phenols

In the early studies on phenols by the NMR method[13,29,77,78] considerable changes in τ^{OH} on dilution with an inert solvent were already observed. However, the degree of self-association of phenols in solution is lower than for alcohols, as can be seen, for example, from a comparison of the concentration variation of the chemical shifts τ^{OH} of phenol and benzylalcohol in carbon tetrachloride[39,40], but is higher than for aniline and particularly for thiophenol[79].

Much work has been done on the effect of various substituents in phenol on its self-association. There is reason to believe that the introduction of electronegative substituents in the *para*- and *meta*-positions of phenols lowers the degree of self-association[39,41], while electropositive substituents increase it[80].

The problem of the effect of *ortho*-substituents on the self-association of phenols was investigated in greater detail. This effect is determined both by the change in the steric accessibility of the phenolic hydroxyl and the formation of intramolecular hydrogen bonds. The introduction of alkyl substituents in the *ortho*-position of phenol lowers its degree of the self-association, as already shown in the early studies on *o*-cresol[39] and 2,6-dimethylphenol[80]. The effect of *ortho*-alkyl substituents on the degree of self-association can be readily illustrated by a comparison[81] of the concentration dependence of the chemical shifts of the hydroxyl protons of 2,6- and 3,5-dimethylphenols in an inert solvent. The slope of the concentration variation of τ^{OH} for the phenol with methyl groups in the *ortho*-positions is much lower than for the phenol with the same substituents in the *meta*-positions. A detailed study of the effect of *ortho*-alkyl substituents on the self-association of phenols has been made[28,82–84]. The overall data obtained in these investigations indicate that an increase in the bulk of the *ortho*-substituents entails a sharp decrease of the degree of self-association of phenols. In 2,6-di-t-butylphenol the bulk of the *ortho*-substituents is so great that it precludes the mutual approach of the hydroxy-groups of two molecules to a distance sufficient for the formation of a hydrogen bond. In inert solvents this phenol is present in the monomeric state and its τ^{OH} is independent of concentration. At low concentrations (less than 0.1 p.p.m.) intermolecular hydrogen bonds are not formed also in solutions of 2,6-dimethyl- and 2,6-di-isopropyl-phenols[84,85]. The chemical shift due to intermolecular hydrogen bonds of *ortho*-substituted phenols is well correlated with the shift of the OH stretching vibration frequency in the infrared spectrum[84]. The importance of the effect of steric screening of the OH groups on the self-association of phenols has also been emphasised by Brodskii et al.[34], who investigated the concentration variation of τ^{OH} for many substituted *ortho*- and *para*-dihydric phenols. *Para*-dihydric phenols with t-butyl groups in their *ortho*-positions do not undergo self-association, while *ortho*-dihydric and trihydric phenols with bridging $-CH_2^-$ groups form dimeric intermolecular association complexes, the equilibrium constants and thermodynamic characteristics of which have been determined.

The introduction of a halogen atom in the *ortho*-position of phenol reduces its degree of self-association[40]. This is consistent with the decrease in the accessibility of the OH group and with the possibility of the formation of an intramolecular hydrogen bond. The heat of formation of the O–H... halogen bond is low, in agreement with Raman spectroscopic data[86]: it varies from 2.4 to 1.7 kcal mole^{-1} on going from *ortho*-chloro- to *ortho*-iodophenol[87]. ΔH for the formation of intermolecular association complexes diminishes in the same sequence[88]. A linear relation between τ^{OH} and the frequency shift of the OH stretching vibrations in infrared spectra has been found for many *ortho*-substituted phenols[89].

In contrast to *ortho*-halogenophenols, which tend to form both intra- and inter-molecular hydrogen bonds, certain *ortho*-substituted phenols form intramolecular hydrogen bonds which are so stable that the intermolecular association is not observed in their solutions. These include, in the first place, *ortho*-nitrobenzene, salicylaldehyde, methyl salicylate, and others[40,90–93]. A comparative study of the concentration dependence of τ^{OH} for *para*-, *meta*-, and *ortho*-nitrophenols showed[94] that the first two phenols, which have no intramolecular hydrogen bonds, form self-association complexes in solution, while the *ortho*-isomer is monomeric.

Data on the composition of the multimers of phenols in the monomer–multimer equilibria are contradictory. Thus a monomer–dimer equilibrium has been suggested[29,82,95,96] for various phenols. However, analysis of the concentration variation of τ^{OH} for many phenols led to the conclusion[30,92] that they are predominantly trimeric, while di-*ortho*-alkyl phenols are largely tetrameric[11]. Thiophenols exist in inert solvents exclusively as monomers and dimers[97].

III. ASSOCIATION

1. Equilibrium Constant for the Formation of Binary Association Complexes

When a substance A dissolves in a solvent B forming hydrogen bonds with A, association complexes with A and B are formed. On the assumption that the self-association of A may be neglected, the following equilibrium is established in the solute–solvent system in the case of binary association:

$$A + B \rightleftarrows AB. \tag{II.1}$$

Its equilibrium constant is given by the expression:

$$K = \frac{\beta(1 - \beta A_0)}{(1 - \beta)(B_0 - \beta A_0)}, \tag{II.2}$$

where A_0 and B_0 are the initial mole fractions of the solute and the solvent ($A_0 + B_0 = 1$), $\beta = x/A_0$ is the degree of association of A with the solvent B, and x is the equilibrium concentration of the association complex AB.

The chemical shift of the proton of A which formed an association complex AB with the solvent B is given by the expression

$$\tau = \beta\,\Delta\tau + \tau_A \qquad (II.3)$$

where $\Delta\tau = \tau_{AB} - \tau_A$ and τ_A and τ_{AB} are the chemical shifts of the free substance A and A hydrogen-bonded to B.

The chemical shifts τ_A and τ_{AB} are usually determined[12,99–100] by extrapolating the concentration variation of the overall chemical shift to $B_0 \rightarrow 0$ and $A_0 \rightarrow 0$ respectively.

In the extreme case with $A_0 \rightarrow 0$, Eqns. (II.2) and (II.3) yield[27,101]

$$(\tau)_{A_0\rightarrow 0} = \frac{K}{1+K}\Delta\tau + \tau^A, \qquad \left(\frac{d\tau}{dA_0}\right)_{A_0\rightarrow 0} = -\frac{K}{(1+K)^2}\Delta\tau\,. \qquad (II.4)$$

Simultaneous solution of Eqns. (II.4) permits the determination of τ_A, τ_{AB}, and K. An interesting method for determining these quantities has been proposed by Mathur and coworkers[102,103]. Substitution of Eqn. (II.2) in Eqn. (II.3) when $B_0 \gg A_0$ yields the linear equation (II.5); all the association parameters can be determined from the slopes and intercepts of the corresponding plots:

$$\frac{1}{\tau - \tau_A} = \frac{1}{K\,\Delta\tau B_0} + \frac{1}{\Delta\tau}\,. \qquad (II.5)$$

Somewhat modified expressions of this type were obtained in special cases in other investigations[82,104]. It is noteworthy that in the methods described the accuracy of the determination of the equilibrium constant and $\Delta\tau$ is fully determined by the reliability with which τ_A is found.

More accurate association parameters can be obtained by analysing the variation of the chemical shifts over a wide range of concentrations[105,106]. Indeed simultaneous solution of Eqns. (II.2) and (II.3) gives the expression

$$\tau = \frac{(1+K) - \sqrt{(1+K)^2 - 4A_0B_0K(1+K)}}{2A_0(1+K)}\Delta\tau + \tau_A. \qquad (II.6)$$

Hence it is clear that, by choosing different values of K, a value can be found such that the sum of the squares of the differences between the calculated and experimental shifts is a minimum. The use of approximate formulae[107] for the estimation of the initial value of K close to the optimum value permits a rapid and reliable determination of the association parameters. An algorithm for the solution of this problem on electronic computers has been developed on the basis of Eqns. (II.2) and (II.6).[108] Nevertheless, it is noteowrthy that the value of this method is somewhat reduced by the need to know accurately τ_A and $\Delta\tau$. This difficulty may be overcome if the condition for a minimum sum of squares of the deviations is replaced by the condition of a maximum correlation coefficient for the linear equation (II.6),[109] which amounts to the same thing for a linear system.

The presence of the inert solvent S in the system causes some displacement of equilibrium, which affects the equilibrium constant. In this case the variation of the chemical shift with concentration is given by the expression[27]:

$$\tau = \frac{(1+KP) - \sqrt{(1+KP)^2 - 4A_0B_0K(1+K)}}{2A_0(1+K)}\Delta\tau + \tau_A, \qquad (II.7)$$

where $P = 1 - S$ and S is the mole fraction of the inert solvent ($A_0 + B_0 + S = 1$). When $P = 1$, Eqn. (II.7) becomes identical with Eqn. (II.6).

If self-association of one of the components takes place in the solution as well as the association of A and B, the two types of equilibria compete, namely self-association described by Eqn. (I.1) and association described by Eqn. (II.1).[27,110] When self-association complexes A_2 and association complexes AB are formed simultaneously in the system under the condition $A_0 + B_0 = 1$, the equilibrium constants are given by the following relations:

$$K_{A_2} = \frac{\alpha[1 - A_0(\alpha+\beta)]}{A_0[1-(2\alpha+\beta)]^2}, \qquad K_{AB} = \frac{\beta[1 - A_0(\alpha+\beta)]}{[1-(2\alpha+\beta)][B_0 - A_0\beta]}, \qquad (II.8)$$

where $\alpha = c/A_0$ and $\beta = x/A_0$ are the degrees of self-association and mutual association respectively, c and x being the equilibrium mole fractions of the complexes A_2 and AB. In this case the observed chemical shift is given by the expression:

$$\tau = 2\alpha\,\tau_{A_2} + \beta\,\tau_{AB}, \qquad (II.9)$$

where τ_{A_2} and τ_{AB} are the chemical shifts of substance A hydrogen-bonded to another species A or B respectively. To facilitate further analysis, the starting point for the reckoning of the chemical shift τ in Eqn. (II.9) was assumed to be the value for substance A in the monomeric state ($\tau_A = 0$). When the degree of self-association is infinitely low ($\alpha \rightarrow 0$ for $A_0 \rightarrow 0$), we obtain from Eqns. (II.8) and (II.9)

$$(\tau)_{A_0\rightarrow 0} = \frac{K_{AB}}{1+K_{AB}}\tau_{AB}, \qquad (II.10)$$

and the slope of the concentration variation of the chemical shift for the cyclic dimer is

$$\left(\frac{d\tau}{dA}\right)_{A_0\rightarrow 0} = \frac{1}{(1+K_{AB})^2}\left[2K_{A_2}\tau_{A_2} - K_{AB}\tau_{AB}\left(1 + \frac{2K_{A_2}}{1+K_{AB}}\right)\right]. \qquad (II.11)$$

For a linear dimer, the first term in square brackets in Eqn. (II.11) is replaced by $K_{A_2}\tau_{A_2}$.

When monomer-n-mer self-association of one of the components takes place in the solution in addition to association, the asymptotic value of the chemical shift at $A_0 \rightarrow 0$ [Eqn. (II.10)] does not change and the limiting slope of the concentration variation of the chemical shift is given by the expression

$$\left(\frac{d\tau}{dA_0}\right)_{A_0\rightarrow 0} = -\frac{K_{AB}}{(1+K_{AB})^2}\tau_{AB}. \qquad (II.12)$$

The presence of an inert solvent in the system alters the conditions defined by Eqn. (II.8). It is then necessary to consider two possibilities.

1. In the general case the concentrations A_0 and B_0 cannot be neglected in comparison with S. Then, bearing in mind that $A_0 + B_0 + S = 1$, we obtain

$$(\tau)_{A_0\rightarrow 0} = \frac{K_{AB}P}{1+K_{AB}P}\tau_{AB}, \qquad (II.13)$$

and the limiting slopes for a cyclic dimer is

$$\left(\frac{d\tau}{dA_0}\right)_{A_0\rightarrow 0} = \frac{1}{(1+K_{AB}P)^2}\left[2K_{A_2}\tau_{A_2} + \frac{K_{AB}^2P^2(1+K_{AB})}{1+K_{AB}P}\tau_{AB} - K_{AB}(1+K_{AB}P)\left(1 + \frac{2K_{A_2}}{1+K_{AB}P}\right)\tau_{AB}\right]. \qquad (II.14)$$

For a linear dimer, the first term in square brackets in Eqn. (II.14) is replaced by $K_{A_2}\tau_{A_2}$. When self-association complexes of an order higher than two (dimers) are present in solution, then

$$\left(\frac{d\tau}{dA_0}\right)_{A_0\to 0}=\frac{K_{AB}P}{(1+K_{AB}P)}\left(K_{AB}P\frac{1+K_{AB}}{(1+K_{AB}P)^2}-1\right)\tau_{AB}\ . \qquad (II.15)$$

Naturally, when $P = 1$, Eqns. (II.13), (II.14), and (II.15) become identical with Eqns. (II.10), (II.11), and (II.12) respectively.

2. The concentrations A_0 and B_0 tend to zero simultaneously ($P \to 0$) so that one can put $S = 1$. Then for dimeric cyclic self-association, we have

$$\begin{aligned}(\tau)_{A_0\to 0}&=0\,,\\ \left(\frac{d\tau}{dA_0}\right)_{A_0\to 0}&=2K_{A_2}\tau_{A_2}+K_{AB}\tau_{AB}.\end{aligned} \qquad (II.16)$$

In the case of linear dimers the first term in the second Eqn. (II.16) is $KA_2\tau_{A_2}$, while in the formation of self-association complexes of an order higher than two (dimers) it is zero.

When several types of equilibria (for example $A + A \rightleftharpoons A_2$, $A + B \rightleftharpoons AB$, and $B + B \rightleftharpoons B_2$ occur simultaneously in solution, simple expressions cannot be obtained for the asymptotic quantities $(\tau)_{A_0} \to 0$, $(d\tau/dA_0)_{A_0} \to 0$, $(\tau)_{B_0} \to 0$, and $(d\tau/dB_0)_{B_0} \to 0$. Several examples of the analysis of such complex systems have been described[111-115].

The chemical shift of the proton in a hydrogen bond can be represented in a general form as a function of the concentrations of the components in solution (x_i), the equilibrium constants for the formation of the association complexes (K_{ij}), and the chemical shifts of the protons in various states (τ_i and τ_{ij}):[12,116]

$$\tau_{obs}=f(x_i,\ K_{ij},\ \tau_i,\ \tau_{ij}). \qquad (II.17)$$

Eqn. (II.17) can be represented by a power series in terms of x_i, the coefficients of different powers of x_i being mixed non-linear functions of τ_i, τ_{ij}, and K_{ij}. The solution of this system by least squares yields a series of inhomogeneous non-linear equations and therefore the parameters τ_i, τ_{ij}, and K_{ij} are not determined unambigously. More accurate values of these parameters can be found, for example, by the "direct search" method[117].

The procedures described for the determination of the equilibrium constants for different types of association do not take into account the non-ideality of the solution and consequently the values of K are obtained in this way with an accuracy determined by a factor which depends on the activity coefficients of the substances undergoing association[118-120].

The determination of the thermodynamic characteristics of the association process in the presence of simultaneous self-association of the components in solution is a complex problem which becomes considerably simplified when it is known with certainty that one of the components does not undergo self-association and only forms association complexes with the second component.

Then the thermodynamic characteristics of the formation of association complexes may be found from the temperature variation of the chemical shift of the proton in the substance which does not undergo self-association. In the presence of a large excess of the solvent ($B_0 \gg A_0$) the product βA_0 in Eqn. (II.2) may be neglected and the following form of the van't Hoff equation is obtained[84,109,121-123]:

$$R\ln\left(\frac{\tau_A-\tau}{\tau-\tau_{AB}}\cdot\frac{A_0+B_0}{B}\right)=-\frac{\Delta H}{T}+\Delta S\,. \qquad (II.18)$$

The chemical shift τ_{AB} and the heat (ΔH) and entropy (ΔS) of formation of the association complex are determined from the conditions of the maximum correlation coefficient for the linear equation (II.18) when τ_{AB} is varied.

2. Alcohols

The study of the concentration variation of the chemical shift of the hydroxyl proton in aliphatic alcohols showed[39,40,50] that the degree of their self-association strongly depends on the solvent, being higher in cyclohexane than in carbon tetrachloride and chloroform. This was explained by the formation of intermolecular hydrogen bonds between the alcohol and the solvent, which leads to a decrease of the degree of the alcohol–alcohol self-association. In general, dilution of an alcohol solution by a solvent having basic properties is accompanied by two processes: dissociation of the multimers and association of the monomers with the solvent[39,101,142]. The changes of the chemical shift in the NMR spectra under the influence of these effects are of the opposite sign: the dissociation of the multimers shifts the OH proton signal towards stronger fields, while association with the base causes the opposite shift towards weaker fields. In weakly basic solvents dissociation of multimers predominates and the τ^{OH} signal is displaced towards stronger fields, while in stronger bases association predominates and the τ^{OH} signal is displaced towards weaker fields. Hence it is clear that the shift due to the formation of hydrogen bonds on association will be greater the more acid the solute and the more basic the solvent. This has served as a basis for assessing the relative acidities of many alcohols by comparing their chemical shifts due to the formation of association complexes with the same base[39]. It was shown that the introduction of chlorine atoms into the methyl group of ethanol increases the shift due to the formation of an association complex with the base, i.e. the acidity of the OH proton increases in the sequence ethanol < monochloroethanol < dichloroethanol < trichloroethanol. This sequence is consistent with the increasing inductive effect of chlorine atoms, which is confirmed by the infrared and ultraviolet spectroscopic studies of solutions of these substances[53,125] and also by the pK values[126].

On the other hand, when the alcohol behaves as a base, for example, in a mixture with chloroform, the chemical shift due to association decreases from ethanol to chlorinated ethanol, in agreement with the decreasing basicity of the hydroxyl oxygen in this sequence[51].

Similarly, it has been shown that the capacity of association with a base, and hence the acidity of the OH proton, increases appreciably in the series propanol < prop-1-enol < prop-1-ynol[39], while the opposite sequence holds in chloroform[51].

A comparative study of the formation of association complexes of t-butyl alcohol in acetone and dioxan showed that dioxan is a stronger base[120].

The association of alcohols with various classes of organic compounds has been investigated in a number of studies[30,40,101]. The formation of 1 : 1 association complexes has been observed in the systems benzyl alcohol–acetone[127] and methanol–pyridine[128]. It has been shown[101,129] that alcohols undergo association with nitriles, the strength of the bond in the methanol–acetonitrile association complex being greater than in the methanol–methyl isocyanide complex, in agreement with the results of an investigation of the vibration spectra of these systems[129]. The bond strength in the association complexes of 2-propanol with *N*-methylacetamide and *NN*-dimethylacetamide[104] is close to that found in the system alcohol–dimethylformamide by infrared spectroscopy[130].

The replacement of the hydroxyl oxygen by sulphur in the alcohol leads to a decrease of bond strength in the association complex with the base[73,131], although the acidity of the proton donor increases. This effect is probably due to the characteristics of the electronic structure of sulphur, which are responsible for the proton-donating and proton-accepting functions of the mercapto-group.

3. Phenols

Phenols, which are stronger acids than alcohols, form more stable association complexes with bases. The formation of such complexes by phenols with various solvents have been investigated in detail by a number of workers.

In the first place one should note the effect of the differences in the acid properties of the phenol and the base on the stability of the complex. Thus the shifts due to the formation of association complexes of 22 phenols with dimethyl sulphoxide are linearly correlated with Hammett's σ constants for substituents, increasing with the acid properties of the phenol[132]. A similar relation was obtained for systems comprising *meta*- and *para*-substituted phenols on the one hand and pyridine on the other[133], which agrees with data for substituted phenol–amine systems obtained by ultraviolet spectroscopy[134,135]. On the other hand, the shift due to association involving phenols is proportional to the basicity of the electron donor[136,137].

A detailed study of systems comprising mixtures of phenols with amines, ethers, sulphoxides, and phosphorus- and carbonyl-containing compounds[138] revealed a linear relation between the shifts due to association and the heats of formation ΔH of the association complexes. Similar results were obtained also by comparing the shifts $\Delta\tau$ due to association and the heats of formation ΔH of the association complexes in phenol–substituted pyridine systems[139]. Earlier similar linear relations were found by comparing the heats of formation of the association complexes with the frequency shifts in the infrared spectra[140,141] and it was emphasised in the second study that a relation of this kind should be observed only for similar compounds with comparable steric effects of the substituents.

With increase of the distance between the atoms forming the hydrogen bond, the strength of the latter diminishes. In agreement with this finding, a linear relation between the chemical shift due to association and the hydrogen bond length was obtained[13] in a study of the association of phenols with bases.

A linear relation between the shift $\Delta\tau$ in NMR spectra and the frequency shift $\Delta\nu$ in infrared spectra on formation of an association complex has been noted in many investigations[13,142–144]. This shows that the variation of these parameters with the electronic structure of the molecules is similar in both cases.

The linear relations examined above, apart from their purely theoretical importance, may also prove useful in determining a number of characteristics of substances which had not been investigated hitherto.

Earlier the effects of intramolecular hydrogen bonds in phenol on its self-association was noted. These bonds have a similar effect also on the capacity of phenols for association. The very weak intramolecular hydrogen bond in *o*-chlorophenol does not prevent either its association even with relatively weak bases such as ether and dioxan[39] or the exchange of the OH proton with methyl alcohol[142]. In contrast, the strong intramolecular hydrogen bonds in *o*-nitrophenyl, salicylaldehyde, and methyl salicylate appreciably hinder their association with basic solvents[39].

Phenols with bulky *ortho*-substituents, which, as already noted, do not undergo self-association in inert solvents, form association complexes with bases, as shown by the shift towards weaker fields of the signal due to the hydroxyl proton in the phenols[28,82–94,150]. The stability of phenol–base association complexes and the chemical shift τ^{OH} on formation of the hydrogen bond diminish with increasing bulk of the *ortho*-substituents in the phenol molecule[28], the association complexes with a stronger base, for example acetone, proving more stable than those with ether.

The study of the association of 2,6-dialkylphenols with dioxan[82] showed that bimolecular complexes are formed in the system. In view of the similarity of the curves relating the chemical shift of the OH proton to the concentration of phenol in dioxan and ethanol, it was suggested[82] that the hydrogen bond in the 2,6-di-t-butylphenol–ethanol complex is formed between the proton of the phenolic hydroxyl and the oxygen of the alcohol. Pokhodenko and Kuts[145], who investigated the effect of the nature of the *para*-substituent in 2,6-di-t-butylphenol on the formation of association complexes with t-butyl alcohol, arrived at a similar conclusion. It was shown that there is a linear relation between the chemical shift of the proton of the phenolic hydroxyl in the association complex and Hammett's σ^- constants for the substituents, with a slope having the same value as in the relation obtained from a similar comparison for monomeric phenols[145–148]. The chemical shift of the hydroxyl proton in t-butyl alcohol on formation of association complexes with phenols also varies linearly with the constants of the substituents in the phenol, but its proportionality coefficient has the opposite sign. This shows that the degree of self-association of the alcohol diminishes with increasing degree of the phenol–alcohol association. These findings are related to the dependence of the stability of the phenol–alcohol association complexes on the electron density at the oxygen and hydrogen atoms in the phenolic hydroxyl. This is consistent with the observed[145] linear relation between the chemical shifts of the proton in the phenol–alcohol association complexes and the association order and also with the autopolarisability of the O...O bond in the complex. Later studies[122] of the temperature variation of the chemical shift of the proton signal from the OH group in a number of *para*-substituted 2,6-di-t-butylphenols on association with ethanol showed that the equilibrium constants and the heats of formation of the association complexes increase linearly with enhancement of the electron-accepting properties of the *para*-substituent in the phenol, i.e. with increase of its acidity. In the same study it was also found that an increase in the stability of the phenol–alcohol association complex entails a lowering of the potential barrier to proton exchange between the phenolic and alcoholic hydroxyls. This finding constitutes experimental confirmation of the opposite variation of the strength of the hydrogen bond (represented by ΔH) and the activation energy E for proton exchange, demonstrated by Sokolov[14,15].

With increased bulk of the *ortho*-substituents in the phenol, the equilibrium constant for the formation of the association complex with methanol diminishes, although the stability of the complex remains virtually unchanged[85]. This is due to the change in the steric effect, as shown by the linear increase of the entropy of formation of the association complex with increasing overall bulk of the *ortho*-substituent. A similar effect of steric factors was observed also in an investigation of the association of 2,6-di-t-butyl-4-methylphenol with aliphatic alcohols[121,123]. It was shown that the heat of formation of the complex changes only slightly on going from methyl to t-butyl alcohol and the change in the degree of association is due to the change in the entropy of formation of the hydrogen bond, which increases linearly with the bulk of the alkyl residue of the alcohol.

The association of phenols with strong bases, such as substituted pyridines, amines, and others is accompanied by the formation of ionic species in which the proton of the phenolic hydroxyl is transferred to the nitrogen atom of the base[39,139,149]. This type of ionisation is more appreciable the more pronounced is the acidic character of the proton donor. The degree of ionisation of course increases on going from alcohols to phenols and from oxygen-containing to nitrogen-containing bases, which are more powerful electron-donating agents.

Complexes of thiophenols with bases have been much less investigated. It is known that their stability is low and as a rule does not exceed 2–3 kcal mole^{-1},[102-103] the degree of association of substituted thiophenols with acetone increasing with the electron-accepting capacity of the substituent due to the increasing strength of the hydrogen bond in the association complexes[151].

Reactivity of Trivalent Phosphorus Derivatives

B.E.Ivanov and V.F.Zheltukhin

The review deals with the most important features of phosphorus(III) derivatives, which determine their chemical properties. These are the biphilicity of the phosphorus atoms due to the presence of a free electron pair and unfilled *d* orbitals and the ambidentate properties of phosphorus(III) derivatives determined by the specific contribution of both nucleophilic elements (O, N, S) and elements with vacant *d* orbitals (Si, Sn) directly linked to the phosphorus atom. Certain limits and characteristics of this contribution have been elucidated and the mechanism of the relevant reactions has been discussed.
The last section deals with the specificity of the behaviour of phosphorus(III) compounds with a phosphorus-halogen bond. The significant role of the *d* orbitals of the phosphorus atom in its chemical reactivity is discussed.
The bibliography comprises 196 references.

CONTENTS

I. INTRODUCTION

Considerable advances in the practical applications of organophosphorus derivatives and the important role of phosphorus compounds in vital processes are responsible for the considerable interest in the chemistry of these compounds. During the last 15–20 years the preparative chemistry of organophosphorus compounds has been considerably developed and an enormous amount of experimental data have accumulated, systematic and general accounts of which have been published in numerous reviews and monographs. Theoretical studies have also been pursued, but the theoretical approach to problems of the reaction mechanism and reactivity of organophosphorus compounds proved to be more difficult, particularly for phosphorus(III) derivatives, and the results obtained have been less significant compared with advances in classical organic chemistry.

This review was undertaken to examine the chemical properties of phosphorus(III) derivatives. It does not give an exhaustive compilation of studies on definite types of reaction but an attempt is made to establish certain relations which determine the chemical behaviour of phosphorus(III) derivatives in reactions. Hudson, Kirby, and others partially dealt with some of these problems in their monographs or reviews. Other problems have been formulated in a definitive form only very recently.

II. THE CONCEPT OF "BIPHILICITY" FOR PHOSPHORUS(III) DERIVATIVES

Phosphorus(III) compounds are very reactive and can enter into a wide variety of reactions. The phosphorus atom can behave either as a nucleophilic or an electrophilic centre. There are also a number of reactions in which the nucleophilic and the electrophilic properties of phosphorus are shown simultaneously.

Thus the nucleophilic properties of phosphines are well known[1,2]:

$$R_3P + R'I \rightarrow R_3\overset{+}{P}R'\overset{-}{I},$$

but in the presence of powerful nucleophilic agents phosphines are also capable of substitution reactions[3]:

$$R_2P{-}R + Na \rightarrow R_2PNa + NaR.$$

A dual reactivity is characteristic also of many other phosphorus(III) compounds, for example[4,5]:

$$(RO)_3P + R'I \rightarrow [(RO)_3\overset{+}{P}R']\overset{-}{I} \rightarrow (RO)_2P(O)R' + RI,$$
$$(RO)_3P + nR'MgI \rightarrow (RO)_{3-n}PR'_n + nROMgI.$$

The capacity of phosphorus(III) compounds to behave both as electron donors and electron-acceptors has been reflected also in the formation of complexes. Kirby[6] concluded that tertiary phosphines can behave as electron-donating species (as a result of the free electron pair of the phosphorus atom) in complex-formation reactions with metal cations, forming complexes similar to those which metals form with amines. The stability of the phosphine complexes is lower than that of the corresponding amine complexes.

However, the formation of complexes with cations such as Ag^+, Pt^{2+}, and certain others takes place via the interaction of their *d* electrons with the vacant *d* orbitals of the phosphorus atom. This is confirmed by the finding[7] that the introduction of strong electron-accepting groups into the phosphine molecule, for example CF_3, entails an increase in the stability of the complex with Pt^{2+} and by the fact that phosphorus trichloride can be displaced from the complex $Ni(PCl_3)_4$ by phosphorus tribromide or trifluoride but not by triphenylphosphine[8].

The dependence of the electron-donating or electron-accepting capacity of phosphorus(III) compounds on the substituents at the phosphorus atom has been clearly revealed by the stability of the complexes formed. Thus the stability of phosphorus(III) complexes with boranes (substances with markedly electron-accepting properties) increases in the series[9]

$$R_3P > (>N)_3P > (RO)_3P >> PCl_3 .$$

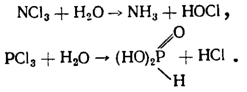
The introduction of electron-accepting substituents, for example, halogens, sharply reduces the electron density at the phosphorus atom, with a corresponding increase of the capacity of such compounds to behave as electron acceptors. Phosphorus(III) halides form complexes with electron donors such as amines[10,11], phosphines[12], and arsines[13]. Phosphorus-containing ligands can be arranged in the following sequence in terms of the stability of the complexes which they form[14]:

$$PCl_3 > PBr_3 >> RPCl_2 >>> R_2PCl \ .$$

Evidently the stability of the two types of phosphorus(III) complexes described above varies with the type of substituent in the opposite sense.

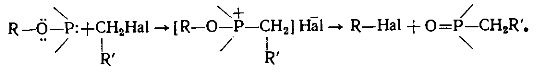
There are many examples of reactions in which phosphorus(III) compounds can behave as nucleophilic or electrophilic agents depending on the type of substituent or the second reactant. Such dual reactivity is one of the specific features of phosphorus(III) atoms. It can be explained by a combination of two factors: the presence at the phosphorus atom of both a free electron pair and vacant *d* orbitals. A characteristic feature of the phosphorus atom is that the participation of its *d* orbitals in the formation of new bonds requires a considerable positive charge, under the influence of which the levels of the *d* orbitals are lowered and their participation in the formation of new bonds becomes energetically favourable[15]. The origin of the positive charge at the phosphorus atom is apparently insignificant. It can be induced by electron-accepting substituents in the initial phosphorus(III) compounds or it can arise as a result of attack of an electrophilic agent on the phosphorus atom.

The presence of vacant *d* orbitals determines the capacity of phosphorus(III) compounds to behave as electron acceptors. The specificity of such involvement of *d* orbitals of the phosphorus atom is clearly illustrated by an example such as the hydrolysis of halogeno-derivatives of nitrogen and phosphorus[16]:



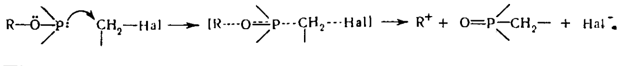
$$NCl_3 + H_2O \to NH_3 + HOCl\,,$$
$$PCl_3 + H_2O \to (HO)_2P(=O)H + HCl\ .$$

In 1962 Syrkin[17] formulated the following postulate: "All outer electrons and all outer orbitals participate in the simultaneous general lowering of the energy of the molecule formed". The application of this principle in the discussion of the reactivity of phosphorus(III) compounds can explain many important features of their behaviour in numerous reactions. Indeed all reactions of phosphorus(III) derivatives involving an increase in valence are based on the participation of both the free electron pair and the vacant *d* orbitals. One of the best investigated examples of this reaction is the Arbuzov rearrangement:



Within the framework of the electronic theory, this reaction may be described as follows. The process begins with the nucleophilic attack of the free electron pair of the phosphorus atom on the electrophilic carbon atom by an S_N2 bimolecular substitution mechanism. The positive charge at the phosphorus atom in the quasiphosphonium cation thus produced makes its *d* orbitals available for reaction. This increases the degree of interaction of the *p* electrons of the oxygen atom with the *d* orbitals of the phosphorus atom and leads to the formation of a new π bond. Probably this process may involve an intermediate stage with formation of an oxonium cation and subsequent elimination of a carbonium cation:

Analysis of extensive experimental data shows that the decomposition of the intermediate quasiphosphonium salt probably takes place by a unimolecular mechanism[18-21]. Moreover, depending on the environment of the phosphorus atom, processes involving a nucleophilic transfer of the electron pair of the phosphorus atom and the interaction of the oxygen *p* electrons with the *d* orbitals in the course of the Arbuzov rearrangement can occur either at different times or synchronously:

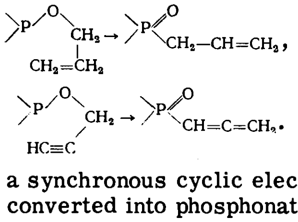


Theoretical examination of the possibility of the participation of the phosphorus *d* orbitals in the formation of additional bonds showed that the formation of fairly strong bonds via the *d* orbitals is possible only when the electron density at the phosphorus atom is reduced[15]. This in fact is the reason for the occurrence of two types of reactions, leading to an increase of the valence of trivalent phosphorus.

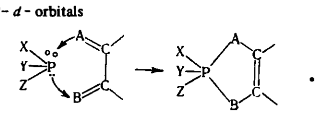
For compounds where the substituents can increase the electron density at the phosphorus atom, the rate-limiting process is the nucleophilic attack by the free electron pair on the electrophilic centre of the second reactant. When the free electron pair is transferred, the electron density at the phosphorus atom is reduced synchronously and conditions are created for the formation of additional σ and π bonds via the *d* orbitals, as shown above for Arbuzov rearrangement. This is satisfactorily consistent with data on the oxidation of phosphorus(III) derivatives by oxygen, peroxides, and peracids[22] and also on their interaction with sulphur[23]. For derivatives where the trivalent phosphorus atom has a reduced electron density, the rate-limiting process is the interaction of the reaction centre having an enhanced electron density with the vacant *d* orbitals of phosphorus. An example of such interaction is that of phosphorus trichloride with amine *N*-oxides[2] and sulphoxides[25]. In this case the process begins with nucleophilic attack by oxygen on the vacant *d* orbitals of the phosphorus atom:

$$R_3N \to O + PCl_3 \to R_3\overset{+}{N}-O-\overset{-}{P}Cl_3 \to R_3N + O{=}PCl_3\,.$$

In this connection the intramolecular rearrangement of the allyl and propargyl esters of acids derived from trivalent phosphorus, investigated in detail by Pudovik et al[26], is also of interest. The authors suggest that the process begins by attack by the free electron pair of the phosphorus atom on the unsaturated centre. However, in this case there is a possibility of a primary interaction between the π electrons of the olefin and the vacant *d* orbitals of the phosphorus atom:

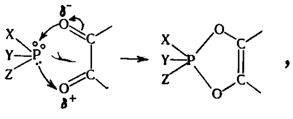


As a result of a synchronous cyclic electron transfer, phosphite is also converted into phosphonate in this case. The concept of the simultaneous utilisation of the free electron pair and the vacant *d* orbitals accounts also for the possibility of the participation of various acids derived from trivalent phosphorus in reactions with diketones, $\alpha\beta$-unsaturated carbonyl compounds, and diene hydrocarbons:



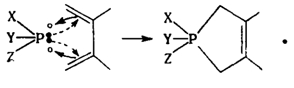
Depending on the electron density of the phosphorus atom, the rate-limiting step in this reaction can be either the transfer of the free electron pair of the phosphorus atom to the electrophilic centre or, conversely, the nucleophilic interaction of the conjugated system with the *d* orbitals of the phosphorus atom[27].

In reactions of $\alpha\beta$-dicarbonyl compounds with esters, ester-amides, and amides of acids derived from phosphorus(III), the nucleophilic properties of which have been revealed in a number of interactions, the rate-limiting process is most likely nucleophilic attack by the free electron pair of the phosphorus atom on the electrophilic centre of the conjugated system and conversely:



where X, Y, Z = OR or NR_2. The electrophilic behaviour of phosphorus in various acid chlorides derived from phosphorus(III) suggests that in this case the rate-limiting process is the interaction of the vacant *d* orbitals of phosphorus with the π-electrons of the conjugated system.

Arbuzov and coworkers and also Petrov and Razumova showed that the reactivity of dienes in interactions with trivalent phosphorus compounds increases in the sequence dimethylbutadiene < isoprene < butadiene < piperylene[28-33]. The ease of the interaction of phosphorus(III) acid derivatives of the type RPX_2 and R_2PX with diene systems increases in the sequence where R has the following significance: NCS < Cl < SR < F < OR < NR_2.[34,35] All these findings convincingly demonstrate that in these cases the rate-limiting step is the interaction of the π-electrons of the diene system with the vacant *d* orbitals of the phosphorus atom followed by the involvement of the free electron pair in the formation of a pentacovalent adduct:



Therefore all the factors favouring an increase in the electron-donating capacity of the conjugated diene and reducing the electron density of the phosphorus atom tend to increase the rate of such processes.

Heteroconjugated systems, which are readily polarised or already have both nucleophilic and electrophilic centres, are capable of interacting at a fairly high rate with any derivatives of phosphorus(III) acids. Depending on the type of the substituents at the phosphorus atom, the rate-limiting step may be the interaction of the free electron pair with an electrophilic centre, or of the π electrons of the heteroconjugated systems with the vacant *d* orbitals[36,37]. It is quite logical to postulate that the interaction in the system (X, Y, Z,)P: $+\underset{|}{A} = \underset{|}{C}-C = B$ involves synchronous formation of the P−A and P−B bonds (at least for the *cis*-form of the conjugated system), since any transition, having once begun, induces the next. By the term "synchronous" we imply that the structures $\gt\bar{P}-A-\underset{|}{C}-\underset{|}{C}-\bar{B}$ and $\bar{A}-\underset{|}{C} = \underset{|}{C}-B-\overset{+}{P}\lt$ are not formed as kinetically independent species or there is no minimum corresponding to them in the energy diagram for the reaction. Such treatment is not of course correct in all cases. Thus it is known[38] that in the interaction of phosphorous triamide with benzil the dipolar form is fairly stable and one cannot of course exclude the possibility that in certain cases it can exist also as a kinetically independent structure, particularly since the contribution of the *trans*-forms of the conjugated systems to the formation of pentacovalent adducts has not so far been accurately established. However, one must always distinguish whether the P−A or the P−B bond is formed faster, i.e. whether the process begins with nucleophilic attack by the free electron pair of phosphorus or with the interaction of the vacant *d* orbitals with the π electrons of the conjugated system—one of these processes will be rate-limiting for the reaction as a whole.

Kirby and Warren (Ref. 6, p. 22) suggested the term biphilicity for the capacity of the trivalent phosphorous atom to donate both an electron pair and *d* orbitals in a single process involving the formation of a new compound and defined it as follows: "A biphilic compound can donate electrons to the substrate to form a σ bond and also to accept electrons at the same centre, which results in the formation of a second σ or π bond".

The definition of "biphilicity" as the capacity of the same reaction centre (in this case the phosphorous atom) to function consecutively or synchronously as an electron donor or acceptor in an interaction with another reactant, involving the formation of two new bonds, differs fundamentally from concepts such as ambidentate properties, dual reactivity, and amphoteric properties; as a concept defining the properties of the reaction centre, it merits recognition.

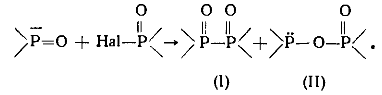
III. AMBIDENTATE PROPERTIES OF PHOSPHORUS(III) DERIVATIVES (DUAL REACTIVITY)

In an estimation of the nucleophilic properties of phosphorus(III) derivatives account must also be taken of the fact that many of these have two nucleophilic centres. Phosphorus(III) compounds with substituents of the type $R\ddot{S}$, $R\ddot{O}$, and $R_2\ddot{N}$ may be included among systems of this kind. Although the ambidentate nature of many phosphorus(III) compounds has been known for a long time and was demonstrated for the first time by A.E. and B.A. Arbuzov[39,40] in 1932 in the interaction of dialkyl phosphite salts with phosphorus-containing acid chlorides and by Kabachnik[41] and Michaelis[42] in the interaction of thiophosphites [phosphorothi-ites] with alkyl halides, these data have not been reviewed systematically and have been inadequately taken into account in the assessment of the occurrence of particular processes with participation of esters, thioesters, and amides of acids derived from phosphorus(III).

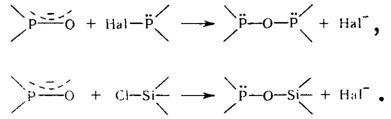
Two mesomeric forms, $\gt\bar{P}=O \leftrightarrow \gt\ddot{P}-\bar{O}$, are possible for an anion of the type $\gt\bar{P}=O$. Depending on the type of substituents at the phosphorus atom, the reaction conditions, and the second reactant, the nucleophilic centre can be either the oxygen or the phosphorus atom.

In the interaction with alkyl halides and carboxylic acid halides[40] and in reactions involving addition to an activated C=C double bond, a carbonyl group, and a C=N bond,[44] the phosphorus atom behaves as the nucleophilic centre in the anion

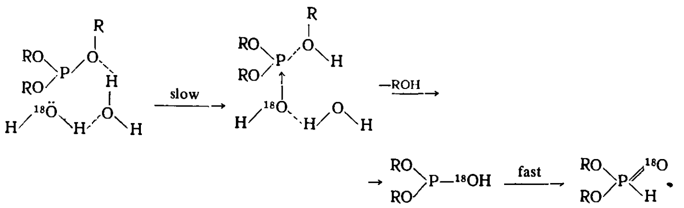
In the reaction of dialkyl phosphite salts with phosphorus(V) chlorides[45] both possible reaction products are formed, the yield of product (I) reaching 90%:



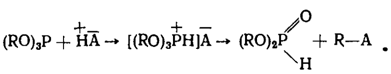
However, in reactions with phosphorus(III) acid chlorides[46] or with chlorosilanes[47-49] the oxygen atom behaves as the nucleophilic centre and trivalent phosphorus compounds are formed preferentially:



Until recently it was believed that esters of phosphinous and phosphorous acids interact in all reactions with electrophilic reagents with participation of the free electron pair of the phosphorus atom. Aksnes and Aksnes[50], who investigated the kinetics of the neutral hydrolysis of phosphites by water with labelled oxygen and analysed the hydrolysis products by infrared spectroscopy, showed that the alkoxy-radical is exchanged for the hydroxy-group with labelled oxygen. On this basis, they concluded that the oxygen of the ester group is protonated in an intermediate stage and the hydrolysis is described by the equation

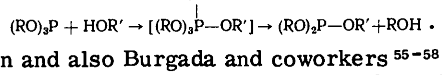


It is now generally accepted that the hydrolysis of phosphites in an acid medium[51] involves the protonation of the phosphorus atom in the phosphite with subsequent decomposition of the intermediate complex to dialkylphosphorous acid:



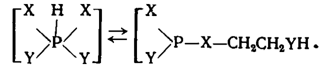
$$(RO)_3P + \overset{+}{H}\overset{-}{A} \rightarrow [(RO)_3\overset{+}{P}H]\overset{-}{A} \rightarrow (RO)_2P\begin{smallmatrix}\nearrow O\\ \searrow H\end{smallmatrix} + R{-}A\,.$$

Transesterification of phosphorus(III) acids is analogous to neutral hydrolysis in many of its details. By analogy with the acid hydrolysis of phosphites, some workers believe[52-54] that in this case the phosphorus atom is also protonated and the breakdown of the intermediate complex is accompanied by the exchange of the alkoxy-groups:



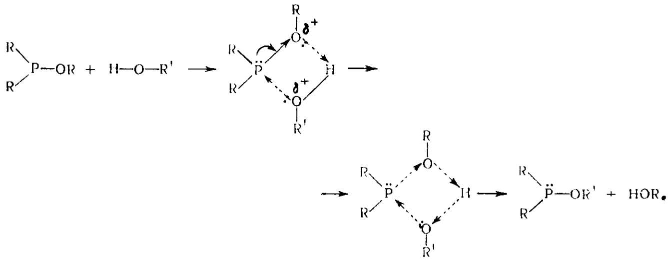
$$(RO)_3P + HOR' \rightarrow [(RO)_3\overset{H}{\overset{|}{P}}{-}OR'] \rightarrow (RO)_2P{-}OR' + ROH\,.$$

Grechkin and also Burgada and coworkers[55-58] showed that the transesterification of the esters and amides of trivalent phosphorus acids with ethanolamine or glycol involves the formation of a pentacovalent product with a spiro-structure and, what is most interesting, there is a possibility of an interconversion of the pentacovalent and trivalent forms:



The isolation of the pentacovalent spiro-product with a phosphorus–hydrogen bond and the demonstration of the interconversions of the trivalent and pentacovalent forms constitutes unquestionable proof of the possible occurrence of transesterification with participation of the free electron pair of the phosphorus atom.

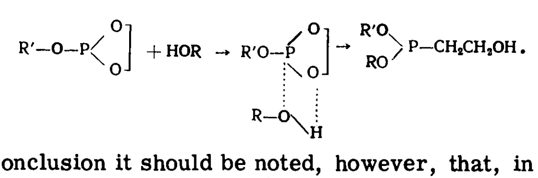
In a study of the kinetics of the transesterification of phosphinic and phosphinous acids with alcohols of different structures, Pudovik and Evstaf'ev showed that the rate of transesterification varies with the *pK* of the alcohol in the opposite sense for trivalent and pentavalent phosphorus acid esters[59-62]. The rate of transesterification of pentavalent phosphorus acid esters, which is a nucleophilic substitution reaction at the tetrahedral phosphorus atom, falls with increase of the acid properties and with decrease of the basic properties of the alcohol. For trivalent phosphorus acid esters, the opposite relation holds. This enabled the authors to suggest that, like neutral hydrolysis, the transesterification involves the initial protonation of the oxygen atom of the alkoxy-group of the phosphinite:



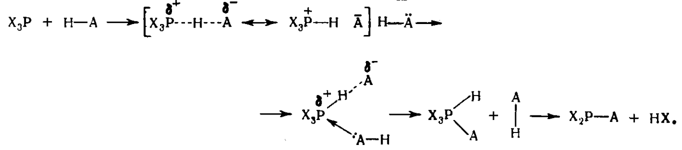
The formation of an 'onium' oxygen atom gives rise to a change in both the bonding pair and in the type of *d–p* interaction of the oxygen–phosphorus bond. This leads to a reduced electron density at the phosphorus atom and gives rise to the possibility of a nucleophilic interaction between the free electrons of the oxygen atom of the alcohol and the vacant *d* orbitals of the phosphorus atom. Such cyclic synchronous electron transfer results in the formation of a "new" phosphinite and a "new" alcohol molecule.

Although these data are apparently in conflict with the results of Grechkin and Burgada, the two sets are in fact complementary rather than mutually exclusive. It may be supposed that, while the initial reversible transition involving the protonation of the phosphorus atom is most likely to be determined by steric factors, in transesterification with alcohols the conditions for thermodynamic equilibrium constitute the decisive factor.

The possibility of the protonation of oxygen is confirmed by data[63] on the transesterification of a cyclic phosphite with alcohols:

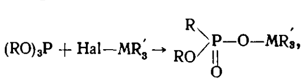


In conclusion it should be noted, however, that, in reactions between phosphorus(III) compounds and substances containing a mobile hydrogen atom, the species responsible for the reaction may not be the trivalent phosphorus compound itself but its complex with a proton donor HA, in which the phosphorus atom behaves as the reactive electrophilic centre:



The ambidentate properties of trivalent phosphorus acid esters have been reflected also in the formation of complexes with a number of elements. The formation of a copper(I) complex was suggested by A. E. Arbuzov[64] as a typical reaction of phosphorus(III) acid esters. Later investigations[65,66] permitted a more detailed study of the metal–phosphorus bond formed.

A number of investigators showed that interaction of phosphorus(III) acid esters with halogeno-compounds of silicon and tin takes place according to the equation[67–71]:

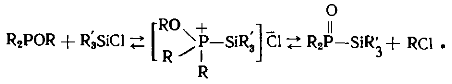


where M = Si or Sn.

Malatesta[68] suggested that the reaction with alkyl halides initially involves the isomerisation of trialkyl phosphite to alkyl phosphonate, which gives rise to the final product by reacting with the halogeno-derivatives of silicon and tin.

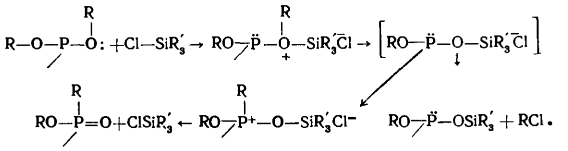
However, Pudovik and Muratova[72] showed that esters of dialkylphosphinous acid can react with halogeno-derivatives of silicon and tin to form stable intermediate complexes. They believe that the complexes are formed as a result of a donor–acceptor interaction between the free electron pair of the phosphorus or oxygen atom and the vacant *d* orbitals of the silicon or tin atom:

If the complex formation involves the participation of the free electron pair of the phosphorus atom and the vacant *d* orbitals of silicon or tin, then the available date on the behaviour of compounds of this kind would lead to the expectation that the breakdown of this complex would result either in the initial materials or compounds with a phosphorus–silicon bond:



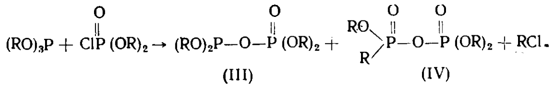
Alkylation of the phosphorus atom is quite unlikely, since this would involve the interaction of the carbonium ion formed with the positively charged phosphorus atom.

On the other hand, if the complex is formed as a result of a donor–acceptor interaction between the free electron pair of the oxygen atom in the alkoxy-radical of the phosphinite and the vacant *d* orbitals of the silicon or tin atom, then the remaining free electron pair of phosphorus in the intermediate complex would interact with the resulting carbonium ion with formation of a phosphorus–carbon bond:

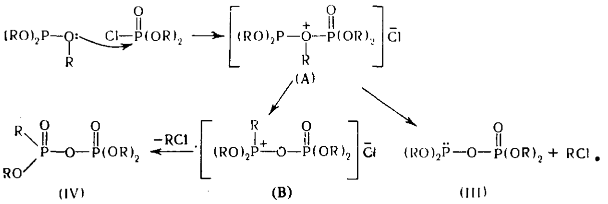


In such donor–acceptor interaction the carbonium ion formed can interact also with the halide anion, as a result of which a phosphorus(III) compound of the type $>\ddot{\mathrm{P}}-\mathrm{O}-\mathrm{SiR}_3$ is formed.

The formation of such a compound has been reported[48], confirming the validity of the mechanism discussed above. It may be supposed that a similar mechanism obtains also in the reaction of triethyl phosphite with a phosphorochloridate ester[45,73,74]:



The authors do not discuss the possible pathways in the formation of subphosphoric acid esters (III), while the formation of compound (IV) is accounted for by the isomerisation of (III) under the influence of the alkyl halide formed. However, the specificity of the structure of the product formed suggests that in this case also the participation of the oxygen atom of the alkoxy-group of the phosphite as a nucleophilic species in the primary step of the interaction is most likely:

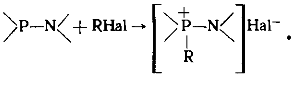


The carbonium ion R^+ is eliminated from the intermediate complex A and interacts with the free electron pair of the trivalent phosphorus atom, which leads to the formation of a quasiphosphonium salt B, or with the chloride ion to form an alkyl halide and compound (III). The decomposition of the salt B yields the product (IV).

It is noteworthy that the examination of the ambidentate properties of trivalent phosphorus acid esters is made very difficult by the fact that few data characterising their behaviour with different reagents are available; the data on the structure of the products formed are not in most cases sufficient to arrive at a conclusion concerning the participation of the phosphorus or oxygen atom in the initial reaction steps, since the structure of the final products may not depend on the mode of attack.

The opposite behaviour is observed for compounds with the bond $>\ddot{\mathrm{P}}-\ddot{\mathrm{N}}<$ or $>\ddot{\mathrm{P}}-\ddot{\mathrm{S}}-$for the vast majority of reactions, the structure of the final product permits a fairly reliable conclusion concerning the participation of the free electron pair of a particular atom in the initial reaction steps. This has been shown in greatest detail for the amides and amido-esters of trivalent phosphorus acids.

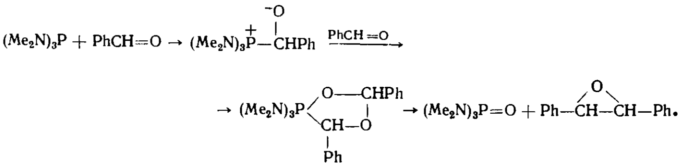
There exists also the view that in trivalent phosphorus acid amides the nucleophilic properties of the nitrogen atoms are reduced and those of the phosphorus atom are enhanced. This is attributed to the occurrence of intense *d–p* interaction[75]. However, only a few reactions of the amido-esters and amides of phosphorus(III) acids take place with participation of the free electron pair of the phosphorus atom, for example reactions with alkyl halides[76,77]:



It is interesting to note that the formation of phosphonium salts is observed for both β-aminoethylphosphine[78] and for *p*-aminophenylphosphines[79]:

$$R_2\ddot{N}-CH_2CH_2\ddot{P}R_2 + R'Hal \rightarrow [R_2N-CH_2CH_2-\overset{+}{P}P_2P'] Hal^-,$$

To account for the formation of an epoxide in the interaction of phosphorous triamides with aldehydes, Mark suggested the following reaction mechanism[80]:



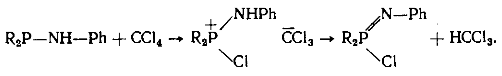
The phosphorus atom behaves as a nucleophilic centre in this reaction. The mechanism is confirmed by measurements of phosphorus-31 chemical shifts and the changes in the PMR spectra of the reaction mixtures.

Hudson and coworkers[81-83] also believe that the phosphorus atom behaves as a nucleophilic centre in the interaction of phosphorous triamides with carbon tetrachloride, which they believe to involve a mechanism with participation of a "positively charged" halogen:

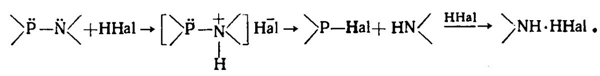
$$(Me_2N)_3P + Cl_4C \rightarrow [(Me_2N)_3\overset{+}{P}Cl\overset{-}{C}Cl_3 \rightarrow (Me_2N)_3\overset{+}{P}CCl_3\overset{-}{Cl}];$$

$$(Me_2N)_3\overset{+}{P}-CCl_3 + (Me_2N)_3P \rightarrow (Me_2N)_3\overset{+}{P}-Cl + (Me_2N)_3P{=}CCl_2.$$

According to their data, in the interaction of *N*-phenyl diphenylphosphinous amide with carbon tetrachloride proton exchange in the ion pair formed leads to the formation of a phosphinimine and chloroform:



The interaction of phosphorus(III) compounds having a P–N bond with hydrogen halides[84-86] differs fundamentally in the reaction products from the analogous reactions of phosphites:



The formation of acid halides with retention of the valence of phosphorus shows that the nitrogen atom behaves as a nucleophilic centre. The interaction of aminophosphines with secondary phosphines takes place similarly[87]:

$$(CH_3)_2P-N(CH_3)_2 + HP(CH_3)_2 \rightarrow (CH_3)_2P-P(CH_3)_2 + HN(CH_3)_2.$$

The appreciably greater basicity of the nitrogen atom compared with phosphorus is indicated by the interaction of dialkyl-(α-aminomethyl)phosphine with secondary phosphines[88]:

$$R'_2P-CH_2NR_2 + HPPh_2 \rightarrow R'_2P-CH_2-PPh_2 + HNR_2.$$

These data and also the fact that the valence of phosphorus remains unchanged suggest that the phenolysis, alcoholysis, and amidolysis reactions of phosphorus(III) acid amides take place with participation of the free electron pair of the nitrogen atom[89-93].

The study of the reactions of alcohols with phosphorous tri(dialkyl amides) showed that the dialkylamine hydrochloride present as an impurity in the triamide has a considerable influence on the rate of the process[94]. The influence of impurities on the rate and also on the mode of reaction has been demonstrated for the interaction of phosphorous triamides with phenolic Mannich bases[95-97].

It is noteworthy that virtually all the reactions investigated with amido-esters and amides of trivalent phosphorus acids were carried out in the presence of appreciable amounts of amine hydrochlorides as impurities. Such acid impurities may lead to the formation either of an activated complex or a phosphonium salt, which probably accelerates the transesterification. This hinders the interpretation of the interaction between trivalent phosphorus acid amides and compounds with a mobile hydrogen atom as a reaction involving the initial protonation of the nitrogen atom.

The complexity of this problem is not restricted to the effects of impurities. In the reactions of trivalent phosphorus acetamides with compounds having a mobile hydrogen atom an activated complex may be formed initially and then react with a second reactant molecule having a mobile hydrogen atom. It is quite likely that the interaction of the amides with hydrogen halides and acetic acid takes place in this way[43,48,49]:

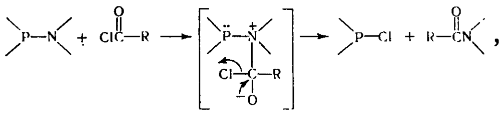
$$>\ddot{P}-NEt_2 + 2HOCOCH_3 \rightarrow >\ddot{P}-OCOCH_3 + Et_2\overset{+}{N}H_2\overset{-}{O}COCH_3.$$

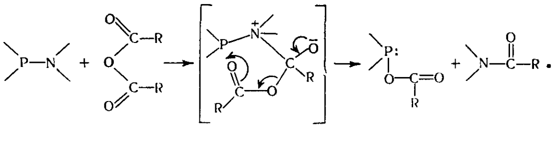
An interesting example of catalysis by compounds with a "hydrogen atom" is the interaction of trivalent phosphorous acid amides with carboxylic acid esters[89]:

$$R-COOR' + >\ddot{N}-\ddot{P}< \rightarrow R-\overset{\overset{O}{\|}}{C}-N< + R'O-P< .$$

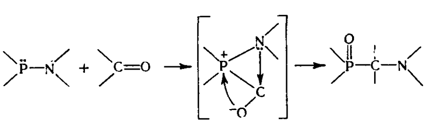
These reactions hardly occur with benzoate and acetate esters. However, phenylacetamide and malonamide are formed in high yields.

The examples of reactions of trivalent phosphorus acetamides with compounds containing a carbonyl group quoted below show that here too the nitrogen atom is the nucleophilic centre: these are reactions with carboxylic acid halides[100-102] and anhydrides[103-106]:

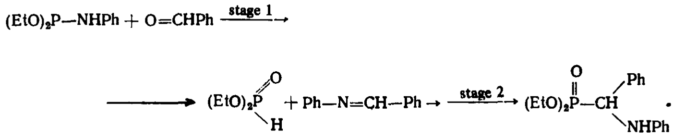




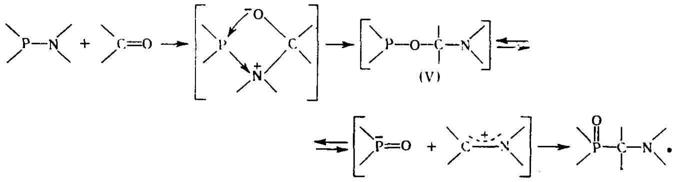
The main products of the reactions of trivalent phosphorus acid amides with aldehydes and ketones are derivatives with the group $>P(O)-\overset{|}{\underset{|}{C}}-N$, [107-110] the formation of which has been explained as follows:



However, Hudson showed[111] that in the reaction between diethyl *N*-phenylphosphoramidite and benzaldehyde, diethylphosphorous acid and the corresponding Schiff base may be isolated as the main products in the initial period:



This was confirmed by following the reaction by infrared spectroscopy and kinetic measurements. As a result, Hudson proposed the following mechanism for the interaction of trivalent phosphorus acid amides with aldehydes:



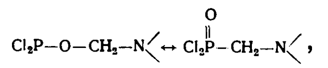
Hudson explains the possibility of the rearrangement of the intermediate compound (V) by the high stability of the ion formed on its decomposition:

This hypothesis does not contradict the literature data on the dependence of the stability of phosphites on their structure. Thus attempts to obtain phosphites by the interaction of trivalent phosphorus acid chlorides with hydroxymethyl derivatives of various kinds[112–115] always resulted in the formation of the corresponding phosphonates and not esters of phosphorus(III) acids.

Even earlier than Hudson, the idea of resonance-stabilised ions,

$$Cl_2P-O^- \leftrightarrow Cl_2\bar{P}=O \text{ and } \overset{+}{C}H_2-N\langle \leftrightarrow CH_2=\overset{+}{N}\langle$$

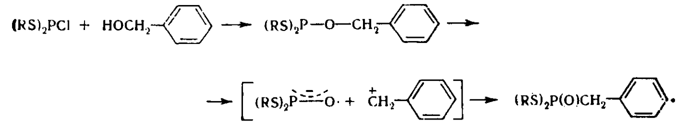
was employed by Rumpf[116] to explain the rearrangement



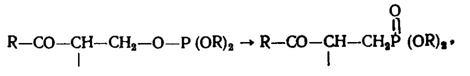
$$Cl_2P-O-CH_2-N\langle \leftrightarrow Cl_2\overset{O}{\overset{\|}{P}}-CH_2-N\langle ,$$

which takes place readily in the interaction between trivalent phosphorus and hydroxymethylamides.

Similar reactions were observed by A. E. Arbuzov and Nikonorov[117] between dialkyl phosphorochloridodithi-ite and benzyl alcohol:



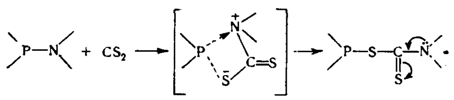
The capacity of phosphites for thermal rearrangement to phosphonates was demonstrated by Rizpolozhenskii and Mukhametov in the reaction with a γ-oxoalkoxy-radical[118]:



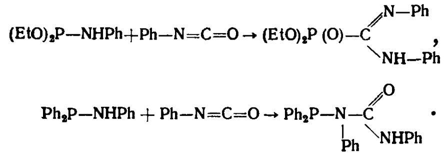
$$R-CO-\underset{|}{C}H-CH_2-O-P(OR)_2 \rightarrow R-CO-\underset{|}{C}H-CH_2\overset{O}{\overset{\|}{P}}(OR)_2 .$$

B. A. Arbuzov and coworkers[119] believe that the rearrangement of the phosphite $R-CONHCH_2OP(OR)_2$ to the phosphonate $R-CONHCH_2-P(O)(OR)_2$ can occur also in the interaction of hydroxymethylamides with triethyl phosphite.

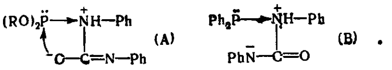
The study of the reactions of phosphoramidites and aminophosphines with carbon disulphide, carbon dioxide, and isocyanates confirms the validity of Hudson's reaction mechanism. Thus in the reaction of carbon disulphide[120] or carbon dioxide[121] with trivalent phosphorus acid amides the process stops at the stage involving the formation of a new phosphorus(III) derivative, the stability of which can probably be explained by the conjugation in the thioamide group:



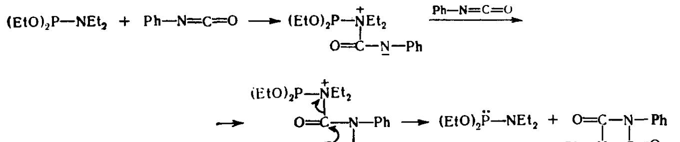
Interesting features of the rearrangement in the intermediate complex were observed in the study of the reaction of diethyl N-phenyl phosphoramidite and diphenylphosphinous anilide with isocyanates[122,123]:



The authors explained the difference by the fact that in the intermediate complex A the alkoxy-groups make the phosphorus atom selective with respect to oxygen as a nucleophilic centre, while phenyl groups favour the interaction with the less powerful nucleophilic centre—the nitrogen atom (intermediate complex B):



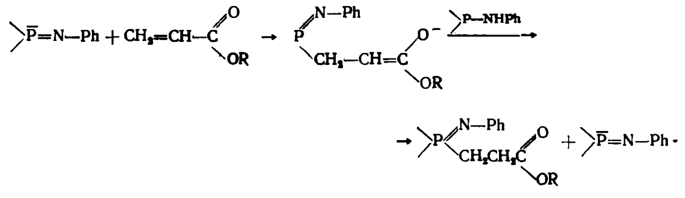
Finally, in contrast to dialkyl N-phenylphosphoramidite, dialkyl NN-diethylphosphoramidite causes only the dimerisation of the isocyanate:



Kabachnik and Gilyarov suggested that, like dialkylphosphorous acids, N-phenylphosphoramidites can exist in two tautomeric forms[124] and found that the anion formed after the elimination of a proton from the aniline-nitrogen constitutes an ambidentate system like the anion of dialkylphosphorous acid:

In reactions with alkyl halides the phosphorus atom is the nucleophilic centre in this anion:

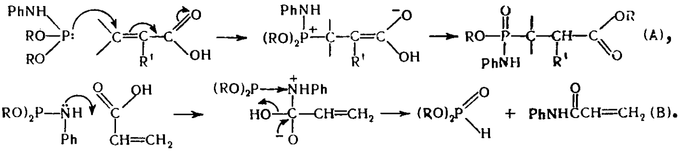
In the reaction of N-phenylphosphoramidites with $\alpha\beta$-conjugated systems in the presence of basic catalysts[125], the electrophilic centre is also attacked by the phosphorus atom:



N-phenylphosphoramidites react with Schiff bases similarly[126,127]:

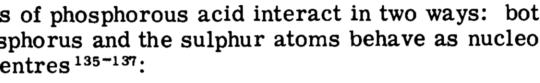
$$(C_2H_5O)_2P{-}NHPh + PhCH{=}NPh \rightarrow (C_2H_5O)_2\overset{NPh}{\overset{|}{P}}{-}CHPh{-}NHPh\,\cdot$$

N-Phenylphosphoramidite reacts somewhat differently[128] with $\alpha\beta$-unsaturated carboxylic acids. In this case the ambidentate properties of both reactants are revealed: either the free electron pair of the phosphorus atom reacts with the electrophilic terminal carbon atom of the conjugated C=C double bond (pathway A) or the free electron pair of the nitrogen atom attacks the carbonyl carbon atom of the unsaturated acid (pathway B):



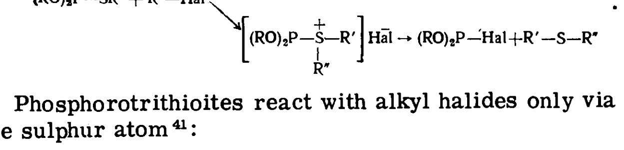
The second pathway begins to predominate when the steric hindrance at the terminal C=C bond increases. Thus the interaction of *N*-phenylphosphoramidite with cinnamic acid leads to the formation of diethyl phosphite and cinnamic acid anilide only.

Compounds with the bond $\gt\ddot{P}{-}SR$ have been investigated in less detail than other types of phosphorus(III) compounds and their chemical behaviour is not known as completely as that of compounds with the $\gt\ddot{P}{-}\ddot{N}\lt$ bond. It has been established that the thioesters of trivalent phosphorus acids are oxidised by hydrogen peroxide and peracids with formation of compounds having the $\gt P{=}O$ group and combine with sulphur to form compounds containing the $\gt P{=}S$ group[129,130]. Interaction of the thioesters with alkyl halides leads to products other than those obtained in the reactions of alkyl halides with esters, ester-amides, and amides of acids with phosphorus(III). The esters of dialkyl-, alkyl-, and diaryl-phosphinothious acids react with alkyl halides only via the free electron pair at the phosphorus atom[131,132]:



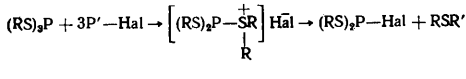
$$\begin{matrix}R'\\R''\end{matrix}\!\!>\!P{-}SR + R'''{-}Hal \rightarrow \left[\begin{matrix}R'\\R''\end{matrix}\!\!>\!\overset{+}{P}\!<\!\begin{matrix}R'''\\SR\end{matrix}\right]\bar{Hal} \rightarrow \begin{matrix}R'\\R''\end{matrix}\!\!>\!\overset{S}{\overset{\|}{P}}{-}R''' + R{-}Hal.$$

The interaction of esters of alkyl- and phenyl-phosphonodithious acids with alkyl halides also leads to the alkylation of the phosphorus atom[133,134]. The instability and the capacity for intermolecular rearrangement to phosphonothioates characteristic of the esters of phenylphosphonodithious acid should be noted[131]. Mixed *O*, *S*-esters of phosphorous acid interact in two ways: both the phosphorus and the sulphur atoms behave as nucleophilic centres[135-137]:



$$(RO)_2P{-}SR' + R''{-}Hal \begin{cases}\nearrow \left[(RO)_2\overset{+}{P}\!<\!\begin{matrix}R''\\SR'\end{matrix}\right]\bar{Hal} \rightarrow RO{-}\overset{O}{\overset{\|}{P}}\!<\!\begin{matrix}R''\\SR'\end{matrix} + R{-}Hal\\ \searrow \left[(RO)_2P{-}\underset{R''}{\underset{|}{\overset{+}{S}}}{-}R'\right]\bar{Hal} \rightarrow (RO)_2P{-}Hal + R'{-}S{-}R''\end{cases}$$

Phosphorotrithioites react with alkyl halides only via the sulphur atom[41]:

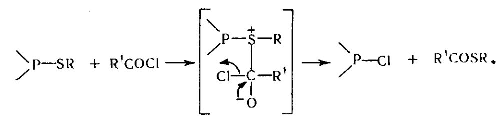


$$(RS)_3P + 3P'{-}Hal \rightarrow \left[(RS)_2P{-}\underset{R}{\underset{|}{\overset{+}{S}}}R\right]\bar{Hal} \rightarrow (RS)_2P{-}Hal + RSR'.$$

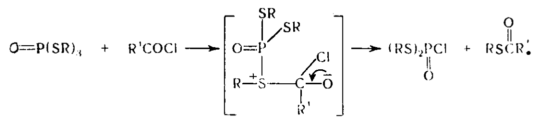
Triphenyl phosphorotrithioites reacts similarly with alkyl halides[138]. However, it is striking that, in contrast to triphenyl phosphite, its intermediate product cannot be isolated:

$$(PhS)_3P + 3CH_3I \rightarrow 3\,PhSCH_3 + PI_3.$$

The nucleophilic interaction of phosphorus(III) thioesters with an unsaturated electrophilic carbon centre has been investigated only in reactions with acid halides. It was shown[137,139,140] that in phosphorotrithioites and in alkyl(aryl)-phosphonothioites and -phosphonodithioites the nucleophilic centre is the sulphur atom:



It is remarkable that even in the molecule of phosphorotrithiolic acid the sulphur atoms can participate in reactions with carboxylic acid halides:

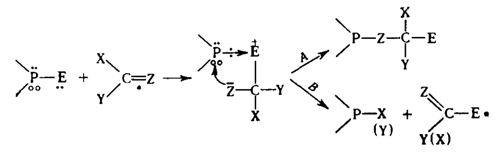


One of the most interesting problems which follow from the examination of the above experimental data is the discovery of the factors which control the selectivity in ambidentate phosphorus–element systems. Although the available experimental data do not provide an exhaustive solution of the problem in many of its aspects, certain relations are revealed quite clearly.

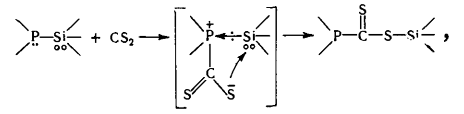
In the first place a fairly sharp difference in selectivity when the P–E system reacts with an electrophilic centre at a saturated and an unsaturated carbon atom is striking. While in the first case the phosphorus atom behaves as the nucleophilic centre of the system, in the second case attack by the free electron pair of the second element (particularly nitrogen and sulphur) is most typical.

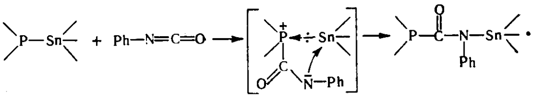
If the phosphorus atom is the nucleophilic centre, a quasiphosphonium complex is formed and the final product is always a derivative of tetracoordinate phosphorus, which depends on the nature of the substituent. On the other hand, when the nucleophilic centre is not the phosphorus atom but another element (O, S, N) directly linked to it, the structure of the final product as a rule indicates a number of rearrangements of the reaction complex formed initially. The specificity of the properties of the phosphorus atom—the presence of both a free electron pair and vacant *d* orbitals—is responsible for the possibility of rearrangements of this kind.

Indeed, when E behaves as the nucleophilic centre in the reaction of the system P–E (E = O, N, or S) with an unsaturated electrophilic carbon atom, an intermediate reaction complex is formed. The reduction of electron density at the atom (the formation of a positive charge) is compensated both by a shift of the binding electron pair of the $P \div E$ bond and a change in the type of $d{-}p$ interaction (it disappears). An increase in electron density at the Z atom may be compensated by interaction with the vacant *d* orbitals of the phosphorus atom, which becomes possible only after the reduction of electron density of the latter due to the shift of the binding electron pair of the P–E bond in the initial nucleophilic attack by E:

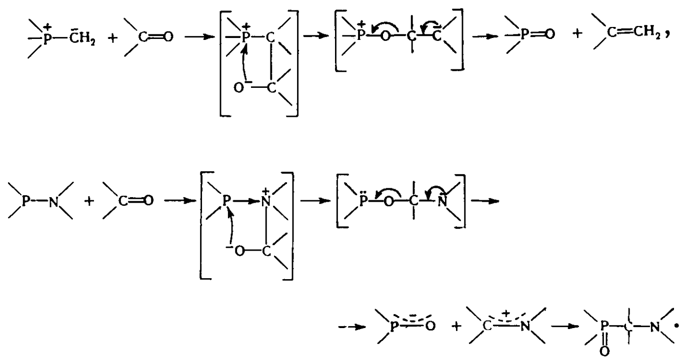


Further reaction of the intermediate reaction complex is determined mainly by the nature of the substituents X and Y. If they are electron-donating, then pathway A will predominate via the stabilisation of the intermediate complex. Electron-accepting substituents X and Y (X = Cl or Br) most often lead to the stabilisation of the intermediate complex via pathway B. This explanation is confirmed both by the experimental data described above and the results obtained in the study of the interaction of compounds of the type $R_3Si-PPh_2$ and $R_3Sn-PPh_2$ with carbon disulphide, isocyanates, and many other electrophilic agents[141-144]. Tin and silicon have only vacant *d* orbitals. Therefore in their compounds with trivalent phosphorus the latter is the only nucleophilic centre and their interaction with an unsaturated electrophilic centre leads to a situation opposite to that described above:





It is striking that the mechanism discussed is essentially analogous to the mechanism proposed to account for the Wittig reaction[145]:



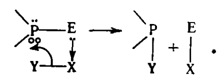
Examination of a wide range of examples of the ambidentate behaviour of derivatives of acids with phosphorus(III) shows that the nucleophilic properties of E in the system P–E diminish in the sequence S > N > O. There is no doubt that this problem is directly linked to the nature of the *d–p* interaction in the P–E system. The changes in nucleophilic properties in the series O, N, and S should be reflected appreciably also in the type of interaction between phosphorus(III) derivatives and heteroconjugated systems. The first studies on these lines, by Pudovik and coworkers[146], led to the discovery of the characteristic features of the behaviour of these systems.

Apparently the concept of the ambidentate properties of phosphorus(III) compounds can significantly facilitate the theoretical analysis of the possible reaction mechanisms in the reaction system and can give a fairly correct indication of the structure of the final reaction products. Therefore it is both urgent and necessary that attention be drawn to the assessment of the ambidentate property as a real property of phosphorus(III) derivatives.

IV. SUBSTITUTION REACTIONS AND CHARACTERISTICS OF SYSTEMS WITH A PHOSPHORUS–HALOGEN BOND IN A SERIES OF PHOSPHORUS(III) DERIVATIVES

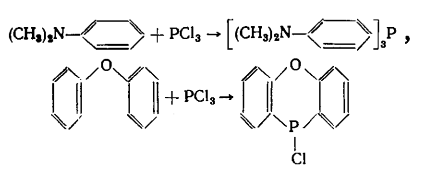
Substitution reactions are most common for phosphorus(III) compounds. They are characteristic of both primary and secondary phosphines as well as the amides, esters, and halides of acids containing phosphorus(III). They frequently take place at very high rates.

Substitution reactions in phosphorus(III) compounds in which the electron density at the phosphorus atom is enhanced and it behaves as a typical nucleophilic centre were analysed in detail in the previous section. A reduced electron density at the phosphorus atom, as a necessary condition for the interaction between a nucleophilic agent and a *d* orbital of phosphorus, arises via the primary attack by the free electron pair of E on the electrophilic centre of the second reactant:

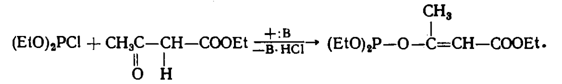


A second type of substitution reaction involves the usual nucleophilic substitution at the phosphorus atom as an electrophilic centre. The introduction of a chlorine (bromine or iodine) atom into any derivative of phosphorus(III) is known to reduce sharply its nucleophilic properties. For example, even powerful nucleophilic agents such as Alk_3P and $(\rangle N)_3P$ can react with only the most reactive compounds after the replacement of the alkyl or amino-group by chlorine[147-150], while $RPCl_2$ and $\rangle NPCl_2$ are incapable of alkylation by alkyl halides. The nucleophilic properties of PCl_3 are not revealed in any reaction and the study of PCl_3 complexes have shown that the phosphorus atom exhibits distinct electron-accepting properties[11-14].

Substitution reactions are most typical for trivalent phosphorus acid chlorides. These reactions take place extremely readily with the majority of the usual nucleophilic agents: alcohols[151], mercaptans[152], phenols[153], and amines[154]. It is noteworthy that the ease of reaction of phosphorus(III) acid chlorides and compounds of the type P–E (where E = N, O, or S) varies in the opposite sense as a function of the nucleophilic properties of the nucleophilic agent. Similar reactions take place with activated benzene derivatives[155,156] (with formation of a P–C bond).

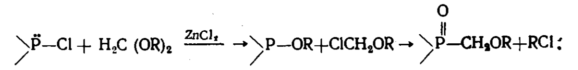


or compounds having a mobile H – C bond, such as acetoacetic ester, the product containing an enol ester bond[157]:

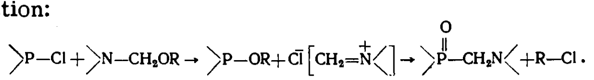


$$(EtO)_2PCl + CH_3C(O)\text{—}CH(H)\text{—}COOEt \xrightarrow[-B\cdot HCl]{+:B} (EtO)_2P\text{—}O\text{—}C(CH_3){=}CH\text{—}COOEt.$$

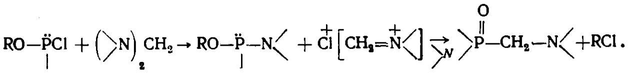
Many substitution reactions, which are of the exchange type in a wider sense than the usual nucleophilic substitution, are known at present. Frequently these reactions constitute the first step in multistage processes leading to the formation of phosphorus(V) derivatives. In many cases these stages can be separated. Thus, while formals do not react with phosphorus(III) derivatives without a catalyst, in its presence the reaction takes place readily[158]:



The replacement in the formal of even one alkoxy-group by an amino-group leads to a sharp increase of the rate of reaction:



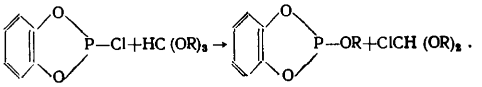
The reactions with di(dialkylamino)methane take place even more readily[159]:



In the orthoesters of carboxylic acid the replacement of an alkoxy-group does not require any catalyst, unlike formals[160–163]:

$$R_n\,PCl_{3-n} + HC(OR')_3 \rightarrow R_nP(OR')_{3-n} + ClCH(OR')_2 \rightarrow R_n(R'O)_{2-n}P(O)\text{—}CH(OR')_2 + R'Cl\ .$$

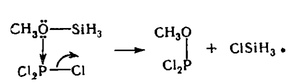
These reactions can be carried out in stages until the substitution of the last halogen at the phosphorus atom. However, in the case of pyrocatecholphosphorous acid chloride [phenylene phosphorochloridite] the reaction ceases after the exchange of one alkoxy-group[162,163]:



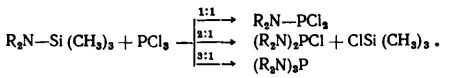
It is remarkable that $Si(OR)_4$ does not undergo a similar interaction with PCl_3 under mild conditions. However, the reaction with PBr_3 and PI_3 takes place vigorously with formation of an alkyl halide and resinous products of unknown structure[164]. The reaction between alkoxytrimethylsilane and PCl_3 takes place in stages[165]. While in the system $(H_3Si)_2O + PCl_3$ no interaction is observed, when there is even only one methoxy-group at the silicon atom the reaction takes place according to the mechanism[166]

$$H_3SiOCH_3 + PCl_3 \rightarrow H_3SiCl + CH_3OPCl_2.$$

The author suggests that the initial stage includes the formation of a four-centre transition complex and the decisive factor is the electron-donating capacity of the oxygen in the Si – O bond:



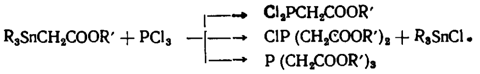
In agreement with this, the exchange reactions of compounds containing an amino-group (which has more pronounced electron-donating properties) and an Si – N bond take place more readily and proceed to higher degrees of substitution[167,168]:



$$R_2N\text{—}Si(CH_3)_3 + PCl_3 \rightarrow \begin{cases} \xrightarrow{1:1} R_2N\text{—}PCl_2 \\ \xrightarrow{2:1} (R_2N)_2PCl + ClSi(CH_3)_3\,. \\ \xrightarrow{3:1} (R_2N)_3P \end{cases}$$

$PhPCl_2$, Ph_2PCl_2, and $O-PCl_3$ react in exactly the same way. This reaction is typical not only for phosphorus(III) halides but also for halogeno-derivatives of sulphur: S_2Cl_2, $SOCl_2$, RSO_2Cl.[169] Probably many other reactions also involve the same mechanism[170,171]:

$$PCl_3 + PhS\text{—}Sn(CH_3)_3 \rightarrow ClSn(CH_3)_3 + (PhS)_3P,$$



$$R_3SnCH_2COOR' + PCl_3 \rightarrow \begin{cases} Cl_2PCH_2COOR' \\ ClP(CH_2COOR')_2 + R_3SnCl\,. \\ P(CH_2COOR')_3 \end{cases}$$

However, with analogous α-ketone or aldehyde derivatives the mode of reaction depends on the substituent at the phosphorus atom[172]:

$$R_3SnCH_2COCH_3 + (RO)_nPCl_{3-n} \rightarrow (RO)_nP(O\text{—}C(CH_3){=}CH_2)_{3-n} + R_3SnCl$$

and at the same time

$$R_3SnCH_2COCH_3 + Alk_2PCl \rightarrow Alk_2P\text{—}CH_2C(O)CH_3 + R_3SnCl.$$

A difference between phosphorochlorodites[173–175] and phosphites[176] is observed also in reactions with α-(halogenomercuri)carbonyl compounds:

$$(RO)_nPCl_{3-n} + ClHgCH_2COR' \rightarrow (RO)_nP(OC(R'){=}CH_2)_{3-n},$$

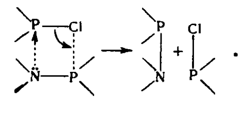
where $n = 1 - 2$ and $R' = H$ or CH_3, and

$$(EtO)_3P + ClHgCH_2CH{=}O \rightarrow (EtO)_2P(O)CH{=}CH_2 + EtCl\,.$$

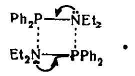
There is also a wide variety of reactions of halogeno-derivatives of phosphorus(III) with other derivatives of trivalent and quinquevalent phosphorus. These are primarily disproportionation reactions in the series of phosphorus(III) derivatives, a typical feature of which is the formation of equilibrium systems[177–180]:

$$PhPCl_2 \rightarrow Ph_2PCl + RCl_3,$$
$$PCl_3 + P(OEt)_3 \rightleftarrows ClP(OEt)_2 + Cl_2POEt,$$
$$PCl_3 + P(OPh)_3 \rightleftarrows ClP(OPh)_2 + Cl_2POPh,$$
$$PCl_3 + P(NR_2)_3 \rightleftarrows ClP(NR_2)_2 + Cl_2PNR_2,$$

and many others[181–183]. The rate of reaction increases in the sequence Ph < PhO < AlkO > R_2N. All these findings suggest that the exchange reactions involve a cyclic mechanism:



Moreover, the capacity of phosphorus(III) derivatives for such cyclic interactions may be the cause of the formation of relatively stable association complexes. Recently Evdakov and coworkers[184] showed that the rate of oxidation of dialkylaminodiphenylphosphine without solvent or in polar solvents is relatively low, but increases sharply in non-polar solvents. They explain the relatively low capacity of this compound for oxidation in a free state by the formation of association complexes:

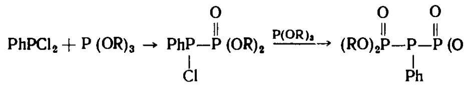


In a non-polar solvent this substance is present in the form of "free" molecules more available for chemical interaction with other reactants.

While the exchange reactions in the series of acid halides derived from phosphorous acid do not lead to a change in the valence of phosphorus, the reactions of halogenophosphines have a mechanism involving the Arbuzov rearrangement[185]:

$$Ph_2PCl + (RO)_nPPh_{3-n} \rightarrow Ph_2P-\overset{\overset{\displaystyle O}{\|}}{P}(OR)_{n-1}(Ph)_{3-n} + RCl$$

or



$$PhPCl_2 + P(OR)_3 \rightarrow PhP(Cl)-\overset{\overset{\displaystyle O}{\|}}{P}(OR)_2 \xrightarrow{P(OR)_3} (RO)_2\overset{\overset{\displaystyle O}{\|}}{P}-P(Ph)-\overset{\overset{\displaystyle O}{\|}}{P}(OR)_2 .$$

While the reaction between a secondary phosphine and a halogeno-derivative of trivalent phosphorus takes place according to the equation[186]

$$\rangle P-H + Hal-P\langle \rightarrow \rangle P-P\langle + HHal,$$

in the case of tertiary phosphines the reaction takes place in quite a different way[187]:

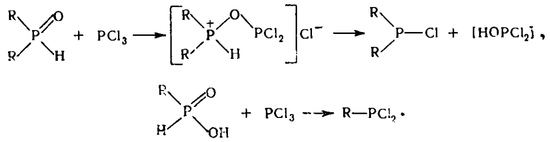
$$(C_4H_9)_3P + PhPCl_2 \rightarrow (C_4H_9)_3PCl_2 + (PhP)_4 ,$$
$$(C_4H_9)_3P + Ph_2PCl \rightarrow (C_4H_9)_3PCl_2 + Ph_2P-PPh_2 .$$

Substitution reactions can take place with phosphorus(V) derivatives as nucleophilic agents and the nature of the nucleophilic centre may be various[188–192]:

$$(RO)_2\dot{P}\overset{-}{=}\dot{O} + ClP(OR)_2 \longrightarrow (RO)_2P-O-P(OR)_2 + \bar{Cl} ,$$

$$(RO)_2P(=O)-O^- + ClP(OR)_2 \longrightarrow (RO)_2P(O)-O-P(OR)_2 + \bar{Cl} ,$$

$$[Ph_3P{=}CHR \longleftrightarrow Ph_3\overset{+}{P}-\bar{C}HR] + ClPPh_2 \longrightarrow [Ph_3\overset{+}{P}-CHR-\ddot{P}Ph_2]\bar{Cl} ,$$

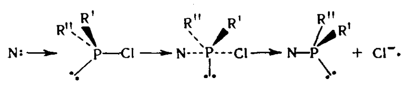


The fact that in the last two reactions[191,192] the decisive factor is the nucleophilic properties of the oxygen atom in the P = O group and not a tautomeric equilibrium between the quinquevalent and trivalent forms of phosphorus is confirmed by the finding that[193]

$$SiHal_4 + nO{=}PPh_3 \rightarrow Hal_{4-n}Si\{[-O-\overset{+}{P}Ph_3]\bar{Cl}\}_n \quad (n = 2,\ 4) .$$

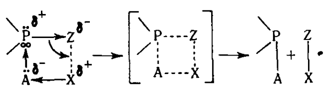
This structure of the adducts was based on infrared spectroscopic and conductimetric data.

The examples of substitution or exchange reactions with participation of a phosphorus – halogen bond quoted above fall far short of exhausting the available literature data. Nevertheless they are extremely typical and are adequate for the discussion of certain problems of the mechanism of those reactions. With the usual nucleophilic agents, substitution reactions at an electrophilic phosphorus atom can take place via a classical S_N2 bimolecular nucleophilic substitution mechanism:



However, so far there are no quantitative data in the literature concerning the true mechanism of the substitution reaction or the elucidation of the role and contribution of the phosphorus *d* orbitals in this mechanism. Nevertheless, the numerous examples quoted, mainly of exchange reactions, can be very readily explained qualitatively if one takes into account the significant contribution of the *d* orbitals of the trivalent phosphorus atom as an electrophilic centre in the substitution reactions. The involvement of the *d* orbitals should alter significantly the type of reaction as a whole.

In the nucleophilic attack by the second reactant on the phosphorus atom a free electron pair of the nucleophilic agent is transferred to the *d* orbitals of the phosphorus atom. According to quantum-chemical concepts, such interaction can be favourable only in the presence of a reduced electron density at the phosphorus atom[15]. Therefore, with increasing electronegativity of the substituent or the number of substituents at the phosphorus atom, its positive charge increases also, which facilitates, owing to the energy factor, the participation of the phosphorus *d* orbitals in the nucleophilic substitution reaction. The involvement of the *d* orbitals of the phosphorus atom makes possible electron transfer via a four-centre cyclic mechanism:



In those cases where the group Z can be readily eliminated in the form of an anion and the process is facilitated by its additional interaction with the electrophilic centre of the second reactant (X = H, $-Si\langle$, etc.), a process of this kind takes place without a change in the valence of the phosphorus atom, i.e. a substitution reaction occurs. Therefore the group Z need not necessarily be eliminated in the form of an anion, since the possibility of a synchronous cyclic electron transfer eliminates the necessity for charge separation both in the transition complex and in the final product, in contrast to classical nucleophilic substitution of type S_N1 or S_N2.

Thus the primary interaction between the electrons of the nucleophilic agent and *d* orbitals of the phosphorus atom leads in the first instants essentially to an increase of coordination and of the valence of the phosphorus atom, but cyclic electron transfer can reduce them both in the final reaction product. Such stabilisation is not the only one possible. One of the other pathways may be a further increase of the valence with retention or increase of the degree of coordination of the phosphorus atom in the final reaction products—these are examples of the reactions mentioned above in which the phosphorus atom exhibits biphilic properties.

The examples of substitution reactions quoted above for the series of phosphorus(III) derivatives reveal a considerable role of the phosphorus *d* orbitals in chemical reactions. Even a purely qualitative hypothesis of this kind can serve as a firm basis for the understanding of the behaviour of phosphorus as a biphilic reagent in an even greater range of chemical reactions.

To estimate the role and contribution of the *d* orbitals of phosphorus in any of its reactions, it is necessary to know at least its relative electron density. On the other hand, a knowledge of this quantity is necessary for the estimation of the nucleophilic properties of the free electron pair of the phosphorus atom. Depending on the nature of the substituent, the charge at the phosphorus atom may change due to the inductive effect of the added group and its capacity for conjugation with the phosphorus *d* orbitals. It is interesting that the π-electron systems of substituents are incapable of $p-\pi$ conjugation with the unshared electron pair of phosphorus, which is explained by the enhanced s-character of the pair[194]. The determination of the contribution of conjugation with the d orbitals to the overall electron density at the phosphorus atom as well as the determination of the latter are undoubtedly some of the most difficult and urgent problems in the chemistry of phosphorus(III) derivatives.

The attempts by Van Wazer and coworkers[195,196] to determine the conjugation effect for phosphorus(III) derivatives by comparing the calculated ^{31}P chemical shifts with the experimental values cannot be regarded as satisfactory because their conclusions concerning the electron density at the phosphorus atom are difficult to reconcile with the chemical properties of the corresponding derivatives. Moreover, the theoretical principles of the calculation of the ^{31}P chemical shifts have been seriously criticised[197]. Thus it might have been expected that dialkylchlorophosphine should be more nucleophilic than trialkyl phosphites. However, the former is much less reactive in classical substitution reactions with alkyl halides[147-149]. On the other hand, the phosphine is incomparably more reactive than phosphites in substitution reactions where the phosphorus atom exhibits its biphilic properties.

---o0o---

Explanations without internal contradictions are at present possible for only a few reactions of trivalent phosphorus. We have attempted to assess on the basis of the chemical properties of phosphorus(III) derivatives the role of the free electron pair and the d orbitals of the phosphorus atom and the effect of substituents and their nature in various reactions. In view of the complexity and the controversial nature of the problems discussed, the specific views expressed cannot be regarded as definitive. The principal aim of the present review was to reveal the many-sided nature of the reaction mechanisms of trivalent phosphorus and to draw attention to the most important problems.

The Present State of the Theory of the Oxidation of Cyclo-olefins

A.A.Syrov and V.K.Tsyskovskii

The review deals with various methods for the oxidation of cyclo-olefins by molecular oxygen, nitric acid, aqueous solutions of palladium and gold chlorides, and also ozonolysis. The effect of the structure of the olefin, the solvent, and reaction conditions on the mechanism of action of the oxidant have been analysed. The aim of the review is to formulate, by examining the reaction mechanisms, the principal trends in the applied studies on the synthesis of aliphatic oxygen-containing compounds (acids, aldehydes, and alcohols) from cyclo-olefins. It has been shown that the use of ozone fulfills most closely the desired aim.

The bibliography contains 182 references

CONTENTS

Introduction

The view that processes involving oxidation by molecular oxygen of straight-chain alkanes, alkylbenzenes, and cycloalkanes constitute the most rapid and cheapest methods for the synthesis of acids, alcohols, and compounds with mixed functional groups has now become firmly established. Indeed, considerable advances have been made in studies on the oxidation of these compounds and many processes have been applied in industry. At the same time, the use of cyclo-olefins for this purpose is of no less interest but studies in this field have not yet gone beyond the initial research stage.

Cyclo-olefins are cyclic compounds with a double bond in the ring. According to modern quantum-mechanical views[1] on the nature of the double bond, one of the bonds between the carbon atoms is formed by hydrid sp^2 orbitals. A vacant $2p$ orbital remains at each carbon atom and these two form a π bond by partial overlapping of the electron clouds. The plane of the $2p$ orbitals is perpendicular to that of the sp^2 orbitals. The mutual overlapping of the electronic orbitals is greater in σ bonds than in π bonds and the former are more stable.

There exists also another description of the double bond, proposed by Pauling[2,3]: two tetrahedrally disposed orbitals at each carbon atom overlap one another forming "banana" bonds.

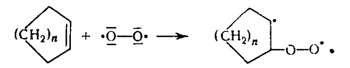
Since the π bond is highly polarisable, multiple C–C bonds readily react with electrophilic agents, i.e. have nucleophilic properties, and are also capable of combining with radicals if the latter are sufficiently reactive.

To facilitate the addition of radicals, it is evidently necessary either to weaken the π bond or to activate the radical. Powerful electrophilic agents such as chlorine, bromine, nitric acid, lead tetra-acetate, potassium permanganate, ozone, and others react as oxidants. In the oxidation the two electrons forming the covalent bond may be transferred either in two stages, one electron at a time (giving a radical process) or by an ionic mechanism, both electrons being involved at once. Substituents at the double bond with a negative inductive effect (–*I* effect) (carbonyl, nitryl, and nitro-groups and others) diminish its nucleophilic properties. The electron density of the π bond and hence also the rate of electrophilic addition are then reduced[4].

I. OXIDATION OF CYCLO-OLEFINS BY MOLECULAR OXYGEN

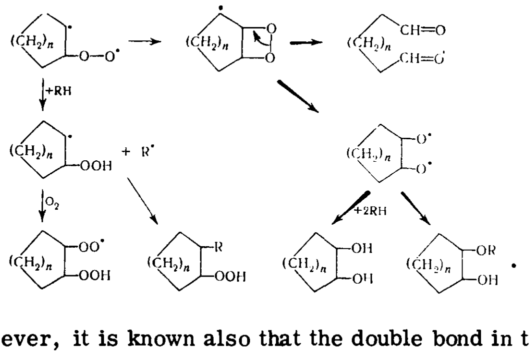
1. The Addition of Oxygen to the Double Bond

The discovery of processes underlying the mechanism of the oxidation is inconceivable without the knowledge of the structure of the oxygen molecule. Mulliken[5] was the first to devote much attention to this problem. According to physical data, the oxygen molecule should have the properties of biradicals (the presence of two unpaired electrons, triplet state, paramagnetism). Therefore oxygen should add directly to the double bond in cyclo-olefin oxidation reactions:



(I.1)

The most probable pathway of further reaction is the formation of a cyclic peroxide, the subsequent rearrangement or radical decomposition of which may lead to the formation of both aliphatic dialdehydes and cycloalkanediols:



(I.2)

However, it is known also that the double bond in the oxygen molecule is fairly stable, the O–O distance (1.2074 Å) being close to the length of the C=O double bond[6] (1.21 Å).

All these data suggest that the electronic structure of the oxygen molecule is more complex than would appear on the basis of the biradical hypothesis. The outer electronic shell of the oxygen atom is known to contain six electrons (two electrons in the 2*s* orbitals and four electrons in the 2*p* orbitals). It is suggested that a three-electron bond is formed when the atoms are combined to form a molecule[7]. Then each oxygen atom uses one of its four valence orbitals for an unshared pair, one for the formation of a single bond, and two for the formation of three-electron bonds:

$$:\!O \div\!\div\!\div O\!: \qquad (I.3)$$

The saturated O=O structure is also possible but it is less favourable energetically and is encountered in one of the excited states (singlet). The reactions with participation of singlet oxygen (for example the oxidation of cyclo-olefins) constitute a new developing branch of chemistry and are outside the scope of the present review†.

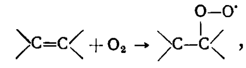
The problem of the electronic state of the oxygen molecule has been discussed on the basis of the molecular orbital method in books by Slater, Spice, and Coulson[25-27]. The molecular orbital method explained for the first time why the oxygen molecule is paramagnetic.

In order to convert O_2 into a biradical, it is necessary to raise the energy by 60–70 kcal mole^{-1}:[28]

$$:\!O \div\!\div\!\div O\!: \rightarrow \cdot\overline{\underline{O}}{-}\overline{\underline{O}}\cdot \ . \qquad (I.4)$$

Such rearrangement of the electron clouds can be induced either thermally or photochemically and at temperatures ≤ 200°C it probably takes place to an insignificant extent (about 10^{-5}%). Consequently, under ordinary conditions the oxidation of hydrocarbons could take place if the activation energy for the removal of hydrogen by the oxygen molecule (or for the addition of the latter to the double bond) were sufficiently low. However, experimental activation energies for the initial steps in the oxidation[29] of various hydrocarbons,

$$RH + O_2 \rightarrow R^\cdot + HO_2^\cdot, \qquad (I.5)$$



$$>\!C{=}C\!< + O_2 \rightarrow >\!\underset{}{C}(O{-}O^\cdot){-}\dot{C}\!<, \qquad (I.6)$$

amount to 15–30 kcal mole^{-1}.

The rearrangement of electron clouds in the oxygen molecule takes place very readily only on interaction with a radical already present in the system, which gives rise to the possibility of the development of a radical reaction chain. The theory of slow radical branched-chain reactions, based largely on the work of Semenov[30] and his school, has been developed in studies on the liquid-phase oxidation of hydrocarbons, in particular cyclo-olefins, which have been activated in some way.

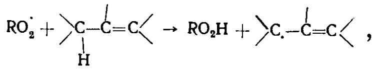
We shall consider in greater detail the existing hypotheses on the oxidation of unsubstituted and substituted cyclo-olefins by molecular oxygen and by other oxidants.

2. Oxidation of Unsubstituted Cyclo-Olefins

The oxidation of cyclohexene and cyclopentene (60° and 80°C) is known to involve the formation[31-42] of a fairly stable hydroperoxide with an HOO group in the *α*-position relative to the double bond. The process kinetics and the mechanism of the formation of the *α*-hydroperoxide from cyclohexene were investigated by Hendry and Russell[43], Erofeev and coworkers[44-49], Mayo and coworkers[50], and others[51].

Numerous studies have been made on the composition and structure of the oligomeric peroxide products formed in the oxidation of cyclohexene[52-57].

In 1956 Reppe and coworkers[58,59] reported the synthesis of epoxycyclo-octane by the oxidation of cyclo-octene by molecular oxygen at 60°C in the presence of a cobalt catalyst. This advance led to new investigations of the effect of ring size on the oxidation mechanism. According to the cummunication by Mayo and coworkers[50], in the oxidation of a series of cyclo-olefins ranging from C_5 to C_8 at 50–80°C there is a gradual change in reaction mechanism. Thus in the oxidation of cyclopentene 86% of the initial olefin reacts by a mechanism involving the abstraction of the allyl hydrogen atom with ultimate formation of cyclopentenyl hydroperoxide:



(I.7)

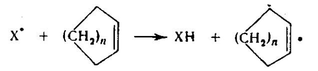
while in the reaction of cyclo-octene the addition mechanism predominates (70%):

(I.8)

with formation of the epoxide, suberic aldehyde, and polymers[58].

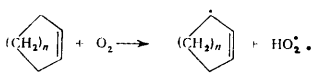
These data are consistent with the observation of de Rosh and Balaceanu[28], who suggested the following reaction mechanism:

$$\text{initiator} \longrightarrow 2X^\cdot, \qquad (I.9)$$



(I.10)

In order to assess the possibility that oxygen adds to the double bond of the cyclo-olefin, we shall consider elementary chain initiation steps in the absence of initiating additives:



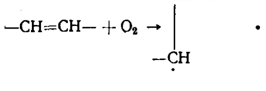
(I.11)

Reaction (I.11) is endothermic, since its heat is

$$q_{(I.11)} = q_{\text{allyl C-H}} - 47 \text{ kcal mole}^{-1} \text{ (the O-H bond dissociation energy in the HO}_2^\cdot\text{radical)},$$

$$84 \text{ kcal mole}^{-1} \geqslant q_{\text{allyl C-H}} \text{ (Ref.60)} \geqslant 77 \text{ kcal mole}^{-1}.$$

The experimental activation energies[29] $E_{(I.11)}$ for reaction (I.11) amount to 15–30 kcal mole^{-1} for different compounds:

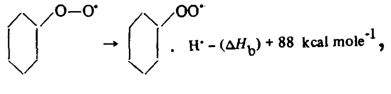


$$-CH{=}CH- + O_2 \rightarrow \begin{array}{l} -CH{-}O{-}O^\cdot \\ \ \ | \\ -\dot{C}H \end{array} . \qquad (I.12)$$

The activation energy for reaction (I.12) is probably fairly high. In the case of styrene[61] it is 30 ± 2 kcal mole^{-1}. To calculate the heat of reaction (I.12) for cyclohexene, we have

$$C_6H_{12} \rightarrow C_6H_{11}^\cdot + {}^\cdot H - 88^{62} \text{ (Ref.62) kcal mole}^{-1}, \qquad (a)$$

$$C_6H_{11}^\cdot + O_2 \rightarrow C_6H_{11}OO^\cdot + 20 \text{ (Refs 28 and 61) kcal mole}^{-1}, \qquad (b)$$



(c)

since the effect of the peroxy-group O–O$^\cdot$ on the elimination of a hydrogen atom from the *α*-position is probably

---

†For the chemistry of singlet oxygen, see Refs. 8–24.

insignificant. Next we used the tabulated heats of formation of the substances from the elements[63]:

$$\text{cyclohexene } \Delta H_{\text{form}} = -6.4 \text{ kcal mole}^{-1},$$

$$\text{cyclohexene } \Delta H_{\text{form}} = -29.5 \text{ kcal mole}^{-1},$$

$$2H \rightarrow H_2 + 104 \text{ kcal mole}^{-1}.$$

Hence, according to Hess's law the heat of reaction is

$$\Delta H_b = 88 - \Delta H_H + [-20 + 83 + \Delta H_{C_6H_{12}} - \Delta H_H],$$

$$q_{(I.12)} = \Delta H_b - \Delta H_{C_6H_{10}} = 28.9 \text{ kcal mole}^{-1}.$$

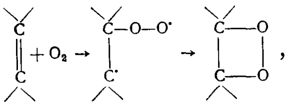
Since we do not know the heat of formation of cyclo-octene, it will be calculated from the known heats of hydrogenation of *cis*-cyclo-octene (−23.53 kcal mole^{-1}) and the heat of formation of cyclo-octane (−29.81 kcal mole^{-1}):[63,64]

$$\Delta H_{\text{form}} = -6.28 \text{ kcal mole}^{-1}.$$

Then, assuming that the energy of the dissociation of a hydrogen atom from the methylene group of cyclo-octane[65] is 94 kcal mole^{-1}, we determine the heat of addition of oxygen to the double bond of cyclo-octene, as in the procedure described above: 40.47 kcal mole^{-1}.

For endothermic reactions, $E > q$ and therefore, by comparing the heats and activation energies for reactions (I.11) and (I.12), it is not difficult to show that reaction (I.11) is more likely in the cyclo-olefin series.

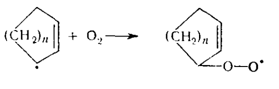
The hypothesis of the possible formation of a cyclic peroxide[33,57,66]:



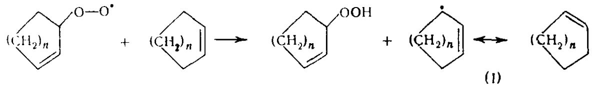
(I.13)

have not so far found experimental confirmation but it still has some supporters[67,68].

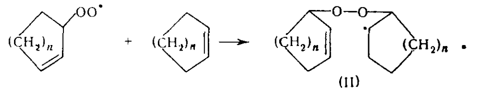
Usually the removal of a hydrogen atom from the allyl system by a peroxy-radical [stage (I.15)] requires a smaller activation energy than its radical addition to a double bond [stage (I.16)]:[69]



(I.14)

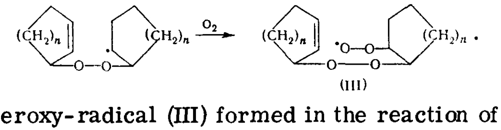


(I.15)



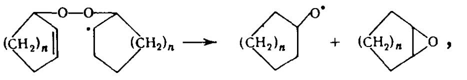
(I.16)

The formation of the allyl radical (I) was established in early studies described in the review of Criegee[70] and Rosenwald[71]. According to Waters[69], the competing radical addition reaction becomes appreciable as the reaction temperature increases. However, Mayo[50] did not find a difference in the reaction mechanism when cycloheptene was oxidised at 60° and 80°C. Probably, the 20 deg difference is insufficient:

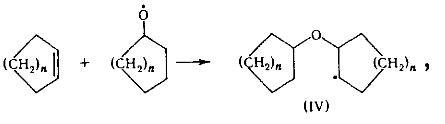


(I.17)

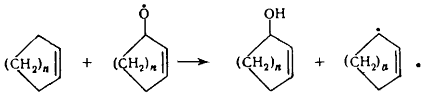
The peroxy-radical (III) formed in the reaction of (II) with oxygen by mechanism (I.17) may undergo further reactions similar to (I.15) or (I.16). The decomposition of the radical (II) [reaction (I.18)] competes with reaction (I.17). It probably predominates in the oxidation of cyclo-octene:



(I.18)



(I.19)

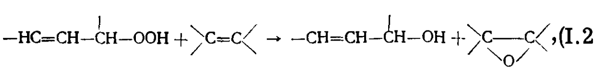


(I.20)

According to Mayo[72], owing to the competition between the elementary stages (I.17) and (I.18), the pathway taken by the oxidation reaction should depend on the partial pressure of oxygen‡.

The yield of epoxides cannot exceed 50% if they are formed only as a result of reaction (I.18). The Prilezhaev reaction occurring simultaneously makes a definite contribution to the accumulation of peroxides in amounts exceeding 50%.[28,50,74-78]

The possibility that epoxides are formed by the mechanism proposed by Hock[37] cannot be excluded[79]:



(I.21)

but special experiments[80] confirmed that the ability of α-peroxides derived from cyclo-olefins to give rise to epoxides in the presence of catalysts at the concentrations usually employed in oxidation reactions is insignificant.

Some investigators[81] believe that the principal epoxide-forming agents in the oxidation of acyclic (C_3) and cyclic (C_6) olefins are acylperoxy radicals, since alkenylperoxy-(alkylperoxy-)radicals are insufficiently reactive in reactions of this kind. Alcohol was not found in the early stages of oxidation in these experiments[79]. It is believed[81] that this supports the above hypothesis.

An epoxyalkane was not found in the simultaneous oxidation of isopropylbenzene and propene at 80–90°C in the presence of azobis(isobutyronitrile) as an initiator[81], although a high concentration of $RO_2^{\cdot}$ radicals was detected by the ESR method[82]. Possibly, under the conditions chosen by these investigators[81], the reaction $RO_2^{\cdot} + {>}C{=}C{<}$ does not occur because of steric hindrance or insufficient reactivity of the peroxy-radical.

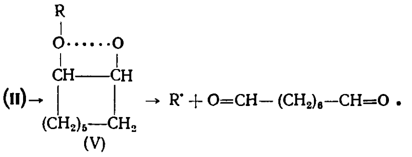
The behaviour of radicals in reactions involving addition to a double bond or the abstraction of an allylic hydrogen atom has for a long time attracted the attention of chemists, since it provides information about the energy of a particular radical[83,84]. Kinetic[85-87] and thermochemical[60] data are now available which confirm the hypothesis[88,89] of the interaction of $RO_2^{\cdot}$ with the olefin double bond.

The absence of an alcohol in the initial reaction period can be readily explained if it is assumed that reaction (I.19)

---

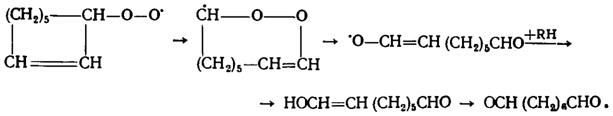
‡For a more detailed description of this problem, see Mayo[73].

predominates over reaction (I.20). The aliphatic aldehydes are probably formed as a result of the decomposition of radical (V):



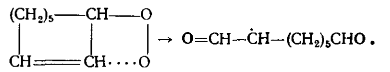
(I.22)

However, together with the mechanism quoted above, one cannot exclude other pathways involving the isomerisation and breakdown of the peroxy-radical [reactions (I.23) and (I.24)]:



(I.23)

The incorporation of the peroxy-group O−O in the cyclo-octene chain reduces the strain in the ring[4]:

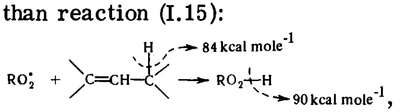


(I.24)

In the oxidation of n-butane and propene[81,90–93] it was shown that such reactions may occur in the liquid phase. Under oxidation conditions, aldehydes are converted into peracids and the latter undergo the Prilezhaev reaction and participate in the formation of epoxycycloalkanes. However, aldehydes and the corresponding acids were found in insignificant amounts in the oxidation of cyclo-octene.

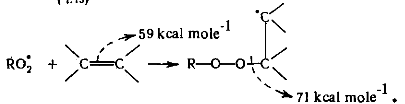
Probably the different compositions of the final products found in the oxidation of cyclohexene and cyclo-octene must be explained on the basis of the differences between the structures of the two cyclo-olefins. It is therefore necessary to assume that in the oxidation of cyclo-octenes the activation energy $E_{(I.15)} > E_{(I.16)}$, while in the oxidation of cyclohexene the opposite relation holds: $E_{(I.15)} < E_{(I.16)}$.

If account is taken of Benson's data[60] on bond dissociation energies, it becomes clear that reaction (I.16) is more exothermic than reaction (I.15):



(I.15)

$$q_{(I.15)} = 84 - 90 = -6 \text{ kcal mole}^{-1}$$



(I.16)

$$q_{(I.16)} = 59 - 71 = -12 \text{ kcal mole}^{-1}$$

In accordance with the concepts developed by Vitvitskii[94], we suggest that the activation energy $E_{(I.16)}$ for reaction (I.16) does not vary in the series of cyclo-olefins, while $E_{(I.15)}$ must depend greatly on the structural characteristics of the given cyclo-olefin. In fact, the number of hydrogen atoms which may participate in the radical substitution reaction (I.15) decreases from 4 in cyclopentene to 2 in cyclo-octene[50].

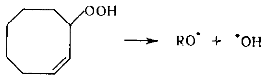
Since among $\geqslant C_5$ cyclo-olefins the cyclopentene ring is the most planar[95], the removal of an α-hydrogen atom from cyclopentene by a peroxy-radical according to mechanism (I.15) leads to the formation of an allyl radical, which may be regarded as a hybrid of two resonance forms and which does not require the expenditure of additional energy on the rearrangement of the ring. An analogous conclusion, which explains the formation of cyclohexenyl α-hydroperoxide, can be readily reached by examining the stereochemistry of cyclohexene.

Cyclohexene is known to have the "half chair" conformation in which four carbon atoms are located in one plane. Two of the remaining atoms are below and above this plane[96]. The "half boat" form is then less stable than the "half chair" form by only 2.7 kcal mole^{-1}.[97]

For the principle of maximum overlap of the orbitals to operate in the allyl radical derived from cyclohexene[50], it is necessary that one of the two non-coplanar carbon atoms should move to the plane of the four carbon atoms. According to the data of Anet and Haq[98], this can be achieved by overcoming a potential barrier of only 5.2 kcal mole^{-1}. For comparison, we may note that a similar inversion of the cyclohexane ring can occur only by overcoming a potential barrier of 14 kcal mole^{-1}.[99] Even under ordinary conditions the fraction of molecules having the "half boat" conformation may be appreciable and in substituted cyclohexenes can actually predominate[100,101].

The low yield of cyclo-octenyl α-hydroperoxide in the oxidation of *cis*-cyclo-octene is probably due to hindrance by energy factors, since in reaction (I.15) it would be necessary to overcome a fairly high energy barrier, which consists of the normal heat of reaction, the energy which must be expended to rearrange the ring in the formation of the allyl radical, and the energy necessary for the rearrangement of the valence shell of the carbon atom attacked.

The homolytic decomposition of cyclo-octenyl α-hydroperoxide with subsequent isomerisation is probably not the only pathway, since epoxides are already detected in the early stages of the oxidation reaction:

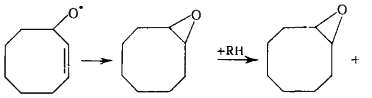


(I.25)

$$\text{ROOH} + M^{2+} \rightarrow \text{RO}^{\cdot} + M^{3+} + {}^{-}\text{OH}, \quad \text{(I.26)}$$

or

$$\text{RO}_2^{\cdot} + \text{RO}_2^{\cdot} \rightarrow 2\text{RO}^{\cdot} + \text{O}_2, \quad \text{(I.27)}$$



(I.28)

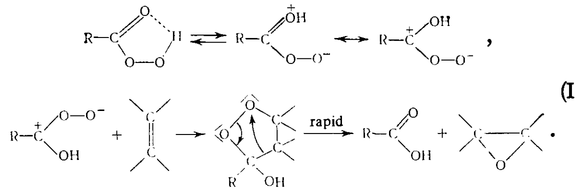
The probability of reaction (I.28) should be greater for cyclo-octene than for cyclohexene, bearing in mind the internal steric saturation of the first compound.

The presence of trigonal carbon atoms reduces the ring strain and it would appear that the C_8 ring, in which the angle between the C−C bonds is 135°, should enter into reactions involving addition to the double bond with considerable difficulty, much less readily at any rate than cyclohexene. The cyclohexane molecule is known to be very stable when all the carbon atoms are in the tetragonal form[4]. Nevertheless attempts at a direct conversion of cyclohexene into an epoxy-derivative by oxygen have so far been unsuccessful. This contradiction is difficult to explain at present.

Thus, according to the concepts developed, cyclic α-hydroperoxides, allyl alcohols, and ketones are obtained by a radical substitution mechanism [reaction (I.15)] and the epoxides and products formed on ring opening at the site of the double bond (i.e. aliphatic aldehydes and acids) are formed by a radical addition mechanism.

(a) The coupled oxidation reactions of olefins with aldehydes, which are used to synthesize epoxides[102–106] in yields greater than 50% or ethers[107,108], have been known for a long time. The study of the oxidation of cyclohexene in cumene[109], ethylbenzene, and other compounds which readily give rise to hydroperoxides, and also (its oxidation) in the presence of various aldehydes showed that coupled processes of this kind involve a radical–chain mechanism.

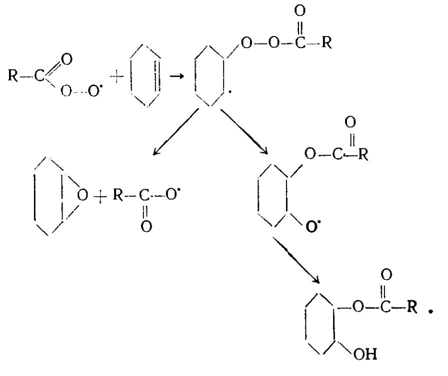
At the same time, systematic studies on the kinetics and mechanism of the interaction of peracids with various olefins (the Prilezhaev reaction) were begun in order to discover the component most active in the formation of chains in joint oxidation reactions. For a long time it was believed that the first stage of this reaction is the heterolytic breakdown of the peracid. However, Kwart and Hoffman[110] suggest a 1,3-dipolar addition mechanism to account for the experimental results:



(I.29)

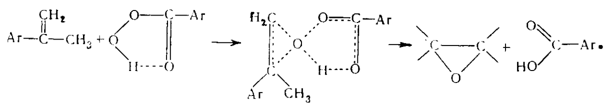
It is now believed, on the basis of kinetic investigations, that the conversion of olefins into epoxy-derivatives by reaction with peracids involves the intermediate formation of an olefin–peracid π complex[111,112,113].

In his study of coupled oxidation, Wittig[114] noted that olefins retard the oxidation of aldehydes. Walling[115] and Ikawa[80] found an explanation for this phenomenon: when aldehydes are oxidised in the presence of olefins, the concentration of acylperoxy-radicals falls, since the latter participate in the following reaction:



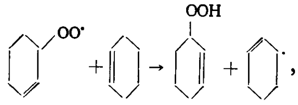
(I.30)

This mechanism has been generally accepted[28,80,116–118], but, as shown, for example, by studies on the oxidation of methylstyrene in the presence of benzaldehyde[119], in some reactions the fraction of epoxides formed by a radical mechanism may be appreciable (> 10%):



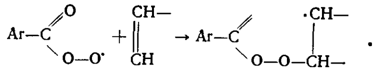
(I.31)

Using the data on the oxidation of cyclohexene in the presence of a small amount of benzaldehyde, Ikawa[80] concluded that, together with benzoylperoxy-radicals, cyclohexenylperoxy-radicals also participate in the epoxide-formation reaction. Indeed, the formation of the α-hydroperoxide predominates in the oxidation of cyclohexene on its own:



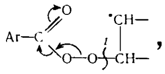
(I.32)

while in the joint oxidation of benzaldehyde and cyclohexene under comparable conditions, the reaction involving the addition of the benzoylperoxy-radical takes place:



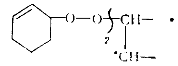
(I.33)

As a result of the inductive effect (shown by arrows)



(I.34)

the dissociation energy of bond 1 should be less than that of bond 2:



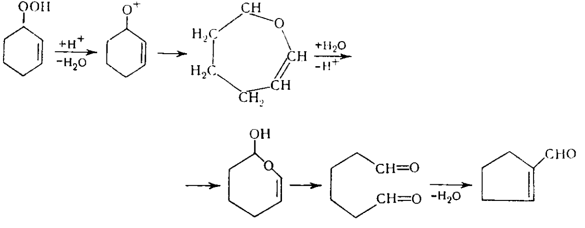
(I.35)

Therefore the addition of the cyclohexenylperoxy-radical to the cyclohexene double bond may be easier, since the following relation has been observed in many radical addition reactions: the greater is the heat of reaction of the radical with the molecule the lower is the activation energy[30].

Thus, according to the current views on the oxidation mechanism, in order to obtain aliphatic oxygen-containing compounds (aldehydes and acids) from cyclo-olefins, either the addition of the peroxy-radical at the site of the double bond or its isomerisation is necessary.

The question arises what conditions would favour the isomerisation of peroxy-radicals or their addition at the site of the double bond. Apparently this requires the choice of appropriate solvents, catalysts, and material for the walls of the reactor in which the oxidation is carried out[120,121] (i.e. the study of the mechanism of homogeneous-heterogeneous catalysis) or deliberate preparation of the required site for attack by oxygen (activation of the double bond, the use of more reactive peroxy-radicals, etc.).

(b) Effect of the solvent. Shine and Snyder[122] investigated the oxidation of cyclohexene by oxygen at 60–80°C in the presence of acetic anhydride and showed that under these conditions cyclohexenyl α-hydroperoxide decomposes heterolytically:



(I.36)

It is known that strongly associated solvents frequently alter the mode of the chain oxidation process[123]. However, so far there is very little information about the effect of such solvents on the mechanism of cyclo-olefin oxidation[124,125].

It has now been established that the formation of intermolecular hydrogen bonds in the oxidation of hydrocarbons has a significant effect on the kinetics, for example in the radical decomposition of hydroperoxides[29]. Together with alcohols and ketones, the latter participate in the reaction with the peroxy-radical and the new radicals thereby formed lead to chain branching. The rate of the elementary steps and hence the rate of the overall oxidation process depends significantly on the properties of the solvent[126,127]. This is because the elementary chain propagation ($RO_2^{\cdot} + RH \xrightarrow{k_2} ROOH + R^{\cdot}$) and chain termination ($RO_2^{\cdot} + RO_2^{\cdot} \xrightarrow{k_6}$ molecular product) reactions, which determine the overall rate of the process, involve the interaction of two dipoles, the magnitude of which depends on the dielectric constant of the medium. The effect of the solvent is particularly pronounced in the oxidation of polar organic compounds (ethyl methyl ketone, ethanol, etc.). The composition of the reaction product is determined by the competition between two pathways in the chain propagation reaction[128]: the interaction of $RO_2^{\cdot}$ with the initial molecule:

$$RO_2^{\cdot} + RH \xrightarrow{k_2} ROOH + R^{\cdot} \qquad (I.37)$$

and the breakdown of $RO_2^{\cdot}$ into products with lower molecular weights:

$$RO_2^{\cdot} \xrightarrow{k_1} R'O^{\cdot} + R''CHO\,. \qquad (I.38)$$

Dilution of ethyl methyl ketone or ethanol with a non-polar solvent (benzene) increases the amount of $RO_2^{\cdot}$ radical decomposition products, since benzene reduces the dielectric constant of the medium. As a result, the rate of reaction W_2 falls. At the same time, the rate of the mutual recombination reaction

$$[2RO_2^{\cdot} \xrightarrow{k_6} \text{molecular products}] \qquad (I.39)$$

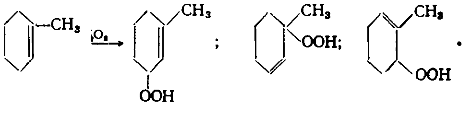
decreases even faster than the rate of reaction (I.37).[129]

However, the amount of theoretical and experimental information about the effect of the solvent on the elementary stages in radical reactions (for example, in the oxidation of non-polar substances) is still inadequate. This makes deliberate control of liquid-phase oxidation reactions significantly more difficult.

3. Oxidation of Substituted Cyclo-olefins

The role of substituents in the oxidation of cyclo-olefins can be followed on the basis of studies already carried out. It is known that the site chosen for attack by oxygen depends in many ways on the nature of the substituent and also on the relative positions of the double bond and the substituent.

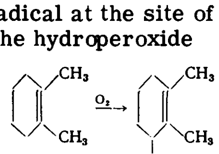
(a) Oxidation by molecular oxygen of compounds in which the substituents have a positive inductive effect. Only methylolefins have been investigated on these lines[51,130,131]. Bolland[131], who oxidised methylcyclohex-1-ene, isolated only three of the theoretically expected six α-hydroperoxide isomers:



(I.40)

The determination of the position of the hydroperoxy-group is fairly difficult and therefore the experimental results are contradictory.

In the oxidation of a cyclo-olefin with methyl substituents at the double bond, which should increase its nucleophilic properties and should apparently facilitate the addition of the peroxy-radical at the site of the double bond, Criegee[70] obtained the hydroperoxide



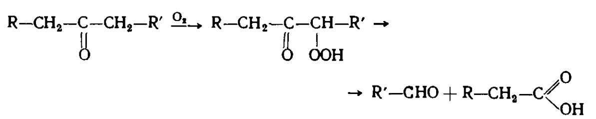
(I.41)

In contrast, Dupont[132] showed that the oxidation of 1,2-dimethylcyclohex-1-ene yields 1,2-dimethylcyclohexane-1,2-diol and 1,2-dimethylcyclohex-1-ene-3-one and a very small amount of αω-diacetylbutane.

It should be noted that, apart from the inductive effect exerted via 2–3 carbon atoms, the number of methylene groups in the chain is of considerable importance.

The South African investigators Arndt et al.[133] reported that in the oxidation of 5-methylnonane the substitution of the hydrogen atom at the tertiary carbon atom is 19 times faster than at a secondary carbon atom. However, under these conditions oxygen does not attack solely the tertiary carbon atom.

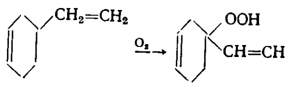
A departure from the α-mechanism



$$R{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}CH_2{-}R' \xrightarrow{O_2} R{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}\underset{\underset{OOH}{|}}{CH}{-}R' \rightarrow R'{-}CHO + R{-}CH_2{-}C\overset{\nearrow O}{\searrow OH} \qquad (I.42)$$

suggested by Langenbeck and Pritzkow[134] (cyclohexanone, tetralone) was observed by Obukhova et al.[135] in the oxidation of 6-undecanone.

(b) Effect of substituents with a negative inductive effect. According to the data of Brill[136] and Tepenitsyna[137], the main reaction product in the oxidation of 4-vinylcyclohexene is a tertiary hydroperoxide:



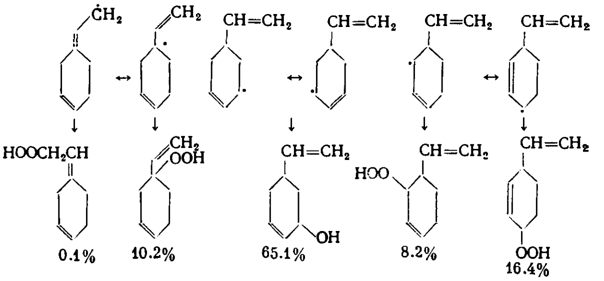
(I.43)

Electronegative substituents as a rule facilitate the removal of a hydrogen atom from a tertiary carbon atom. Since the polar effect of the vinyl group is not very pronounced, the resonance stabilisation of the radical

(I.44)

should favour α-substitution.

Nevertheless, Farrissey[138] observed the formation of a complex mixture of hydroperoxides in the oxidation of 1-vinylcyclohex-4-ene:



(I.45)

A similar deviation from the normal relative activity is shown by those cyclic olefins in which either the tertiary allyl carbon atom or the double bond in which it is involved are outside the ring[138]. According to the transition state theory, the formation of an allyl radical requires the maximum overlapping of the *p* and π orbitals, for which it is necessary that the C–H bond dissociated should be axial relative to the plane of the double bond. If the double bond or its allyl carbon atom are outside the ring, this requirement involves a loss of a degree of freedom of rotation[139]. Moreover, the H–H interaction between the allyl and the vinyl hydrogen in such a conformation is a maximum[140].

Consequently when an H atom is dissociated from a tertiary carbon atom, both of the above factors can markedly increase the energy of the transition state.

The polar effect of the carboxy-group should hinder the dissociation of a hydrogen atom from $H-\overset{\diagdown}{\underset{\diagup}{C}}-COOH$ more than from $H-\overset{\diagdown}{\underset{\diagup}{C}}-CH_2-COOH$ because the electric field due to the dipole of the HOOC group decreases in proportion to the cube of the distance[69].

The oxidation of compounds with an unprotected carboxy-group is frequently accompanied by decarboxylation. This side reaction may become the main one under certain conditions. For example, in the oxidation of cyclohexanecarboxylic acid in acetic acid the main product is cyclohexanone[141] and in the oxidation of methyl cyclohexanecarboxylate[142] the main products are the monomethyl esters of butanetricarboxylic and α-oxopimelic acids. Evidently in this case it is important to know the location in space of both the $\overset{\diagup}{\underset{\diagdown}{C}}=O$ group and the hydrogen atom at the tertiary carbon atom.

Azanovskaya and Ablova[143,144] investigated the effect of substituents on the oxidisability of cyclo-olefins without determining the position of the hydroperoxy-group formed in this process. They investigated ethers and esters (acetate and benzoate) and halogeno- and amino-derivatives of cyclohex-1-en-3-ol. It was found that ethers are oxidised most readily. Cyclohexenol is oxidised with greater difficulty than with cyclohexene[145]. Esters react only in the presence of initiators. The amino-derivatives were not oxidised at all (even in the presence of an initiator). However, the inhibiting effect of the amino-group is not always shown. For example, in the oxidation of ε-caprolactam a hydroperoxide is formed:

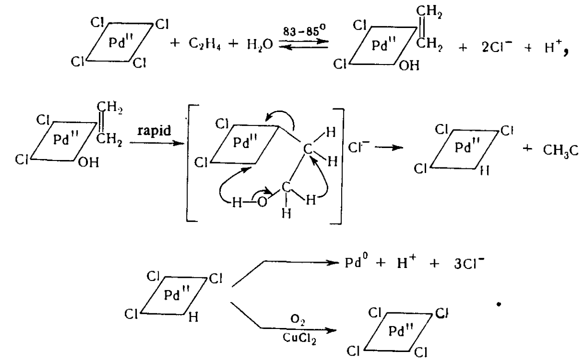
$$-\underset{\substack{|\\OOH}}{HC}-NH-CO- \qquad (I.46)$$

together with its decomposition products[147]. Here the basicity of the imino-group is low due to the conjugation of the carbonyl π bond and the unshared electron pair of the nitrogen atom.

Thus the data discussed in the present review lead to the conclusion that the total experimental and theoretical facts available at present on the oxidation of cyclo-olefins by molecular oxygen are insufficient to allow a reliable prediction of the conditions for the selective ring opening at the site of the double bond and the formation of aliphatic dicarboxylic acids.

II. OXIDATION OF CYCLO-OLEFINS TO CARBONYL COMPOUNDS. CATALYSIS BY PALLADIUM, GOLD, MERCURY, AND THALLIUM SALTS

The oxidation of cyclo-olefins in the presence of aqueous solutions of palladium and gold salts has not been adequately investigated, since the main effort of investigators has been concentrated on the elucidation of the mechanism of the oxidation of aliphatic olefins[148]. It is now known that saturated cyclic ketones can be obtained in this way from cyclic olefins[149,150], while aliphatic olefins yield acyclic aldehydes and ketones[151]. For example, when ethylene is introduced into an aqueous solution of palladium chloride, reaction probably takes place by the following mechanism[152]:



(II.1)

The studies on the oxidation of olefins in the presence of mercury and palladium salts have been reviewed by Halpern[152].

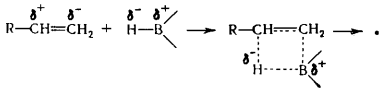
III. OXIDATION OF CYCLO-OLEFINS BY ELECTROPHILIC AGENTS

In order to obtain aliphatic oxygen-containing compounds from cyclo-olefins, it is probably more convenient (compared with molecular oxygen) to employ typical electrophilic agents such as lead and thallium acetates, nitric acid, ozone, etc.[153]

The mechanism of the oxidising action of lead tetra-acetate has been elucidated to a considerable degree by the fundamental work of Criegee[153]. However, because of their high cost, lead tetra-acetate and especially thallium tri-acetate[154,155] cannot compete with molecular oxygen or nitric acid.

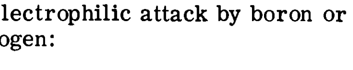
1. Hydroboration–Oxidation

The addition of boranes to unsaturated compounds involves a four-centre transition state[156]:



$$R-\overset{\delta^+}{C}H=\overset{\delta^-}{C}H_2 + \overset{\delta^-}{H}-\overset{\delta^+}{B}\diagdown \longrightarrow \underset{\overset{\delta^-}{H}\cdots\cdots\overset{\delta^+}{B}}{R-CH\overset{\cdots}{=}CH_2} \longrightarrow . \qquad (III.1)$$

However it is still not clear which factor is more important in this step: electrophilic attack by boron or nucleophilic attack by hydrogen:

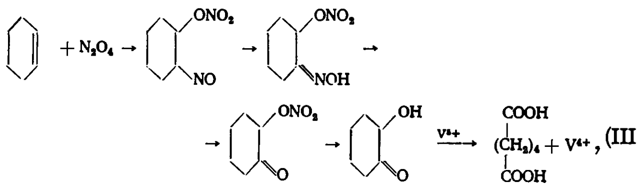


$$\rightarrow R-CH_2-\underset{\substack{|\\ \diagup B \diagdown}}{CH_2} \xrightarrow{[H_2O_2]} R-CH_2-CH_2OH .$$

Hydroboration may be a convenient method for the preparation of alcohols when a cheap source of diborane is available[157,158]. These problems are dealt with in greater detail in Brown's monograph[156].

2. Oxidation of Cyclo-olefins by Nitric Acid

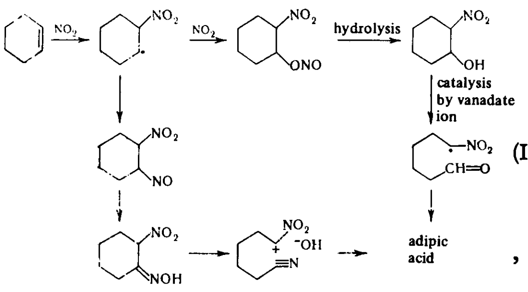
The interest in the use of nitric acid for the selective cleavage of the ring at the double bond increased greatly after the discovery of the catalytic effect of ammonium metavanadate mixed with copper powder[159]. However, this process has many disadvantages, most of which are associated with the high corrosivity of nitric acid. The mechanism of the oxidation of cyclo-olefins by nitric acid in the presence of a catalyst is still obscure in many ways[160,161]. Franz[162] suggests that in this reaction nitrogen tetroxide is the most active reagent. The tetroxide is formed on decomposition of intermediate compounds produced as a result of the oxidative dissociation of nitric acid:



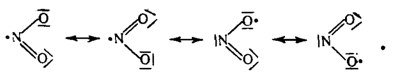
(III.2)

$V^{4+} + HNO_3 \rightarrow V^{5+}$.

Gut and Lindenmann[163] put forward a mechanism according to which the oxidation begins with a free radical addition of NO_2 to the cyclo-olefin double bond:



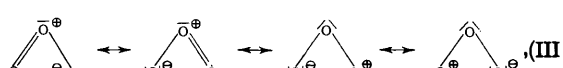
(III.3)



(III.4)

3. Ozonolysis

It has been firmly established that ozone[6],



(III.5)

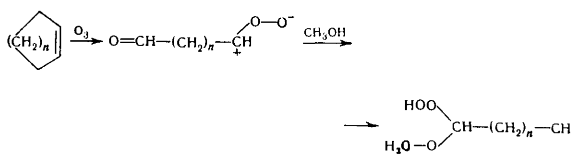
adds quantitatively at the site of the double bond. An extensive literature shows a pronounced interest in the problem of the utilisation of ozone as an oxidant[164,165]. There is no doubt that, after improvement in the design of ozonisers, ozone will find very wide application.

Data are already available on the technical application of ozone for the conversion of aliphatic olefins into alcohols and aldehydes and also for the conversion of oleic acid into azelaic and pelargonic acids in high yields[167,168]. There has been a recent report on the construction of a factory for the ozonolysis of soya bean oil with a projected output of 4500 tons per year[169].

The addition of ozone to the double bond of an olefin is very rapid and therefore the rate of reaction is limited mainly by the rate of migration of ozone to the olefin.

The application of modern physical experimental methods made it possible to begin an investigation of the kinetics of the interaction between ozone and olefins. According to the data of Williamson and Cvetanovic[170,171], the rate constant for the second-order reaction between ozone and cyclopentene in carbon tetrachloride at 25°C is 2×10^5 litre $mole^{-1}\ s^{-1}$.

Without considering the problem of the mechanism of the primary attack on the double bond by ozone, we may note that the composition and origin of the ozonolysis products of cyclo-olefins in proton-donating solvents (for example in methanol at ±50°C) can be accounted for by Criegee's mechanism:

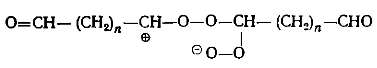


(III.6)

The formation of methoxyhydroperoxides constitutes the main reaction pathway. One cannot exclude the possibility that aldehyde and hydroperoxy-groups react with one another during ozonolysis[172,173] with formation of an oligomer:

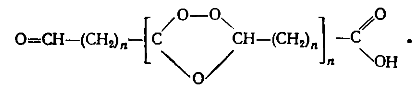
$$\left[-(CH_2)_n-\underset{OH}{CH}-O-O-\underset{OCH_3}{CH}-(CH_2)_n-\right]_n .\qquad (III.7)$$

Moreover there is a possibility of the dimerisation of dipolar ions by the following mechanism:



$$O{=}CH-(CH_2)_n-\underset{\oplus}{CH}-O-O-\underset{\ominus O-O}{CH}-(CH_2)_n-CHO\qquad (III.8)$$

or their polymerisation:



(III.9)

Pathways (III.8) and (III.9) are not unique and their contribution to the overall reaction mechanism is small.

Methoxyhydroperoxides (together with polyperoxides) can be subsequently oxidised by a suitable oxidant[174,175] to acids or reduced catalytically to aldehydes or alcohols[176,177].

The attempts to combine in one stage processes involving the ozonolysis of cyclo-olefins and the oxidation *in statu nascendi* of the peroxy-products are extremely interesting. For this purpose, cyclo-olefins have been subjected to ozonolysis in acetic acid[178] (at 40–80°C) and also in aqueous emulsion or an alkaline solution of hydrogen peroxide[179] (at 20–25°C). The yield of dicarboxylic acids was ≥ 80%.

Oxidation by lower peracids (C_1–C_3) of alkoxyhydroperoxides obtained by the ozonolysis of substituted cyclo-olefins in alcohols permits the synthesis of various derivatives of aliphatic polycarboxylic acids (for example, butane-1,2,4-tricarboxylic acids from 4-vinylcyclohex-1-ene or cyclohex-1-ene-4-carboxylic acid[180,181]).

The ozonolysis proper takes place fairly readily without the need for special apparatus and the solvents employed are as a rule available commercially. A certain risk of detonation of peroxides and ozonides can be eliminated by selecting appropriate process conditions.

It is noteworthy that many aspects of the detailed mechanism of the ozonolysis of cyclo-olefins have not yet been elucidated[182] and the composition of the products depends to a considerable extent on the solvent and the ozonolysis conditions.

Nevertheless, regardless of the composition of the peroxy-products, their subsequent processing by oxidation or reduction gives a fairly high final yield of acids, aldehydes, or alcohols (≥ 80%). Therefore, bearing in mind the likely availability of oxidants (O_2, H_2O_2, and  $CH_3-C(=O)OOH$) and reductants [H_2, $(iso-C_3H_7O)_3Al$, $LiAlH_4$, CH_3-S-CH_3, etc.), we are inclined to believe that ozonolysis may be the most suitable method for the conversion of cyclo-olefins into aliphatic oxygen- containing compounds.

Nuclear Magnetic Resonance and Its Applications in Chemical Research

E.I.Fedin

The fundamentals of nuclear magnetic resonance spectroscopy are briefly described. The applications of the method in chemistry are demonstrated and the possible developments of the application of nuclear magnetic resonance in studies on molecular and crystal structures are indicated.
The bibliography includes 75 references.

CONTENTS

I. INTRODUCTION

Nuclear magnetic resonance (NMR) is one of the outstanding discoveries of the twentieth century, which has now taken an honourable place among the principal methods for research in structural chemistry. The method needs no special recommendation. The literature devoted to NMR is enormous. The bibliography in Leche's monograph published in 1963 includes about three thousand references and in the last two years more than two hundred papers, dealing either with the method itself or demonstrating its possibilities in various branches of solid state physics, molecular physics, in structural studies, and in the solution of the principal problems of theoretical chemistry, have been published. This journal has already included a review on the chemical applications of NMR. The aim of the present review is to give a simple systematic account of the principles of NMR and its main applications, and this has largely determined its form. However, the embodiment of this aim in print may fall short of these words—of the kind that might have been used in a lecture or in a leisurely conversation. Therefore it must be emphasised that the description of the principal problems of NMR spectroscopy within the framework of a journal article is exceptionally difficult and the present review is merely a compromise between the intention and the feasibility of its realisation.

The treatment of the subject should include a detailed description of problems such as magnetic anisotropy of bonds, multiplicity of the spectra, and the role of the strength of the permanent magnetic field and of interactions with nuclei having a spin $I > 1/2$; certain facts are included for the first time in a review of this type. Its bibliography in no way claims to give an exhaustive coverage of the literature. The interested reader should consult the required references in monographs[1-10].

II. MAGNETIC PROPERTIES OF ATOMIC NUCLEI

Many stable nuclei have spins $I > 0$ (Table 1). The presence of the spin leads to a magnetic moment: if the spin I is compared with the circulation of the nuclear charge, then its rotation is equivalent, in accordance with the usual classical concepts of magnetic phenomena, to a circular current which gives rise to a magnetic moment $\mu = e\hbar/2m_{\mathrm{p}}c$. For a proton,

$$\mu_p \simeq \frac{4.8\times10^{-10}\times1\times10^{-27}}{23\times10^{10}\times1836\times9\times10^{-28}} \simeq \frac{1}{2}\times10^{-23}.$$

As a rule, heavier nuclei have magnetic moments smaller than μ_{p}. The existence of the nuclear magnetisation of matter was confirmed experimentally in 1937 by Lazarev and Shubnikov[11], who measured the static magnetic susceptibility of solid hydrogen in the temperature range between 1.76° and 4.22°K. The magnetic properties of atomic nuclei have played a notable role in many branches or optical spectroscopy, in electron spin resonance (ESR) spectroscopy, in nuclear quadrupole resonance (NQR), etc. The vast majority of NMR studies have been made on nuclei having a spin $I = 1/2$. Their sequence in terms of decreasing numbers of relevant papers is as follows: ^{1}H, ^{19}F, ^{31}P, ^{13}C, ^{29}Si, etc.

III. RESONANCE CONDITIONS

A nucleus with a spin $I = 1/2$ has two allowed orientations in an external magnetic field: roughly speaking, the magnetic moment of such a nucleus may be oriented either parallel or antiparallel to the vector H_0. Evidently the parallel orientation is energetically favourable and the antiparallel orientation is not. When a specimen containing such nuclei is placed in a magnetic field H_0, its energy structure becomes enriched by two magnetic energy levels, the distance between which is

$$\Delta E = g\mu_0 H_0 \quad (1)$$

where $g = \mu/I\mu_0$ is the splitting factor (i.e. gI is the number of nuclear magnetons μ_0 in the experimental value of the nuclear magnetic moment). Therefore transitions between the levels involve the following energy quanta:

$$h\nu_0 = g\mu_0 H_0 \quad (2)$$

or, in other words, at a frequency

$$\nu_0 = \frac{g\mu_0}{h} \cdot H_0 = \gamma_0 H_0 \quad (3)$$

there is an effective interaction between the electromagnetic radiation incident on the specimen and the series of energy levels of the magnetic moments of the nuclei.

Table 1. Properties of the nuclei.

Isotope	γ_0, Hz g^{-1}	Natural content, %	Spin I	Isotope	γ_0, Hz g^{-1}	Natural content, %	Spin I

Eqn. (3) defines the condition for nuclear magnetic resonance. The values of γ_0 (in units of Hz G^{-1}) are listed in Table 1. Thus, when the field strength H_0 of the laboratory magnet is known, the NMR frequency for the given nucleus can be calculated simply by multiplying together γ_0 and H_0. For protons at field strengths of 9400, 14 092, and 23 450 G, the resonance frequencies are 40, 60, and 100 MHz respectively, for ^{31}P nuclei in a 14 092 G field μ_0 = 24.4 MHz, etc. Condition (3) was obtained on the basis of quantum concepts. It is interesting that the classical treatment leads to exactly the same resonance condition. Let us consider a magnetic dipole moment μ in a field H_0. According to Larmor's theorem[12], the dipole μ will precess around the direction of H_0 at a frequency

$$\nu_0 = \frac{\gamma}{2\pi} H_0,$$

where γ is the gyromagnetic ratio of the dipole. When an additional small magnetic field H_1 is applied at right angles to H_0 in the plane of the vectors $\vec{\mu}$ and H_0, the dipole is subjected to a force which tends to alter the angle θ between $\vec{\mu}$ and H_0. When the field H_1 remains in the plane of the vectors $\vec{\mu}$ and H_0 for an unlimited time (synchronisation of the Larmor precession of the vector $\vec{\mu}$ and the rotation of the additional field H_1), the angle θ will change significantly, i.e., in other words, the application of an external field H_0 leads to a marked change in the nuclear magnetisation of the specimen. On the other hand, if the rates of rotation of μ and H_1 do not coincide, and field H_1 will not affect appreciably the overall magnetic moment of the specimen. Next it was found that $\gamma/2\pi = \gamma_0$, i.e. on the basis of Larmor's theorem, we obtain the same resonance condition as from quantum considerations.

The above discussion based on vectors enriched our ideas about NMR: in order to induce resonance, electromagnetic radiation must be circularly polarised and the magnetic vector H_1 must rotate in a plane perpendicular to the vector H_0. In practice a rotating magnetic field is created as a component of a linearly oscillating field: an electric field at a frequency ν_0 is applied to the coil of the circuit tuned to the same frequency; the axis of the coil is positioned at right angles to a permanent magnetic field H_0. It is well known that a field $2H_1 \sin 2\pi\nu_0 t$ varying sinusoidally with time may be regarded as a superposition of two fields $H_1 \sin 2\pi\nu_0 t$ rotating in opposite directions. One of these components gives rise to NMR and the other hardly interacts with the specimen.

IV. NUCLEAR MAGNETIC RELAXATION

The above resonance conditions indicate merely the possibility of the phenomenon but do not guarantee that it will occur. Both groups of discoverers of NMR [13,14] were extremely worried about the difficulties associated with the relaxation processes in the system of nuclear spins. In fact, having carried out an experiment in which the specimen is exposed to quanta of the required magnitude, we stimulate transitions between the magnetic energy levels. Then the probability of transitions from a lower to an upper level (absorption of energy) w^+ and transitions from an upper to a lower level w^- are equal: $w^+ = w^-$. If the populations of the lower and upper levels are identical, the same number of nuclei would pass from the lower to the upper level and conversely per unit time and NMR would not be observed at all.

It was found that within the spin system energy exchange processes take place very effectively and it may be assumed that the system is in thermal equilibrium at a certain temperature (spin temperature), which, generally speaking, is not equal to the temperature of the specimen T. This implies that the attainment of thermal equilibrium within the spin system takes place many powers of ten faster than processes involving energy exchange between the spin system and its surroundings.

In this case the populations of the upper (n_2) and lower (n_1) nuclear magnetic energy levels will not be equal; according to the Boltzmann distribution law, their ratio is

$$\frac{n_2}{n_1} = \exp\left(-\frac{2\mu H_0}{kT_s}\right). \tag{4}$$

If it is assumed that $T_S \simeq T$, then in a field $\geqslant 10^4$ G, we have for protons

$$\frac{n_2}{n_1} \simeq 1 - \frac{2\mu H_0}{kT}. \tag{5}$$

This small difference between the populations is in fact responsible for the occurrence of NMR: w^+n_1 and w^-n_2 nuclei undergo transitions per unit time from below upwards and from above downwards respectively; it is clear from the foregoing that $w^+n_1 > w^-n_2$, i.e. power is absorbed from the radiofrequency field H_1 by the system of nuclear spins. In the absence of some external process which acts in the opposite sense, the field H_1 equalises the populations of the nuclear magnetic levels after a finite time interval and absorption ceases. Such a situation is called saturation.

Regardless of the state of aggregation of the specimen (liquid, gas, or solid), the substance containing nuclear magnetic moments is called a "lattice".

Since nuclear magnetic resonance is observed in practice (and has actually become one of the principal physical research methods in chemistry!), we must conclude that there exists an effective process which returns the spin system to thermal equilibrium with the lattice. Such a process is called spin–lattice relaxation.

On complete saturation, $n_2 = n_1$. Eqn. (5) shows that formally this implies an exceptionally large increase in the temperature of the spin system: $T_S \to \infty$. According to the Second Law of Thermodynamics, the energy exchange process between the heated spin system and the lattice, which is, for example, at room temperature, then takes place in only one direction, from the hot to the cold object, i.e. there must be spin–lattice relaxation.

Indeed simple considerations show that the temperature equalisation process between the spin system and the lattice takes place exponentially:

$$\Delta n_0 - \Delta n_t = (\Delta n_0 - \Delta n_a)\, e^{-t/T_1},$$

where Δn_0 is the difference between the populations of the nuclear magnetic energy levels at $T_S = T$, Δn_1 the difference between the populations observed at time t, Δn_a the initial difference between the populations, and T_1 the time constant or simply the spin–lattice relaxation time.

The physical cause of the spin–lattice relaxation in diamagnetic specimens is the thermal fluctuation of the local magnetic field of the specimen. Bloembergen[15] showed that one can isolate from the thermal vibration spectrum a component with a frequency ν_0 which corresponds to a randomly varying magnetic field in the specimen; this gives rise to transitions between nuclear magnetic energy levels, and is in fact responsible for the lowering of the spin temperature T_S.

These fluctuating local magnetic fields are also one of the causes of spin–spin relaxation, which is responsible for the rapid attainment of the spin temperature T_S. Spin–spin coupling can take place without energy exchange with the external medium. This is the so called "flip-flop" process, in which two interacting nuclei change orientations simultaneously in an external field. Since they do not require an expenditure of energy, such processes can occur very rapidly. They restrict significantly the lifetime of the nucleus in a fixed state and make an appreciable contribution to the line width observed for solids.

In liquid and solid specimens magnetic nuclei are separated by distances of the order of 1 Å and therefore any nucleus is in a local field $\mu r^{-3} \simeq 10$ G, which upsets the resonance condition (3) obtained for an isolated nucleus. This infringement is not very serious if resonance is observed in strong fields; its effect is that NMR is not observed at a single rigorously defined frequency ν_0 but over a range of frequencies $\Delta\nu_0$. The width of this range depends on the effectiveness of the averaging of the local field under the action of thermal motion. In crystals, where the nuclei do not change places,

$$\Delta\nu_0 \simeq \frac{H_{\text{loc}}}{\gamma_0} \simeq 10\,\text{kHz}.$$

This implies that, when the precession phases of two nuclear magnetic moments coincide at any instant but their resonance frequencies differ by 10 kHz, then after only 10^{-4} s their phases will diverge. The time required for the loss of "phase memory" is called the spin–spin relaxation time; in contrast to the spin–lattice relaxation time, it is denoted by T_2. It follows from the foregoing considerations that the time T_2 is closely related to the NMR line width. One of these relations has already been used implicitly. If $\Delta\nu_0$ is the line width, then $T_2 = (\Delta\nu_0)^{-1}$. On the other hand, when the NMR line has the form described by the function $g(\nu)$ and its area is constant, the amplitude $g(\nu)_0$ should fall as a consequence of line broadening. For this reason, there should be a direct proportionality between the NMR line amplitude and the spin–spin relaxation time:

$$T_2 = k\,[g(\nu_0)].$$

Below it will be shown that $k = 0.5$.

For crystals, the NMR lines are broad and $T_2 \leqslant 10^{-4}$ sec. At the same time the spin–lattice relaxation in diamagnetic crystals is very ineffective; T_1 may reach 10^4 s and more. Thus T_2 is smaller by a factor of tens of millions than T_1. This marked inequality ensures, firstly, the validity of the concept of the spin temperature, and, secondly, the possibility of experiments with *negative* values of T_S.

After the specimen has been placed in a magnetic field H_0, equilibrium nuclear magnetisation will be attained after a time interval which is several times longer than the spin–lattice relaxation time T_1. If, observing certain precautions[16], the direction of the field H_0 is then rapidly reversed, the populations of the nuclear magnetic energy levels are also reversed: the upper unfavourable level will contain more nuclei than the lower favourable level. In accordance with Eqn. (5), this means that the absolute spin temperature $T_S < 0$. It is quite clear that a spin system with a negative absolute temperature is essentially much "hotter" than a spin system in a state of saturation, for which the temperature was considered to be infinitely high. Experiments with negative spin temperatures have served as a starting point for purposeful research, which culminated in the creation of masers and lasers.

However, the simple concepts in nuclear magnetic relaxation employed by Bloch, who gave the first quantitative description of the phenomenon of nuclear magnetic resonance, are more important for the purposes of the present review.

V. BLOCH EQUATIONS

Let us consider the formulation of an NMR experiment in a specific form. In order to describe the phenomenon, rectangular coordinates are introduced with the z axis directed along the lines of force of the magnetic field, the y axis is vertical (the coil giving rise to the radiofrequency field H_1 is also as a rule directed along the vertical axis), and the x axis is perpendicular to the yz plane.

Bloch's approach consists in a detailed examination of the components M_X, M_Y, and M_Z of the nuclear magnetisation of the specimen. It is simplest to elucidate the behaviour of the longitudinal component M_Z. If there were no spin–lattice relaxation ($T_1 \to \infty$), then M_Z would be constant, since the Larmor precession of the nuclear magnetic moments around the direction of the magnetic field does not affect their z-projections, i.e. it does not alter their sum either: $dM_Z/dt = 0$.

The question now arises of the changes occurring in the presence of relaxation. We already know that spin–lattice relaxation equalises the temperatures of the spin system and the lattice. If at a temperature T we have a corresponding equilibrium nuclear magnetisation and at some instant the magnetisation M_Z deviates from M_0 for any reason, spin–lattice relaxation should ensure an exponential return of M_Z to M_0, the time constant of this process being T_1. The mathematical form of the situation outlined above is evident:

$$\frac{dM_z}{dt} = -\frac{M_z - M_0}{T_1}. \tag{6}$$

The fate of the other two components of magnetisation, M_X and M_Y, is somewhat more complex. In fact, even in the absence of spin–lattice relaxation one cannot assume that these components are constant, since we have the Larmor precession. By exact analogy with the equations for the motion of a top, we must write

$$\frac{dM_x}{dt} = \omega_0 M_y \quad\text{and}\quad \frac{dM_y}{dt} = -\omega_0 M_x.$$

We have already spoken of the short period of phase memory, which is characteristic of a nuclear spin system. Mention was also made of the energy transitions between the nuclear magnetic moments, which do not affect the overall energy of the system. From the standpoint of the classical vector model, such processes involve changes in M_X and M_Y without changing M_Z. Thus, for a given overall nuclear magnetisation M_Z, deviations of M_X and M_Y are possible; clearly, such a distinction need be introduced only when the characteristic time T_2 for this transverse (spin–spin) relaxation is not equal to T_1. When $T_2 \neq T_1$, the equations for the transverse components must be written in the form

$$\begin{aligned} \frac{dM_x}{dt} &= \omega_0 M_y - \frac{M_x}{T_2}, \\ \frac{dM_y}{dt} &= -\omega_0 M_x - \frac{M_x}{T_2}. \end{aligned} \tag{7}$$

Eqns. (6) and (7) are known as the Bloch equations.

VI. NMR LINE FORM FOR LIQUIDS AND GASES

In order to make any useful deductions from the Bloch equations, it is necessary to consider the factors responsible for the deviations of the components M_X, M_Y, and M_Z from their equilibrium values. We are principally interested in the electromagnetic wave having quanta $h\nu_0$, with the aid of which the NMR phenomenon is in fact observed. The transitions stimulated by these quanta actually give rise to the difference between the populations of the energy levels at the given temperature, which in practical terms implies changes in M_X, M_Y, and M_Z. In the analysis of Eqns. (6) and (7) one should speak not of the quanta $h\nu_0$ but of the magnetic field of the coil, with a current generated by a radiofrequency oscillator at a frequency ν, which is close to ν_0. This weak magnetic field $H_1 \sin 2\pi\nu t$ is added geometrically to the external magnetic field H_0.

When account is taken of the field H_1, Bloch's equations become markedly complicated. A natural method of simplifying the equations is to introduce new variables in which the radiofrequency field H_1 is at rest. In other words we introduced an observer "sitting" at the end of the vector H_1 and undergoing tens of millions of revolutions per second in this imaginary centrifuge. For such an observer, Bloch devised new components ($\omega = 2\pi\nu$) instead of the mutually perpendicular nuclear magnetisation components M_X and M_Y:

$$\begin{aligned} u &= M_x \cos\omega t - M_y \sin\omega t, \\ v &= -M_x \sin\omega t - M_y \cos\omega t. \end{aligned} \tag{8}$$

In Eqns. (8) u is the component of the magnetisation of the specimen varying in phase with H_1 and v is the component displaced by 90° relative to H_1. When the u and v components are employed, Bloch's equations become

$$\begin{aligned} &\frac{du}{dt} + \frac{u}{T_2} + (\omega_0 - \omega)v = 0, \\ &\frac{dv}{dt} + \frac{v}{T_2} - (\omega_0 - \omega)u + \gamma H_1 M_z = 0, \\ &\frac{dM_z}{dt} + \frac{M_z - M_0}{T_1} - \gamma H_1 v = 0. \end{aligned} \tag{9}$$

Eqns. (9) have a wide variety of consequences, but, from our point of view, the most important are their steady-state solutions corresponding to the case where M_Z = const., u = const., and v = const., i.e. to rotation of u and v synchronised with the vector H_1 and to a constant z-component of the nuclear magnetisation. All three derivatives of Eqn. (9) are then zero and we obtain three equations in three unknowns: u, v, and M_Z. By solving these equations, it is easy to derive the following formulae:

$$\begin{aligned} u &= \frac{\gamma H_1 T_1 T_2 (\omega_0 - \omega) M_0}{1 + T_2^2(\omega_0 - \omega)^2 + \gamma^2 H_1^2 T_1 T_2}, \\ v &= -M_0 \cdot \frac{\gamma H_1 T_2}{1 + T_2^2(\omega_0 - \omega)^2 + \gamma^2 H_1^2 T_1 T_2}, \\ M_z &= M_0 \cdot \frac{1 + T_2^2(\omega_0 - \omega)^2}{1 + T_2^2(\omega_0 - \omega)^2 + \gamma^2 H_1^2 T_1 T_2}. \end{aligned} \tag{10}$$

To elucidate the significance of these results, we shall consider the case where the oscillator producing H_1 is tuned exactly to the NMR frequency: $\omega = \omega_0$. From Eqn. (10), we obtain for exact resonance ($u = 0$)

$$v = -\frac{M_0 \gamma H_1 T_2}{1 + \gamma^2 H_1^2 T_1 T_2} \quad\text{and}\quad M_z = \frac{M_0}{1 + \gamma^2 H_1^2 T_1 T_2}.$$

We now compare these results with the quantum characteristics of NMR which are also already known. Clearly the v component describes the absorption of the energy of the electromagnetic wave incident on the spin system. The lower longitudinal magnetisation M_Z compared with the equilibrium value M_0 (before the spin system is exposed to the quanta $h\nu_0$), due to the presence in the denominator of the term $\gamma^2 H_1^2 T_1 T_2$, can be reasonably related to saturation.

Consequently the expression for v in Eqn. (10) describes the NMR absorption line shape. In physics this is known as a Lorentzian line. A second important result is a quantitative estimate of the saturation effect. In fact, when $\gamma^2 H_1^2 T_1 T_2 \ll 1$, saturation does not affect the NMR line form. Evidently, in the absence of saturation the amplitude of the NMR signal is directly proportional to the radiofrequency field strength H_1. It is frequently important to achieve the maximum amplitude of the NMR signal. However, it is clear from Eqn. (10) that the maximum amplitude is achieved at the expense of an appreciable broadening of the magnetic resonance line. On further increase of the radiofrequency field strength, saturation is fully shown: the signal shows a simultaneous decrease of its amplitude and broadening.

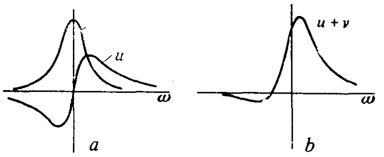

Figure 1. *a*) Absorption (*v*) and dispersion (*u*) signals; *b*) sum of absorption and dispersion signals.

The practical conclusion is that, in order to attain maximum resolution, it is necessary to employ minimum values of H_1 compatible with adequate sensitivity. The somewhat indefinite nature of this recommendation reflects the necessity to seek a compromise, the adequacy of which in each particular case depends on the skill of the operator.

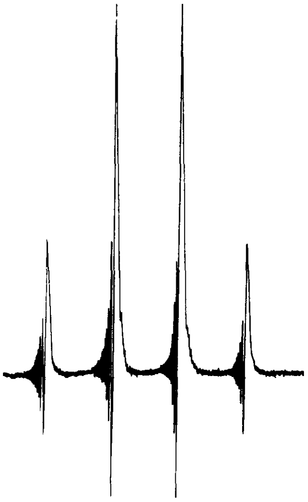

Figure 2. Quartet of the CHO proton in acetaldehyde. With a resolution of about 3×10^{-9}, slow pass conditions are not fulfilled even at a sweep rate of 0.05 Hz s^{-1}; RYa-2305 spectrometer.

It follows from Eqn. (10) that, apart from the absorption signal (the *v* component), there exists also another component of the NMR signal (the *u* component) in phase with the radiofrequency field H_1. The form of this signal is shown in Fig. 1*a*. When the NMR spectrometer is not accurately tuned, the signal recorded may contain a fraction of the *u* component or the so called dispersion signal. An example of such incorrect tuning is presented in Fig. 1*b*. Evidence of this type of error by the operator is revealed by the passage of the signal through the zero line.

It is important to note that the Lorentzian line should be symmetrical about the resonance frequency ω_0. The maintenance of this symmetry in high-resolution NMR spectra is difficult, since it can be achieved only by fairly slow sweep through the NMR line.

In the most frequently encountered design of the NMR spectrometer the spectrum is recorded by a slow linear variation (sweeping) of the magnetic field H. Usually this is done with the aid of special sweep coils. It would appear that there are no obstacles to varying the current in the sweep coil within any desired limits. However, we then encounter the problem of the stability of the high-resolution spectrometer. Therefore in practice there exists for each spectrometer an optimum sweep rate for which a reasonable compromise is achieved between the requirements of optimum resolution and adequate stability of the resonance conditions. For the vast majority of NMR spectrometers at present in use, this compromise is achieved for the narrowest NMR signals at the expense of a more or less serious infringement of the slow sweep conditions. Appropriate analysis of the complete Bloch equations[8] shows that the absorption signal symmetry is then distorted; the passage through the NMR line is accompanied by distinct transient processes (Fig. 2). In the American literature these oscillations have been called "wiggles". The existence of wiggles sometimes leads to misunderstanding in the estimation of the resolution achieved and interpretation of the spectra. Sometimes instead of "wiggles" the term "ringing" is used. This is a very graphic term. The system of nuclear spins is similar to an unusually sensitive resonator. A slow pass resembles the stroking of a bell, but when the bell is struck, it rings! For solids, Eqn. (10) does not hold (see Section XIV).

VII. HIGH AND LOW RESOLUTION

We have now acquired sufficient information to explain quantitatively the origin of the terms "high" and "low" resolution which are popular in NMR spectroscopy. The resolving power of spectroscopic apparatus is limited by the width $\Delta\nu$ of the line recorded at a frequency ν (Fig. 2). The width is measured in different ways; one of the usual definitions is that of the distance between the points at a height equal to half of the line amplitude. It is clear from Eqn. (10) that $|v_{\max}| \simeq M_0\gamma H_1 T_2$ when saturation effects are not observed. On substituting in Eqn. (10) the particular value $v_1 = \frac{1}{2}M_0\gamma H_1 T_2 = v_{\max}/2$ and neglecting saturation as before, we find that the NMR line width is $\Delta\nu = 1/\pi T_2$. Experiments showed that pure diamagnetic liquids give rise to a line with a width of 0.1–0.2 Hz. Consequently, for such lines $T_2 \simeq 1$ s. At operating frequencies of 60 and 100 MHz lines as narrow as this ensure a resolution $\Delta\nu/\nu \simeq 10^{-9}$. This is the maximum resolution achieved at the present time in nuclear magnetic resonance; for a long time nuclear magnetic resonance was a "world champion" among spectroscopic research methods. In the Mössbauer effect [nuclear gamma resonance (NGR)] discovered ten years ago resolutions up to 10^{-16} are achieved but the actual quanta which have to be employed in the Mössbauer effect are 10^{10} to 10^{11} times larger than in nuclear magnetic resonance. Therefore the NMR method remains unsurpassed as regards the details which can be distinguished with its aid in the energy structure of matter. The boundary separating high and low resolution is of course arbitrary. In proton magnetic resonance (PMR) of organic liquids a resolution ranging from $(1-2) \times 10^{-8}$ to $(2-5) \times 10^{-9}$ is usually achieved. One begins to regard the resolution as unquestionably low when $\Delta\nu/\nu > 10^{-6}$. Estimates of the quality of resolution in the range 10^{-6}–10^{-8} depend on which end of the range is approached: the resolution is regarded as high in experiments with solids, viscous liquids, and liquid crystals, and low in those with non-viscous liquids.

The role of the viscosity η was established in a classical study by Bloemberger et al.[17], who showed that the spin–lattice relaxation time T_1 depends on η. T_1 varies within wide limits when the ratio $\eta/T(°K)$ is altered; this variation has a minimum in the vicinity of $\eta/T(°K) = 1$ P deg^{-1}. The minimum value of T_1 is in the range 10^{-2}–10^{-4} s. For such rapid spin–lattice relaxation, the lifetime of each nucleus in the upper energy level is correspondingly very short. The indeterminacy principle predicts that the restriction of the lifetime Δt will widen the nuclear magnetic energy levels, i.e. will increase the width $\Delta\nu$ of the NMR line, since the indeterminacy product $\Delta\nu\Delta t \simeq 1$. Therefore for the minimum values of T_1, $\Delta\nu \simeq 10$ kHz, i.e. we enter the region of low-resolution NMR. In non-viscous liquids and gases $T_1 \simeq T_2$. Thus, if we follow the fate of the NMR line due to a particular specimen on cooling from the gaseous state to the liquid and crystal states, the very narrow peaks become increasingly broader as the temperature is reduced and the viscosity increases; after crystallisation of the specimen, when $\Delta\nu \geqslant 10$ kHz, the time T_2 remains unchanged on further increase of $\eta/T(°K)$, while the spin–lattice relaxation time increases, which results in the previously described situation, typical for solids, where $T_1 \gg T_2$.

VIII. THE CHEMICAL SHIFT

Almost all the quantities which we introduced in the discussion of the nature of nuclear magnetic resonance were independent of the chemical properties of the specimen. Chemical properties reflect a wide variety of structural features of the electron cloud of the molecule. We have to show how the electronic structure affects the resonance conditions of the magnetic nuclei in the atoms constituting the molecule investigated.

The simplest case is the nuclear magnetic resonance of atomic hydrogen. According to Eqn. (3) and the data in Table 1, the resonance conditions for a proton correspond to $\nu_0 = 4257.7\,H_0$ (Hz). The question arises how the resonance frequency ν_0 varies under the influence of the spherical 1s electron shell surrounding each proton. The answer to this problem comes from the theory of diamagnetism[18]. When a magnetic field H_0 is applied to our hypothetical specimen, a circulating electric field is induced in the electron shell of the atom, and according to Faraday's law this is proportional to the rate of variation of the magnetic field dH/dt. Under the influence of this field, the momentum associated with the electron shell alters and the rate of its variation is proportional to dH/dt. As a result, the total change in momentum is independent of the rate of increase of the magnetic field and is simply proportional to the square of the radius of the orbit in which electron circulation takes place and to the steady magnetic field strength. The increased momentum of the s electron generates a proportionate magnetic moment which, according to the Lenz law, gives rise to a magnetic field opposed to H_0. Thus the nuclei of hydrogen atoms in a magnetic field H_0 are in fact exposed to the field

$$H_{\text{eff}} = H_0(1-\sigma), \qquad (11)$$

where σ is the diamagnetic screening constant.

For the purpose of subsequent exposition, it is important to emphasise that the greater is the absolute value of σ the smaller is H_{eff}. This is an obvious consequence of the negative diamagnetic susceptibility of our specimen: $\chi < 0$. Suppose that the specimen investigated contains two types of protons with screening constants σ_1 and σ_2. Then the corresponding effective fields are $H_1 = H_0(1-\sigma_1)$ and $H_2 = H_0(1-\sigma_2)$. If the spectrometer operates at a fixed frequency ν_0, then, in order to observe the NMR of the first nucleus, it is necessary to apply to the specimen the "resonance" field

$$H_{\text{res}_1} = \frac{\nu_0}{\gamma_0(1-\sigma_1)} \simeq \frac{\nu_0}{\gamma_0}(1+\sigma_1),$$

and the resonance of the second nucleus will be "seen" in the field

$$H_{\text{res}_2} = \frac{\nu_0}{\gamma_0}(1+\sigma_2) = H_0(1+\sigma_2).$$

Consequently the greater is the diamagnetic screening the stronger must be the resonance field; in other words, an increase in screening displaces the NMR signal towards stronger fields. The difference, on the magnetic field scale, between the relevant signals is

$$\Delta H = H_{\text{res}_2} - H_{\text{res}_1} = H_0(\sigma_2 - \sigma_1).$$

Evidently the chemical shift ΔH is proportional to the strength of the magnetic field employed in the apparatus. This is an important factor to which we shall frequently return later.

In order to compare the spectra recorded in different magnetic fields, one usually employs a dimensionless relative chemical shift:

$$\frac{\Delta H}{H_0} = \sigma_2 - \sigma_1. \qquad (12)$$

Thus, the intervals between the signals of chemically non-equivalent nuclei observed in the NMR spectra are determined directly by the diamagnetic screening constants. The calculations and estimates of these constants are important for high-resolution NMR spectroscopy. The structural interpretation of chemical shifts is very valuable in modern chemistry.

In successful cases the chemical shifts observed in the NMR spectra indicate directly the number of non-equivalent groups of atoms and the relative signal intensities yield an unambiguous estimate of the numbers of atoms in the corresponding groups. In many cases such information is sufficient to determine the structure of the molecule. However, the diamagnetic screening constants σ are susceptible also to a more profound treatment.

1. Interpretation of Chemical Shifts

The value of σ for the hydrogen atom was calculated for the first time by Lamb[19]. This quantity can be simply estimated. The diamagnetic moment induced in the atom is

$$\mu_d = -\frac{ne^2}{6mc^2} H_0 \langle r^2 \rangle, \qquad (13)$$

where e is the electronic charge, m the electronic mass,

$\langle r^2\rangle$ the mean square of the radius of the electronic orbit, and $n = 1$ for the hydrogen atom. The magnetic field set up by the moment μ_d at the centre of the electronic orbit is

$$H_d \simeq \frac{\mu_d}{r^3} \simeq \frac{ne^2}{6mc^2}\langle r^{-1}\rangle H_0.$$

The ratio of H_d and H_0 gives an estimate of the screening constant:

$$\sigma = \frac{ne^2}{6mc^2}\cdot\frac{1}{\langle r\rangle}. \qquad (14)$$

By substituting the values of e, m, and c and assuming that $\langle r\rangle = 0.5\times10^{-8}$ cm, we obtain $\sigma_H \simeq 10^{-5}$. By a rigorous calculation, Lamb found $\sigma_H = 2\times10^{-5}$. Thus the magnetic field at the nucleus of the hydrogen atom is smaller by 20 p.p.m. than the external field H_0. If small changes in n are postulated (equivalent in our estimate to changes in electron density at the atom considered), the screening is directly proportional to such changes. If Eqn. (14) gave an exhaustive description of the magnetic screening of nuclei, proton NMR would be an ideal method for the measurement of the distribution of electron density in organic molecules. However, this is not so.

The calculation of σ for the hydrogen molecule (H_2) proved to be much more difficult. This is quite reasonable: here the problem loses spherical symmetry, which significantly complicates the physical nature of the magnetic screening. In the molecule it is necessary to consider the screening of a given nucleus as the sum of the following contributions: (a) the diamagnetic contribution due to the spherical component of the electron cloud centred at this nucleus and (b) the magnetic fields set up at this point by the magnetic circulation of other electrons. The first contribution is described by an equation of type (14) and always reduces the external field H_0. The magnetic fields set up by other electrons can be of either sign; if they add to the external fields, such a contribution is called "paramagnetic". We shall consider this problem in somewhat greater detail. If the molecule under consideration has an electron cloud with a non-zero overall orbital momentum L and a spin moment S, the energy of the molecule in the ith state will be[3]

$$\varepsilon_i = \varepsilon_i^{(0)} - \frac{ehL_z}{4\pi mc}H_0 - \frac{ehH_0}{2\pi mc}S_z + \frac{e^2H_0^2}{6mc^2}\Sigma\langle r_i^2\rangle,$$

where L_Z and S_Z are the projections of the corresponding moments on the direction of the magnetic field H_0 and $E_i^{(0)}$ is the energy of the molecule in the absence of a magnetic field. We shall not consider a molecule with true paramagnetism and throughout subsequent exposition it will be assumed without additional stipulation that the electron shells are filled—all possible states with both positive and negative projections of the moments on the z axis are occupied: $L = 0$ and $S = 0$, i.e. there is no paramagnetism in our specimens in the true sense of the word. The last term in the expression for the energy E_i is responsible only for diamagnetism and the "paramagnetic" contributions to the magnetic field, acting on the given atomic nucleus, arise only because the electron cloud of the molecule is not spherical. The magnetic screening in ^{31}P, ^{19}F, and similar heavy atoms is complicated by the fact that the orbital moment L does not become identically zero; as a result, a large paramagnetic component appears in the screening constant. This will be treated in greater detail below.

If two hydrogen atoms are placed at a small distance from one another and are "forbidden" to form a chemical bond, the screening constant of one atomic nucleus will be independent of the diamagnetic circulation in the electron shell of the neighbouring spherical atom: the orbital moment of the 1s shell is zero ($l = 0$) and the spin moment in this model treatment is neglected in view of the above decision to disregard paramagnetic molecules. The question then arises of the origin of the "paramagnetic" contribution to the screening of the protons in the H_2 molecule. The answer is given below.

2. Magnetic Anisotropy

The covalent H–H bond has axial symmetry—its electron cloud may be approximately represented by an ellipsoid of rotation. Evidently, in contrast to the case where a spherical atom is placed in a magnetic field, the intensity of induced diamagnetic currents will vary for different orientations of the half-axis a of this ellipsoid, which is directed along the bond relative to the constant magnetic field H_0. Moreover the deviations of the electron cloud from the cylindrical form lead to the appearance of Van Fleck paramagnetism[3], i.e. the susceptibilities become

$$\chi_i = \chi_{di} - \chi_{pi} = \alpha_i\chi_{di};\ i = x, y, z.$$

Therefore the magnetic susceptibility χ_l for $a \parallel H_0$ is not equal to the susceptibility χ_t for $a \perp H_0$. Consequently the deviations from spherical symmetry should make the magnetic susceptibility anisotropic: the longitudinal susceptibility χ_l is not equal to the transverse susceptibility χ_t.

When the molecule participates in thermal motion, it assumes all possible orientations relative to H_0 and the time-average magnetic moment of the bond considered (or group of atoms) is not zero. The following quantity is a measure of the anisotropy of the magnetic susceptibility of an n-electron shell[13]:

$$\Delta\chi = \chi_l - \chi_t = \frac{ne^2}{4mc^2}(\alpha_l\langle r^2\rangle_l - \alpha_t\langle r^2\rangle_t);\ 0 \leqslant |\alpha| \leqslant 1. \qquad (15)$$

According to the definition (15), $\Delta\chi$ is a magnetic dipole. It is easy to establish a relation between the anisotropy of the magnetic susceptibility of the given bond $\Delta\chi$ and the change in the screening of the given nucleus $\Delta\sigma$ which arises under the influence of $\Delta\chi$. McConnell[20] showed that

$$\Delta\sigma = \frac{\Delta\chi}{3R^3}(3\cos^2\theta - 1), \qquad (16)$$

where R is the distance from the centre of the dipole $\Delta\chi$ to the given nucleus and θ is the angle between the axis of the anisotropic bond and R. It is important to emphasise that in many cases (C=O, C=C, and other bonds) $\langle r_t^2\rangle$ has two values: $\langle r^2\rangle_x$ and $\langle r^2\rangle_y$, and therefore, strictly speaking, for such bonds it is necessary to introduce two values of the magnetic anisotropy: $\Delta\chi_x$ and $\Delta\chi_y$.

Thus a classification of the model forms of electron shells and the corresponding magnetic susceptibilities may be proposed (Table 2; $ne^2/4mc^2 = k$).

Table 2 shows that in the general case it is virtually impossible to calculate $\Delta\chi$ (the values of α_i are determined by the wave functions of excited molecular states).

Quantum-mechanical calculation[21] yields a screening constant $\sigma(H_2) = 23\times10^{-6}$ for the H_2 molecule; the local screening of each proton by "its" electron gives $\sigma_{loc} = 28\times10^{-6}$ and the "paramagnetic" contribution is $\sigma_n = -5\times10^{-6}$. The accuracy of this calculation is not very great, but on its basis and in combination with Lamb's data one may assert, firstly, that the 1*s* electron, distributed around a given proton, is responsible for a screening effect of about 25 p.p.m. in the molecule and, secondly, that the deviations from spherical symmetry of the electron shell can give rise to a 20% change in the local screening. Thus in proton NMR the dominant contribution to screening comes from the proton's "own" electron and the changes of σ under the influence of the anisotropy of the magnetic susceptibility of the neighbouring bonds are smaller by a factor of ten. The effect of the magnetic anisotropy can be of either sign. This is caused, firstly, by the fact that, as the angle θ varies, the factor $3\cos^2\theta - 1$ changes sign in the vicinity of $\theta_0 = 54°44'$. Therefore, when $\Delta\chi > 0$, the correction $\Delta\sigma$ calculated by Eqn. (16) is positive (shift to a stronger field) for $\theta = 0$ and negative (shift to a weaker field) for $\theta = 90°$. Secondly, $\Delta\chi$ can be of different signs. It is then extremely important to agree exactly on the significance of the terms "positive $\Delta\chi$" and "negative $\Delta\chi$".

Table 2.

Form of electron shell	$-\chi_z$	$-\chi_x$	$-\chi_y$	$\Delta\chi$
Ellipsoid	$\alpha_z k\langle r^2\rangle_z$	$\alpha_x k\langle r^2\rangle_x$	$\alpha_y k\langle r^2\rangle_y$	$k(\alpha_z\langle r^2\rangle_z - \alpha_x\langle r^2\rangle_x)$ $k(\alpha_z\langle r^2\rangle_z - \alpha_z\langle r^2\rangle_y)$
Circular cylinder	$k\langle r^2\rangle_z$	$\alpha_x k\langle r^2\rangle_x$	$\alpha_x k\langle r^2\rangle_y$	$k(\langle r^2\rangle_z - \alpha_t\langle r^2\rangle_t)$
Ring (one-dimensional)	kR^2	0	0	kR^2
Sphere	$\frac{3}{2}k\langle r^2\rangle$	$\frac{3}{2}k\langle r^2\rangle$	$\frac{3}{2}k\langle r^2\rangle$	0

Experiment shows that misunderstandings frequently arise in this problem, associated with the differences between the traditional concepts in magnetochemistry and those which have arisen in NMR spectroscopy. Let us consider some examples. In the hypothetical measurement of the magnetic susceptibility of an acetylene single crystal we found that the anisotropy of the diamagnetic susceptibility is positive, i.e. the diamagnetic susceptibility χ_l measured along the triple bond is higher than the diamagnetic susceptibility χ_t measured in a perpendicular direction. But the diamagnetic susceptibility is *negative*. Therefore, strictly speaking, we are dealing with positive anisotropy of negative magnetic susceptibility, i.e. $\Delta\chi < 0$. However, the NMR method is used almost exclusively to investigate diamagnetic properties and for acetylene one usually assumes that $\Delta\chi > 0$. Accordingly, Eqn. (16) predicts a shift to stronger fields for the acetylene proton located on the triple bond axis ($\theta = 0$), which is in fact observed. Because the distance R is short, this shift is very considerable and sets the upper limit to the effect of magnetic anisotropy: $\Delta\sigma(C{\equiv}C) \simeq 4 \times 10^{-6}$. For single and double bonds, the anisotropy of diamagnetic susceptibility is negative, i.e. $\Delta\chi < 0$; accordingly, the NMR signals of nuclei on the bond axis and within a cone with an angle of 54°44′ at the apex are shifted towards weaker fields. A striking case of positive diamagnetic anisotropy is provided by benzene and similar aromatic molecules. The 6π electrons of benzene circulate in a ring of conjugated bonds, the average radius of which is close to 1.4 Å. Using Table 2 (annular current), we obtain $\chi_l \simeq 100 \times 10^{-30}$. Consequently for benzene $\Delta\chi = 100 \times 10^{-30}$ (per molecule) or $\simeq 60 \times 10^{-6}$ (per mole). It is interesting that this rough estimate agrees satisfactorily with the results of the measurements of the static magnetic susceptibility of benzene. Calculation by Eqn. (16) shows that such anisotropy displaces the signal of its "own" protons (i.e. protons in the plane of carbon atoms at a distance $R = 2.48$ Å from the centre of the molecule) by about 2×10^{-6} towards weaker fields. This is the so called "aromatic shift". It is frequently also called the shift due to annular currents. In full agreement with the foregoing, the annular current in benzene can displace the signals of "alien" protons towards stronger fields, when these protons are located in a conical region the axis of which is normal to the plane of the molecule. Thus in pure liquid benzene the proton magnetic resonance (PMR) signal is displaced approximately by 0.6×10^{-6} towards stronger fields relative to a 1% solution of benzene in carbon tetrachloride.

In ferrocene—a sandwich compound of iron with two C_5H_5 rings—the NMR signals of the cyclopentadienyl protons are displaced towards stronger fields by 3.3 p.p.m. relative to benzene[6]. This shift permits an unambiguous choice in favour of the calculation by Shustorovich and Dyatkina[22], according to which, and in contrast to Dahl and Ballhausen[23], there is a negative charge on the C_5H_5 ring of ferrocene (since the molecule is neutral as a whole, a double positive charge is localised at the Fe atom). The conclusion of Dehn and Mulay[24] that 4.8 electrons circulate in each C_5H_5 ring, i.e. that iron has a negative charge appears to contradict the finding of Shustorovich and Dyatkina[22]. The magnetic susceptibilities of ferrocene are $\chi_z = -162 \times 10^{-6}$, $\chi_x = -104 \times 10^{-6}$, $\chi_y = -108 \times 10^{-6}$, and $\Delta\chi = 56 \times 10^{-6} \simeq \Delta\chi_{\text{benz}}$. The conclusion that iron has a negative charge arose as a result of the application to ferrocene of the annular current model (Table 2). In fact, if one assumes that $\Delta\chi = kR^2$ and remembers that $R_{C_5H_5} < R_{C_6H_6}$ and also that two C_5H_5 rings are responsible for $\Delta\chi$, it is found that the number of electrons in the rings is reduced compared with the initial value $n = 5$. However, it is evident from the comparison of the values of χ_z and $\chi_\perp$ for ferrocene with Table 2 that the estimate of kR^2 gives a value of χ_z which leads to $n \simeq 20$, i.e. all the π electrons of the molecule contribute to the longitudinal susceptibility. The charge on the rings cannot be estimated by assuming that $\Delta\chi = kR^2$.

Hence it follows that the dipole $\Delta\chi$ of the real magnetic anisotropy of ferrocene is localised at the centre of the Fe atom and has very little effect on the screening of the C_5H_5 protons, i.e. here $\theta \simeq 60°$ and the angular factor in Eqn. (16) is close to zero. Thus, despite the conjugation of the C_5H_5 rings, the annular current effect in ferrocene is appreciably weaker, i.e. the corresponding PMR signal should be displaced towards stronger fields. The estimates quoted above show that this gives rise to approximately half the shift which needs to be explained. The other half of the observed shift is due to the *negative* charge of the rings, which confirms the view of Shustorovich and Dyatkina: the metal behaves not as an acceptor but as an electron donor in relation to the C_5H_5 rings.

Here it is appropriate to recall yet again that the positive anisotropy of the diamagnetic susceptibility of benzene, ferrocene, and acetylene molecules corresponds exactly to the negative anisotropy of the magnetic susceptibility of the same molecules. In many literature sources the second magnetochemical sign convention is employed; the McConnell formula is then written in the form

$$\Delta\sigma = \frac{\Delta\chi}{3R^3}(1 - 3\cos^2\theta).$$

In the interpretation of the PMR spectra the considerations described above make it possible in most cases to achieve a satisfactory understanding of the experimental data.

3. Paramagnetic Screening in Heavy Atoms

For heavier atoms, the calculation or qualitative treatment of σ involves considerable difficulties. One may regard it as a general rule that σ increases in parallel with the atomic number, i.e. there is an increase in the frequency interval ν_0 in which the NMR signal of nuclei of a given kind may be observed in a given field H_0.

It must be emphasised that, for ^{19}F, ^{31}P, and similar atoms, one can no longer regard diamagnetic screening as the main contribution to the observed chemical shift. In the discussion of the screening in the hydrogen atom and in the H_2 molecule the absence of an orbital momentum in the *s* electron shell plays an important role. For *p*, *d*, and other electrons, the orbital momentum is not zero, i.e. these electrons give rise to a strong magnetic field at the atomic nucleus. The strength of this field is directly proportional to the magnetic moment of the electron (10^{-20} erg $Gauss^{-1}$) and is inversely proportional to the cube of the average distance between the corresponding electron and the nucleus. For fluorine, the average distance of the $2p$ electron from the nucleus is 0.25 Å, i.e. the magnetic field which it sets up amounts to hundreds of thousands of oersteds. This is tens of times more than the typical values of H_0 in NMR spectrometers and therefore it would appear that ^{19}F NMR should be observed at frequencies many times higher than $\gamma_F H_0$. In reality, when F atoms are bound in molecules, the intramolecular electric fields force the *p* electrons to precess and the so called "freezing" of the orbital motion of the $2p$ electron takes place[3,25]; the magnetic field of the $2p$ electrons at the ^{19}F nucleus is close to zero. In a magnetic field H_0 the orbital momentum is partly "unfrozen" and the *p* or *d* electrons have a very powerful influence on the screening of the nucleus and are responsible for the paramagnetic contribution to σ. For ^{19}F, the diamagnetic term $\sigma_d \simeq 10^{-5}$ and $\sigma_p \simeq -20 \times 10^{-4}$. Thus the chemical shifts of ^{19}F and ^{31}P are largely determined by the paramagnetic contribution to the screening due to the spherically asymmetric electron orbits.

4. Chemical Shift Scales

In the measurement of the PMR chemical shifts standard chemical shift scales are employed. Tetramethylsilane (TMS), which has a very high value of σ, is most used as an internal standard; for the vast majority of substances, the NMR signals of protons occur in weaker fields than the TMS signal. In the so called δ scale the position of the TMS signal is assumed to be zero and the shifts to weaker fields are treated as positive; the shift is measured in parts per million (p.p.m.). The higher is the numerical value of δ, the weaker the screening of the corresponding proton. This is a disadvantage of the δ scale.

The parallel variation of the screening constant and the numerical value of the chemical shift is maintained in the τ scale, where the reference point is also the TMS signal but its position has been arbitrarily and quite unjustifiably assumed to be 10 p.p.m. Consequently the zero of the τ scale corresponds to $\delta = 10$ p.p.m.; evidently

$$\delta = 10 - \tau$$

or

$$\tau = 10 - \delta.$$

A disadvantage of the τ scale is the change in the sign of τ for shifts with $\delta > 10$ p.p.m., characteristic of acids and protons involved in strong hydrogen bonds. The negative signs of τ is physically quite meaningless. On the other hand, the negative sign of δ indicates either a powerful effect of the magnetic anisotropy of the molecule or an unusually effective concentrations of electron density at the corresponding chemical bond. Possibly, the most convenient would be a scale (we shall call it the τ^* scale) in which the TMS signal would be at 25 p.p.m.: on this scale the value of τ^* could be roughly identified with the electron density at the corresponding hydrogen atom.

In order to elucidate the significance of the symbols introduced and to learn how to employ them correctly, we shall consider an example. The PMR signal of the methyl group in ethyl is usually displaced by 1.25 p.p.m. towards weaker fields relative to the TMS signal. Consequently on the δ scale this shift is $\delta(CH_3) = 1.25 \times 10^{-6} = 1.25$ p.p.m. and on the τ scale it is $\tau(CH_3) = 8.75 \times 10^{-6}$. Such notation is sometimes inconvenient in the context of a given paper and a different procedure is resorted to: the scale designation is written as a multiplier of the shift, i.e. the shift of the methyl group on the δ scale is written

$$\sigma(\mathrm{TMC}) - \sigma(\mathrm{CH_3}) = \delta(\mathrm{CH_3}) = 1.25 \times 10^{-6} = 1.25\,\delta.$$

Here the symbol δ on the right-hand side has the significance

$$\delta = \frac{\sigma(\mathrm{TMC}) - \sigma(\mathrm{X})}{10^6\,|\,\delta(\mathrm{X})\,|} \equiv 1 \times 10^{-6},$$

i.e. $\delta = 1$ p.p.m. reckoned from the tetramethylsilane signal. Thus the phrases "the methyl group has a shift $\delta(CH_3) = 1.25 \times 10^{-6}$", "the methyl group has a shift $\tau(CH_3) = 8.75 \times 10^{-6}$", "the PMR of the methyl group was observed at 1.25 δ", and "the position of the peak due to methyl protons is at 8.75 τ" have in practice the same significance. Sometimes for brevity the multiplier 1×10^{-6} = p.p.m. is omitted and the chemical shift is written in the form $\delta(CH_3) = 1.25$.

IX. PRINCIPAL EMPIRICAL RELATIONS IN CHEMICAL SHIFT SERIES

The chemical shift is an important parameter of a high-resolution NMR spectrum. Impressive experimental data on the chemical shifts in the NMR of ^1H, ^{19}F, ^{31}P, and certain other nuclei have now accumulated. The chemical shifts in high-resolution PMR have assumed particularly great importance in the structural analysis of organic compounds, organic derivatives of the elements, and inorganic compounds. A typical PMR chemical shift diagram is presented in Fig. 3. Extensive compilations of the chemical shifts of protons and other nuclei can be found in monographs[5,6,9,10]. One of the first such compilations was published in this journal[26].

Handbooks dealing with compounds investigated by the NMR method and compilations of chemical shifts[27,28] are of great assistance in day to day work. Since the number of investigations with active employment of NMR reaches several thousand per year, a complete grasp of this stream of results can be achieved only with the aid of the card indexes published by several firms[29,30].

The following comments may be made on the PMR chemical shift diagrams. The PMR signals of transition metal hydrides occur in the strongest fields (the negative part of the δ scale). The nature of these extremely high shifts has been frequently discussed but its causes are still not clearly understood. The simplest qualitative explanation is based on the high electron-donating activity of

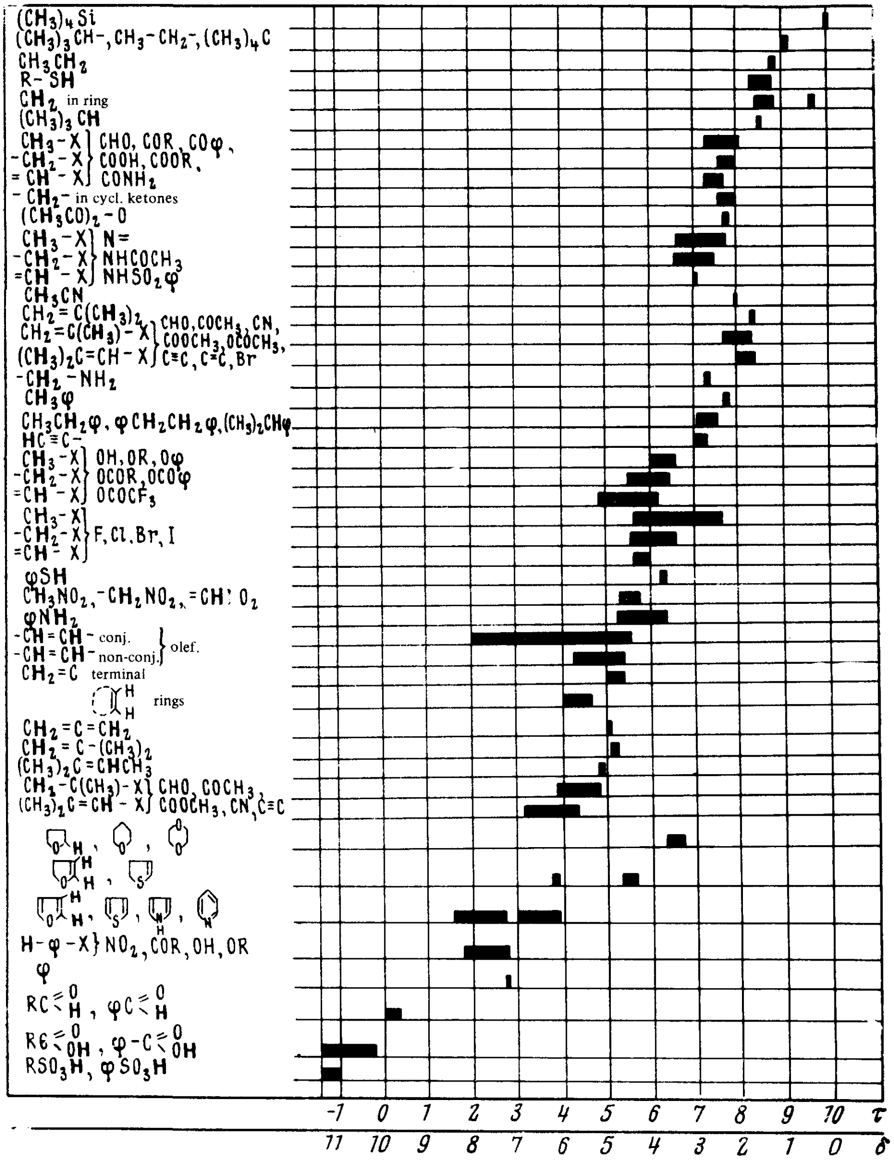

Figure 3. Diagram of NMR chemical shifts of protons.

transition metals and the tendency towards the formation of a helium type electron shell in the hydride hydrogen atom.

In the vicinity of the zero of the δ scale are the signals of the methyl groups attached to germanium and silicon atoms. The signals of cyclopropane and the terminal groups of fairly long ($n > 5$) alkane molecules are located between zero and unity on the δ scale. Methyl groups in ethyl and similar radicals give rise to a signal in the vicinity of 1.25. Methylene groups in the same radicals can give rise to PMR signals in the range $1 \leqslant \delta \leqslant 4$, depending on the properties of the atoms to which the radicals are attached; in certain organometallic compounds the CH_2 and CH_3 signals change places: the signal of the CH_2 protons occurs in stronger fields. Olefinic protons give rise to resonance peaks in the region $4 \leqslant \delta \leqslant 6.5$. Signals of hydroxyls and similar groups can be very markedly displaced under the influence of solvents which modify the intermolecular hydrogen bonds. In the absence of a hydrogen bond, the PMR of OH protons is in the vicinity of 2δ, very strong intermolecular bonds displace the signal to 10δ, and finally chelate protons give signals in the vicinity of 18δ, which is characteristic of extremely strong acids. However, this cannot be interpreted directly as implying the "stripping" of the chelate proton. Neutral aromatic molecules give signals in the region $6.5 \leqslant \delta \leqslant 8.0$. The signal of the aldehyde group is usually observed in the range $8 \leqslant \delta \leqslant 10$. It is possible to observe a satisfactory correlation between the donor-acceptor properties of substituents and the chemical shifts. As stated in the preceding paragraph, electron-donating and electron-accepting substituents displace the signal towards stronger and weaker fields respectively.

As already mentioned, the range of ^{31}P and ^{19}F chemical shifts is much wider than the brief interval corresponding to changes in the screening of protons. The NMR chemical shifts of ^{19}F and ^{31}P are less characteristic than the PMR shifts. As a rule structural conclusions are arrived at on the basis of a detailed spectrum, taking into account the spin–spin interaction. One discusses largely, not the absolute values of the shifts, but the changes under the influence of a suitable selected series of substituents[6,9].

X. SPIN–SPIN COUPLING

Five years after the discovery of NMR, Proctor, Gutowsky, and coworkers[31] observed a characteristic splitting in the NMR signals from many chemical compounds. This discovery was made immediately after this group of investigators succeeded in constructing a magnet with a field homogeneity of the order of 10^{-7} (exceeding by a power of ten the homogeneity of the magnetic fields in the best spectrometers previously available). It was then found that the NMR signals previously incorrectly attributed to chemically different atoms show further splitting into two and more components when the resolving power of the apparatus is increased. The principal feature of these multiplets proved to be that their splitting was independent of the magnetic field H_0. This finding demonstrated unambiguously a fundamental difference between the nature of the splitting and the chemical shift [see Eqn. (12)]. Simple relations observed in the study of the symmetry and the number of components in these new details of NMR spectra showed that the reason for the complication is indirect interaction of the nuclear magnetic moments via bonding electrons located between the atoms to which these nuclei belong.

To illustrate the mechanism of this interaction, we shall turn to the HD molecule. The reason why we are not discussing the spin–spin coupling in the H_2 molecule will be made clear below. The nucleus with a spin of 1/2 then interacts magnetically only with the electron shell of its "own" atom. The direct dipole–dipole effect of the magnetic moment of the electron μ_e on the magnetic moment of the nucleus μ_n in a liquid specimen will be largely averaged out by the thermal motion of the molecule and contact interaction[3] which is proportional to the density of the s electrons of the nucleus, plays the main role. Spin–spin coupling is therefore transmitted only via bonds which have non-zero s character.

Suppose that the HD molecule is in the ground state: two electrons are in the bonding orbital. The coupling of the nuclear and electronic magnetic spin moments in the H atom makes the antiparallel orientation of these moments more favourable than the parallel orientation. The antiparallel orientation of the electron spins in the HD molecule does not require further justification: this is a consequence of the existence of a covalent bond. Consequently the electron in the D atom, for which the mechanism of the coupling between the electronic and nuclear spins is the same as in the H atom, endeavours to orient the nuclear spin of the deuteron antiparallel to its own and hence antiparallel to the spin of the proton, i.e. the sign of the coupling between the nuclei is positive. Theory and experiment[33] have shown that the reversal of the sign of the spin–spin coupling is also possible: situations occur where the mechanism discussed leads to parallel orientation of the magnetic moments of the interacting nuclei.

As a result of the presence of the spin–spin coupling in the HD molecule, the NMR signal of deuterium ceases to be a singlet line. In simple words, the factor which orients the magnetic moment of the nucleus is the magnetic field. As has been frequently mentioned, protons have a spin of 1/2, i.e. are capable of being oriented in the field in two ways: along the field and in opposition to it. We also know that the populations of these states differ at room temperature by several tens of p.p.m. This difference is quite sufficient to detect the NMR signal with the aid of modern electronics. However, its intensity can be measured in the most favourable case only with an accuracy of several thousand p.p.m. Therefore in practice in half of the molecules of the specimen the deuterium nuclei will be subjected to the field

$$H'_{\text{eff}} = H_0(1-\sigma) + H_{ss},$$

while in the other half the magnetic field at the deuterons will be

$$H''_{\text{eff}} = H_0(1-\sigma) - H_{ss}.$$

Consequently the signal of the relevant nucleus will be converted into a doublet with equal component intensities. The distance between the doublet components is $2H_{SS}$ gauss. Since at present precise measurements of magnetic fields are made by determining accurately the NMR frequency[6], it was reasonable to characterise the spin–spin coupling by a constant measured on the frequency scale (not in gauss but in hertz). The value of $2H_{SS}$ measured in hertz units is called the spin–spin coupling constant and is denoted by J. For the HD molecule, J = 43 Hz.

The signal due to the second nucleus of the molecule is of course also a doublet with the same distance between the components. Table 1 shows that it is very difficult to observe the doublets simultaneously: owing to the considerable difference between the magnetic moments of the H and D nuclei, the resonance in a given field H_0 occurs at frequencies which differ by a factor of almost seven in the two cases. Therefore in the HD molecule the total NMR spectrum consists of two doublets the distance between the centres of which exceed by six powers of ten the doublet splitting. In the nomenclature adopted this spectrum is of the type AX: the designation of nuclei by letters from different ends of the alphabet is a symbolic representation of the fact that $\nu_A - \nu_X = \Delta\nu \gg J_{AX}$, i.e. the difference between the resonance frequencies of these nuclei is many times greater than the degree of spin–spin coupling between them.

XI. THE NUMBER OF LINES IN THE SPECTRUM

We established that the NMR spectrum of an AX system with two nuclei having spins of 1/2 consists of four lines—a doublet of doublets. It is not difficult to extend the considerations dealt with in the previous section to an AM...P...Z system of n non-equivalent nuclei with spins of 1/2. If each of the $n-1$ neighbouring nuclei is linked to the nucleus under consideration by spin–spin coupling, then, by numbering the neighbours in order of decreasing coupling we find that the nearest neighbour splits the signal of the given nucleus into a doublet and each component of this doublet becomes a doublet itself as a result of the interaction with the second neighbour, etc. Thus the signal of the given proton becomes a multiplet consisting of 2^{n-1} components. There will be as many multiplets as there are nuclei in the system, i.e. altogether in the spectrum of a system of n interacting nuclei there will be

$$m = n \times 2^{n-1} \tag{17}$$

peaks.

Eqn. (17) gives the multiplicity of the PMR spectrum when the distances between the multiplets exceed greatly the splitting within them, i.e. the chemical shifts $\nu_0\delta_{ik}$ exceed approximately by a power of ten the corresponding spin–spin coupling constants:

$$\nu_0\delta_{ik} \geqslant 10J_{ik}. \tag{18}$$

If condition (18) holds for each pair of nuclei, then the corresponding spectrum is called a first-order spectrum. Eqn. (17) gives the maximum multiplicity for such spectra.

A decrease in the number of lines in a first-order spectrum may be caused by some kind of equivalence of the nuclei. We shall consider only two principal types: chemically and magnetically equivalent nuclei. Chemically equivalent nuclei are those with identical screening (identical chemical shifts). According to the laws of quantum mechanics, spin–spin coupling within a group of chemically equivalent nuclei cannot be detected. This in fact is the reason for our choice of the HD molecule as a model for the discussion for the mechanism of spin–spin interaction: the chemical equivalence of the protons in the H_2 molecule precludes the observation of a powerful (J = 280 Hz) spin–spin coupling. Therefore, when p nuclei have the same chemical shift, then, instead of $p \times 2^{n-1}$ lines, this group gives only one line, which is split into $2^{(n-p)-1}$ components when there is different spin–spin coupling between the remaining nuclei of the system and each nucleus within the group of the chemically equivalent nuclei. Thus the multiplicity of the spectrum is then significantly reduced.

Further simplification or, the so called degeneracy of the spectra, can occur due to fortuitous equality of certain spin–spin coupling constants or when there are multiple relations between them. Then two or more peaks coincide.

Apart from chemical equivalence, there is also a possibility of magnetic equivalence of the nuclei. A group of chemically equivalent nuclei is said to be magnetically equivalent when each of them undergoes the same spin–spin interaction with any nucleus of another group of nuclei. Naturally, under these conditions the second group also consists of magnetically equivalent nuclei.

The methyl and methylene protons of the ethyl group may be regarded as constituting the most widely known case of magnetic equivalence. For any hindered conformation of the ethyl group, methyl protons, for example, would have the same chemical shifts but would undergo different interactions with the protons of the methylene group, i.e., while maintaining their chemical equivalence, they would be magnetically non-equivalent.

The rapid rotation of the methyl group around a single C–C bond leads to the averaging of the spin–spin interaction constant, and in the presence of sufficiently strong magnetic fields the ethyl group gives rise to a PMR spectrum of the type A_2X_3. It is easy to establish the form of the spectrum. Owing to the equality of the constants, the signal of the methyl group instead of being a doublet of doublets becomes a triplet with intensity ratios of 1 : 2 : 1, since the central peaks coincide. The spectrum of the methylene protons instead of comprising eight (2^3) equal peaks will consist of a quadruplet with a binomial intensity distribution 1 : 3 : 3 : 1. It is easily seen that the sum of the relative intensities is equal to the corresponding spin multiplier 2^{n-1} in Eqn. (17). This is an additional illustration of the fact that binomial multiplets are only a very special case of spin–spin splitting in high-resolution PMR spectra.

When the chemical shifts diminish, there is as a rule an appreciable increase in the number of lines in the spectrum compared with the multiplicity predicted by Eqn. (17). The reason is the occurrence of the so called combination lines. In the examination of the scheme which led to formula (17) it was suggested that only pure transitions take place between the energy levels formed. Thus the A transition is one in which the state of only the A nucleus is altered. However, in many-spin systems there is a possibility also of transitions in which there is a simultaneous change in the state of several nuclei. Thus in three-spin systems there is a possibility of a transition from the situation ↑↓↓ to ↓↑↑. Usually the intensities of these lines are low, but for $\nu_0\delta \leqslant J$ the combination transitions lead to a sharp increase in the number of lines. To illustrate this, the table taken from Braier et al. is quoted[33].

n	2	3	4	5	6	7
m_{min}	4	12	32	80	192	448
m_{comb}	0	3	24	130	690	2555
m_{max}	4	15	56	210	792	3003

Such a large number of lines causes significant difficulties in the interpretation of the spectra: the individual multiplets may overlap and the assignment ceases to be unambiguous. Frequently in the spectra of many-spin systems the lines are so close to one another that instead of individual peaks a common outline is observed. Under these conditions, differing sets of parameters can lead to virtually identical spectra. The calculation of the spectrum should give a set of parameters (chemical shift δ_i and spin–spin interaction constant J_{ik}) corresponding unambiguously to the observed spectrum. Such a calculation is a typical quantum-mechanical problem. For a system of n nuclei with spins of 1/2, the number of energy levels is 2^n, i.e. the secular equation for a two-spin system is of the fourth degree and the equation for a three-spin system is of the eighth degree. In fact the symmetry properties of the spin systems make it possible to reduce significantly the degree of the secular equation. Thus for a two-spin system, the secular equation becomes

$$\begin{vmatrix} H_{11}-E & 0 & 0 & 0 \\ 0 & H_{22}-E & H_{23} & 0 \\ 0 & H_{32} & H_{33}-E & 0 \\ 0 & 0 & 0 & H_{44}-E \end{vmatrix} = 0, \tag{19}$$

i.e. the problem reduces to the solution of two linear equations and one quadratic equation. Fig. 4 presents the spectrum of an AB system, i.e. a two-spin system with a chemical shift $\nu_0\delta_{AB}$ close in magnitude to the spin–spin coupling constant J_{AB}. The solution of Eqn. (19) leads to the result

$$\nu_0\delta_{AB} = \sqrt{\Delta_{14}\,\Delta_{23}}; \qquad A_1 : A_2 = \Delta_{23} : \Delta_{14}. \tag{20}$$

It is important to note that, in contrast to a system AX, in the analysis of a system AB the spectrum yields directly only the value of J_{AB} and the chemical shift is obtained only as a result of the calculation. For more complex systems, none of the NMR spectral parameters can be obtained by direct measurement of any interval between the peaks.

The complex spectra of many-spin systems are analysed on electronic computers[34] and also with the aid of binary and multiple resonance methods[9]. Eqn. (20) shows that the distance between the two inner components of the spectrum of the AB system is appreciably smaller than the chemical shift $\nu_0\delta_{AB}$. As a result of this phenomenon, in the case of small shifts the multiple set of lines in the spectrum frequently merges into one peak, which reduces the reliability of the interpretation. All these difficulties are largely obviated when the operating frequency of the spectrometer is increased: the increase of the chemical shifts is then accompanied by a narrowing of the spin multiplets due to the disappearance of the combination lines; both factors tend to simplify the spectrum up to the limiting case of a set of doublets of equal intensity.

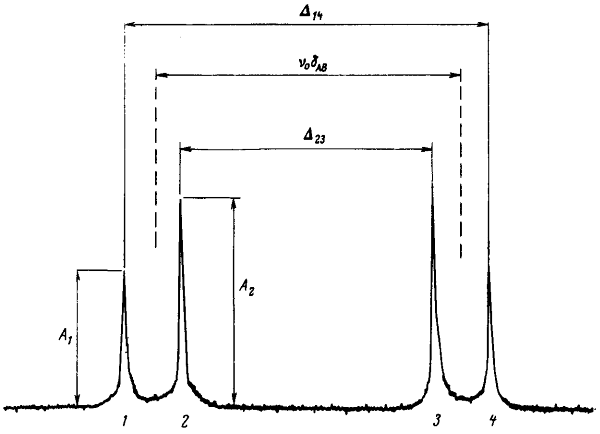

Figure 4. Spectrum of an AB system.

It is not difficult to calculate the frequency at which a given spectrum will become such a simple set of doublets. Suppose that $\delta_{\min}$ is the minimum chemical shift and $J_{\max}$ the maximum spin–spin coupling constant. Then the width of the spin multiplet will be approximately $2J_{\max}$ and for the spectrum to be simple the following condition must be fulfilled:

$$\nu_0\delta_{\min} \geqslant 20J_{\max}$$

If simple spectra are considered necessary for $\delta_{\min} \simeq 10^{-8}$ and $J_{\max} \simeq 10$ Hz (typical values for monoalkylbenzenes), then the required frequency is $\nu_0 = 2 \times 10^{10}$ Hz. This exceeds by a factor of one hundred the maximum value of ν achieved by 1968.[35] The above estimate clearly illustrates the principal trend in the design of NMR apparatus: a steady increase in the strength of the magnetic fields employed and in the corresponding values of ν_0 (proportional to them).

It is important to note that, apart from simplifying the spectra, an increase in ν_0 greatly improves the sensitivity. This is because an increase in ν_0 entails an increase in the spacing between the nuclear magnetic levels. At the same time there is also an increase in the size of the quantum absorbed by the specimen and in the difference between the populations of the upper and lower levels. In practice the sensitivity increases in proportion to ν_0^n, where the power exponent is in the range $1 \leqslant n \leqslant 2$.

XII. PRINCIPAL EMPIRICAL RELATIONS IN SPIN–SPIN COUPLING CONSTANT SERIES

The experimental values of the constants J are very useful in studies on the structures of complex organic compounds. In contrast to the chemical shifts, these values depend little on the nature of the solvent, the concentration of the test substance, etc. The conclusions arrived at with the aid of the spin–spin coupling constants are distinguished by high reliability.

Table 3 lists the values of J for saturated organic compounds. Only individual items in this table need to be commented upon. The change in the sign of the *gem* constant (row 1) with the valence angle was predicted theoretically by Karplus[32] and soon confirmed experimentally by the double resonance method[36]. The high values of the axial–axial constant (row 4) constitute one of the principles underlying the conformational studies of substituted cyclohexanes and similar problems in more complex compounds[37]. In those cases where the splitting of the hydroxyl proton signal indicated in row 8 is observed experimentally, it indicates unambiguously the absence of proton mobility; the disappearance of the multiplet structure of the signal permits the measurement of the rate of proton exchange (see Section XIII).

The constants J_{ab} for unsaturated compounds are given in rows 10–26 of Table 3. Here the most interesting finding appears to be the theoretically predicted[38] rule $J_{trans} > J_{cis}$, which has always been confirmed experimentally. This rule is invaluable in the study of the stereochemistry of the reactions of olefinic hydrogen atoms[39]. It is a special case of the dependence of J_{ab} on the angle between the half-planes containing the bonds CH_a and CH_b, investigated by Karplus[38]. This relation also constitutes a useful method for stereochemical investigations in most cases where the C–C bond is intermediate between a single and a double bond[40]. The useful relations in the series of conjugated cyclic compounds do not require further comment.

The interaction constants $J(^{13}C-H)$ play a major role in structural analysis by the NMR method. If the principal carbon isotope carbon-12 had a magnetic moment the ^1H NMR spectra would have been much more complex than is actually observed. Fortunately only the nucleus of carbon-13, the natural concentration of which is 1.1%, has a spin of 1/2. Therefore when the sensitivity of the spectrometer is enhanced, the proton resonance spectra show the so called ^{13}C satellites: doublet signals due to molecules in which the light carbon isotope is replaced by the heavy isotope. In the centre of this spin–spin doublet there is a signal two hundred times more intense and corresponding to protons joined to carbon-12. It has been found that the $J(^{13}C-H)$ splitting makes it possible to distinguish clearly the hybridisation of the carbon atom to which the given proton is linked. According to Muller and Pritchard[41], the values of $J(^{13}C-H)$ for methane, ethylene, and acetylene are respectively 125, 156, and 250 Hz. These three points together with the origin of coordinates (fourth point) lie quite accurately on a straight line when the $J(^{13}C-H)$ values are plotted against the amount of s character. This observation gave rise to an extensive literature. One may quote as a good example the work in

Table 3. Spin–spin proton coupling constants (from data issued by the Varian Company).

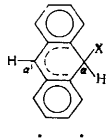
which it was shown unambiguously on the basis of the values of the $J(^{13}C-H)$ constants that in the molecule of dihydroanthracene[42]



the α-atom of the benzene ring is sp^3-hybridised:

$$J_\alpha(^{13}C-H)=127\,Hz,\quad J_{\alpha'}(^{13}C-H)=163\,Hz.$$

Measurements of the constants for the spin–spin coupling between protons and ^{29}Si, $^{117(119)}Sn$, Pb, $^{203(205)}Tl$, and ^{199}Hg nuclei are widely used in the chemistry of organometallic compounds. Typical values of these constants are listed in Table 4. An interesting example of the importance of these data is provided by the work of Nesmeyanov et al.[43] It was found that in the spectrum of C_5H_5Tl the signal due to the cyclopentadienyl protons is a narrow singlet with a chemical shift typical for compounds of this type without the slightest trace of spin–spin interaction with thallium nuclei.

At the same time Table 1 shows that thallium has no non-magnetic isotopes and it is evident from Table 3 how strong the spin–spin J(Tl–C–H) interaction usually is. The singlet nature of the PMR signal of C_5H_5Tl indicates complete exclusion of the spin–spin coupling. This is important evidence confirming the generally accepted view[44] concerning the mechanism of the spin–spin coupling, to which the Fermi contact interaction makes the main contribution. Such interaction is non-zero only when there is an appreciable electron density at both nuclei. Only s electrons can come into contact with the nucleus and therefore when the chemical bond involves pure p or d states, the absence of spin–spin interaction is to be expected. Univalent thallium forms a bond with the cyclopentadienyl ring via a $6p$ electron and the admixture of the s state to this chemical bond from thallium does not exceed 10^{-3} according to the data of the experiment quoted, since otherwise signs of splitting in the PMR signal would have been noticeable. Similar observations were made in the study of organophosphorus compounds. The constant $J(^{31}P-C-H)$ for tricoordinate phosphorus in the fragment $^{31}P-CH_2$ is several times smaller than for pentacoordinate phosphorus, which can be reasonably related to the tendency towards lone pair formation and the corresponding decrease of the s character of the $P^{III}-C$ bond.

Table 4. Metal–proton spin–spin coupling constants.

No.	Type	J(M-H), Hz	No.	Type	J(M-H), Hz

Spin–spin interaction with nuclei which have spins $I > 1/2$ leads to appreciable changes in the NMR spectra. Apart from a magnetic moment, such nuclei also have a quadrupole electric moment. The interaction of the nuclear quadrupole moment with an inhomogeneous electric field fluctuating as a result of thermal motion, which must exist in the specimen, leads to rapid reorientation of the nucleus, i.e. constitutes an additional mechanism of nuclear magnetic relaxation. Depending on the contribution of this mechanism, the spin–spin multiplets associated with the nuclei participating in the interaction with the quadrupolar nucleus can be either altogether "diffuse", or significantly broadened, or can comprise a set of sharp peaks of virtually the normal type.

The contour of the signals obtained is sometimes unexpectedly freakish. We may quote several examples. The simplest[45] is provided by deuterium exchange in 2-methylpentane; the 1,2-methyl protons in $(CH_3)_2-CH-(CH_2)_2CH_3$ give rise to a distinct doublet with a splitting of 6.62 Hz. In 2-deutero-2-methylpentane $(CH_3)_2-CD-(CH_2)_2CH_3$ the signal due to the $(CH_3)_2$ group proved to be a triplet with intensity ratios of 1 : 1 : 1 and a splitting of about 1 Hz. The form of this signal demonstrates unambiguously that deuterium is precisely in the position indicated. The ratio of the spin–spin interaction constants $J(CH_3-CD)/J(CH_3-CH) = 0.1512 \pm 0.008$, which agrees well with the ratio $\gamma_D/\gamma_H = 0.1535$.

^{14}N nuclei also have a spin $I = 1$, i.e. should give rise to 1 : 1 : 1 triplets. However, the high magnetic moment leads to an even more effective quadrupole relaxation of the ^{14}N nuclei; these nuclei execute such rapid transitions that the width of the signals of the protons linked to ^{14}N via a spin–spin interaction also increases markedly. Then the PMR signal is sometimes absent altogether. Thus in formamide the signals of the NH_2 protons are clearly visible only on saturation of the ^{14}N resonance[46].

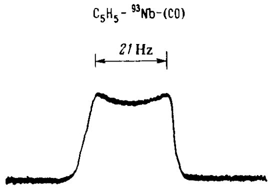

Figure 5. PMR signal of cyclopentadienyl protons in cyclopentadienylniobium tetracarbonyl.

It is important to emphasise that for ^{14}N the 1 : 1 : 1 ratios indicate only the integral line intensities. The observed pattern is altered by the different peak widths: the outer lines of the triplet correspond to levels with a shorter lifetime and therefore they are 40% wider and correspondingly lower than the central peak.

^{11}B and ^{35}Cl are typical examples of nuclei with a spin $I = 3/2$. In accordance with the possible number of states of the 3/2 spin in a magnetic field, such nuclei should give rise to a quartet. Indeed the ^{19}F NMR signal of the B–F group in 3-fluorobarene proved to be a quartet with intensity ratios of 1 : 1 : 1 : 1, all the peaks having approximately the same integral intensity and width. The NMR spectra of compounds with spin–spin coupling between the ^1H, ^{19}F, ^{31}P, and ^{35}Cl nuclei do not show this type of pattern: the quadrupole relaxation of the nuclei obliterates the multiplet and a single averaged peak is observed. The ^{93}Nb nucleus has a spin $I = 9/2$. Spin–spin coupling with such a nucleus leads to the formation of a decaplet all the components of which have the same integral intensity. However, in a multilevel system of this kind the probability of transitions is such that the extreme peaks of the multiplets are longest-lived and hence have the highest amplitude[47]. A typical spectrum is presented in Fig. 5. Evidently quadrupole relaxation in the Nb nucleus leads to a broadening of the multiplet components such that only a characteristic outline with maxima at the edges remains. After dividing the distance between the maxima by the number of intervals between the peaks, we obtain an approximate estimate $J(Nb-C-H) \simeq 2$ Hz.

XIII. CHEMICAL EQUILIBRIUM AND CONFORMATIONAL TRANSITIONS

Nuclear magnetic resonance proved to be a very sensitive and reliable method for detecting tautomeric equilibria, prototropy and exchange processes, intramolecular motion, etc. The reasons for the effectiveness of the method for these phenomena have already been given in essence when discussing the question of the magnetic equivalence of the methyl and methylene protons in the ethyl group. If the rate of a process whereby a given nucleus is transferred from a situation A to a situation B is high compared with the frequency range $\Delta\nu_{AB}$ which separates the ν_A and ν_B peaks in the spectrum, the effective field acting upon the nucleus becomes averaged. Therefore instead of two peaks only one is observed and its width is close to the natural width of the NMR line, i.e. is determined by the spin–spin relaxation time T_2. By reducing the temperature, it is possible to ensure that the residence time τ in each state (let $\tau_A = \tau_B = \tau$) is comparable to T_2. This leads to a broadening of the observed peak. Further retardation of the process leads to the "spreading" of the line over the entire frequency range $\Delta\nu$, and, when the latter is sufficiently wide, the line becomes virtually unobservable. Finally, when the given process ceases completely, two distinct peaks with frequencies ν_A and ν_B will of course arise in the spectrum and their width will again be determined by T_2. When the temperature is raised somewhat relative to the point corresponding to such "freezing out" of the exchange process, we yet again note signs of broadening of the peaks: the new widths, as in the previously discussed case of the other end of the temperature range, will be $T_2^{-1} + \tau^{-1}$. All these processes can be described mathematically in detail with the aid of Bloch's equations. However, for the purpose of the present review, the overall pattern of the changes with temperature observed in the NMR spectra of certain systems has been outlined adequately above.

The simplest example of the equilibrium of the type described is the keto–enol tautomerism, the study of which by nuclear magnetic resonance revealed a number of fundamental facts. Here the starting point was the investigation of acetylacetone[48], which at room temperature proved to be a mixture of the keto- and enolic forms in proportions of 4 : 1. It is important to stress that the detection of tautomers and the measurement of their concentration can be achieved with the aid of NMR much more reliably than by any other method, since each form is associated with a particular set of lines. Thus the enolic form of acetylacetone and similar compounds is characterised by the formation of a strong intramolecular hydrogen bond; a six-membered ring system of conjugated bonds is formed. In such systems there is a very marked shift of the hydroxyl proton signal towards weaker fields: from 13 to 20 p.p.m. on the δ scale. The signal of the methylene protons of the keto-form is displaced approximately by 10 p.p.m. towards stronger fields; the two signals can be very reliably distinguished. In more complex molecules there is a tendency for the enolic form to predominate at low temperatures. Thus 4-acetoacetylphenyl ether[49] shows no signs of the presence of the keto-form up to 100°C and only in the melt at 150°C does the ketone content reach 20%. The rate of interconversion of the equilibrium forms is low, since the corresponding peaks of the OH and CH_2 protons are broadened by no more than 1 Hz. These data provide a rough estimate of the height of the barrier inhibiting the ketone $\rightleftharpoons$ enol interconversion. It is significant that the estimate based on the Arrhenius equation, which is invariably invoked in all more accurate investigations in this field, is $\nu = \nu_0 \exp(-U/kT)$. Here the frequency ν_0 can be reasonably compared with intermolecular vibrations, i.e. is close to 10^{13} Hz. In other words ν_0 is the number of attempts at bond dissociation. The observed frequency ν of the ketone $\rightleftharpoons$ enol transitions represents the number of successful attempts at overcoming the barrier inhibiting the transition from one tautomeric form to another. For high-resolution NMR spectra, the observed frequency may be assumed to be $\nu \simeq 1$ Hz. Thus, let us suppose that at a low temperature in the absence of equilibrium $\nu = 0$ and the line width is > 1 Hz. Then the specimen is heated to a temperature T_C at which the line broadens approximately by 1 Hz due to the limited lifetime of a given tautomer. Under these conditions, the barrier is

$$U = kT_c \ln 10^{13} \simeq 55T_c, \tag{21}$$

where U is the height of the barrier in cal mole^{-1} and T_C the temperature on the Kelvin scale. For 4-acetoacetylphenyl ether, Eqn. (21) gives $U \simeq 20$ kcal mole^{-1}. It has been shown[50] that the accuracy of this estimate is ±3 kcal mole^{-1}.

As a rule, owing to the reduced strength of the hydrogen bond, the keto-enol tautomeric process is accompanied by prototropy, which leads to an additional temperature dependence of the hydroxyl proton NMR line width[51].

The prototropy also obeys the Arrhenius equation, in which the frequency factor and the activation energy can be readily determined from the NMR spectra recorded at different temperatures. In fact, an increase in line width of the order of 1–2 Hz can be readily detected in PMR spectra at low temperatures. This means that, for an activation energy $\Delta E \simeq 2$ kcal mole^{-1} which is frequently encountered, one can observe with certainty at a temperature of about 200°K proton exchange processes with a frequency factor $\nu_0 = e^5 = 140$ Hz. It is quite impossible to observe such weak processes by other methods.

An extensive literature has been published on the problem of *cis*- and *trans*-enolisation. A rigorous experimental examination of this problem proved to be possible only with the aid of NMR. A series of investigations by Kabachnik and coworkers[52,53] made it possible to study the kinetics and mechanism of the conversion of a *trans*-enol into the *cis*-enol. It was demonstrated convincingly that in solutions the *cis*-enol is more favoured by energy factors than the *trans*-enol.

In organometallic chemistry NMR made it necessary to postulate new types of tautomerism. Thus cyclopentadienyl derivatives of germanium and silicon show an unusual pattern of temperature changes in their NMR spectra. A single narrow signal due to the protons of the cyclopentadienyl ring accompanied by narrow ^{13}C satellites with a splitting of the completely normal kind is observed at high temperatures, while at low temperatures the typical pattern of cyclopentadiene involved in σ-addition is obtained. The question arises how to represent the structure of such a molecule in the intermediate temperature range where the form of the PMR spectrum clearly indicates that the protons of the cyclopentadienyl ring participate in a dynamic process, which averages out the immediate environment. At least two explanations can be proposed. A widely held view is that of Piper and Wilkinson[54], according to which at high temperatures there is rapid metallotropic migration along the perimeter of the cyclopentadienyl ring, at low temperatures the rate of this migration is vanishingly small, and in the range corresponding to the dynamic process the rate of migration is comparable to the chemical shift between the signals of protons involved in sp^2- and sp^3-hybridisation. In other words, according to Piper and Wilkinson, a change of temperature alters only the quantitative measure of the observed phenomenon: the sharp difference between the high-temperature and low-temperature PMR spectra may be accounted for by a more or less fortuitous factor: at high temperatures the rate (frequency) of migration is greater than the chemical shift, while at low temperatures it is lower.

Another explanation is almost self-evident: one can relate the narrow singlet arising at high temperatures to centrosymmetric addition of the cyclopentadienyl ring to the metal (C_{5v}-bonding). Then the intermediate temperature range corresponds to a sandwich–σ-bond transition in which the interconversion of the σ and C_{5v} molecules (tautomerism) takes place, its rate diminishing as the temperature is reduced, in parallel with the increasing concentration of the σ-molecules. When the temperature is reduced sufficiently, only the stable σ molecules remain in solution.

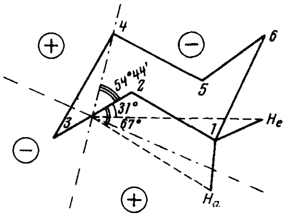

Figure 6. Location of the axial (H_a) and equatorial (H_e) protons in cyclohexane relative to the C_2-C_3 bond in different screening zones.

In principle nuclear magnetic resonance permits a valid choice between the two explanations of the experimental data.

The most widely known example of conformational changes observed with the aid of NMR is provided by the cyclohexane spectrum. The axial and equatorial hydrogen atoms in this molecule are located in different ways relative to the dipole associated with the magnetic anisotropy of the C_2-C_3 bond (Fig. 6). Therefore at low temperatures, at which this molecule may be regarded as rigid, the PMR spectrum is a doublet: the axial protons are screened to a greater extent and their signal is displaced towards weaker fields by 0.2×10^{-6}. On raising the temperature, the inversion of the cyclohexane ring begins and the PMR doublet signal is gradually converted into a singlet, in accordance with the laws already described. At room temperature the rate of inversion is relatively low and the cyclohexane signal is significantly broadened. The shift Δ_{ae} between the signals of the axial and equatorial protons and the available information about molecular geometry permit the calculation of the magnetic anisotropy of the C–C bond. The data thus obtained are significantly more accurate than the estimates of magnetic anisotropy based on magnetochemical concepts[55]. Nuclear magnetic resonance is one of the most effective methods for the investigation of conformations and there is an extensive literature on its application in this field[37,56–58].

XIV. STUDIES ON CRYSTAL STRUCTURES

High-resolution nuclear magnetic resonance is very actively employed in organic chemistry. Until recently low-resolution NMR was largely employed in inorganic chemistry and yielded a number of first class results concerning the fine details of the crystal lattice structure and also the details of thermal motion in the solid state, which are quite unobtainable by other methods.

Diffusion and vibrations of crystallised water molecules[59], the mechanism of the ferroelectric transition[60], the retarded motion in molecular crystals[61], and the exact determination of the coordinates of light atoms[62] are typical examples of problems successfully investigated by low-resolution NMR.

NMR chemical shifts in the solid state are difficult to observe: they are usually hundreds and thousands of times smaller than the observed line width. In Section VI it was already stated that in solids $T_1 \gg T_2$, in contrast to liquids where $T_1 \simeq T_2$. This inequality is caused both by higher values of T_1 and lower values of T_2 compared with the liquid state.

The decrease of the spin–spin relaxation time T_2 implies that the energy exchange processes in the nuclear spin system are very rapid. This entails a corresponding increase in line width. The increase of the spin–lattice relaxation time T_1 implies a sharp reduction in energy transfer from the nuclear spin system to the lattice. In other words, the magnetic nuclei form in the crystal lattice a highly isolated physical system; heat exchange between the lattice and the nuclei is strongly hindered. Therefore it is possible to introduce the concept of the spin temperature (see Section IV). The NMR line form for the crystal cannot be predicted in the general case. Bloch's equations are inapplicable to solids for a simple reason. They have been formulated essentially for a single nucleus and the problem of line form in the spectra of solids must be treated on the basis of statistical laws. In fact, the random motion of molecules in a liquid or gas leads to complete averaging of the intermolecular contribution to the local magnetic field; for an exact description of the phenomenon of nuclear magnetic resonance, it is quite sufficient to take into account only the phase differences between the magnetic moment of an arbitrary nucleus and the vector of the rotating magnetic field H_1 applied to the specimen.

On the other hand, in a solid the radiofrequency field H_1 is much smaller than the local magnetic field H_{loc} caused by the mutual effects of the nuclear magnetic moments fixed in the crystal. Therefore the line form cannot be a function of only H_1 and simple parameters such as T_1 and T_2; it depends fundamentally on the detailed distribution of the nuclear magnetic moment in the crystal structure and in a rigorous approach requires the examination of the specimen as a whole. The difficulties in the theoretical treatment of this problem have not as yet been overcome.

However, Van Vleck[63] showed that, when the crystal structure of the specimen is known, it is possible to find certain numerical characteristics of the line form—the so called moments. If the deviation of the magnetic field from the condition of exact resonance is denoted by the symbol h, the line form is described by a function $g(h)$. It is easy to show that $g(h)$ is symmetrical relative to the point $h = 0$. The nth order moment of the function $g(h)$ is defined as

$$\Delta\overline{H^n} = \int_{-\infty}^{+\infty} g(h)\, h^n dh. \tag{22}$$

Since the function $g(h)$ is even, all the odd moments ($n = 1$, 3, 5) become zero and only the even moments need to be calculated. The Van Vleck formula is most widely used in practice for the calculation of the second moment:

$$\Delta H^2 = \frac{9}{4}\cdot\frac{1}{N}\mu^2\sum_{k}^{n}\sum_{i} r_{ik}^{-6}(3\cos^2\theta_{ik} - 1)^2, \tag{23}$$

where r_{ik} is the distance between the ith and kth nuclei in the unit cell, n the number of types of crystallographically non-equivalent nuclei in the unit cell, and θ_{ik} the angle between the direction of the constant magnetic field H_0 and r_{ik}.

Comparisons of Eqns. (22) and (23) shows that NMR permits a structural analysis whereby the coordinates of the magnetic nuclei can be determined with high accuracy. The analysis can be carried out by the method of trial and error[64]. Suppose that we have a hypothetical structure A_1 in which specific trial values can be attributed to the distances r_{ik} and the angles θ_{ik}. Then, for any orientation of the single crystals in the field H_0, it is possible to calculate by Eqn. (23) the second moment $\Delta\overline{H}^2_{1c}$. Having recorded the real NMR signal for the same orientation of the crystal, it is possible to evaluate by Eqn. (22) the experimental value ΔH^2_{1e}. When the two numbers are highly inconsistent, it is necessary to revise the hypothetical structure, i.e. to employ for the calculation a new structure A_2, etc. until in the pth stage of the procedure satisfactory agreement between $\Delta\overline{H}^2_c$ and $\Delta\overline{H}^2_e$ is obtained. McCall and Hamming[62] showed that the process described permits the determination of 15 independent structural parameters for a triclinic structure. With increase in the symmetry of the structure, the number of independent parameters is of course smaller and in the simple cubic structure it reduces to a single parameter—the lattice constant. Therefore McCall and Hamming suggested, instead of the method of trial and error, a direct procedure for the structural analysis of single crystals by the NMR method: not more than 15 (depending on the symmetry of the crystal) measurements of the second moment are made. According to Eqn. (23), this set of numbers leads to 15 (or less) equations with 15 unknowns. The solution of this set permits, in principle, the determination of all the required structural parameters. However, Lundin and coworkers[60] and Dereppe et al.[64] showed that the McCall algorithm is unstable relative to unavoidable experimental errors and its practical application does not yield unambiguous results; practically useful conclusions can be derived only by improving the method of calculation significantly. Kitaigorodskii[65] stated that the NMR method can be very useful in the concluding stages of the X-ray diffraction analysis of single crystals. It has been shown[66] that, in order to arrive at a sufficiently reliable result, it is necessary to alter significantly the method of measurement and the experimental values of the second moment must be evaluated by an electronic computer. The accuracy of the structural analysis of single crystals by the NMR method would be indisputable if a rigorous theory of the NMR line shape for solids were available. Provotorov[67] has obtained important results in studies in this direction. Unfortunately it is not yet possible to give a rigorous theoretical explanation even of the almost self-evident fact of the rapid "decay" of the wings of the lines (at distances 2–3 times greater than the line width at half height). The creation of a theory predicting the behaviour of the line, if only at the wings, would convert the low-resolution NMR method into a regular method for improving the accuracy of the results of the X-ray structural analysis of crystals containing hydrogen and fluorine.

In many cases the magnetic nuclei in the crystal form physically isolated pairs or triplets. These cases have been examined by Pake[68] and Powles and Gutowsky[69] respectively. A typical example of the existence of isolated pairs is provided by water of crystallisation. Here the NMR signal proved to be a doublet in which the distance between the components is given by

$$\Delta H = \frac{3}{2}\gamma\hbar r^{-3}(3\cos^2\theta - 1),$$

where the notation has the same significance as in Eqn. (23). For water molecules, $r = 1.5$ Å and $\Delta H_{\max} \simeq 20$ G. Methyl groups are a typical example of nuclear triplets isolated in the crystal. It has been shown[70] that methyl groups at rest separated by distances greater than 3 Å give rise to a complex multiplet spectrum, the form of which changes with the orientation of the single crystal in the magnetic field.

The magnitude of the splitting observed in the spectrum of an isolated group may depend markedly on temperature. The explanation is that, when internal motions arise in the specimen, there is a possibility of additional averaging of the local field at the nucleus under consideration; when the motion is sufficiently rapid, instead of the multiplier $3\cos^2\theta - 1$ having a particular value, it is necessary to calculate its average value over the reorientation period. As in the discussion of the analogous questions in Section XIII, here one must regard as "sufficiently rapid" those motions whose rate exceeds significantly the interval between the observed multiplet components expressed in frequency units. Thus a broad NMR signal is observed for a rigid lattice (low temperatures), while at a high temperature the higher rate of internal motions appreciably diminishes the distance between the components of the NMR signal. A smooth structureless NMR line also consists of separate component pairs. Therefore on raising the temperature, with the consequent appearance of fairly rapid internal motions in the crystal, the single broad NMR line becomes narrower.

The events described are fully analogous to the changes occurring in high-resolution NMR spectra associated with chemical exchange (see Section XIII) but with the difference that the distances between the components and their width in the low-resolution spectrum are greater by a factor of several thousands, since their origin is different. Therefore, as the internal motions are "unfrozen", the characteristic changes in the low-resolution spectrum occur at frequencies $\nu_c \simeq 10^3-10^4$ Hz and not approximately 1 Hz as in the high-resolution spectra. Such a marked change in critical frequencies leads to an appreciable modification of the coefficient in Eqn. (21). If T_c is the temperature at which the width of the low-resolution signal begins to change, the height of the corresponding energy barrier is approximately[50]

$$U(\text{cal mole}^{-1}) = 37\ T_c\,(^\circ\text{K}). \tag{24}$$

A somewhat higher accuracy may be achieved by using a more complex expression:

$$U = kT_c \times 2.5\,\lg\frac{n}{\Delta}\sqrt{\frac{kT_c}{2J}}, \tag{25}$$

where n is the multiplicity of the barrier, Δ the NMR line width for $T \leqslant T_c$, J the moment of inertia of the molecule with respect to the reorientation axis, and k the Boltzmann constant.

This formula does not entail a greater experimental complexity—it is only necessary to consider additional information about the specimen. An explanation of the validity of the strikingly simple formulae (21) and (24) also follows from the form of Eqn. (25): all the parameters describing the structure of the specimen in a specific form are included in the logarithmic term and, when reasonable assumptions are made about the range of their variation, their effect on the final result is small.

The method described by Levich et al.[17] is widely used in the calculation of energy barriers; it requires extremely laborious experiments and frequently leads to contradictory results due to the inadequate accuracy of the measurements.

The sensitivity of broad-band NMR for slow motions led to the discovery in a number of crystals of unexpected displacements and reorientations of large molecules[71]. A word of warning against a common error is appropriate here. The results of the experiments are expressed in terms of curves representing the variation of the width and the second moment of the line with temperature. At certain temperatures these curves show distinct jumps, corresponding to changes by a factor of several units, which are sometimes interpreted as sudden "unfreezing" of a particular type of internal motion. In fact these points correspond to only one type of event: the frequency of the motion under consideration, which varies smoothly with temperature, becomes equal to the width of the NMR line (or the distance between its components); a real phase transition can coincide only fortuitously with the jump in the temperature variation of the NMR line width.

If the crystal has a rigid lattice, in which the thermal motion is confined to small oscillations about equilibrium positions, the NMR line width hardly changes up to fusion, where the width diminishes by a factor of tens of thousands and a high-resolution spectrum is produced. In crystals containing fluorine the chemical shifts are sometimes so great that in modern apparatus (with a field $H_0 = 23\,400$ Oe) they can be observed also in crystals, i.e. in broad-band spectra[72].

XV. PROSPECTS FOR THE IMMEDIATE FUTURE

The question arises of the way in which the NMR method will develop further and the contribution which such development may make to chemistry. It is risky to attempt an answer to these questions but certain trends in present day developments are so clear that their extrapolation to the immediate future and beyond is quite valid.

As in any physical method, the experimental technique is of decisive importance. The available working frequencies, i.e. the strength of the magnetic field H_0, will continue to increase. Electromagnets with a ferromagnetic 28 200 gauss core (120 MHz for protons) and superconducting 51 200 gauss solenoids (220 MHz for protons) are now used in practice. One may expect that "ordinary" (with iron) 35 000 gauss magnets (150 MHz for protons) and highly strengthened fields in iron-free solenoids will be produced. The advantages of such developments were dealt with in adequate detail in Sections VIII and X. Briefly, these involve an increase in the sensitivity and reliability of the method, since the spectra will be simpler. The range of applications will be extended. However, devices with powerful and ultrapowerful magnetic fields will remain rare and will be available only to large complex research centres.

A second important trend in the development of instrumentation will be miniaturisation and improvement in the reliability and simplicity of operation as well as a reduction in price of NMR spectrometers for every day analytical investigations in the chemical laboratory. The results already achieved in 1968 by the firms Perkin-Elmer (P-12 spectrometer), Varian (T-60 spectrometer), and JEOL ("Minimar" spectrometer) show that the construction of a simpler and more reliable NMR spectrometer, no more expensive than the present day gas–liquid chromatographs, is quite realisable.

The automation of analytical investigations by the NMR method constitutes an extremely important task. This is part of the general problem of the automation of research. The Varian and JEOL companies have achieved decisive advantages in this field. It has been shown that in the near future one may expect a large scale employment in chemical research of automated analytical laboratories comprising mass spectrometers, NMR and infrared spectrometers, and other essential devices, the sequence and conditions of the operation of which (including the most complex types of techniques) will be specified by computing and controlling devices, in accordance with the problem formulated by the chemist and based on the fundamental physical relations specified in the program for the device and also on the results of previous solutions of similar problems. The creation of such automated systems will free qualified specialists from routine day to day analyses and will reduce to a minimum the likelihood of an erroneous assignment of spectral lines, will greatly enhance the labour productivity of chemists specialising in synthesis and also spectroscopists. At present the range of applications of high-resolution NMR is somewhat restricted by the requirement of a low viscosity of the specimen. Here revolutionary changes are close at hand. Waugh and coworkers[73,74] showed that it is possible to devise a system where pulses of a radiofrequency field H_1 are applied to the specimen in such a way that the dipole–dipole interaction of the nuclei in the crystal lattice will be reduced to zero with a decrease of the chemical shift by a factor of only $\sqrt{3}$. Consequently it will be possible to obtain the NMR spectra of solids. It is found that the resolving power of the NMR method for solids will be even greater than for liquids and for crystals of ultimate purity may reach $10^{-11}-10^{-12}$. The consequences of the large scale employment of this technique by chemists and physicists are difficult to assess; there is no doubt that important discoveries will be made, which will have the most far-reaching influence on both quantum chemistry and the physics of the solid state.

The pulse technique also requires the obligatory application of computers for the interpretation of results. Pulse NMR spectrometers will be increasingly used also in kinetic liquid-phase investigations. The studies described in Section XIII on the kinetics of slow chemical reactions were made using conventional NMR spectrometers. A pulse spectrometer allows the recording of the spectrum tens and hundreds of times faster and thus gives rise to the possibility of investigating fairly rapid processes. This brief list of the immediate prospects for the NMR method shows that its importance in chemistry will increase. The converse influence is also evident—namely the requirements of chemical laboratories to a large extent determine the range of interests of specialists developing the theory of the NMR method and improving its technique. Experience obtained in the "old" branches of spectroscopy shows that such mutual enrichment can continue for many decades. Predictions for such a long period must necessarily be rather vague.

One may also hope that the logic underlying the theoretical concepts will be enriched and their power will be enhanced; such a favourable course of events may occur following the joint interpretation of the vast and occasionally overlapping experimental data accumulated in various branches of radiospectroscopy (NMR, NQR, ESR), in studies based on the Mössbauer effect, β-spectroscopy, optical spectroscopy, etc.

The following are the simplest examples of such overlapping: information on electron density $|\psi(0)|^2$ at the nucleus obtained from experiments on the Mössbauer effect and measurements of the spin–spin coupling constants the nuclei of the same metals in NMR spectroscopy; data on the magnetic anisotropy of bonds accumulated by the NMR method and information concerning the deviations of these bonds from spherical symmetry obtained by the NQR method; rigorous linear relations between the spin–spin coupling constants and chemical shifts and between spin–spin coupling constants and acidity; correlation between NMR chemical shifts and the vibration frequencies of the corresponding bonds; comparison of NMR chemical shifts with those in β-ray spectra. These and many other facts constitute a wide range of experimental parameters, which may serve as a basis for the creation of a reliable theoretical apparatus which will predict exactly even the exceptionally small effects measured in NMR spectroscopy which play such an important role in chemistry.

The significantly many-sided nature of the tasks which arise in attempts at a rigorous treatment of problems of the chemical bond shows that success in the development of the theory may be achieved using the empirical facts indicated above within the framework of the technique based on finite Fermi systems [75].

Preparative Aspects of the Radiation Chemistry of Organic Compounds

I.V.Vereshchinskii

This review attempts to examine the preparative possibilities inherent in the use of ionising radiation, largely for the synthesis of organic compounds which are difficult to obtain or which are obtained for the first time.
The bibliography includes 86 references.

CONTENTS

I. INTRODUCTION

The first attempts to employ ionising radiation for the preparation of compounds more complicated than the initial components were made in the earliest days of radiation chemistry. The pioneer investigations of the radiation-induced synthesis of organic compounds were made in the 1950's. The wider availability and the improvement of the sources of ionising radiation led to a real possibility of a radiation-chemical synthesis of organic compounds not only on the laboratory scale but also on a preparative scale. However, preparative radiation-chemical synthesis is still not widely used. To some extent this is probably because organic chemists specialising in syntheses are still unaccustomed to regard this method as normal; on the other hand, the attention of chemists specialising in radiation chemistry is concentrated either on the study of the mechanism of radiation-chemical reactions or on devising large scale radiation-chemical technical processes.

Radiation-chemical syntheses are usually performed by irradiating liquid mixtures or solutions of organic compounds. The effects of ionising radiation are much more various and complex than those occurring in photochemical reactions†. Ionising radiation affects all the mixture components non-selectively, the radiation energy absorbed being distributed in proportion to the mole (more precisely electronic) fraction of each component. Frequently, particularly in those cases where aromatic compounds are present, effects occur which involve charge transfer from one component to another.

The general characteristic features of radiation-induced synthetic processes are as follows.

1. The feasibility of carrying out the process at temperatures as low as required; this makes it possible to increase the yield of the desired product by increasing the solubility of the gaseous components of reaction mixtures and to decrease the contribution of degradative and resinification processes by creating conditions suitable for the preparation of thermolabile compounds.

2. Absence from reaction mixtures of impurities due to added catalysts or initiators or their decomposition products.

3. Ease of inertialess regulation of the process and the possibility of altering very rapidly the dose rate or of stopping the process.

4. Lower fire risk and explosion risk, since the processes can be carried out under conditions far from the inflammation or detonation limits of the reaction mixtures.

Radiation-induced preparative synthesis has many specific advantages over photochemical synthesis: (1) the process can be carried out in highly coloured, opaque, turbid, or inhomogeneous systems; (2) the constancy of the radiation energy absorbed in the reaction space is ensured regardless of the formation on the vessel walls of a screening film or scale; (3) the harmful selective effect of light on reaction products having a high molar extinction coefficient in the spectral region close to the incident light is eliminated.

The radiation-chemical yields‡ of the products of the radiation-chemical synthesis may vary widely depending on the nature of the radiation-chemical process and its conditions. They are particularly high in the case of radiation-chemical initiation of chain reactions where the effect of radiation is virtually limited to the initiation stage, since for low absorbed doses the role of other radiation-chemical reactions is negligible [1,2].

When irradiating liquid-phase systems for preparative purposes, it is most convenient to employ cobalt-60

---

†The characteristics, phenomenology, and the theory of radiation-chemical processes have been described in a number of monographs [1-5].

‡The radiation-chemical yield is the absolute number of species (molecules, ions, free radicals, etc.) formed in the chemical system on absorption of 100 eV of the energy of ionising radiation. It is denoted by the symbol G. The radiation-chemical yield, sometimes called the energy yield, is an important quantitative characteristic of radiation-chemical reactions. The yield is calculated from the relation $G = 10^2\ \Delta c/D$, where Δc is the absolute change in concentration, i.e. the absolute number of species referred to unit volume or unit mass, and D is the dose absorbed in electron-volts referred to the same unit volume or unit mass. An extensive compilation of G values has been made.

γ-radiation. A very important factor in such cases is the impossibility, in principle, of the generation of induced radioactivity in the object irradiated. The high penetrating power of the γ-radiation from the cobalt-60 isotope makes it possible to carry out synthetic reactions in both glass and metallic apparatus without a significant decrease of the dose rate in the object irradiated.

A number of isotopic devices of various designs have been constructed at scientific establishments and have been described in a monograph[7] and in technical papers[8-14]. MRKh-γ-100 apparatus, designed for radiation-chemical research, is manufactured on industrially[13].

In radiation-induced synthetic reactions with low radiation-chemical yields, it is desirable to employ electron accelerators. However, the relatively low penetrating power of accelerated electrons requires the use of fairly thin inlet windows or membranes in the irradiation vessels and virtually excludes the possibility of experiments at elevated pressures. Additional difficulties are associated with the intense heating of the irradiated system as a result of the absorption of a considerable amount of radiation energy and the complexity of thermostatic devices.

II. RADIATION-INDUCED SYNTHESIS OF HALOGENO-SUBSTITUTED HYDROCARBONS

The liquid-phase radiation-induced chlorination of 1,1,1,5-tetrachloropentane leads to the synthesis of highly chlorinated polychloropentanes[15-17]:

$$C_5H_8Cl_4 \rightarrow C_5H_7Cl_5 \rightarrow C_5H_6Cl_6 \rightarrow C_5H_5Cl_7 \rightarrow C_5H_4Cl_8 \rightarrow C_5H_3Cl_9 \rightarrow C_5H_2Cl_{10}.$$

The radiation-chemical yield of polychloropentanes diminishes with increasing extent of chlorination. Each succeeding chlorine atom is introduced into the polychloropentane molecule with greater difficulty than the previous one. The increase in the number of chlorine atoms diminishes the polarisability of the C–H bond, while the influence of the inductive effect increases, consequently the attack by chlorine on the C–H bond becomes the slowest stage. When the process was carried out under mild conditions at low temperatures (less than 120°C), a number of polychloropentanes were isolated from the reaction mixture and identified. Decachloropentane, the isomers of which probably have the structural formulae $CCl_3CHClCHClCCl_2CCl_3$ and $CCl_3CCl_2CH_2CCl_2CCl_3$, was synthesised for the first time. The isomer isolated is a white crystalline substance with a camphor smell[18].

The synthesis of tetrabromoxylene by radiation-induced bromination of xylene is also a multistage reaction with a parallel-consecutive mechanism[81].

In contrast to radiation-induced chlorination and bromination processes in which free chlorine or bromine participates, the radiation-induced fluorination is an indirect reaction. Studies on the radiolysis of fluorohydrocarbons showed that the radiolytic stability of the C–F bond is comparable to the radiolytic stability of bonds in hydrocarbons, but the radiation-chemical yields of the fluorohydrocarbon radiolysis products are somewhat lower than for hydrocarbons.

Fluorohydrocarbons have been used as fluorinating agents to form new fluorine–carbon bonds or to introduce fluorine-containing groups and also as components of mixtures subjected to ionising irradiation.

In sealed-tube experiments with γ-irradiation of benzene–carbon tetrafluoride mixtures, fluorobenzene and α-trifluorotoluene were synthesised in approximately equal amounts[19]:

$$C_6H_6 + CF_4 \rightarrow C_6H_5F + CHF_3,$$
$$C_6H_6 + CF_4 \rightarrow C_6H_5CF_3 + HF.$$

The radiation-chemical yield increases with the carbon tetrafluoride content in the mixture and is independent of temperature in the range investigated. The maximum value $G(C_6H_5CF_3) = 1.3$ was obtained in a mixture containing 37 wt.% CF_4. In CF_3Br–C_6H_6 mixtures $G(C_6H_5F)$ increases from about 0.22 to about 1.5 with increase of temperature from 27° to 250°C, while $G(C_6H_5CF_3)$ remains approximately 2.

It has been suggested that the radiolytic reactions of fluorohydrocarbons take place both by an ionic and a radical mechanism. The ionic intermediate, for example CF_3^+, acts upon the C–F bond; radical processes take place simultaneously.

In the radiolysis of two-component mixtures of CF_4, SiF_4, BF_3, and C_2F_6 with benzene, nitrobenzene, or toluene, fluorine-containing compounds were synthesised[20]. In the CF_4–$C_6H_5NO_2$ mixture the yield of *m*-fluoronitrobenzene increases linearly with the electronic fraction of CF_4 and is independent of irradiation temperature. In the radiolysis of toluene-containing mixtures, trifluoromethyl derivatives are mainly formed.

The radiation-induced synthesis of ethyl bromide from gaseous ethylene and hydrogen bromide is the first industrial radiation-chemical synthetic process[21]. The reaction is carried out in ethyl bromide solution, the composition being chosen so that ethylene and hydrogen bromide are largely consumed during passage through the irradiation zone. The reaction is carried out at –2°C and a dose rate of about 40 rad s^{-1}. The chain reaction is initiated by bromine atoms produced by the radiation. The radiation-chemical yield reaches 3.9×10^4.

The competitiveness of the radiation-induced process depends to a considerable degree on the relative costs of anhydrous hydrogen bromide used in the radiation-chemical synthesis and of 48% hydrobromic acid employed in the "usual" chemical reaction with ethyl alcohol:

$$C_2H_5OH + HBr \rightarrow C_2H_5Br + H_2O.$$

The water formed carries away an appreciable amount of the hydrogen bromide dissolved in it.

The radiation method, which permits the synthesis of ethyl bromide from simple starting materials, virtually without side products, has advantages over other synthetic methods such as initiation with peroxides or reaction with aluminium bromide.

The addition of HBr to various α-olefins ranging from propene to octene has been investigated at temperatures between –79° and 25°C. The addition takes place predominantly contrary to the Markovnikov rule and leads to the formation of primary bromoalkanes (up to 90% of products). The radiation-chemical yield is about 10^3 in the gas phase and about 10^5 in the liquid phase[22].

The preparative synthesis of 1-bromo-2-chloro-1,1,2-trifluoroethane, used as an inhalation anaesthetic, is also an example of radiation-induced hydrobromination of halogeno-substituted ethylene:

$$F_2C{=}CFCl + HBr \rightarrow BrF_2C{-}CHFCl.$$

The reaction is performed at temperatures between –70° and +20°C over a wide range of dose rates, from 0.5 rad h^{-1} to 15 Mrad h^{-1}, and pressures up to 20 atm. The yield of the desired product reaches 89% of theoretical[23].

III. RADIATION-INDUCED SYNTHESIS OF ORGANIC SULPHIDES AND DISULPHIDES

The addition of butanethiol to pent-1-ene resulted in the synthesis of the corresponding dialkyl sulphide[24]:

$$RSH + CH_2{=}CHR' \rightarrow RSCH_2CH_2R'.$$

The reaction was carried out in cyclohexane solution under the action of X-rays; n-butyl pentyl sulphide was formed in 75–95% yield, G reaching 8×10^4.

Disulphides may be obtained from substituted mercaptans. The introduction of an OH group into the mercaptan molecule reduces significantly its radiation stability and gives rise to the possibility of the preparative synthesis of substituted disulphides. While in the γ-irradiation of ethanethiol the yield of decomposition products does not exceed 5, on irradiation (at a dose rate of 0.8×10^{15} eV ml^{-1} s^{-1}) of β-hydroxyethanethiol, G reaches 400. Crystals of the disulphide[25] $HOCH_2CH_2SSCH_2CH_2OH$ are isolated from the reaction mixture in yields up to 70%.

IV. RADIATION-INDUCED SYNTHESIS OF NITROGEN-CONTAINING ORGANIC COMPOUNDS

Among the radiation-induced syntheses of nitrogen-containing compounds, it is necessary to consider primarily the processes which result in the formation of compounds with C–N bonds.

1. Syntheses Based on Nitrogen Oxides

The reactions with nitrogen oxides have been little investigated to date. The trapping of unstable products by nitrous oxide, widely used in radiation-chemical experiments, has not found preparative application.

Among reactions with nitric oxide, the radiation-chemical synthesis of nitroso-derivatives of halogeno-substituted methane and ethane is of preparative interest. They are obtained by irradiating carbon tetrachloride (or chloroform, bromoform, trichloronitromethane, trichloroethane) with a stream of electrons (dose 10^8 rad) at room temperature in the presence of a stream of NO (15 litre h^{-1}).[26,27] The CCl_3 or CH_3CCl_2 radicals formed by radiolysis react with NO:

$$\dot{C}Cl_3 + NO \rightarrow CCl_3NO$$

or

$$CH_3\dot{C}Cl_2 + NO \rightarrow CH_3CCl_2NO.$$

$G(CCl_3NO)$ is in the range between 4.4 and 6.0; the chemical yield is 50% at 10% conversion: $G(CH_3CCl_2NO) = 0.5$. In the reaction with chloroform, dichloronitrosomethane was synthesised together with dichloroformaldoxime:

$$CHCl_3 \rightarrow \dot{C}HCl_2 + \dot{C}l$$
$$\dot{C}HCl_2 + NO \rightarrow CCl_2{=}NOH \rightarrow HCCl_2NO$$

This new compound, stable only at low temperatures, is obtained with $G = 0.5$ and a chemical yield of 20%.

The synthesis of dimeric nitrosobenzeneiron tricarbonyl, obtained by γ-irradiation of a benzene solution of nitrobenzene and iron pentacarbonyl, has been described[28]:

$$C_6H_5NO_2 + Fe(CO)_5 \rightarrow C_6H_5NO_2Fe(CO)_4 + CO,$$
$$2C_6H_5NO_2Fe(CO)_4 \rightarrow [C_6H_5NOFe(CO)_3]_2 + 2CO_2.$$

2. The Addition of Acetonitrile to Unsaturated Compounds

The addition of acetonitrile to olefins under the action of ionising radiation takes place fairly successfully[29], in contrast to photochemical addition sensitised by acetone or benzophenone. Sealed-tube experiments with a considerable excess of acetonitrile in an argon atmosphere lead to the formation of addition products (Table 1).

Table 1. Radiation-chemical yields of products of addition of acetonitrile to unsaturated compounds under the action of cobalt-60 γ-radiation, (dose rate 3.84×10^5 rad h^{-1}).

Olefin	Product	Yield, %	*G*
Hex-1-ene	heptyl cyanide	35	1.2
Hept-1-ene	octyl cyanide	36	1.2
Oct-1-ene	nonyl cyanide	45	1.2
Dec-1-ene	undecyl cyanide	40	1.2
Dodec-1-ene	tridecyl cyanide	42	1.2
Cyclopentene	cyclopentylacetonitrile	38	1.2
Cyclohexene	cyclohexylacetonitrile	45	1.2
Cyclo-octene	cyclo-octylacetonitrile	47	1.2
Cyclodecene	cyclodecylacetonitrile	43	1.2
Cyclododecene	cyclododecylacetonitrile	35	1.1
Norbornene	norbornylacetonitrile	65	1.7
Norbornadiene	nortricyclylacetonitrile	60	1.6
Benzene	benzyl cyanide	10–15	0.2

Table 2. Radiation-induced synthesis of diamines[31,32] by γ-irradiation in the absence of air (dose $\simeq 10^{21}$ eV ml^{-1}).

Initial amine	Diamine synthesised	Radion-chemical yield, *G*
Diethylamine	*meso*-* and racemic* *NN*-diethylbutane-2,3-diamine	0.77
Triethylamine	*meso*-* and DL-2,3-di(diethylamino)-butane	2.9
Trimethylamine	*NNN'N'*-tetramethylethylenediamine	2.5
N-Methyldiethylamine	*meso*-*NN*-diethyl-*N'N'*-dimethylbutane-2,3-diamine* *NNN'N'*-tetraethylethylenediamine 1-diethylamino-2-ethylmethylamino-propane*	0.5
1-Methylpiperidine	1,2-dipiperidinoethane	0.37
	meso-1,1'-dimethyl-2,2'-dipiperidyl*	0.75
	1-methyl-2-(piperidinomethyl)piperidine*	0.39
Benzylamine	*meso*-stilbenediamine	2.76
	N-Benzylidenebenzylamine	0.11
t-Butylamine	*NN'*-di-t-butylformamidine*	0.026
	2-amino-1-t-butylamino-2-methylpropane*	0.025
	2,5-dimethylhexane-2,5-diamine	0.008

*Synthesised for the first time.

The addition takes place exclusively contrary to the Markovnikov rule:

$$RCH{=}CH_2 + CH_3CN \rightarrow RCH_2CH_2CH_2CN.$$

Nitriles, products of the addition of the CN radical to olefins, are also formed in low yields (2–3%).

3. Synthesis of Amines and Radiation-induced Amidation

Under the action of γ-radiation, aliphatic and aromatic amines enter into reactions not involving C–N bonds. As a result of the removal of a hydrogen atom from the α-position, radicals are formed which dimerise to form diamines[30–33].

The following reactions take place with mono-, di-, and trialkylamines in which all the alkyl groups attached to the same nitrogen atom are identical:

$$(C_2H_5)_2NCH_2CH_3 \rightarrow (C_2H_5)_2N\dot{C}HCH_3 + H,$$

$$2\,(C_2H_5)_2N\dot{C}HCH_3 \rightarrow \underset{(C_2H_5)_2N\quad N(C_2H_5)_2.}{CH_3CHCHCH_3}$$

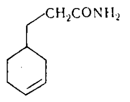
If the irradiation of amines results in the formation of radicals of various compositions and structures, then the set of diamines (dimerisation products) becomes more complex (Table 2). The low *G* in the case of t-butylamine is due to the absence of a hydrogen atom in the α-position relative to the nitrogen atom. The radiolysis gives rise to the radicals $CH_2C(CH_3)_2NH_2$ and $(CH_3)_3CNH$.

Table 3. Yields and radiation-chemical yields of diene amidation products[37].

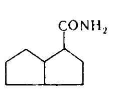
Initial diene	Addition product	Yield, %	*G*
4-Vinylcyclohexene	I	35	3
1,5-cyclo-octadiene	II	50	3.5
Norbornadiene	III	75	5

Attempts at radiation-induced synthesis of quaternary ammonium salts containing a phenyl group from aryl halides were unsuccessful[34]. Trialkylamines react with aryl halides to form trialkyl- or dialkyl-ammonium salts ($G < 7$), but this reaction is of no preparative interest.

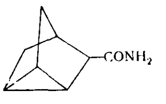
The amidation of olefins by formamide under the action of γ-radiation or as a result of a photochemical reaction initiated by acetone leads to the synthesis of 1 : 1 addition products. The high chemical yield makes both methods suitable for synthetic purposes[35]. In contrast to the addition to olefins, photochemical addition of formamide to dienes with formation of 1 : 1 products takes place with a low yield[36]. Under the action of γ-radiation, the addition to dienes occurs with an appreciable yield (Table 3) and may be used for synthetic purposes.



(I)



(II)



(III)

Carbamoyl radicals $CONH_2$ are formed as a result of the direct action of radiation on formamide, while the diene, the concentration of which in the reaction mixture is low, is little affected by the radiolytic processes.

V. RADIATION-INDUCED SYNTHESIS OF ORGANOPHOSPHORUS COMPOUNDS

Several trends have now been established in the field of radiation-induced synthesis of compounds with C–P bonds. The radiation-chemical reactions of aliphatic or cyclic hydrocarbons with phosphorus trichloride or its alkyl-(cycloalkyl)-substituted derivatives, leading to the synthesis of compounds of the type $RPCl_2$ and $RR'PCl$, constitute a large group of processes. Reactions involving addition of PCl_3 to unsaturated compounds constitute another group. The use of γ-irradiation has led to interesting preparative possibilities based on the introduction of aryl groups R into quaternary phosphonium salts $[RP(R')_3]Hal$ and phosphonic acid esters $RP(O)(OR')_2$.

1. Synthesis of Alkyl(cycloalkyl)-substituted Phosphorus Trichloride Derivatives

The reactions of phosphorus trichloride with a number of aliphatic and cyclic hydrocarbons have been investigated[38,39]. The main products of the synthesis are alkyl- or cycloalkyl-phosphorus dichloride—the products of the substitution of a chlorine atom by a hydrocarbon group. When the alkyl(cycloalkyl)-substituted derivatives are used as the initial phosphorus compounds, disubstituted derivatives[38] and various compounds with a more complex structure are formed (Table 4). The synthesis is carried out in simple glass apparatus in an inert gas at atmospheric pressure and room temperature, the hydrogen chloride evolved being passed through an absorber. A finely dispersed orange deposit, the amount of which is proportional to the dose absorbed, is formed as a side product. This deposit is the product of the decomposition of tetrachlorodiphosphine P_2Cl_4 and is a polymeric substance of variable composition: $R(H_2)ClP_n$, where n = 20–30.

A reaction mechanism involving the participation of free radicals and excited molecules of the initial components has been proposed:

$$RH \rightarrow R^{\cdot} + H^{\cdot},$$
$$PCl_3 \rightarrow {}^{\cdot}PCl_2 + Cl^{\cdot},$$
$$H^{\cdot} + PCl_3 \rightarrow HCl + {}^{\cdot}PCl_2,$$
$$Cl^{\cdot} + RH \rightarrow HCl + R^{\cdot};$$
$$R^{\cdot} + {}^{\cdot}PCl_2 \rightarrow RPCl_2,$$
$$R^{\cdot} + R^{\cdot} \rightarrow R_2,$$
$$R^{\cdot} + Cl^{\cdot} \rightarrow RCl,$$
$${}^{\cdot}PCl_2 + {}^{\cdot}PCl_2 \rightarrow P_2Cl_4$$

and also

$$RH^{*} + PCl_3 \rightarrow HCl + RPCl_2,$$
$$PCl_3^{*} + RH \rightarrow HCl + RPCl_2.$$

Table 4. Yields of organophosphorus compounds synthesised under the action of γ-radiation[39].

Initial hydrocarbon	Initial phosphorus compound	Molar ratio	Dose absorbed, eV, ml^{-1}	Compound synthesised	B.p. (*p*, mmHg)	d_4^{20}	n_D^{20}	Yield, mole litre^{-1}
Cyclopentane	PCl_3	1.0:1.2	3.4x10^{20}	cyclopentyldichlorophosphine*				0.5
Cyclohexane	PCl_3	1.0:1.2	5.0x10^{20}	cyclohexyldichlorophosphine				0.5
Cyclohexane	cyclo-$C_6H_{11}PCl_2$	1.3:1.0	5.0x10^{20}	dicyclohexyldichlorophosphine*	T. m.p.23°	—	—	0.05
	PCl_3 and cyclo-$C_6H_{11}PCl_2$			dicyclohexylchlorophosphine				0.2
–		1.0:1.3	5.0x10^{20}	cyclohexenyltetrachlorodiphosphine*	130—135 (0.5)	1.4582	1.5865	0.2
n-Hexane	PCl_3	1.0:1.2	4.0x10^{20}	isohexyldichlorophosphine				0.5
			5.6x10^{21}	hexenyltetrachlorodiphosphine*	111—120 (0.5)	1.3205	1.5402	0.2
n-Hexane	$C_6H_{13}PCl_2$	1.0:1.0	5.0x10^{21}	dihexylchlorophosphine*	105—113 (0.2)	0.959	1.4862	0.2
n-Heptane	PCl_3	1.0:1.2	4.0x10^{20}	isoheptyldichlorophosphines				0.6
n-Octane	PCl_3	1.0:1.2	4.0x10^{20}	iso-octyldichlorophosphines*				0.6

*Compound synthesised for the first time.

The reaction mixtures consist mainly of $RPCl_2$, R_2PCl, and $R'(PCl_2)_2$, the proportions of which depend on the dose absorbed. The fraction of R_2PCl and $R'(PCl_2)_2$ in the reaction mixture increases with the dose. This suggests that these compounds are formed largely from alkyldichlorophosphines

$$RPCl_2 \rightarrow R'PCl_2 + H^{\cdot} \text{ or } \rightarrow R\dot{P}Cl + Cl^{\cdot},$$
$$R'PCl_2 + {}^{\cdot}PCl_2 \rightarrow Cl_2PR'PCl_2,$$
$$R\dot{P}Cl + RH \rightarrow R_2PCl + H^{\cdot},$$
$$R\dot{P}Cl + R^{\cdot} \rightarrow R_2PCl.$$

The radiation-induced synthesis of higher dichlorophosphines, various dialkylchlorophosphines, and other compounds based on them is of considerable preparative interest, since chemical methods for their preparation via organomercury, organocadmium, and organomagnesium compounds or by oxidative chlorophosphonation using a fast stream of oxygen are relatively complex and the yield is low.

In the radiation-induced synthetic reactions described above phosphorus trichloride is the main phosphorus-containing starting material. Another possible version of the synthetic reaction is based on the use of free (elemental) white phosphorus and alkyl chlorides as reactants. When solutions of white phosphorus in carbon tetrachloride are γ-irradiated, a number of products are formed[40], the yields of which depend significantly on temperature (Table 5).

Table 5.

Temp., °C	Radiation-chemical yield, G						
	Red P	PCl_3	CCl_3PCl_2	C_2Cl_6	Polymer $(CCl_2)_n$	consumption	
						CCl_4	P
25	22	1.4	4.5	3.1	1	10	28
130	<0.5	9.5	41	3.1	12	100	51

From the point of view of the preparation of compounds with a C–P bond, the synthesis of trichloromethylphosphorus dichloride is of greatest preparative interest. There are competitive reactions involving the formation of red phosphorus and low-molecular-weight products, which show different temperature dependences. While at room temperature red phosphorus is formed preferentially, at temperatures above 100°C the products are almost exclusively PCl_3 and CCl_3PCl_2. The mechanism of the reactions involves the addition of free radicals R, formed by the radiolysis of CCl_4, to dissolved P_4 phosphorus species:

$$R^{\cdot} + P_4 \rightarrow RP_4 \quad (R = CCl_3 \text{ or } Cl).$$

Further reactions of this adduct lead either to the formation of a red phosphorus polymer[41] or to the synthesis of low-molecular-weight products:

$$RP_4 + CCl_4 \rightarrow RP_4Cl + {}^{\cdot}CCl_3.$$

The activation energy for this chain propagation reaction is 8.2 kcal $mole^{-1}$.

Interesting preparative possibilities arise when red phosphorus activated by radiation and containing terminal CCl_3 groups is treated with chlorine, bromine, or other reagents which rupture P–P bonds[40]. When such activated phosphorus was dissolved in bromine, the previously unknown trichloromethylphosphorus dibromide CCl_3PBr_2 was synthesised.

2. Synthesis of Products of Addition of Phosphorus Trichloride to Unsaturated Hydrocarbons

Whe mixtures of liquid olefins with phosphorus trichloride are irradiated, radical-chain addition takes place:

$$RCH{=}HCR' + PCl_3 \rightarrow \underset{PCl_2}{RCH}{-}\underset{Cl}{CHR'}.$$

Olefins which do not show a tendency towards polymerisation by a free-radical mechanism (cyclo-olefins, n-olefins) give rise mainly to 1 : 1 addition products (Table 6)—α-chloroalkylphosphorus dichlorides; telomerisation products are formed with other types of olefin[42,43].

Table 6. Yields and radiation-chemical yields of products of addition of phosphorus trichloride to unsaturated hydrocarbons (irradiation with cobalt-60 γ-rays at room temperature).

Initial hydrocarbon	Hydrocarbon : PCl_3 (vol.%)	Dose absorbed, eV, ml^{-1}	Substance synthesised	Yield, mole $litre^{-1}$	G*, mol./ /100 eV	Refs.
Cyclopentene	1:2**	$7\cdot10^{18}$	$(cyclo\text{-}C_5H_8Cl)PCl_2$	0.6		44
	1:1				173	43

*Dose rate 7×10^{-3} r h^{-1}.
**Molar ratio.

To elucidate the optimum conditions for the radiation-chemical synthesis of the 1 : 1 addition product, the accumulation of chlorocyclohexyldichlorophosphine (CCHDCP) was investigated as a function of three principal parameters: temperature in the range 33–140°C, dose rate in the range between 1.5 and 55 rad s^{-1}, and the proportions of the initial components in the reaction mixture[44].

The linear variation of the yield of CCHDCP with the dose absorbed is observed only at low conversions. When the dose absorbed and hence the conversion is high, the reaction product (CCHDCP) accumulates and the proportions of the components begin to differ appreciably from the optimum values. The effective activation energy was determined from the temperature variation of the radiation-chemical yield as 5.9 kcal $mole^{-1}$. The rate of accumulation of CCHDCP is proportional to the square root of the dose rate and the order of the reaction with respect to each component is unity.

The radical-chain addition of PCl_3 to cyclohexene is described by the following mechanism:

$$PCl_3 \rightarrow {}^{\cdot}PCl_2 + Cl^{\cdot},$$
$$C_6H_{10} \rightarrow {}^{\cdot}C_6H_9 + H^{\cdot},$$
$$C_6H_{10} + {}^{\cdot}PCl_2 \rightarrow {}^{\cdot}C_6H_{10}PCl_2,$$
$$C_6H_{10}PCl_2 + PCl_3 \rightarrow ClC_6H_{10}PCl_2 + {}^{\cdot}PCl_2.$$

Chain termination takes place by the reactions:

$$\cdot PCl_2 + \cdot PCl_2 \rightarrow P_2Cl_4,$$
$$\cdot C_6H_{10}PCl_2 + \cdot PCl_2 \rightarrow PCl_2C_6H_{10}PCl_2,$$
$$\cdot C_6H_{10}PCl_2 + \cdot C_6H_{10}PCl_2 \rightarrow (C_6H_{10}PCl_2)_2.$$

When the dose rate is high, alkenyldichlorophosphine and alkyldichlorophosphine are formed, probably due to disproportionation and dehydrochlorination reactions.

Very similar kinetics were observed in the study of the radiation-chemical addition of phosphorus trichloride to linear mono-olefins, in liquid and gaseous phases[45]. The formation of two isomers of the main product and the increased reactivity of the olefins on displacement of the double bond from a terminal carbon atom to an inner carbon atom has been explained by postulating the formation in the initiation stage of a bridge-type dichlorophosphinealkyl radical.

The radiation-chemical yields of chloroalkyldichlorophosphines, reaching 10^4 mol./100 eV, suggest that γ-initiated reactions of phosphorus trichloride with unsaturated compounds could be successfully carried out on a larger scale[46,47].

3. Synthesis of Phosphonium Salts from Aryl Halides

While the synthesis of phosphonium and other quaternary 'onium salts from alkyl halides takes place readily on heating, the synthesis of 'onium salts from aryl halides is fairly complicated. γ-Irradiation of mixtures containing halogeno-substituted aromatic hydrocarbons has proved a very effective method for the synthesis of a number of quaternary phosphonium salts (Table 7). The radiation-chemical yields of arsonium salts are much lower and stibonium salts are formed with a negligible G.

The radiation-chemical synthesis has the following characteristic features: (1) a pronounced dependence of G of the 'onium salt on the mole fraction of the aryl halide in the mixture; the maximum is displaced towards higher contents of the aryl halide; (2) a significant increase in the percentage incorporation of triphenylphosphine on addition to the reaction mixture of various types of solvent; the curves relating the percentage incorporation to the amount of added solvent show a tendency towards saturation.

A mechanism with participation of positive ions and electrons derived from the solvent (S) has been proposed for dilute solutions:

$$S \rightarrow S^+ + e^-,$$
$$S^+ + (C_6H_5)_3P \rightarrow S + (C_6H_5)_3P^+,$$
$$e^- + C_6H_5Br \rightarrow C_6H_5 + Br^-,$$
$$(C_6H_5)_3P^+ + C_6H_5 \rightarrow (C_6H_5)_4P^+.$$

4. Synthesis of Phenylphosphonates

Trialkyl phosphites react with alkylhalides to form dialkyl esters of alkylphosphonic acid (Arbuzov rearrangement):

$$P(OR')_3 + RHal \rightarrow RP(O)(OR')_2 + R'Hal.$$

A similar thermal reaction cannot be achieved with aryl halides, but the use of γ-radiation allows the preparative synthesis of a number of phenyl phosphonates (Table 8).

The data presented in Table 8 show that the radiation-chemical yields of phenyl phosphonates are a maximum when iodobenzene is used as one of the reactants. In this case other characteristics of the reaction are a decrease of G proportional to the square root of the dose rate and a negative temperature coefficient of the reaction rate.

Table 7. Properties and yields of quaternary 'onium' salts synthesised under the action of cobalt-60 γ-radiation (dose rate 6×10^3–8×10^5 r h^{-1}).[48,49]

Starting materials	Mole %	Phosphonium salt	G	Rel. incorp. of phosphine(arsine)		M.p., °C properties of substance

$(CH_3O)_3P + C_6H_5Br$	50:50		4.9	5.4	
$(CH_3O)_3P - C_6H_5I$	50:50		250	0.1	
$(C_2H_5O)_3P + C_6H_5Br$	50:50	$C_6H_5P(O)(OC_2H_5)_2$	4.0	8.0	267
$(C_2H_5O)_3P + C_6H_5I$	50:50		28	0.6	
$(iso\text{-}C_3H_7O)_3P + C_6H_5I$	50:50	$C_6H_5P(O)(O\text{-}iso\text{-}C_3H_7)_2$	11	0.7	—
$(CH_3O)_3P + p\text{-}ClC_6H_4I$	70:30	$(CH_3O)_2P(O)C_6H_4Cl$	68	0.6	264—268
$(CH_3O)_3P + p\text{-}BrC_6H_4CH_3$	70:30	$(CH_3O)_2P(O)C_7H_7$	2.5	1	262—265
$(CH_3O)_3P + m\text{-}C_6H_4Cl_2$	70:30	$(CH_3O)_2P(O)C_6H_4Cl$	1.9	1.5	265—268
$(CH_3O)_3P$ + 2-bromothiophen	50:50	$(CH_3O)_2P(O)C_4H_3S$	9.7	1	248—255

It has been suggested that the process has a chain mechanism:

$$\cdot C_6H_5 + P(OR)_3 \rightarrow C_6H_5P(OR)_3,$$
$$C_6H_5P(OR)_3 + C_6H_5I \rightarrow [C_6H_5P(OR)_3]^+I^- + \cdot C_6H_5.$$

The quasi-phosphonium salt formed as a result of the addition of an iodine atom to a phosphorus(IV) free radical breaks down with formation of the desired product:

$$[C_6H_5P(OR)_3]^+I^- \rightarrow C_6H_5P(O)(OR)_2 + RI.$$

Quadratic chain termination can occur via reactions of the phenyl radicals with one another or with intermediate phosphorus-containing radicals. The rate of the processes is probably determined by the formation of the quasi-phosphonium salt, which depends on the strength of the C–H bond in the aryl halide, the electron affinity of the halogen, and the solvation of the ions produced.

VI. RADIATION-INDUCED SYNTHESIS OF ORGANOTIN COMPOUNDS

The radiation-chemical synthesis of organotin compounds of the type R_2SnBr_2 and R_3SnBr is based on the reaction of an alkyl bromide RBr with metallic tin under the action of γ-radiation. The synthesis of dibutyltin dibromide (DBTDB) have been most thoroughly investigated[51–56]. The compound was synthesised in a bench-type apparatus and described by Miretskii et al.[56] n-Butyl bromide with a purity of 99% and tin powder containing not less than 99.5% of tin were employed. The experiments were performed mainly at 85–90°C and atmospheric pressure with vigorous stirring. The average absorbed dose rate was about 100 rad s^{-1}.

The interaction of n-butyl bromide with tin in the presence of γ-radiation is fairly selective, the main product being DBTDB and a certain amount of tributyltin bromide and stannous bromide.

One of the characteristics of the radiation-chemical synthesis of DBTDB is the induction period. Application of various techniques led to the discovery of the optimum conditions for the reaction under which there is virtually no induction period. The introduction into the reaction mixture of various compounds activating the reaction, for example n-butyl alcohol or water, proved to be highly effective[57].

The study of the parameters of the reaction occurring virtually without an induction period led to the discovery of its principal macrokinetic features[58]. A very important factor in the radiation-chemical process proved to be temperature. The effective activation energy determined from the kinetic curves for the accumulation of DBTDB in the range 20–95°C proved to be 12 kcal $mole^{-1}$. The rate of formation of DBTDB is proportional to the square root of the dose rate in the range 175–2.5 rad s^{-1}.

The formation of DBTDB probably involves a chain mechanism. This is suggested by the following findings: (1) the radical-chemical yield reaches 10^3–10^4 mol./100 eV at a high conversion; (2) the reaction system shows characteristic behaviour on introduction of activating species; (3) the rate of reaction depends on the square root of the dose rate. When irradiation is stopped, the reaction ceases immediately, but recommences at the previous rate after the source of radiation is reintroduced. An additional piece of evidence in favour of a chain mechanism is provided by observations of the effect of inhibiting additives on the rate of formation of DBTDB. Special experiments showed that oxygen in the reaction system or the introduction of electron-accepting additives such as benzoquinone, hydroquinone, or *m*-dinitrobenzene cause appreciable inhibition of the reaction. The author of the review suggested the following probable mechanism for the chain process, the principal feature of which is that all the chain-propagation stages take place on the surface of tin.

Initiation:

$$RBr \rightarrow R^{\cdot} + Br^{\cdot},$$

and (or)

$$RBr + e \rightarrow R^{\cdot} + Br^{-}.$$

Chain propagation:

$$R^{\cdot} + Sn \rightarrow RSn,$$
$$RSn + RBr \rightarrow R_2SnBr,$$
$$R_2SnBr + RBr \rightarrow R_2SnBr_2 + R^{\cdot}.$$

Chain termination:

$$R^{\cdot} + Br^{\cdot} \rightarrow RBr,$$
$$R^{\cdot} + R^{\cdot} \rightarrow R_2,$$
$$R_2SnBr + Br^{\cdot} \rightarrow R_2SnBr_2,$$
$$Br^{\cdot} + Br^{\cdot} \rightarrow Br_2.$$

The formation of tributyltin monobromide and $SnBr_2$ may involve the reactions

$$R_2SnBr + R^{\cdot} \rightarrow R_3SnBr,$$
$$Br^{\cdot} + Sn \rightarrow SnBr,$$
$$SnBr + RBr \rightarrow SnBr_2 + R^{\cdot}.$$

The study of the radiation-induced synthesis of DBTDB homologues (from C_3 to C_9) showed that the macrokinetic features of all the reactions are very similar, dialkyltin dibromides being formed with fairly high radiation-chemical (500–1000 mol./100 eV) and chemical (80–85%) yields[59]. The synthesis of a number of dialkyltin dibromides in appreciable amounts permitted the determination for the first time of their physical constants (Table 9).

Table 9. Properties of dialkyltin dihalides synthesised by the radiation-chemical method[59].

Dialkyltin dibromide	n_D^{20}	d^{20}	M.p., °C
$(C_3H_7)_2SnBr_3$	1.5480	1.87	43
$(C_6H_{13})_2SnBr_2$	1.5270	1.537	8.3
$(C_7H_{15})_2SnBr_2$	1.5230	1.4720	20.5
$(C_8H_{17})_2SnBr_2$	1.5180	1.4157	20.2
$(C_9H_{19})_2SnBr_2$	1.5147	1.383	20.1

The radiation-chemical synthesis of dialkyltin dibromides has a number of useful characteristics: it is a single-stage selective process, the desired product is formed in high yield, there is no fire or detonation risk, and the process is readily controlled.

VII. RADIATION-INDUCED SYNTHESIS OF OXYGEN-CONTAINING COMPOUNDS

The radiation-induced oxidation of hydrocarbons at moderate temperatures is of no interest from the standpoint of the selective synthesis of oxidation products because of the lack of selectivity and low radiation-chemical yield of the products.

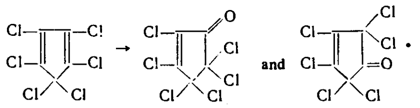
The oxidation of halogeno-olefins, in particular chloroethylenes, is of definite importance for the synthesis of valuable organic substances used as intermediates for various syntheses. Laboratory studies established that liquid tetrachloroethylene is oxidised by gaseous oxygen to tetrachloroepoxyethane and trichloroacetyl chloride on γ-irradiation at temperatures in the range 20–120°C.[60] The oxidation was carried out in a bench-type radiation-chemical apparatus[61] with a linear radiation source located coaxially in the reaction space, the average dose rate in the apparatus being about 100 rad s^{-1}. The flow rate of gaseous oxygen at atmospheric pressure was 1–2 litre min^{-1} per litre of the tetrachloroethylene taken for oxidation (with vigorous stirring of the reactants). The process was carried out in batches at 120°C and above, the duration of a single operation being 5–10 h. Trichloroacetic acid obtained by the radiation-chemical method is 4–5 times cheaper than the acid usually obtained by the oxidation of chloral with a mixture of nitric and sulphuric acids[62].

Liquid trichloroethylene is oxidised by gaseous oxygen to dichloroepoxyethane and dichloroacetyl chloride on γ-irradiation. Trichloroepoxyethane was obtained for the first time; 146 g of trichloroethylene treated with a stream of oxygen for 150 min at a flow rate of 0.3 litre min^{-1}, heated to 72°C, and exposed to γ-radiation (dose rate 0.4 rad s^{-1}) gave a mixture containing 60% of trichloroepoxyethane[63]. The optimum parameters for the synthesis of the acid chloride using the bench-type apparatus mentioned above at an average dose rate of about 25 rad s^{-1} are as follows: oxidation at 50–60°C at atmospheric pressure of oxygen flowing at a rate of 1–2 litre min^{-1} per litre of trichloroethylene. The process is carried out in batches and the duration of the oxidation is about 10 h.

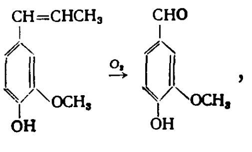
The radiation-chemical synthesis of trichloroethylene oxidation products has considerable advantages. Firstly, the cost of methyl dichloroacetate obtained from the acid chloride is approximately three times smaller than that of the product obtained by the usual chemical synthesis via chloral[64].

The radiation-induced oxidation of chloroethylenes and tetrafluoroethylene[65], leading to the synthesis of carbonyl fluoride COF_2, epoxytetrafluoroethane $(CF_2)_2O$, and a liquid polyperoxide $(-CF_2-CF_2-O-O-)_n$ is a typical chain process with an appreciable radiation-chemical yield.

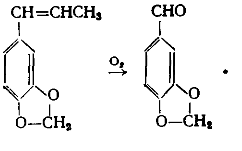
The radiation-chemical oxidation of hexachlorocyclopentadiene leads to the synthesis of hexachlorocyclopentenone[66]:



The radiation-chemical oxidation involving a double bond in the α-position relative to an aromatic ring is highly selective[67–70]. Thus vanillin was synthesised by the radiation-chemical oxidation of isoeugenol:



and heliotropin was obtained from isosafrole:

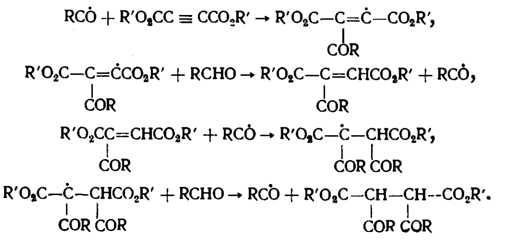


The addition of aldehydes to acetylenedicarboxylate esters has not been described previously[71]. On γ-irradiation in evacuated tubes (dose rate 4 × 10^5–4.5 × 10^5 rep h^{-1}) at 22°C, butyraldehyde, isobutyraldehyde, and acetaldehyde add to dimethyl- or diethyl-acetylenedicarboxylates with formation of diacylsuccinates (Table 10).

Table 10.

Starting materials	Dose absorbed, 10^6rep	Addition product	Yield, %	G, mol./100 eV
Butyraldehyde (0.264 M) Dimethyl acetylene-dicarboxylate (0.06 M)	10.4	dimethyl 2,3-dibutyryl-succinate	23	54
Acetaldehyde (0.30 M) Dimethyl acetylene-dicarboxylate (0.072 M)	18.8	dimethyl 2,3-diacetyl-succinate	31	54
Acetaldehyde (0.304 M) Diethyl acetylene-dicarboxylate (0.072 M)	18.8	diethyl 2,3-diacetyl-succinate	2	46
Isobutyraldehyde (0.225 M) Diethyl acetylene-dicarboxylate (0.051 M)	17.4	diethyl 2,3-di-isobutyryl-succinate		

The addition takes place by a free radical mechanism:



$$RCHO \rightarrow R\dot{C}O + H,$$
$$R\dot{C}O + R'O_2CC \equiv CCO_2R' \rightarrow R'O_2C-\underset{\displaystyle COR}{\underset{|}{C}}=\dot{C}-CO_2R',$$
$$R'O_2C-\underset{\displaystyle COR}{\underset{|}{C}}=\dot{C}CO_2R' + RCHO \rightarrow R'O_2C-\underset{\displaystyle COR}{\underset{|}{C}}=CHCO_2R' + R\dot{C}O,$$
$$R'O_2\underset{\displaystyle COR}{\underset{|}{C}}C=CHCO_2R' + R\dot{C}O \rightarrow R'O_2C-\underset{\displaystyle COR}{\underset{|}{\dot{C}}}-\underset{\displaystyle COR}{\underset{|}{C}}HCO_2R',$$
$$R'O_2C-\underset{\displaystyle COR}{\underset{|}{\dot{C}}}-\underset{\displaystyle COR}{\underset{|}{C}}HCO_2R' + RCHO \rightarrow R\dot{C}O + R'O_2C-\underset{\displaystyle COR}{\underset{|}{CH}}-\underset{\displaystyle COR}{\underset{|}{CH}}--CO_2R'.$$

VIII. RADIATION-INDUCED SYNTHESIS OF ORGANOSILICON COMPOUNDS

The addition of silanes to ethylene under the action of radiation leads to the formation of telomerisation products[72]. In the gas phase methylsilane and dimethylsilane form 1 : 1 and 1 : 2 telomers. For a silane : : ethylene ratio of 3 : 1 at 50°C the radiation-chemical yields are $G(CH_3CH_2CH_2SiH_3) = 38$ and $G(CH_3CH_2CH_2SiH_2CH_3) = 15$. At temperatures close to 250°C $G(CH_3CH_2CH_2SiH_3)$ reaches several hundreds. The mechanism of the telomerisation chain reaction is evidently ionic.

Under the action of γ-radiation, triphenylsilane adds to the double bond of oct-1-ene and cyclohexene[73]. Irradiation for 63 h of a mixture of 0.15 M triphenylsilane and 0.05 M octene in a sealed tube in an atmosphere of nitrogen at 65°C at a dose rate of 810 000 rep h^{-1} leads to the synthesis of 1-octyltriphenylsilane (700 mg) and hexaphenyldisiloxane (210 mg). A mixture of triphenylsilane and cyclohexene gives triphenylcyclohexylsilane and hexaphenyldisiloxane.

The addition of chlorosilane olefins takes place readily under the action of ultraviolet light[74]. When mixtures of various ethylene derivatives with trichlorosilane, dichlorosilane, methyldichlorosilane, or ethyldichlorosilane were exposed to ionising radiation, a large number of compounds were synthesised, some for the first time[75,76]. The telomerisation reaction takes place at a temperature not exceeding 120°C.

The preparative possibilities of the method, which permits the synthesis of the compounds $R'SiCl_2$ and $R'R'SiCl_3$ from fluoro-olefins $C_nH_{2n-m}F_m$ are illustrated in Table 11, where certain compounds synthesised for the first time are listed.

Table 11. Fluorine-containing chlorosilanes obtained by radiation-induced synthesis[75].

Starting materials	Product of synthesis	d^{20}	n_D^{20}	B.p., °C/mmHg	Percentage utilisation of starting materials	G, mol/100 eV
$C_3F_6 + HSiCl_3$	$(C_3HF_6)SiCl_3$	1.6170	1.3610	84/756.5	95	190
$C_3F_6 + H_2SiCl_2$	$(C_3HF_6)_2SiCl_2$	1.7202	1.3413	160	80	100
$C_3F_6 + CH_3HSiCl_2$	$(C_3HF_6)CH_3SiCl_2$	1.4610	1.3338	94/749	85	225
$C_3F_6 + C_2H_5HSiCl_2$	$(C_3HF_6)C_2H_5SiCl_2$	1.4342	1.3710	110—112/752	95	180
$C_2F_4 + HSiCl_3$	$(C_2HF_4)ClSiCl_2$	1.5138	1.3645	--	11	1.6

The chain reaction is initiated by $SiCl_3$ radicals formed from trichlorosilane under the action of radiation:

$$HSiCl_3 \rightarrow H^{\cdot} + {}^{\cdot}SiCl_3\,,$$

$$RCH{=}CH_2 + {}^{\cdot}SiCl_3 \rightarrow R\dot{C}HCH_2SiCl_3,$$

$$R\dot{C}HCH_2SiCl_3 + HSiCl_3 \rightarrow RCH_2CH_2SiCl_3 + {}^{\cdot}SiCl_3.$$

The reactions with other substituted chlorosilanes takes place similarly.

The CH_3 and C_6H_5 groups in methylphenyldichlorosilane and dimethylchlorosilane can be chlorinated by the radiation method[77].

Another method for synthesising a number of organosilanes involves the condensation of unsubstituted and alkyl(aryl)-substituted chlorosilanes $(R'R'')_nSiHCl_{3-n}$, the molecule of which must contain a mobile hydrogen atom, with alkyl and aryl halides[79-82]:

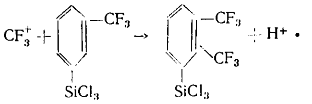
$$(R'R'')_nSiHCl_{3-n} + RCl \rightarrow (R'R'')_nSiRCl_{3-n} + HCl\,.$$

The reaction results in the introduction of a new group R into the chlorosilane molecule. A large series of chlorosilanes containing a wide variety of substituents was synthesised in this way with appreciable radiation-chemical yields (Table 12). The condensation reaction takes place at a temperature not exceeding 360°C. It has been established that the radiation-chemical synthesis of chloroperfluoroalkyl(aryl)-silanes takes place at lower temperatures than the synthesis of non-fluorinated alkyl(aryl) chlorosilanes[82].

An interesting example of the radiation-induced synthesis of fluoroaryl-substituted chlorosilanes is provided by the preparation of trichloro-2,3-di(trifluoromethyl)phenylsilane, which has not been described previously[83]. Irradiation of evacuated sealed tubes with a mixture of equal volumes of $\alpha\alpha\alpha$-trifluorotoluene and tetrachlorosilane at an average dose rate of 87 rad s^{-1} resulted in the synthesis of the desired product with $G \simeq 3$. The set of processes leading to the synthesis may include the following radical and ionic reactions:

$$SiCl_4 \rightarrow {}^{\cdot}SiCl_3 + {}^{\cdot}Cl\,,$$

$$R_FH \rightarrow \begin{cases} {}^{\cdot}R_F + H^{\cdot} \\ Ph^{\cdot} + {}^{\cdot}CF_3 \\ {}^{\cdot}CF_3^+ + {}^{\cdot}C_6H_5 + e^- \end{cases},$$



Although the data presented in the review are unquestionably fragmentary, there is hardly any doubt that preparative radiation-induced synthesis of many organic compounds is the simplest and the most rational procedure.

Table 12. Radiation-chemical synthesis of substituted chlorosilanes[81].

Chlorosilane	Aryl halide	Component ratio	Temp., °C	Product of synthesis	G
$HSiCl_3$	C_6H_5Cl	1:1	175	$C_6H_5SiCl_3$	300
$HSiCl_3$	p-$C_6H_4Cl_2$	1:3	170	p-$C_6H_4(SiCl_3)Cl$	100
$HSiCl_3$	p-$C_6H_4Cl_2$	2:1	300	p-$C_6H_4(SiCl_3)_2$	100
$HSiCl_3$	o-$C_6F_4Cl_2$	4:1	250	o-$C_6F_4(SiCl_3)_2$	60
$HSiCl_3$	1,2,4-$C_6H_3Cl_3$	1.2:1	175	$C_6H_3Cl_2(SiCl_3)$	70
CH_3SiHCl_2	C_6H_5Cl	1:2	300	$CH_3(C_6H_5)SiCl_2$	300
$C_6H_5SiHCl_2$	C_6H_5Cl	1:1	300	$(C_6H_5)_2SiCl_2$	150
$(CH_3)_2SiHCl$	p-$C_6H_4Cl_2$	4:1	300	p-$C_6H_4[Si(CH_3)_2Cl]Cl$ p-$C_6H_4[Si(CH_3)_2Cl]_2$	80 87
$(CH_3)_2SiHCl$	m-$C_6H_4Cl_2$	4:1	300	m-$C_6H_4[Si(CH_3)_2Cl]Cl$	80
$CH_3(C_6H_5)SiHCl$	p-$C_6H_4Cl_2$	2:1	300	p-$C_6H_4[SiCH_3(C_6H_5)Cl]_2$	20
$(C_6H_5)_2SiHCl$	p-$C_6H_4Cl_2$	2:1	300	p-$C_6H_4[(C_6H_5)_2SiCl]_2$	15

Together with the preparative radiation-induced synthesis described above, carbonylation, carboxylation, hydroxylation, nitration, and nitrosation reactions, synthesis of glycols, reactions involving the addition to olefins of telogens such as, for example, alcohols, aldehydes, mercaptans, etc. (see the relevant reviews[84-86]), occurring under the action of radiation, are also known. One cannot exclude the possibility that in certain cases some of the reactions enumerated may find preparative applications.

Advances in Organic Geochemistry

S.M.Manskaya

Two research fields embraced by the concept "organic geochemistry" are discussed. The first includes works on the abiogenic formation of organic compounds and the second deals with studies on the phenomena involving the formation and transformations of fossil organic matter and its importance in geochemical processes. This branch of geochemistry has been defined by certain Soviet investigators as "geochemistry of organic matter".

The present review deals with modern studies on aminoacids, carbohydrates, lipids, porphyrin structures, carotenoids, aromatic compounds of the type of lignin, and flavonoids in contemporary and ancient deposits in connection with problems of petroleum and coal formation.

On the basis of the investigations described, the author of the review believes it to be possible to define the future tasks in the geochemistry of organic matter and rational procedures for carrying them out.

The bibliography includes 111 references.

CONTENTS

1. PRINCIPAL FIELDS OF RESEARCH IN ORGANIC GEOCHEMISTRY

The branch of geochemistry under consideration (organic geochemistry) has been treated in a number of symposia[1,2] comprising papers of a fairly wide variety of types. Some of these are devoted to problems of organic cosmochemistry—the abiogenic formation of organic compounds. Others deal with modern concepts concerning the organic materials in coals, petroleum, and petroleum-bearing rocks. Reports on organic cosmochemistry and on the investigation of organic structures in coals and petroleum, scarace organic substances, and paleontological specimens were presented at the Fourth International Congress on Organic Geochemistry (Amsterdam, September, 1968). It is noteworthy that both natural phenomena characterised by the concept "organic geochemistry" gave rise to two different fields of geochemical research.

In the Soviet literature these two fields are fairly clearly distinguished. The first includes work on the abiogenic formation of organic compounds associated with organic cosmochemistry and problems of the origin of life. The second deals with studies on individual stages in the formation of fossil organic matter and its importance in geochemical processes. This branch of geochemistry has been defined by some Soviet investigators as "geochemistry of organic matter"[3,4].

In the present review it is necessary to consider in the first place the principal features of the first field: the abiogenic formation of organic compounds, the origin of life on earth, and the creation of the biosphere in which fossil organic matter was formed.

Meteorites are important objects for the investigation of organic matter of abiogenic origin. At present numerous data are available, showing the extraterrestial abiogenic nature of the organic material of meteorites[5,6]. A high-molecular-weight of carbon compound with a condensed aromatic structure has been isolated from carbonaceous chondrites[7].

The primary cold matter of the earth's mantle resembles the rocky meteorites. As a result of the rise of the earth's temperature due to radioactivity, readily fusible substances evolved from the earth's mantle in liquid and gaseous forms and formed its outer shells: aqueous (the ocean) and gaseous (the atmosphere)[8-10].

In his monograph Vinogradov[11] describes the probable situation on the earth's surface before the formation of the biosphere. The amount of oxygen in the atmosphere was negligibly small at that time and there was no ozone screen. Life could develop only in the water of the ocean where it was protected from cosmic radiation. Biogenic synthesis was probably preceded by radiogenic and photogenic formation on the earth of complex organic molecules. Oparin's theory of the origin of life[12] is based on the hypothesis of an abiogenic synthesis of primary organic molecules. Oparin and his coworkers performed numerous experiments whereby it was possible to synthesise under laboratory conditions biologically important compounds from ammonia, methane, and formaldehyde under the action of ultraviolet rays and radioactive emission[13-15]†. Aminoacids and nucleotides were synthesised in this way. The abiogenic synthesis of adenosine triphosphoric acid (ATP)—the principal source of energy in all present day organisms—from polyphosphates was achieved under the action of short-wavelength ultraviolet light. Oparin postulates the existence of an enormous number of catalysts which were responsible for the occurrence of a wide variety of reactions in prebiological systems (protobionts).

Nicotinamide adenine dinucleotide (NAD^+) is a universal hydrogen-transfer agent in the living cell. Its presence has been established in all present day organisms; microbes, plants, and animals. It is suggested that NAD^+ was first formed in an early stage of the evolution of organic matter. Similar universal catalysts were also other coenzymes and to an even greater extent enzymes with exclusive specificity and enormous catalytic activity. Thus the enzyme hexokinase accelerates the reaction of ATP with glucose by a factor greater than 10^{11} and alcohol dehydrogenase accelerates the oxidation of alcohol by a factor greater than 10^9. The principal components of all

---

[†] Similar experiments were carried out for the first time by Miller [S. Miller, J. Amer. Chem. Soc., 77, 2351 (1955)] [Editorial Note].

these enzymes are proteins. The specificity of enzymes is associated with a strictly ordered arrangement of the aminoacid residues in the polypeptide chain and a definite packing of this chain in the protein molecule. In this connection there arose the hypothesis of the formation in the course of evolution of a "molecular-matrix" apparatus with the properties of polynucleotides[16,17]. Further development of the primary hydrocarbon systems was an important stage in the generation of life.

According to Oparin's concepts (Ref. 14, p. 56), "a characteristic feature of life is that it is not simply scattered in space but consists of individual very complex systems separated from the outer environment (organisms), which continuously interact with the external medium and the internal structure of which is extremely well adapted to their prolonged existence, continual self-renewal, and spontaneous reproduction under the given conditions of the universe surrounding them".

Vinogradov[11] believes that the formation of complex organic compounds in the water of the ocean, which led to the appearance of organisms, resulted in the first profound transformation in the composition of the ocean and the entire hydrosphere, in the atmosphere, and in many processes occurring on the earth's surface. The mechanism of photosynthesis, which includes the reduction of water with liberation of free oxygen, arose in the course of the evolution of the simplest organism. This led to the accumulation of oxygen in the atmosphere and the formation of the ozone screen so that life became possible not only in water but also on dry land.

Boichenko[18] points out the role of the metal-containing oxido-reductases in the evolution of photosynthesis. With the appearance of manganese in the chloroplast lipids, the oxidation-reduction potential necessary for the evolution of oxygen was attained. The biosphere was at one time investigated on a wide front by Vernadskii[19,20], who found that organisms should be investigated in relation to the medium where they lived or live, i.e. in relation to the earth's crust. This led to a new geochemical problem—the study of the chemical composition of living matter, i.e. the average chemical composition of living organisms in relation to geochemical processes occurring in the earth's crust. A new branch of geochemistry—biogeochemistry—also arose.

The role of organisms or living matter in geochemical properties was studied by Vinogradov[21] on a large amount of material. The elementary chemical composition of sea organisms was determined taking into account their evolutionary development and position in the system of nomenclature. Subsequently the effect of the medium on the elementary composition of organisms was elucidated[22].

Koval'skii[23], who studied the effect of the medium (chemical elements) on metabolism in organisms, concluded that the biochemical or physiological mechanisms of adaption to geochemical conditions are important factors in the evolutionary process. It is suggested that the microelements concentrated by plants may accumulate in structural components of the cells (nuclei, mitochondria, ribosomes) and influence the occurrence of mutations.

As a result of the development of living matter in the biosphere, the products of the decomposition of the organisms, which gave rise to fossil organic matter, also began to accumulate. Vinogradov states (Ref. 24, p. 4) that it is difficult to separate the geochemical role of living matter from the geochemical role of organic substances formed after the death of the organisms. The appearance of deposits of coal, petroleum, lime, and other organic rocks itself altered the face of the earth; later Vinogradov states (Ref. 24, p. 11) "...in order to elucidate the mutual effects in the organic substance—rock system, we must be able to distinguish the individual properties of particular organic molecules. This is why it is necessary to concentrate attention on and to intensify the study of the molecular composition of organic substances, the role of which in geological processes cannot be over-estimated".

New studies on the geochemistry of organic matter show investigations of individual organic compounds and methods of their conversion in natural processes may prove very useful for the solution of many geochemical problems.

Here we may include the following branches of geochemistry: (1) the study of the chemical composition of the organic matter of different types of peat and fresh and seawater deposits together with the biochemical processes occurring in them, which determine the initial stages in the formation of different types of coal and petroleum; (2) the study of the organic fraction of paleontological specimens in order to establish the phylogenetic differences and to elucidate the preservation conditions; (3) discovery of the organic structures responsible for the concentration of rare elements in caustobioliths and other natural materials.

In his examination of the principal problems of the chemical study of the world ocean, Zenkevich[25] attributed considerable importance to the investigation of organic matter. Starting with the postulate that "organic matter is a trigger actuating the diagenetic processes in sea deposits", Zenkevich believes that the first task to be performed is the study of the chemical composition of organic matter in oceanic water and deposits and the determination of the individual organic compounds.

Much serious work, described in symposia, monographs, and individual articles, has been done on the chemical balance of organic matter in the ocean and also on its composition. This includes the studies by Skopintsev[26,27] who developed the hypothesis that the bulk of the dead organisms of the plankton decomposes in the upper layer of the ocean. This hypothesis is confirmed by numerous data on the distribution in the sea of ammonia, nitrates, organic carbon, nitrogen, and phosphorus. Romankevich[28,29] followed the relations governing the distribution of organic carbon and nitrogen in the surface layer and in the bulk of the deposits in the Pacific Ocean. In the deep water part of the Pacific Ocean the degree of mineralisation of the organic matter of the phytoplankton in the water and on the surface of the bottom amounts to 99.93–99.99%.

As one moves away from the foot of the continental shelf to the central part of the ocean, the content of organic carbon and nitrogen in the deposits diminishes to minimal values (0.25% of organic carbon and 0.05% of nitrogen relative to the non-silicate and non-carbonate material of the deposits).

Lisitsyn[30] investigated the present day deposits in the Bering sea. The biomass of the phytoplankton in the Bering sea consists largely (90%) of diatomaceous algae. In this connection the distribution of silicon in the waters and deposits of this reservoir is of definite interest.

Much attention has been devoted to the study of the organic matter of present day and ancient sea and continental deposits in connection with the conditions governing the formation of petroleum. Veber[31] attributes particular importance to the study of bitumens in the organic matter of the deposits as a function of the conditions of their formation in the facies.

Rodionova[32] studied by biochemical-bitumenological analysis the composition of the hydrocarbons in more than 2000 rock specimens from the Devonian and Lower Carboniferous periods in the Volga-Ural petroleum- and gas-bearing region. The results of the chromatographic separation of the individual bitumen fractions enabled her to determine the distribution of hydrocarbons in the organic matter of rocks of different lithological composition and different geological ages.

2. STUDY OF INDIVIDUAL ORGANIC COMPOUNDS IN DIFFERENT STAGES OF THEIR CONVERSION INTO FOSSIL ORGANIC MATTER

The modern theory of the organic origin of petroleum is based on the following concepts: (1) the nature of the materials from which petroleum was derived; (2) the processes and conditions in the formation of petroleum; (3) the migration and accumulation of petroleum[33-35]. The principal compounds in petroleum are hydrocarbons of the methane, naphthene, and aromatic types. Hydrocarbons similar to those detected in petroleum have been found in all sedimentary rocks, ranging from ancient to contemporary deposits[36].

The majority of investigators agree with the hypothesis that the principal biochemical source of petroleum hydrocarbons are fats and fatty acids. Fats included in the group of lipids constitute a mixture of esters of glycerol (a trihydric alcohol) and high-molecular-weight fatty acids. The principal fatty acids entering into the composition of fats are palmitic $CH_3(CH_2)_{14}COOH$, stearic $CH_3(CH_2)_{16}COOH$ oleic $CH_3(CH_2)_7CH=CH(CH_2)_7COOH$, linoleic $CH_3(CH_2)_4CH=CHCH_2CH=CH(CH_2)_7COOH$, and linolenic $CH_3CH_2CH=CHCH_2CH=CHCH_2CH=CH(CH_2)_7COOH$.

All living organisms contained the enzymes (lipases) which catalyse the hydrolysis of fats with formation of glycerol and fatty acids. The decarboxylation of fatty acids in the course of their conversion into petroleum hydrocarbons might have occurred in the first place under the influence of bacterial enzymes and also under the action of physical factors—temperature and pressure.

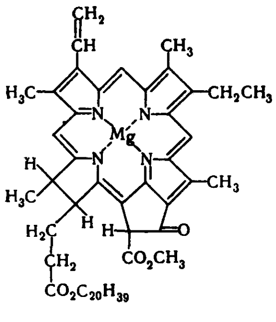
Abelson[37] devoted much attention to kerogen as the most probable source of petroleum hydrocarbons in the course of formation of petroleum from the decomposition products of the phytoplankton. He postulates also the possibility of a secondary transformation of kerogen (the insoluble fraction of the organic matter in ancient deposits). The fatty acids liberated after the death of the phytoplankton interact with other compounds or are acted upon by micro-organisms (depending on the conditions in the medium). In both cases they can serve as the starting material for the formation of petroleum hydrocarbons or an insoluble kerogen complex. The data obtained by Williams[38], who established a sharp decrease of the ratio of fat carbon to the total content of carbon in the organic matter of the deposits compared with its value in algae, are of interest in this connection. Williams determined this ratio as 0.3 for diatomaceous algae and 0.2 for mixed algae. In the organic matter from the deposits taken at a depth of 20 m the ratio is 0.08 and at a depth of 400 m it is 0.02. For the dissolved organic matter at depths of 20 and 400 m, the ratio is 0.004 and 0.003 respectively.

Brooks and Smith[39] determined the relative amounts of hydrocarbons with even and odd numbers of carbon atoms in living plants, coals with different degrees of metamorphism, in different types of petroleum, and in natural gas. They suggested that in many cases the same plants can serve as starting materials for the formation of both coal and petroleum, depending on the biochemical conditions and early diagenesis. Wood gave rise to the formation of humus coal, and small plant particles (leaves and others) containing large amounts of lipids may have been involved in the formation of lake or sea silt. Deposits of this type served as a source for the formation of petroleum. Characteristic differences in the composition of humus and sapropel types of fossil organic matter have been demonstrated[40,41].

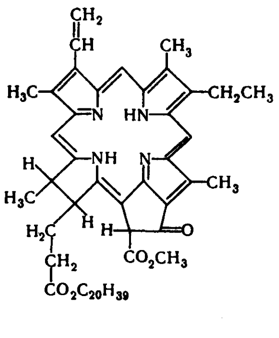
In the hypotheses concerning the genesis of petroleum considerable importance is attributed to pigments: chlorophyll and carotenoids. Porphyrin pigments of the type of chlorophyll were first detected by Treibs[42] in different types of petroleum, asphalts, and tars, which confirmed the theory of the organic origin of petroleum.

The products of the decomposition of chlorophyll and haemoglobin in natural materials have been extensively investigated at the present time and the possible pathways in their conversion into petroleum porphyrins have been demonstrated. Orr et al.[43] proposed a mechanism for the conversion of chlorophyll via a number of intermediates into the porphyrin structures of the deposits and petroleum. Among the intermediate decomposition products postulated in the mechanism, pheophytin and phaeophorbide, chlorophyll derivatives without magnesium, have been detected in deposits.

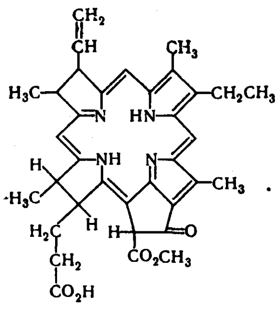
Studies on the organic matter of the present day deposits in the Pacific Ocean, taken from various depths (from 30 to 7500 m), established that chlorophyll decomposition products predominate markedly over unchanged chlorophyll[28]:



chlorophyll a

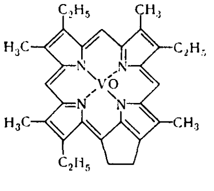


phaeophytin a

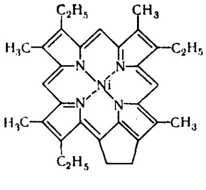


phaeophorbide a

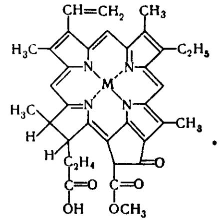
Hodgson et al.[44] demonstrated in model experiments the conversion of phaeophytin and its derivative chlorene into petroleum porphyrins. In sedimentary rocks and in hydrocarbon accumulations porphyrins are encountered mainly in the form of vanadium or nickel complexes. There exists the hypothesis that pigments having the porphyrin structure with a metal atom in the ring (chlorophyll with magnesium, haemin with iron) lose the metal in the subsequent reactions of the organic material. Metal-free porphyrins are encountered in fossil organic matter fairly rarely—probably the interaction of vanadium or nickel with the free porphyrins is relatively rapid:



V-porphyrin



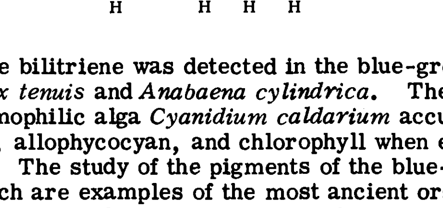
Ni-porphyrin



Metal-chlorene

Hodgson et al.[45] investigated the distribution of porphyrins and chlorene in polycyclic aromatic compounds in 250 specimens of soils, deposits, and sedimentary rocks of different ages, ranging from the early Precambrian period up to the present day. Ni- and V-porphyrins were detected in all the specimens, which indicates their wide distribution in sedimentary formations. They are found mainly in fine-grained clastic sea rocks with ages ranging from the Tertiary to the Precambrian periods. Chlorenes are encountered predominantly in contemporary deposits and in soils. Fe-Porphyrins have been found in a small number of specimens. Hodgson and coworkers extracted Fe-porphyrin from gilsonite with the aid of methanesulphonic acid and then obtained it in the form of free porphyrin. This enabled them to investigate on models the interaction of porphyrin with nickel, copper, cobalt, zinc, and both divalent and trivalent iron and to obtain complexes of these compounds.

In connection with the importance of the study of porphyrin structures in the geochemistry of organic matter, mention should be made of the pigments in the blue-green and purple algae. These are phycocyans, allophycocyans, and phycoerythrins—complexes of proteins and plant bile pigments. Bile pigments are regarded as derivatives of porphyrins—tetrapyrroles with an open chain. An example of such a pigment is bilitriene which has a blue-green colour:



The blue bilitriene was detected in the blue-green algae *Tolypothrix tenuis* and *Anabaena cylindrica*. The unicellular thermophilic alga *Cyanidium caldarium* accumulates phycocyan, allophycocyan, and chlorophyll when exposed to light[46]. The study of the pigments of the blue-green algae, which are examples of the most ancient organisms on earth, can provide new data for the characterisation of the Precambrian kerogen, recently investigated by Hoering[47]. Paleobotanists demonstrated the existence of the blue-green algae in the Precambrian period[48].

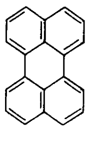
Chlorophyll in green plant leaves is always accompanied by yellow pigments—carotenoids, which belong to the group of isoprenoids. Carotenoids can be divided into two classes: (1) hydrocarbons (carotenes) and (2) xanthophylls—oxygen-containing derivatives of carotenes.

Vallentyne[49,50] investigated the carotenoids from fresh and sea water deposits; he succeeded in isolating carotenoids from fresh water deposits 20 000 years old. Data on the content of carotenoids in the waters and deposits of the Pacific Ocean were obtained by Romankevich[28].

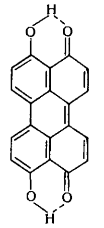
Kojama et al.[51] investigated plant pigments (chlorophylls and carotenoids) in lake deposits by paper chromatography and spectrophotometry. They established that both the total pigments and their individual fractions decrease in the deposits on the bottom on going from surface to deeper layers.

The study of perylene, a polycyclic aromatic hydrocarbon ($C_{20}H_{12}$) consisting of five rings, is of interest. It has been detected in the distillate from crude petroleum, in present day deposits, and in ancient sedimentary rocks[52]. It has been suggested that biogenic pigments are a source of perylene and other polycyclic aromatic compounds[53,54]. A likely biological precursor of perylene may be the widely distributed quinone, similar to 4,9-dihydroxyperylene-3,10-quinone, isolated from the Ascomycete *Daldinia concentrica*[55]. Another quinonoid pigment similar to perylene—erythroaphin—has been isolated from insects of the family Aphididae[56].

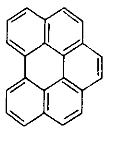
The reduction of these pigments results in the formation of 1,12-benzoperylene and coronene together with perylene:



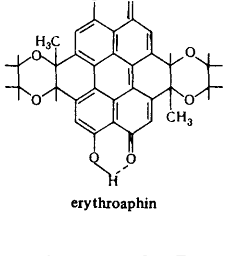
perylene



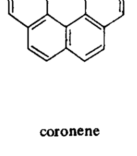
4,9-dihydroxyperylene-3,10-quinone



1,12-benzoperylene



erythroaphin



coronene

Recent investigations by Douglas and coworkers[57,58], who studied isoprenoid and other hydrocarbons and pigments in coorongite and torbanite and also in the algae *Botryococcus braunii* from which these deposits were formed, are of considerable interest.

In the last 10–15 years the attention of investigators was attracted to the determination of the decomposition products of proteins and carbohydrates in various waters, present day deposits, and organic matter of sedimentary rocks[59,60]. The publication of a large number of papers on this question can be accounted for, on the one hand, by the biochemical importance of these compounds in living organisms, and, on the other hand, by the relative ease of their determination in fossil organic matter.

The variation of the qualitative composition of aminoacids with preservation conditions, the composition of rocks with which they are mixed, and the geological age of rocks has been investigated. Siliceous shale and argillaceous minerals contain appreciable amounts of aminoacids[60,61]. It has been suggested that the presence in rocks of certain thermostable aminoacids be used as a geological thermometer[62].

Studies on the preservation of aminoacids in the skeletal residues of organisms are of great interest. Abelson[62,63] isolated aminoacids from ancient trilobites of the Ordovician period and peptides from shells and bony residues of the Pleistocene period buried in asphalt. Jones and Vallentyne[59] isolated from the fossil shells of *Mercenaria mercenaria* (Pleistocene), after dissolution of the mineral component, 0.3 g of periostracum fibres—the organic fraction of the shells. The set of aminoacids in this fraction proved to be close in composition to that of the conchiolin of present day shells. Florkin[64] quotes the chemical composition of a typical mother-of-pearl conchiolin found in the fossil shells of the Eocene period (about 60 million years old).

Examples are known of the preservation under geological conditions of collagen and protein characteristic of vertebrate animals and detected in fossil bony residues, horns, teeth, and fish scale[65]. There has been a remarkable discovery of protein of the collagen type in the mummified skin of a fossil amphibian, the geological age of which corresponded to the Lower Permian period (about 200 million years ago)[66].

In most studies on fossil organic matter and the pathways followed in its formation, the carbohydrate content in various natural materials was investigated together with the determination of the aminoacids. The literature on this question has been collected in monographs and reviews[3,67,68]. The studies of Swain and coworkers[69], who determined the monosaccharides in the hydrolysates of fossil residues (Devonian–Permian period) of 25 plant species, are striking. They succeeded in revealing the evolutionary change from the algal polysaccharide rich in galactan to a polysaccharide of the cellulose type characteristic of cordaites.

In many geochemical processes associated to some extent with organic matter, humic substances play a notable role. The term humic substances is not fully defined even when applied to their most thoroughly investigated representatives—humic acids. It is believed that the dark-coloured humic acids are polymeric compounds which dissolve in dilute solutions of alkali and are readily reprecipitated by aqueous acid solutions. Chemically humic acids are characterised as a heteropolycondensate with a high reactivity owing to the presence of active functional groups.

The information about soil humic acids and their chemical composition and properties available at present is extensively described in Kononova's monograph[70]. Humic acids in peat constitute the basis of the organic component of human coal. Humic acids are present in the non-compacted deposits of sea and continental origin constituting in some cases more than 50% of the total organic matter in the rock[60,71].

Humic acids may be formed from various organic compounds which enter into the composition of the living population of soils, peats, and silts and which are liberated after the death and breakdown of the organisms. The presence of phenolic components and also nitrogen-containing groupings is characteristic of humic acid. One of the sources of phenolic compounds in humic acids may be their synthesis by micro-organisms from carbohydrates[72,73].

Among phenolic compounds which participate in the formation of humic acids, the most important role belongs to lignin. Lignin is widely distributed in all plants with a vascular system and a mechanical tissue. The involvement of land plant lignins in the formation of soil and peat humic acids is confirmed by the detection of lignin structures in the two materials[74,75].

The role of lignin has been decisive in the formation of the organic component of humus coal and lignites. Brefer[76,77] justly regards lipids and lignins as the most important organic compounds participating in the formation of present day and ancient deposits.

The fundamental outline of the aromatic structure of lignin and the pathways of its formation from photosynthetic products have now been largely elucidated[78]. The complex polymeric lignin molecule is constructed of compounds of the phenylpropane series.

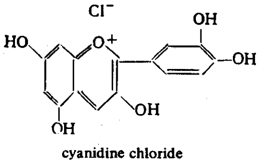
After the death of plants under natural conditions, lignin is acted upon by biological and physicochemical factors in the medium. Under the influence of these factors, depolymerisation processes, i.e. partial rupture of bonds between individual monomers, takes place in the lignin on the one hand and on the other secondary condensation processes occur[79]. The composition of humic acids may include both individual lignin monomers as well as its larger units and also secondary condensed aromatic structures.

The possible pathway of the biological breakdown of lignin and its participation in the formation of humic acids is indicated in the mechanism presented below.

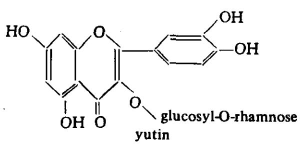
The mechanism shows the sequence of reactions in the biological breakdown of lignin to the monomers. Further reaction leads to the decomposition of the side chain—demethylation and oxidation with formation of protocatechuic acid. Structures of the hydroxy-*p*-benzoquinone type are readily formed from protocatechuic acid in natural processes. The interaction of aromatic lignin structures with nitrogen-containing compounds in the formation of humic acids takes place, according to current hypotheses, after the demethoxylation and oxidation of the aromatic components to quinones[80].

New studies on aromatic soil pigments[81,82], in which the P_g fraction (green pigment) is regarded as a perylene derivative, are of considerable interest. A close genetic relation between these pigments and humic acids is suggested.

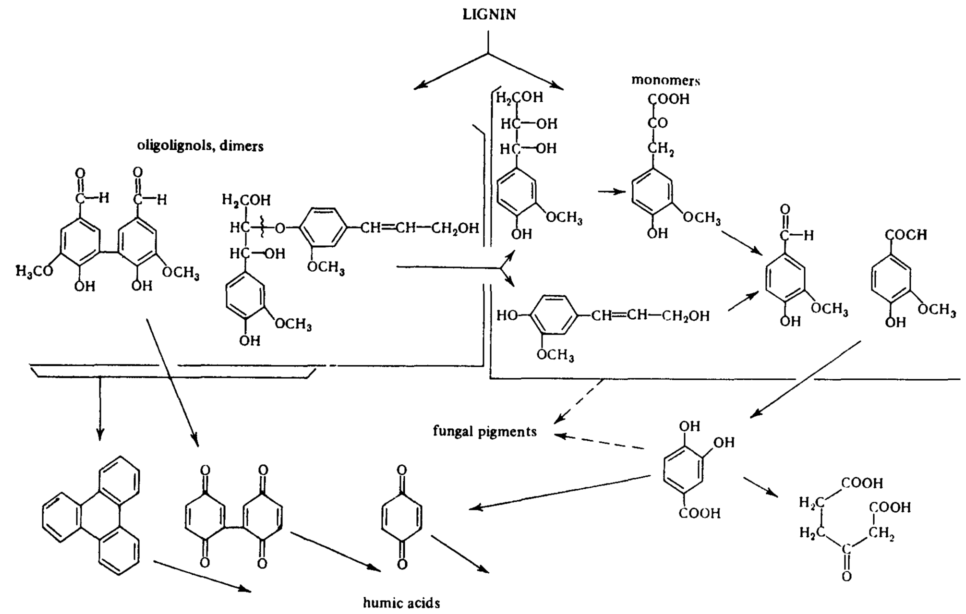
Flavonoids are included among the phenolic compounds fairly widely distributed among plants and undoubtedly participating in natural processes. Flavonoid pigments are a group of water-soluble phenolic glycosides the principal structural unit of which is the flavone skeleton $C_6-C_3-C_6$. Compounds of the type of anthocyanin, which are responsible for the wide variety of raspberry-red and violet tints in various parts of plants, and yellow pigments of the rutin type are known to be present among them:



cyanidine chloride



yutin .



Mechanism of the possible geological breakdown of lignin and its participation in the formation of humic acids.

In plants, flavonoids and lignin are genetically related in their biosynthesis via common precursors, which are phenylalanine and cinnamic acid[83]. Flavonoid pigments are characteristic mainly of higher plants and few are known among spore-bearing plants[84]. Bendz et al and coworkers[85,86] isolated from the green moss *Bryum cryophylum O. Mårt* two anthocyanin pigments. These workers isolated from the cell walls of the sphagnum moss *Sphagnum magellanicum* and *Sphagnum nemoreum* a pigment which they characterised as a copolymer of a flavonoid of the anthocyanin type and lignin structures.

The detection of phenolic acids and flavonoid pigments in the pollen of various plants is of great interest[87,88]. The colour of the pollen ranging from pale-yellow to dark-brown, in various plant species depends on the presence of two types of pigments: flavonoids and carotenoids. Inglett et al.[89] determined in the ether-soluble fraction of pollen tars, hydrocarbons, sterols, and fatty acids. In the alcoholic fraction of defatted pollen they found nitrogen-containing components and about 20 flavonoids including rutin and quercetin.

Lunden[90] reviewed briefly the studies on the chemical composition of the pollen of various plants. Free amino-acids, polypeptides, and proteins have been found in the pollen of the majority of plants.

Considerable amounts of nucleoproteins and deoxyribonucleic acids have been detected. Among carbohydrates, starch, cellulose, pentosans, and reducing sugars were discovered. Lactose was detected in the pollen of *Forsythia*—for the first time in a plant material.

Pollen flavonoids have been separated by chromatography and their spectra have been investigated in the same way as those of chlorophyll and carotenoids.

Fatty acids were isolated from the pollen of five conifer species and analysed by gas–liquid chromatography. Oleic, linoleic, palmitic, and stearic acids were found[91]. The ash content of pollen is 1–7%, potassium predominates in the ash (20–45%), there is frequently much silicon (2–10%), and manganese and titanium have been detected.

After the elimination of fats, proteins, and water-soluble material from pollen, a fairly large amount of non-extractable substances remains in the test samples. In certain pine species between 20 and 57% of such substances were found in the pollen. In the past century these substances were called "pollenins" and the exceptional strength of the outer coats of pollen grains was explained by their presence. Pollenins frequently combine with cutin, also a little investigated substance, which impregnates the outer cell walls of the epidermis of leaves and plant stalks. Matic[92] investigated cutin from the leaves of the agave and concluded that it is a polyester of acids containing 16 and 18 carbon atoms in an unbranched chain and 2 or 3 hydroxy-groups.

In the 1930's pollenin from the pollen of conifers and sporopollenins from the spores of lycopodium were isolated by Zetzsche and Vicari[93]. These substances are resistant to the action of concentrated solutions of alkali and many acids but are oxidised on heating with nitric or chromic acids and alkaline permanganate. Zetzsche et al.[94] isolated sporopollenin preparations from tasmanite and Chulkovo brown coal of the Moscow Basin. The first preparation, which they called tasmanin, had the composition $C_{90}H_{134}O_{15}(OH)_2$ and the second, called bothrodendrin, had the composition $C_{90}H_{111}O_{12}(OH)_9$. Descriptions of these interesting studies have been included in monographs on the chemistry of coal[95,96] but until recently they were not developed any further. The presence of sporopollenins in exine (the outer coat of pollen grains) is responsible for the morphological stability of pollen grains, which made possible the widely familiar spore and pollen analysis. Chemical studies on fossil pollen significantly supplement the microscopic observations. Recently Brooks and Shaw[97] investigated the sporopollenins from rocks of different ages. They believe that the older forms of kerogen are identical in many respects with sporopollenin formed from deposited spores. They believe that the fossil sporopollenins are polymers of carotenoids and their esters, present in the pollen of the initial plants.

They present data on the isolation of aromatic acids from the sporopollenins as a result of alkaline treatment: *p*-hydroxybenzoic, *m*-hydroxybenzoic, protocatechuic, and vanillic.

The information presented above on the chemical composition of present day and fossil pollen suggests the presence in sporopollenins of condensed structures formed from flavonoid compounds and compounds of the lignin type. Their determination in small amounts is quite feasible[98].

3. THE ROLE OF ORGANIC MATTER IN THE MIGRATION AND CONCENTRATION OF CHEMICAL ELEMENTS

Numerous data are now available confirming the importance of organic matter in the migration and concentration of chemical elements[3]. The detection in the organic matter in rocks or in paleontological residues of the decomposition products of highly polymerised natural compounds (aminoacids, aromatic structural units of lignin and flavonoids, and compounds with porphyrin structures) enables us to postulate not only the individual stages in the reactions of these compounds but also the possible conditions for their interaction with metals. Earlier the various ways in which uranium, germanium, vanadium, molybdenum, copper, gold, and other elements accumulated in the organic matter of sedimentary rocks were characterised by the present author[3]. An example of such a process is the distribution of germanium and other metals in fossil coals. Ratynskii and Glushnev[99] noted an increased zinc and lead content in fractions of coal material having the minimal density and relatively rich in components of the exine group (pollen and spores). Their experimental investigations led to a quantitative assessment of the bond between a number of metals and the organic component of the coal material. The following affinity series was established: Ge > W > Ga > Be > Nb > Mo > Sc > Y > La > Zn > Pb.

Earlier Ratynskii and Shterenberg[100] established that germanium is concentrated in the vitrain fraction of coal. The vitrain fraction of coal is formed mainly as a result of natural transformations of polymeric lignin molecules. Structures containing ortho-hydroxyquinonoid groupings responsible for the accumulation of germanium and other rare elements in the organic matter of coals at the peat stage of their formation can be readily formed from lignin in natural processes[101].

It has been noted[102] that the enhanced concentrations of rare elements (germanium, uranium, vanadium, and others) in coal inclusions are associated with plant tissues in fossil wood and bark. It is known that the chemical compositions of the cell walls in the bark and wood of present day plants and also the compositions of extractable substances differ considerably[103]. In this connection it is important to elucidate which of these compounds were involved in the formation of coal inclusions and the concentration of rare elements in them.

It is noteworthy that the organic content of silicon-impregnated inclusions in coal strata known as coal balls, large opal-containing lens-shaped discs found in brown coals[104], has not been investigated. Only isolated chemical studies on mineralised plant residues have so far been made.

An organic fraction in an amount of 0.1–0.2% has been isolated (and investigated) from silicon-impregnated wood of conifers (Cretaceous) and stalks of a lycopodium species—genus Lepidodendropsis (*Lepidodendropsis kazachstanica Senk*, Devonian period)[105]. After alkaline nitrobenzene oxidation, small amounts of aromatic aldehydes derived from lignin were discovered in the organic fraction. Knoche and Ourisson[106] extracted with a benzene–methanol mixture an organic fraction (3 mg) from argillaceous inclusions in sand deposits containing residues of the horsetail *Equisetum brongniarti*. Chromatography on silica gel of the extract led to the determination of the following compounds: n-tricosane, n-pentacosane, and n-nonacosane, which are characteristic of the present day horsetail *Equisetum sylvaticum*.

Recently data have been published characterising the mutual effects of the organic matter and the mineral components in sedimentary rocks and paleontological residues. One may include here the studies on the formation of framboids with participation of sulphate-reducing bacteria: these investigations have been reviewed critically by Kizil'shtein[107]. It was found that the aminoacid composition of shell conchiolin differs in the mineralised and non-mineralised layers[108].

Long et al.[109] showed experimentally that montmorillonite minerals act as acid catalysts in the condensation of aromatic compounds to cyclic structures. The observations on present day organisms are of interest. Thus Werner[110] established appreciable differences in the nucleoside-phosphate metabolism of the diatomaceous alga *Cyclotella cryptica* cultivated in a medium with and without $Si(OH)_4$. Drum[111] observed the formation and distribution of opal in the cell walls of the birch when birch twigs were kept in sodium metasilicate solution for 12–24 h.

The study of reactions of this type may prove useful for the elucidation of the form in which chemical elements are combined with fossil organic matter.

---o0o---

The results of modern investigations presented in this review suggest the future tasks in the geochemistry of organic matter and rational methods for their fulfilment. One of such tasks is the study of the individual organic compounds in present day and ancient deposits, in fossil coals and coal inclusions, and in the organic fraction of mineralised plant and animal residues. It is essential to investigate it in greater depth lipids, porphyrin structures and carotenoids and aromatic compounds of the type of lignin and flavonoids in the course of their biosynthesis in present day organisms. The knowledge of the accompanying enzymic reactions and the intermediates formed will help elucidate the transformations of these compounds in the course of their conversion into fossil organic matter.

One may expect that studies of this kind will lead to the discovery of new possibilities for elucidating the nature of complex natural formation such as kerogen, land and sea humus, and sporopollenins.

The next important task is to establish the specific structures of the organic compounds responsible for the concentration of rare elements in the organic matter of peats, coals, and shale. Experiments on models play a significant role in the solution of this problem.

No less important is the investigation of organic compounds in paleontological residues. The chemical study of paleontological specimens by modern microchemical and physical methods will help discover new aspects of the evolution and phylogeny of organisms. Another aim of studies of this kind is to elucidate the geochemical and paleoclimatic conditions in which the residues of the organisms were preserved and their chemical composition was transformed. The study of the corresponding organic compounds is phylogenetically similar present day organisms is one of the ways in which this problem may be solved.

Advances in the Thin-layer Chromatography of Inorganic Ions

M.P.Volynets and A.N.Ermakov

The review deals with studies published during 1960-1967 and partly in 1968 on the applications of thin-layer chromatography. Much attention has been devoted to the description of specific procedures which improve the efficiency of the method. Possible applications of the method in inorganic and analytical chemistry have been noted. The bibliography comprises 228 references.

CONTENTS

I. INTRODUCTION

Thin-layer chromatography (TLC) on plates, which has been fairly widely used in organic chemistry, has found increasing application in inorganic chemistry starting in the 1960's. This is demonstrated by the increase in the number of publications. Thus one paper dealing with the application of thin-layer chromatography in inorganic chemistry was published in 1960, four papers were published in 1962, about twenty papers in 1965, thirty papers in 1966, and more than sixty papers in 1967.

The scope of thin-layer chromatography and in many cases some of its advantages over other methods for the separation and concentration of microamounts of substances are responsible for its vigorous development together with other effective methods such as extraction, column chromatography, etc. The method may be used to separate and identify from several tens of microgrammes to tenths and sometimes hundredths of a microgramme of complex mixtures.

The universality and simplicity of the method and the clear-cut separation after a short period of analysis make thin-layer chromatography (in combination with sensitive analytical methods) suitable for the solution of many problems involving the determination of microgramme amounts of elements.

Although in the last three years many publications on inorganic thin-layer chromatography have appeared, adequate reviews are not available. The wide scatter of the publications is a considerable inconvenience to readers. A number of monographs[1-7], apart from describing the principle of the method and the experimental technique, discuss mainly the applications of thin-layer chromatography in organic analysis. These publications deal very briefly and by no means exhaustively with data on inorganic thin-layer chromatography and the specific thin-layer chromatographic procedures for inorganic ions are not indicated. There are a number of reviews on inorganic thin-layer chromatography[8-16] but they are not sufficiently comprehensive.

We hope that our attempt to give as far as possible a complete review of studies on inorganic thin-layer chromatography between 1960 and 1967 inclusive (partly in 1968) and to deal with the principal trends, possibilities, and applications of the method for the analysis of inorganic ions will prove useful to readers, particularly now when the interest in this method by chemists increases steadily, as shown by the widening of the range of its applications and the increase in the number of relevant publications from year to year.

In the present review we shall only describe briefly the principle of the method and the experimental technique, because these problems have been thoroughly dealt with in the books and reviews mentioned above. In each section we shall note the characteristic procedures which enhance the effectiveness of inorganic thin-layer chromatography.

The experimental technique is as follows. Small amounts of the test solutions (of the order of 1–5 μl) are placed at the starting point on a thin layer of sorbent covering a plate. The plate is dried and the edge below the starting line is immersed in a mobile solvent contained in a hermetically sealed chamber. As the solvent moves along the layer of sorbent, the ions of the elements are separated in accordance with the partition coefficients under the given conditions. The position of the solvent front line is noted and after the plate has been dried the zones containing the elements are detected by spraying with solutions of appropriate reagents which give rise to colour or luminescent reactions with the elements to be detected. When radioactive elements are separated, radiometry and radioautography are employed.

The quantitative characteristic of the position of the substance in a chromatogram is its R_f value (the ratio of the distance between the starting line and the centre of the spot to the distance between the starting line and the solvent front line). The R_f value is characteristic of a given compound on a given sorbent in a given system, and depends on a number of conditions: experimental method, purity and moisture content of the sorbent, thickness of the layer, purity of the solvent, amount of substance deposited, duration of separation, etc, (see Ref. 6, p. 7). Therefore in order to obtain reproducible R_f values, it is necessary to perform experiments under rigorously standardised conditions. The standard conditions recommended by Stahl for thin-layer chromatography[17] are quoted below: (1) plate dimensions 200 × 200 mm and 200 × 100 mm; (2) thickness of dry layer 0.1–0.3 mm; (3) plates stored in a closed vessel over silica gel; (4) distance from the starting line to the lower edge of the plate 15 mm and to the side edge 10 mm; (5) distance traversed by the solvent (distance between the starting line and the solvent front line) 100 mm; (6) chamber saturated with solvent vapour (chamber closed by a ground lid and walls lined with strips of filter paper wetted with the mobile phase; (7) plate immersed in the solvent to a depth of 0.5 cm; (8) elution temperature 18–25°C; relative humidity of air 40–65%; (9) standard sorbents; (10) careful purification of the solvents; (11) size of sample of 0.1–1% solution 1–5 μl.

Since not all these conditions are observed in practice, the R_f values quoted in the literature may differ and the R_f values quoted in the Tables below must be regarded only as a comparative characteristic of the separation of ions of the elements.

II. QUALITATIVE INORGANIC THIN-LAYER CHROMATOGRAPHY

1. SEPARATION OF CATIONS

Alkali and Alkaline Earth Elements

A number of studies have been made on the separation of these elements[18-28]. Solutions of the acetates[5,18], sulphates[18], nitrates, chlorides[20-22,24-26], and polyiodides[27] of alkali and alkaline earth elements are deposited on the sorbent layer. The time taken by the solvent front to rise to a height of 10 cm varies from 10 to 120 min, depending on the composition of the mobile phase. Initially various investigators employed silica gel without added gypsum. Mixtures of methanol, ethanol, and propanol with acetic acid and also with addition of acetylacetone and other complex-forming substances have been used as a mobile phase[18-21]. However, under these conditions a clear separation was not achieved.

Best results are obtained on cellulose[22,23] and corn starch[26]. The R_f values for cations in the chromatography of individual specimens and their mixtures are usually the same. These methods make it possible to separate and detect 1×10^{-8}–5×10^{-9} equiv. of each of the test cations, i.e. smaller amounts than in paper chromatography. On cellulose, it is possible to separate any alkaline earth element from mixtures with others when its relative content in the mixture is as low as 1 : 500. Magnesium may be separated[23] not only from large amounts of beryllium, calcium, strontium, and barium but also from iron, titanium, cobalt, nickel, zinc, zirconium, cadmium, antimony, and bismuth.

It has been noted that the method involving the use of heteropolyacids as sorbents[20] is unsuitable for the rapid separation of alkali metals. However, on oxinegermanododecamolybdate, using 0.01 M NH_4NO_3, it proves possible to separate caesium from other alkali metals and also from yttrium, ruthenium, zirconium, niobium, and strontium.

A mixture of cellulose with zinc hexacyanoferrate(II), which is selective in relation to alkali metal ions[24], has been used for the rapid (16 min) separation of sodium, potassium, rubidium, and caesium. Rapid separation of these elements is achieved when 0.2 M ammonium nitrate is used as a mobile solvent.

Alkali metals are also satisfactorily separated on other inorganic ion exchangers, for example, on thin layers of crystalline zirconium and titanium phosphates. The latter is the best sorbent for the separation of alkali metals, particularly sodium and potassium[25].

In the separation of elements of this group considerable difficulties arise in connection with the detection of the alkali metals on the chromatogram. It is very difficult to choose a sensitive reagent giving a colour or luminescent reaction under these conditions. Sometimes solutions of violuric acid are employed[18,21] but this does not always yield good results. Therefore alkali metals are frequently identified radioautographically[20,24,25]. Alkaline earth metals are detected by illumination with ultraviolet light after spraying the plate with a solution of 8-hydroxyquinoline[22,26].

Transition Elements

The majority of studies[19,26,28-56], on inorganic thin-layer chromatography have dealt with the separation of mixtures of transition elements in different combinations. The sorbents most frequently employed are silica gel[19,29-33,36-40,42,43,48,49,52,53] and cellulose[34,46,50,54], and also alumina[37,45,51], starch[26,35,41], etc. Mixtures of compounds of the elements separated are deposited on the plate in the form of solutions of the chlorides or nitrates[31,33-37,40,41,43,52,54], sulphates[38], and sometimes various complexes[29,30,37,46,49,53]. The mobile phases employed to separate transition elements are extremely varied. In many cases acetone[19,26,35,39,41,42,46,48,51,52], various alcohols (ethanol, methanol, butanol, and others)[30,34,36,39,42,44,45,53], inorganic acids[31,32,36,50,54], organic acids[28,30], etc., are used as one of the components. The duration of chromatography ranges from 10–30 to 120–180 min. The choice of the reagent for detection is determined by the composition of the mixture to be separated. Rubeanic acid is used to identify copper, cobalt, nickel, and platinum[30,38,51], 8-hydroxyquinoline is used to determine zinc, cadmium, iron, mercury, chromium, and aluminium[33,34,35,39,40], ammonium sulphide is used for cadmium, iron, bismuth, copper, lead, mercury, and silver[26,36,41], dithizon is used for lead, silver, and mercury[40], and stannous chloride is used for rhenium, noble metals[45,51,52], and others. Elements separated in the form of chelate complexes are detected on the chromatogram by their intrinsic colour[29,37,41,49]. The separation of various combinations of transition elements has been described: iron, nickel, cobalt, copper, manganese, chromium, silver, zinc, cadmium, aluminium, and mercury[19,26,27-42]; titanium, zirconium, thorium, scandium, UO_2^{2+}, and niobium[43]; vanadium, molybdenum, tungsten, and rhenium[44,45,54]; niobium and tantalum[47]; noble metals[48-53].

Certain characteristic features and procedures in the thin-layer chromatographic method used to separate this group of elements may be indicated. For example, in order to improve the separation of 1-nitroso-2-naphthoxides of iron, nickel, cobalt, and copper, repeated chromatography has been employed with the aid of two solvent systems[29]; iron(III) and cobalt are separated in a solvent containing pentyl alcohol and, when the plate is placed in a system containing dioxan, copper, iron(II), and nickel are separated.

Two-dimensional chromatography has been used successfully[35] to separate iron, aluminium, and chromium and zinc, cobalt, manganese, and nickel.

The method of circular chromatography on a thin layer of sorbent usually gives a clearer separation than on paper. The zones of different elements consist of sharply outlined concentric rings. Thus noble metals are very readily separated on a layer of alumina[51]. Hashmi and Adil[51] succeeded in obtaining by this method about fifteen chromatograms on a 10 × 20 cm plate, the formation of each taking about 2 min. Mercury, copper, cadmium, nickel, and zinc have been separated by circular chromatography on a thin layer of silica gel impregnated with dithizon[42]. The solutions analysed are deposited at the centre of the plate and the mobile solvent (mixture of acetic acid and acetone) is supplied from a dropping funnel at the point of deposition. The dithizonates of these cations form coloured rings in the chromatograms.

A number of transition metals have been separated by thin-layer chromatography of their complexes with dithizon (silver, gold, palladium, and yttrium)[49], 1-nitroso-2-naphthol (cobalt, nickel, manganese, and iron)[37], thiocyanate complexes (zinc, copper, cadmium, cobalt, and nickel)[30], and others.

An interesting procedure involving precipitation thin-layer chromatography has been used[33] to separate copper, iron, and cobalt on a layer of silica gel 0.2 mm thick containing 14% of 8-hydroxyquinoline as the reagent precipitating the metals. The zones of the different elements consist of discrete bands, the content of a particular element being estimated approximately from the width of the band.

Recently thin-layer chromatography on ion exchangers has been increasingly employed, liquid anion exchangers (high-molecular-weight amines and salts of quaternary ammonium bases)[31,54], with which silica gel or cellulose are impregnated, being used particularly extensively. It is best when the carrier is inert with respect to the impregnating phase. Aqueous acid solutions are usually employed as eluents. It has been shown that, by varying the concentration of the acid in the eluent and the type of ion exchanger, it is possible to achieve satisfactory separation of a wide variety of mixtures of inorganic ions. Apart from liquid anion exchangers, anion exchangers such as Amberlite CG-400[28], Dowex-1, and DEAE-cellulose[46,55] and the cation exchangers Amberlite CG-120[28] and Dowex-50[55,56] are used in thin-layer chromatography.

In thin-layer chromatography with phase reversal, which is employed fairly frequently—in particular also for the separation of transition metals, the carrier is usually silica gel. The stationary phase is most often tributyl phosphate (TBP) (solutions in ethyl ether[32], benzene[43], and carbon tetrachloride[50]). Nickel–copper–silver–zinc–iron, cobalt–copper–silver–zinc–iron (mobile phases—aqueous acid solutions)[32], niobium–tantalum (mobile phase—solution of ammonium thiocyanate in a mixture of oxalic and 6 *N* hydrochloric acids)[47], rhodium–ruthenium–palladium–gold (mobile phase—2 *N* hydrochloric acid)[47], etc. mixtures have been separated on such sorbent layers. Solutions of di-(2-ethylhexyl)phosphoric acid (D2EHPA) and tri-iso-octylamine (TIOA)[33] are also employed as stationary phases, which in this case function also as cation- and anion-exchangers respectively. Erbium–holmium–terbium–gadolinium, europium–lanthanum, yttrium–strontium (D2EHPA), and zinc–cobalt–manganese (TIOA) mixtures have been separated on resins impregnated with these reagents.

Non-transition Elements

Certain non-transition elements (bismuth, antimony, cadmium, arsenic, tin, selenium, tellurium, and thallium) have been separated from one another and from transition elements in a number of investigations[28,34,36,57-63], where sometimes the same procedures were employed as in the separation of transition elements, for example separation of the complexes[58], thin-layer chromatography on the ion-exchange resins Amberlite CG-400 and CG-120[28], etc.

The sorbents used to prepare the thin layers were of a wide variety of types: silica gel[59,61,63], kieselguhr[57], cellulose[34-58], starch[60], and ion-exchangers[28]. The mobile solvents in partition thin-layer chromatography frequently include alcohols (ethanol, propanol, and butanol) or ketones [acetone, hexone (4-methyl-2-pentanone—Ed. of Translation), ethyl methyl ketone, and others] and various acids (hydrochloric, nitric, acetic, and tartaric). Selenium and tellurium are separated with a solution of TBP in benzene. Solutions of ammonium fluoride (for arsenic, iron, and bismuth)[28] or sodium chloride (for arsenic, cadmium, and barium)[28] are used as eluents in ion-exchange processes on resins. The duration of the chromatographic process is as usual 10–180 min.

Colour reactions of the elements with dithizon[57,60] and ammonium sulphide[36,57] are used for identification. Arsenic, antimony, and tin separated in the form of dithizonates are identified by their intrinsic colour[58].

The groups of elements for which methods of separation have been developed are listed below: bismuth, antimony, cadmium, arsenic, lead, mercury, and thallium[57]; arsenic, antimony, and tin[34,58-60]; arsenic, iron, and bismuth[28]; arsenic, cadmium, and barium[28]; selenium and tellurium[61-63]; bismuth from lead, cadmium, copper, and nickel and lead from cadmium, nickel, and copper[66].

Lanthanides

The separation of lanthanides which have similar properties is one of the most complex problems in analytical chemistry. Difficulties increase when it is necessary to separate ultrasmall amounts of the elements. In this case it is helpful to employ together with paper chromatography also thin-layer chromatography, which permits the separation and identification of submicrogramme amounts of lanthanide mixtures. A number of papers have been published on the methods for the separation of lanthanides[64-69]. Various two- and multi-component mixtures of lanthanides can be separated by thin-layer chromatography. The chromatographic separation process terminates after 10–180 min. The zones containing the separated elements can be successfully located with Arsenazo III[69] and 8-hydroxyquinoline[64,66] and also radiometrically[64,65,68].

Di-(2-ethylhexyl)phosphoric acid (D2EHPA) is widely used for the separation of lanthanides. The high separation factor for lanthanides achieved when they are extracted by D2EHPA led to studies on partition chromatography involving the application of this acid either as a mobile solvent or as the stationary phase on various carriers: silica gel D for thin-layer chromatography[66], a copolymer of poly(vinyl chloride) and poly(vinyl acetate)[64], and others. In experiments by the phase reversal method the sorbent layer is impregnated with D2EHPA dissolved in a mixture of carbon tetrachloride and ethyl ether[64] or in butanol[65]. It cannot be dissolved in toluene, since the sorbent layer impregnated with such a solution cracks.

The technique of horizontal thin-layer chromatography can also be employed at 60–80°C.[64] The mobile phase in the phase reversal method is usually hydrochloric or nitric acid solution at different concentrations. Elements with a high atomic number migrate more slowly than those with a low atomic number at any constant acidity. With increasing acidity of the eluent, the rate of migration of the lanthanides down the plate increases also. The ion-exchange mechanism of the interaction between lanthanides and the sorbent has been noted[67].

Elution with nitric acid leads to better results in some cases, more clearly outlined spots being obtained, which is probably due to rapid equilibration in the system nitric acid–D2EHPA. It is suggested that the introduction of complex-forming substances into the mobile phase should also improve the separation of difficult mixtures.

To improve the separation of lanthanides, the repeated elution procedure employed; it improves, in particular, the separation of cerium and praseodymium[66]. The separation of lanthanides is best carried out on as thin a sorbent layer as possible, with a high content of D2EHPA[67]. Three-component and four-component mixtures of elements can be separated by this method (for example: lanthanum–praseodymium–samarium; terbium–gadolinium–erbium[64]; lanthanum–cerium–praseodymium–samarium; lanthanum–cerium–neodymium–samarium; praseodymium–samarium–gadolinium; neodymium–samarium–gadolinium; samarium–europium–gadolinium; gadolinium–terbium–dysprosium; terbium–dysprosium–holmium–erbium; terbium–dysprosium–holmium–yttrium; holmium–erbium–ytterbium; holmium–yttrium–ytterbium[66]; and others).

The separation of mixtures of a large number of lanthanides may be achieved by increasing the sorbent layer capacity, by altering the thickness of the sorbent layer, and by using two-dimensional chromatography (in two mutually perpendicular directions). Thus by one-dimensional chromatography with a thickened sorbent layer (500 μm against 250 μm usually employed) with 12 ml of D2EHPA + 34 ml of n-butyl alcohol applied to 30 g of silica gel, it is possible to separate up to 5 elements of the cerium and yttrium groups: lanthanum–cerium–praseodymium–samarium–europium (mobile solvent—0.5 *N* hydrochloric acid); terbium–dysprosium–holmium–erbium–ytterbium (4 *N* nitric acid)[66]. In two-dimensional chromatography with the same eluents and with deposition of mixtures of substances at two points on the left-hand and right-hand edges of the plate, it is also possible to separate five elements of the yttrium group (7 μg of an ytterbium–erbium–holmium–dysprosium–terbium mixture at each spot) and four elements of the cerium group (35 μg of a lanthanum–cerium–neodymium–samarium mixture at each spot[67]).

D2EHPA can also be used as a mobile phase[65,68]. One then uses silica gel, without the addition of gypsum, impregnated with buffer solutions or acids (perchloric acid gives more reproducible results than hydrochloric acid). The mobile phase, a solution of D2EHPA in carbon tetrachloride, is first equilibrated with the stationary phase. Since D2EHPA is itself very strongly adsorbed on silica gel, two solvent fronts are formed, the first being due to the migration of carbon tetrachloride along the plate. When dilute solutions of D2EHPA are employed, the second front lags appreciably behind the first. Therefore 1 M D2EHPA solutions are employed in order to avoid this phenomenon.

It was found that, when the mixtures of substances to be analysed by the phase reversal method are deposited on the plate in the form of aqueous solutions, the pH of the stationary phase alters and 5–10% of the lanthanide (detected with the aid of radioactive isotopes) remains at the site of deposition in the chromatographic experiments. Therefore it is best to employ solutions of mixtures in organic solvents. This procedure yields spots which are usually symmetrical. "Tails" and jagged spots are rarely encountered. The spots which migrate with the solvent front are very narrow which permits the separation of up to five components (cerium–samarium–europium–gadolinium–terbium and promethium–samarium–europium–gadolinium–terbium) when, for example, 0.15 M perchloric acid is used as the stationary phase and 1 M D2EHPA in carbon tetrachloride as the mobile phase. Lanthanum and cerium are separated with 0.01 M perchloric acid as the stationary phase and heavy lanthanides (lutetium–ytterbium–thulium) are separated using 1.75 M perchloric acid and 0.5 M D2EHPA[68]. In the separation of lanthanides and in the removal of impurity elements from them solutions of DBP in benzene (1 : 1 and 1 : 10)[69] have been employed as the mobile phase in addition to D2EHPA; under certain conditions, it proved possible to separate with their aid cerium(IV)–thorium–UO_2^{2+}, neodymium–UO_2^{2+}, neodymium–praseodymium, cerium(III)–cerium(IV), europium(II)–europium(III), and other mixtures which are normally difficult to separate.

Non-lanthanide impurities (iron, copper, nickel, calcium, mercury, and zinc) in amounts between 10^{-1} and 10^{-2}% have been detected in mixtures of lanthanides[69] using acetone as the mobile solvent.

Actinides

It is of particularly great interest to employ the fast and highly sensitive thin-layer chromatographic method for the analysis of tracer amounts of radioactive elements, particularly short-lived isotopes. However, the number of studies in this field is still very limited[43,70–74].

The combination of thin-layer chromatography for the separation of elements with subsequent radioautographic recording of the spots on photographic (or X-ray) film has proved very successful in the detection of submicroamounts of radioactive elements. At the same time it is possible to employ colour or luminescent reagents[71–74]. The rapidity and simplicity of analysis by this method, the clear-cut separation, and the clarity of the results are the advantages of this procedure compared with other micromethods. Silica gel is usually employed as a carrier for the stationary phases.

In experiments with uranium ores and in the treatment of irradiated nuclear fuel selective separation of uranium from as large a number of other ions as possible is of great importance. It is therefore not fortuitous that several thin-layer chromatographic studies concerning this problem have been made[43,70–72], since the method is very rapid and economical. It has proved possible[72] to separate uranium on a sorbent layer consisting of silica gel and cellulose and fixed with starch from 55 cations (including the most important cations—uranium decomposition products). The mobile solvent was a mixture of hexone [4-methyl-2-pentanone (Ed. of Translation)], and TBP saturated with 4.7 *N* nitric acid. Separation from thallium proved to be impossible under these conditions.

Selective separation of uranium(VI) from a mixture with iron, nickel, cobalt, and zinc in sulphuric acid solution has been achieved using tri-iso-octylamine. This liquid amine has been particularly effective in experiments by the phase reversal method designed to separate uranium from molybdenum, cobalt, nickel, zirconium, thorium, and other elements[71]. In connection with the development of studies on the synthesis of new transplutonium elements, the problem of the separation of microamounts of the transplutonium elements from the main bulk of uranium or plutonium and also from the fission products is of undoubted interest. The possibility of the separation of microgramme amounts of uranium and plutonium from tracer amounts of americium and curium by thin-layer chromatography on silica gel using a mixture of TBP and benzene as the mobile solvent has been demonstrated[73].

The extraction of plutonium and its separation from uranium and other elements present at the same time by the thin-layer chromatographic method proposed by Volynets and Milyukova[74] can be usefully carried out in studies on solutions of complex composition with high β- and γ-activity when it is desirable to work with minimal volumes for reasons of safety. In the system 3 M nitric acid–23% solution of TBP in Synthin it is possible to separate quantitatively by this method plutonium(IV) and plutonium(VI) from plutonium(III). By combining the partition of plutonium(IV) in the systems 3 M nitric acid–23% TBP solution in Synthin and 1 M perchloric acid–23% TBP solution in Synthin with a single pass of the mobile phase, it is possible to separate quantitatively plutonium from uranium, lanthanides, zirconium, nickel, lead, copper, chromium, and iron and to determine radiochemically its amount in the spot with an error of ±10–15%. The duration of analysis of 0.03 ml of the initial solution is 60–90 min.

Heterovalent Forms

One of the interesting fields of application of the thin-layer chromatographic method is the separation of elements in various valence states. Studies have been made on the separation by this method of the heterovalent forms of mercury, arsenic, antimony, chromium, selenium, tellurium, iron, plutonium, cerium, and europium (Table 1). Usually the separation is very clear-cut. Silica gel fixed to the plate with starch or gypsum is most often employed as a sorbent.

Complete and Systematic Analysis of Cations

Some of the studies on inorganic thin-layer chromatography deal with the behaviour of large groups of cations and anions under particular conditions[78–86]. The chromatographic behaviour of many ions has been studies on thin cellulose or silica gel layers impregnated with both neutral organophosphorus compounds (TBP, tri-n-octylphosphine oxide, and others[81,83]) and liquid ion exchangers (amines, alginic acid, etc.), using solutions of hydrochloric, nitric, sulphuric, hydrobromic, hydriodic, thiocyanic, perchloric, and other acids[71,80,82,84,85].

The separation of a number of cations and anions having similar properties by thin-layer chromatography on organic and inorganic ion exchangers (Dowex-1 × 10, Dowex-50, Chelex 100, zirconium hydroxide, and others) has been described[87]. The effects of the composition of the eluents on the chromatographic behaviour of a large group of cations on cellulose have been investigated[86,88].

Methods for the separation of a wide variety of numerous combinations of elements have been suggested on the basis of such systematic studies and the determination of the differences in the behaviour of ions.

For qualitative semimicroanalysis, it has been suggested that 40 cations and 19 anions be detected by circular thin-layer chromatography with a duration of analysis, including the time required for the preparation of the solution to be analysed, of 2–3 h (duration of chromatographic process 2 min).

The principles governing the choice of sorbents and solvents for optimum chromatographic separation have been

described[89]. The most compact and in practice most convenient graphical presentation of the results has been adopted, for example, in Refs. 82, 83, and 90.

The present author believes that the value of such systematic studies consists in the fact that, on the basis of known R_f data, it is possible to choose rapidly the conditions for the separation of many mixtures of elements in the solution of specific problems. Thus Brinkmann et al.[82] demonstrated in a series of qualitative separations the suitability of the recorded R_f values for analysis by thin-layer chromatography in hydrochloric acid solutions on liquid anion exchangers (nickel–cobalt–manganese–zinc, nickel–cobalt–copper–manganese–iron, aluminium–indium–gallium, aluminium–titanium–uranium–iron, aluminium–uranium–iron–zirconium, copper–cadmium–lead–bismuth–mercury, lead–bismuth–tin–cadmium, zinc–cadmium–lead, arsenic–antimony–tin, arsenic–antimony–bismuth, and many two-component mixtures have been separated). Naturally, the separation should be carried out under standard conditions.

2. SEPARATION OF ANIONS

After the thin-layer chromatographic layer had been successfully applied in inorganic analysis for the separation of cations, studies began on its employment for the separation of anions. The thin-layer chromatography of a number of inorganic anions has been investigated[91,92]. Halides and pseudohalides, halogen oxy-acids, phosphates, sulphates, polythionates, and others have been separated by this method (Table 2).

Cellulose, starch, and silica gel are usually employed as sorbents. Ion-exchange resins have also been used to separate chlorine-36, bromine-82, and iodine-131.[55]

In the separation of anions the mobile solvents should be more polar than in the separation of cations because anions are less solvated and have a lower capacity for the formation of solvate systems with solvents other than water[93,94]. Usually systems containing methanol, acetone, water, and ammonium hydroxide are employed in the separation. Only iodides show a tendency to migrate also in non-polar solvents.

Among special procedures used to separate anions, mention should be made of *precipitation chromatography* for the separation of I^-, Br^-, Cl^-, and PO_4^{3-} on silica gel powder impregnated with silver nitrate as the precipitant[107] and *two-dimensional chromatography* of mono-, di-, and tri-phosphoric acids on a thin layer of cellulose[108]. The following mixtures of radioactive anions have been successfully separated: Cl^-, SO_4^{2-}, and PO_4^{3-};[109] Cl^-, ClO_2^-, ClO_3^-, and ClO_4^-;[106] I^-, IO_3^-, and TeO_3^{2-}.[110]

In the study of halides it was established that the R_f values increase with the atomic weight of the anion and are almost independent of the cation. The separation of halides from cations on cellulose is due to a cation-exchange process. In thin-layer chromatography on cellulose (in contrast to paper chromatography) there is a possibility of complete separation of cations from anions due to the larger area of contact and the larger number of exchange steps per unit length.

Phosphates cannot be separated on a sorbent layer fixed with gypsum since insoluble calcium phosphate is formed. Usually in such cases the sorbent is fixed with starch. Whereas on paper the separation of condensed phosphates with $n = 1–8$ and $n > 8$ is possible over a period of 16 h, thin-layer chromatography takes 1 h.

The possibility of separating and detecting micro-amounts of twenty inorganic anions has been investigated[92].

3. THIN-LAYER CHROMATOGRAPHY OF COMPLEX COMPOUNDS

As already mentioned earlier, certain elements have been separated in the form of complexes[111]. Thus, when suitable mobile solvent systems were selected, it proved possible to separate the dithizonates of arsenic, antimony, and tin[58], cadmium, copper, cobalt, mercury, manganese, nickel, zinc, lead, and bismuth[112,113], silver, gold, palladium, and platinum[49], 1-nitroso-2-naphthoxides of cobalt, nickel, manganese, and iron[29,37], diethyldithiocarbamates of chromium, manganese, iron, cobalt, copper, zinc, silver, cadmium, mercury, lead, calcium, magnesium, bismuth, tin, and antimony[114,115], cyanide complexes of iron[116,117], certain Complexonates, in particular those of cobalt, rhodium, and platinum[53], cobalt(II) and cobalt(III), manganese(II) and manganese(III)[116,117], acetylacetonates of iron, cobalt, and chromium[116,117], and other complexes. The square planar complexes of platinum(II) and palladium(II) have been separated by thin-layer chromatography[118].

The use of the thin-layer chromatographic method for the fine separation of geometrically isomeric complexes, namely the *cis- trans*-isomeric complexes of cobalt[119,120] and platinum[121], is of great interest. The purity of the preparations may be determined and the hydration and hydrolysis of these complexes may be investigated by thin-layer chromatography. The stoichiometric composition of palladium(II) complexes with certain phosphorus-containing organic compounds has been studied[122]. The composition of the palladium(II) phosphorodithioate complex has been determined as 1 : 1 by thin-layer chromatographic versions of the isomolar series and molar ratio methods.

The examples quoted above evidently do not exhaust the possibilities of thin-layer chromatography in studies on complexes, but the rate of development of studies in this field is still inadequate.

4. THIN-LAYER CHROMATOGRAPHY AND RADIOCHEMICAL METHODS

Since thin-layer chromatography permits the separation and identification of small amounts of substances, this micromethod constitutes a good auxiliary procedure in radiochemistry. With its aid, it is possible to separate also inactive substances labelled with radioactive isotopes. The recording in some way (radiometry, radioautography) of the emission by the components separated on the chromatogram constitutes an excellent, highly sensitive method for their detection.

The possibility of a rapid chromatographic process and of recording particle tracks in thick-layer emulsions makes the method attractive for the separation and detection of short-lived isotopes. The principle of the separation of inactive and active substances is the same. The studies on thin-layer chromatographic radiochemical analysis have been reviewed[123].

Thin-layer chromatography and the radiochemical method may be combined in two versions[124]: (1) radioactive substances are separated on a plate and then determined; (2) inactive substances separated on a plate are converted into active substances and then determined. In the latter case one may use in principle either the so called method of radiochemical reagents or irradiation with neutrons. Both these methods are still relatively little employed because of technical difficulties. When the chromatogram is irradiated with neutrons, the impurities contained in the sorbent are also activated and interfere. The method of radiochemical reagents also imposes certain requirements: the sorbent must be inert and the excess reagent must be readily removed. Because of these requirements, the radiochemical reagent method has limited applicability. Mercury, copper, and cadmium separated on a plate have been determined by treatment with $H_2{}^{35}S$ prepared in a special apparatus from $ZN^{35}S$ and 2 *N* sulphuric acid[124].

The methods for the separation of radioactive substances are more numerous. They are all largely associated with the separation of mixtures of elements produced by radioactive breakdown. For example, thorium-234 (decomposition product) has been separated by thin-layer chromatography on silica gel in 25 minutes from small amounts of uranyl nitrate with the aid of a mixture of solvents consisting of ether, water, and TBP[109]. Chlorine-38, sulphur-35, and phosphorus-32, produced by irradiation of ammonium chloride with neutrons[109], can be successfully separated. The elements are detected in the chromatogram radiometrically and are identified by their half-lives.

In studies by thin-layer chromatographic and radiometric methods of the chemical behaviour of sodium pyrophosphate and sodium salts of chlorine acids (solid specimens and solutions) during neutron activation[106], higher phosphates were not detected among the reaction products and only $P_2O_7^{4-}$, PO_4^{3-}, and PO_3^{3-} were separated and identified. The presence of cations (copper, zinc, and magnesium) had a catalytic effect on the cleavage of pyrophosphate on irradiation and influenced the quantitative ratios of various forms. After irradiation of the solid salts and solutions of NaCl, $NaClO_2$, $NaClO_3$, and $NaClO_4$, the radioactivity of Cl^- ions was found to be maximum in all cases. The addition of Cu^{2+} ions increased the extent of formation of chloride.

Examples of the separation of microamounts of two- and multi-component mixtures of radioactive substances without a carrier, which are of interest for radiochemists ($^{140}Ba-^{140}La$, $^{133}Ba-^{133}Cs$, $^{47}Ca-^{47}Sc$, Sr–Y, $^{72}Zn-^{72}Ga$, $^{95}Nb-^{182}Ta$, $^{95}Zr-^{95}Nb$, $I^--IO_3^--TeO_3^{2-}$, $SO_4^{2-}-PO_4^{3-}$, etc.) have been quoted[110]. The positions of the zones containing various elements were established automatically with the aid of a counter and a pen recorder.

In order to follow the separation of the test elements, radioactive isotopes may be introduced into the solution and their emission can be used to investigate by radiometric and radioautographic methods the distribution of the mixture components on chromatograms, as was done, for example in Refs. 69, 125, 126, and others.

For radioautographic detection of spots, use is usually made of an X-ray film, which remains in contact for a specified time with the chromatographic plate and is then developed in the usual way. A semiquantitative visual analysis and photometric quantitative measurements may be made on the basis of the intensity of the blackening of the spots under the influence of the radioactive emission.

5. ELECTROPHORESIS OF INORGANIC IONS

One of the promising trends in the development of the thin-layer chromatographic method is thin-layer electrophoresis. A description of the equipment for and technique of electrophoresis in a thin layer of carrier may be found, for example, in Refs. 127–131. Electrophoresis in a thin layer of carrier (both low- and high-voltage) differs little in experimental technique and apparatus employed from paper electrophoresis but does have a number of characteristic features: the layer of carrier on the plate may be impregnated with a larger amount of electrolyte than paper and because of this the electric field may be applied for longer periods (without risk of rapid drying of the layer), which in turn increases the effectiveness of the separation. The absence of a fibrous structure in the carrier eliminates diffusion-dependent spreading of the spots, so that the zones of the elements separated are more compact than in paper electrophoresis and the separation is more clear-cut. Owing to the greater capacity of the carrier layer compared with paper much greater amounts of the substances may, if necessary, be deposited for separation without the formation of diffuse spots. This is very important in the analysis of highly pure specimens where it is necessary to separate very small amounts of impurities. As a result, it is possible to achieve a much greater analytical sensitivity than in paper electrophoresis.

The possibility of varying the carrier is another advantage of inorganic thin-layer electrophoresis. Acetylcellulose[132] and cellulose[131], quartz sand[129], starch[133], heteropolyacid salts[134], kieselguhr[131], silica gel with starch[135,136] or with gypsum[137], a mixture of Teflon and cellulose[138], and photographic gelatine[139] have been used as carriers in this method.

Various mixtures of cations and anions can be satisfactorily separated by thin-layer electrophoresis (Table 3).

The separation of elements by electrophoresis is based on the difference in the stabilities of the complexes formed by the ions of the elements with a complex-forming agent (electrolyte) and in the case of alkali metals on the different degrees of association of the ions with the electrolyte anions[140].

The association constants of alkali[141] and alkaline earth[142] metal ions have been determined by the electromigration method from the mobilities.

Combination of thin-layer electrophoresis with thin-layer chromatography in two-dimensional separation has not been described in inorganic analysis but may prove to be useful.

III. QUANTITATIVE INORGANIC THIN-LAYER CHROMATOGRAPHY

The thin-layer chromatographic method for the separation and concentration of ultramicroamounts of substances is particularly important when combined in a rational manner with quantitative methods for the determination of the separated components. While inorganic thin-layer chromatography is widely used for a qualitative characterisation of chemical mixtures, the quantitative applications of this method have been described in a comparatively small number of publications and mainly in recent years. The method of quantitative microanalysis with the aid of thin-layer chromatography is employed in two versions: analysis after removal from the sorbent of the separated components and direct determination on the plate[143–145].

1. DETERMINATION OF SUBSTANCES AFTER ELUTION FROM THE ADSORBENT

In this case the substance to be determined is first removed from the adsorbent by elution with a suitable solvent from the zone on the plate where it was localised.

Table 3. Thin-layer electrophoresis

Elements separated	Carrier	Electrolyte	Potential gradient, V cm^{-1}	Duration, min	Method of detection	References
Rb and Cs	quartz sand	3.5×10^{-3} M solution (w.r.t.W) of ammonium paratungstate	19	18	radiometry	129
Ditto	ditto	0.34 M $K_4Fe(CN)_6$ + 0.052 M KNO_3	8.5	30	ditto	140
Li, Na, K, Rb, Cs	silica gel G	NH_4Cl + HCl buffer solution (pH 2.18) in 1 : 2 propylene glycol–water mixture	circular electric field with a potential of 400–500 V and a current of 40–45 mA		spraying with colour and luminescent reagents	137
Na, K, Rb, Cs	heteropoly acid salts	0.001–0.1 M NH_4NO_3	50	20	radioautography	134
Lanthanides	acetylcellulose (cellogel)	0.2–0.8 M solution of α-hydroxy-isobutyric acid	40–70	~30	radiometry, radioautography	132
	cellulose	1.1 M solution of α-hydroxy-isobutyric acid, pH 2.4	60 (cooling to -10°)	120	ditto	138
32 cations	ditto	0.1 M solution of α-hydroxy-isobutyric acid	50	20	spraying with 1% ethanol solution of 8-hydroxyquinoline, NH_3 vapour, u.v.light	131
20 cations	silica gel + starch	0.15 M citric acid solution	1200 V/30 cm	20	spraying with suitable reagent	135
33 cations and 13 anions	kieselguhr	0.05 M solution of lactic acid (cations); 0.1 *N* NaOH (anions)	13–45	from 2 to 5	radiometry	130
IO_3^- and IO_4^-	Alabaster (Ignited gypsum)	0.05 M $(NH_4)_2CO_3$	300–400 V/30 cm	90–120	radiometry	128
20 anions	silica gel S–HR and starch	0.05 M Na_2CO_3	1000 V/30 cm	20	colour reactions	136

Usually the sorbent is scraped off along the outline of the spot and then transferred to the elution vessel. In the resulting solution the substance is determined by one of the sensitive (usually instrumental) methods, for example spectrophotometrically, polarographically, etc. Precautions must be taken to prevent losses in the transfer of the sorbent on the one hand and to ensure complete extraction on the other. The effect of impurities which are also eluted from the sorbent is screened off by using selective and specific methods for the determination of the relevant element.

This method is more time consuming than direct determination on the chromatogram, is more complex, and may involve certain losses of the substance but at the same time it allows determination of the isolated components by highly sensitive and accurate micromethods. To reduce the errors in this version of quantitative thin-layer chromatography, special devices are employed to elute the substances from the chromatographic zones[146–148].

Two methods have been described for the isolation of the components from the layer of adsorbent by additional elution[149]. In the first method after elution of the mixture in a vertical direction the adsorbent layer is dried, part of the adsorbent around the spots (visible in ultraviolet light) is removed, and a pentagon cut out from ashless filter paper is placed on the adsorbent near the spot. The plate with the adsorbent and the paper is covered by glass and with the aid of a paper bridge horizontal elution with a fast-acting eluent, which displaces the components from the adsorbent to the upper part of the paper pentagon, is carried out. The part of the paper containing the substance is cut off and the substance is extracted with a suitable solvent. In the second method the additional elution from the adsorbent layer containing the spots is carried out in an open chamber with a fast-acting eluent. The substance is concentrated in a small part of the layer which is then scraped off the plate. The substance is extracted from this part of the adsorbent by the usual methods.

The substances eluted from the adsorbent in one way or another are determined by different procedures. In some investigations[150–153] microgramme amounts of nickel, uranium, cobalt, and bismuth were determined spectrophotometrically with morpholine-N-dithiocarbonate after their separation from other elements of the $(NH_4)_2S$ or H_2S groups on cellulose powder. Condensed phosphates have been determined as phosphomolybdenum blue[101] after elution from a layer of cellulose powder.

In the analysis of the components of semiconductor alloys, gold was determined[154] (after separation of other elements) by oscillographic inversion polarography.

After removal from the plate of the section of sorbent containing the substance to be determined, the latter can be determined with fairly high accuracy without elution. For this purpose, thin-layer chromatography is combined with reflection spectroscopy. The separation is usually carried out on cellulose or silica gel layers. After the detection of the element with the aid of a suitable reagent, the layer with the spot is taken off the plate, ground carefully in an agate mortar to a homogenous mixture, and placed in the reflection cell of a spectrophotometer. Usually between 0.05 and 6–10 μg of the test substance is determined with a relative error of ±2–6%. For example, the following substances have been determined by this method: aluminium, bismuth, cadmium, chromium, cobalt, copper, iron, lead, manganese, mercury, nickel, silver, tin, and zinc[155]; chromium[156]; iron, nickel and cobalt[157]; copper, nickel, and zinc[158].

Very high sensitivity was achieved in the determination of uranium in minerals using activation analysis[159]. Uranium separated quantitatively from impurities on a thin layer of silica gel was carefully transferred from the plate together with the sorbent into a polyethylene bag and was irradiated in a reactor with a neutron stream (1.7×10^{12} neutron $cm^{-2}s^{-1}$) for 30 min. The amount of uranium in the sample was determined from the activity of the neptunium-239 formed from the uranium. A calibration curve relating the area of the neptunium-239 peak at 106 keV to the amount of uranium in the sample was first obtained. The activity was measured 4 h after irradiation.

The sensitivity of the method is 0.02%.

Mass spectrometry is used for the analysis of small amounts of a substance sorbed on a thin layer[160]. The specimen in a thin glass capillary with a sealed end is put in the chamber of the mass spectrometer so that after the evacuation and heating (150–200°C) of the source the sorbed substance is evaporated and enters the electron beam of the source. In this way it is possible to analyse all substances stable at a given temperature and having a vapour pressure $> 10^{-7}$ mmHg.

2. DIRECT DETERMINATION ON THE PLATE

Since sharply outlined small spots of the separated substances are usually obtained in thin-layer chromatography, the components can be successfully determined directly on the chromatogram. This procedure is very rapid. The plotting of calibration curves under rigorously identical conditions lowers the error resulting from the possible non-uniform distribution of the substance in the thickness of the layer. At any rate, we believe that the error in such determination should not exceed the error due to the losses of the substance in the elution process.

Direct determinations on the plate can be carried out by various procedures: (1) by a semiquantitative method involving the visual comparison of the size and colour intensity of the spots with the dimensions and colour of a spot formed in the chromatography of known amounts of the substance; (2) quantitatively from the accurately measured area of the spot; (3) by photometric investigation of the spot (in some cases in ultraviolet light); (4) by measuring the emission of radioactive substances, etc.

In a direct quantitative determination it is particularly necessary to standardise carefully the conditions of the chromatographic processes (uniformity of the thickness of the sorbent layer and its grain size, its purity, and its moisture content, identical times taken by the solvent to traverse the plate, deposition of exact volumes of the solvent, saturation of the chamber with solvent vapour, controlled amounts of the reagent required for development, temperature, etc.).

Some of these procedures will now be considered.

Determinations from the Area of the Spot

The technique of this method is simplest, no special apparatus is required, and the determination is fairly rapid. The content of the substance in the spot is calculated on the basis of the fact that the logarithm of the weight of the substance is a linear function of the square root of the spot area[143].

In this case it is possible to make determinations using a calibration plot (which is best constructed on the basis of data obtained on the chromatographic plate used in the analysis of the test specimen) or by the method of additions (calculation by a formula). An advantage of the second procedure is that it does not require the plotting of a calibration graph and is more accurate.

The spot areas are determined with a planimeter or by superimposing a sheet of transparent paper on the layer outlining the spots, and measuring the areas of the resulting figures by placing the outlines against millimeter paper.

For example, chromic acid has been determined by the method described (from the area of the spot)[161]. The linear relation between the amount of chromic acid and the area of the coloured spot was found to hold in the range 50–300 μg of CrO_3. The error of the determination was ±6%.

The method has been used to analyse mixtures of potassium and magnesium acetates[143] and also for the determination of 1–7 mg of PO_4^{3-} per litre in the presence of chloride ions and 1–5 mg ml^{-1} each of I^-, Br^-, and Cl^-, when these were present simultaneously, after separation of the anions by thin-layer precipitation chromatography[107].

Densitometric Method

After the development of the spots on the chromatograms with colour reagents, the substances are determined from calibration plots with the aid of special devices (densitometers) using a linear relation between the dimensions and colour intensity of the spot on the one hand and the amount of the element contained in it on the other[162].

Nickel, cobalt, copper, lead, manganese, chromium, mercury, zinc, bismuth, iron, barium, and strontium have been determined in this way[163]. In the determination of 0.1–3.2 μg of the element the possible error is in the range between 0.2 and 2.1%. Densitometric measurements on a chromatogram with the aid of a chromoscan [chromoscope? (Ed. of Translation)] have been made after separation of microgramme amounts of iron, nickel, and cobalt[164].

A special device described by Pataki and Kunz[165] may be used for a direct quantitative determination on thin-layer chromatograms of spots containing fluorescent substances.

The Radiochemical Method

Spots containing radioactive substances are scanned directly on the chromatograms with the aid of special apparatus whereby the content of the given element may be found from the distribution of radioactivity on the plate. An example of the application of this method[166] is the determination of $^{125}I^-$.

3. ANALYSIS OF NATURAL AND TECHNICAL MATERIALS BY THIN-LAYER CHROMATOGRAPHY

Very few studies have so far been made in this field. In many cases when the weight of the test objects is very small, the chromatographic micromethod for the separation of elements in combination with highly sensitive methods for the subsequent quantitative determination proves to be very promising. The simplicity and rapidity of the method make it suitable for large scale analysis.

Analysis of Natural Objects

The thin-layer chromatographic method combined with densitometric determination of the elements directly on the chromatogram may be used to analyse the magnetic fraction of cosmic dust (the iron–nickel–cobalt system)[164]. The weight of the specimen analysed (cosmic spheres found in the region where the Tunguska meteorite fell) was 3–10 μg. The separation was carried out on a thin layer of KSK silica gel fixed with starch. The mobile solvent was a 99 : 1 mixture of acetone and 3 *N* hydrochloric acid. The duration of the chromatographic process was 15–20 min. The elements were detected by spraying with solutions of rubeanic acid and 8-hydroxyquinoline. The average relative error of the determination at the 0.95 confidence limit was ±22% for iron, ±15% for nickel, and ±9% for cobalt.

Thin-layer chromatography has been used for the qualitative analysis of sulphide ores and minerals[167], as well as for the quantitative determination of tellurium in minerals containing mercury (cinnebar)[126], using TBP-benzene mixture (3 : 7) to separate tellurium from Hg, Au, Sb, As, and Bi. Microgramme amounts of tellurium were determined spectrophotometrically with bismuth II after elution from the sorbent; for a 100 mg sample the accuracy was within ± 10%.

The possibility of semiquantitative analysis of water (including natural water) under field conditions using microcrystalline cellulose as a sorbent has been investigated[168]. The mobile solvent for the separation of the cations was a solution of Complexon(III) [sodium salt of EDTA (Ed. of Translation)] in dilute nitric acid to which was added dioxan and antipyrine or a solution of *sym*-collidine in nitric acid. A mixture of ethanol, pyridine, water, and concentrated ammonia was used to separate the anions. After spraying with a suitable reagent, calcium (10 mg ml^{-1}), magnesium and iron (1 μg), aluminium (0.02 μg), manganese (0.3 μg), Cl$^-$ (5 μg), SO$_4^{2-}$ (20 μg), PO$_4^{3-}$ (25 μg), F$^-$ (5 μg), NO$_3^-$ (10 μg), and SO$_3^{2-}$ (100 μg) were determined visually.

Analysis of Technical Materials

Thin-layer chromatography has been used[154] to separate microgramme amounts of components of semiconductor alloys based on lead, tin, and indium. The following mixtures have been separated on a thin layer of silica gel fixed with starch using various eluents: lead–gallium; lead–antimony; lead–tin; tin–zinc; tin–gallium; tin–indium; tin–gold; tin–arsenic; indium–aluminium. The possibility of a quantitative determination of the elements (after elution from silica gel) by oscillographic inversion polarography has been demonstrated for gold. In this determination the standard deviation was 2.8%.

In the analysis of technical preparations of lanthanides (neodymium and yttrium oxides) by thin-layer chromatography, non-lanthanide impurities (iron, copper, mercury, zinc, and calcium) were detected when their content in the lanthanide mixture was 10^{-2}–10^{-1}%.[69]

Thin-layer chromatography can be conveniently employed in the analysis of highly pure materials at the stage of separation where the main bulk of the interfering elements has already been separated by some other procedure. This was done, for example, in the determination of 10^{-3}–10^{-5}% of lanthanides in highly purified uranyl nitrate[125]. The initial salt sample taken for analysis weighed 0.05–5 g. The main bulk of uranium (90–95%) was separated by preliminary extraction and the final separation of milligramme amounts of uranium and microgramme amounts of lanthanide impurities was achieved by repeated ascending thin-layer chromatography on silica gel with a mobile solvent consisting of a 5 : 95 TBP–benzene mixture. The sum of lanthanides remaining at the starting point after elution from silica gel was determined spectrophotometrically with Arsenazo III or Arsenazo M. The standard deviation was about 5–8%.

IV. POSSIBLE APPLICATIONS OF THIN-LAYER CHROMATOGRAPHY IN ANALYTICAL AND INORGANIC CHEMISTRY

On the basis of our own experience and the literature, we believe that the rapid and simple thin-layer chromatographic method will be used in future in combination with sensitive quantitative analytical methods (luminescence analysis, spectrophotometry, polarography, radiography, mass-spectrometry, etc.) and in different versions (partition, ion-exchange, precipitation, multi-dimensional, and gradient chromatography, thin-layer electrophoresis, etc.) for the following purposes: (1) as a method for the separation and concentration of substances and the analysis of various natural and industrial micro-objects using samples down to 10^{-5}–10^{-6} g (minerals, inclusions, articles produced in semiconductor engineering and electronics, etc.); (2) for the rapid separation and identification of short-lived radioactive elements (for example transplutonium elements) with radioautographic detection of the elements on a thick layer of emulsion; (3) as a rapid control method for the determination of the purity of preparations at different stages of the purification of substances (probably largely with a sensitivity of 10^{-2}–10^{-3}%); (4) in a preparative version for the separation of milligramme amounts of elements free from specified impurities (for example in the preparation of standards); (5) for the investigation of the chromatographic behaviour of compounds of metal ions in different valence states (in particular in the study of the disproportionation of elements); (6) for the investigation of problems of complex formation, the mechanism and kinetics of sorption, many other theoretical questions, etc.

---o0o---

During the preparation of this review for the press, a number of studies were published, the most interesting of which are listed below.

Transition elements: iron–copper, cobalt–copper, iron–cobalt, and cobalt–lead mixtures have been separated by thin-layer chromatography[169]; the glycinate complexes of cadmium, cobalt, copper, nickel, platinum, and zinc have been separated on cellulose layers[170]; chromium, iron, zinc, and nickel have been separated on carboxymethyl- and DEAE-cellulose[171]; manganese and mercury[172], the noble metals[173–179], and rhenium, molybdenum, tungsten, and vanadium[180–182] have been separated; zirconium has been isolated and separated from scandium, yttrium, thorium, uranium, and the lanthanides[183]; cations of analytical groups III and IV have been separated by thin-layer ion-exchange and precipitation chromatography[184].

Non-transition elements: microgramme amounts of indium have been separated from iron, aluminium, gallium, and titanium on cellulose layers[185]; arsenic, antimony, and tin have been separated in the form of pyrrolidinedithiocarbamates[186]; arsenic, antimony, and bismuth[187] and selenium and tellurium[188,189] have been separated.

Lanthanides and actinides: scandium, yttrium, the lanthanides, thorium, and uranium have been separated[190,191].

Heterovalent states: tellurium(IV) and tellurium(VI)[192] and arsenic(III) and arsenic(V)[193] have been separated; the separation of iodine in various states of oxidation has been achieved[194].

Systematic thin-layer chromatography: a number of studies have been made on the systematic thin-layer chromatography of many cations[195–201].

Anions: the sorption behaviour of twenty seven inorganic anions has been investigated[202]; the behaviour of halides[203] and phosphates[204] has been studied.

Radiochemistry: a number of papers have been published on the combination of thin-layer chromatography and radiochemistry[280–210].

Thin-layer chromatography of complexes: the separation of various cations in the form of complexes has been described—as glycinates[170], pyrrolidinedithiocarbamates[186], diethyl dithiocarbamates[211], complexes with salicylaldoxime[212], diketonates[213,214], pyridylazonaphthoxides[215,216], EDTA complexes[217], and others[218–220].

Quantitative thin-layer chromatography: spectrophotometric determination of iron[221,222]; densitometric determination of zinc[223,224]; determination of aluminium, beryllium, and chromium[225]; determination of metal ions in water[226]; analysis of minerals[227].

Thin-layer electrophoresis: this has been used to separate iodine in different states of oxidation[194] and the mixtures[228] ^{90}Sr–^{90}Y and ^{212}Rb–^{212}Bi.

The Structure of Hydrazones

Yu.P.Kitaev, B.I.Buzykin, and T.V.Troepol'skaya

The review surveys the present state of research on the conformation, isomerism, and intramolecular interactions of molecules of the immense class of organic compounds containing a hydrazone group. A list of 221 references is included.

CONTENTS

I. INTRODUCTION

Compounds whose molecules contain the hydrazone grouping

$$>C=N-N< \qquad (I)$$

belong to the huge class of azomethines and are distinguished from other members of this class (imines, oximes, etc.) by the presence of two interlinked nitrogen atoms.

Being very readily available substances, hydrazones have found wide application in synthetic chemistry for the preparation of compounds of most diverse structure, and in analytical chemistry for the identification and isolation of carbonyl compounds, and for the detection of a large number of metal cations. Their application has been reported as plasticisers and stabilisers for polymers, polymerisation initiators, antioxidants, etc. However, the most valuable property of hydrazones is, perhaps, their great physiological activity. Among them are found herbicides, insecticides, nematocides, rodenticides, and plant growth regulators. The value of hydrazones in fighting tuberculosis is well known. Substituted hydrazones have been found to exhibit spasmolytic activity, hypotensive action, and activity against leukaemia, sarcomas, and other malignant neoplasms. The possibility is being investigated of using substituted hydrazones for the treatment of schizophrenia, leprosy, and other illnesses.

An attempt is made in the present review to consider on a uniform basis compounds in which the hydrazone group (I) is present in an open chain, and only the outermost atoms of the system can form part of rings. For convenience we shall henceforward term the nitrogen atom in the azomethine group the imine nitrogen, and the other atom the amine nitrogen.

The triatomic hydrazone group is characteristic of a large number of organic compounds of the type

$$\begin{matrix} R \\ X \end{matrix}\!\!>C{=}N{-}N\!<\!\!\begin{matrix} R' \\ Y \end{matrix} \qquad \text{(II)}$$

where R, R′, X, and Y can vary widely. We will use the term "hydrazones" as a general name for compounds having the structure (II). When R′ = Y = H we have "unsubstituted hydrazones"; when R′ = Alk(Ar, Az) and Y = H, "alkyl(aryl, acyl)hydrazones", and when R′ = Alk (Ar, Alk, Alk) and Y = Alk(Ar, Ar, Az) "dialkyl(diaryl, alkylaryl, acylalkyl, etc.)hydrazones"; and also with X = H we have an "aldehyde hydrazone", with X = Alk, Ar, Az a "ketone hydrazone", and so on. If R′ = NH_2CO the compounds (II) are semicarbazones, and if R′ = NH_2CS they are thiosemicarbazones. Dihydrazones of α-dicarbonyl compounds are usually termed "osazones".

Where X = Hal, NO_2, OAlk, OAr, the compounds are α-halogeno-hydrazones† or α-nitro(alkoxy, aryloxy)-hydrazones; when X = N : NR they are formazans, X = NHNHR hydrazidines, X = NH_2, NHR, NRR′ amidrazones; and with X = OH, SH hydrazides and thiohydrazides are formed. Furthermore, R′ and Y may together constitute the residue of a carbonyl compound, in which case the structure (II) acquires the form (III), and compounds of this class are termed "azines":

$$\begin{matrix} R \\ X \end{matrix}\!\!>C{=}N{-}N{=}C\!<\!\!\begin{matrix} R' \\ X' \end{matrix} \;; \qquad \text{(III)}$$

with R = R′ and X = X′ they are symmetrical, or simply azines of the carbonyl compounds (aldazines, ketazines); and when R ≠ R′ and X ≠ X′ we have mixed azines. Thus in naming the hydrazone we first state the name of the carbonyl compound and then name the substituents attached to the nitrogen atom together with the word "hydrazone", e.g. ethyl isopropyl ketone methylphenylhydrazone‡

$$\begin{matrix} i\text{-Pr} \\ \text{Et} \end{matrix}\!\!>C{=}N{-}N\!<\!\!\begin{matrix} \text{Ph} \\ \text{Me} \end{matrix} \;. \qquad \text{(IV)}$$

In present-day chemical literature there is an increasing tendency to name hydrazones more briefly and independently—aromatic arylhydrazones (II: R = R′ = Ar; X, Y = H or Ar), aliphatic arylhydrazones (II: R = Alk; R′ = Ar; Y = H or Ar; X = H or Alk), aldhydrazones (R′ = X = Y = H), ketohydrazones (R and X = Ar, Alk, etc.; R′ = Y = H), keto-acylhydrazones (R and X = Ar, Alk, etc.; R′ = Az; Y = H), etc.—although a special nomenclature has not yet been developed.

It is undoubtedly impossible to give in a single paper an exhaustive review of the literature on the structure and the chemistry of hydrazones, and therefore the authors have not pursued this aim. However, the absence of generalisations of the numerous fresh results on the structure of hydrazone molecules has led us to make an attempt at a systematic discussion. Still, individual aspects of the structure and especially the chemistry of certain types of hydrazones have already been considered many times in special reviews [1-18] or incidentally in reviews concerned mainly with other classes of compounds [19-26].

Henceforward we shall usually give references to papers in which earlier results are often critically discussed. The large number of publications on various aspects of the chemistry of hydrazones makes it necessary to examine separately the structure, the chemical properties, methods of preparation, and the application of hydrazones.

II. GENERAL INFORMATION

Unsubstituted hydrazones, alkylhydrazones and certain arylhydrazones, and azines of simple aliphatic aldehydes and ketones are colourless or very slightly coloured liquids possessing a characteristic odour [4,27,28]. The boiling point rises with increase in the molecular weight of R, X, R′, or Y (II). Alkylhydrazones having a branched carbon chain possess lower boiling points than their analogues having a straight chain. The phenylhydrazones of aromatic and heterocyclic aldehydes and ketones are solids, mostly slightly coloured. Several arylhydrazones, especially the 4-nitro- and 2,4-dinitro-derivatives, have a well-developed crystal structure and sharp melting points, so that they are convenient for identifying carbonyl compounds. Carbazones, semicarbazones and thiosemicarbazones, and sometimes azines are used for this purpose.

Unsubstituted hydrazones, alkylhydrazones and certain arylhydrazones, and azines are bases, forming salts with acids. Increase in the electron-acceptor character of R′ and Y is accompanied by a fall in basic strength, p-nitrophenylhydrazones being acidic substances [29]. 2,4-Dinitrophenylhydrazones are weak acids, in which the value of pK_a varies with the nature of R and X [30].

Crystallographic analysis indicates [31-33] that the grouping $>C{=}N{-}N<$ in hydrazones possesses a planar structure, although the coplanarity may break down in certain sterically hindered molecules [31]. The length of the C=N bond in hydrazones depends on the nature of the substituents R, R′, X, and Y, varying between 1.27 and 1.35 Å [31-33], which somewhat exceeds the values of 1.24 [34] and 1.255 Å [35] for aliphatic imines, in which the order of this bond is closer to 2. [35] The presence of a lone pair of electrons on the amine nitrogen atom in hydrazones, capable of conjugation with π-electrons, leads to a decrease in the order of the C=N bond and hence an increase in its length. In 1966 Bayer and Häfelinger [35] correlated the stretching frequences ν with the carbon–nitrogen bond length l and also order p (Fig. 1), which provided a fairly easy method for estimating the variation in length and order of the bond with change in the character of the substituents [14].

Although Bayer and Häfelinger's constructions involved certain assumptions, they yield results which agree quite well with calculations [14] of the bond order by the LCAO-MO method. On the basis of spectroscopic data the latter method of calculation gives estimates of 1.80–1.90 for the order of the C=N bond in hydrazones [9,14].

Less attention has, of course, been paid to the length of the N–N bond in hydrazones, which varies between 1.38 and 1.41 Å [31-33], being rather shorter than in hydrazine (1.46 Å [36]). It is difficult to make any definite statement on the order of the N–N bond, since existing data are insufficient for valid comparisons and conclusions. Calculations by the LCAO-MO method show [9] that this bond order approximates to 1.2 in semicarbazones. The length of the N–C bond (between the amine nitrogen atom

---

†σ-Halogeno-hydrazones are often termed "halogeno-hydrazides" or "hydrazones of acid halides".

‡A better and more succinct name would be "2-methyl-pentan-3-one methylphenylhydrazone" (Ed. of Translation).

and carbon in a substituent R′) is close[31-33] to the values for a C−N single bond (1.47 Å)[37], but it decreases, of course, when conjugation is present between the hydrazone group and the R′ or Y radical, and in methylglyoxal bisamidinohydrazone, for example, it is 1.35 Å.[32] The C=N−N angle is often close to the theoretical value (120°), although cases of substantial deviations are known. In methylglyoxal bisamidinohydrazone and in ribose *p*-bromophenylhydrazone, for example, this angle is 117° [31,32], but in anisaldehyde azine it is 111.2° [33]. Other angles in the hydrazone group are mostly close to the theoretical values, although the observed deviations differ with different types of hydrazones[31-33].

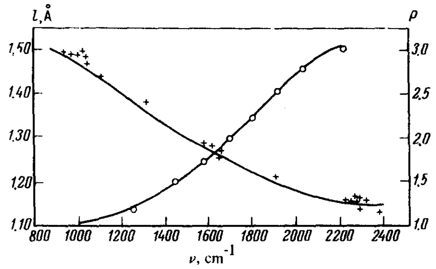

Figure 1. Variation of ν with *l* and *p* for the carbon-nitrogen bond[35].

Because of the specific character of the azines (III) coplanarity of the azine group may be destroyed by rotation of the imine fragments about the N−N bond (Fig. 2) [38,39]. Calculations based on dipole moments show that the angle of deflection of the planes of the imine fragments is $\theta = 60-70°$ in most aliphatic and alicyclic aldazines and ketazines. In benzylideneazine this angle $\theta = 20°$, whereas the molecule of the azine of salicylaldehyde is planar as a consequence of intramolecular hydrogen bonding[39].

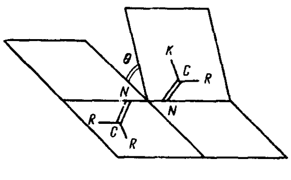

Figure 2. Conformation of azine grouping[39].

It is not possible to estimate the energies of the bonds in the hydrazone group, or to examine the effect of the structure of the molecule on them, since the literature does not contain the necessary data on the group as a whole, while available values of bond energies for the fragments are quite contradictory. The energy of the C=N bond has been given as 94, 132, and 139.5 kcal mole⁻¹ by Pauling, Palmer, and Syrkin respectively (see bibliography[34]). The energy of the N−N bond depends greatly on the nature of the radicals attached to the nitrogen atoms, and varies from 57 kcal mole⁻¹ in hydrazine to 22 kcal mole⁻¹ in hydrazobenzene[40], but has not been determined in hydrazones. This evidently applies also to the energy of the C−N bond in the hydrazone group; the values found for amines lie in the ranges 70−80 and 80−90 kcal mole⁻¹ in aliphatic and aromatic amines respectively[40]. Even from these data it can be concluded that the N−N bond is the weakest in the hydrazone group. The energy of internal rotation about the $=N-N\langle$ bond in the dialkylhydrazones of cyclic ketones appears from the nuclear magnetic resonance spectra to be ~11 kcal mole⁻¹ [41].

The group moment has not been determined for hydrazones, values for the individual bonds being used in the additive vectorial calculation of dipole moments[9,14,39,42,43]. The difference in electronegativity between carbon and nitrogen atoms causes polarisation of the C=N and N−C bonds in the direction of the more electronegative nitrogen atom. Values of μ for the C=N bond in the earlier papers—0.9, 2.40, 2.27, 2.5 D—are extremely contradictory[42,43]. From the dipole moments of aliphatic aldimines Everard and Sutton found that $\mu_{C=N} = 1.4-1.5$ D.[44] Kitaev and his coworkers[43] used the experimental dipole moments of various azomethines to obtain a mean value of 1.5 D. A monograph[45] gives the values $\mu_{C=N} = 1.4$ D, $\mu_{C-N} = 0.45$ D, and $\mu_{H-N} = 1.31$ D.

It is also fairly difficult to reach any conclusion on the group refraction, and calculations are based on values of *R* for the component atoms of the hydrazone group or on the bond refractions $R_D = 3.67$, 1.57, 1.99, and 1.76 for the C=N, C−N, N−N, and N−H bonds respectively[46]. Different authors give values of 8.205, 8.45, and 8.277 [4,46,47] for R_D of the group =N−N= in aliphatic ketazines. Kost and Grandberg[47,48] give such values as

$R_D = 5.871$,

$R_D = 6.245$.

for the hydrazone group in pyrazolines, which can be regarded as cyclic hydrazones.

Considerably more work has been done on the infrared spectra of hydrazones. The hydrazone group does not possess a characteristic absorption band, observations usually being based on that of the C=N bond, and with the monosubstituted compounds also on the N−H bond. Depending on the structure of the surrounding radicals, absorption of moderate intensity by C=N lies in the range 1570−1680 cm⁻¹ [9,14,27,28,35,39,49-75] (see Table 1), and the N−H stretching band in unsubstituted and monosubstituted hydrazones is located in the range 3150−3400 cm⁻¹ [9,43,53,59,69,72,76-78].

In the region of 1600 cm⁻¹ arylhydrazones show superimposition of the absorption frequency due to the azomethine group on that due to the aromatic ring[14,28,53,55,59]. If steric conditions in the hydrazone molecule do not prevent *p*−π conjugation, the frequency of the C=N bond shifts to longer wavelengths[14,28,39,58,61,62,69,70,73]. In alkylhydrazones the structure of the alkyl radicals has little effect on the C=N frequency, whereas the structure of the radicals in the carbonyl component has a substantial effect[69]. The C−N absorption band in hydrazones lies in its usual range, and is considered only in a complete interpretation of the spectrum[59,72]. In this connection the band in the range 1525−1550 cm⁻¹, which sometimes produces a different interpretation[54], has recently been assigned to N−H deformation vibrations alone or together with C−N vibrations[51,68,72].

* Bis-2,4-dinitrophenylhydrazones of α-dicarbonyl compounds.

Considerably less work has been done on the Raman spectra than on the infrared spectra of hydrazones. Lines attributable to C=N absorption occur in the range 1610–1660 cm^{-1} in the Raman spectra (see Table 1) [14,39,53,79-83]. These spectra enable absorption due to C=N in arylhydrazones to be distinguished from that due to the aryl ring system, which, as already mentioned, is not possible from the infrared spectra.

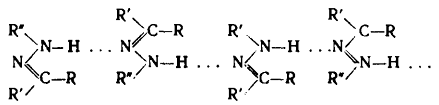
In the near ultraviolet hydrazones usually have two absorption bands, but sometimes a third may appear, or even only one band (Table 1) [14,28,49,57,65-67,76,84-98].

The presence of unsaturated groups capable of conjugation—in any radical of the hydrazone structure—results in a bathochromic shift in the absorption maximum (Table 1). The introduction of electron-acceptor substituents into the phenyl ring of the hydrazones of aromatic aldehydes and ketones has an analogous effect, which is most clearly developed with *para*-substitution[49,84,87,89,93-96,99]. Only a slight bathochromic displacement of λ_{max} but a very considerable increase in intensity of absorption occur[88] on passing from the mono- to the bis-2,4-dinitrophenylhydrazones of α-dicarbonyl compounds.

Nuclear magnetic resonance has been applied many times and extremely usefully to study of the structure of hydrazones[28,100-102]. Without discussing in detail the proton magnetic resonance spectra of hydrazones, we note merely that the chemical shift due to the aldehyde proton in the hydrazones of aldehydes (I: X = H) is τ = 3.2–3.8 ppm, and that due to the NH proton in monosubstituted and unsubstituted hydrazones is considerably more affected by surrounding groups[38,100-102].

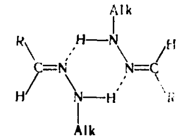
III. HYDROGEN BONDING

The presence of C=N and N–H groups in monosubstituted and unsubstituted hydrazones makes intermolecular hydrogen bonding possible. Several alkylhydrazones and phenylhydrazones are in fact associated in the liquid state, and in solutions molecules of the solvent are involved in the association[69,99-108]:

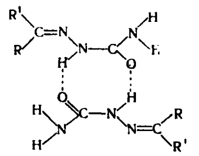


where R, R′ = Alk and R″ = Alk, C_6H_5. The stability of the resulting complexes depends both on the structure of the hydrazone and on the nature of the solvent. With phenylhydrazones, for example, the stability diminishes in the sequence of solvents—dimethyl sulphoxide > acetone > pyridine > nitrobenzene > chlorobenzene > isodurene[102].

It has been suggested that dimers are formed by intermolecular hydrogen bonding of the *syn*-form

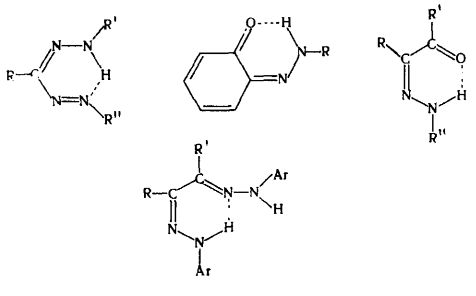


in solutions of the alkylhydrazones of aliphatic aldehydes[69]. The formation of dimeric together with linear association complexes is observed in solutions of semicarbazones



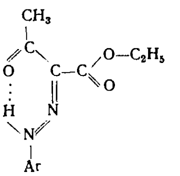
the former being the more stable[9].

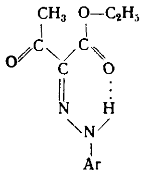
A strong intramolecular hydrogen bond is present in formazans[1,2,109], osazones[110], and monoarylhydrazones of *o*-quinones, semicarbazones, thiosemicarbazones, alkylhydrazones, and arylhydrazones of keto-acids[9,14,50,53,54,99], and in bisphenylhydrazones of α-dicarbonyl compounds[111]



where the hydrogen bond results in formation of a stable chelate system.

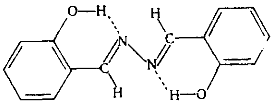
Arylhydrazones of ethyl αβ-dioxobutyrate are present in solutions as a mixture of roughly equal quantities of isomers containing an intramolecular hydrogen bond formed by the hydrazone proton with a keto-group or the ester grouping[99]: i.e. both possible alternatives





are realised in this case.

A hydrogen bond is formed in hydrazones also when a hydroxy-group is present and appropriately located in the carbonyl or hydrazine portion. Thus in the azines of *o*-hydroxybenzaldehydes a hydrogen bond is responsible for their luminescence[112], and also for the coplanarity of the atoms in the azine group[39]

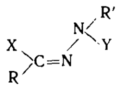


IV. ISOMERISM OF HYDRAZONES

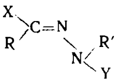
Hydrazones include examples of both stereoisomerism and structural isomerism, while in some cases tautomeric equilibrium of two or even three forms is observed. Isomerism of the skeleton and metamerism are due to the possibility of preparing hydrazones from both isomeric hydrazines and isomeric carbonyl compounds—to the possibility of wide variation in R, R′, X, and Y in (II)—and is of no special interest. Cases of stereoisomerism (geometrical and optical) and position isomerism in the hydrazone group (conversion into azo-compounds or into alkenylhydrazines), with the tautomeric equilibrium of the isomeric forms involved in these changes, are considerably more interesting. Quite often isomeric transitions and tautomeric equilibrium of the various forms of hydrazones are combined, which makes it more difficult to solve the problem.

V. GEOMETRICAL ISOMERISM

The geometrical isomerism of the hydrazones of aldehydes and unsymmetrical ketones is a particular case of isomerism in the $\rangle$C=N−Z system. By analogy with oximes, the isomer in which the substituted or unsubstituted amino-group and the hydrogen atom in the aldehyde derivatives (X = H) or the smaller radical in the ketone derivatives (X < R) are in the *cis*-position with respect to the C=N bond is usually termed the *syn*-isomer (V), and that in which they are in the *trans*-position the *anti*-isomer (VI)[11,100]:



(V) *syn*-isomer



(VI) *anti*-isomer

When R and X are complicated it is necessary, in order to avoid confusion, to indicate which isomer is regarded as *syn* and which as *anti*: this is sometimes effected by stating after the type of isomer the group which occupies the given position relative to the amino-group, e.g. the *syn*-phenyl isomer of acetophenone 2,4-dinitrophenylhydrazone[113].

Geometrical isomerism was postulated in hydrazones by analogy with oximes, and very many papers have been devoted to this question. However, some of the earlier papers must be treated with caution, and the designations α- and β-forms must be accepted for the compound having the lower and higher melting point respectively, since only in a few cases were geometrical isomers actually isolated[11,13].

The matter is complicated by the fact that many hydrazones, especially those containing a nitroaryl substituent, tend to exhibit polymorphism. Thus acetaldehyde *syn*-2,4-dinitrophenylhydrazone exists in four polymorphic modifications, having melting points of 145−146°, 157−158°, 160−161°, and 165−166°C respectively[13,101]. Polymorphism may be the reason for the appearance of different colours in a hydrazone, even if the two modifications have the same melting point and identical ultraviolet and infrared spectra. Only by means of X-ray examination has it been possible to establish that 1-phenylpropane-1,2-dione bis-2,4-dinitrophenylhydrazone, which crystallises from acetic acid as orange−yellow and from nitrobenzene as red needles, is present in different crystalline modifications[114].

Hydrazones are characterised also by phototropy. On standing in sunlight benzaldehyde phenylhydrazone acquires an orange−red colour, which disappears when kept in the dark for a long time. The loss of colour is slower than its appearance[11].

In addition, arylhydrazones are able to form mesomorphic phases. Transition of the phenylhydrazones of *p*-nonyloxy- and *p*-decyloxy-benzaldehydes into the nematic state takes place at 94−95° and at 91−92°C respectively, the transition from the nematic into the liquid state occurring at 97−98° and 93−94°C [115].

Many problems in the stereochemistry of hydrazones have been solved during recent years by the application of the most modern physical methods. The nuclear magnetic resonance spectra as well as the infrared and ultraviolet spectra are widely used for these purposes, but a combination of several methods has proved the most fruitful. The existence of geometrical isomers has been recorded in unsubstituted hydrazones[106], methyl-[27,107], dimethyl-[108,116], methylphenyl-[105,117], aryl-[11,77,102,113], and 2,4-dinitrophenyl-hydrazones[13,100,101,113,118,119], and in thiosemicarbazones[13,77,100,119-121], azines[122-126], acylhydrazones[127,128], formazans[1,2,109], *α*-nitroarylhydrazones[129], 2,4-dinitrophenylhydrazones of quinones[130], and arylhydrazones of *α*-dicarbonyl compounds[88,131].

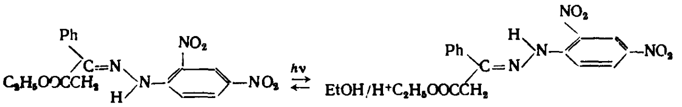
The *syn*-configuration of hydrazones is the more stable. If neither substituent attached to the amine nitrogen atom (R′ or Y) is a hydrogen atom, hydrazones of aldehydes (X = H) are formed, and exist solely in the *syn*-configuration not only in the solid but also in the liquid state and in solutions. A bulky substituent (R′ or Y) produces the same effect even by itself, but equilibrium between *syn*- and *anti*-forms can then be observed in solutions. Thus the dimethyl-, methylphenyl-, and 2,4-dinitrophenylhydrazones and the semicarbazones of aldehydes exist in the *syn*-configuration[101,105,108,119,120]. Equilibrium is slowly established in solutions of 2,4-dinitrophenylhydrazones and semicarbazones, but the process can be accelerated by adding a catalyst, e.g. sulphuric acid. The relative proportions of *syn*- and *anti*-forms depends on the nature of the solvent, as indicated by the following values from the nuclear magnetic resonance spectra of acetaldehyde 2,4-dinitrophenylhydrazone[101]:

in dibromomethane and nitrobenzene	2 : 1
in pyridine, acetone, and dimethylformamide	4 : 1
in tetramethylurea and dimethyl sulphoxide	7 : 1

The rate of isomerisation is fairly low, only a small quantity of the *anti*-isomer being formed during recrystallisation of the *syn*-isomer. This enables the *anti*-form to be isolated or at least enriched by fractional crystallisation of the equilibrium mixture. Acetaldehyde 2,4-dinitrophenylhydrazone containing 85% of the *anti*-isomer has been prepared[101] by crystallising the equilibrium mixture containing only 33%. The size of the radicals in the carbonyl component (R, X) also affects the position of equilibrium between the isomeric forms: when one of them becomes larger, the percentage of the *syn*-form increases. Branching of the carbon chain at the *α*-position relative to the hydrazone group displaces the equilibrium towards the *syn*-form more than does lengthening the straight chain by the same number of carbon atoms. The various hydrazones of isobutyl [?t-butyl] methyl ketone are present in the *syn*-form in any state[100,103,105-108] (see Table 2).

However, not all hydrazones form equilibrium mixtures in solution. Acetophenone phenylhydrazone is obtained in the *syn*-form, which is preserved in solution[102]. A hydrogen bond usually stabilises the *anti*-form[11].

One isomer can be converted into the other in various ways. The stable *syn*-2,4-dinitrophenylhydrazone of ethyl benzoylacetate (VII) obtained from the reaction passes, on prolonged illumination in benzene solution, into the labile *anti*-form (VIII), which can be changed back into the *syn*-form by heating an alcoholic solution in the presence of catalytic quantities of hydrochloric acid[132]:



(VII) *syn*-isomer m.p. 161.5–163.5°C

(VIII) *anti*-isomer m.p. 121–121.5°C

A similar situation is found with *ω*-bromoacetophenone 2,4-dinitrophenylhydrazone[133].

Isomerisation of the geometrical forms of hydrazones can be caused not only by hydrochloric acid and irradiation but also by iodine, sulphur dioxide, hydrogen sulphide, yellow mercuric oxide, caustic potash, sodium ethoxide, sulphur, acetic and other acids, heating to the melting point, etc.[11,113]. Interconversion of the geometrical forms is observed also during the chemical reactions of bromination[116], acylation[134], saponification, and esterification[46]. The explanation of isomerisation during a reaction is that in the *anti*-isomer, for example, the mobility of the methine hydrogen atom (X = H) exceeds that in the *syn*-isomer, perhaps for steric reasons[116].

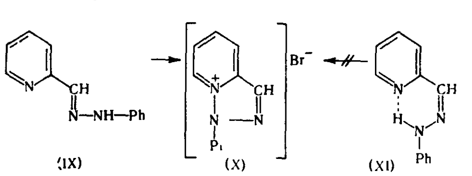
(*a*) In solution in dibromomethane or in chloroform.

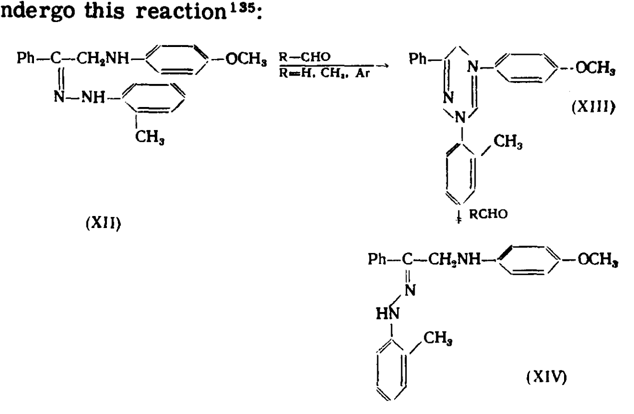
(*b*) In the initial stages (immediately after dissolution).

Although interconversion of the geometrical forms can be observed, it is not yet possible to establish chemically the structure of each form of a hydrazone. Pyridine-2-aldehyde *syn*-phenylhydrazone (IX) is converted by the action of *N*-bromosuccinimide into 1-phenyl-1,2-diaza-8-azoniaindene bromide (X), whereas the *anti*-isomer (XI), in which the atoms are more favourably arranged for ring closure, does not yield (X):



(IX) (X) (XI)

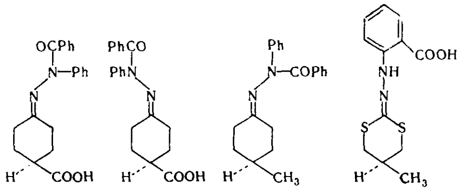
Nevertheless, *ω*-*p*-methoxyanilinoacetophenone *syn*-*o*-tolylhydrazone (XII) reacts with aldehydes to form triazine derivatives (XIII), whereas the *anti*-isomer (XIV) does not undergo this reaction[135]:



(XII) (XIII) (XIV)

Pearson et al.[136] suggested that geometrical isomers of hydrazones could be identified by their rearrangement into amides, but unfortunately this yields a mixture of amides, which makes the problem more difficult to solve. Khromov-Borisov[113] suggested the genetic relation with pyrazolone as a criterion for establishing the stereochemical structure of a hydrazone. In this case the corresponding pyrazolone must be hydrolysed, decarboxylated, or subjected to other reactions, which greatly limits the range of application, and furthermore introduces the possibility of isomerisation during such operations. The *anti*-structure was attributed[137] to one of the forms of the phenylhydrazone and the bisphenylhydrazone of benzil on the basis of their ability to form a complex with tin(IV) chloride.

The hydrazones (XV), (XVII), and (XVIII) could be resolved into enantiomers[138], their optical activity being explained by molecular asymmetry, as is shown in the case of (XV) and (XVI):

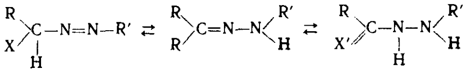


(XV) (XVI) (XVII) (XVIII)

The hypothesis of these workers[138] (repeated by others[11,39]), that the third valency of the imine nitrogen atom in compounds (XV)-(XVIII) does not lie in the C=N plane, is inconsistent with the results of modern X-ray[31-33] and conformational analysis[39,120] of hydrazones. This is a case of atropoisomerism, resulting from the absence of a plane of symmetry in the isomeric forms.

VI. ISOMERISM OF THE TYPE HYDRAZONE ⇌ AZO-COMPOUND

The molecular structure of monosubstituted hydrazones (II: Y = H) has been most often discussed in the literature. It is accepted that three forms—hydrazone (XX), azo-compound (XIX), and alkenylhydrazine (XXI)—are possible:



(XIX) (XX) (XXI)

It is well known that hydrazones and the isomeric azo-compounds are able to exist independently, and also that azoalkanes and arylazoalkanes can be converted into hydrazones[9,11,13,14,42,43,56-58,62,63,81,98,99,102,103,131]. Thus many examples are known of the conversion into hydrazones of azo-compounds formed by coupling arenediazonium salts with aliphatic compounds[20], and also in the Japp-Klingemann reaction[21,140,141]. Diarylazo-compounds, formed by coupling monosubstituted hydrazones with arenediazonium salts, change into formazans either spontaneously or under the influence of alkalis[142,143]. It has been reported that azoalkanes, arylazoalkanes, arylazosteroids, and other azo-compounds are converted into hydrazones under the influence of acids[141,144-146], alkalis[144,147,148], and free radicals[144]. Dondoni and his coworkers have shown[147] that the catalytic activity of tertiary amines in converting azo-compounds into hydrazones in benzene solution is proportional to their pK_a-value in water. Furthermore, the catalytic activity of the amines depends on the type of solvent, diminishing in the sequence—anisole > chlorobenzene > dioxan > benzene—in the case of triethylamine. Several workers[145,147] have observed also the spontaneous transformation of azo-compounds into hydrazones: thus on prolonged storage methylazobenzene rearranges into benzaldehyde methylhydrazone[145].

Considerably greater divergence of views among investigators has been found on the question of the isomerisation of hydrazones into azo-compounds (see Refs. 3, 11, 13, 14, 57, 144, 145, and 149-157 and references in these papers). Baly and Tuck's communication[154] on the possibility of the conversion of phenylhydrazones into phenylazoalkanes by the ultraviolet irradiation of their solutions was criticised by Stobbe and Nowak[155]. Soon after this Busch and Dietz[156] isolated, instead of the expected azo-tautomer, a product of the autoxidation of the phenylhydrazone, which has since been found[149-153,158] to be an azo-hydroperoxide

$$\underset{\displaystyle OOH}{\underset{|}{R-CH}}-N=N-Ph$$

(XXII)

The azo-hydroperoxide (XXII) differs from the azo-tautomer (XIX: X = H) in the presence of the HOO group attached to the carbonyl carbon, which, however, does not entail any great changes in the ultraviolet spectra of these compounds, studied for evidence of isomeric transitions. Therefore Grammaticakis[159] in 1948 and later O'Connor[57], both of whom used ultraviolet spectroscopy to study the changes undergone by arylhydrazones in solutions, reached the erroneous conclusion that the isomerisation hydrazone → azo-compound took place in solution. In fact, however, several investigations have shown[149-153,158] that autoxidation with formation of an azo-hydroperoxide (XXII) occurs under these conditions. O'Connor and Henderson's statement[152] that oxygen may not only take part in forming the hydroperoxide (XXII) but also catalyse the transition (XX) → (XIX) evidently requires verification, since repeated attempts to use this method to convert cyclohexanone phenylhydrazone into phenylazocyclohexane have been unsuccessful[13]. However, the possibility of the isomerisation of hydrazones into azo-compounds is supported by the formation of phenylazomethane when the product of the reaction between phenylhydrazine and formaldehyde is distilled in steam[154]. The use of alkali as catalyst for this reaction enables the azo-compound to be obtained as the main product[160].

Final confirmation of the isomerisation of hydrazones into azo-compounds has been given in a series of publications by Ioffe and his coworkers[28,145,161-163]. In 1965 they accomplished the isomerisation of alkylhydrazones of aliphatic aldehydes and ketones in the presence of an alkaline catalyst, the more volatile azo-compound being distilled off at the same time[161]. They later reported a series of such conversions[145,162], of alkylhydrazones of aromatic aldehydes[163] among others, and also the isomerisation of formaldehyde phenylhydrazone into phenylazomethane[28]. The rate of isomerisation of alkylhydrazones of aromatic carbonyl compounds is lower than that of aliphatic alkylhydrazones, evidently because the conjugated chain is considerably shorter in the latter than the chain of $\pi-\pi-p$ conjugation in the former molecules[163]. The possibility of the isomerisation (XX) → (XIX) is indicated also by the formation of diarylazo-compounds when arenediazonium salts are coupled with monosubstituted hydrazones[142,143]. Thus evidence for the isomerisation (XX) → (XIX) in the hydrazones is as indisputable as that for the isomerisation (XIX) → (XX). Only the phenylhydrazones of aliphatic carbonyl compounds have not yet proved capable of isomerisation, because of their tendency to Fischer cyclisation and nitrile cleavage[28], but even these difficulties can evidently be overcome by choosing appropriate conditions.

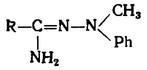
The occurrence of the isomeric transformations (XIX) → (XX) and (XX) → (XIX) indicated the possibility of the tautomeric equilibrium (XIX) ⇌ (XX). Numerous investigations have established that arylhydrazones, alkylhydrazones, semicarbazones, and thiosemicarbazones of aliphatic and aromatic aldehydes and ketones exist in the hydrazone form[9,11,13,14,18-20,38,42,56,58,81-84,102,144,145,149-151,158] and that the above tautomeric equilibrium is not established in the absence of a catalyst[157,162,163]. In 1967 Simon and Moldenhauer[157] noticed, while investigating hydrogen exchange in preparations labelled with tritium, that the equilibrium (XIX) ⇌ (XX) can be observed with phenylhydrazones and semicarbazones if alkali is added to their alcoholic solutions. From kinetic measurements the content of the azo-tautomer in an alkaline alcoholic solution of benzaldehyde phenylhydrazone has been estimated[107] as ~10^{-9}%. Ioffe[162,163] has shown that the content of the azo-form present in the equilibrium mixture in the presence of alkali is considerably higher with the alkylhydrazones of aliphatic and aromatic carbonyl compounds. The most probable explanation of this difference is the breakdown, on the isomerisation of benzaldehyde phenylhydrazone, in the length of the $\pi-\pi-p-\pi$ conjugation chain, which is absent in aliphatic alkylhydrazones[162]. The position of tautomeric equilibrium in alkaline solutions of alkylhydrazones depends on the structure of the substituents in both hydrazine and carbonyl portions of the hydrazone. The content of the azo-tautomer is greater in the alkylhydrazones of aldehydes than in those of ketones. Branching of the alkyl group of the hydrazine shifts the equilibrium towards formation of (XIX)[162]. Unsymmetrical azo-compounds can be obtained from various isomeric hydrazones, and three forms may then be present in equilibrium[157], for example[162]

$$C_2H_5CH{=}N{-}NHCH\genfrac{}{}{0pt}{}{CH_3}{CH_3} \overset{B^-}{\rightleftarrows} C_2H_5CH_2{-}N{=}N{-}CH\genfrac{}{}{0pt}{}{CH_3}{CH_3} \overset{B^-}{\rightleftarrows} C_2H_5CH_2{-}NH{-}N{=}C\genfrac{}{}{0pt}{}{CH_3}{CH_3}$$

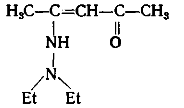
VII. ISOMERISM OF THE TYPE HYDRAZONE ⇌ ALKENYLHYDRAZINE

The concept of the hydrazone ⇌ alkenylhydrazine type of isomerism has considerable value for the interpretation of the mechanisms of certain reactions undergone by hydrazones, primarily the Fischer–Arbuzov reaction, and this isomerism has long been the subject of many investigations, very often being studied at the same time as the hydrazone ⇌ azo-compound isomerism. At an early stage Freer[164] drew attention to the ready oxidisability of some phenylhydrazones and the relative stability of others, and suggested that the former had an alkenylhydrazine structure; in confirmation he was able to establish differences in the chemical behaviour of the two groups of phenylhydrazones on reaction with oxygen, benzoyl chloride, etc. Subsequently the use of various chemical and physicochemical methods has shown that arylhydrazones, alkylhydrazones, disubstituted hydrazones, semicarbazones, thiosemicarbazones[9,14,56,58,102,103,157], and ω-methyl-ω-phenylamidrazones (XXIII)[165], as noted above, are present in the hydrazone form both in the solid state and in solutions. Quantum-chemical calculations have shown[96] that, for example, the semicarbazone form is energetically more advantageous than the alkenylhydrazine form by 15 kcal $mole^{-1}$. The hypothetical existence of the alkenylhydrazine form in solutions of arylhydrazones of aliphatic aldehydes and ketones, based on polarographic data[166], could not subsequently be confirmed[13,14].

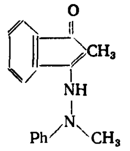
The alkenylhydrazine structure has been established for dialkylhydrazones (XXIV)[167], methylphenylhydrazones (XXV)[168], and monoarylhydrazones (XXVI)[11,169,170] of β-dicarbonyl compounds, derivatives of pentane-2,4-dione, cyclohexane-1,3-dione, indane-1,3-dione, 1-phenylpropane-1,3-dione, etc. The molten phenylhydrazone of ethyl acetoacetate is also regarded as having the alkenylhydrazine structure (XXVII)[170].



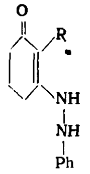
(XXIII)



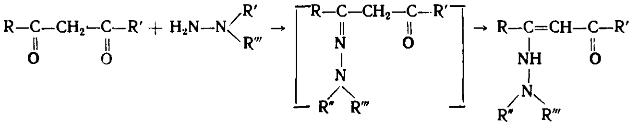
(XXIV)



(XXV)

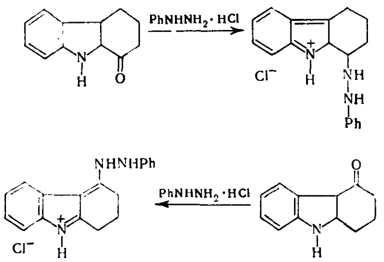


(XXVI)

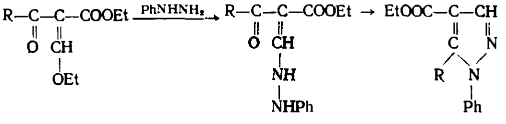


(XXVII)

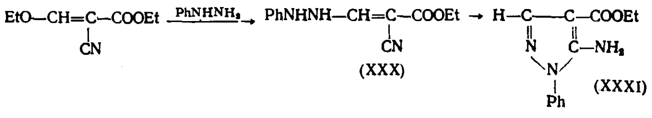
The reaction of 1,2,3,4-tetrahydro-1(and 4)-oxocarbazoles with phenylhydrazine hydrochloride yields products, to which the alkenylhydrazine structure has been assigned on the basis of their infrared spectra[171]:



The alkenylhydrazine structure is possessed by the hydrazones of 5-formylbarbituric acids[172] and by compounds (XXVIII) and (XXX), which are prepared as follows[173-175]:

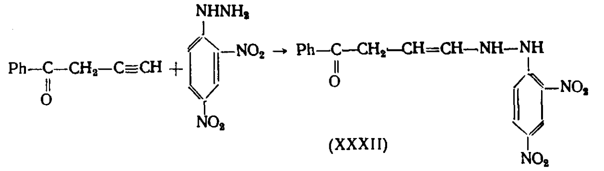


(XXVIII) (XXIX)



(XXX) (XXXI)

Alkenylhydrazines of type (XXVII) can sometimes be formed by the reaction of acetylene derivatives with arylhydrazines[176]:



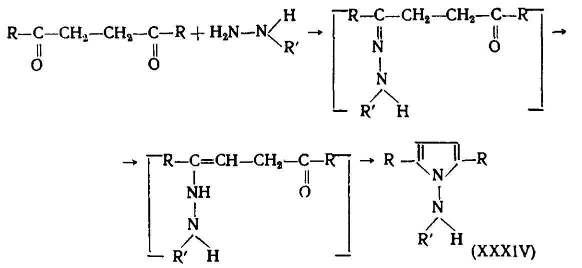
(XXXII)

Unsubstituted and β-substituted hydrazides and thiohydrazides of carboxylic acids

$$\mathrm{R{-}\underset{\underset{Z}{\|}}{C}{-}NH{-}NH{-}R'}$$
(XXXIII)

(where Z = O, S and R' = H, Alk, Ar, Az) represent a kind of alkenylhydrazine (cf. II, XX, XXI) in which the α-carbon atom has been replaced by a heteroatom.

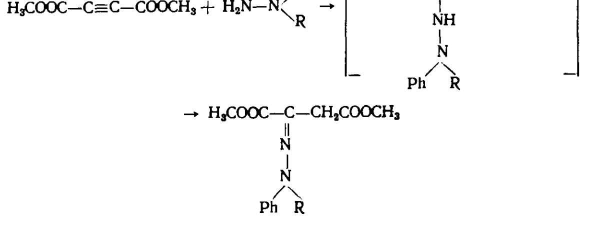
The possibility of the isomerisation hydrazone → alkenylhydrazine (XX → XXI) is suggested by the numerous examples of the formation of 1-aminopyrroles when γ-dicarbonyl compounds react with hydrazine hydrate and with the hydrazides of formic, acetic, benzoic, isonicotinic, phthalic, and other acids[11,177,178]:

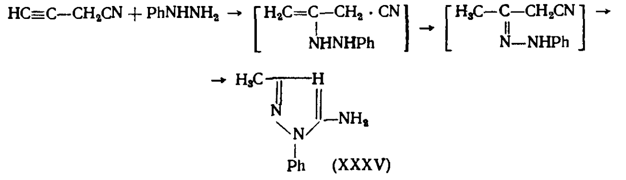


(XXXIV)

It is supposed that formation of the compounds (XXIV)–(XXVII) also passes through a hydrazone stage. The concept of the isomerisation (XX) → (XXI) is widely used in explaining the mechanism of the Fischer–Arbuzov preparation of indoles from arylhydrazones[5-7,15]. Similar isomerisation had been suggested earlier[179] to explain the formation of osazones from α-hydroxycarbonyl compounds and hydrazine derivatives, and has been confirmed by the most recent investigations[180].

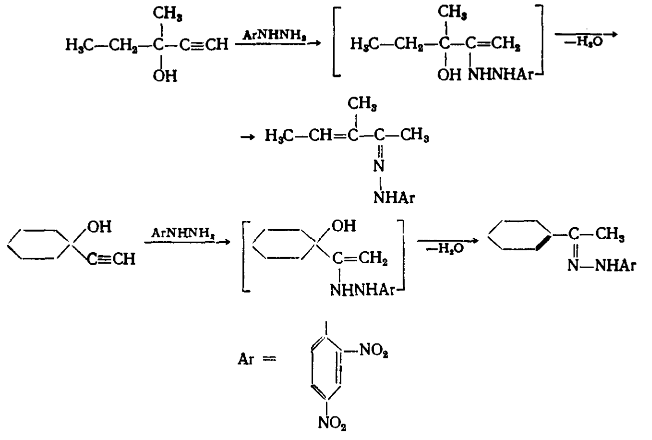
Isomerisation of alkenylhydrazines into hydrazones (XXI → XX) can be observed when arylhydrazines react with acetylene derivatives. The alkenylhydrazines can be isolated only in certain cases (e.g. XXXII [176]), the reaction usually yielding arylhydrazones or products of their further conversion[11,181]:





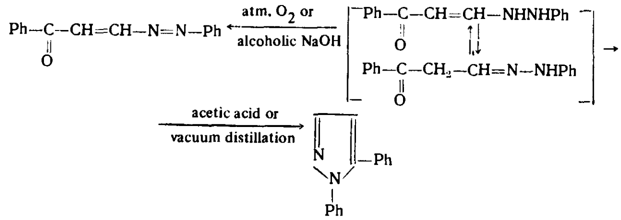
(XXXV)

With derivatives of prop-2-ynol the reaction is accompanied by dehydration[182]:

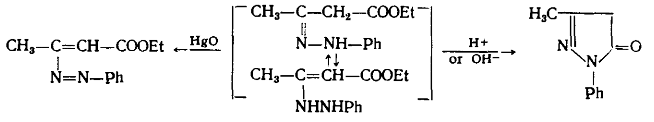


When heated in acetic acid the alkenylhydrazines (XXVIII) and (XXX) are converted into the corresponding pyrazole derivatives (XXIX) and (XXXI), which apparently involves an intermediate stage of isomerisation into the hydrazones[174,175].

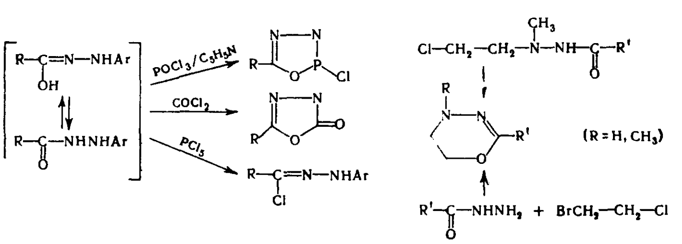
The possibility of the tautomeric equilibrium hydrazone ⇌ alkenylhydrazine (XX ⇌ XXI) is probably suggested by the dual reactivity of the arylhydrazones of β-dicarbonyl compounds and of the hydrazides, thiohydrazides, and hydrazones of certain heterocyclic compounds, e.g. pyrimidine derivatives, etc.[11,19,22]. Aryl hydrazones of β-dicarbonyl compounds (XXIV–XXVII): R″ = H) are converted by oxidants into azoalkenes, but when distilled or heated in acetic acid they are cyclised into pyrazole derivatives[11,169]:



Similar behaviour is shown by the unstable phenylhydrazone of ethyl acetoacetate, obtained in ethereal solution from the ester and phenylhydrazine. When heated with mercury(II) oxide in alcohol it forms ethyl phenylazocrotonate, but in acid and alkaline media it cyclises into 3-methyl-1-phenylpyrazolone[183]:



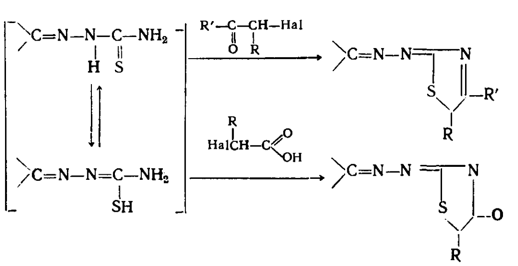
There are numerous examples of reactions in which hydrazides, thiohydrazides, and diacylhydrazines behave as compounds having an α-hydroxy-hydrazone structure[11,19,22,184,185]:



And conversely, the hydrolysis of α-halogeno-hydrazones results in separation of a hydrazide[11,186], instead of the α-hydroxy-hydrazone, which is also an example of the isomerisation (XX) → (XXI):

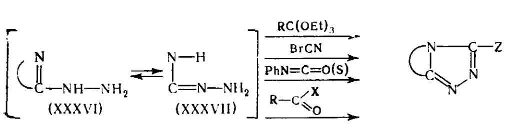
$$\underset{Cl}{\underset{|}{R{-}C}}{=}N{-}NH{-}R' \xrightarrow{HO^-} \left[\underset{OH}{\underset{|}{R{-}C}}{=}N{-}NH{-}R'\right] \rightarrow \underset{O}{\underset{\|}{R{-}C}}{-}NH{-}NH{-}R'$$

The widely known[187-194] condensations of thiosemicarbazides and thiosemicarbazones with α-halogeno-carbonyl compounds and α-halogeno-carboxylic acids to form thiazoline derivatives are based on their capacity for thione ⇌ thiol tautomerism[98], which in this case is a further variety of the hydrazone ⇌ alkenylhydrazine tautomerism:

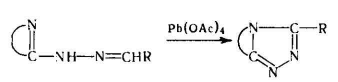


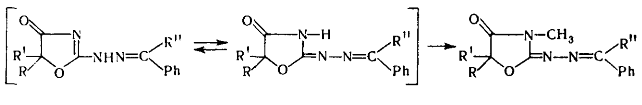
An analogous reaction is characteristic of selenocarbazide and selenocarbazones[195].

Examples of dual reactivity are widely known also with heterocyclic hydrazines containing the grouping (XXXVI) (cyclic amidrazones). They undergo not only reactions characteristic of the hydrazine structure but also reactions characteristic of the hydrazone form (XXXVII)[11,17,196]. Tautomerism of the given type is usually assumed[197]:



(X = Hal, OAlk, OH, OCOR); Z = R, NH$_2$, Ph, OH, SH)

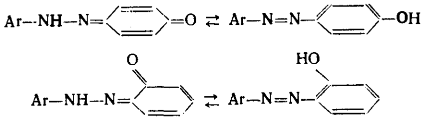




However, dual reactivity merely suggests the possibility of the transitions (XX) → (XXI) and (XXI) → (XX), but does not prove the establishment of tautomeric equilibrium, although the occurrence of tautomerism is very often deduced from this fact[5-7,11,15,140,198,199]. Although dual reactivity may be a consequence not of tautomerism but of migration of the reactive centre in the system, it is very likely that equilibrium is actually established in several cases. Thus Razumov et al.[200] have recently reported occurrence of the tautomerism (XX) ⇌ (XXI) in the hydrazides of phosphorylated carboxylic acids, and a paper already referred to[157] has reported establishment of the above tautomeric equilibrium in certain semicarbazones in alkaline alcoholic solutions, although it is very greatly displaced towards the hydrazone tautomer. But the above papers still do not permit any final or general conclusions to be drawn, and the question of the occurrence of the hydrazone ⇌ alkenylhydrazine tautomerism has not yet been finally settled.

VIII. OTHER TYPES OF ISOMERISM OF HYDRAZONES

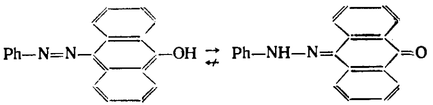
Prototropic isomerism of the quinone arylhydrazone ⇌ hydroxyazobenzene type, which is closely similar to the hydrazone ⇌ azo-compound type, has been known for a long time, widely studied, and discussed repeatedly[11,13,201,202]. Whereas the isomerisation (XX) ⇌ (XIX) involves 1,3-migration of a hydrogen atom, the isomerisation of arylhydrazones of quinones involves 1,7-migration of a proton in derivatives of *p*-benzoquinone and 1,5-migration in those of *o*-benzoquinone. In view of the above and several other peculiarities, this isomerism is usually considered individually, most often in relation to the structure of azo-dyes[202]. These changes were studied considerably earlier and in greater detail than the isomerism (XX) ⇌ (XIX). Detailed investigations have been made of the transitions (XXXVIII) → (XXXIX) and (XXXIX) → (XXXVIII), and also of cases of the tautomerism



(XXXVIII) (XXXIX)

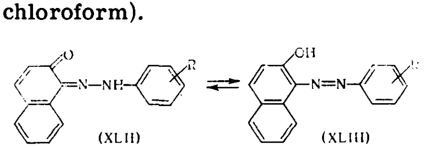
The numerous papers on this problem have been summarised in a review by Ershov and Nikiforov[25].

Whereas benzoquinone derivatives exist in the azo-form even in solution, certain substituted derivatives of naphthaquinone and anthraquinone exhibit a tautomeric equilibrium of the type (XXXVIII) ⇌ (XXXIX) in solution, and 10-phenylazoanthrol (XL) exists only in the hydrazone form (XLI) (see bibliography in Ref. 25):



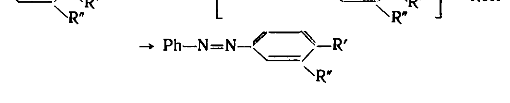
(XL) (XLI)

Substituents in both parts of the molecule have a substantial effect on the position of equilibrium. Accumulation of azo and hydroxyl groups in the quinone ring tends to shift the equilibrium towards the hydrazone form[25,203-205]. The influence of substituents in the phenyl ring of the hydrazine component on the position of the equilibrium (XXXVIII) ⇌ (XXXIX) is illustrated by Table 3[206] for the series 1-R-phenylazo-2-naphthol (solution in deuterated chloroform).



(XLII) (XLIII)

Derivatives of *p*-quinones react comparatively readily with substituted hydrazines, but the resulting hydrazones are converted under the reaction conditions into azobenzenes, with the loss e.g. of an alcohol molecule[207]:



Prototropic isomerism, closely similar to the alkenylhydrazine → hydrazone type of isomerism, was observed by Ioffe and Kochetov with allylhydrazones, which in the presence of alkalis are converted into mixed azines[208]:

$$\mathrm{AlkCH{=}N{-}NH{-}CH_2{-}CH{=}CH_2 \xrightarrow{HO^-} AlkCH{=}N{-}N{=}CH{-}CH_2{-}CH_3}$$

Another type of isomerism, in which the double bond migrates from the nitrogen atom into the aliphatic chain (beyond the α-position), was reported by Abramovitch and Spenser[53], though for cyclic hydrazones:

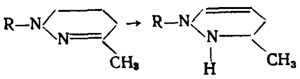


Table 3. Content of hydrazone form in the system (XLII) ⇌ (XLIII)[206].

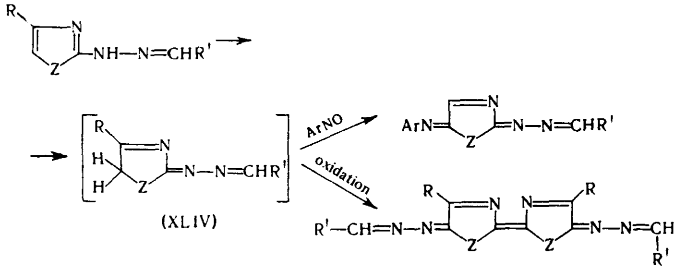
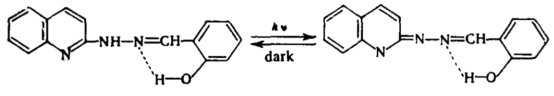
R	(XLII), %	R	(XLII), %
4-CN	97	H	79
3-CN	91	4-HCl	78
3-Cl	81		
3-OMe	81	4-Me	69
3-Me	80	4-OMe	52

Thiazol-2-ylhydrazones[209] and selenazol-2-ylhydrazones[195] behave in certain reactions probably in the isomeric form (XLIV), which is formed by migration of a hydrogen atom from the hydrazone group to the 5-position in the ring:

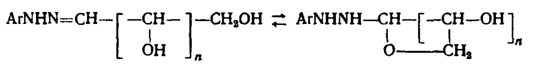


(XLIV)

Wong and Bruscato[210] invoke analogous migration of a hydrogen atom into a heterocyclic ring to explain the photochromism of quinolylhydrazones, which had previously been explained[24] by hydrazone ⇌ azo-compound isomerisation:



Arylhydrazones of sugars exist in two isomeric forms: in the hydrazone (XLV) the carbohydrate radical has an open chain; the hydrazine (XLVI) contains the carbohydrate residue in a cyclic configuration[31,36,211-214]:

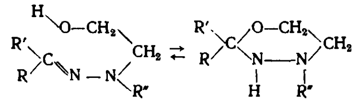


$$\mathrm{ArNHN{=}CH{-}\left[{-}\underset{OH}{CH}{-}\right]_n{-}CH_2OH \rightleftarrows ArNHNH{-}CH{-}\left[{-}CH{-}OH\right]_n}$$

(XLV) (XLVI)

X-Ray examination indicates that ribose p-bromophenylhydrazone exists in the crystalline state in the hydrazone form[31], whereas arabinose p-bromophenylhydrazone is present in the hydrazine form[36], and many similar examples are known. Open-chain products are formed when (XLVI) is acylated[211]. This suggests that the isomerisation (XLVI) → (XLV) takes place, which is confirmed by a study of the polarographic behaviour of arabinose phenylhydrazone[212], this compound existing in the solid state in the form (XLVI). The tautomeric equilibrium (XLV) ⇌ (XLVI) may be established in solutions of the arylhydrazones of sugars, as is confirmed by spectral data[213,214].

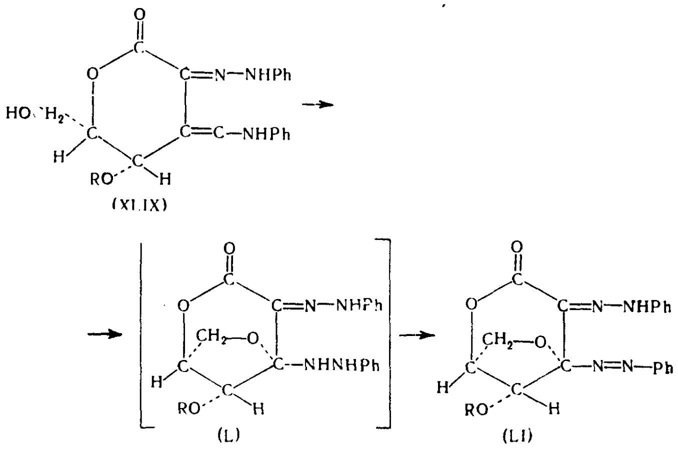
Whereas the tautomerism (XLV) ⇌ (XLVI) is established in the hydrazones of sugars by addition at the C=N bond of a hydroxy-group present in the carbonyl component, Ioffe and Potekhin[215,216], simultaneously with Dorman[217], described a new type of ring–chain tautomerism, involving addition at the C=N bond in the hydrazone of a hydroxy-group present in the hydrazine component:



(XLVII) (XLVIII)

This tautomeric equilibrium is established both in solutions and in the pure substances (liquids) in the case of derivatives of aliphatic carbonyl compounds. Increasing the temperature, the polarity of the solvent, and the molecular weights of the radicals R and R′ and decreasing the molecular weight of R″ tend to increase the content of the hydrazone form (XLVII). Unsubstituted 2-hydroxyethylhydrazones (R″ = H)[215] and also the derivatives (XLVII) of aromatic aldehydes exist in the hydrazone form[216].

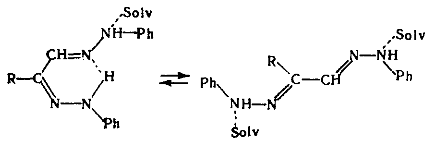
The conversion of (XLIX) into (LI) by the action of a periodate, described by El Khadem and El Ashry[218], is easily explained on the assumption that (L) is formed as an intermediate product:



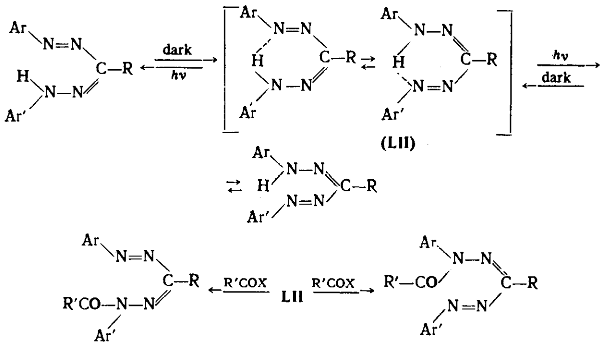
(XLIX)

(L) (LI)

Bisphenylhydrazones of α-dicarbonyl compounds are known to exist in a chelate form[110,111], which is present in solutions in equilibrium with the isomeric open-chain form[111]:



Formazans are in general capable of the interconversions indicated below, and a tautomeric equilibrium is apparently established in solution, as is indicated by the results of acylation, when both possible acylformazans are obtained from (LII)[1,2,10]:



IX. INTRAMOLECULAR INTERACTIONS

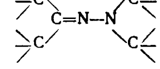
The presence of the grouping

$$\rangle C{=}N{-}N\langle \qquad \text{(I)}$$

makes hydrazones a convenient model for studying $\pi-p$ conjugation[9,14,27,28,39,56,59,60,70,79-85,93,94,163,219-221]. The chief condition for interaction to occur between the π-electrons of the C=N bond and the lone pair of electrons on the amine nitrogen atom is that the hydrazone fragment (I) should be planar[31-33], which permits appropriate orientation of the p- and π-orbitals. The development of the $\pi-p$ type of conjugation in the molecules of hydrazones has been observed in studies of the infrared[59,60,69,70], Raman[79,81,82], ultraviolet[84,85,93,94], and nuclear magnetic resonance[219] spectra and also the optical properties of these compounds[27,28,56,94,220,221]. When conjugation is present, the electronic spectra of hydrazones show a bathochromic shift in the band corresponding to the $\pi \rightarrow \pi^*$ transition[84,85,93,94]. In the vibrational spectra $\pi-p$ conjugation leads to a lowering of the C–N stretching frequency[59,60,70,79,81,82]; in such hydrazones the C–N frequency lies in the range 1590–1620 cm^{-1}, whereas in aliphatic imines it lies between 1650 and 1670 cm^{-1} [34]. The higher the degree of conjugation the larger is $\Delta\lambda$ or $\Delta\nu$. The simple mono- and di-alkylhydrazones of saturated and unsaturated aldehydes and the phenylhydrazone of formaldehyde show high exaltation of molecular refraction, which indicates a considerable degree of conjugation in these systems[27,28,56,220,221]. Whereas in unsaturated hydrazones and alkylhydrazones, in semicarbazones and thiosemicarbazones, $\pi-p$ conjugation occurs within the hydrazone group[27,81,82,94], in arylhydrazones the π-system of the benzene ring is involved in conjugation, $\pi-p-\pi$ conjugation now being observed[28,59,60,81], and in alkylhydrazones of aromatic and unsaturated aldehydes $\pi-\pi-p$ conjugation is present[56,94,163,220,221].

A specific effect of conjugation in hydrazones is an increase in intensity of the C=N absorption band in the Raman spectra on passing from unsubstituted hydrazones to alkylhydrazones[14] and an increase in the exaltation of molecular refraction on passing from mono- to di-alkylhydrazones of $\alpha\beta$-unsaturated aliphatic aldehydes[220]. These facts indicate an increase in degree of conjugation, which can be explained by a change in the hybridisation of the electron orbitals of the amine nitrogen atom in the hydrazone group. In unsubstituted hydrazones the hybridisation of this atom is close to sp^3, and the orbital of its p-electrons is not parallel to that of the π-electrons of the C=N bond, although partial overlapping is already possible. Substitution on the amine nitrogen changes the pyramidal configuration of its bonds into a planar arrangement, as a consequence of which the hybridisation of the nitrogen atom approaches sp^2, which increases the overlapping of p- and π-orbitals[14].

Steric hindrance is one factor affecting the degree of $\pi-p$ conjugation in the hydrazone group. A considerable diminution in the conjugation effect is noticeable in the methylphenylhydrazones of aldehydes[59], and conjugation of the given type is almost completely absent in the methylphenylhydrazones and dialkylhydrazones of ketones[60,93,94]. The reason for the decrease in and even complete absence of $\pi-p$ conjugation when an alkyl group is introduced into a monosubstituted hydrazone of a ketone is that, owing to steric hindrance, the grouping



cannot be planar, as is readily evident when the structure of these compounds is examined with Briegleb–Stuart models: the groups are deflected about the N–N bond, which destroys the appropriate orientation of π- and p-orbitals.

Kitaev and his coworkers[39] have remarked that in azines, in which a considerable conjugation effect had been reported earlier[79], the $\pi-p$ type of conjugation is more strongly developed than the $\pi-\pi$ type, as might have been expected from the planar structure of azine molecules (III). The deflection of the C=N groups about the N–N bond (Fig. 2) is confirmed by spectroscopic data[38,39,51] and by the results of an investigation of the structure of azines by means of the dipole moments[39]. The conditions for $\pi-\pi$ conjugation are destroyed by the deflection, and at a certain angle of rotation (θ = 60–70°) the π-orbitals of one C=N group become able to interact with the p-orbital of the nitrogen atom in the other C=N group[39].

Hexamethylphosphoric Triamide in Organic Chemistry

H.Normant

CONTENTS

I. INTRODUCTION

Chemists have recently being paying increasing attention to the effect of solvents on the occurrence of chemical reactions, especially the effect of dipolar aprotic solvents [1-5]. Among the latter the most interesting is the hexamethyltriamide of orthophosphoric acid $OP(N(CH_3)_2)_3$ (Hexametapol) or trisdimethylaminophosphine oxide. It is often denoted by the letters HMPA or HMPT†; the latter designation seems to be the better, since it reflects the triamide character of the compound. Recent publications on this solvent [6-8] refer in particular to its immense solvent power for a large number of organic and inorganic substances and macromolecular compounds, and also to its use as a copolymerisation catalyst.

The present Review presents data on the physical and chemical properties of hexamethylphosphoric triamide and its use as a reaction medium.

II. PHYSICAL AND PHYSICOCHEMICAL PROPERTIES

Triamides of orthophosphoric acid were obtained by Michaelis [9] by the reaction of phosphoryl chloride with excess of a secondary amine. When dimethylamine is used, this reaction yields the hexamethyltriamide of orthophosphoric acid:

$$O{=}PCl_3 + 6HNMe_2 \rightarrow O{=}P(NMe_2)_3 + 3Me_2\overset{+}{N}H_2Cl^-$$

When this reaction is conducted in an inert solvent, the first chlorine atom in the phosphoryl chloride molecule is easily replaced (exothermic process), but the system must be heated to effect substitution of the remaining two chlorine atoms. The hydrogen chloride liberated in the reaction is neutralised with sodium carbonate, ammonia, or other base, which diminishes the consumption of dimethylamine. After separation of the salts (dimethylamine hydrochloride, sodium carbonate, ammonium chloride) the filtrate contains HMPT, which is purified.

Hexamethylphosphoric triamide is a mobile, colourless liquid, which is miscible with water in all proportions. It forms complexes with chlorinated solvents [10], and can therefore be isolated from aqueous solutions of the latter. Table 1 gives partition coefficients for the amides—dimethylformamide (DMF), methylacetamide (MA), and HMPT—in mixtures of chloroform, methylene dichloride, and ethylene dichloride with water.

Table 1.

Compound	DMF	MA	HMPT
$CHCl_3$—H_2O	0.77	0.099	5.53
CH_2Cl_2—H_2O	0.57	0.088	2.07
ClC_2H_4Cl—H_2O	0.29	0.039	0.58

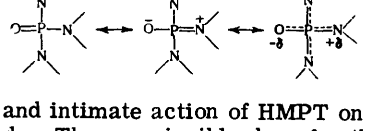
Hexamethylphosphoric triamide is miscible with polar and non-polar organic liquids, but not with saturated hydrocarbons (petroleum ether). It is an exceptional solvent for a large number of polymers [6], various gases [6], and a large number of inorganic salts [8]‡.

Hexamethylphosphoric triamide has a pyramidal structure [11]. The P–O bond may be more or less ionic or covalent in character in different molecules depending on the substituents [11,12]:

$$F_3P{=}O \qquad (Me_2N)_3\underset{\delta^+}{P}{=}\!{=}\underset{\delta^-}{O} \qquad Me_3\underset{+}{P}{-}\underset{-}{O}$$

In the HMPT molecule it is usually accepted that the P–O bond is 50% ionic, whereas the NPO bond can be represented as

Thus the following limiting structures



---

†The abbreviation HMPTA is also used in the literature.

‡Prolonged and intimate action of HMPT on the skin must be avoided. The permissible dose for the rat is 6 g kg^{-1}.

are suggested for the HMPT molecule. The symmetrical distribution of positive charge on the grouping

and the enhanced electron density on the oxygen atom confer both electron-acceptor and electron-donor character on the HMPT molecule.

The melting point of HMPT is 7.20°C, and its cryoscopic constant 6.93 ± 0.07.[14] It boils at 235°C (760mm)[15], 125°C (15 mm), 120°C (10 mm),[10] and 68–70°C (1 mm). The vapour pressure is very low at ordinary temperature (0.07 mmHg at 30°C),[17] and its temperature dependence has been published[18]. The density is $d_4^{20} = 1.0253$.[19] Values published for the refractive index are $n_D^{20} = 1.4582$[19] and $n_D^{25} = 1.4570$;[20] another publication[21] reports values measured by various methods at various wavelengths. The viscosity is 3.5 cS at 60°F.[15] The dielectric constant is $\epsilon_{20°} = 30$,[4] and its temperature dependence has been published[22]. The dipole moment $\mu = 4.31$ D;[13] however, values obtained for the pure liquid (5.37 D) and in benzene solution (5.54 D) differ greatly from this value[22].

Table 2.

Stretching vibration	Absorption band, μm
C—N	7.1—9.8
P—O	7.5—8.5
P—N	⩾ 13.9

The compound absorbs in the infrared[21] (Table 2). The frequency of the P–O bond is 8.7 μm.[23] The position of this band varies little[24] with the nature of the solvent: it occurs at 8.26, 8.32, 8.32, 8.30, and 8.28 μm in carbon tetrachloride, chloroform, pentachloroethane, 1,1,2,2-tetrachloroethane, and methylene dichloride respectively.

The enthalpy of formation from phosphoryl chloride and dimethylamine is $H_{f(gas)} = 114$ kcal mole^{-1}.[25]

The ^{31}P chemical shift in the nuclear magnetic resonance spectrum, relative to 85% orthophosphoric acid, is $\delta = 23.4$ ppm.[26]

1. Properties of Hexamethylphosphoric Triamide

The ability of a solvent to supply its pair of electrons to a compound AH (e.g. chloroform) can be assessed by various physicochemical methods, in particular by means of nuclear magnetic resonance[27]. For every solvent we can calculate the quantity $\delta_\infty(CHCl_3)$:

$$\Delta\delta_\infty(CHCl_3) = \delta_\infty - \delta$$

where δ_∞ and δ are obtained by extrapolating to infinite dilution solutions of chloroform in the given solvent and in an inert solvent (cyclohexane) respectively. The values in Table 3 were first determined by Martin[28], published later[29], and confirmed by another worker[4].

Infrared spectroscopy has yielded similar results. Increase in the basic strength of the solvent is accompanied by a considerable change in the C–Br frequency in aliphatic and unsaturated bromides. The same changes have been shown to occur with solvent–bromide interaction as with solvent–proton interaction[29,30].

Table 4 lists some characteristics of dipolar aprotic solvents. It is readily seen that, among the solvents included, HMPT has the lowest dielectric constant and the greatest basic strength. Because of its electric-donor power HMPT associates with organic and inorganic compounds.

Table 3.

Solvent	$\Delta\delta_\infty$	Solvent	$\Delta\delta_\infty$
Cyclohexane	0	Cyclohexanone	1.06
Dioxan	0.64	$OP(OC_4H_9)_3$	1.28
$P[N(CH_3)_2]_3$	0.68	DMF(dimetliylformamide)	1.30
Ether	0.70	DMSO (dimethyl sulphoxide)	1.34
Oxolan	0.80	TMU (tetramethylurea)	1.37
Acetone	0.94	HMPT	2.03

Thus HMPT is able to form various complexes with compounds containing a labile hydrogen atom. These include, besides chloroform[31], polyhalogenated ethanes[24]. Solvation occurs at the oxygen atom of the phosphoryl group, not at a nitrogen atom. Study of the infrared spectra enables these compounds to be arranged in the sequence of diminishing electron-acceptor power:

$$CHCl_3 > CHCl_2—CCl_3 > CCl_2H—CHCl_2 > CH_2Cl_2$$

The sequence

$$(Me_2N)_3PO > (EtO)_3PO > (EtS)_3PO > (PhS)_3PO > (Et_2N)_3PO$$

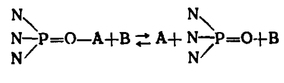
shows that the electron-donor character of HMPT exceeds that of the other phosphorus oxides, its homologue $((C_2H_5)_2N)_3PO$ coming at the end of the series[32].

Table 4.

Solvent	Dielectric constant ϵ	Dipole moment, D	Δj, ppm
DMF	36.7	3.90	0.78
DMSO	49	4.03	1.05
Ethylene glycol	95	4.86	0.41
Thiolan dioxide	44	4.7	0.78
HMPT	30	4.3—5.3	1.89

Acids, phenols, alcohols, aromatic amines, and glycols form stable crystalline complexes with HMPT (Table 5).[33] Among acids which form complexes with HMPT are nicotinic, isonicotinic, and *o*- and *m*-toluic acids. The toluidines (*ortho- meta-* and *para*) must be included with aniline; 1- and 2-naphthols and various chlorinated phenols must be included with phenol itself[34].

A complex formed by HMPT with a compound A containing a hydrogen atom can be broken down by a stronger acid B:



$$(N)_3P{=}O{-}A + B \rightleftarrows A + (N)_3P{=}O{+}B$$

This method can be used in the separation of acids; it has been employed to separate terephthalic acid from isophthalic acid[33].

A study has been made of the infrared spectra of the complexes formed by HMPT with ketones and with hydrogen halides. The association constant of HMPT with the latter compounds increases in the sequence—HBr < HCl < HF—whereas the acidity diminishes in this sequence, from hydrogen bromide to hydrogen fluoride[35].

Table 5.

Compound		M.p., °C
$C_6H_4(COOH)_2 \cdot 2$ HMPT	*ortho-* *meta-* *para-*	70 52 128
 $\cdot 2$ HMPT		152
$C_6H_5CH_2OH \cdot$ HMPT		10
$C_6H_5NH_2 \cdot$ HMPT		<0
 $\cdot 2$ HMPT		132
$C_2H_4(OH)_2$.2HMPT		—20

It has been reported[33] that HMPT forms complexes with various unsaturated hydrocarbons—$CH{:}CH$, $CH{:}C$, $CH_2{:}CH$, $CH{:}C.C_6H_5$, $CH_2{:}CH.CH{:}CH_2$, $CH_2{:}CH.C_6H_5$—but no information is available on the structure of these complexes.

Basic solvents are known to form complexes with Lewis acids, the complex being more stable the more basic the solvent: $(C_2H_5)_2O.BF_3$ < Oxolan.BF_3 < HMPT.BF_3. Examples of crystalline complexes of HMPT with certain Lewis acids are given below.

Complex	M.p., °C	Ref.
HMPT x BF_3	175	35
HMPT x $BClPh_2$	159-160	37
HMPT x $POCl_3$	170-180	
HMPT x $POBr_3$	165-180	

Table 6.

Metal	Complex	Anion
Ag	MSX	halide
Co, Ni, Mn, Fe^{II}, Cu^{II}	MS_2X_2	halide
Pb^{II}	MS_3X_2	halide
Mg, Zn, Cd	MS_4X_2	halide
Co, Ni, Mn, Fe^{II}	MS_4X_2	ClO_4^-
Cr^{III}, Fe^{III}	MS_6X_3	halide
Ti, Sn	MS_2X_4	halide

Crystalline complexes can be obtained also by the reaction of HMPT with certain metal salts. The infrared spectra and the dipole moments show that coordination with metal cations takes place at the oxygen atom in the phosphoryl group[13,38]. The number of solvent molecules involved in complex formation may vary. Neutral molecules of the type MS_2X_2 and ions of the type $[MS_4]^{2+}$ have a tetrahedral structure[13,38]. Table 6 gives the types of complexes formed with various metal salts.

Stable complexes of HMPT with thorium and uranium tetrachloride and tetrabromide have been obtained recently, and have proved to be more stable than analogous complexes with dimethyl sulphoxide[39]. Thus the more basic is a dipolar aprotic solvent, the more easily does it form complexes.

The stability of solvated organomagnesium compounds increases with increase in the basic strength of the solvent, and a more basic solvent can displace a less basic solvent from a solvate[36]:

$$2(C_2H_5)_2O.RMgX < 2\ \text{Oxolan}.RMgX < 2HMPT.RMgX.$$

Symmetrical organomagnesium compounds are soluble in HMPT.[40] Insoluble compounds RMgX.2HMPT are formed with RMgX, and very stable complexes $MgBr_2$.4HMPT with magnesium bromide[41]. Geminal organomagnesium compounds

(I) (II)

where A = OR[42] or Hal[43] are intramolecular complexes. Addition of HMPT favours stabilisation and increase in reactivity of the ionised form (II) formed from the carbenoid form (I). However, the rate of the double decomposition

$$CH_3.CH{:}CH.CH_2\text{-}Zn + CdCl_2 \rightleftharpoons CH_3.CH{:}CH.CH_2\text{-}Cd + ZnCl_2$$

decreases with increase in the basic strength of the solvent as the cadmium atom becomes more solvated[44]. Because of the immense solvating power of HMPT, organometallic compounds can be obtained by their direct reaction with metals; organocadmium compounds have been obtained in this way[45]. Among the saturated halogen compounds only the iodides have been studied. With unsaturated bromides HMPT forms complexes at 0°C. A complex of melting point 112°C, soluble in acetone, has been obtained from cadmium bromide and HMPT.

2. Use of Hexamethylphosphoric Triamide in Electrochemistry

Little use has been made of HMPT as a solvent for electrochemical purposes. The literature contains no information on its application as solvent in polarography.

A voltametric study of HMPT has enabled a stable reference electrode of the Ag/Ag^+ type to be obtained. The electrical activity of HMPT depends considerably on the nature of the cation present and on the water content of the medium[46]; it has been studied in a medium containing sodium and lithium perchlorates with different quantities of water. The results indicate that HMPT differs greatly from other solvents[47,48]. It can also be used as a solvent for electrolysis. Metal salts which dissolve in it[49] undergo ionisation with the formation of ion-pairs, and perhaps dissociation with the formation of ions.

In some cases ionisation results in the formation of coloured anions (HMPT solvates anions weakly). Thus deeply coloured red solutions are formed on the dissolution in HMPT of certain organometallic compounds, e.g. $(C_6H_5)_3CM$, $(C_6H_5)_2CHM$, and $C_6H_5CH_2M$, where M represents an alkali metal or MgX. An ethereal solution of benzylmagnesium chloride is colourless, but a solution of the same compound in HMPT has the characteristic red colour of the benzyl anion[47,48].

It has not proved possible to electrolyse organometallic compounds in HMPT. However, inorganic salts can be electrolysed by using a soluble anode M and a platinum cathode (where MX = $MgBr_2$, which is soluble in ether as $2(C_2H_5)_2O.MgBr_2$; and MX = CaI_2).

The electrolytic reduction of an α-unsaturated ketone to a saturated ketone takes place in HMPT with an 80% yield[49]:

3. Polarity of Solvents

The term polarity in reference to dipolar aprotic solvents must be taken as implying various physical quantities (ϵ, μ, $\Delta\delta$, ...). The nucleophilic substitution

$$n\text{-}C_4H_9Br + N_3^- \rightarrow n\text{-}C_4H_9N_3 + Br^-$$

can be used for comparing solvents. The rate constant and the activation energy of this reaction conducted in HMPT indicate the exceptional role of this solvent (a high value of k and an abnormally low value of E are observed). Satisfactory correlation is obtained between the dependence of $\lg k$ on $1/\epsilon$ and on $\Delta\delta$ (ppm).[4]

The polarity of solvents can be expressed also in terms of semi-empirical parameters, such as the constant Z[50,51] or the parameter F[52]. According to the values of Z protic and dipolar solvents can be arranged in the sequence

CH_3OH, C_2H_5OH, t-C_4H_9OH, CH_3CN, $HCON(CH_3)_2$, $CHCl_3$, HMPT, Iso-octane

and according to the values of F in the sequence

CH_3OH, C_2H_5OH, t-C_4H_9OH, CH_3CN, HMPT, $HCON(CH_3)_2$, $CHCl_3$, Iso-octane

The above results show the "ambivalence" of HMPT.[52]

III. CHEMICAL PROPERTIES

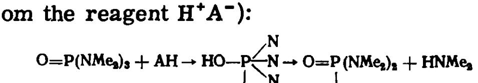
1. Action of Nucleophilic Reagents

Hexamethylphosphoric triamide exhibits considerable resistance to attack by nucleophilic reagents (unlike the amides of carboxylic acids, it does not undergo hydrolysis in alkaline media), and can itself be used as a nucleophilic and basic reagent.

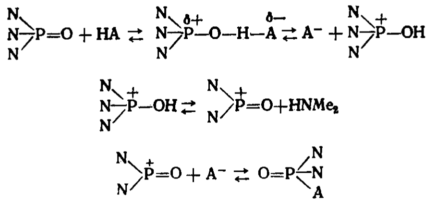
Various derivatives of the alkali metals can be obtained in HMPT. Alkali-metal hydroxides do not react with HMPT at 80°C, but do so at higher temperatures (110 to 120 °C). The inertness of HMPT towards nucleophilic reagents can be explained by great steric hindrance around the positively charged phosphorus atom.

2. Action of Electrophilic Reagents

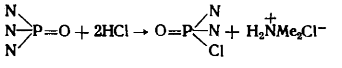
Protic acids and Lewis acids act vigorously on HMPT, with replacement of one or more dimethylamino-groups by A (from the reagent H^+A^-):



Because of the strongly developed basic character of the solvent, electrophilic reagents also form 1 : 1 complexes with it. These complexes, which are more or less stable, give various substitution products when heated. The mechanism of the reaction is assumed to be



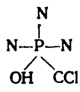
Dry gaseous hydrogen chloride reacts with HMPT according to the equation



Further cleavage of P–N bonds does occur, but with great difficulty.

In aqueous media the dimethylamino-group is replaced by hydroxyl:

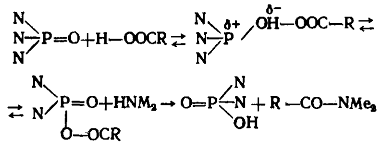
In acid media the rate of hydrolysis is of the same order as for the CO–$N(CH_3)_2$ bond[16]. The complex formed by HMPT with chloroform is unstable, and decomposes when heated. Among the reaction products HO–$P(N(CH_3)_2)_2$ has been identified[53] by nuclear magnetic resonance. According to the above scheme a pentacoordinated phosphorus derivative



should be present during the reaction, which seems improbable. Carboxylic acids yield stable complexes (1 : 1) with HMPT, their decomposition temperatures being 180–200°C. Transamidation[54]

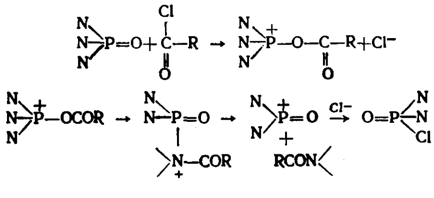
$$O{=}P(NMe_2)_3 + 3\,RCOOH \rightleftarrows O{=}P(OH)_3 + 3RCONMe_2$$

involves formation of a diamido-anhydride as an intermediate stage:



Similar reactions have been accomplished with aromatic, heterocyclic, and sulphonic acids. When the proportions of the reagents are HMPT : RCOOH = 1 : 3, orthophosphoric acid and the corresponding amides are formed[55].

Phenols, but not alcohols, form quite stable complexes§ in HMPT. The crystalline complexes of HMPT acid with chlorides $((CH_3)_2N)_3PO.OPCl_3$ decompose when heated, with replacement of a dimethylamino-group by chlorine:



(III)

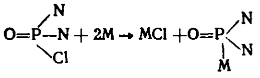
---

§The structure of these complexes has not been established.

The monochlorinated derivatives (III) can be obtained also (which is extraordinarily interesting) in the chlorides of inorganic acids (thionyl chloride, phosphoryl chloride)[56,57]:

$$2O{=}P(NMe_2)_3 + O{=}PCl_3 \rightarrow 3O{=}P(Cl)(NMe_2)_2$$
$$O{=}P(NMe_2)_3 + O{=}PCl_3 \rightarrow 2O{=}P(Cl)(NMe_2)_2$$

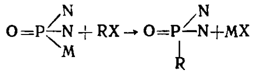
The monochlorinated derivatives can be used to prepare derivatives of the alkali metals[5,58]:



$$O{=}P(N)(N)Cl + 2M \rightarrow MCl + O{=}P(N)(N)M$$

(IV)

where M = Li, Na, K. The latter are in turn used for the preparation of various phosphoramides (V):



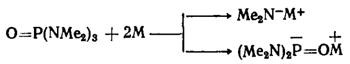
$$O{=}P(N)(N)M + RX \rightarrow O{=}P(N)(N)R + MX$$

(V)

The results of several reactions will be found in Refs. 58 and 59.

3. Action of Alkali Metals

Alkali metals interact with HMPT to yield two anions (via the radical-ions)—the dimethylamide anion (VI) and the phosphorodiamidite anion (VII):



$$O{=}P(NMe_2)_3 + 2M \rightarrow Me_2N^-M^+ \quad (VI)$$
$$\rightarrow (Me_2N)_2\bar{P}{=}O\overset{+}{M} \quad (VII)$$

Saturated alkyl bromides react with HMPT to form tertiary amines (VIII) and phosphoramides (IX)

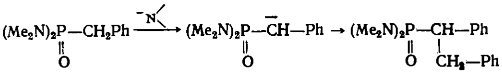
$RNMe_2$

(VIII)

$$O{=}P(NMe_2)_2R$$

(IX)

Under these conditions benzyl chloride does not form the benzyl derivative (X), but yields the compound (XI):



$$(Me_2N)_2P(O){-}CH_2Ph \xrightarrow{^-N\langle} (Me_2N)_2P(O){-}\bar{C}H{-}Ph \rightarrow (Me_2N)_2P(O){-}CH(CH_2{-}Ph){-}Ph$$

(X) (XI) (XII)

The benzyl derivative (X) can be obtained by the reaction between (IV) and benzyl chloride in a mixture of ether and benzene. Sodamide acts on the compound (X) in HMPT to give a good yield of (XII). This result indicates that, in a mixture of the two anions (VI) and (VII), the stronger base (VI) converts (X) into the carbanion (XI), which easily gives (XII).

The two anions formed by the interaction of HMPT with alkali metals are able to metallate weakly acidic hydrocarbons (triphenylmethane forms blood-red solutions); this phenomenon is not observed in benzene solution[60]. The base (VI) acts as a metallating agent, and is stronger than (VII). In fact, (IV) does not react with triphenylmethane even on heating. On the other hand, the conjugate acid $OPH(N(CH_3)_2)_2$, obtained as in Ref. 61, displaces triphenylmethane from its sodium salt.

The compound (VII) gives various products with unsaturated systems. Azobenzene yields after hydrolysis the compound[62]

$$Ph{-}N(P(O)(NMe_2)_2){-}NHPh$$

(XIII)

With phenylacetylene (or with β-bromostyrene) a twofold excess of (VII) gives the diphosphoramide[63]

$$Ph{-}CH(P(O)(NMe_2)_2){-}CH_2{-}P(O)(NMe_2)_2$$

(XIV)

The compound (VII) interacts with non-enolisable ketones to yield products in which the latter have condensed into epoxides[64]. In alkali-metal phosphites $MPO(OR)_2$ (sodium is the best cation) this reaction is possible also with aromatic aldehydes. No reaction occurs in non-polar solvents, but in HMPT a high yield is obtained[65]:

$$2Ar_2C{=}O + O{=}\bar{P}(NMe_2)_2\overset{+}{M} \rightarrow Ar_2C\overset{O}{-}CAr_2 + O{=}P(NMe_2)_2\bar{O}\overset{+}{M}$$

4. Hexamethylphosphoric Triamide as Catalyst

A few readily occurring reactions are known in which HMPT acts as a catalyst. Thus the formation of carbodiimides from isocyanates

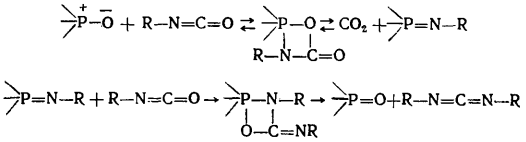
$$2R{-}N{=}C{=}O \rightarrow CO_2 + R{-}N{=}C{=}N{-}R$$

goes more rapidly, at a lower temperature, and with a better yield in the presence of small additions of HMPT[66,67] than of dimethyl sulphoxide (Table 7).

Table 7.

Solvent, mole	Phenyl isocyanate, mole	Temp., °C	Time, h	Yield, %
DMSO, 0.006	0.45	162–164	2.5	13
HMPT, 0.008	—	113–135	1.6	27

In the presence of HMPT phosphonimides are formed in similar reactions:



$$\rangle\overset{+}{P}{-}\bar{O} + R{-}N{=}C{=}O \rightleftarrows \rangle P(O){-}N(R){-}C{=}O \rightleftarrows CO_2 + \rangle P{=}N{-}R$$
$$\rangle P{=}N{-}R + R{-}N{=}C{=}O \rightarrow \rangle P(N{-}R){-}O{-}C{=}NR \rightarrow \rangle P{=}O + R{-}N{=}C{=}N{-}R$$

The rate of reactions involving exchange of radicals between trialkylborines and alk-1-enes

$$Bu_3B + CH_2{=}CH(CH_2)_7{-}CH_3 \rightarrow CH_2{=}CH{-}CH_2{-}CH_3 + Bu_2B(CH_2)_9{-}CH_3$$

is also increased by HMPT.[68] Chlorosilanes undergo disproportionation in the presence of 0.5–15% of HMPT at elevated temperature[69]:

$$2MeSiCl_2H \rightleftarrows MeSiCl_3 + MeSiClH_2$$

IV. USE OF HEXAMETHYLPHOSPHORIC TRIAMIDE AS ELECTRON-DONOR REACTION MEDIUM

A. FORMATION OF ANIONS AND METALLATION

Exchange between hydrogen and a metal yields anions or other organometallic compounds:

$$AH + MR \rightleftarrows RH + MA \text{ or } (M^+ + A^-)$$

The equilibrium is displaced to the right if AH is a stronger acid than RH, or if R^- is a stronger base than A^-. Table 8 gives an acidity scale for various compounds AH.

The solvent plays an important part in exchanges between hydrogen and a metal. Electron-donor solvents promote ionisation of the molecules AH and MR:

$$S_1 + \overset{\curvearrowright}{H-A} \rightleftharpoons (H^+, A^-)S$$

$$S_1 + \overset{\curvearrowright}{M-R} \rightleftharpoons (M^+, R^-)S$$

and yield solvated ion-pairs. If the dielectric constant of the solvent is sufficiently high, dissociation may occur:

$$(M^+, R^-)S \rightleftarrows (M^+ + R^-), S$$

in which the cations M^+ are strongly solvated, and the anions R^- are weakly solvated. Free anions are highly reactive in dipolar aprotic solvents, especially in HMPT, in which the electron-donor character is most strongly developed.

Table 8.

AH	pK_a	Solvent	pK_a
CH_4	50	NH_3 (liq.)	34
$PhCH(CH_3)_2$	37	$PhNH_2$	27
$Ph_2C=CHCH_3$	36	acetone	19
$PhCH_3$	37	t-C_4H_9OH	19
Ph_2CH_2	35	CH_3OH	16
Ph_3CH	33	H_2O	14
$HC\equiv CH$	26	H_2O	—
Fluorene	25	H_2O	—
Indene	21	H_2O	—
$PhC\equiv CH$	21	H_2O	—
Cyclopentadiene	17	H_2O	—

1. Alkoxide and Phenoxide Anions [70]

Alcohols and phenols which are relatively strong acids can interact with alkali-metal hydrides and amides in HMPT to yield more reactive unsolvated anions RO^- or ArO^- than when hydroxylated solvents are used. Similar reactions are possible with alcohols possessing little acidity (t-butyl and allyl alcohols) and with diols, from which diglycolates are formed. With acids the reaction products are alkali-metal salts RCOOM (the silver salt is an exception), which are converted into esters.

It is also noteworthy that very many alkali-metal salts possess extraordinarily high—sometimes unlimited—solubility in HMPT.

2. Anions of Amides [70]

Aliphatic amines are too weak acids to be converted into amides by alkali-metal hydrides and amides. I am aware of only one example of such a reaction—the formation of lithium methylamide [71]

$$CH_3NH_2 + MNH_2 \rightleftarrows CH_3NH-M + NH_3$$

Stronger organometallic bases are required for aliphatic amines. Arylamines ArNHR (R = H, Alk, Ar), indole, carbazole, and phenothiazine form sodium derivatives with sodium hydride or sodamide in HMPT at room temperature. Aniline may give the doubly charged anion $C_6H_5N^{2-}$; carboxyamides and amides can also react in the cold. The sodium derivatives of indole, acetanilide, and phthalimide are soluble without limit.

3. Carbanions of Hydrocarbons

The rate of exchange between hydrogen and a metal depends on the acidity of the hydrocarbon, the strength of the base, and the polarity of the solvent. The influence of these three factors will be examined in the following sections.

(*a*) Carbanions of alkynes. Organomagnesium compounds react with alkynes in HMPT in the cold [72]:

$$R-C\equiv C-H + i\text{-}PrMgCl \rightarrow R-C\equiv C-MgCl + C_3H_8$$

A similar reaction is possible with organozinc compounds [73]:

$$2\,Ph-C\equiv CH + Et_2Zn \rightarrow (Ph-C\equiv C)_2Zn + 2C_2H_6$$

The reaction takes place instantaneously in HMPT, in contrast to other polar solvents [73] (Table 9). The strength of the base plays an important part in such reactions [74]. Thus phenylacetylene (as also acetylene itself) does not react with sodium hydride in HMPT.

Table 9.

Solvent	Oxolan	DMF	DMSO	HMPT
Half reaction time at 50°C, s	129	270	200	8

In the presence of suitable bases alkynes undergo isomerisation: hept-1-yne yields a mixture of heptynes, the main component of which is the isomer hept-2-yne.

At room temperature the more basic alkali-metal amides form the alkynylides RC : CNa. It is noteworthy that acetylene and phenylacetylene, which form complexes with HMPT, do not give sodium derivatives in pure HMPT.

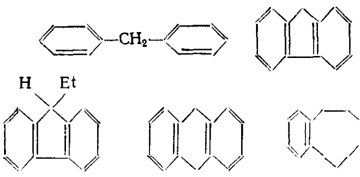
(*b*) Carbanions of triphenylmethane. In solvents of low polarity (ether, oxolan) triphenylmethane does not react with Grignard reagents to give compounds of the type $(C_6H_5)_3CM$ (where M = MgX). With isopropylmagnesium chloride in HMPT this reaction goes smoothly at 90°C. [75] Stable alkali-metal derivatives $(C_6H_5)_3CM$ (where M = Li, K, Na) can be obtained in HMPT from the corresponding hydrides and amides. In liquid ammonia metal amides form $(C_6H_5)_3CM$, but addition of ether decomposes them if M = Na, Li. In oxolan triphenylmethane cannot be metallated either by sodium hydride or by sodamide even at the boiling point of this solvent: stronger bases, e.g. $C_6H_5CH_2Na$, $CH_2:CHCH_2Na$, are necessary for the reaction [76].

Under similar conditions triphenylgermane can be converted into $(C_6H_5)_3GeM$.

In HMPT triphenylmethane is able to react with lithium aminoalkynylides [77]:

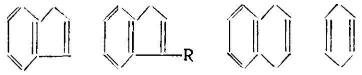
$$\rangle N-C\equiv C-Li + Ph_3CH \rightarrow \rangle N-C\equiv C-H + Ph_3CLi$$

(*c*) **Hydrocarbons of the diphenylmethane type.** Diphenylmethane and various hydrocarbons of related structure



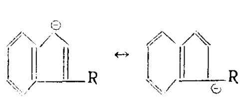
and metallated in HMPT medium[78]. Being less acidic than triphenylmethane, diphenylmethane undergoes exchange only with isopropylmagnesium chloride in HMPT. The reaction takes place at 100°C (red carbanion); on the other hand, it goes very readily at room temperature with the hydrides and still better with the amides of alkali metals. Formation of an organosodium compound is possible even in a less polar medium. Fluorene is able to give organomagnesium compounds at 135–140°C in xylene, and at 40°C in HMPT. Organozinc compounds can also be obtained in the latter solvent[73]. Dihydroanthracene can be metallated in good yield even in the cold both by isopropylmagnesium chloride and by sodium hydride. In HMPT in the cold dihydrodibenzocycloheptene is converted into a dark orange carbanion (at position 5).

(*d*) **Hydrocarbons of 1,4-diene structure**[72]. A study has been made of the compounds

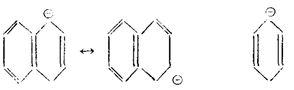


In solvents of low polarity indene reacts with ethylmagnesium bromide at 100°C to yield magnesium derivatives; with isopropylmagnesium chloride in HMPT a similar reaction takes place at only 30°C. Metallation with sodium hydride in HMPT can be accomplished at 0°C (exothermic process) with formation of a reddish-orange anion, which undergoes partial conversion into a dianion.

Alkylindenes react similarly to indene (in HMPT exchange between H and MgX begins at 35°C). The intensely coloured red anion is in a mesomeric form:



The anions formed from 1,4-dihydronaphthalene and especially from cyclohexa-1,4-diene exhibit a tendency to aromatisation:



(XV) (XVI)

The anion (XVI) can be formed when (XV) is treated with isopropylmagnesium chloride in HMPT at 90–95°C. The action of sodamide in HMPT produces considerable polymerisation.

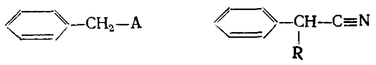
When isopropylmagnesium chloride interacts with 1,3-diphenylpropene in HMPT at room temperature, a red anion is formed:

$$Ph-CH=CH-CH_2Ph \rightarrow Ph-CH=CH-\overset{\ominus}{C}H-Ph$$

In this case, too, alkaline reagents cause considerable polymerisation.

4. Carbanions formed by Compounds containing Labile Hydrogen[79]

(*a*) **Derivatives of phenylacetic acid.** A hydrogen atom present in compounds containing phenyl and electron-acceptor groups is labile:



where A = COOH, CN. Phenylacetic acid reacts with isopropylmagnesium chloride or sodamide in HMPT in the cold to form a dianion; the disodium derivative is completely soluble in this solvent.

Benzyl cyanide on treatment with sodium hydride or sodamide in HMPT at 0°C forms a reddish-violet anion together with a certain amount of a dianion. α-Alkylbenzyl cyanides form singly charged anions at 0°C.

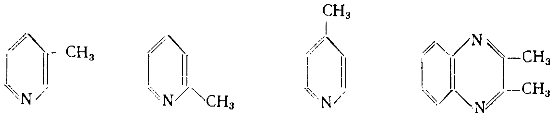
(*b*) **Derivatives of malonic acid.** The compounds

$CH_2(COOEt)_2$, $CH_2(CN)COOEt$, $CH_2(CN)_2$, $CH_2(COCH_3)COOEt$, $CH_2(COCH_3)_2$,

are metallated by sodium hydride or sodamide in HMPT at 0°C, the reaction mixture always containing a small quantity of dianions.

(*c*) **Aromatic compounds containing methyl groups.** Toluene and 2-methylfuran do not react with sodamide or sodium hydride in HMPT. 2-Methylthiophen reacts very slightly.

In the series of picolines

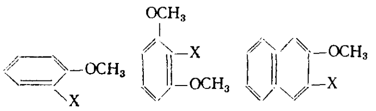


the methyl group exhibits acidic properties in positions 2 and 4, and in HMPT the 2-isomer reacts with isopropylmagnesium chloride to form a red anion. At 0°C the 2- and 4-isomers are able to react with sodamide to form sodium derivatives; with sodium hydride the reactions are very difficult. The 3-isomer is not known to react with sodamide in HMPT. 2,3-Dimethylquinoxaline is more acidic than 2-methylpyridine: it reacts with sodamide in HMPT at room temperature to form a greenish-violet dianion:

(*d*) **Various compounds containing labile hydrogen.** Alkaline reagents convert haloforms into CX_3^- anions, which in liquid ammonia readily add to the carbonyl group in ketones[80]. In HMPT this reaction goes with difficulty, but exchange with isopropylmagnesium chloride takes place readily. Novel organomagnesium compounds have been prepared by conducting the reaction in a 5 : 1 mixture of oxolan and HMPT at 80°C:[1,2,81,82]

$$X_3C-H + i\text{-}PrMgCl \rightleftarrows C_3H_8 + X_3C-MgCl$$
$$(X{=}Cl,\ Br).$$

Among methoxylated aromatic compounds



which are able to react to different positions, only the last forms a red carbanion on reaction with sodamide in HMPT.

In compounds containing an alkylthio-group, which is a better electron acceptor than the alkoxy-group, the anion can be stabilised by resonance:

$$\text{—CH}_2\text{—S—R} \rightarrow \text{—}\overset{\ominus}{\text{C}}\text{H—}\bar{\text{S}}\text{—R} \longleftrightarrow \text{—CH=}\overset{\ominus}{\underline{\text{S}}}\text{—R}$$

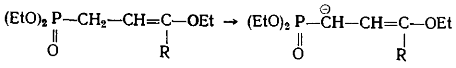
those which have been studied are[83]:

$HC(SEt)_3$, $H_2C(SEt)_2$, $PhCH(SEt)_2$, $PhCH(SPh)_2$

These compounds react with alkali-metal amides in liquid ammonia to form carbanions. The analogous reactions in HMPT yield different results: in di- and tri-ethylthiomethane the carbon–sulphur bond is cleaved; sodamide acts on 4-phenyl-3,5-dithiaheptane at 0°C to form a dark green carbanion; and the most acidic compound αα-diphenylthiotoluene is metallated by sodium hydride at 0°C.

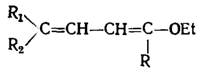
Acetophenone and acetonitrile react with sodium hydroxide in HMPT at 0°C with the loss of one or more protons.

Phosphonates[10] are readily converted into carbanions[84] by the action of sodium hydroxide:



$$(\text{EtO})_2\underset{\text{O}}{\overset{\|}{\text{P}}}\text{—CH}_2\text{—CH=}\underset{\text{R}}{\text{C}}\text{—OEt} \rightarrow (\text{EtO})_2\underset{\text{O}}{\text{P}}\text{—}\overset{\ominus}{\text{C}}\text{H—CH=}\underset{\text{R}}{\text{C}}\text{—OEt}$$

On condensation with carbonyl compounds they give ethoxydienes



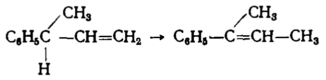
$$\text{R}_1\text{R}_2\text{C=CH—CH=}\underset{\text{R}}{\text{C}}\text{—OEt}$$

which are difficultly accessible by other methods[85].

These few examples indicate that carbanions are formed in HMPT quite easily, with the use of weaker bases and lower temperatures than are required for reaction in other solvents.

B. ISOMERISATION AND POLYMERISATION

Various isomerisations of prototropic type can occur in alkaline media, involving mesomeric carbanions. Such reactions occur considerably more rapidly in the presence of polar solvents. In dimethyl sulphoxide the allyl rearrangement is possible at 25°C, but in t-butyl alcohol only on heating[86]:



$$\text{C}_6\text{H}_5\underset{\text{H}}{\overset{\text{CH}_3}{\text{C}}}\text{—CH=CH}_2 \rightarrow \text{C}_6\text{H}_5\text{—}\overset{\text{CH}_3}{\text{C}}\text{=CH—CH}_3$$

No systematic study of the various rearrangements in HMPT has yet been made, but certain results have already been obtained. The isomerisation of allylbenzene into propenylbenzene takes place in HMPT in the presence of sodium hydride in the cold[78]:

$PhCH_2—CH=CH_2 \rightarrow Ph—CH=CH—CH_3$ (yield 70%)

Under these conditions there is little formation of condensation products, but this becomes considerable if a stronger base (sodamide) is used, or a weak base (isopropylmagnesium chloride) at a high temperature[87]. In such cases anionic polymerisation takes place. Table 10 gives some examples of hydrocarbons which readily form anions under the influence of isopropylmagnesium chloride.

The rapid disappearance of colour on treatment with sodium hydride or sodamide is an indication of polymerisation, as in the case of allylbenzene, for example. Alkenes can be efficiently polymerised by means of organomagnesium compounds in solvents of low polarity, but under these conditions the reaction must be conducted under slight pressure in the presence of halides of metals of Groups IVb, Vb, and VIb.

The capacity for mesomerism of the allyl anion has been shown by the action of sodamide in HMPT at room temperature:

$$\text{CH}_3\text{—}\overset{\text{CH}_3}{\text{C}}\text{=CH—S—Bu} \rightarrow \overset{\ominus}{\text{C}}\text{H}_2\text{—}\overset{\text{CH}_3}{\text{C}}\text{=CH—S—Bu} \longleftrightarrow \text{CH}_2\text{=}\overset{\text{CH}_3}{\text{C}}\text{—}\overset{\ominus}{\text{C}}\text{H—S—Bu}$$

Table 10.

Hydrocarbon	Colour of anion
$PhCH_2—CH=CH—CH_3$	red
$Ph_2C=CH—CH_3$	red
$PhCH=CHCH_2CH=CH—CH_3$	pale pink
$PhCH=CHCH_2C≡C—C_5H_{11}$	dark blue
$PhC≡CCH_2CH=CH_2$	red
$PhCH_2C≡C—C_5H_{11}$	red

The resulting red anion is alkylated predominantly at the α-position relative to the sulphur atom[88].

The isomerisation

$$\underset{\text{(XVII)}}{\text{PhCH=CH—CH}_2\text{OR}} \rightleftarrows \underset{\text{(XVIII)}}{\text{Ph—CH}_2\text{—CH=CH—OR}}$$

(where R = C_2H_5, n-C_7H_{15}) takes place readily in HMPT under the influence of bases[89]. The ethers (XVIII) are characterised by an infrared absorption band at 1660 cm^{-1}. In acid media they form the 2,4-dinitrophenylhydrazone of the corresponding ketone, which is easily identified. The ethers (XVII) can be obtained by condensing cinnamyl bromides with sodium alkoxides in oxolan. If the same reaction is accomplished in HMPT, or the sodium derivatives of the cinnamyl alcohols (obtained in HMPT) are treated with alkyl halides RX, the ethers (XVIII) are the main products. The isomerisation of (XVII) into (XVIII) is effected by means of alkoxides in basic solvents. The ethers (XVII) dissolve in HMPT and form red anions under the action of sodamide, the colour subsequently becoming dark blue. Non-distillable products were isolated on hydrolysis. Isomerisation of (XVII) into (XVIII) is rapid in the presence of dry sodium t-butoxide in a 1 : 9 mixture of HMPT and benzene.

Thus the mesomerism of carbanions under the influence of bases in HMPT can be represented

$$\text{Ph—CH=CH—}\bar{\text{C}}\text{H—OR} \longleftrightarrow \text{Ph—}\bar{\text{C}}\text{H—CH=CH—OR}$$

However, it appears that dimethyl sulphoxide may be a better solvent for the isomerisation of alkenes. Thus in the presence of potassium t-butoxide but-1-ene isomerises into but-2-ene more readily in dimethyl sulphoxide than in HMPT and tetramethylurea[90].

C. USE OF ANIONS

Reactions involving the intermediate formation of anions occur more rapidly in dipolar aprotic solvents. Thus the rate of alkylation of derivatives of sodiomalonic ester in benzene is greatly increased by the addition of 10–20% of such a solvent[91], and the use of pure HMPT increases the reaction velocity with ethyl and butyl bromides by factors of 21 and 54 respectively. Dimethyl sulphoxide as solvent has a less marked effect on the rate of the corresponding reactions, which are accelerated by factors of 6.3 and 15 respectively.

Substitution Reactions

(*a*) Carbon–halogen bond

Halogen–halogen exchange

$$MX + RX' \rightleftarrows RX + MX'$$

involves nucleophilic substitution of X′ for X, but the result depends on the nature of the protic or aprotic solvent[3]. The specific solvation of the halogen in the alkyl halides by hydrogen bonding is significant in protic solvents. Solvation is stronger with small anions, so that the nucleophilic character of the halide anions is opposite to their basic strength:

$$I^- > Br^- > Cl^- > F^-$$

In dipolar aprotic solvents, on the other hand, nucleophilic character and basic strength of the anions coincide.

In HMPT exchange reactions often compete with those involving elimination

$$X^- + \underset{\displaystyle H}{R{-}\underset{|}{C}H{-}CH_2{-}X'} \rightleftarrows R{-}CH{=}CH_2 + HX + X'^-$$

Table 11 gives exchange results for the reaction n-$C_7H_{15}Br$ + MX.[92] The conversion RBr → RCl is effected by the action of lithium chloride, although such exchange is generally accomplished by the use of halides of metals in subgroups 1b and 2b. Potassium iodide brings about a 73% yield in the reaction RBr → RI.

Table 11.

MX	Solvent	Temp., °C	Duration of reaction, h	min	Substitution, %	Elimination, %	Unchanged bromide, %
LiF	HMPT-oxolan	65	7	15	3	0	68

u_2Cl_2	HMPT	100	47	30	30	19	3

*Distilled off as produced.

In HMPT the fluoride and chloride ions are especially strong bases, and are able to eliminate hydrogen bromide from secondary bromides (Table 12).[92] The extent of elimination is increased by neutralising the hydrogen bromide evolved with lithium carbonate. This is a good method for the preparation of alkenes.

Toluene-p-sulphonates of tertiary alcohols do not form alkenes on reaction with lithium chloride in HMPT (exchange is very rapid even in the cold)[92]:

Which reaction occurs is greatly affected by the temperature: at ~ 60°C substitution is favoured; at 100–110°C elimination predominates.

Table 12.

MX	Solvent	Temp., °C	Duration, h	min	Substitution, %	Elimination, %	Unchanged, %
LiF	HMPT	90—100	8	50	0	74	11.5

LiCl+Li_2CO_3	HMPT	90	10		7	79	4

(*b*) Carbon–oxygen bond

Table 13 gives results for alkylation with the formation of *O*-substituted products[70].

The basic character of the anions RO^- is exhibited in various elimination reactions—formation of an epoxide, formation of the alkenes, oct-1-ene and butadiene, by the action of sodium ethoxide and sodium butoxide on tetramethylene dibromide.

Table 13.

Compound	Sodium compound	Solvent	Reagent	Product	Yield, %
BuOH	NaH	HMPT	$PhCH_2Cl$	$BuOCH_2Ph$	89

The yield of 40% resulting from acylation should be improved in a mixture of HMPT with a non-polar solvent.

(*c*) Carbon–nitrogen bond

Table 14 gives results for alkylation with the formation of *N*-substituted products[70].

Very rapid reaction occurs in HMPT between alkali-metal azides and primary bromides with the formation of organic azides:

$$RBr + N_3^- \rightarrow RN_3 + Br^-$$

With n-butyl bromide the reaction occurs more slowly in dimethylformamide and dimethyl sulphoxide than in HMPT.

The activation energy of this reaction is 15–17 and 13.5 kcal mole^{-1} in dipolar aprotic solvents and in HMPT respectively.

Table 14.

Compound	Sodium compound	Solvent	Reagent	Product	Yield, %

(*d*) Carbon–carbon bond

In HMPT alkylations take place with the formation of carbanions, the study of which is of great interest. In a mixture of HMPT and a non-polar solvent high yields are obtained when alkali-metal or magnesium salts were used. Thus the reaction

$$Et_3OC\,(CH_2)_5{-}Cl + NaCN \rightarrow EtO_2C{-}(CH_2)_5{-}CN$$

can give nitriles in 90% yield[93].

Various nitriles can be obtained also by the alkylation of other nitriles[94]

$PhCH_2CN$ and CH_3CN.

Table 15. RMgBr + R′–Br.

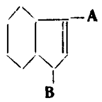
1. Condensation with Organomagnesium Compounds

In aliphatic ethers and even in oxolan aliphatic organomagnesium compounds do not react with halogenated compounds R′X in which X is not very labile, but these reactions can be conducted successfully in HMPT[95] (Table 15).

For organomagnesium derivatives of indene[96] and of fluorene[96] see Tables 16 and 17 respectively.

Reactions with organomagnesium derivatives of 2-alkylpyridines are indicated in Table 18.

Table 16*. Organomagnesium derivatives of indene.



Organomagnesium compound	Hydrocarbon	Antagonist compound	Reaction product	Yield, %
i-PrMgCl	indene	C_2H_5I	$A{=}C_2H_5$ $B{=}H$	62
i-PrMgCl	ditto	Et_2SO_4	$A{=}C_2H_5$ $B{=}H$	92
i-PrMgCl	»	C_4H_9I	$A{=}C_4H_9$ $B{=}H$	82
i-PrMgCl	»	$CH_3C_6H_4SO_2OC_4H_9$	$A{=}C_4H_9$ $B{=}H$	64

Under these conditions condensation can be accomplished with satisfactory yields between saturated organomagnesium compounds and alkyl halides, saturated organomagnesium compounds and alkynyl halides, and magnesium alkynyls and alkyl halides.

Organomagnesium compounds (other than aromatic Grignard reagents) react with vinyl bromide with the elimination of hydrogen bromide.

2. Condensation with Derivatives of Alkali Metals

Table 19 lists some examples of condensations in which alkali-metal derivatives are used[77].

An alkyl bromide does not react with monosodium acetylide in oxolan, but such reaction is possible in dipolar aprotic solvents, in particular in dimethylformamide[97].

Table 18. Pyridine derivatives

*In oxolan.

In HMPT yields of 60–70% are obtained in such condensation (Table 20).[98]

However, these reactions can be accomplished also in oxolan to which 10% of HMPT has been added, which tends to diminish the relative proportion of elimination reactions.

Table 20.

RX	Solvent	Reaction temp., °C	Further heating °C for h		Reaction product	Yield, %

The reaction goes especially well with primary halogen derivatives (bromides, chlorides) and toluene-*p*-sulphonates, and also when liquid ammonia is used as solvent, in which these reagents are less soluble. In HMPT the acetylide ion is a strong base, and causes considerable elimination in the cases of secondary and tertiary halides and toluene-*p*-sulphonates. Some of the acetylene derivatives obtained are listed in Table 21.[98]

Table 21.

Alkynes containing a trialkylgermyl group can similarly be obtained[99] in 60% yield:

$$Et_3Ge(CH_2)_4Br + NaC\equiv CH \rightarrow Et_3Ge(CH_2)_4C\equiv CH$$

The same method enables disubstituted derivatives of alkynes to be obtained under mild conditions[100] (Table 22). In procedure A sodium hydride in oxolan is used if the subsequent reaction is carboxylation or alkylation. In procedures B and C the active reagent is sodamide in HMPT in the cold:

$$CH\equiv CH \xrightarrow[\text{oxolan}]{Na} CH\equiv C{-}Na \xrightarrow[\text{HMPT}]{RX} R{-}C\equiv C{-}H \rightarrow$$
$$\xrightarrow[\text{HMPT}]{NaNH_2} R{-}C\equiv C{-}Na \xrightarrow{R'X} R{-}C\equiv C{-}R'$$

Similarly, substituted alkynylamines can be obtained[84] by the use of RX or toluene-*p*-sulphonates:

$$(R)(R')N{-}C\equiv C{-}Li \xrightarrow{RX} (R)(R')N{-}C\equiv C{-}R$$

Tables 23 and 24 give data on the alkylation of various compounds[101].

Nucleophilic aromatic substitution is accelerated in dipolar aprotic solvents, but this applies only to the reactions of halogenated benzenes. Thus *o*- and *p*-chloronitrobenzenes and their derivatives arylate sodiomalonic and sodioacetoacetic esters in high yield[102]:

where R = OC_2H_5, CH_3. Reaction is most rapid in HMPT. The comparable solvents can be arranged in the sequence HMPT > dimethyl sulphoxide > dimethylformamide.

Table 22.

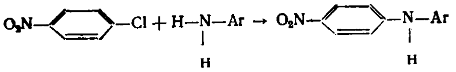
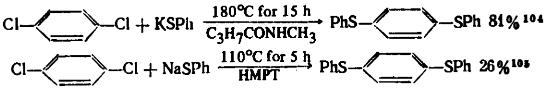
Partial replacement of chlorine by the dimethylamino-group does not occur in HMPT, unlike the reaction in dimethylformamide. The reaction velocity in HMPT is especially increased in the presence of copper[103]:



Reaction with *p*-dichlorobenzene occurs very slowly:



Some examples of arylation with bromobenzene and chlorobenzene under quite mild conditions have been reported in which the yields were satisfactory[70,106]. The reactions must occur by a mechanism of cleavage and addition, although the intermediate formation of dehydrobenzene has not been demonstrated.

Table 25 gives the results for several reactions[106].

depending on the nature of the cation, the alkylating agent, and the solvent. Little information is yet available on the part played by HMPT ¶.

In a study of the reaction of bromoethane with sodium phenoxide and 2-naphthoxide it was shown that the percentage of *O*-alkylated products increased with the basic character of the solvent[107]† (see Table 26).

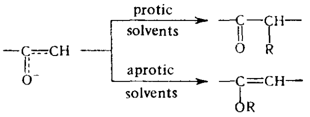
The mechanism of the reaction has been discussed[3]. Our results show that in HMPT alkylation occurs predominantly (86–100%) with the formation of *O*-substituted products[70].

When pyrrole is alkylated in a basic solvent, *N*-alkylated products are formed (at the more electronegative element)[108]. Benzyl chloride reacts with sodium indole in HMPT to give an 81% yield of *N*-benzylindole[70].

Table 26.

Solvent	Alkylation	
	C-derivative, %	*O*-derivative, %
CH$_3$OH	35	65
CF$_3$CH$_2$OH	93	7

In protic solvents (alcoholic alkalis) the enolates of ketones form mainly *C*-alkylated products[109]. It has recently been shown[110] that *O*-alkylated products—ethers of the enols—predominate in dipolar aprotic solvents:



The alkylating agent used was $(C_2H_5)_3OBF_4$ or an alkyl sulphate[110] (Table 27).

The effect of the solvent on the direction of alkylation of sodium ketones was first mentioned in a discussion of the reaction between bromoethane and the sodium derivative of diphenylacetophenone[111]:

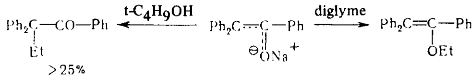


Table 27.

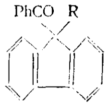
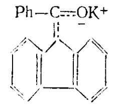
*DME = 1,2-dimethoxyethane. HMPT was not used.
**C-Derivatives and poly-*O*- and -*C*-derivatives.

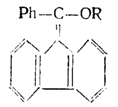
Alkylation of the potassium enolate (XX) in various solvents, including HMPT, gave *C*- and *O*-alkylated products (XIX and XXI)[112] (Table 28), isopropyl bromide being used as alkylating agent.



(XIX)



(XX)



(XXI)

Table 28 shows that the yield of the enol ether is considerably increased in HMPT, which is capable of considerable solvation of alkali-metal cations.

Table 28.

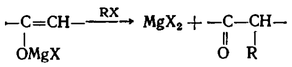
Weaker bases, such as organomagnesium compounds, react with enolisable ketones in the presence of HMPT to give yields of magnesium derivatives of the enolic form[113]. Table 29 gives data on the reaction between various organomagnesium compounds and di-isopropyl ketone[113]. The action of n-butylmagnesium bromide at 55°C produces considerable enolisation[113] in the ketones—butanone (75%), 2,4-dimethylpentan-3-one (95%), and cyclohexanone (90%).

¶For the influence of HMPT on the alkylation of the enolates of acetoacetic ester and pentane-2,4-dione see Refs. 196 and 197 (Editors).

†The changed ratios of *O*- and *C*-substituted products was explained[107] by selective solvation—by the formation of strong hydrogen bonds by the fluorinated alcohol (Editors).

In HMPT magnesium enolates are alkylated at a carbon atom by alkyl sulphates, toluene-*p*-sulphonates, and methyl iodide[114]:



$$\underset{\displaystyle\text{OMgX}}{-\text{C}}{=}\text{CH}- \xrightarrow{\text{RX}} \text{MgX}_2 + -\underset{\displaystyle\text{O}}{\overset{}{\text{C}}}-\underset{\displaystyle\text{R}}{\text{CH}}-$$

this being impossible in solvents of low polarity.

Table 29.

$(i\text{-Pr})_2Mg$	100	0	0

In the presence of strongly solvated cations (alkali-metal derivatives) *N*-alkylation takes place, with the formation of sodium iminoalkenylamines[115] (Table 30). With iodoethane high yields of *C*-alkylated derivatives are formed.

Table 30.

Polyalkylated product	—	—	—	—	4	12	3	0	9

Under the influence of a sufficiently strong base an ambident anion is able to form a dianion. Thus acetanilide has been quantitatively *N*-alkylated after the addition of sodamide in HMPT.[70] In liquid ammonia this reaction leads to the formation of a singly charged anion, but in excess of n-butyl-lithium in ether or oxolan a dianion is formed, with the formation of *C*-alkylated derivatives[116]:

$$CH_3-\underset{\displaystyle O^-\ Li^+}{P}{=}N-Ph \longrightarrow \overset{+\ -}{LiCH_2}\underset{\displaystyle O}{C}{=}N-Ph\ \ Li^+ \xrightarrow[2)\ H_2O]{1)\ PhCH_2Cl} Ph-CH_2-CH_2-\underset{\displaystyle O}{\overset{}{C}}-NH-Ph$$

Similar results can be obtained with methanesulphonamides[117].

4. Formation of Cyclopropane Compounds and Stereochemistry

Cyclopropane derivatives can be obtained by condensing unsaturated compounds (esters, nitriles, ketones) with carbanions formed from various α-halogen derivatives (esters, nitriles, ketones). The formation of these compounds is immensely influenced by the solvent: thus the following reaction yields the *cis*-isomer in benzene, and the *trans*-isomer in HMPT:

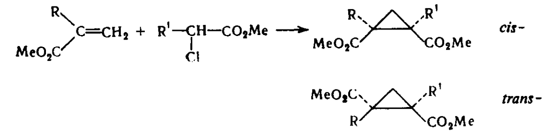

Table 31 gives some quantitative results on the formation of *cis*- and *trans*-isomers of various cyclopropane derivatives in benzene and in a mixture of benzene and HMPT[118,119].

Table 31.

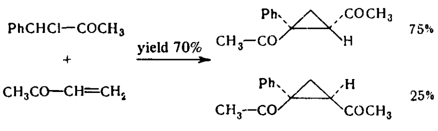
R and R′	Yield, %	Isomers, % *trans*	Isomers, % *cis*
C_6H_6			
R=R′=CH_3	71	7	93
R=H, R′=CH_3	70	17	83
R=R′=Et	55	0	100
R=H, R′=Ph	43	0	100
R=CH_3, R′=Ph	38	0	100
C_6H_6+HMPT (50:50)			
R=R′=CH_3	60	64	36
R=H, R′=CH_3	70	90	10
R=R′=Et	67	75	25
R=H, R′=Ph	65	56	21
R=CH_3, R′=Ph	46	43	25

A similar experiment has been made with α-chlorinated ketones. The highly reactive carbanion formed in HMPT enabled α-halogeno-ketones to be used, as the presence of a hydrogen atom in the α′-position made it possible for this reaction to compete with the Favorskii reaction; and also permitted the use of but-3-en-2-one, which under ordinary conditions polymerises before it can react. The reactions undergone by the butenone with various compounds and the yields are listed in Table 32.[120]

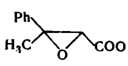
Table 32.

CH_3—CO—CH=CH_2	ROOC—CHCl—COOR	73
	Ph—CHCl—$COCH_3$	70
	Ph—CHCl—COOR	58
	CH_3—CHCl—$COCH_3$	40
	CH_3CHCl—COOR	10

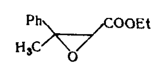
The investigations have refined the stereochemistry of the condensation



In HMPT the Darzens reaction between acetophenone and ethyl chloroacetate[121] leads to the formation predominantly of the isomer (XXII) (Table 33).



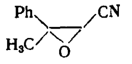
(XXII)



(XXIII)

The reaction between acetophenone and chloroacetonitrile results in the epoxides (XXIV) and (XXV)

(XXIV)



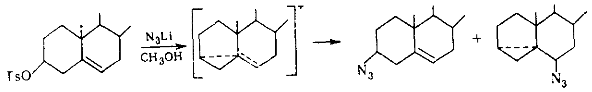
(XXV)

In HMPT a good yield is obtained, but approximately equal quantities of the isomers are formed [Table 34].

Table 33.

Solvent	Base	Duration of reaction, h	Yield, %	(XXII), %
Hexane	NaH	18	50	53
	NaH	8	25	50
Benzene	$NaNH_2$	8	40	50
Benzene		1.5	30	51
HMPT	$t\text{-}C_4H_9OK$	8	57	48
	NaH	1.5	70	59

Another example of the influence of the solvent on the mechanism and the stereochemistry of reactions occurs in steroid chemistry. The 5-en-3β-yl toluene-*p*-sulphonate (XXVI) [122] and the 20β-yl compound (XXX) [123] form different products, depending on the type of solvent (protic or aprotic), on reaction with alkali-metal azides. In methanol the compound (XXVI) yields, via an intermediate carbonium ion (XXVII), derivatives of an inactive steroid (XXIX) (S_N1 mechanism).

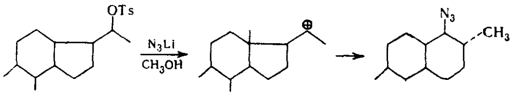


(XXVI) (XXVII) (XXVIII) (XXIX)

Table 34.

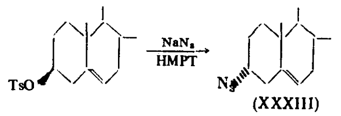
Solvent	Base	Duration of reaction, h	Yield, %	(XXIV), %
Benzene	$NaNH_2$	1.5	5	58
	$t\text{-}C_4H_9OK$	—	50	64
$t\text{-}C_4H_9OH$	$t\text{-}C_4H_9ONa$	—	60	63
$HMPT\text{-}t\text{-}C_4H_9OH$	$t\text{-}C_4H_9OK$	—	73	55
HMPT	NaH	—	62	45

The toluene-*p*-sulphonate (XXX) yields, on rearrangement of the intermediate carbonium ion (XXXI), the D-homo-derivatives (XXXII):



(XXX) (XXXI) (XXXII)

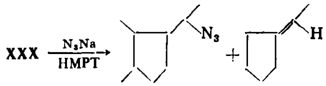
In aprotic dipolar solvents such reactions occur by an S_N2 mechanism with inversion of configuration:



(XXXIII)

The yield of the product (XXXIII) increases with the basic character of the solvent S (Table 35).

The toluene-*p*-sulphonate (XXX) forms mainly the 20α-azide (XXXIV) together with, owing to elimination, a small quantity of the derivative (XXXV):



(XXXIV) (XXXV)

Table 35.

Solvent	DMSO	*N*-Methylpyrrolidone	HMPT
(XXXIII), %	30	71	93

The yield of the product (XXXIV) also increases with the basic character of the solvent, as is evident from Table 36.

Reducing the azides with lithium tetrahydroaluminate gives good yields of the corresponding aminosteroids.

Table 36.

Solvent	DMSO	*N*-Methylpyrrolidone	HMPT
(XXXIV), %	46	53	65

PhMgBr	$PhCH{=}CHBr$	$PhC{\equiv}C{-}H$	20	126

Elimination Reactions

Reactions involving elimination may lead to the formation of carbenes, alkynes, or arynes. It has been noted earlier that the basic character of anions is most strongly developed in HMPT, so that elimination is often accompanied by nucleophilic substitution (S_N2). In HMPT elimination of hydrogen halides and of groups attached to sulphur is possible, but no systematic studies have yet been made of such processes. Halogenated vinyl compounds very readily undergo elimination under the influence of weak bases (organomagnesium compounds) in HMPT (Table 37).

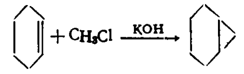
*Contains no unchanged benzyl chloride.
**Isolated as hydrochloride.

Elimination products can be obtained from various compounds by the action of H^-, NH_2^-,[127,128] and $CH{:}C^-$ [129] in HMPT. Table 38 shows that several of the reactions—the production of cyclopropyl cyanide, the production of acetylenic derivatives with and without rearrangement—give good yields. The action of such a strong nucleophile as NH_2^- on benzyl bromide in a mixture of HMPT and benzene yields tribenzylamine.

Compounds containing an α-halogen atom form stilbene or polyenes both in liquid ammonia and in HMPT. Analogous elimination is produced by the action of the acetylide ion on cinnamyl chloride, when 1,6-diphenylhexa-1,3,5-triene is obtained[129]:

$$PhCH{=}CH{-}CH_2Cl \rightarrow Ph{-}(CH{=}CH)_3Ph$$

It has been shown that these reactions do not involve the intermediate formation of carbenes, although in principle this seems possible: the reaction of chloroform and potassium hydroxide with cyclohexene in HMPT produces norcarane[130]:



Compounds containing sulphur can also undergo elimination. Thus alkenes are formed when arenesulphonates are heated in dipolar aprotic solvents[131] (Table 39):

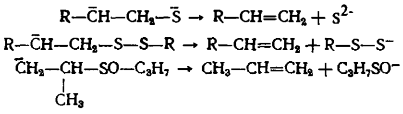
$$\underset{OSO_2Ar}{-CH}{-}CH_2{-} \rightarrow {-}CH{=}CH{-} + ArSO_3H$$

Table 39.

Sulphonate	Solvent	Temp., °C	Time, h	Alkene	Yield, %
Cyclohexyl toluene-p-	DMSO HMPT	90—95 100	5 6	cyclohexene cyclohexene	61 62
1-Methylheptyl benzene-	DMSO HMPT	100—107 100	0.75 3	octene octene	52 61.5

When cyclohexyl benzenesulphonate is heated in the presence of sodamide in HMPT to 40°C, cyclohexene is formed (58%).[128] In HMPT the acetylide anion converts ethoxyethyl methanesulphonate into ethoxyethylene $CH_2{:}CH.OC_2H_5$.[129]

The autoxidation of thiols, disulphides, sulphones, and sulphoxides is often accompanied by undesirable β-elimination with the formation of alkenes[132]:



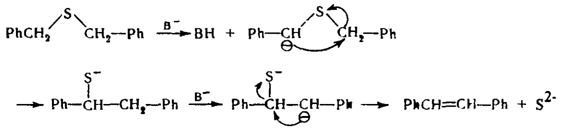
$$R-\bar{C}H-CH_2-\bar{S} \rightarrow R-CH=CH_2 + S^{2-}$$
$$R-\bar{C}H-CH_2-S-S-R \rightarrow R-CH=CH_2 + R-S-S^-$$
$$\bar{C}H_2-\underset{\substack{|\\ CH_3}}{CH}-SO-C_3H_7 \rightarrow CH_3-CH=CH_2 + C_3H_7SO^-$$

In protic solvents aliphatic sulphones are decomposed with difficulty to alkenes (the action of potassium hydroxide requires temperatures above 200°C), but the same compounds in HMPT undergo elimination at 80°C, although reaction is slow[133] (Table 40).

Table 40. Elimination (KOH–HMPT at 80°C).

Reactant	Product	Time, h	Yield, %
$(CH_3)_3C-S-S-C(CH_3)_3$	isobutene	20 141	36 63
$(CH_3)_3C-S-C(CH_3)_3$	isobutene	20 141	2 11
	butadiene	150	1
$i\text{-}C_3H_7-SO-C_3H_7$	propene	141	28
$n\text{-}C_4H_9\underset{\substack{\parallel\\ O}}{S}-C_4H_9$	isomeric butenes	141	10

In the presence of a base B⁻ [134] HMPT promotes the conversion of dibenzyl sulphide, through an intermediate carbanion, into stilbene:



It thus becomes clear why this sulphide can be obtained in high yield in oxolan:

$$PhCH_2SH \xrightarrow[2)\ PhCH_2Cl]{1)\ NaNH_2} S\,(CH_2-Ph)_2 \quad (83\%)$$

whereas in HMPT a considerable amount of stilbene is formed[135].

Autoxidation of Anions

Effective autoxidation of a large number of compounds which form anions is possible at room temperature[136]. The reactions occur especially efficiently in dimethylformamide or dimethyl sulphoxide in the presence of potassium t-butoxide as base. The following mechanism is possible[137] for the oxidation of toluene—formation of carbanion

$$PhCH_2-H + B^- \rightarrow BH + BHCH_2^- \tag{1}$$

formation of benzyl radical

$$PhCH_2^- + O_2 \rightarrow Ph-\dot{C}H_2 + O^{\cdot-} \tag{2}$$

formation of peroxy-radical

$$Ph\dot{C}H_2 + O_2 \rightarrow PhCH_2-O-O^{\cdot} \rightarrow \tag{3}$$

Autoxidation is more rapid the more rapidly is the carbanion formed.

The possibility of using HMPT as reaction medium in autoxidation was first noted by Wallace. It is to be preferred to other dipolar aprotic solvents for two main reasons.

1. It cannot give a carbanion, and therefore its oxidation is impossible. If isotopic exchange is carried out in the presence of a base between toluene, in which the methyl group is labelled with tritium, and various dipolar solvents, the times indicated in Table 41 are required for 10% exchange to occur[138].

Table 41.

Solvent	Time, min
Dimethyl sulphoxide	6
Dimethyl sulphone	12
1-Methylpyrrolid-2-one	48
Thiolan 1-monoxide	420
HMPT	14000

Table 41 shows almost complete absence of exchange with HMPT, the hydrogen atoms in which occupy the β-position with respect to the PO group. Dimethyl sulphoxide undergoes considerable autoxidation, which is possible also with diglyme and dioxan[139].

2. It is stable to the action of bases (even potassium hydroxide at 80°C), and is therefore more convenient than carboxyamides and lactams.

Table 42.

RSH (mole)	KOH/RSH	Solvent	RSH converted, %	Yield of RSO_2H, % (a)	Yield of R_2S_2, % (a)	Temp., °C	Time, h
C_6H_5SH (0.025)	4	HMPT	99	90	6.4	23.5	12

$(C_6H_{11})_3CSH$	4	HMPT	100	62.5	37.4	80	42

(*a*) 100 x moles of product/theoretical moles.
(*b*) *o*-Sulphobenzoic acid is not formed.

Thiols and disulphides are oxidised to sulphonic acids in the highest yields (95–100%) in HMPT:[140]

$$RSH \rightarrow RSO_3H$$
$$R_2S_2 \rightarrow RSO_3H$$

Tables 42 and 43 [140] give data on the oxidation of thiols and disulphides by bases (only potassium hydroxide was used as base in Table 42).

The autoxidation of sulphides yields a mixture of carboxylic and sulphonic acids[141]. Tables 44 and 45 give data on the oxidation of sulphides.

The reaction of sulphoxides with potassium t-butoxide in HMPT at 80°C results in the formation of a mixture of carboxylic and sulphonic acids[142] (Table 46).

Ketones undergo autoxidation to acids, cyclic ketones forming dibasic acids (Tables 47 and 48). The reaction velocity is higher in HMPT than in the other two solvents: HMPT > $t\text{-}C_4H_9OH$ ≫ water. Of the three bases—potassium, sodium, and lithium hydroxides—the first two are the more effective (the reactions occur with surprisingly high yields). The character of the ketones is also of significance, those of them which easily form carbanions undergoing autoxidation more rapidly[143].

Table 43.

R_2S_2 (0.0125 M)	Solvent	Base (0.1 M)	Temp., °C	R_2S_2 converted, %	Yield of RSO_3H, %	Yield of RSH, %	Time, h

$(C_6H_5)_2S_2$	HMPT	KOH	80	98	99	0	22.5
$(C_6H_5)_2S_2$	DMF	KOH	23.5	98.5	90	0.3	40
$(o\text{-}CH_3\text{—}C_6H_4)_2S_2$	HMPT	KOH	80	98	98	0	23

Under the influence of bases (t-butyl alcohol or potassium hydroxide) in HMPT, aromatic hydrocarbons are oxidised to the corresponding acids[138] (Table 49).

Methylthiophens are also converted into acids. The 2-isomers, which are able to form carbanions that are strongly stabilised by resonance, give high yields of the acids[144] (Table 50).

Table 44. Oxidation of benzyl sulphides [(*a*)].

(*d*) The oxidation of toluene under these conditions has been studied by Hofmann and his coworkers.

D. COMPARISON OF DIPOLAR APROTIC SOLVENTS

The preceding discussion has shown that S_N2 and S_E2 reactions are accelerated in dipolar aprotic solvents, the reaction velocity depending on the donor power of the solvents:

dimethylformamide < dimethyl sulphoxide < tetramethylurea < HMPT.

These solvents contain various polar groups: CO in dimethylformamide and tetramethylurea, SO in dimethyl sulphoxide, and PO in HMPT, with hydrogen atoms at different distances from these groups. The differences in structure among the solvents explain their varying stability and their different behaviour, which is sometimes undesirable in certain reactions.

Table 45. Oxidation of sulphides (*a*).

(*d*) Verified by gas–liquid chromatography.
(*e*) Verified by gas–liquid chromatography.
(*f*) Russell and his coworkers found methanesulphonic acid and dimethyl sulphone on oxidation with a mixture of potassium t-butoxide and dimethyl sulphoxide[137].

1. Reactivity of Polar Group

A negative charge on oxygen gives the solvent a basic character. The atom adjacent to the oxygen (carbon, sulphur, or phosphorus) acquires a positive charge, which favours attack by nucleophilic agents B^-, either present initially or formed during the reaction. As a result, dimethylformamide and tetramethylurea may form amide ions able to compete with B^-:

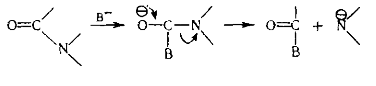

Table 47. Influence of solvent and base on the oxidation of acetophenone (*a*).

Base	Solvent	Temp., °C	Yield of benzoic acid, %	$10^2 O_2$ (*c*)/ketone molar	Time, h
t-C_4H_9OK	t-C_4H_9OH	23.5	66	1.60	45
t-C_4H_9OK	HMPT	23.5	88	4.88	44
KOH	HMPT	80	62	2.14	44
KOH	HMPT	23.5	35	0.42	44
NaOH	HMPT	80	60	2.00	21

LiOH	HMPT	80	14	0.009	24.5
LiOH	HMPT	25.0	—		24.5
LiOH	H_2O	80	—		42

(*a*) The concentrations used were 0.05 M acetophenone and 0.15 M base with an oxygen pressure of 1 atm.
(*b*) 100 x theoretically calculated moles of acid per mole of ketone. Except for the use of lithium hydroxide, the whole of the ketone is converted with a yield of 90–100%.
(*c*) Calculated from rate of consumption of oxygen.

Table 48. Oxidation of cyclic ketones (*a*).

Ketone	Temp., °C	Time, h	Base	Acid (yield, %)
Cyclohexanone	23.5	20	CH_3ONa	adipic (100)
Cyclohexanone	80	24	CH_3ONa	adipic (>90)
Cyclohexanone (*b*)	23.5	78	NaOH	adipic (94)
Cyclohexanone (*b*)	80	68	NaOH	adipic (82)
Cyclohexanone (*b*)	23.5	24	NaOH	adipic (81)
Cyclohexanone (*b*)	80	19	NaOH	adipic (88)
Cyclopentanone	23.5	23	CH_3ONa	glutaric (95)
Cyclopentanone	80	23	CH_3ONa	glutaric (100)
Cyclopentanone (*b*)	23.5	26	NaOH	glutaric (49)
Cyclopentanone (*b*)	80	24	NaOH	glutaric (76)
Cyclopentanone	23.5	19	CH_3ONa	pimelic (44)
Cyclopentanone	80	21	CH_3ONa	pimelic (41)
Cyclopentanone	80	21	CH_3ONa	dodecanoic (40)

(*a*) The concentrations used were 0.025 M ketone and 0.15 M base with 75 ml of HMPT.
(*b*) Results obtained mainly by the use of potassium hydroxide.

Such decomposition is improbable with HMPT, in which the phosphorus atom is sterically blocked, so that it is considerably more difficult for HMPT to form ions like the amide ions formed by dimethylformamide and tetramethylurea.

Strong bases (organic compounds of alkali metals) act effectively on dimethylformamide, dimethyl sulphoxide, and tetramethylurea, but do not act on HMPT under the conditions normally employed. Nor do organomagnesium compounds react with tetramethylurea and HMPT.[145,146]

Table 49.

ArH	ArCOOH	Yield, %
Toluene	benzoic acid	25—30
o-Xylene	phthalic acid	35—40
m-Xylene	isophthalic acid	50
p-Xylene	terephthalic acid	15
Tetralin	phthalic acid	46

Thus organometallic compounds (of the alkali metals and magnesium) can be obtained in HMPT. On the other hand, it is desirable to prepare them in a mixture of HMPT and a non-polar solvent (benzene, toluene). This precaution is unnecessary with unreactive organometallic compounds. Thus organocadmium, organozinc, organotin, etc. compounds can be obtained by direct reaction between the metal and the halogen derivatives in pure HMPT.

Table 50. Oxidation of alkylthiophens in HMPT.

Reactant (0.5 mole)	Base (0.15 M)	Temp., °C	Product	Yield, % (*a*)	Duration, h	Rate of consumption of oxygen	Rate of relative to toluene
2-Methylthiophen	t-C_4H_9OK	80	thiophen-2-carboxylic acid	75.8	70	0.0380 0.0320	1.50 (*b*)
2,5-Dimethylthiophen	t-C_4H_9OK KOH	23.5 80	thiophen-2-carboxilic acid	19.9 2.2	48 25	0.0075 0.0013	0.32 0.06
3-Methylthiophen	t-C_4H_9OK	80	thiophen-3-carboxylic acid	13.4 19.2	23 70	0.0334 0.0008 0.0007	1.40 0.03 (*c*)
Toluene	t-C_4H_9OK	80	benzoic acid	47.8	24	0.0230	1.00

(*a*) All yields based on theoretical.
(*b*) Rate of oxidation = moles of oxygen per mole of reactant per minute.
(*c*) Mean of two separate reactions.

Sodium hydride can be used in various reactions with dimethylformamide, but it partly reacts with the latter even at room temperature[147]. Its use in reactions with dimethyl sulphoxide as solvent is not without danger, as the latter contains oxygen, and explosions are possible even at low temperatures[148].

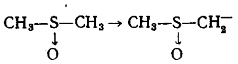
Alkali-metal hydrides and amides do not interact with tetramethylurea or HMPT.

Alkali-metal hydroxides react readily with dimethylformamide, dimethyl sulphoxide, and tetramethylurea, but do not react with HMPT even at 80°C.

2. Electron-acceptor Effect of Polar Group

The electron-acceptor effect of the polar group makes an α-hydrogen atom labile; on loss of a proton the solvent is converted into a carbanion. Thus dimethylacetamide and dimethyl sulphoxide yield the corresponding carbanions:

$$(CH_3)_2N-\underset{\underset{O}{\|}}{C}-CH_3 \rightarrow (CH_3)_2N-\underset{\underset{O}{\|}}{C}-CH_2^-$$



$$CH_3-\underset{\underset{O}{\downarrow}}{S}-CH_3 \rightarrow CH_3-\underset{\underset{O}{\downarrow}}{S}-CH_2^-$$

Tetramethylurea and HMPT, in which the hydrogen atoms are in the β-position, are able to lose these atoms only in exceptional circumstances. The resulting carbanions are able to undergo the same reactions as those produced during substitution, addition, autoxidation, etc.

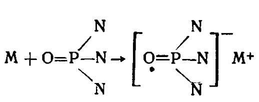
The ease with which the "dimsyl" anion is formed and its reactivity make it an excellent agent in syntheses[149]. On the other hand, dimethyl sulphoxide is not recommended as a solvent for reactions involving carbanions.

From the points of view of basic character and stability HMPT is regarded as the most suitable among dipolar aprotic solvents for the production and application of anions. At present most of these reactions are accomplished in liquid ammonia, but a great future belongs to HMPT, in view of the convenience of operation, absence of protolysis (e.g. preparation of $(C_6H_5)_3CM$), better solubility of various agents (e.g. higher aliphatic bromides).

V. USE OF HEXAMETHYLPHOSPHORIC TRIAMIDE AS ELECTRON-ACCEPTOR REACTION MEDIUM

A. FORMATION OF RADICAL-ANIONS

Normant and his coworkers were the first to observe that HMPT is able to dissolve alkali metals (lithium, sodium, potassium) with the formation of light blue solutions[150]. It was shown simultaneously that the solutions contained radical-anions and were paramagnetic[151–153]:



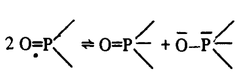
Electron spin resonance spectra were recorded for various concentrations

$$M + n\ \mathrm{HMPT} \leftrightarrows (M^+\ .\ .\ .e^-)_n\ \mathrm{HMPT}$$

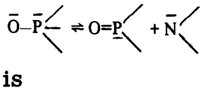
The stability of the radical-ions depends on the concentration and the nature of the cation. At concentrations near molar the blue colour disappears after 10–15 min with potassium, and after 5–6 h with sodium and lithium.

Other metals—magnesium[154] and the alkaline-earth metals (calcium, strontium, barium)[155]—also dissolve in HMPT. Freshly prepared solutions of these metals are light blue, having an absorption maximum at 770 nm. At the same concentration solutions of magnesium are more stable than those of sodium; solutions of the alkaline-earth metals have little stability, especially those of barium. In time the blue colour of the radical-anions passes into pale yellow (λ_{max} = 390 nm).

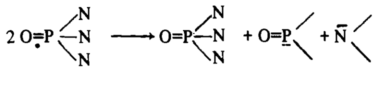
We have previously reported that this decomposition yields two anions and have suggested a mechanism[156]. The most probable scheme seems to be that the mesomeric radical-anion dismutates:



The resulting dianion is in turn converted into two anions:



The overall equation is



Polycyclic hydrocarbons are able to act as electron acceptors towards metals, and several radical-ions have recently been obtained in HMPT. The ease of formation of radical-ions depends on three main factors[157]—(*a*) the electron affinity of the hydrocarbon, which is always lower than that of a non-enolised ketone[158] (benzene < < phenanthrene < biphenyl < anthracene < *o*- and *p*-terphenyls < benzophenone < fluorene), (*b*) the reducing power of the metal (alkali metals > magnesium > alkaline-earth metals), and (*c*) the solvating power of the solvent (highest with HMPT, then dimethoxyethane and oxolan).

Biphenyl and naphthalene in oxolan form with lithium and sodium radical-ions which are used in various syntheses[159–161].

Radical-ions of naphthalene (1) and anthracene (2) are obtained also with sodium in HMPT.[162] Solutions of (2) are stable, but those of (1) decompose with time. This latter process has not yet been investigated; either the solvent may be decomposed by the radical-ion, or electron transfer may occur from naphthalene to HMPT. The acceptor powers of naphthalene and of HMPT cannot be compared by spectrophotometric methods, since unstable solutions of radicals are formed. Insufficient work has been done on determining the reduction potential of HMPT. Biphenyl and naphthalene do not form radical-ions with magnesium in oxolan, but their formation is possible in liquid ammonia[163]. The appearance of radical-ions in HMPT has also been observed by means of electron spin resonance[155].

Products of the interaction of naphthalene with magnesium in liquid ammonia are green after removal of most of the solvent; the magnesium–naphthalene–ammonia compound is decomposed by dimethyl sulphoxide and is insoluble in oxolan, but is dissolved by HMPT to form stable green solutions. Other radical ions of the type $ArH{\cdot}Mg^+$ can be obtained from these solutions[164]. In HMPT magnesium forms radical-ions with anthracene, pyrene, and 1,1-diphenylethylene[154]. Radical-ions of biphenyl can also be obtained in HMPT by the action of such metals as calcium, strontium, and barium.

Naphthalene, being a better electron acceptor than biphenyl, is able to accept an electron from the radical-ion of the latter to form the corresponding green radical-ions[155]:

$$\mathrm{Ph{-}Ph^{\cdot}} + \mathrm{Naph} \rightleftarrows \mathrm{Naph^{\cdot}} + \mathrm{Ph{-}Ph}$$

The electronic spectra of the various radical-ions obtained in HMPT do not depend significantly on the nature of the cation (Na^+ or Mg^{2+}), but their absorption maxima are slightly displaced to longer wavelengths in oxolan. HMPT is a good solvent for the preparation of ketyls[165].

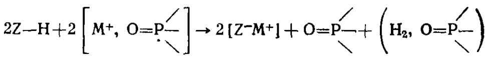
Radical-anions may be produced not only on the dissolution of metals but also during the electrolysis of alkali-metal salts in certain solvents (ammonia and the lower amines). Two laboratories have recently shown—simultaneously and independently—that HMPT may also be such a solvent[49,166]. When magnesium bromide is electrolysed with a calomel electrode in HMPT, an unstable light blue coloration appears around the cathode[49], and this is stabilised by the addition of lithium chloride[166]. In alcoholic medium (HMPT absent) evolution of hydrogen is observed. In HMPT containing a minute amount of alcohol a weak light blue coloration is evident in the catholyte, and electrolysis is not accompanied by hydrogen evolution. These facts indicate that HMPT accepts an electron with formation of a radical-ion.

B. APPLICATION OF RADICAL-ANIONS

The solutions of radical-ions formed when alkali metals are dissolved in HMPT can be used for those reactions—metallation, reduction, isomerisation, polymerisation, etc.—which occur in solutions of these metals in liquid ammonia[151].

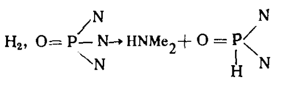
1. Formation of Anions and Metallation

Solutions of radical-anions are nucleophilic reagents, able to replace labile hydrogen in compounds containing it:



$$2Z{-}H + 2\left[M^+,\ O{=}\dot{P}\Big\langle\right] \rightarrow 2\,[Z^-M^+] + O{=}P\Big\langle + \left(H_2,\ O{=}P\Big\langle\right)$$

the anion Z^- or a metallated product being obtained. Hydrogen is not evolved in these reactions, but is bound by the HMPT into a complex, which decomposes according to the equation



$$H_2,\ O{=}P(N)_2{-}N \rightarrow HNMe_2 + O{=}P(H)(N)_2$$

The reactions occur more effectively with potassium and lithium than with sodium. For these reactions the HMPT can be mixed with other solvents (ether, oxolan, benzene). The radical-ions tend to decompose, and the stoichiometric quantity of ZH is introduced into the reaction mixture at the very start in order to avoid such decomposition.

Table 51 gives results for the production of several heteroanions[167]. Information on the metallation of certain "acidic" hydrocarbons is given in Table 52.[168]

The aprotic solvent HMPT enables very weak acids (e.g. toluene) to be metallated by alkali metals. The action of lithium or potassium produces the deep red colour characteristic of the benzyl radical. Carboxylation yields phenylacetic acid, but always in low yield (the red solutions are decolorised). 1,3-Diphenylpropane and ethylbenzene have also been detected among the decomposition products.

Metallation by alkali metals in HMPT should be applicable to macromolecules containing labile hydrogen atoms—polyvinyldiphenylmethane, polyvinylfluorenone.

Alkynes, which are stronger acids than the above hydrocarbons, are not metallated by alkali metals when the solvent is HMPT alone. When a mixture of hexyne and HMPT is shaken with potassium and heated at 55°C, 37% of hexyne is recovered: the radical-ion decomposes. Even phenylacetylene, a relatively acidic compound, is not metallated. The phosphorodiamidite anion, which appears on decomposition of the radical-ion, is bound to both ends of the triple bond.

Table 51.

Metallated compound	Metal	Reactant	Product	Yield, %
n-C_4H_9OH	Na	$PhCH_2Cl$	$C_4H_9OCH_2Ph$	77
$Ph{-}NH{-}C_2H_5$	K	C_2H_5I	$Ph{-}N(C_2H_5)_2$	77
	Na	CH_3I		85
CH_3CONH_2	K	$PhCH_2Cl$	$CH_3CO{-}NH{-}CH_2Ph$	negligible*

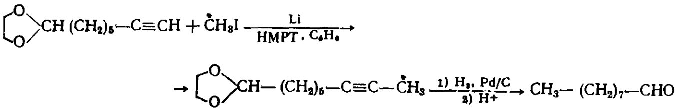
*Negligible yield also when sodamide employed.

This great difference in the behaviour of alkali metals is HMPT and in liquid ammonia can be explained by the formation of complexes between alkynes and HMPT. However, metallation is possible in a mixture of HMPT and a non-polar solvent (benzene, toluene, etc.), where the complexes will be decomposed. Table 53 gives results obtained by the use of a mixed solvent[169].

Table 52.

Hydrocarbon	Metal	Reactant	Product	Yield, %
Ph_3CH	Na	CO_2	$Ph_3C{-}COOH$	50
—	K	$PhCH_2Cl$	$Ph_3C{-}CH_2{-}Ph$	90
—	K	$PhCOCl$	$Ch_3C{-}CO{-}Ph$	70
——	K	$Br(CH_2)_4Br$	$Ph_3C(CH_2)_4CPh_3$	60
Ph_2CH_2	Na	CO_2	$Ph_2CH{-}COOH$	30
—	K	n-C_4H_9I	$Ph_2CH{-}C_4H_9$	64
—	K	$PhCH_2Cl$	$Ph_2CH{-}CH_2{-}Ph$	66
—	K	$Br(CH_2)_4Br$	$Ph_2CH(CH_2)_4CHPh_2$	87
—	Li	—	—	90
—	Li	—	—	65
	Na	C_2H_5I		73
$PhCH_3$	Li	CO_2	$PhCH_2{-}COOH$	negligible
Ph_3GeH	K	n-C_4H_9Br	$Ph_3Ge{-}C_4H_9$	62

The same conditions have been effectively applied to the preparation of nonanal[170], which is formed as an intermediate in the synthesis of labelled oleic acid:



The yield of the labelled compound is 95% based on the iodomethane.

Formation of carbanions is successful if the functional group of the compound is attached to an active CH_2 or CH_3 group[154] (Table 54). In some cases (acetophenone, acetonitrile) it is necessary to use a mixture of HMPT with an inert solvent to avoid the formation of condensation products. A mixture of solvents is also in carbonylation and acylation.

Table 53.

Alkyne	Reactant	Product	Yield, %
$Et_2NCH{-}C{\equiv}CH$	$Br(CH_2)_4Br$	$C{\equiv}C{-}CH_2NEt_2$ $(CH_2)_4$ $C{\equiv}C{-}CH_2NEt_2$	50
$PhC{\equiv}CH$	CO_2	$PhC{\equiv}C{-}COOH$	70
$HC{\equiv}CH$	n-$C_6H_{13}Br$*	$CH_3(CH_2)_5{-}C{\equiv}CH$	14
$HC{\equiv}CH$			50

*HC ⁝ C, a stronger base in HMPT, causes the elimination of hydrogen bromide.

2. Reduction of Unsaturated Compounds

The transfer of electrons from a radical-ion to an unsaturated system A=B results in the formation of a dianion:

$$(1)\quad A{=}B + 2\left[M^+,\ O{=}\dot{P}{\lessgtr}\right]^- \rightarrow 2O{=}P{\lessgtr} + M^+A^-{-}B^-M^+$$

HMPT is again regenerated, and may in principle act in catalytic quantities.

Table 54.

Metallated compound	Metal	Reactant	Products
$PhCH_2COOH$	Na	CO_3	$PhCH(COOH)_2$
$Ph{-}CH_2{-}CN$	K	$PhCH_2Cl$	$PhCH(CN){-}CH_2{-}Ph + PhC(CN){-}(CH_2Ph)_2$
$CH_2(COOEt)_2$	K	$CH_2{=}CHCH_2Br$	$RCH(COOEt)_2$*
$CH_2(CN)(COOEt)$	K	$CH_2{=}CHCH_2Br$	$R{-}CH(COOEt)(CN) + R_2C(COOEt)(CN)$
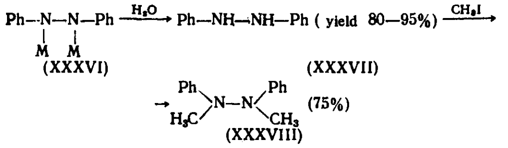
	K	$CH_2{=}CHCH_2Br$	$PhCOCH_3$	K	$CH_2{=}CHCH_2Br$	$PhCOCH_2{-}R + PhCOCH_2R + PhCOCR_3$
CH_3CN	K	$C_7H_{15}Br$	$C_7H_{15}CH_2CN + (C_7H_{15})_2CH{-}CN$

*R = CH₂ : CHCH₃.

Another possible path for this reaction is the formation of a dimeric dianion alone:

$$(2)\quad A{=}B + 2\left[M^+,\ O{=}P{\lessgtr}\right]^- \rightleftarrows 2O{=}\dot{P}{\lessgtr} + 2A^{\cdot}{-}B^-,\ 2M^+ \rightarrow B^-{-}A{-}A{-}B^-,\ 2M^+$$

Let us examine reaction (1) in greater detail. In HMPT—an aprotic solvent—the monomeric dianion is produced in the free form, and can then be used in various reactions (reduction, alkylation, etc.), in contrast to liquid ammonia and primary amines, in which the monomeric dianion is present in protonated form. On treating a solution of azobenzene in HMPT with an alkali metal, we obtain the compound (XXXVI), which is hydrolysed to 1,2-diphenylhydrazine (XXXVII) and alkylated by iodomethane to (XXXVIII):[171]



(XXXVI) (XXXVII) (XXXVIII)

Table 55.

Unsaturated compound (0.1 M)	Metal (0.2 g-atom)	Product	Yield, %
$PhCH{=}N{-}Bu$	K	$Ph{-}CH_2{-}NH{-}Bu$	70
$PhCH{=}N{-}Bu$	Li	$Ph{-}CH_2{-}NH{-}Bu$	65
$C_6H_{11}N{=}CH{-}CH(CH_3)_2$	Li	$C_6H_{11}NH{-}CH_2{-}CH(CH_3)_2$	50
		$Ph_2C{=}NH$	33
$Ph_2C{=}N{-}NH{-}Ph$	Li	$+Ph{-}NH_2$	33
$(H_{13}C_6)(H_3C)C{=}N{-}Ph$	Li	$(H_{13}C_6)(H_3C)CH{-}NH{-}NH{-}Ph$	60
	Li		
$Ph_2C{=}N{-}OH$		$+PhNH_2$	8
		$Ph_2C{=}NH+$	50
		$PhCH{=}N{-}Ph$	10
$(C_5H_{10})C{=}NOH$	Li	$(C_5H_{10})CH{-}NH_2$	25

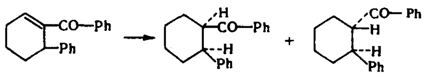
Compounds containing the grouping CH : N (imines, oximes, hydrazones) may undergo reduction. Thus benzophenone phenylhydrazone (Table 55) is reduced in a protic medium (oxolan and t-butyl alcohol); the yield of benzophenone oxime is determined using thin-layer chromatography by hydrolysis and conversion to the 2,4-dinitrophenylhydrazone. Rearrangements of this type have been found only with aldoximes[172,173].

In the case of ethers of phenols and arylamines subject to the action of alkali metals the benzene ring may undergo either reduction or cleavage. In protic medium elimination is insignificant, since the resulting radical-ion adds a proton and is converted into a radical:

where A = OR, NR₂. The latter, in its turn, is reduced, and then protonated. Hydrolysis of the final product yields cyclohexenone (data on the Birch reduction):

Table 56 gives results for the reduction of certain aromatic compounds in a mixture of HMPT and t-butyl alcohol[171,174].

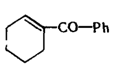
The chemical reduction of α-ethylenic ketones by alkali metals in liquid ammonia and primary amines results in the formation of saturated ketones. This reaction can be effected also in HMPT using lithium and potassium (yield 80%) and the same ratio of isomers for the ketone (XXXIX):[175]



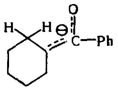
(XXXIX) *cis* (80%) *trans* (20%)

Data on the reduction of several ketones are given in Table 57.[174]

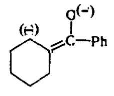
Electrolytic reduction involves electron transfer from the radical-ion to the substance which is reduced. The ketone (XL) is converted into a high yield (around 80%) of the saturated ketone when an ethereal solution of magnesium bromide or calcium iodide is used as electrolyte.



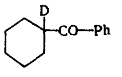
(XL)



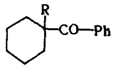
(XLI)



(XLII)



(XLIII)



(R = CH_3, $—CH_2—CH=CH_2$)

(XLIV)

Table 56.

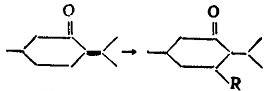
Aromatic compound	Product	Yield, %
Anisole	cyclohex-2-enone	50
Phenetole	cyclohex-2-enone	25
NN-Dialkylanilines (CH_3, C_2H_5)	cyclohex-2-enone	20
2-Ethoxynaphthalene	tetralone	60
1-Methoxynaphthalene	1-methoxynaphthalene	15
	1,2-dihydronaphthalene	15
	1,4-dihydronaphthalene	30

The mechanism of this reduction in an aprotic solvent has not yet been finally established. Some results indicate that the enolate ion (XLI) is formed more rapidly than the dianion (XLII). In fact treatment of the ketone (XLI) with a solution of lithium in HMPT followed by the action of deuterium oxide yields the α-deuterated ketone (XLIII). The same lithium derivative yields α-alkylated ketones (XLIV).[176]

Table 57.

Unsaturated ketone	Yield of saturated ketone, %	Unsaturated ketone	Yield of saturated ketone, %
$CH_3—CO—CH=C(CH_3)_2$	60	$CH_3COC(CH_3)=CH—CH(CH_3)_2$	55
$CH_3COCH=CH—Ph$	30	Isophorone	60
$CH_3COCH=CH—Et$	30	Carvone	40
$CH_3COCH=CH—CH(CH_3)_2$	40	Pulegone	65
$CH_3COCH=CH\text{-}n\text{-}C_5H_{11}$	45		

Formation of an α-substituted ketone (XLVI) is possible from pulegone (XLV):



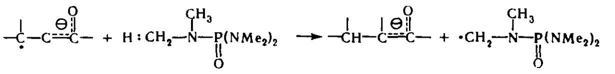
(XLV) (XLVI)

where R = CH_3 (60%), allyl (63%).

Formation of the enolate ion (XLI) has been clearly established when liquid ammonia is used as solvent. With HMPT as solvent a radical mechanism also seems possible, in which (*a*) the ketone is reduced to a radical-ion:

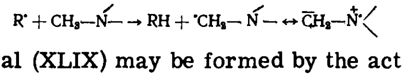
(XLVII)

(*b*) The radical-ion (XLVII) forms the enolate ion (XLVIII) with a methyl hydrogen of the HMPT, which gives the radical (XLIX):



(XLVIII) (XLIX)

It is known that tertiary amines can act as hydrogen donors towards radicals[177,178]:



The radical (XLIX) may be formed by the action of alkali metals on HMPT in the presence of various aliphatic-aromatic hydrocarbons. The action of potassium on toluene enables various derivatives—in particular ethylbenzene and 1,3-diphenylpropane—to be isolated without protonation. The same operations with ethylbenzene yield cumene[179]. Under similar conditions tetralin gives mono- and di-methyltetralins (undoubtedly dimers).[179] The same results have been achieved by the electrolytic reduction of tetralin in HMPT in the absence of contamination by a protic solvent[166].

Under the same reduction conditions α-ethylenic acids are converted into saturated acids[174]:

$$PhCH=CH—COOH \rightarrow Ph—CH_2—CH_2—COOH\ (60\%)$$
$$(CH_3)_2CH—CH=CH—COOH \rightarrow (CH_3)_2CH—CH_2—CH_2—COOH\ (65\%)$$

In a mixture of HMPT with ether or oxolan lithium does not reduce oct-3-yne or hex-3-yne, but causes them to isomerise into alk-1-ynes[174]:

$$CH_3C \equiv C—CHOHCH(CH_3)_2 \rightarrow CH \equiv C—CH_2—CH_2—CHOH—CH(CH_3)_2\ ‡$$

In a 1 : 5 mixture of HMPT and benzene, on the other hand, only *trans*-alkenes are formed after reduction:

$$C_6H_{13}C\equiv C—CH_3 \rightarrow C_6H_{13}CH=CH—CH_3\ (60\%)$$
$$C_4H_9C\equiv C—C_5H_{11} \rightarrow C_4H_9CH=CH—C_5H_{11}\ (55\%)$$

3. Reduction with Elimination

The transfer of electrons from a radical-ion to a molecule A–B may result in the formation of (*a*) an anion and another radical:

or (*b*) two anions:

Rupture of the bond in the molecule AB is facilitated when the anions A^- and B^- are stabilised by conjugation. Table 58 gives several examples[180].

---

‡Since these results are unpublished[174], it is not possible to amend the formulae and the text (Ed. of Translation).

Hexa-alkyldigermanium compounds have recently been cleaved by means of potassium in HMPT to give a quantitative yield of the potassium derivatives, which are stable in HMPT and condense with halides of metals in the same group to give mixed compounds[181] $R_3Ge-MR'_3$, where M = Ge, Si, Sn.

Table 58.

Initial cpd.	Metal	Reagent	Product	Yield, %
$PhCH_2Cl$	K	H_2O	$PhCH_2—CH_2—Ph$	75
$PhOCH_3$	K	H_2O	$Ph—OH$	80
$PhO—CHPh_2$	K	H_2O	$Ph—OH+Ph_2CH_2+Ph_3COH$	*
Ph_3P	K	C_2H_5I	$Ph_2P—C_2H_5$	58
$CH_3S—S—CH_3$	K	$PhCH_2Cl$	$CH_3S—CH_2—Ph$	81
$CH_3S—S—CH_3$	K	$ClCH_2CH_2OH$	$CH_3S—CH_2—CH_2OH$	56
$CH_3—NH—NH—Ph$	Li	H_2O	$PhNH_2$	14
$Ph_3C—CH_2Ph$	K	CH_3I	$Ph_3C—CH_3$	72
$Ph_3Ge—GePh_3$	K	$PhCH_2Cl$	$Ph_3Ge—CH_2—Ph$	56

* PhOH 47%; CH_2Ph_2 52%; Ph_3COH 46%.

The cleavage of ethers by alkali metals in HMPT has been studied in part in Ref. 89. Reduction is possible when the ether contains a weakly acceptor group. Aliphatic ethers cannot be cleaved. Diaryl ethers give phenols. Data on the cleavage of alkyl aryl ethers are given in Table 59, and data on aryl benzyl ethers in Table 60.

Table 59.

Ether	Products (yield, %)
$C_6H_5O-CH_3$	C_6H_5OH (76-80)
$C_6H_5O-C_2H_5$	C_6H_5OH (20) + C_6H_5OH.HMPT complex (65)
2-$C_{10}H_7$-OCH_3	$C_{10}H_8$ (48) + 2-naphthol.HMPT complex (38)
2-$C_{10}H_7OC_2H_5$	2-naphthol.HMPT complex (51)

Reduction does not always proceed smoothly: the carbanion may cause elimination with the formation of 1,2-diphenylethane, as has already been observed in liquid ammonia[182]:

$$PhCH_2^- + Ph—CH_2—OCH_2—Ph \rightarrow Ph—CH_2—CH_2—Ph + PhCH_2O^-$$

Ethers may undergo the Wittig rearrangement[183], which results in the formation of alcohols:

$$Ar—O—\overline{C}\langle \rightarrow Ar—\overset{|}{\underset{|}{C}}—O^-$$

Table 61 shows the reduction of some β-unsaturated ethers.

The reduction of aryl toluene-*p*-sulphonates by potassium in HMPT yields mainly phenols, but when aryl phosphates are reduced, hydrocarbons are formed[89]:

$$ArO—\underset{\underset{O}{\|}}{P}—(OEt)_2 \xrightarrow[2)\ H_2O]{1)\ K,\ HMPT} Ar—H$$

Table 60.

Ether	Cleavage product (yield, %)
$C_6H_5CH_2OC_6H_5$	$C_6H_5CH_3$ (21) + C_6H_5OH (55) + C_6H_5OH.HMPT complex (16)
$C_6H_5CH_2OC_6H_5$	C_6H_5OH (29) + C_6H_5OH·HMPT complex (31)
$C_6H_5CH_2OC_7H_{15}$	$C_6H_5CH_3$ (60) + $C_7H_{15}OH$ (70)
$(C_6H_5CH_2)_2O(K)$	$C_6H_5CH_3$ (60) + $C_6H_5CH_2OH$ (44) + $C_6H_5CHOHCH_2Ph$ (15)
$(C_5H_5CH_2)_2O(Li)$	$C_6H_5CH_3$ (20) + $C_6H_5CH_2OH$ (33) + $C_6H_5CHOHCH_2Ph$ (27)+ + $C_6H_5CH_2CH_2Ph$ (2)
$(C_6H_5)_2CHOC_6H_5$	$(C_6H_5)_2CH_2$ (50) + C_6H_5OH (44) + C_6H_5OH.HMPT complex (12) + $(C_6H_5)_3COH$ (44)
$(C_6H_5)_2CHOC_7H_{15}(K)$	$(C_6H_5)_2CH_2$ (53) + $C_7H_{15}OH$ (64) + $Ph_2CHC_7H_{15}$
$(C_6H_5)_2CHOC_7H_{15}(Li)$	$(C_6H_5)_2CH_2$ (42) + $C_6H_5CHOHC_6H_5$ (4) + $C_7H_{15}OH$ (64) + + $(C_6H_5)_2CHC_7H_{15}$
$(C_6H_5)_3COC_7H_{15}$	$(C_6H_5)_3CH$ (73) + $C_7H_{15}OH$ (66)

Such reduction can be effected also in liquid ammonia[184]. Non-aliphatic mixed ethers containing a heteroatom Z can be converted under the same conditions into two anions:

$$Ar—O—Z \rightarrow Ar—O^- + Z^-$$

where Z = B, Si, Ge, Sn. On protonation ZH is obtained (indirect reduction of ZX to ZH), and on alkylation the derivatives Z–R[185] (see Table 62).

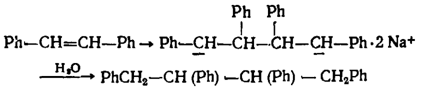
Table 61.

Ether	Products (yield, %)
$CH_2=CHCH_2OC_6H_5$	C_6H_5OH (26) + C_6H_5OH.HMPT complex (33)
$CH_2=CHCH_2OC_7H_{15}$	$C_7H_{15}OH$ (73)
$C_6H_5CH=CHCH_2OC_6H_5$	C_6H_5OH (44) + C_6H_5OH.HMPT complex (46)
$C_6H_5CH=CHCH_2OC_7H_{15}$	$C_7H_{15}OH$ (67)
	$CH_3—CH=CH—CH_2OH$ (29)
	$CH_3—CH=CH—CH_2OC_4H_9$ (43)

4. Condensation and Polymerisation

Since HMPT is widely used as a Lewis base in many processes, including those involving organometallic compounds, it may find application also in anionic polymerisation[186]. This type of polymerisation is observed in radical-ionic solutions of alkali metals with various activated vinyl compounds[157,158,187]. The species M^+, $HMPT^•$ and M^+, $ArH^•$, which are formed in HMPT, may serve as radical-ions.

In the presence of sodium in HMPT *trans*-stilbene gives a dianion, protonation of which yields "*meso*"-1,2,3,4-tetraphenylbutane[150]:

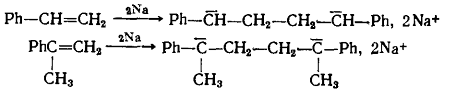


$$Ph{-}CH{=}CH{-}Ph \rightarrow Ph{-}\underline{C}H{-}\overset{Ph}{\overset{|}{C}H}{-}\overset{Ph}{\overset{|}{C}H}{-}\underline{C}H{-}Ph\cdot 2\,Na^+$$
$$\xrightarrow{H_2O} PhCH_2{-}CH\,(Ph){-}CH\,(Ph){-}CH_2Ph$$

Table 62.

Compound A.OR	Reagent	Products (yield, %)
$B(OC_6H_5)_3$	n-C_4H_9Br	$C_6H_5O{-}n{-}C_4H_9$ (93)
$(CH_3)_3SiOC_6H_5$	H_2O	C_6H_5OH (17) + C_6H_5OH.HMPT complex (53)
$(CH_3)_3SiOC_6H_5$	n-C_4H_9Br	$C_6H_5O{-}n{-}C_4H_9$ (83)
$(C_6H_5)_3SiOC_6H_5$	C_3H_5Br	$C_6H_5OC_2H_5$ (67) + $(C_6H_5)_3SiOSiPh_3$ (12)
$\begin{matrix}H_3C\\H_5C_6\end{matrix}\!>Si(OC_6H_5)_2$	C_2H_5Br	$C_6H_5OC_2H_5$ (65) + C_6H_5OH.HMPT (22)
$HSi(OC_6H_5)_3$	$ClSi(C_6H_5)_3$	$C_6H_5OSi(C_6H_5)_3$ (34)
$(C_2H_5)_3GeOC_6H_5$	$ClCH_2C_6H_5$	$C_6H_5OCH_2C_6H_5$ (92)
$(C_4H_9)_3SnOC_6H_5$	C_4H_9Br	$C_6H_5OC_4H_9$ (79), $Sn(C_3H_9)_4$ (77)

Styrene and α-methylstyrene have been dimerised in oxolan solution in the presence of sodium, which is used as electron donor with respect to the carbon atom adjacent to the phenyl group[188]:



$$Ph{-}CH{=}CH_2 \xrightarrow{2Na} Ph{-}\bar{C}H{-}CH_2{-}CH_2{-}\bar{C}H{-}Ph,\ 2Na^+$$
$$\underset{\underset{CH_3}{|}}{PhC}{=}CH_2 \xrightarrow{2Na} Ph{-}\underset{\underset{CH_3}{|}}{\bar{C}}{-}CH_2{-}CH_2{-}\underset{\underset{CH_3}{|}}{\bar{C}}{-}Ph,\ 2Na^+$$

This condensation goes still further with potassium in oxolan at between −40° and −30°C and in the presence of small quantities of HMPT as electron donor. After hydrolysis the reaction mixture contains a certain amount of dimers; all the polymers obtained are of low molecular weight. Solutions of diphenylmagnesium in HMPT are used as initiator for the anionic polymerisation of styrene, α-methylstyrene, and 2-vinylpyridine. The stability of the active centres has been determined spectrophotometrically. Polymerisation is quantitative[189]. Naphthalene–magnesium–HMPT solutions also bring about the polymerisation of styrene[164].

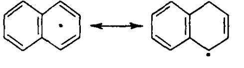
From the results obtained and some unpublished data[190] it can be concluded that HMPT–alkali-metal systems, even when present in small quantities, considerably increase the rate of polymerisation. They enable lower temperatures to be used and various difficult copolymerisations to be brought about more completely. The polymerisation promoters used are active in the presence of HMPT.

C. COMPARISON OF ELECTRON ACCEPTORS

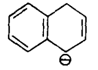
When electron acceptors are used, they are generally completely regenerated (in the case of reduction) or 50% reduced (in the production of anions and metallation). Compounds containing one or more multiple bonds—aromatic ketones and polycyclic hydrocarbons—are acceptors. In the presence of metals aromatic ketones form radical-ions (ketyls) (L), which are converted into alcohols (LI) on protonation followed by reduction:

$$Ar_2C{=}\dot{O} \leftrightarrow Ar_2\dot{C}{-}O^- \quad Ar_2CHOH$$
(L) (LI)

Polycyclic hydrocarbons react with active metals to yield radical-ions and dianions. Thus naphthalene is able to form the radical-ion (LII) or the dianion (LIII):



(LII)



(LIII)

The latter (LIII) is protonated and converted into dihydronaphthalene by a compound Z–H capable of forming Z^- or a metal derivative Z–M.

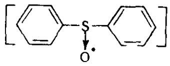
The system (L) acceptor–alkali metal is most effective in oxolan in various reactions involving metallation followed by carbonylation, especially when the products are to undergo chemical separation[159–171]. But the presence of the acceptor and its reduction product in the reaction medium is very often an undesirable condition for studying the reaction and isolating the products. This difficulty disappears when the system HMPT—alkali metal is used, since the acceptor and its reduction product are then soluble in water, and can easily be separated.

D. COMPARISON OF DIPOLAR APROTIC SOLVENTS

The solvents—dimethylformamide, tetramethylurea, and dimethyl sulphoxide—have been compared above from the viewpoint of their donor power. These same solvents can be acceptors of electrons, because of the presence of a polar group, and are able to form radical-ions, though these are unstable.

Aromatic ketones, in virtue of their carbonyl group, also form radical-ions (LIV), in which delocalisation of the negative charge promotes stabilisation:

(LIV)



(LV)

Amides, which are not stabilised, decompose rapidly into two anions[191–193]:

In tetramethylurea alkali metals form fairly unstable light blue solutions, the colour of which is preserved for several seconds at ordinary temperatures and for 1 min at −40°C.[191,192] Only triphenylmethane is metallised in this solution by a potassium–sodium alloy.

Similar phenomena are observed when HMPT is used as solvent, but the radical-ions formed are more stable. At ordinary temperatures the mean lifetime of such a radical-ion varies from 10–15 min with potassium to several hours with lithium and sodium.

Aromatic sulphoxides approach diaryl ketones, since their polar group SO is conjugated with phenyl groups. The radical-ion (LV), however, is less stable.

In the presence of potassium, solutions of diphenyl sulphone in 1,2-dimethoxyethane yield a light blue coloration, which is unstable even at −70°C and gives an electron spin resonance signal[194]. With dimethyl sulphoxide under the same conditions, alkali metals form the "dimsyl" anion (LVII):[195]

(LVI) (LVII)

The radical-ion (LVI) would be unstable, but would play the same part as amides containing hydrogen in the α-position relative to the carbonyl group (dimethylacetamide, *N*-methylpyrrolidone) and enolisable ketones, which yield enolate anions with alkali metals:

The stability of the radical-ions formed by different solvents can be placed in the sequence—HMPT˙ < < $((CH_3)_2N)_2CO^{\cdot}$ > $(CH_3)_2CO^{\cdot}$—in which HMPT is the only dipolar aprotic solvent that enables active solutions of metals to be used in syntheses.

Hydrophobic Regions on the Active Surface of Choline-esterases

M.I.Kabachnik, A.A.Abduvakhabov, I.I.Agabekova, A.P.Brestkin, R.I.Volkova,
N.N.Godovikov, E.I.Godyna, S.S.Mikhailov, M.Ya.Mikhel'son, V.I.Rozengart,
E.V.Rozengart, and R.V.Sitkevich

The methods of synthesis of *S*-alkyl(aryl) derivatives of methylphsophonothioic acid and methods for the investigation of their anticholine-esterase activity have been briefly described. Data confirming the anticholine-esterase activity of the compounds synthesised are presented.

It has been shown that, in the inhibition of choline-esterases by organophosphorus compounds, the hydrophobic sorption of these substances on the active surface of the enzymes plays an important and sometimes a decisive role.

It is suggested that the presence of hydrophobic regions on the active surface of choline-esterases tends to increase the probability of the sorption of acetylcholine (a choline esterase substrate) on this surface.

The bibliography includes 68 references.

CONTENTS

I. INTRODUCTION

Choline-esterases (CE) are important enzymes for vital processes whose purpose is to hydrolyse acetylcholine (AC), one of the mediators in nerve excitation. According to modern concepts[1-5], the catalytic centres in these enzymes consist of two distinct regions which are separated in space: anionic and esterase regions. The anionic region is probably formed by the carboxylate anion of a dibasic aminoacid included in the polypeptide chain of the enzyme. This may be an aspartic or glutamic acid residue. The role of the anionic region consists in the specific sorption of the trimethylammonium group of acetylcholine, which helps to ensure a favourable orientation of the substrate molecule on the active surface of the enzyme.

The esterase component, where the hydrolysis of acetylcholine takes place, is located at a distance of 4–5 Å from the anionic component. It has a complex structure in which the hydroxyl of serine, an aminoacid also included in the polypeptide chain of the enzyme, plays a central role. Proton-donating and proton-accepting groups are present in the immediate vicinity of the serine hydroxyl. These may be respectively the tyrosine hydroxyl and the imidazole group of histidine.

It is still unknown how the functional groups comprising each of these active components are located in the overall structure of the enzyme, i.e. whether they belong to the same polypeptide chain or to different chains, but it may be supposed that the mutual approach of these groups, leading to the formation of the active centre, takes place at the instant of interaction with the substrate and involves its direct participation[5,6].

The information available on the structure of the active surface of choline-esterase is largely due to large-scale and intense studies on the properties and activity of organophosphorus inhibitors (OPI), carried out at an increasing rate for more than 25 years[7-10].

The following mechanism of the hydrolysis of acetylcholine by choline-esterases has been generally accepted. Initially the substrate is sorbed on the active surface of the enzyme with formation of a Michaelis complex and subsequent acetylation of the serine hydroxyl. The last stage involves the deacetylation of the enzyme by water and the restoration of its initial structure. There is every reason to suppose that this is not spontaneous water hydrolysis but a more complex process.

It is known that the inhibition of choline-esterase by OPI consists in the phosphorylation of the serine hydroxyl in the esterase component of the enzyme. In contrast to the deacetylation of choline-esterases, which occurs in the enzymic hydrolysis of acetylcholine and other substrates, dephosphorylation takes place extremely slowly and therefore the inhibition is almost irreversible. It is significant that the hydrolysis of the phosphorylated enzyme requires the dissociation not of an *O*-acyl but of an *O*-alkyl bond, which is not characteristic of choline-esterases.

The activity of the inhibitor depends primarily on its phosphorylating capacity, i.e. on the effective positive charge of the phosphorus atom. However, the anticholine-esterase activity of OPI is not determined solely by their phosphorylating capacity[7,10-13]. Ionic and ion-dipole interactions also plays an important role. They are shown most clearly on introduction of a cationic group into the eliminated component† of the OPI molecule. OPI is then fixed on the anionic region of the enzyme as a result of which the probability of the reaction between the inhibitor and the esterase component is enhanced. First examples of such cationic OPI were investigated in 1955–1958—they contained ammonium[14-17] or sulphonium[18-26] groups.

---

† We refer to the group of atoms linked directly to the phosphorus atom and split off on phosphorylation of choline-esterase as the eliminated component of the OPI molecule.

In the study of the first ammonium OPI it was impossible to demonstrate sufficiently clearly the role of the 'onium group, since the tertiary analogues of thiophosphonylcholine are so highly protonated owing to the high basicity of the amino-nitrogen at biological pH values that conversion to a quaternary base enhances the anticholine-esterase activity only by a factor of 3–4.

The role of the positive charge was revealed much more clearly in studies on certain OPI containing sulphides and sulphonium groups[20–26]. In sulphide OPI the sulphur atom is incapable of being protonated under the usual conditions and therefore the appearance of a charge on conversion into sulphonium compounds increases the anticholine-esterase activity by a factor of 2000–3000.[26] Later a similar striking increase of activity was achieved also with nitrogen-containing OPI derived from aromatic amines of low basicity. Such amines are protonated to only a slight extent at pH 7–8 and therefore the appearance of a charge on their conversion into quaternary bases also increases the activity of such OPI by a factor of several thousand[27].

The position of the 'onium atom in the OPI molecule is very important. The greatest effect is achieved when the atom carrying the positive charge is located in the eliminated component of the OPI molecule at the same distance from the phosphorus atom as that between the quaternary nitrogen atom and the carbonyl carbon in acetylcholine.[8,24,25]

It should be noted that, on introduction of a cationic group into the OPI molecule, there is not only a possibility of ionic interaction but, by virtue of the inductive effect, there is a significant increase also in electrophilic phosphorylating capacity. These two effects are difficult to separate experimentally[24,26,28].

The electrophilic reactivity of OPI and their capacity to interact with the anionic component of the enzyme are the two properties of the inhibitor which have been widely discussed in numerous publications dealing with the relation between the structure of OPI and their activity.

However, as will be shown below, these two factors do not exhaust the possibilities of the interaction between OPI and the active surface of choline-esterase. It may be supposed that Coulombic attraction is not the only important factor in the interaction between the cationic "head" of acetylcholine and the anionic group of choline-esterases. The three methyl groups linked to the nitrogen atom also play a significant role in this interaction[29,30]. It has been found that uncharged 3,3-dimethylbutyl acetate, the t-butyl group of which imitates sterically the trimethylammonium group of acetylcholine, is hydrolysed by choline-esterase only a little more slowly than acetylcholine itself[31,32]. Hence it may be supposed that the introduction of the t-butyl group in the required position into the molecule of the choline-esterase inhibitor can also intensify its interaction with the enzyme. There is also some other evidence in support of this hypothesis, for example the high anticholine-esterase activity of the pinacolyl esters of alkylphosphonic acids[8,12].

The first results of studies on this problem[33,34] led to the hypothesis that, around the active centre of choline-esterases, there are several hydrophobic regions which can interact with the alkyl groups of both substrates and inhibitors[5].

The hypothesis of the "hydrophobic interaction" is nowadays widely used in enzymology. It has been shown for various enzymes, such as pepsin, chymotrypsin, trypsin, carboxypeptidase, and others, that the rate of the enzymic hydrolysis of substrates depends significantly on the size of their constituent hydrocarbon groups capable of being sorbed on the hydrophobic regions of the catalytic centre of the enzyme[35–39].

The mechanism of the inhibition of choline-esterases was not examined previously from this standpoint. This review presents the results of systematic studies on the "topography" of the hydrophobic regions located on the active surface of horse serum choline-esterase and the acetylcholine-esterase from bull erythrocytes.

II. MATERIALS FOR INVESTIGATION

Enzymes. We employed a preparation of choline-esterase from horse blood serum (BuCE, EC, 3.1.1.8), manufactured at the Mechnikov Institute, which had a purification factor of 60 and a specific activity of 1.2–1.6 μmole of AC per minute per milligramme of protein at 25°C, pH 7.5, and a substrate concentration of 0.02 M.

The stroma of bull erythrocytes carefully washed free of haemoglobin and then lyophilised, serves as a source of acetylcholine-esterase (ACE, EC, 3.1.1.7).[40,41]

OPI preparations. These consisted of *S*-alkyl(aryl) derivatives of methylphosphonothioic acid some of the physicochemical constants of which are listed in Table 1.

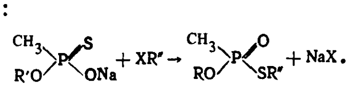
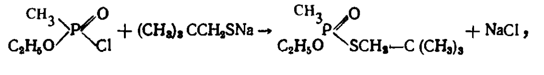
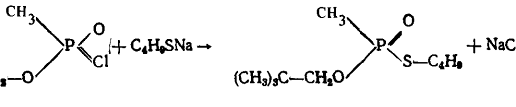
The general method for the preparation of S-alkyl O-ethyl methylphosphonothiolates and O-ethyl S-(ω-phenylalkyl)-methylphosphonothiolates (series I) and also O-alkyl S-n-butyl methylphosphonothiolates (series IV) consisted in the alkylation of sodium O-alkyl methylphosphonothioate with the corresponding alkyl halides or ω-halogenophenylalkanes[33,34,42-44]:



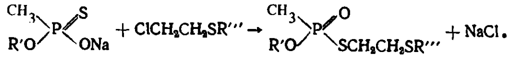
Exceptions were O-ethyl S-(2,2-dimethylpropyl) methylphosphonothiolate (Table 1, compound 1.10), which was synthesised by the reaction of O-ethyl methylphosphonochloridate with sodium 2,2-dimethylpropanethiolate[34]:



and S-n-butyl O-2,2-dimethylpropyl methylphosphonothiolate (Table 1, compound IV, 5.2), which was obtained by the interaction of O-2,2-dimethylpropyl methylphosphonochloridate with sodium butanethiolate:



All the S-(β-alkylthioethyl) O-ethyl methylphosphonothiolates (series II) and O-alkyl S-(β-ethylthioethyl) methylphosphonothiolates (series V) were obtained by the reaction of sodium O-alkyl methylphosphonothioate with β-chloroethylalkyl sulphide[45,46]:



Next compounds of series II and V were converted by dimethyl sulphate into the corresponding S-methyl methosulphates:

$$C_2H_5O\,(CH_3)\,P\,(O)\,S\,(CH_2)_2\overset{+}{S}(CH_3)\,R'''\cdot\overset{-}{S}O_4CH_3 \text{ (series III)}$$

$$\text{and } R'O\,(CH_3)\,P\,(O)\,S\,(CH_2)_2\overset{+}{S}\,(CH_3)\,C_2H_5\cdot\overset{-}{S}O_4CH_3 \text{ (series IV):}$$

O-Alkyl methylphosphonothioates were obtained by the hydrolysis of O-alkyl methylthiophosphonochloridates[47]:

Some of the physical constants and the pK_a values of these substances are listed in Table 2.

III. RESEARCH METHODS

1. Estimation of Anticholine-esterase Activity

The anticholine-esterase activity of the OPI was estimated from the rate constant k_{II} for their interaction with the enzyme[4,48,49].

The enzyme (E) and the inhibitor (I) were incubated in the presence of 0.007 M phosphate buffer for a definite period (t, minutes) and then acetylcholine was added to the reaction mixture. The reaction between the OPI and the enzyme tended to cease completely in a dilute reaction mixture containing acetylcholine at a concentration corresponding to complete saturation of the enzyme by the substrate. The acetic acid formed in the hydrolysis of acetylcholine under the action of the residual concentration of the enzyme was determined by potentiometric titration with 0.1–0.12 N sodium hydroxide solution. The rate of reaction A_t corresponding to t minutes of incubation of E with

I was determined from the slope of the experimental linear plots of the volume of the solution of alkali against time. In some of the experiments A_t was found from the change in the concentration of acetylcholine in the reaction mixture, which was determined by Hestrin's method[50].

Since the reaction was carried out under standard conditions, the measured rates A_t were directly proportional to the corresponding concentrations of the active centres of the enzyme $[E]_t$. Accordingly the values of $[E]_t$ were calculated from the formula

$$[E_t] = [E]_0\, A_t/A_0, \qquad (1)$$

where A_0 is the rate of the enzyme reaction in the absence of the inhibitor with all other conditions kept constant and $[E]_0$ the initial concentration of the active centres of the enzyme in the reaction mixture. $[E]_0$ for the given initial enzyme solution was determined in a preliminary experiment by Berry's method[15,52] involving partial phosphorylation of the active centres of the enzyme (between 20 and 80%) with a highly active organophosphorus inhibitor—Gd-42 (Tables 1 and 6, compound III. 32)—at a known concentration, the inhibitor being completely consumed in the reaction. The end of the reaction was inferred from the constancy of A_t as a function of the duration of incubation of E with I. The data obtained were used to calculate k_{II} by the equation

$$k_{II} = \frac{2.303}{t\,([I]_0 - [E]_0)} \lg \frac{[E]_0\,([I]_0 - x)}{[I]_0\,([E]_0 - x)}\,, \qquad (2)$$

where $[I]_0$ is the initial concentration of the OPI in the reaction mixture and x the decrease of the concentration of the enzyme and the OPI calculated from the difference $[E]_0 - [E]_t$. This formula is readily transformed into another more convenient for practical use[53]:

$$k_{II} = \frac{2.303}{t\,([I]_0 - [E]_0)} \lg \left[\frac{A_0}{A_t}\left(1 - \frac{[E]_0}{[I]_0}\right) + \frac{[E]_0}{[I]_0}\right]. \qquad (3)$$

The concentration in the reaction mixture of the inhibitor of low activity was always many times higher than that of the enzyme, i.e. $[I]_0 \gg [E]_0$. In this case Eqns. (2) and (3) become

$$k_{II} = \frac{2.303}{t\,[I]} \lg \frac{A_0}{A_t}\,. \qquad (4)$$

However, for the majority of the OPI, the constant k_{II} falls significantly with increase in time t.[54,55]

Kinetic studies have shown[55-57] that this type of relation between k_{II} and t follows from the generally accepted two-phase mechanism of the interaction between E and I:

$$E + I \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} EI \xrightarrow{k_3} EI' + P_t, \qquad (5)$$

where EI is the enzyme–inhibitor complex, analogous to the Michaelis complex, EI′ the phosphorylated enzyme, and P*t* the corresponding mercaptan split off from the OPI on phosphorylation of the enzyme. Therefore we found the value of k_{II} corresponding to the beginning of the reaction between E and I.

For certain OPI, the constant k_{II} was determined at different temperatures, which made it possible to find the activation energy E_{act} for the inhibition of choline-esterases and to calculate the pre-exponential factors *PZ* in the Arrhenius equation.

2. Determination of the Rate Constants for Alkaline Hydrolysis

To estimate the electrophilic reactivity of the OPI, we determined the rate constants for their alkaline hydrolysis. An aqueous or aqueous alcoholic solution of the OPI was incubated at 25°C with a 2.5-fold excess of sodium hydroxide. The concentration of the OPI in the reaction mixture $[I]_0$ was usually 0.01 M and that of alkali $[B]_0$ was 0.025 M. The pH at the beginning of the reaction was 10.5–10.8. Samples were removed at definite time intervals and their sodium hydroxide concentration was determined by potentiometric titration. The pH at the beginning of the experiment fell by not more than 0.3. The hydrolysis rate constant k_{OH} was calculated from the formula

$$k_{OH} = \frac{2.303}{t\,([B]_0 - [I]_0)} \lg \frac{[I]_0\,([B]_0 - x)}{[B]_0\,([I]_0 - x)}\,,$$

where x is the decrease of the concentration of NaOH and the OPI during the experiment, determined from the difference between the amounts of alkali consumed in the titration of a control reaction mixture ($t = 0$) and in the experiment after a period of incubation t.

The OPI containing a cationic group in the molecule are hydrolysed rapidly and their k_{OH} were found by direct titration of the reaction mixture at pH 10.5.[58] Since the concentration of OH^- ions in these experiments was constant, k_{OH} was calculated from the equation

$$k_{OH} = \frac{2.303}{t\,[OH]} \lg \frac{[I]_0}{([I]_0 - x)}\,,$$

where x is the decrease of the inhibitor concentration determined from the amount of alkali consumed in the titration.

Determination of pK_a. To estimate the electrophilic reactivity of certain OPI, we also employed the ionisation constants (pK_a) of the corresponding *O*-alkyl methylphosphonothioates.

All the pK_a determinations were made by measuring the pH (using a silver, silver chloride electrode at 20°C) of partly neutralised (degree of neutralisation 30, 50 and 80%) 3.5×10^{-3}–50.1×10^{-3} M acid solutions. Since the ionic strength of the solution did not exceed 0.01, a correction for activity coefficients was not introduced. The calculation was based on the formula

$$K_a = [H^+]\frac{[Na^+] + [H^+] - \frac{K_W}{[H^+]}}{M - \left\{[Na^+] + [H^+] - \frac{K_W}{[H^+]}\right\}}.$$

Since O-alkyl methylphosphonothioates can exist in two tautomeric forms (Table 2), the pK_a values for both forms were calculated by the method described previously[59]. These values characterise the effective positive charge at the phosphorus atom in the acids and consequently to some extent also the phosphorylating capacity of the corresponding esters. Since the pK_a values of the acids vary relatively little when the size of R increases from CH_3 to $C_{10}H_{21}$ (Table 2), one may assume that the phosphorylating capacities of the corresponding OPI are also virtually identical. For other series of OPI, a similar conclusion follows from the constancy of the alkaline hydrolysis rate constant within each series (Tables 3, 5, and 6). Thus the OPI in each series react with the esterase component of choline-esterases as phosphorylating agents of virtually equal effectiveness.

A. Effect of the Structure of the Hydrocarbon Group in the Eliminated Components of OPI on their Anticholine-esterase Activity

The first series of OPI used to investigate the effect of hydrophobic sorption on the rate of phosphorylation of the enzyme have the general formula

where R = H, $C(CH_3)_3$, $CH(CH_3)_2$, or C_6H_5.

The results of these investigations are presented in Table 3 and show that the rate constants for alkaline hydrolysis (k_{OH}) and also the activation energies E_{act} for the compounds investigated in reactions with choline-esterases are almost constant, while the inhibition rate constants k_{II} differ sharply.

In the subseries of straight-chain alkane derivatives (compounds I.1–I.9) the constants k_{II} increase with the length of the chain of the alkyl group up to the hexyl derivative (I.5) for BuCE and up to the octyl derivative (I.7) for ACE. Further increase in the length of the alkyl chain in the case of BuCE does not cause significant changes in k_{II} and in the case of ACE actually leads to an appreciable decrease of the constant[33,34] (Fig. 1). Thus a simple increase in the length of the hydrocarbon group leads to a sharp increase of the rate of inhibition—by a factor of 170 for ACE and 600 for BuCE.

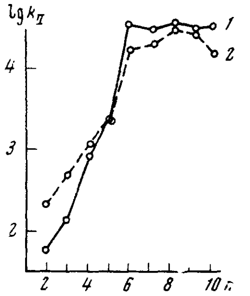

Figure 1. Variation of the rate constants k_{II} for the inhibition of BuCE (curve *1*) and ACE (curve *2*) by compounds of the type $C_2H_5O(CH_3)P(O)SC_nH_{2n+1}$ with the length *n* of the straight alkyl chain.

The second subseries of compounds, in which the alkylthio-substituent contained a t-butyl group at different distances from the phosphorus atom (compounds I.10–I.15), proved to be extremely interesting. The $C(CH_3)_3$ group is a complete steric analogue of the $N(CH_3)_3$ group in the acetylcholine molecule. The first member of this subseries (I.10) exhibits a fairly high anticholine-esterase activity. Then [compound (I.11)] k_{II} decreases. In experiments with BuCE subsequent members of the subseries (I.12–I.13) showed an increase of k_{II} with increase in the number of methylene groups *n*, but the change in k_{II} on going to compounds I.14 (*n* = 5) and I.15 (*n* = 6) is already small (Fig. 2). In experiments with ACE there was a continuous increase of k_{II} with *n*.

Next it was found that in this subseries of OPI all three methyl residues at the quaternary carbon atoms are important. The replacement of one methyl residue by a hydrogen atom, i.e. the replacement of the t-butyl group by an isopropyl group, results in a significant decrease of k_{II}, particularly for OPI with a small n (compounds I.16–I.18). A feature of the compounds of the third subseries which distinguishes them from those of the second is the absence of a decrease of k_{II} on going from the first member (I.16, $n = 1$) to the second (I.17, $n = 2$). The variation of k_{II} with n in this subseries has much in common with that for compounds of the first subseries.

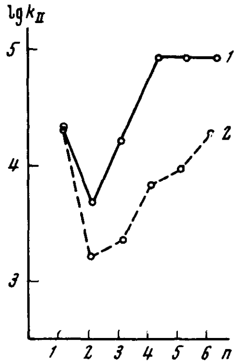

Figure 2. Variation of the rate constants k_{II} for the inhibition of BuCE (curve *1*) and ACE (curve *2*) by compounds of the type $C_2H_5O(CH_3)P(O)S(CH_2)C(CH_3)_3$ with the number of methylene groups n.

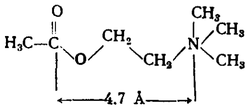
In the fourth subseries of the first series of OPI (I.21–I.24) under consideration an ω-phenylalkyl group is attached to sulphur. The high anticholine-esterase activity of the first member of the subseries (I.21, $n = 1$) is striking here. On going to the second member (I.22, $n = 2$), k_{II} decreases sharply. Further increase of n leads to an increase of k_{II}, up to $n = 4$.[44]

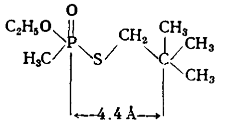
The very high anticholine-esterase activity of individual members of this series of OPI is particularly noteworthy. Thus the rate of inhibition of BuCE by compounds I.13, I.14, I.15, I.20, I.21, I.23, and I.24 is not inferior to that by an inhibitor as powerful as armin ($k_{II} = 2 \times 10^{-5}$).[49]

The data obtained will make it possible to elucidate the effect on k_{II} of the gradual conversion of the terminal methyl group into a t-butyl group. This effect is seen from an examination of Table 4, which lists the relative values of k_{II} for the OPI. k_{II} for the first compound in each of the five groups ($n = 1$, $n = 2$, $n = 3$, $n = 4$, and $n = 6$) was assumed to be unity.

Table 4 shows clearly that the gradual "conversion" of the methyl into a t-butyl group is accompanied in all cases, except for the inhibition of ACE by compounds with $n = 4$ and 6, by an increase of k_{II}. To what extent this increase is specific, i.e. whether it is associated with the presence of the tetrahedral t-butyl group as such or whether it is due to a simple increase in the "bulk" of the alkyl substituent, can be seen by comparing the constant k_{II} for compounds containing a t-butyl group with those for the corresponding compounds with an n-butyl group. The greatest effect of the t-butyl group for BuCE and ACE was observed with the compound in which $n = 1$. Here the distance between the quaternary carbon atom and the phosphorus atom is almost equal to the distance between the quaternary nitrogen atom and the carbonyl carbon atom in the AC molecule:



Acetylcholine



Compound I.10

Table 4. Variation of the inhibiting activity of compounds of the type $C_2H_5O(CH_3)P(O)S(CH_2)_nR$ as the group R is varied from methyl to t-butyl for different n (based on the results in Table 1).

Compound	n	R	k_{II} (relative values)	
			BuCE	ACE
I.1	1	CH_3	1	1
I.2	1	CH_2CH_3	2	2
I.16	1	$CH(CH_3)_2$	10	7
I.10	1	$C(CH_3)_3$	330	90
I.4	1	C_4H_9	40	12
I.2	2	CH_3	1	1
I.3	2	CH_2CH_3	6	2
I.17	2	$CH(CH_3)_2$	17	2
I.11	2	$C(CH_3)_3$	34	3
I.5	2	C_4H_9	275	30
I.3	3	CH_3	1	1
I.4	3	CH_2CH_3	3	2
I.18	3	$CH(CH_3)_2$	3	1
I.12	3	$C(CH_3)_3$	22	2
I.6	3	C_4H_9	40	18
I.4	4	CH_3	1	1
I.5	4	CH_2CH_3	15	6
I.19	4	$CH(CH_3)_2$	23	3
I.13	4	$C(CH_3)_3$	35	3
I.7	4	C_4H_9	16	14
I.6	6	CH_3	1	1
I.7	6	CH_2CH_3	1	1.5
I.20	6	$CH(CH_3)_2$	3	2
I.15	6	$C(CH_3)_3$	3	1
I.9	6	C_4H_9	1	0.7

It is striking that here k_{II} for compound I.10 is approximately eight times higher than k_{II} for its isomer I.4. A similar effect of the complete conversion of the methyl into a t-butyl group is observed for compound I.3 ($n = 4$) and I.6 ($n = 4$) in relation to BuCE. In all other cases the isomers with a straight alkyl chain have a higher value of k_{II} than the compounds with a t-butyl group.

Table 3 shows that the observed increase of k_{II} as the hydrocarbon group of the OPI becomes longer and more branched is caused solely by a change in the probability factor—the pre-exponential factor PZ in the Arrhenius equation. The activation energy E_{act} is almost constant: it amounts to 12.0–12.5 kcal mole^{-1} for the interaction of the OPI investigated with BuCE and between 10.7 and 11.0 kcal mole^{-1} for the interaction with ACE. The rate constants for the non-enzymatic alkaline hydrolysis of these compounds proved to be invariant to an equal extent: they vary from 0.13 to 0.15 litre mole^{-1} min^{-1} at pH 10.5.[33,34] As stated above, these findings indicate that the electrophilic phosphorylating capacity of this series of OPI is identical. The differences between them are determined by the different rates of their sorption on the membrane and consequently the different concentrations at any instant of the sorbed and appropriately oriented OPI molecules on the surface of the enzyme. This is equivalent to differences in the rate of formation of an enzyme–inhibitor EI complex, which has in fact been confirmed by careful kinetic analysis[56,57].

Since the reaction takes place in water, the increase in the extent of sorption of the OPI molecules with increase in the size of the *S*-alkyl substituent may be associated solely with the presence on the surface of the enzyme of hydrophobic regions: the hydrophilic medium (water) displaces the hydrocarbon groups of the OPI to these hydrophobic regions of the enzyme and thereby ensures their more complete sorption. Regions of this kind in the polypeptide chain of the enzyme may be formed by leucine, isoleucine, valine, and phenylalanine residues.

Evidently one of such hydrophobic regions, adapted for the sorption of the trimethylammonium group of acetylcholine, surrounds the anionic component of the active centre of the enzyme. One cannot exclude the possibility that the t-butyl group of compound I.10, in which the distance between the group and the phosphorus atom is close to that between the esterase and anionic sites of the enzyme, is sorbed precisely on this region. In this connection we must note yet again the higher value of k_{II} for compound I.10 compared with that for its isomer I.4.

Table 5. Inhibiting activity of series III compounds: *S*-methyl methosulphates of *S*-(*β*-alkylthioethyl) *O*-ethyl methylphosphonothiolates with the formula

Series & no.	R'''	k_{II}, litre mole^{-1} min^{-1}		k_{II}(ACE) / k_{II}(BuCE)	k_{OH} litre mole^{-1} min^{-1}
		BuCE	ACE		
III.31	CH_3	$1.0 \cdot 10^6$	$5.5 \cdot 10^7$	55.0	17.0
III.31	C_2H_5	$3.7 \cdot 10^6$	$2.5 \cdot 10^8$	67.5	17.0
III.33	n-C_4H_9	$1.1 \cdot 10^7$	$2.2 \cdot 10^8$	20.0	20.0
III.34	n-C_6H_{13}	$8.9 \cdot 10^7$	$1.1 \cdot 10^9$	12.4	21.4
III.35	n-C_8H_{17}	$1.0 \cdot 10^8$	$4.6 \cdot 10^8$	4.6	25.0
III.36	n-$C_{10}H_{21}$	$1.8 \cdot 10^8$	$4.0 \cdot 10^8$	2.2	19.0

The nearest homologue of substance I.10, i.e. substance I.11 (R = t-C_4H_9, $n = 2$), has a constant k_{II} smaller by a factor of 3.5. The distance between the phosphorus atom and the tertiary carbon atom in this compound (5.3 Å) is somewhat greater than the optimum value (4.7 Å) and the methyl groups sorbed on the hydrophobic surround of the anionic component prevent the exact orientation of the electrophilic phosphorus atom in relation to the hydroxy-group of the esterase site of the enzyme. Hence follows a sharp decrease of the probability factor *PZ* (by a factor of 6 for BuCE and 8 for ACE).

However, on further increase of n in this subseries an increase of k_{II} is again observed (up to $n = 4$ for BuCE and up to $n = 6$ for ACE). The rate of formation of the enzyme–inhibitor complex increases. Apparently on the surface of the enzyme there is yet another hydrophobic region of a similar type separated from the first by hydrophilic units. In BuCE it is undoubtedly complementary to the t-butyl group, as can be seen from the data in Table 4 (groups with $n = 4$ and $n = 6$). In ACE this is not so and, with the exception of the first compound ($n = 1$), the isomeric compounds with straight-chain alkyl substituents are in all cases more active than the compounds with the t-butyl group and the activity of the OPI with $n = 6$ altogether depends little on the structure of the terminal group. The isopropyl derivatives (Table 3) behave similarly to the straight-chain subseries but with the difference that these compounds reach the second hydrophobic region of the enzyme starting with $n = 4$ (compound I.19). This corresponds to the chain length with $n = 6$ in the subseries of the straight-chain alkyl derivatives.

The phenylalkyl derivatives containing the bulky phenyl group at the end of the chain show the same type of variation of k_{II} as in the subseries with the t-butyl group.

Although in relation to ACE this behaviour is shown less markedly, nevertheless the increase of k_{II} with increasing length of the hydrocarbon group in the compounds of the first and second subseries (Table 3) suggests that in ACE in the vicinity of the anionic site there is also a hydrophobic region, although its role is less pronounced than that of the hydrophobic region surrounding the anionic site.

It is noteworthy that a similar relation between the rate of inhibition of ACE and the structure of the hydrocarbon group in derivatives of di-O-ethyl phosphorothioate was found by O'Brien and Bracha[60]. Their investigations confirmed the above conclusions concerning the existence of hydrophobic regions in the vicinity of the anionic site of the enzyme.

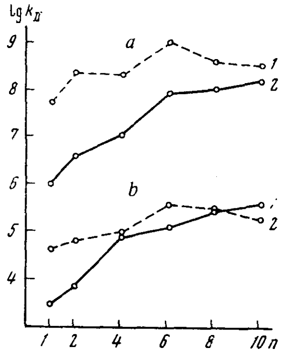


Figure 3. Variation of the rate constants k_{II} for the inhibition of BuCE (curves *1*) and ACE (curves *2*) by compounds of the type $C_2H_5O(CH_3)P(O)SC_2H_4\overset{+}{S}(CH_3)C_nH_{2n+1}$ (*a*) and $C_2H_5O(CH_3)P(O)SC_2H_4SC_nH_{2n+1}$ (*b*) with the length *n* of the straight alkyl chain.

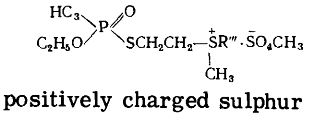
In order to show that the second hydrophobic region in both BuCE and ACE is in fact located beyond the anionic site, compounds of series of II and III were investigated. Compounds of series III are of particular interest:



$$\begin{matrix} HC_3 \\ C_2H_5O \end{matrix} \!\!>\! P \!\!<\!\! \begin{matrix} O \\ SCH_2CH_2\text{—}\overset{+}{S}R''' \cdot \overset{-}{S}O_4CH_3 \\ \qquad\qquad\qquad | \\ \qquad\qquad\qquad CH_3 \end{matrix}$$

They contain a positively charged sulphur atom which should be fixed precisely at the anionic site of the enzyme. If the hypothesis of the existence and particular location of the above hydrophobic region is correct, an increase in the size of the hydrocarbon group R''' should entail an increase in the inhibiting activity of these compounds.

The data in Table 5 and Fig. 3 show that k_{II} does indeed increase with increase in the size of R''', particularly in reactions with BuCE. Compound III.36 is more active than III.31 by a factor of 180 in relation to BuCE and by a factor of 7.3 in relation to ACE. The increase of R''' is accompanied by an appreciable equalisation of the k_{II} for the two enzymes. While the first two compounds (III.31 and III.32) inhibit ACE 60–70 times faster than BuCE, the inhibition by the last compound III.36 is only 2.2 times faster[46,61] (Table 6).

Table 6. Inhibiting activity of series II compounds. *S*-(β-alkylthioethyl) *O*-ethyl methylphosphonothiolates:

$C_2H_5O(CH_3)P(O)SC_2H_4SR'''$

Series and no.	R'''	k_{II}, litre mole^{-1} min^{-1}		$k_{II}(ACE)$ / $k_{II}(BuCE)$	k_{OH} litre mole^{-1} min^{-1}
		BuCE	ACE		
II.25	CH_3	$3.2\cdot10^3$	$4.0\cdot10^4$	12.5	0.29
II.26	C_2H_5	$6.8\cdot10^3$	$6.0\cdot10^4$	8.8	0.28
II.27	*n*-C_4H_9	$7.8\cdot10^4$	$9.0\cdot10^4$	1.2	0.31
II.28	*n*-C_6H_{13}	$1.3\cdot10^5$	$4.0\cdot10^5$	3.1	0.28
II.29	*n*-C_8H_{17}	$3.0\cdot10^5$	$3.3\cdot10^5$	1.1	0.29
II.30	*n*-$C_{10}H_{21}$	$4.0\cdot10^5$	$2.0\cdot10^5$	0.5	0.27

It is significant that, apart from these findings, in this series of compounds the rate constants for non-enzymatic alkaline hydrolysis also vary within very narrow limits (16.0–22.0 litre mole^{-1} min^{-1}) and therefore here too one may speak of the constancy of the electrophilic reactivity of the OPI.

A similar relation between k_{II} and R obtains also for compounds with an uncharged sulphur atom (series II, Table 6 and Fig. 3):

Compound II.30 inhibits BuCE approximately 130 times faster and ACE only five times faster than compound II.25. In this series an increase in the size of R leads not only to an equalisation but actually to a reversal of the relative values of k_{II} for the enzymes investigated: substance II.25 inhibits ACE 12.5 times faster than BuCE, while the inhibition of ACE by compound II.30 is slower by a factor of 2 than that of BuCE (Fig. 3). Here too the rate of alkaline hydrolysis is virtually the same for all the substances.

Thus the data obtained leave no doubt about the existence of a hydrophobic region beyond the anionic site. This region is fairly extensive: in BuCE at a distance equivalent to 3–5 methylene groups from the anionic site there is a region which greatly increases the sorption of the t-butyl group.

In ACE this region is less distinctive and evidently this is why the hydrophobic properties of OPI do not play such an important role in the inhibition of ACE as in the inhibition of BuCE.

In the determination of the inhibiting effect of compounds of series II and III additional data were obtained on the different roles of the anionic sites in BuCE and ACE in the sorption of charged OPI. The ratio of the constants k_{II} for corresponding pairs of charged and uncharged OPI varies from 140 to 680 for BuCE and from 1400 to 4200 for ACE (Table 7).

Thus in the sorption of OPI by enzymes the anionic region plays a more important role in ACE than in BuCE, while the hydrophobic environment of the anionic site is more important in BuCE.

Table 7. Comparative estimates of the inhibiting activities of *S*-(β-alkylthioethyl) *O*-ethyl methylphosphonothiolates $C_2H_5O(CH_3)P(O)SC_2H_4SR'''$ and their *S*-methyl methosulphates $C_2H_5O(CH_3)P(O)SC_2H_4\overset{+}{S}(CH_3)R'''.SO_4CH_3$ (according to data in Tables 5 and 6)

R		CH_3	C_2H_5	C_4H_9	C_6H_{13}	C_8H_{17}	$C_{10}H_{21}$
Ratio of k_{II} values for charged and uncharged OPI	BuCE	320	550	140	680	330	450
	ACE	1370	4200	2440	2750	1400	2000

B. Effect of the Structure of the Hydrocarbon Group in the Non-eliminated Components of the OPI on their Anticholine-esterase Activity

The next three series of compounds (IV, V, and VI) were synthesised in order to elucidate the hydrophobic region surrounding the esterase component of the enzyme. The reactivity of a series of *O*-n-alkyl *S*-n-butyl methylphosphonothiolates was investigated first:

(series IV, Table 8), where R' represents n-alkyl groups with a chain length comprising between 1 and 10 carbon atoms[47,62,63]. As mentioned above, the phosphorylating capacity of these compounds is virtually the same.

Table 8. Inhibiting activity of series IV compounds. *O*-n-alkyl *S*-n-butyl methylphosphonothiolates:

$R'O(CH_3)P(O)SC_4H_9$

Series and no.	R'	k_{II}, litre mole^{-1} min^{-1}		Series and no.	R'	k_{II}, litre mole^{-1} min^{-1}	
		BuCE	ACE			BuCE	ACE
IV.37	CH_3	$5.8\cdot10^1$	$2.6\cdot10^2$	IV.41	C_6H_{13}	$5.0\cdot10^4$	$4.2\cdot10^3$
I.3	C_2H_5	$5.2\cdot10^2$	$1.2\cdot10^3$	IV.42	C_7H_{15}	$1.1\cdot10^6$	$4.5\cdot\ 0^3$
IV.38	C_3H_7	$4.5\cdot10^3$	$5.6\cdot10^3$	IV.43	C_8H_{17}	$3.6\cdot10^5$	$4.1\cdot10^3$
IV.39	C_4H_9	$1.2\cdot10^4$	$1.4\cdot10^4$	IV.44	C_9H_{19}	$7.0\cdot10^5$	$6.2\cdot10^3$
IV.40	C_5H_{11}	$1.6\cdot10^4$	$6.8\cdot10^3$	IV.45	$C_{10}H_{21}$	$6.2\cdot10^4$	$2.9\cdot10^3$

Table 8 shows that the anticholine-esterase activity of the compounds investigated depends significantly on the length of the *O*-alkyl group. In experiments with BuCE a gradual increase in the length of the group up to heptyl leads to an increase of the inhibition rate constant. The heptyl derivative proved to be a very powerful inhibitor of BuCE, its anticholine-esterase activity exceeding that of the methyl derivative by a factor of 18 000. A further increase in the length of the substituent entails some decrease of k_{II}.

A different type of relation with the structure is observed in the interaction of the OPI of this series with ACE. The anticholine-esterase activity increases with hydrocarbon chain length only as far as butyl (the butyl derivative is 50 times more effective than the methyl derivative). The anticholine-esterase activity of the OPI with longer alkyl groups (between pentyl and decyl) is somewhat lower and varies within narrow limits. The variation of the anticholine-esterase activity in this series is determined, as in the previous series, mainly by the variation of the capacity of the OPI for the formation of an enzyme–inhibitor complex as a result of the sorption of the hydrocarbon components of the alkoxy-groups on the hydrophobic regions of the active surface of the enzyme.

The relations found in these experiments resemble those described above for studies on the series of *S*-n-alkyl *O*-ethyl methylphosphonothiolates (Table 3), but differ from them in important details.

Comparison of the effects of both series of OPI on BuCE showed that, with increase in the length of the alkoxy-group, the maximum effect is observed for the heptyl derivative, whereas variation of the length of the alkylthio-group shows the maximum effect with the hexyl derivative. Bearing in mind that in the first case the hydrocarbon group is linked to the phosphorus atom via an oxygen atom and in the second via a sulphur atom, one may assume that the maximum anticholine-esterase activity of these two series of compounds corresponds to the same length of the alkoxy- or alkylthio-substituents.

Table 9. Inhibiting activity of series V and VI compounds in relation to BuCE. *O*-n-alkyl *S*-(β-ethylthioethyl) methylphosphonothiolates and their *S*-methyl methosulphates:

$$R'O(CH_3)P(O)SC_2H_4SC_2H_5 \quad (V)$$

$$R'O(CH_3)P(O)SC_2H_4\overset{+}{S}(CH_3)C_2H_5\cdot\overset{-}{S}O_4CH_3 \quad (VI)$$

Series and no.	R′	k_{II}, litre mole^{-1} min^{-1}	Series and no.	R′	k_{II}, litre mole^{-1} min^{-1}
V.53	CH_3	$9.6\cdot10^2$	VI.60	CH_3	$7.7\cdot10^5$
II.26	C_2H_5	$4.4\cdot10^3$	III.32	C_2H_5	$3.8\cdot10^6$
V.54	C_3H_7	$5.8\cdot10^4$	VI.61	C_3H_7	$3.8\cdot10^7$
V.55	C_4H_9	$1.6\cdot10^5$	VI.62	C_4H_9	$4.8\cdot10^7$
V.56	C_5H_{11}	$1.7\cdot10^5$	VI.63	C_5H_{11}	$7.5\cdot10^7$
V.57	C_6H_{13}	$3.7\cdot10^5$	VI.64	C_6H_{13}	$1.8\cdot10^8$
V.58	C_7H_{15}	$2.8\cdot10^6$	VI.65	C_7H_{15}	$2.5\cdot10^8$
V.59	C_8H_{17}	$1.1\cdot10^6$	VI.66	C_8H_{17}	$2.8\cdot10^8$

This finding can have two explanations. The first involves the assumption that the hydrophobic regions located beyond the anionic and esterase components of the active centre of the enzyme are equidistant from these sites. The second involves the recognition that the sorption of the alkoxy- and alkylthio-groups takes place on the same region of the enzyme surface.

The second assumption must be immediately rejected in relation to ACE. In the series of *S*-n-alkyl *O*-ethyl methylphosphonothiolates the maximum activity on ACE (as well as on BuCE) is attained with the hexyl derivative (Table 3), whereas in the *O*-alkyl *S*-n-butyl methylphosphonothiolate series the butyl derivative is the most active (Table 8).

In order to obtain additional information about the localisation of the hydrophobic regions of choline-esterase with which alkoxy-groups may interact and in particular in order to find whether these groups are sorbed in the region of the anionic component of the enzyme, special experiments were carried out, consisting in the investigation of the anticholine-esterase activity of two series of OPI[62]—*O*-n-alkyl *S*-(β-ethylthioethyl) methylphosphonothiolates (series V) and the corresponding *S*-methyl methosulphates (series VI). The choice of these OPI was based on the fact that the reaction of choline-esterase with OPI of type VI, containing the sulphonium group, should necessarily involve the interaction of the 'onium group with the anionic site. Under these conditions, the alkoxy-group is incapable of being sorbed on the hydrophobic regions in the vicinity of the anionic centre. The results of the investigation of these two series of OPI in relation to BuCE are presented in Table 9.

Table 9 shows that, with increase in the length of the hydrocarbon component in the alkoxy-group in the OPI series of type V, there is an appreciable increase of k_{II}. The maximum value of k_{II} was noted for the heptyl derivative (higher by a factor of 2900 than for the methyl derivative). The constant k_{II} for the octyl derivative is somewhat lower. In the series of OPI of type VI the anticholine-esterase effect also increases with the length of the hydrocarbon component of the alkoxy-group. Comparison of these two series of inhibitors shows that all the *S*-methyl methosulphates have k_{II} values higher by 2–3 powers of 10 than their uncharged analogues.

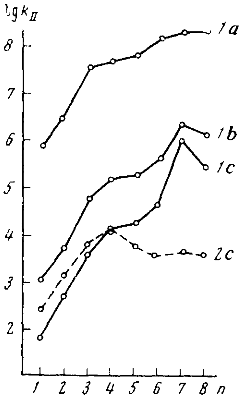


Figure 4. Variation of the rate constants k_{II} for the inhibition of BuCE (curves *1*) and ACE (curve *2*) by compounds of the type $C_nH_{2n+1}O(CH_3)P(O)SR$ with the length *n* of the straight alkyl chain: *a*) $R = C_2H_4S(CH_3)C_2H_5$; *b*) $R = C_2H_4SC_2H_5$; *c*) $R = n\text{-}C_4H_9$.

One may assume with certainty that the higher anticholine-esterase activity of the *S*-methyl methosulphates observed in all cases depends on the interaction between the charged sulphonium group and the anionic site of BuCE and in particular on the associated orienting effect. Therefore one may assume that the increase of the anticholine-esterase activity with increasing length of the hydrocarbon component of the alkoxy-group is also a consequence of the orienting effect, due to its sorption on a suitable hydrophobic region of BuCE.

Since the anionic centre of BuCE in the interaction with series VI OPI is occupied by a group containing sulphonium sulphur, one may conclude that the hydrophobic region of the active surface of BuCE on which the alkoxy-group is sorbed is located outside the anionic site of the enzyme.

In all probability the alkoxy-group of uncharged OPI is also sorbed on the same hydrophobic region of choline-esterase. This conclusion follows from an examination of Fig. 4, where the variation of lg k_{II} with the number of carbon atoms in the alkoxy-group is plotted for the OPI of series IV, V, and VI.

Fig. 4 shows that the curves representing the effect on BuCE by the inhibitors of all three series vary in exactly the same sense and actually coincide in detail (the sharp rise on increasing n from 1 to 3, the inflection in the region with $n = 3-5$, and another sharper rise as n is increased to 7). This agreement can only be explained by the fact that the hydrocarbon components of the alkoxy-groups of the OPI of all three series interact with the same hydrophobic region of BuCE. The overall extent and location of this region probably correspond sterically to the heptyl group. However, the stepped form of the curve may be an indication that in fact we are dealing here with two hydrophobic regions separated by a hydrophilic group.

Fig. 4 also shows that the effects of the same series of OPI on BuCE and ACE (curves *1* and *2*) differ significantly. Whereas up to $n = 4$ the inhibition of both enzymes is almost the same, further increase in the length of the hydrocarbon group, which results in an appreciable increase of effectiveness in relation to BuCE, has completely no effect on the capacity of the OPI to inhibit ACE. We are inclined to explain this difference by the fact that in the region of the esterase centre ACE has not two but only one hydrophobic region, corresponding sterically to the butyl group.

To characterise more fully the steric configuration of the hydrophobic regions located in the vicinity of the esterase centre of the choline-esterases, a study was made of the effect on the choline-esterases of compounds containing a branched substituent in the alkoxy-group[64] (compounds IV.46–IV.51):

$$(H_3C)(R'O)P(=O)SC_4H_9 \, ,$$

where $R' = (CH_3)_2CH(CH_2)_n$.

Table 10. Inhibiting activity of series IV compounds. *S*-Butyl *O*-isoalkyl methylphosphonothiolates:

$R'O(CH_3)P(O)SC_4H_9$

Series & no.	$R' = (CH_3)_2CH(CH_2)_n$	k_{II}, litre mole^{-1} min^{-1}	
	n	BuCE	ACE
IV.46	0	$4.5\cdot10^2$	$3.2\cdot10^3$
IV.47	1	$4.4\cdot10^3$	$1.5\cdot10^4$
IV.48	2	$3.4\cdot10^4$	$6.1\cdot10^4$
IV.49	3	$3.9\cdot10^4$	$4.3\cdot10^5$
IV.50	4	$6.5\cdot10^4$	$9.3\cdot10^3$
IV.51	5	$3.1\cdot10^4$	$8.6\cdot10^3$

Table 10 shows that, with increase in the length of the hydrocarbon group, the anticholine-esterase activity of the compounds in relation to BuCE increases up to the isoheptyl derivative, while that in relation to ACE increases up to the isohexyl derivative. Further increase in the length of the group results in a decrease of k_{II}, the decrease for BuCE being slight (approximately by a factor of 2). On the other hand, in the case of ACE k_{II} for the isoheptyl derivative is smaller by a factor of 46 than for the isohexyl derivative. Moreover, it is seen that the first members of this series of compounds, up to the isohexyl derivative, are more active in relation to ACE than BuCE.

Above it was shown that an increase in the length of the alkoxy-group in the series of *O*-n-alkyl *S*-butyl methylphosphonothiolates does not result in a significant change of the electrophilic activity of the phosphorus atom in these compounds. It may be supposed that also in the series of *O*-isoalkyl derivatives the length of the hydrocarbon substituent will not have a significant influence on the magnitude of the effective positive charge of the phosphorus atom. This means that in this series too the factor determining the anticholine-esterase activity should be the hydrophobic interaction between the isoalkyl group and the hydrophobic regions on the surface of choline-esterase.

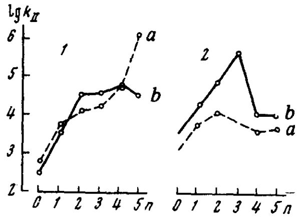

Figure 5. Variation of the rate constants k_{II} for the inhibition of BuCE (diagram *1*) ACE (diagram *2*) by compounds of the type $C_2H_5(CH_2)_nO(CH_3)P(O)SC_4H_9$ (*a*) and $(CH_3)_2CH(CH_2)_nO(CH_3)P(O)SC_4H_9$ (*b*) with the number of methylene groups n.

Since there is every reason to suppose that the hydrocarbon components of the isoalkyl and n-alkyl derivatives interact with the same parts of the enzyme, it is of interest to compare the effects of both series of compounds. Such a comparison is made in Fig. 5, where the isoalkyl derivatives are represented by compounds with an isopropyl substituent located at different distances from the phosphorus atom (curve *b*) while the series of OPI with straight-chain alkoxy-groups consists of compounds containing the ethyl group at the same distances (curve *a*). Thus compounds with the same length of a straight hydrocarbon chain are compared at each point. In the case of BuCE (Fig. 5) it is seen that initially (for $n = 0$ and 1) the branching of the substituent has no effect. For $n = 2-3$, i.e. in the region of the inflection in the curve, the branched-chain compounds are somewhat more effective, but on further increase in the length of the substituent the branched-chain group not only does not increase the anticholine-esterase activity but becomes a serious obstacle in the interaction between the OPI and the enzyme: k_{II} for the branched-chain compound with $n = 5$ is lower by a factor of 34 than for the corresponding straight-chain alkyl derivative.

In the interaction with ACE (Fig. 5), the branching of the substituent initially enhances appreciably the anticholine-esterase effect. The contribution of the branched-chain group is particularly pronounced for $n = 3$: k_{II} for this compound is higher by a factor of 63 than the constant for the corresponding OPI with a straight-chain substituent. Further separation of the isopropyl group from the phosphorus atom prevents the interaction of the OPI with ACE:

k_{II} diminishes by a factor of 46 and approaches the values of the rate constants for the straight-chain OPI. A still greater increase in the length of the substituent does not alter the anticholine-esterase activity of either series of OPI.

The above data confirm and complement the above considerations concerning the characteristics of the hydrophobic regions in the vicinity of the esterase component of the active centre of the choline-esterases. Probably in BuCE this region actually consists of two hydrophobic components. In general they are both complementary to hydrocarbon substituents with a straight-chain structure but the first, located closer to the esterase site, is not quite so rigorously specific and therefore the branching of the hydrocarbon substituent of the OPI does not prevent its sorption. The structure of the second (more remote) hydrophobic region is adapted solely for the sorption of a straight-chain substituent.

In ACE there is only one hydrophobic region. Its structure differs significantly from that of the first hydrophobic region of BuCE and is rigorously complementary to the isohexyl group (the maximum in curve *2b* in Fig. 4).

Yet another comparison is of interest for the characterisation of the configurational features of the hydrophobic region in the vicinity of the esterase component of the choline-esterases. Above, in the discussion of the anticholine-esterase properties of the OPI containing a branched-chain component in the alkylthio-group, it was noted that the introduction of a t-butyl substituent into this group significantly increases the capacity of the OPI to inhibit choline-esterase (Table 3).

An organophosphorus inhibitor containing the t-butyl group in the alkoxy-part of the molecule was synthesised[64]. Comparison of its activity with a series of other OPI described above shows how the gradual introduction of such a group affects the anticholine-esterase properties (Table 11).

Table 11. Anticholine-esterase effectiveness and the rate of alkaline hydrolysis (40°C) of OPI of the type $RCH_2O(CH_3)P(O)SC_4H_9$.

Series and no.	R	BuCE		ACE		k_{OH}, litre mole^{-1} min^{-1}
		k_{II}, litre mole^{-1} min^{-1}	relative value	k_{II}, litre mole^{-1} min^{-1}	relative value	
I.3	CH_3	$5.2\cdot10^2$	1	$1.1\cdot10^3$	1	0.145
IV.38	CH_3CH_2	$4.5\cdot10^3$	9	$5.8\cdot10^3$	5	0.160
IV.47	$(CH_3)_2CH$	$4.4\cdot10^3$	8	$1.5\cdot10^4$	13	0.146
IV.52	$(CH_3)_3C$	$9.5\cdot10^2$	2	$5.9\cdot10^3$	5	0.200
IV.39	$n\text{-}C_4H_9$	$1.6\cdot10^4$	30	$6.8\cdot10^3$	6	—

For comparison, the table also lists the anticholine-esterase activities of substances with R = $n\text{-}C_4H_9$, which is isomeric with the t-butyl group.

Table 11 shows that the degree of branching of the group R has little effect on the mobility of the P–S bond, which we estimated from the rate constant for alkaline hydrolysis. Consequently, the anticholine-esterase activities found must also be attributed to the different capacities of the hydrocarbon groups for sorption on the active surface of the enzyme.

Examination of the data for BuCE shows clearly yet again that the hydrophobic part of this enzyme has a structure complementing an unbranched hydrocarbon group. Indeed the replacement of one H atom by a CH_3 group on going from I.3 to IV.38 (increase in the length of the straight chain) increases the activity by a factor of 9, while the replacement of a second hydrogen atom by a methyl group (compound IV.47) has no effect despite the increase in the size of the group, and the introduction of a third methyl group (compound IV.52) causes a distinct decrease of activity. At the same time compound IV.39 is 15 times more active than the isomeric t-butyl derivative.

Compound IV.47 is the most effective in relation to ACE, the introduction of a third methyl group reducing the activity by a factor of 2.5. The straight-chain compound with R = $n\text{-}C_4H_9$ has no advantages compared with the t-butyl derivative.

Thus the hydrophobic region in ACE, in contrast to BuCE, complements best the isobutyl group. The above comparison leads to the conclusion that the fit of the hydrophobic regions in the vicinity of the esterase centre in both choline-esterases to the tetrahedral structure of the t-butyl group is poor. Therefore in the series of compounds investigated the introduction of such a group into the alkoxy-substituent results in a distinct hindrance of the sorption of the inhibitor on the active surface.

---o0o---

Analysis of the results of the investigations leads to a general hypothesis concerning the location of the hydrophobic regions in the vicinity of the active centres of BuCE and ACE and certain characteristics of these regions[65].

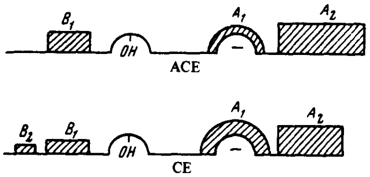

Figure 6. Topography of the hydrophobic regions on the active surface of ACE and BuCE.

The structure of the hydrophobic regions on the active surface of choline-esterase is shown schematically in Fig. 6. In the vicinity of the anionic centre there are two hydrophobic regions: A_1 surrounding directly the anionic centre and A_2 located at some distance beyond it. There is reason to believe that in BuCE region A_1 plays a relatively greater role than in ACE. Thus, according to Augustinsson[66], van der Waals forces play a major role together with Coulombic forces in the interaction of substrates and inhibitors with the anionic site in BuCE, while in ACE purely Coulombic forces predominate. The region A_2 is also different in the two choline-esterases: in BuCE its extent corresponds to a chain of six carbon atoms and in ACE to a chain of eight carbon atoms. The steric configuration of this region in both enzymes is such that it complements best groups containing the highly branched t-butyl substituent.

Near the esterase site of BuCE there are two hydrophobic regions separated by a hydrophilic group. The overall extent of these hydrophobic regions corresponds to a chain of seven carbon atoms. They are both in general complementary to straight-chain groups, but the first (B_1) is not quite so rigorously specific and branched-chain groups can also be sorbed on it.

In ACE there is only one hydrophobic region, the structure of which differs significantly from that of the B_1 region in BuCE: it is rigorously complementary to the isohexyl group.

An important characteristic of the steric configuration of the B_1 regions in both enzymes is that they are completely unadapted for the sorption of groups containing the t-butyl substituent. Thus differences in the structures and extents of the hydrophobic regions located on the active surface of BuCE and ACE have been established. It is quite likely that these differences are to a large extent responsible for the different properties of the two choline-esterases.

The problem naturally arises of the biological value of this type of structure of the active surface of the choline-esterases. What is the purpose of the extensive hydrophobic regions surrounding the catalytic centre of the enzyme? It is hardly likely that the hydrophobic regions were formed in the evolutionary process solely as essential constructional details. The following hypothesis may be put forward: acetylcholine consists of highly hydrophilic molecules capable of being sorbed not only at the active site of choline-esterases but also at any other site on the polypeptide chains of the enzyme. Such sorption would lead to retardation of the hydrolysis of acetylcholine. The hydrophobic regions prevent the "parasitic" sorption of acetylcholine and thereby increase the likelihood of its sorption at the active centre of choline-esterase. They play the role of a kind of energy "hill" from which the acetylcholine molecule "rolls down" on to the active site of the enzyme. In this way the effective cross-section of the active site of the enzyme in the hydrolysis of acetylcholine is increased.

In this connection it is essential to consider also the problem of the structure of the active site of the choline receptor (CR). There is very significant evidence suggesting the hypothesis that there are hydrophobic regions also around the CR active site[5] and that there must be at least three of them: one fits the methyl groups of acetylcholine, another serves as the anionic site of the choline receptor, and the third is a site with affinity for the ester group. This hypothesis is supported by the enormous amount of factual data on the relation between the structure and the effect of substances blocking the choline receptor which have now accumulated. The empirical rule according to which acetylcholine must be made more "bulky" in order to prepare blocking substances was formulated long ago. Indeed, the introduction into the acetyl component of the acetylcholine molecule of phenyl, cyclohexyl, and large alkyl groups converts acetylcholine from an exciting to a blocking agent. An increase in the "bulk" of the cationic head has the same effect. It is striking that, as acetylcholine becomes more "bulky" at either end, its cholinomimetic, exciting effect is gradually weakened, then the blocking effect appears, and its intensity increases. This is easily understood. Not only rapid sorption but also easy desorption of the substance from the receptor is important for the exciting effect[67,68]. Retardation of desorption leads to the blocking effect. Naturally, the introduction of bulky hydrophobic groups into the acetylcholine molecule increases the interaction with the hydrophobic regions in the vicinity of the active site of the choline receptor and hinders desorption.

It is reasonable to suppose that, for the interaction of acetylcholine itself with choline-esterases, the biological purpose of the hydrophobic regions consists in a reduction of the "parasitic" sorption and an increase in the probability of the collision of the acetylcholine molecule with the active site of the choline receptor.

Returning now to the problem of choline-esterases we must finally conclude that the inhibiting capacity of the organophosphorus inhibitors depends, at any rate for the series of compounds which we investigated and possibly others as well, not only on the intrinsic phosphorylating capacity of the compound (electrophilic reactivity) but mainly on the rate of sorption, i.e. the rate of formation of the enzyme–inhibitor complex.

The Juvenile Hormone of Insects and Its Analogues

Yu.S.Tsizin and A.A.Drabkina

The review deals with the chemistry of the juvenile hormone of insects and its analogues. The literature data on the isolation, determination of the structure, and synthesis of the juvenile hormone and natural compounds imitating its activity are quoted. Synthetic substances exhibiting the activity of the hormone are described and the problem of the relation between their structure and physiological activity is discussed.
The bibliography includes 134 references.

CONTENTS

I. INTRODUCTION

In recent years there has been a considerable increase of interest in insect hormones. While the chemical nature of the hormones of vertebrates has been successfully investigated for more than 50 years, the information about the structure of the most important insect hormones was obtained only as late as the 1960's. Nevertheless, apart from their great theoretical importance, studied on the endocrinology of insects may lead to the creation of fundamentally new means for combating pests.

A distinctive feature of insects is a clear-cut development in discontinuous stages during the growth process according to the scheme egg → larva (several stages) → pupa → adult insect (imago). The development and growth of the larva is accompanied by moulting. In some families the chrysalis stage is absent. The larval development and metamorphosis (the transformation into the adult insect) are under hormonal control.

The endocrine system of insects consists of the following components: groups of neurosecretory cells of the brain and the abdominal nerve chain, corpora cardiaca, corpora allata, and prothoracic glands or their analogues. The polypeptide hormone of the neurosecretory cells has been called the activating hormone, since one of its main functions is to stimulate the activity of the prothoracic glands, which produce the moulting hormone (acdysone), and the corpora allata, which secrete the juvenile hormone (JH). The development of insects is controlled by the activating hormone, ecdysone, and the juvenile hormone[1-3]. Moulting takes place in the presence of an enhanced secretion of ecdysone, and the juvenile hormone prevents metamorphosis, preserving the larval nature of the moulting; it is non-specific even within different insect orders. The amount of juvenile hormone varies in different stages of insect development: it is absent in the embryonic period, appears in the moulting stage, and in pupal moulting its concentration falls. Moulting of the imago is possible only in the absence of the juvenile hormone. The removal of the corpora allata from larvae leads to the formation of dwarf imagos[4]. The introduction into the insect organism of the juvenile hormone in the pre-imago period, when the hormone should be absent, leads to additional moulting and the appearance of giant forms. It is noteworthy that the giant individuals are non-viable and as a rule soon die[5,6]. In adult insects the juvenile hormone again begins to be produced and fulfils a number of functions the principal of which is gonadotropic. It has been shown that the juvenile hormone is identical with the gonadotropic hormone[7-10] and that the necessary condition for the regulation of ovogenic processes by the juvenile hormone is the absence of ecdysone[6]. Finally, the juvenile hormone has a prothoracotropic activity, stimulating the function of the prothoracic glands, which produce ecdysone[11,12].

Even before the determination of the structure of the juvenile hormone, a number of natural and synthetic compounds with juvenile-hormonal activity were found. Such activity is shown by extracts of plant, bacterial, and animal origin[13,14]. The juvenile hormone and its analogues influence insects both following injection and local application. In this connection it has often been suggested that the juvenile hormone and substances imitating its activity might be applied to combat harmful insects[15-19]. Hormonal insecticides should have a number of advantages over "traditional" insecticides. It is believed that they ought to be non-toxic to warm-blooded animals, should be effective in trace amounts, and that insects would be unable to develop resistance to them.

Since a large number of compounds with juvenile-hormonal activity are now known, it has become necessary to estimate quantitatively their effectiveness. The most suitable object for this purpose proved to be the pupae of the flour beetle *Tenebrio molitor* and the wax moth *Galleria mellonell*. The activity is expressed in "tenebrio" and "galleria" units. One "tenebrio" unit[20] and one "galleria" unit[21] are defined as the minimum amount of the substance in microgrammes which has a positive effect in 40 and 50% respectively of the test insects. Hence the specific activity of substances may be expressed as the number of "tenebrio" or "galleria" units per microgramme. Frequently the amount of test substance in microgrammes per insect is recorded and the effect is determined from the extent of preservation of the larval or pupal characteristics and is estimated on an n-point scale established arbitrarily for the insect species tested[22,23].

In order to unify the methods for the estimation of juvenile-hormonal activity, Wigglesworth[24] suggested that the minimal amounts of the test substance, expressed in microgrammes per gramme of insect weight, which give rise to a positive effect should be compared.

There are a number of reviews in the Soviet[3,25] and non-Soviet[1,2,26–29] literature on insect hormones. In most of them the biological aspects are considered. The latest review by Röller and Dahm deals mainly with the work of the authors themselves[28]. Nevertheless the problem of the synthesis of the juvenile hormone has attracted the attention of chemists in various countries: in the last two years nine versions of the synthesis of the juvenile hormone have been published. The problem of the relation between the structure and biological activity of juvenile hormone analogues is also extremely important. Therefore it is of interest to review the information on the chemistry of the juvenile hormone and substances imitating its activity.

II. ISOLATION AND DETERMINATION OF THE STRUCTURE OF THE JUVENILE HORMONE

Work on the isolation and determination of the structure of the juvenile hormone is associated with the name of the great American entomologist Williams. It is extremely difficult to isolate the juvenile hormone from the corpora allata because the glands contain a negligible amount of the hormone. Williams observed that the abdomens of the males of the large butterflies *Hyalophora cecropia* and *Samia cinthia* contain an unusually large amount of the juvenile hormone[30–33]. By extracting with ether the abdomens of the males of *Hyalophora cecropia*, he obtained a neutral oil with a considerable juvenile-hormonal activity. This extract, called "cecropia oil", served as a source for the isolation of the juvenile hormone. The preparation of purified extracts has been frequently reported[20,27,34]. Karlson[20] used for this purpose double chromatography on alumina and achieved purification by a factor of 8.

By 1965 three groups of American investigators carried out intensive research on the isolation of the juvenile hormone from "cecropia oil". It is interesting to compare their results. Williams and Law[35], who employed extraction with methanol, chromatography on silicic acid, and gas–liquid chromatography, obtained a fraction which was more active than the initial "cecropia oil" by a factor of 50 000. They showed by mass-spectrometry that the active component in an epoxy-derivative of the ethyl ether of a C_{16} aliphatic acid with a molecular weight of 284. However, tests on synthetic specimens of methyl (±)-9,10-*cis*- and (±)-9,10-*trans*-epoxyhexadecanoates showed that they are completely inactive although their mass spectra did not differ from that of the active fraction isolated from "cecropia oil". The isomeric synthetic epoxides and the natural juvenile hormone were not separated on the gas-liquid chromatograph employed by Williams and Law. The investigators were at the threshold of discovery and only the inadequate resolving power of their instruments prevented them from determining the exact structure of the juvenile hormone[28].

Meyer[36] reported a degree of purification by a factor of 3×10^5 using a five-stage process including gas-liquid chromatography. Two active fractions were obtained. Repeated chromatography did not lead to the isolation of the individual substances. According to Röller[28], the active fractions contained an admixture of the pyrolysis products of the juvenile hormone, which is unstable in chromatography above 210°C.

Finally in the same year a group of investigators at Wisconsin University led by Röller[37,38] isolated the juvenile hormone from "cecropia oil" in a pure form having obtained a degree of purification by a factor of 1.05×10^5. At all stages biological control was based on *Tenebrio molitor* larvae. The initial unpurified "cecropia oil" had an activity of 25 "tenebrio" units, while the pure juvenile hormone had an activity of 2.6×10^6 "tenebrio" units per microlitre. Later Röller improved the method of isolation of the juvenile hormone by replacing one thin-layer chromatographic stage by molecular distillation (Scheme 1)[39].

Scheme 1

Isolation of the juvenile hormone from the butterflies *Hyalophora cecropi a*

Process		Activity "tenebrio" units per μg	Overall activity, %
I. Extraction with ether	875 abdomens (380 g) ↓ 180 g of crude oil	0.04	100
II. Precipitation at −80°C	↓ 47 g of purified oil ↓	0.13	85
III. Molecular distillation (60–90°C, 2×10^{-5} mmHg)	5.4 g of distillate ↓	1.1	83
IV. Thin-layer chromatography, silica gel *G*, chloroform : ethyl acetate = 2:1, zone with $R_f = 0.6–0.9$	440 mg ↓	13	80
V. Thin-layer chromatography, silica gel *G*, chloroform : pentane = 2:1, zone with $R_f = 0.05–0.3$	5.4 mg ↓ 810 μg of JH	100	75
VI. Gas–liquid chromatography		5000	56

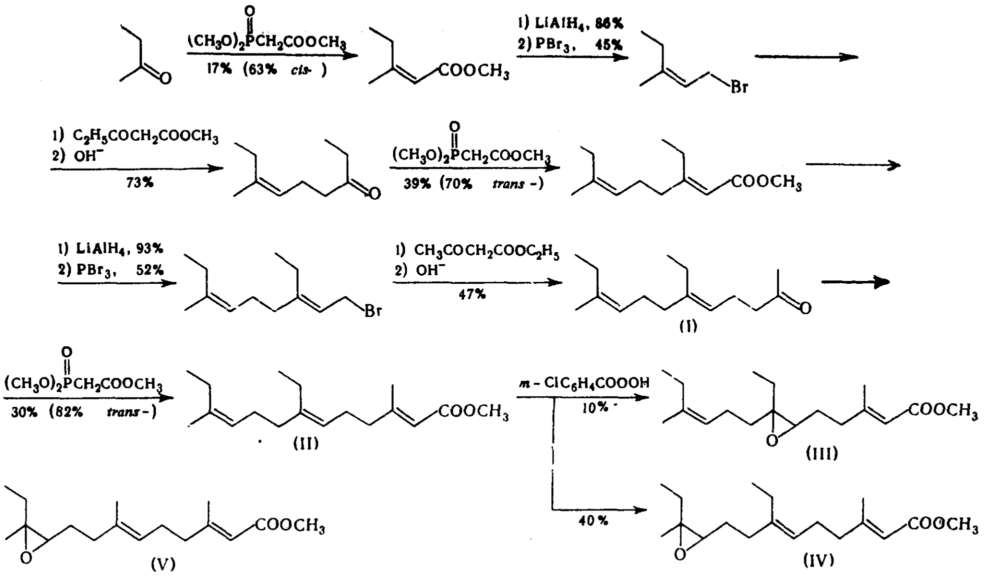
Although Röller and coworkers had at their disposal not more than 0.2–0.3 mg of the pure substance, the structure of the juvenile hormone was established in less than two years. The study of the juvenile hormone and the product of its reduction by hydrogen over palladium (20–30 μ g) on a combined gas chromatograph and mass-spectrometer[40] led to the determination of the overall formula ($C_{18}H_{30}O_3$), the molecular weight (294), the presence of a methoxycarbonyl group, branching, and three double bonds or rings[41]. The cleavage of 15 μg of the juvenile hormone with osmium tetroxide and periodate and investigation of the PMR spectrum (200 μg) in combination with mass-spectrometric data led to the identification of the juvenile hormone as methyl 10,11-epoxy-7-ethyl-3,11-dimethyltrideca-2,6-dienoate (IV) with the *trans*-configuration of the substituents at the 2,3-double bond.

The configuration of the substituents at the 6,7-double bond in the oxiran ring was not elucidated. A few months later Röller and coworkers[42] reported the first synthesis of racemic juvenile hormone. The synthesis was carried out by a gradual increase in chain length (Scheme 2).

The introduction of the double bonds by three applications of the phosphonate modification of the Wittig reaction was accompanied by the separation of the *cis*- and *trans*-isomers. In the first case the isomers were separated by fractionation on a 60 cm Teflon column and in the second and third cases by adsorption chromatography on silica gel. The last stage, the conversion of (II) into the epoxy-derivative with *m*-chloroperbenzoic acid, led to a mixture of epoxides (III) and (IV), which were separated by thin-layer chromatography on silica gel. Conversion of the triene ester (II) into the epoxy-derivative by the van Tamelen method[44] gives (IV) without an admixture of the isomer in a yield of 60%. At the same time Röller and Dahm[45] obtained by a similar mechanism a further four geometrical isomers of the juvenile hormone and later they synthesised all eight isomers of the hormone[28].

Comparison of the biological activities of the natural juvenile hormone and the synthetic specimens showed that

Scheme 2



synthetic methyl (±)-*trans*,trans,*cis*-10,11-epoxy-7-ethyl-3,11-dimethyltrideca-2,6-dienoate (IV) has the same activity as the natural hormone. The remaining isomers are less active (Table 1). All eight isomers of the juvenile hormone have also been obtained by the Hoffman La Roche Company, but their synthesis has not been published. The results of tests of these isomers on the bug *Rhodnius prolixus* are quoted by Wigglesworth[24] (Table 1).

Table 1. Physiological activity of the juvenile hormone and its isomers.

Compound	Configuration			Activity	
	C 2—3	C 6—7	C 10—11	"Tenebrio" units per μg (Ref.28)	g/g of insect wt. (Ref.24)
Natural hormone	—	—	—	5000	
Synthetic (±)-isomer 1	*trans-*	*trans-*	*cis-*	5000	0.18
Ditto 2	*trans-*	*trans-*	*trans-*	2000	0.6
» 3	*trans-*	*cis-*	*cis-*	200	1.8
» 4	*trans-*	*cis-*	*trans-*	150	13.5
» 5	*cis-*	*trans-*	*cis-*	10	9.0
» 6	*cis-*	*trans-*	*trans-*	10	16.0
» 7	*cis-*	*cis-*	*cis-*	10	63.0
» 8	*cis-*	*cis-*	*trans-*	10	45.0
Synthetic 6,7-epoxy-derivative of (±)- isomer	*trans-*	*trans-*	*trans-*	200	18.0
Synthetic ethyl ester 1 of (±)-isomer	*trans-*	*trans-*	*cis-*	40000	0.18

It has still not been shown whether the juvenile hormone derived from "cecropia oil" is optically active. Biological tests of the (±)-*trans*,*trans*,*cis*-isomer on *Tenebrio molitor* showed that either the enantiomers have the same biological activity, or, what is more likely, the natural juvenile hormone is also a mixture of the (+)- and (−)-forms[28]. This problem will have to be solved in the future.

In 1968 Meyer isolated from "cecropia oil" a second juvenile hormone (V), which is produced by the corpora allata in smaller amounts. It differs from (IV) by the presence of a methyl instead of an ethyl group at C_7. The isolation was based on the application of gas–liquid chromatography in the last stage. It was shown[46] that the ratio of the hormones varies, depending on the stage of development of the insect, between 4 : 1 and 7 : 1. It is suggested[16] that the second hormone is a precursor in the biosynthesis of (IV) and is responsible for 13–20% of the endocrine activity. Röller[28] did not detect the second active substance in "cecropia oil".

The biosynthetic pathways for the juvenile hormone are unknown. It has been established that insects synthesise the acyclic sesquiterpenes farnesal and farnesol from mevalonate[47,48]. However, so far it has not been shown whether the isoprene units are methylated at some stage in the biosynthesis or whether insects employ other precursors.

The mechanism of the action of the juvenile hormone is also unknown. The latest electrophysiological studies[49] appear to confirm the earlier hypothesis that the juvenile hormone affects the permeability of cell membranes[50].

All the hormones known until recent years belong to two classes of natural substances. They are either peptides and aminoacids or steroids. Ecdysone is not an exception in this sense, since it contains the hydrocarbon skeleton of cholesterol. The determination of the structure of the juvenile hormone of insects, which is a terpenoid, significantly extends out concepts concerning hormones. In this connection it should be noted that recently substances with a powerful hormonal activity—prostaglandins—were discovered in the secretions of vertebrates; like the juvenile hormone, they do not belong to any of the classes indicated above[51].

III. SYNTHESIS OF THE JUVENILE HORMONE

Less than two years have elapsed since the first synthesis of the juvenile hormone achieved by Röller and Dahm. During this period, eight versions of the synthesis of this biologically active compound have been reported. Synthetic studies are being carried on in the laboratories of the largest universities and commercial companies in the USA and Western Europe. Few natural substances are being investigated so intensively, which is evidence of a considerable interest in the juvenile hormone. In the synthesis of the juvenile hormone molecule the greatest difficulties are encountered in the formation of three centres which can give rise to geometrical isomers. Two approaches to the problem of the synthesis of the juvenile hormone can be clearly distinguished. The first is based on the use of highly stereospecific reactions which lead to the formation of the required isomers and the second involves reactions which yield a mixture of the *cis*- and *trans*-isomers with their subsequent separation by means of effective fractionating columns, and column, thin-layer, or gas–liquid chromatography.

It is at present difficult to assess fully the advantages and disadvantages of all the known syntheses of the juvenile hormone. Many of these have been described very schematically. So far as is known, no attempt has been made so far to separate the synthetic juvenile hormone into enantiomers.

The stereospecific syntheses consist of a large number of stages and use certain new reactions, methods, and reagents. Below they are described in greater detail.

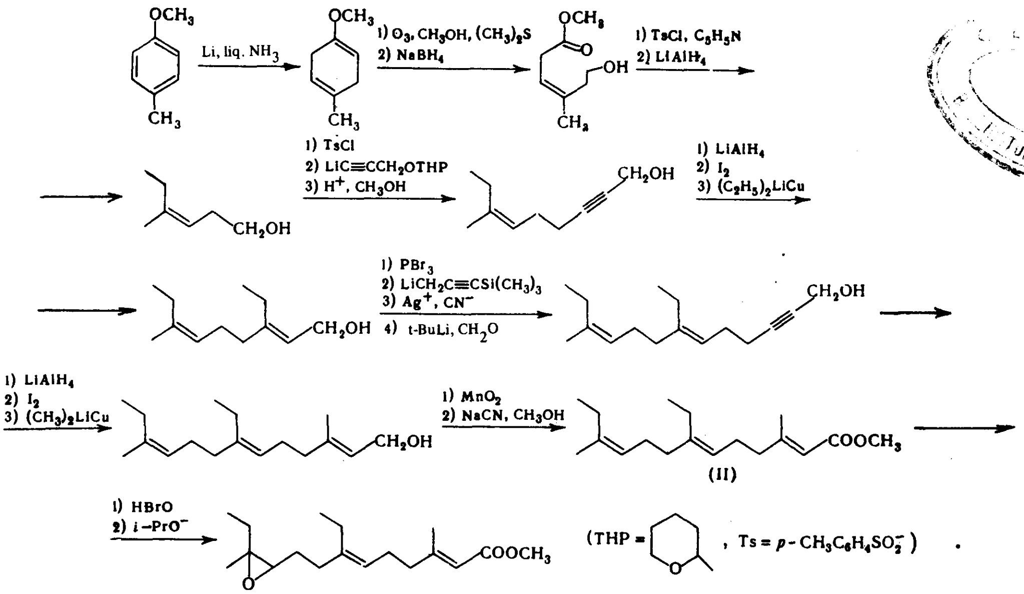
The stereospecific synthesis of the juvenile hormone was achieved in 1968 by Corey and coworkers[52] at Harvard University. Corey's scheme is based on a starting material which ensures the formation of the *cis*-configuration in the oxiran ring and certain new methods developed by the author were employed (Scheme 3).

The product of the Birch reduction of *p*-methoxytoluene was ozonised, converted into an aldehyde-ester, and reduced with sodium borohydride. The reduction of the *p*-toluenesulphonate of the resulting hydroxyester with lithium aluminium hydride led to the formation of the *cis*-isomer of a C_7 unsaturated alcohol. The reaction of the *p*-toluenesulphonate of the unsaturated C_7 alcohol with the lithium derivative of propargyl tetrahydropyranyl ether in hexamethylphosphoramide and subsequent treatment with acid methanol gave an acetylenic C_{10} alcohol. To convert the latter into *trans*, cis-3-ethyl-7-methylnona-2,6-dienol, Corey employed the stereoselective *C*-alkylation with alkylcopper reagents which he discovered recently[53–55]. Next the diene alcohol was converted into the bromide, which was alkylated with the lithium derivative of 1-trimethylsilylpropyne[56]. After the removal of the trimethylsilyl protecting group, an unsaturated hydrocarbon was obtained, which was converted by the action of t-butyllithium and paraformaldehyde into a C_{16} acetylenic alcohol. The repeated application of the stereoselective alkylation reaction in the synthesis led to the preparation of a C_{17} *trans,trans,cis*-triene alcohol. Treatment of the C_{17} alcohol with an excess of manganese dioxide in hexane at 0°C and subsequently with sodium cyanide and methanol gave the methyl ester of a trienoic acid (II). This new method for the conversion of aldehydes into carboxylic acid esters was also developed by Corey[57] and is of general value (yields in excess of 95%). The ester (II) was converted into the epoxy-derivative by treatment with hypobromite and subsequent elimination of hydrogen bromide.

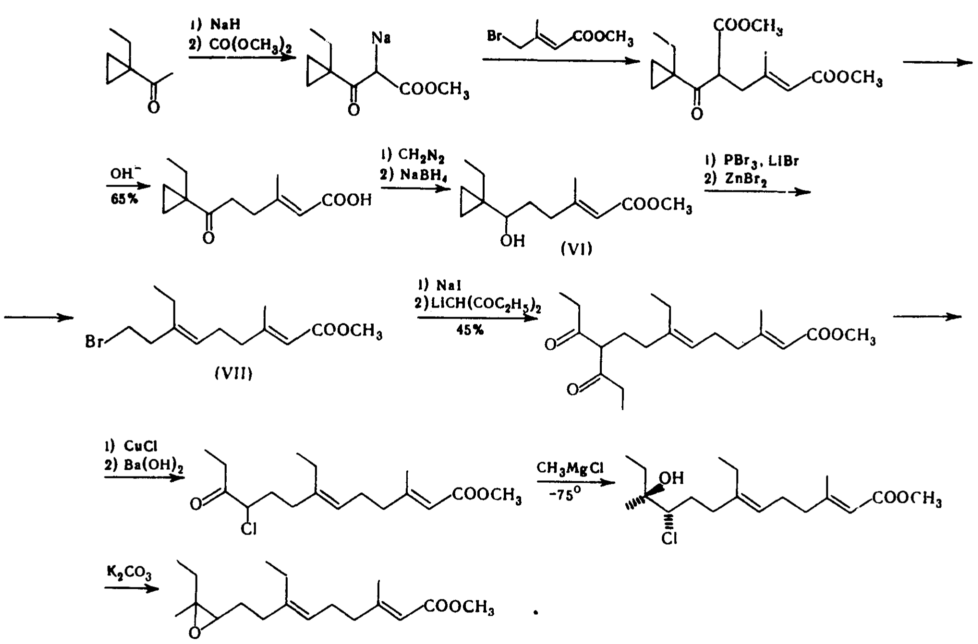
Johnson's twelve stage synthesis yields the racemic juvenile hormone containing admixtures of less than 8% of the *trans,trans,trans*-isomer and 0–5% of the *trans,cis,cis*-isomer. It is based on the application of Julia's method[59,60] for the synthesis of trisubstituted olefinic bonds, which includes the rearrangement of cyclopropylmethanols into homoallylic bromides. In all stages except two the products were obtained in yields greater than 90% (Scheme 4).

The sodio-derivative of the product of the Claisen condensation of 1-acetyl-1-ethylcyclopropane with carbonic ester was converted by reaction with methyl *trans*-γ-bromo-ββ-dimethylacrylate[61] into a ketodiester. The latter was converted in three stages into the hydroxyester (VI) and then into the homoallylic bromide (VII) by a modification of Julia's method developed by the author[62]; (VII) contained less than 5% of the *trans,cis*-isomer. The bromide (VII) was converted into the corresponding iodide and condensed with the lithio-derivative of hepta-3,5-dione. After substitution with chlorine of the mobile hydrogen atom in the β-diketone formed and alkaline

Scheme 3



Scheme 4

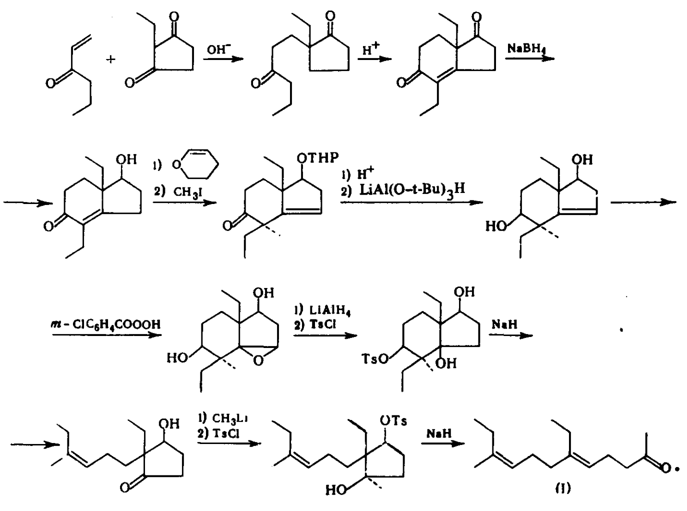


hydrolysis, the reaction product was purified by preparative gas–liquid chromatography and then treated at –75°C with an excess of methylmagnesium chloride, hydrogen chloride being eliminated with potassium carbonate in methanol, which ensures the *cis*-configuration of the substituents in the oxiran ring (< 8% of the *trans*-isomer). The stereospecific synthesis of an important intermediate for the preparation of the juvenile hormone, *trans,cis*-6-ethyl-10-methyldodeca-5,9-dien-2-one, was achieved at the Institute of Steroid Chemistry of the Syntex Corporation in California [compound (I) in Scheme 5][63].

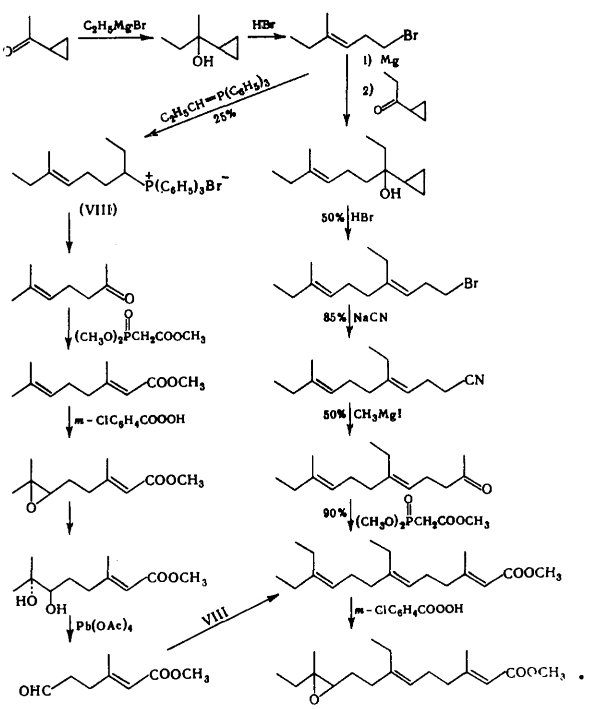
Brown et al.[64] developed two methods for the synthesis of a mixture of isomers of the juvenile hormone (Scheme 6). The authors state that the preparation exhibits 0.3 of the activity of the natural hormone and is used for entomological studies. Double bonds are formed both by the Julia method and by the Wittig reaction.

At the beginning of 1969 a further two papers on the synthesis of the juvenile hormone were published almost simultaneously. The synthesis achieved by Schulz[65]

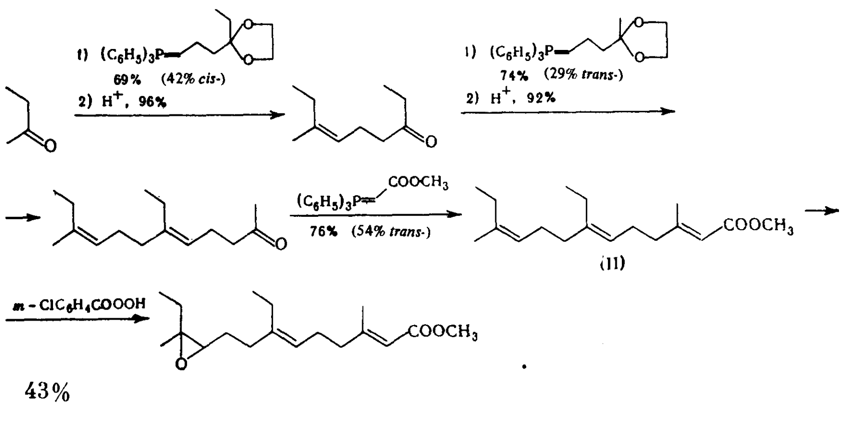
Scheme 5



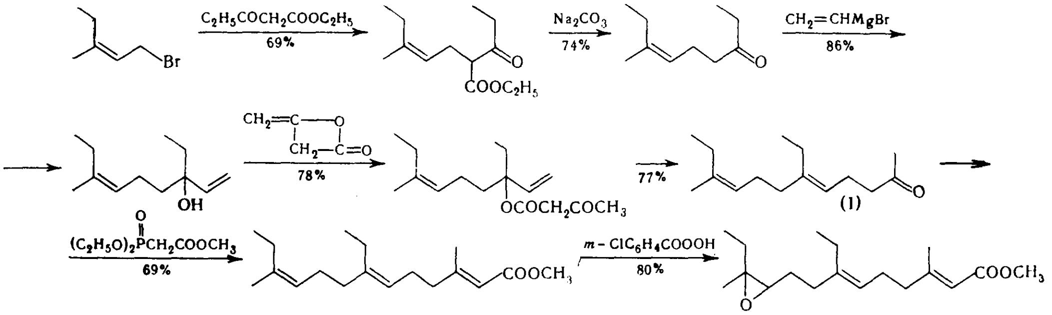
Scheme 6



Scheme 7



Scheme 8

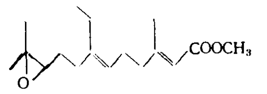


includes only three stages for the formation of the C_{17} skeleton: $C_4 + C_6 + C_5 + C_2$. The synthesis consists in a gradual increase in chain length using the Wittig reaction (Scheme 7).

The isomers of the C_{10} and C_{15} ketals and of the triene ester (II) were separated by fractionation on a Teflon column (l = 100 cm). The ketones obtained after hydrolysis were additionally purified by chromatography on silica gel. The authors state that they can obtain by this method all the geometrical isomers of the juvenile hormone and its homologues with different substituents at C_3, C_7, and C_{11}. However, it should be noted that the syntheses of the phosphoranes derived from the initial ketals and the separation of the isomers are fairly laborious processes.

Mori et al.[66] achieved a non-stereospecific synthesis of the juvenile hormone [compounds (IV) and (V)] and yet another homologue, which differs from the juvenile hormone by the presence of a methyl instead of an ethyl group at C_{11} [compound(IX)]. The final product consisted of a mixture of isomers. The synthesis is based on the application of the Normant[67] and the Carrol–Caymel[68] reactions and the phosphonate modification of the Wittig reaction[43]. The ratio of the *cis*- and *trans*-isomers in the intermediate and final product was determined by gas-liquid chromatography (Scheme 8).

The intermediate C_{10} and C_{15} ketones were obtained as individual isomers by the fractionation of the dioxolan derived from the C_{10} ketone[69] and repeated recrystallisation of the semicarbazone of the C_{15} ketone.



(IX)

IV. NATURAL AND SYNTHETIC ANALOGUES OF THE JUVENILE HORMONE

1. Farnesol Derivatives

At the beginning of the 1960's natural and synthetic compounds exhibiting the juvenile-hormonal activity in insects were discovered[20,27,70–75]. It was already clear that the structure of the juvenile hormone resembles that of terpenes. Farnesal and farnesol, acyclic sesquiterpenes widely distributed in nature, attracted particular attention. They were detected in the organisms of beetles[70], butterflies[47,76], bumble bees[77], and other insects. The hypothesis that farnesol functions as the juvenile hormone[70,72] was not confirmed[27,37,75]. Biological tests on a number of natural and synthetic terpenoids showed that none of them has a sufficiently high activity to be identified with the juvenile hormone[20,27,76,78].

Nevertheless these studies helped elucidate the structural elements responsible for the physiological activity, elucidate the relation between the shape and dimensions of the molecules and their juvenile-hormonal activity, and solve the problem of the mechanism of the action of the juvenile hormone at a molecular level. To obtain compounds more readily available than the juvenile hormone in order to combat harmful insects, the search for substances imitating its activity has been begun.

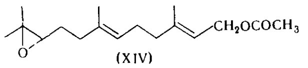
It is noteworthy that experiments designed to determine the juvenile-hormonal activity have been performed on different objects and by different methods (injection and surface application) and therefore it is frequently impossible to compare the results obtained by different investigators. Insects of different species show different sensitivity in relation to the juvenile hormone and its analogues. Hence there is a potential possibility of creating selective hormonal insecticides. The most active substances are described below and data on the relation between their structure and biological activity are given.

Tests of farnesol isomers on the pupae of the flour beetle *Tenebrio molitor* showed that *trans,trans*-farnesol (X) has the maximum activity[79]. This finding holds also for other sesquiterpenes: the *trans*-isomers are the most active[24,28]:

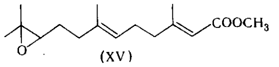
(X) R=OH, (XI) R=OCH_3, (XII) R=$N(C_2H_5)_2$, (XIII) R=$OCOCH_3$

Farnesyl methyl ether (XI) and farnesyldiethylamine (XII) are more effective by a factor of 10 and 17 respectively than farnesol (X) in tests on the pupae of the wax moth *Galleria mellonella*[80,81]. The length of the terpene alcohol molecule and the position of the hydroxy-group are important for juvenile-hormonal activity. Thus geraniol, linalo-ol and bisabolol are inactive. The effect of the length of the molecule on juvenile-hormonal activity is clearly shown by alkyl methyl ethers. Dodecyl methyl ether is the most active[80,82]. A change in chain length by three carbon atoms leads to total loss of activity. The presence of groups with a definite polarity is also essential for activity. Farnesene and dihydrofarnesene on the one hand and the highly polar farnesylic acid, dodecyl alcohol, and dodecylamine on the other are completely inactive or show a weak activity. Moreover, Schneiderman[80] noted the importance of molecular properties such as the capacity to form complexes with proteins and lipoproteins and to penetrate cell membranes.

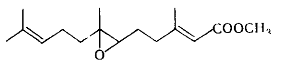
After the detection of the epoxy-group in the juvenile hormone, a number of sesquiterpene epoxides were obtained. 10,11-Epoxy-*trans,trans*-farnesyl acetate (XIV) shows a higher activity than farnesyl acetate (XIII).[44,83] The conversion of the methyl ester of *trans,trans*-farnesylic acid into an epoxy-derivative with *m*-chloroperbenzoic acid in dichloromethane gives a mixture of epoxides [80% of (XV) and 20% of (XVI)], which were separated by thin-layer chromatography:



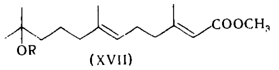
(XIV)



(XV)



(XVI)



(XVII)

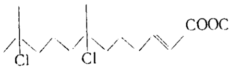
(R=CH_3, C_2H_5)

Tests with surface application on *Tenebrio molitor* showed that (XV) is 1600 times more active than farnesol (X), while (XVI) is inactive[83]. It is interesting that (XV) is less active than farnesol when injected[28].

Compounds with *O*-alkyl substituents at C_{11} [compound (XVII)] also exhibit juvenile-hormonal activity[84].

Law and Williams[85] obtained the most active synthetic product by passing hydrogen chloride through an alcoholic solution of farnesylic acid. It consists of at least 22 components, five of which are active[39] and is known as "Law's mixture"[86] or "synthetic juvenile hormone"[87]. When "Law's mixture" is obtained in various alcohols, the juvenile-hormonal activity varies as follows: ethanol > methanol > propanol > pentanol. When the reaction is carried out in ethanol, a highly active product, effective in insects of various species, is obtained[24,85,88-90].

Sorm and coworkers[91] isolated the principal component of "Law's mixture" obtained in methanol. It is the dihydrochloride of the methyl ester of farnesylic acid (XVIII):



(XVIII)

Compound (XVIII) showed a high juvenile-hormonal activity in relation to the bugs *Pyrrhocoris apterus*[91-95], *Rhodnius prolixus*[24], and others.

Farnesol[96] and a number of similar compounds[97,98] have been patented as insecticides and agents preventing the metamorphosis of insects.

At the beginning of 1969 a very interesting paper was published by Wigglesworth[24] in which he quotes the results of tests of 42 compounds on *Rhodnius prolixus*. All eight isomers of the juvenile hormone (Table 1) and the most active synthetic and natural substances were tested for the first time under identical conditions. Most of the specimens tested by Wigglesworth were obtained from the Hofman-La Roche Company. Many specimens have not been described in the literature. Table 2 lists the most interesting compounds. Using earlier data[79-81] and the results of his own investigations, Wigglesworth[24] formulated the following postulates.

1. A definite length and shape of the molecule is necessary for juvenile-hormonal activity. Substituents at the 2,3- and 6,7-double bonds must have the *trans*-configuration.

2. The balance between the lipophilic and hydrophilic groups in the molecule is significantly reflected in its juvenile-hormonal activity. Marked hydrophilic properties due to the presence of groups such as hydroxyls and carboxyls or, conversely, unduly lipophilic properties of the molecule lead to a decrease or disappearance of activity. The small differences in the structure of membranes in different insect species account for the significant difference in their sensitivity to juvenile hormone preparations.

3. Substances which are most active on local application are also active when injected. There are, however, exceptions. The physical properties of the cuticle (the external skeleton of insects) and the amount of lipids in the haemolymph influence the penetration of the hormone and are responsible for the specific differences in sensitivity.

4. The differences in geometrical form and possibly in physical properties (for example, the proportions of the polar and non-polar groups in the molecule) appear to be more important for juvenile-hormonal activity than the presence of specific chemical groups.

5. In an early paper Schmialek[47] pointed out that an important factor influencing juvenile-hormonal activity is

the ease with which a given hormonal preparation breaks down in the insect organism. This, for example, explains the higher activity of farnesyl methyl ether compared with farnesol.

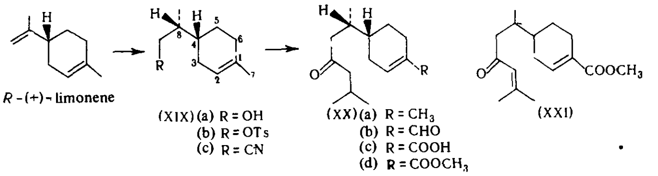
Table 2. Juvenile-hormonal activities of farnesol derivatives.

Compound	Structural formula	Activity, μg/g of insect wt.
Farnesol		45.0
Farnesyl methyl ether		0.6
10,11-Epoxyfarnesyl methyl ether		0.9
Farnesylic acid		90.0
Law's mixture		2.7
Dihydrochloride of methyl ester of farnesylic acid		2.2
Dihydrochloride of ethyl ester of farnesylic acid		0.5
Ethyl 11-chloro-3,7,11-trimethyldodeca-2-enoate		1.8
Ethyl ester of 10,11-epoxyfarnesylic acid		2.2
10,11-Epoxy-3,7,11-trimethyldodec-2-enoic amide		90.0
10,11-Epoxy-3,7,11-trimethyldodec-2-enoic *NN*-diethylamide		9.0
Ethyl 10,11-epoxy-3,7,11-trimethyldodec-2-enoate		0.5
Farnesyldiethylamine		1.8
Dodecyl methyl ether		250.0
Synthetic juvenile hormone		0.18

2. Juvabione and Its Analogues

In 1965 Sláma and Williams[99] accidently observed that the larvae of the bug *Pyrrhocoris apterus* undergo additional moulting on coming into contact with paper of American origin. Since such changes are caused only by the juvenile hormone[100], experiments were performed to isolate the active substance called the "paper factor"[99,101,102]. Bowers showed that the "paper factor" is present in the wood of the balsam fir *Abies balsamea*, which is used as the principal new material for the manufacture of paper pulp in Canada and the Northern USA. Further studies led to the determination in the structure of the "paper factor"[103]. It proved to be the methyl ester of the known todomatuic acid isolated by Japanese chemists from sulphite liquors, and was given the trivial name juvabione (XXd). Another active monocyclic sesquiterpene—dehydrojuvabione (XXI)—was isolated by Sorm and coworkers[104] from a fir native to Czechoslovakia.

Juvabione and dehydrojuvabione act selectively on bugs of the family *Pyrrhocoridae* and are inactive in tests on other insects[24,99,101,104]. Recently the absolute configuration of juvabione was established. Earlier Japanese investigators believed that both asymmetric centres of the (+)-todomatuic acid have the *R*-configuration[105]. The conversion of *R*-(+)-limonene into (+)-todomatuic acid (XXc) and (+)-juvabione (XXd), identical with the natural compounds, was achieved in 1968.[106]

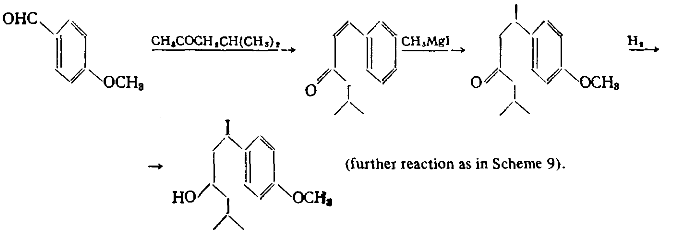


The unsaturated alcohol (XIXa) was obtained by the hydroboration and oxidation of natural limonene with subsequent separation of the 3,5-dinitrobenzoates of the epimeric alcohols. Initially the configuration of compound (XIXa) was established incorrectly. Subsequently X-ray diffraction analysis of the *p*-iodobenzoate of the alcohol (XIXa) showed that the (+)-todomatuic acid and (+)-juvabione obtained by the authors have the 4(*R*),8(*S*)-configuration of the asymmetric centres[107].

The first synthesis of (±)-juvabione was achieved by a 15-stage procedure starting with *p*-methoxyacetophenone (Scheme 9). All the stages take place with high yields; the overall yield of the mixture of the diastereoisomers of todomatuic acid was 6.8%. The diastereoisomers were separated by the crystallisation of the semicarbazones[108,109].

Tests of the biological activities of the compounds obtained on *Pyrrhocoris apterus* showed that the synthetic (±)-juvabione is less active by a factor of approximately 2 than the natural (±)-juvabione (XXd). The methyl ester of (±)-epitodomatuic acid is even less active.

A mixture of (±)-juvabione diastereoisomers was obtained by Indian investigators by a similar procedure, differing only in the first stages[110]:



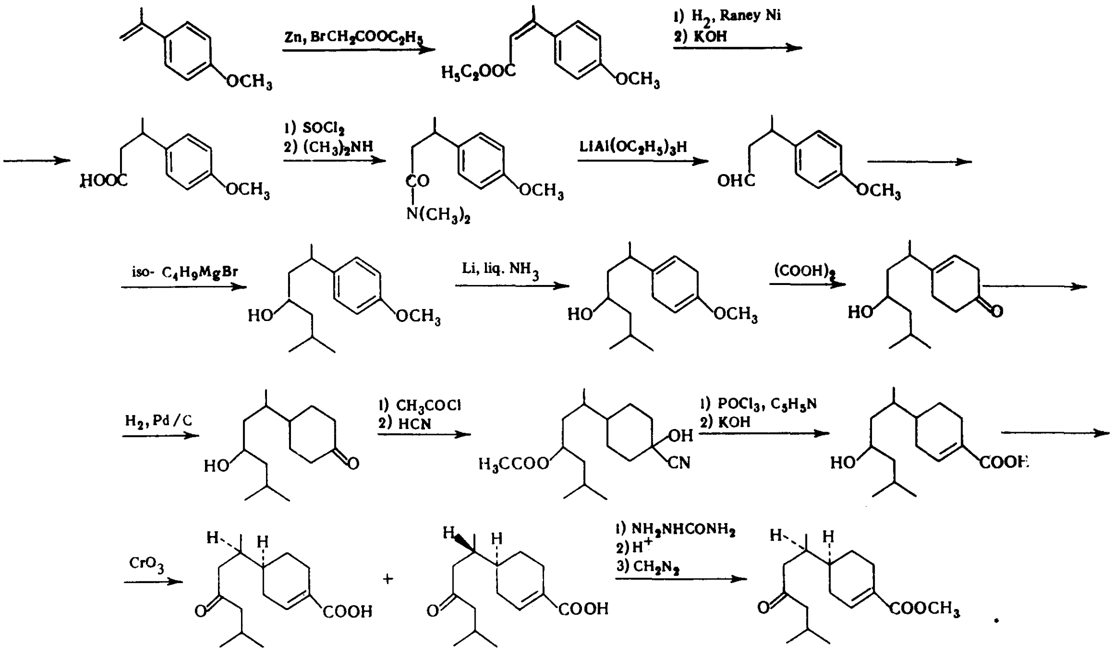
(further reaction as in Scheme 9).

The diastereoisomers could not be separated by thin-layer or gas–liquid chromatography, as had been noted also by Japanese chemists[109].

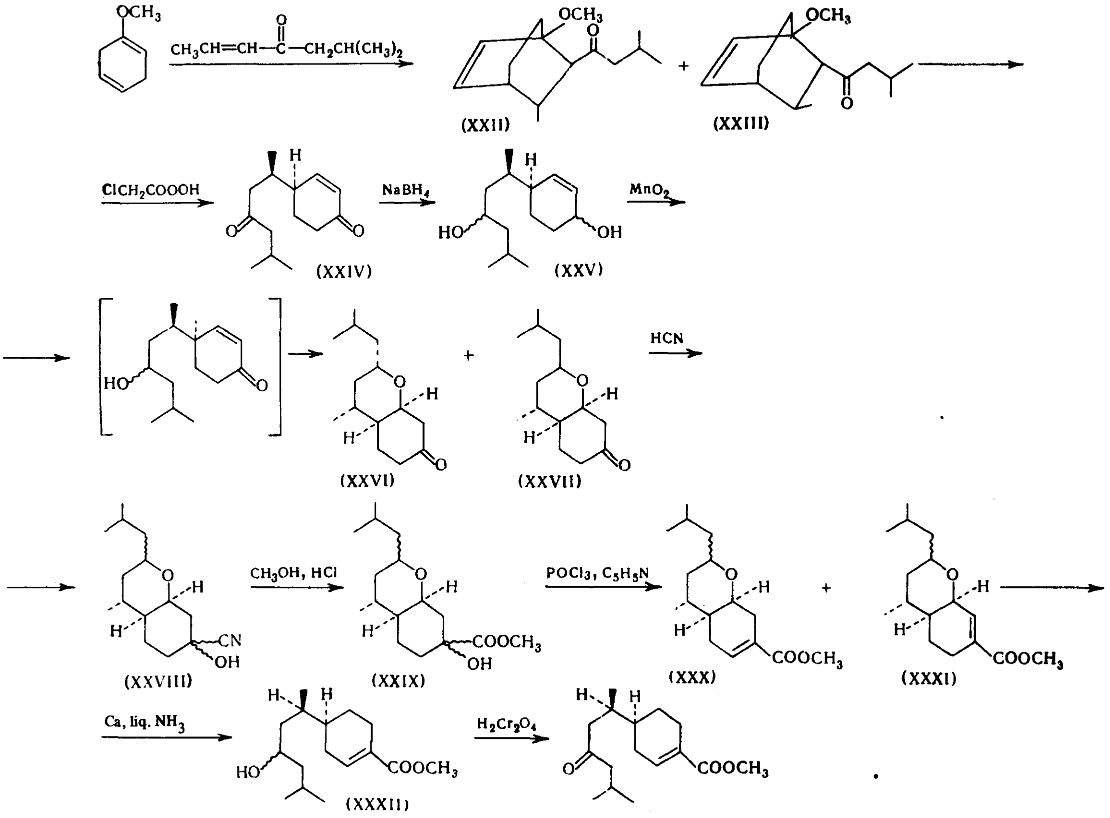
Birch et al.[111] developed a novel stereospecific synthesis (±)-juvabione (Scheme 10). Diels–Alder condensation of 1-methoxycyclohexa-1,4-diene with *trans*-6-methylhept-2-en-4-one gave a 75–80% yield of the adducts (XXII) and (XXIII) in proportions of 1 : 1. The rigid cyclic system and the different positions of the carbonyl group and the double bond ensure sufficient differences in the properties of the isomers to allow their separation on a fractionating column. Oxidation of the isomer (XXII) with chloroperacetic acid gave the diketone (XXIV), which was reduced with sodium borohydride to a mixture of stereoisomeric diols.

Oxidation of (XXV) with manganese dioxide gives a 5 : 1 mixture of the ketoesters (XXVI) and (XXVII), which were separated by chromatography on silica gel. The PMR spectra of both isomers indicate a *cis*-fusion of the rings,

Scheme 9

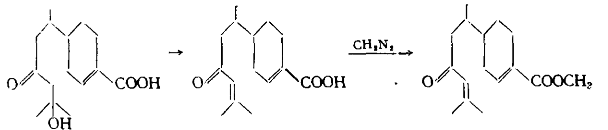


Scheme 10



i.e., they differ in the configuration of the side chain. Although both isomers can be converted into juvabione, only the isomer present in a larger amount was used in the preparation of the cyanohydrin (XXVIII). (XXVIII) was converted in the usual way into the hydroxyether (XXIX), the dehydration of which with phosphorus oxychloride in pyridine led to the formation of a 2 : 1 mixture of the unsaturated esters (XXX) and (XXXI), which were separated by chromatography on silica gel. Cleavage with calcium in liquid ammonia leads to the hydroxyester (XXXII), which is oxidised by chromic acid to (±)-juvabione.

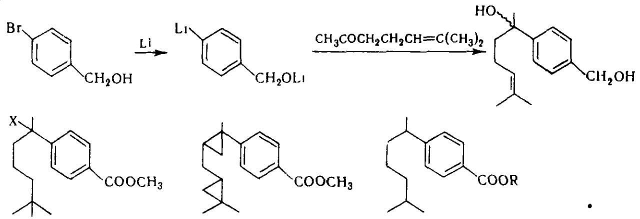
A non-stereospecific synthesis may be achieved by reduction of the double bond in (XXIV) followed by a selective reaction of the diketone with HCN and subsequent conversion of the cyanohydrin into an $\alpha\beta$-unsaturated ester. The authors of the first synthesis of (±)-juvabione obtained also dehydrojuvabione as a mixture of (±)-dihydrojuvabione and its stereoisomer. The method of synthesis resembles in many ways that of juvabione. The double bond conjugated with the carbonyl group was formed in the last stages by dehydration of the unsaturated hydroxy-acid[112]:



(XXI) .

Juvabione and dehydrojuvabione, which act selectively on different insect species, are active only when employed in microgramme amounts, while the juvenile hormone and some of its synthetic analogues suppress metamorphosis in amounts of 0.001–0.0001 μg. In search for more effective selective hormonal insecticides, Czechoslovak investigators[18] synthesised a series of aromatic analogues of juvabione. The specific effect of these compounds on bugs of the family *Pyrrhocoridae* is maintained[19,95].

The compounds obtained were patented, since some of them are 100 times more active than juvabione[113]. Moreover, they are comparatively readily available. The key stage in the synthesis is the condensation of the lithium derivative of benzyl alcohol with 6-methylhept-5-en-2-one. The subsequent reactions yielded a number of analogues of juvabione which were tested on two species of the family *Pyrrhocoridae*:

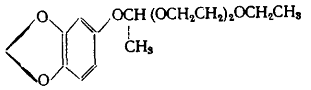


(X = Cl, Br) (R = CH₃, C₂H₅ etc.) .

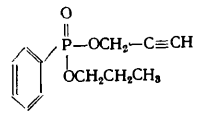
The observed differences in sensitivity show that the preparations may be specific even within a single family.

3. Synergists

Synergists for insecticides such as pyrethrines or carbamates have found wide application in practice. In his attempt to employ the JH-active 10,11-epoxyfarnesyl methyl ether together with synergists, Bowers[114] observed that some of them exhibit a distinctive juvenile-hormonal activity. The experiments were performed on pupae of the flour beetle *Tenebrio amolitor* and larvae of the bug *Oncopeltus fasciatus*. The synthetic synergists sesoxane (XXXIII) (in doses up to 0.5 μg) and Niagara 16 388 (XXXIV) show the highest activity. The remaining synthetic and natural synergistic agents (sesamin and sesamolin) are inactive or weakly active:



(XXXIII)



(XXXIV)

Bowers showed that sesoxane acts similarly to other substances with juvenile-hormonal activity and not by activating the corpora allata.

At present the juvenile hormone and its analogues are being very intensively investigated. There is no doubt about the theoretical value of such studies. Certain important problems, in particular the determination of the mechanism of the action and of the biosynthesis of the juvenile hormone will probably be elucidated in the near future. Possibly a more rigorous correlation will be established between the structure and physiological activity of the compounds. The prospects for practical application of compounds with juvenile-hormonal activity as a "third generation" of chemical pesticides are very good and therefore further development of studies in this field is to be expected.

---o0o---

During the preparation of the review for the press, a number of studies on the synthesis of the juvenile hormone[115–118] and substances with juvenile-hormonal activity were published[119–123]. The work of Czechoslovak investigators on tests of compounds of the farnesyl series on *Galleria mellonella* is noteworthy[124].

Studies on the mechanism of action[125,126] and the effect of JH-active substances on the metamorphosis[127,128], ovogenesis[129], and metabolism[130] of insects are being continued.

Bowers' report on the preparation of methylenedioxyphenyl ethers, some of which showed an activity higher than that of the juvenile hormone when tested on the beetle *Tenebrio molitor* and the bug *Oncopeltus fasciatus*, is extremely interesting[131]. The sterilising effect of JH-active substances on introduction into insect males is noteworthy[92,132].

The publication of two reviews on insect hormones[133,134] should be noted.

The Application of Nuclear Magnetic Resonance in the Study of the Conformational Equilibria of Cyclic Compounds

T.M.Ivanova and G.P.Kugatova-Shemyakina

The NMR spectroscopic methods used to investigate mobile conformational equilibria and to determine the rate constants are discussed. A critical comparison has been made of the accuracy of the results obtained by high-resolution and spin-echo NMR methods. A systematic account of the thermodynamic parameters of the ring inversion of cyclic compounds obtained by NMR methods has been given. The possibility of employing NMR spectra for the determination of conformational equilibrium constants is discussed.
The bibliography includes 224 references.

CONTENTS

I. INTRODUCTION

In recent years there has been an intense development of the field of structural chemical studies which has come to be called conformational analysis. The development of Barton's ideas[1] concerning the relation between the physical and chemical properties of molecules, in particular between reactivity and the steric position of atoms and groups of atoms, proved to be extremely fruitful in a wide variety of chemical fields. Particularly important advances have been made in the conformational analysis of cyclic compounds for which a comparatively small number of conformations (in many cases not more than two) is possible owing to the limitations imposed on structural isomers. The interest in conformational studies has been largely reflected by the simultaneous publication of two extensive monographs[2,3].

Both chemical methods, based on definite reactions of model compounds, and many physical methods, with the aid of which it is possible to establish either the complete structure of the molecule (X-ray analysis, electron diffraction, microwave spectra) or certain details of this structure (dipole moments, vibrational spectra, NMR spectra, optical rotatory dispersion) are used at present to investigate conformations. Among the latter group of methods, NMR spectra occupy a special place. By virtue of their specificity, NMR spectra permit in many cases a rapid and reliable determination of the steric orientation of groups containing magnetically active nuclei and the relative amount of such groups in the molecule. They are more selective, than, for example, dipole moments and vibrational spectra; in the latter the vibrations of individual bonds and groups are frequently not entirely characteristic, which may lead to conclusions with little justification. Moreover, NMR spectra permit the investigation of processes involving the attainment of conformational equilibrium and the determination of the lifetime of the molecule in each form, while with the aid of other methods only indirect conclusions concerning such problems may be made. Although the method began to be developed comparatively recently, extensive data have now accumulated on fixed conformations and also on the inversion of cyclic systems. Without exaggeration, one may say that conformational analysis has to a large extent stimulated the development of the NMR method for the study of mobile equilibria. A number of techniques have been developed permitting the determination of the thermodynamic parameters of the ring inversion of cyclic systems. The most extensive studies of this kind have been made for cyclohexane derivatives, but there are also data on the inversion of other cyclic compounds, in particular medium-ring and heterocyclic compounds. Extensive data on the NMR spectra of rigid polycyclic systems, mainly steroids, are given in the book of Bhacca and Williams[4].

This review deals with the application of NMR spectra in the study of mobile conformational equilibria, mainly of monocyclic systems. Initially, methods which have now been developed for the investigation of ring inversion will be considered and their comparative accuracy will be estimated. The second part of the review gives a systematic account of the data on the thermodynamic parameters of the inversion of cyclic compounds obtained with the aid of NMR methods. The scope of the use of NMR spectra for the determination of conformational energies in six-membered rings is also briefly discussed. The majority of published results concern proton magnetic resonance spectra, but in recent years interesting data have been obtained with the aid of the fluorine resonance, also discussed in the review.

II. METHODS FOR THE INVESTIGATION OF RING INVERSION

The conformational hypotheses concerning the structure of cyclohexane and many other derivatives are based on the concept of the rapid conversion of one chair form of the molecule into another with the boat forms as intermediates. In this process the axial bonds of one chair conformation become the equatorial bonds in the other and conversely. Since it was shown in early studies that the axial and equatorial protons of six-membered rings are magnetically non-equivalent, the study of the inversion of cyclic systems is a special case of the study of the exchange of protons (or other magnetically active nuclei) between non-equivalent positions; hindered rotation and intermolecular exchange in chemical reactions belongs to the same class of problems.

In recent years the "kinetic" field of NMR spectroscopy has been developing very vigorously. A number of methods and theoretical procedures have been developed, whereby one can use all the parameters of NMR spectra which vary with the rate of exchange of the nuclei: the multiplicity of the spectrum, intensity ratios, chemical shifts, and component widths.

The existing methods belong mainly to two categories: high-resolution and spin-echo spectroscopy. Their fundamental principles and practical applications in the study of ring inversion will be discussed below. The applicability of the method is undoubtedly not limited to the inversion of cyclic compounds; all the relations between the parameters of the spectrum and the rates of exchange may be applied to hindered rotation and, after appropriate modification, to the study of chemical reaction kinetics. In the investigation of mobile conformational equilibria, one usually employs the methods of high-resolution spectroscopy, which have been developed in detail. Detailed descriptions of these procedures are given in a number of monographs[5,6] and in this review only their principal postulates will be briefly described. The double-resonance and spin-echo methods, recently proposed for the investigation of ring inversion, will be considered in greater detail.

1. High-resolution NMR Spectroscopic Methods

The theoretical basis of these methods is the semiclassical treatment of Gutowsky et al.[7], who examined the Bloch equations for two protons with resonance frequencies ω_A and ω_B undergoing exchange between equilibrium positions A and B (it is assumed that the lifetime $\tau_A = \tau_B = \tau$). The expression for the total magnetisation averaged with respect to proton exchange is[7]:

$$G = \overline{G}_A + \overline{G}_B = \frac{-2\omega M_0\tau\{2+(1/T_2 - i\Delta\omega)2\tau\}}{(1+2\alpha_A\tau)(1+2\alpha_B\tau)-1}, \qquad (1)$$

where, as usual, $\alpha_A = 1/T_2 - i(\Delta\omega + \delta\omega/2)$, $\alpha_B = 1/T_2 - i(\Delta\omega - \delta\omega_2)$, M_0 is the equilibrium value of nuclear magnetisation, $\Delta\omega$ the difference between the applied radiofrequency ω and the frequency of the midpoint between two resonance components, and T_2 is the transverse relaxation time. Eqn. (1) was obtained on the basis of simple considerations by McConnell[8], who included directly in the Bloch equations terms taking into account the exchange: G_A/τ and G_B/τ. For non-identical probabilities $p_A \neq p_B$ of the presence of the proton in A and B (p_A and p_B may be regarded as the "molar concentrations" of A and B),

$$p_A + p_B = 1 \quad \tau_A/p_A = \tau_B/p_B, \qquad (2)$$

analytical expressions defining the total magnetisation were obtained by Gutowsky and Saika[9] and subsequently by other investigators[10,11].

It follows from Eqn. (1) that the form of the NMR spectrum is determined by $\delta\omega$, T_2, and the rate of proton exchange $1/\tau$. At high rates of exchange ($\tau\delta \ll 1$) one signal with a frequency ω_0 is observed; with increase of τ, the signal gradually widens, and for $\tau > \sqrt{2}/2\pi\delta\omega$ two broad signals are observed. The value of τ corresponding to the merging of the signals may be called the coalescence point. On further growth of τ, the width of the signals diminishes and the distance between them increases to $\delta\omega$ (Fig. 1).

Eqn. (1) contains an implicit relation between all the parameters of the NMR spectrum and the rate of exchange, but for the solution of practical problems it is convenient to obtain analytical relations between $1/\tau$ and quantities measured directly from the spectrum. Such relations have been obtained for three readily measurable parameters: (a) the distance between the lines (for $\tau\delta \ll 1$);[13] (b) the intensity ratios I_{max}/I_{min} for incomplete resolution of the doublet[14-16]; (c) the line widths in the limiting cases of rapid and slow exchange[17,18].

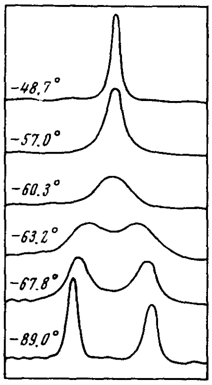

Figure 1. Spectra of $C_6D_{11}H$ at different temperatures[12].

a. Change in the distance between the components of the spectrum. An explicit expression relating the distance between the signals to the rate of exchange was obtained by Gutowsky and Holm[13]. Starting with Eqn. (1), they obtained an equation of the fifth degree in $\Delta\omega$, which becomes very simple when the width of the lines $1/T_2$ is small compared with the distance $\delta\omega$ between them:

$$\delta\omega_e = (1-2/\tau^2\delta\omega^2)^{1/2}\,\delta\omega; \quad \tau\delta\omega > \sqrt{2}. \qquad (3)$$

Thus, when measuring the distance $\delta\omega_e$ between the components under various conditions (usually the lifetime is varied by altering the temperature), it is possible to determine τ by Eqn. (3) provided that the distance $\delta\omega_\infty$ is known for $\tau \to \infty$. In practice, however, failure to take into account the widths of the components may introduce a significant distortion into the results already when $1/T_2\delta\omega > 1/3$.[13] Gutowsky and Holm showed that this is equivalent to applying a correction to $\delta\omega_\infty$. The true distance $\delta\omega$ may be obtained from a plot of $\delta\omega/\delta\omega_\infty$ against $2/T_2\delta\omega_\infty$.[13] In practice T_2 may be determined from the line width when $\tau \to 0$; $\delta\omega_\infty$ is measured at $\tau \to \infty$.

b. Intensity ratio in the spectrum. Starting with postulates analogous to those discussed above, it is possible to express the average lifetime τ of the protons undergoing exchange in terms of the ratio r of the intensity at the maximum of the signal to the intensity in the centre of the spectrum, between the signals, when the symmetrical doublet (or other symmetrical multiplet signal) is completely resolved[14-16]. The expression is of the form

$$\tau\delta\omega = \sqrt{2}\,[r + (r^2 - r)^{1/2}]^{1/2}; \quad \tau\delta\omega > \sqrt{2}. \qquad (4)$$

The determination of the rate of exchange reduces in this case to the measurement of the intensity at the maximum and the minimum intensity in the "hollow" between the signals for different degrees of incomplete resolution. It is also necessary to know the distance $\delta\omega$ between the components at $\tau \rightarrow \infty$. Expressions of this kind, relating τ to the peak intensity of the signal for rapid[10] and slow[11] exchange, have been obtained in a number of studies.

c. Change in signal width. The applicability of the methods described above is restricted to the range of comparatively low rates of exchange. In order to obtain the necessary parameters, all the measurements must be made over a narrow temperature range below the point of coalescence. Moreover, it is also necessary to know the chemical shift $\delta\omega$ at $\tau \rightarrow \infty$, which sometimes gives rise to additional difficulties. Meiboom and coworkers[15,17] and Piett and Anderson[18] suggested that the variation of the transverse relaxation time with τ be used for the estimation of the rates in the extreme cases of rapid and slow exchange. Employing the approach of Gutowsky and Saika[9], Piett and Anderson[18] showed that, for low rates of exchange, the observed line width is

$$1/T_2' = 1/T_2 + 1/\tau, \qquad (5)$$

where T_2 is the transverse relaxation time in the absence of exchange and T_2^1 is the "new" transverse relaxation time. When the rate of exchange diminishes, the width of each component will tend to an effective natural value. For rapid exchange, the following expression was obtained:

$$1/T_2' = 1/T_2 + p_A p_B (\delta\omega)^2 \tau. \qquad (6)$$

The line width can be determined either directly from the high-resolution spectrum or by the usual methods based on measurements of signal decay. It is significant that the temperature variation of line widths may be slower and may be observed over a wider range than, for example, the temperature variation of the distance between the components described by Eqn. (3). Therefore the above methods greatly extend the range of measurable rates of exchange.

2. Methods Based on Complete Calculation of the Spectrum

In recent years a new approach to the determination of the rates of exchange from NMR spectra became possible as a result of the availability of high-speed computers. It reduces to the complete analysis of the outline of an AB or more complex systems as a function of the lifetime τ. A general quantum-mechanical theory of the effect of exchange on the parameters of the NMR spectrum, based on the time variation of the components of the density matrices, was developed by Kaplan[19] and Alexander[20]. The corresponding expressions for the system AB were obtained by Heidberg et al.[21]. The method involving the complete calculation of the spectrum requires the derivation of the equations and their numerical solution for each specific problem. The value of τ, which gives the best description of the spectrum when the other parameters are specified is determined by an iterative procedure. As a rule, the calculated and observed spectra are compared visually. However, recently Jonáš et al.[22] developed a convenient program for the comparison of the observed and calculated outlines by means of a computer.

3. Double Resonance

Recently a double-resonance technique was proposed for the investigation of the rates of exchange. The method was developed by Forsen and Hoffman[23,24] and applied in the study of the rate of inversion of cyclohexane by Anet and Burn[25]. The idea of the method is as follows. Suppose that there is exchange between two non-equivalent positions A and B, and the following two obligatory conditions are fulfilled: (1) the lifetimes τ_A and τ_B must be sufficiently long for a satisfactory resolution of the signals A and B; (2) the lifetime τ_A must be comparable to the spin-lattice relaxation time T_{1A}. If the signal B is saturated instantaneously, the signal A will decay exponentially with the time constant τ_{1A}:

$$M_z^A = M_0^A\,[\tau_{1A}/\tau_A \exp(-t/\tau_{1A}) + (\tau_{1A}/T_{1A})], \qquad (7)$$

where M_0^A is the initial magnetisation of A. The new "generalised" relaxation time τ_{1A} is defined thus:

$$1/\tau_{1A} = 1/\tau_A + 1/T_{1A} \qquad (8)$$

and the new equilibrium magnetisation is given by

$$M_z^A(t \rightarrow \infty) = M_0^A(\tau_{1A}/T_{1A}). \qquad (9)$$

Thus the ratio of the initial and final magnetisations M_0^A/M_Z^A, which can be readily obtained experimentally, yields τ_{1A}/T_{1A}; by plotting $\lg[M_Z^A(t) - M_Z^A(t \rightarrow \infty)]$ against t, we obtain a straight line with slope τ_{1A}. It is then easy to determine τ_A and T_{1A} from Eqn. (9).

When the saturating field at B is removed, the A signal returns to its initial value M_Z^A, but the corresponding relation is not exponential; in the general case it cannot be described with the aid of a single time constant[23,24]. Forsen and Hoffman examined also two other possibilities: the return of the magnetisation of the signal to the initial value after saturation of the same signal and after the simultaneous saturation of the A and B signals[23]. Subsequently the same workers[24] applied the method to the study of exchange between several non-equivalent positions. As already stated, the double-resonance method can be applied only over a very restricted range of rates of exchange, since the lifetime must be comparable to the spin–lattice relaxation time. The latter may be varied somewhat by the addition of paramagnetic substances. The lower limit to the measured rates is imposed by the requirement that the signals do not overlap, i.e. the lifetime must be greater than the reciprocal of the distance between the corresponding lines.

The advantages of the method are due primarily to the fact that the lifetimes measured with its aid cannot be determined by other high-resolution procedures. Moreover, it is noteworthy that the experiment in which two parameters (rate of exchange and spin–lattice relaxation times) are measured simultaneously is relatively simple and the amount of calculation in the interpretation of the data is also small. The method does not require a very high resolution and an accurate determination of the chemical shifts. However, a high sensitivity of the detecting system is essential.

4. The Spin-echo Method

Recently Gutowsky, Allerhand and coworkers[26-31] developed a fundamentally new approach to the determination of the rate of proton exchange from NMR spectra. It is based on the observation of spin-echo signals† when a chain of high-frequency pulses in the Carr–Purcell sequence[32] is applied to the spin system investigated: at time $t = 0$ a 90° pulse is applied and then at times $(2n - 1)t_{av}$ a sequence of 180° pulses is observed. These pulses generate a spin echo at times $2nt_p$ (here t_p is the period between the 90° pulse and the first 180° pulse). In the general case the amplitudes of the observed echo signals are functions of the shift $\delta\omega$, the spin–spin coupling constant J, the transverse relaxation time T_2^0 in the absence of exchange‡, the distance between the 180° pulses, t_{av}, the population of the p_A and p_B levels, and the rate of exchange $1/2\tau$. It is important that the duration of the pulses is short compared to T_2 (and to the spin–lattice relaxation time T_1) and also to the intervals between the pulses, so that the relaxation and exchange effects during the application of the pulse may be neglected.

The simplest relations between these quantities are obtained for the AB system when $J = 0$. For this case, Allerhand and Gutowsky[26,27] employed a semiclassical approximation taking into account the exchange terms[7,8,13]. Earlier Luz and Meiboom[33] obtained an approximate analytical expression for the decay of the spin-echo signals under conditions where (1) the distance between the 180° pulses is small ($t_{av} \ll T_2$) and (2) the exchange is fairly rapid ($1/2\tau \gg \delta\omega$):

$$1/T_2 = 1/T_2^0 + p_A p_B (\delta\omega)^2 \tau \,[(1 - 2\tau/t_{av}) \tanh t_{av}/(2\tau)]. \qquad (10)$$

Gutowsky and Allerhand showed[26,27] that, although Eqn. (10) may be applied over a fairly wide range of values of the independent variables, for high values of t_{av} and for slow exchange its application leads to significant errors. Their general examination of the problem led to the conclusion that the expression for the variation of the magnetisation component may be represented by two terms, one of which varies exponentially with time and the other is pseudoexponential. However, the latter is small in most practical cases, so that only the contribution of the exponential term need be considered.

The following expression was obtained for identical populations $p_A = p_B = 0.5$:[27]

$$1/T_2 = 1/T_2^0 + 1/2\tau + 1/t_{av} \sinh^{-1} F ,$$

where

$$F = (1/\tau\sigma) \sinh (t_{av}\sigma/2); \quad \sigma = [(1/\tau)^2 - (\delta\omega)^2]^{1/2} . \qquad (11)$$

In the limiting cases Eqn. (11) leads to the following relations. (1) Slow exchange ($1/\tau < \delta\omega$):

$$1/T_2 = 1/T_2^0 + 1/2\tau . \qquad (12)$$

(2) Rapid exchange ($1/\tau \geqslant \delta\omega$):

$$1/T_2 = 1/T_2^0 + 1/2\tau - {}^1/_2 [(1/\tau)^2 - (\delta\omega)^2]^{1/2} . \qquad (13)$$

For very rapid exchange ($1/\tau \gg \delta\omega$), Eqn. (13) yields the result obtained on the basis of another approximation by Piett and Anderson[18]:

$$1/T_2 = 1/T_2^0 + {}^1/_4 (\delta\omega)^2 \tau . \qquad (14)$$

Eqn. (13) can also be used to determine the rates of exchange from the line widths in high-resolution NMR spectra; it can be applied in the case of much lower rates of exchange than Eqn. (14).

When the distance between the pulses diminishes ($t_{av} \rightarrow 0$), $1/T_2$ approaches asymptotically the effective natural line width (independent of the rate of exchange). This gives rise to the possibility of determining T_2^0 from spin-echo experiments with very rapid repetition of pulses.

Thus the rate of exchange $1/\tau$ may be determined by measuring the spin-echo signal decay as a function of the distance between the 180° pulses. Since Eqn. (11) includes, apart from τ and t_{av}, also the two independent variables T_2^0 and $\delta\omega$, it is usually solved by iterative methods[26,27]. Allerhand and Gutowsky developed programs whereby it is possible to obtain "true" values of the parameters after, as a rule, not more than ten iterations. The initial values of $1/\tau$ and $\delta\omega$ may be chosen with the aid of the Luz–Meiboom equation [Eqn. (10)].

The spin-echo method has the advantage that in this case there is no need for a direct determination of the parameters $\delta\omega$ and T_2^0; they are obtained additionally in the iterative process from the functional relation between $1/T_2$ and $1/t_{av}$. We may note that, in order to calculate the amplitude of the echo signals, it is by no means obligatory to express the variation of T_2 in an analytical form: it is possible to solve directly modified Bloch equations in a numerical form by means of appropriate programs. Although such calculations do require a considerable machine time, accurate values are then obtained over the entire range of variation of the parameters. However, for the majority of practical problems, the relation between T_2 and $1/t_{av}$ is satisfactorily described by Eqn. (11).

The semiclassical approach described above can be applied only to a system AB. If the coupling constant J_{AB} is comparable to the chemical shift, $\delta\omega$, significant changes may be introduced into the results of the spin-echo experiments. Allerhand and Gutowsky[31] examined, using a quantum-mechanical approach, the time variation of the components of the density matrix[20,21] for the system AB under conditions corresponding to the application of a Carr–Purcell sequence of pulses. In the general case eight recurrent equations were obtained, the coefficients of which are complex functions of the experimental quantities. However, as in the case examined above, a significant success may be achieved here by the numerical solution of the equations. By varying the independent variables τ, $\delta\omega$, J, and t_{av} over a wide range, Allerhand and Gutowsky showed that the results obtained[26,27,30] for an AB system with $J = 0$ are not applicable to interacting nuclei for low rates of exchange. When $1/2\tau$ (s^{-1}) is small compared with the geminal coupling constant J, modulation of the echo signal amplitudes should be observed. The modulation frequency depends on the distance between the pulses t_{av}, the constant J, and also $\delta\omega$, particularly if $J/\delta\omega \simeq 1$. In the limiting case where $J = 0$, the same results are obtained as in the semiclassical theory. The modulation greatly depends also on the rate of exchange. When $1/2\tau$ increases, the modulation frequency falls and the time variation of the echo signal amplitude approaches the exponential form. When $1/2\tau \gtrsim 20J$, the relation is rigorously exponential and can be described by a single decay constant. Thus in spin-echo experiments geminal coupling may be neglected only at high rates of exchange. In particular, for cyclohexane, which is an A_6B_6 system, $J_{HH} = 12.6$ Hz,[34] and therefore the semiclassical approach may be employed here at rates of inversion $k > 1/200$ s^{-1}. All these results have been qualitatively confirmed in spin-echo experiments with 1,1-difluorocyclohexane[31].

Gutowsky et al.[29] also developed a general theory of the effect of rates of exchange on the spin-echo signal amplitudes based on the formal matrix approach of Anderson and Weiss[35-37]. Among the series of interesting consequences

---

† For transient processes, see Ref. 6, p. 61.

‡ It is assumed that the transverse relaxation times for positions A and B are equal.

of this treatment, the authors demonstrated an analogy between the exchange effects and the quadrupole spin–lattice relaxation effects and showed that in principle quadrupole relaxation times may be measured by spin-echo methods§.

5. Accuracy of the Determination of the Rate Constant by Different NMR Methods

When a particular method is employed, it is necessary to bear in mind the resulting accuracy in the determination of the rate constant and then in the thermodynamic parameters of the system. Frequently, as experimental data accumulated, it became clear that many NMR methods probably involve serious systematic errors. The determination of the barrier to the hindered rotation of NN-dimethylformamide constitutes a striking example; its estimates vary from 7 to 24 kcal $mole^{-1}$,[23] while the experimental error quoted in each case does not exceed 1 kcal $mole^{-1}$.

Apart from the purely experimental errors (instability of the field, incorrect calibration, inaccuracies in temperature measurement), systematic errors can arise as a result of an incorrect choice of the model for the description of the real system. The simple semiclassical model for an AB system with $J = 0$ [7,9,13] becomes inapplicable in more complex cases where it is necessary to estimate the rate from equations for a system with $J \neq 0$.[19,20,39] However, even if the application of the semiclassical model is justified, usually further simplifications are made in order to obtain analytical relations and to employ readily available parameters: differences between the chemical shifts, intensity ratios, and line widths.

High-resolution NMR methods permit the measurement of the rate constant within very narrow ranges. The least accurate is the widely used method for the determination of the rate constants based on the merging of the signals at the coalescence temperature. In the first place the coalescence temperature cannot be determined with sufficient accuracy. This method yields no information about the process kinetics unless one assumes that Eyring's pre-exponential factor may be used and a transmission coefficient of unity is adopted.

The methods for the determination of τ from the change in the chemical shift and the intensity ratio are suitable only for low rates of exchange at temperatures below the coalescence point. Usually $\delta\omega_e$ is small and varies within a narrow temperature range; for example, for cyclohexane appreciable changes in $\delta\omega_e$ are observed between 64° and 72°C, i.e. over a range of only 6 deg. In order to increase $\delta\omega$, it is necessary to employ spectrometers with a higher field strength. $\delta\omega_\infty$ must be measured fairly accurately; a 10% error in the measurement of $\delta\omega_\infty$ leads to a much greater error in the thermodynamic parameters. A high accuracy in the measurements of $\delta\omega_e$ is also necessary, particularly when $\delta\omega_e$ approaches $\delta\omega_\infty$, i.e. in the region where $\delta\omega$ is already relatively insensitive to changes in temperature. Moreover, there is a possibility of a temperature variation of $\delta\omega_\infty$,[26,40] and failure to take this into account must lead to an additional systematic error in the determination of the rate of inversion. For very low rates of exchange, Eqn. (3) leads to large errors in the determination of τ and may not be used[16].

Allerhand, Gutowsky, and coworkers[41] analysed Eqns. (3) and (5) and showed that they yield high values of the rates, the error depending on the ratios of three parameters: $\delta\omega$, $1/\tau$, and the transverse relaxation time T_2^0. In particular, when Eqn. (3) is used, the error for a chosen pair of values of $\delta\omega$ and $1/\tau$ increases as T_2^0 falls.

Since both methods yield rate constants over a limited range of temperatures, small systematic errors in the measurement of τ may lead to considerably greater errors in the activation parameters. To extend the range of measured rates, the relation between line width and τ is employed in high-resolution methods at temperatures above the coalescence point. Here the inaccuracies may be attributed to the employment of temperatures close to the coalescence point of approximation (6), which is suitable only for very high rates of exchange[41]. However, it is precisely in the range of temperatures close to T_C that the contribution of the "exchange term" is most significant. In this case one may employ a more general expression for line width[10,40]. With increase in the rate, the contribution of the exchange term becomes extremely small and approaches the experimental error in the determination of line widths. In practice such a limiting value of the broadening due to exchange amounts to 0.05 Hz. Evidently, for systems which are not very complex, the most reliable values of τ may be obtained by complete calculation of the outline of the spectrum for various values of τ and subsequent comparison with the experimental spectra[21,22].

The spin-echo method developed by Gutowsky, Allerhand, and coworkers has a fundamental advantage: it permits the determination of the rates of exchange over a much wider range than high-resolution NMR methods. In particular, this applies to the region of high rates, where (for specified values of $\delta\omega$ and T_2^0) the maximum measurable rate depends on the accuracy with which it is possible to determine T_2^0/T_2 when this quantity tends to unity. In this case the limit of the possible errors in τ measured by the spin-echo method is

$$^1/_2\tau \leqslant p_A p_B T_2^0 (\delta\omega)^2 \, . \tag{15}$$

Such rates of exchange are not measurable by high-resolution NMR methods. The most favourable situation for measurement by the spin-echo method obtains in the case where the transverse relaxation time of the test substance is high, as, for example, in $C_6D_{11}H$ ($T_2^0 = 10$ s at $-100°$ and 85 s at 25°C). The spin-echo method permits the investigation of the ring inversion of deuterocyclohexane in the range where the rate varies by five powers of ten[30]: from 0.5 s^{-1} to 4×10^4 s^{-1}, extending thereby the range of attainable τ by a factor of more than 50. These data were obtained by Allerhand, Chen, and Gutowsky on a 24 MHz spectrometer. Evidently, by employing spectrometers with a higher field strength, the range of rate constants may be extended further by a factor of several units. The accuracy of the determination of τ by spin-echo methods does not exceed the accuracy of the high-resolution NMR method (10–20%), but, since τ is measured over a much wider range, the thermodynamic parameters obtained should be more reliable.

Spin-echo measurements have yet another advantage: they permit the determination at the same time of $\delta\omega$ and T_2^0, and $\delta\omega$ may be obtained at high rates of exchange for which high-resolution NMR spectroscopy is inapplicable.

Despite its undoubted advantages, the spin-echo method is comparatively rarely used to determine the rates of exchange. To a large extent, this is because the method has been developed quite recently. It requires additional

---

§ Powles and Strange[38] examined approximately the determination of the rate of intermolecular exchange for an AB system from spin-echo experiments.

apparatus, which has only now begun to be produced commercially outside the USSR and is more time-consuming than high-resolution NMR methods. The interpretation of the results is laborious and requires special programs and considerable machine time. Probably spin-echo measurements also include some phenomenological errors the source of which is as yet obscure. The point is that these measurements tend to yield high values for $\delta\omega$. Thus low-temperature NMR spectra yield $\delta\omega = 0.48$ p.p.m. for $C_6D_{11}H$[12,42,43] and $C_6D_8H_3$,[44] while the value obtained from spin-echo results for the same temperatures is higher by approximately 30%. In the study of 1,1-difluorocyclohexane[31] by the spin-echo method it was necessary to adopt $\delta\omega = 18.5$ p.p.m.; the value $\delta\omega = 15.6$ p.p.m., determined from low-temperature NMR spectra[22], gave a poor agreement between the results. The possible reasons for these discrepancies have been discussed[29]. The inconsistency is probably associated with the fact that the approximation in which the decay of the echo signal amplitudes is described by a single constant T_2 becomes inapplicable and it is necessary to take into account the pseudoexponential terms.

III. ENERGY PARAMETERS OF THE INVERSION OF CYCLIC COMPOUNDS

1. Cyclohexane

The classical model for the investigation of ring inversion by NMR spectroscopy is cyclohexane. The interest in this molecule is due, on the one hand, to the fact that it occupies a central place in the theory of conformational analysis. On the other hand, the rates of inversion of cyclohexane are in a favourable range and therefore it is frequently used to test a particular method.

Cyclohexane and its derivatives have been investigated by all the NMR spectroscopic methods developed hitherto (Table 1). At the coalescence temperature and below the

[1] Erroneous value; according to Jensen et al.[45], the value should be $\Delta H = 5.9$ kcal mole^{-1}.

[2] For chair–chair ring inversion. [3] At 40 MHz. [4] Chair–boat. [5] Value averaged with respect to the temperature range investigated. [6] Calculation by Alexander's method[20]. [7] Calculation for case AB.[20] [8] For half-chair–half-chair inversion. [9] For half-chair–boat inversion.

cyclohexane (C_6H_{12}) spectrum consists of a twelve-spin system, is extremely complex, and cannot be approximated by a simple doublet[45] or quartet[46]. However, these difficulties are eliminated when deuterated derivatives are employed[12,25,30,42]. At low temperatures the $C_6D_{11}H$ spectrum consists of two broad lines of equal intensity; the signal width may be greatly reduced with the aid of H–D double resonance[25,42,43]. With increase of temperature, the signals become broader and merge at the coalescence temperature (−61.4°C), above which a single narrow line is observed (Fig. 1).

If the rate constant is determined for a number of temperatures, the thermodynamic parameters of the inversion process may be obtained from the usual relations:

$$k = \frac{kT}{h}\exp(\Delta S^{\neq}/R)\exp(-\Delta H^{\neq}RT)\,, \qquad (16)$$

$$\Delta H^{\neq} = -R(\partial \ln k/\partial T^{-1})_p - RT\,, \qquad (17)$$

$$\Delta S'^{\neq} = (\Delta H^{\neq} - \Delta F^{\neq})/T\,, \qquad (18)$$

$$k = {}^1/_2\tau = A\exp(-E_a/RT)\,. \qquad (19)$$

The data in Table 1 show that the Gibbs free energies of activation for the inversion of cyclohexane agree to within 0.2 kcal mole^{-1} in six cases out of seven[¶], while the values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ differ significantly. Only the parameters obtained by high-resolution methods agree satisfactorily[25,42,43]. The ring inversion of cyclohexane has been investigated over the widest temperature range by the spin-echo method[30], which should apparently have yielded the most accurate values of the energy parameters. However, the results of Allerhand, Chen, and Gutowsky do not agree with the results from high-resolution spectra[†], the differences being illustrated in Fig. 2.

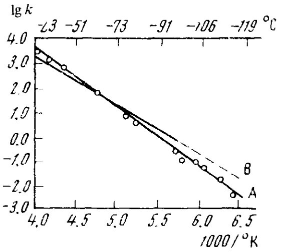

Figure 2. Temperature variation of the rate constant for ring inversion in cyclohexane determined by high-resolution (B) and spin-echo (A) methods[46].

The discrepancies are evidently associated with large systematic errors in the determination of the temperature variation of the rate constant. There are particularly large differences in the entropies found by different workers: they vary from +4.9 to −6.5 e.u. These results show that the experimental values of $\Delta S^{\neq}$ must be treated with caution in a discussion of the mechanism of ring inversion and the structure of the molecule in the transition state. In a number of studies attempts were made to estimate the entropy on the basis of the possible symmetry of the intermediate form[12,46,98]. If the rotational and vibrational contributions are neglected, such estimates may be made either by taking into account the symmetry numbers σ and the statistical weight w,[12,46] or by calculating directly the number of possible ways in which one form can be converted into another[25,98]. If the half-chair form is adopted for the intermediate state, the number of such ways is six and $S = R \ln n = 3.6$ e.u. Calculation from the expression $\Delta S = R \ln(w^{\neq}/w)\,(\sigma/\sigma^{\neq})$ also yields a positive entropy[98]. Harris[‡] pointed out that the entropies can be negative only when the intermediate state has a planar shape in the ring inversion process. However, according to calculations[99], the energy of this state should be of the order of 30 kcal mole^{-1}. The agreement between the ΔS values predicted on the basis of symmetry and the experimental data from high-resolution spectra[25,42,43] may be evidence of a high reliability of the latter.

Recently computational methods have been widely used for the investigation of the conformations of cyclic compounds[99-104]. They are based on the calculation of the energy of the molecule by classical methods for specified potential functions, taking into account mainly the extension of the bonds, the deformation of valence angles, the torsional strain, and the interaction of atoms not linked by valence bonds. Cyclohexane was investigated in greatest detail by Hendrickson[99,104]. Fig. 3, taken from Hendrickson's paper[104], shows the geometry of the intermediate states in the chair–boat inversion of the symmetrical forms. The boat–skew boat conversion is achieved by a pseudorotation the potential barriers for which are low, in contrast to the barriers in symmetrical transitions. Hendrickson obtained the following values for the barriers in the transitions: chair–chair 11.0 kcal mole^{-1}, chair–boat 6.4 kcal mole^{-1}, and chair–twist-boat 5.6 kcal mole^{-1}. Evidently all the calculated values agree very well with experiment.

It is noteworthy that in all the conformational calculations for cycloalkanes a considerable improvement is achieved when the valence angles corresponding to minimum strain are assumed to be not tetrahedral but 112°,[102-104] which agrees with the latest electron diffraction data for cyclohexane[105] and certain cycloalkanes[106].

2. Cyclohexene

Compared with cyclohexane, the ring inversion of cyclohexene and its conformations have been investigated in much less detail. Nevertheless the conformational studies on these molecules are just as important, since the cyclohexene ring is included in a large number of natural compounds and determines their structure to a great extent.

The geometry of the cyclohexene ring is determined to a considerable degree by the presence of a double bond: four carbon atoms must be located in one plane. As a result, cyclohexene can adopt the form either of a half-chair or a boat (Fig. 4). Thermodynamic calculations showed that[107] the boat form is less stable to the extent of 2.7 kcal mole^{-1} than the half-chair. However, the valence angles of the trigonal and tetrahedral carbon atoms in both conformations must be distorted. Corey and Sneen[108] determined by vector analysis the cyclohexane (half-chair) model for which the simultaneous distortion of all the valence angles is a minimum. A similar determination was made by Boucourt and Hainaut[109], who suggested that 112° be adopted for all the tetrahedral angles in cyclohexene.

Many experimental data now show that cyclohexene and some of its derivatives exist in the half-chair conformation[110-114]. The frequencies of the skeletal vibrations and the CH vibrations in the infrared and Raman spectra of gaseous, liquid and solid cyclohexene also agree better with the half-chair form[115].

[¶] It is interesting to compare the parameters of the ring inversion of cyclohexane obtained from NMR spectra with data derived by other methods. The first estimates of the height of the barrier in cyclohexane varied from 10 to 14 kcal mole^{-1}.[91,92] Later direct measurements of the decay of ultrasound yielded 8.3 kcal mole^{-1} [93] and 10.8 kcal mole^{-1}.[94] The following values have been obtained for the energy of the labile intermediate form, which cannot be estimated directly from NMR spectra: 5.9 kcal mole^{-1},[95] 5.5 kcal mole^{-1},[96] and 4.8 kcal mole^{-1}.[97]

[†] The spin-echo results agree with those of Harris and Sheppard[46], who also determined the rate constants over a fairly wide temperature range. However, subsequently Harris and Sheppard[98] reinterpreted their measurements in a different way and obtained $H = 10.3$ kcal mole^{-1}, in agreement with the enthalpies found by Anet and coworkers[25,42].

[‡] Ref. 40 in the paper of Bovey et al.[48]

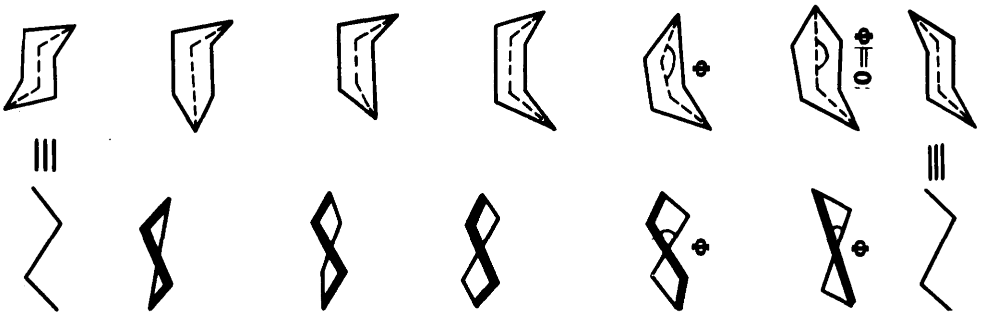

Figure 3. Intermediate states in the symmetrical ring inversion of cyclohexane[104].

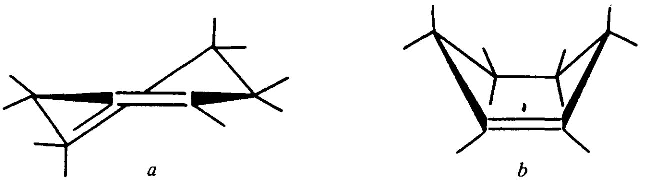

Figure 4. Cyclohexene conformations: *a*) half-chair; *b*) boat.

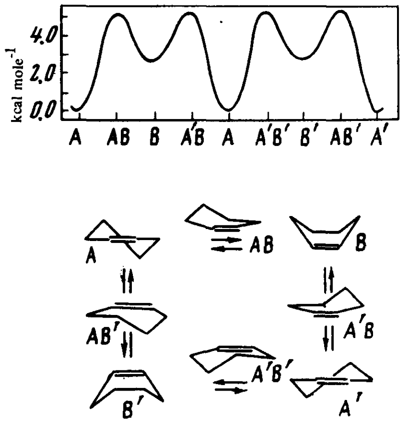

Figure 5. Intermediate forms and the energy barrier in the ring inversion of cyclohexene[60].

As for cyclohexane, one conformer of cyclohexene may be converted into another. Until recently, the rate of conversion and the potential barrier separating the conformers were unknown. It might have been supposed that, in view of the characteristics of the structure of cyclohexene, the half-chair—half-chair conversion would be much faster than the chair—chair conversion. Recently Anet and Hag[60] showed that the rate of inversion of cyclohexene approaches the upper limit accessible to NMR methods. At room temperature the NMR spectrum of cyclohexene shows the signal due to the olefin protons (5.59δ) and the complex multiplets of the allylic (1.96δ) and homoallylic (1.65δ) protons[116]. Anet and Hag[60] investigated *cis*-3,3,4,5,6,6-hexadeuterocyclohexene. At −150°C the band due to the homoallylic protons is significantly split and becomes a doublet at −164°C. Since at −170°C δ_{a-e} does not yet reach a constant value, it may be supposed that δ_{a-e} for cyclohexene is actually 24 Hz§.[60] The rate constant determined from the coalescence temperature of the signals is $k = 53$ s^{-1}, whence the free energy of activation $\Delta F^{\neq} = 5.3$ kcal mole^{-1}. Thus in cyclohexene the height of the barrier in the ring inversion process is smaller by a factor of approximately two than in cyclohexane. Since the energy of the boat form is higher than that of the half-chair form[107], it may be supposed that the boat form is intermediate in the inversion process. The possible pathways in the inversion process and the corresponding forms of the barrier proposed by Anet and Hag[60] are presented in Fig. 5. The authors adopted a structure with five carbon atoms in one plane (AB, AB′, A′B′) as the transition state, since the distortion of the valence angles and the interaction between methylene groups would be too high for the completely planar form. The enthalpy and entropy of activation for the inversion process cannot be determined directly from the NMR spectroscopic data[60]. The values quoted in Table 1 were obtained by taking into account the symmetry of the possible transition states and the statistical factors. The average lifetime of the cyclohexene molecule before inversion at 25°C may be calculated from $\Delta H^{\neq}$ and $\Delta S^{\neq}$. It proved to be about 10^{-9} s, i.e. smaller by five powers of ten than the lifetime of the cyclohexane molecule (4×10^{-4}).

Apart from unsubstituted cyclohexene, the inversion of 4-bromocyclohexene was also investigated[61]. At −159°C Jensen and Buchweller[61] observed a complete separation of the signals due to the tertiary proton corresponding to the axial and equatorial orientations with $\delta_{a-e} = 27.3$ Hz. The rate constant ($k = 47.7$ s at −124°C) and the height of the barrier ($\Delta F^{\neq} = 5.93 \pm 0.1$ kcal mole^{-1}) obtained by these investigators are very close to the corresponding values for unsubstituted cyclohexene. Jensen and Buchweller also determined the conformational energy of bromine in the cyclohexene ring (about 0.1 kcal mole^{-1}), which proved to be smaller almost by a factor of four than the energy of the substituent in cyclohexane. This result is in qualitative agreement with Sakashita's data obtained

---

§ The assignment of the signal in the weak field to an equatorial proton and that in the strong field to an axial proton was made by analogy with cyclohexane. It has been confirmed by the study of the ring inversion of 4-bromocyclohexene[61].

from vibrational spectra[117]. In practice, however, the values determined both from the vibrational spectra and NMR spectra are smaller than the experimental errors and therefore one may suppose that in 4-bromocyclohexene the axial form has no advantage over the equatorial form on energy grounds. However, the axial form of 3-halogenocyclohexenes is probably more favourable[118].

In a number of studies attempts were made to determine the preferred conformations of cyclohexene derivatives from the widths of the NMR signals[119-121]. Some information about the geometrical structure of the cyclohexene ring can be derived also from the vicinal coupling constants. The values of J_{HH} were determined for three cyclohexene derivatives[122-124]. The dihedral angles for the half-chair forms of conduritols[124] were calculated from the Karplus equation and compared with the values determined from Barton's models[123,125] and calculated by Corey and Sneen[108]. All three methods give similar valence angles, but these are only approximate.

The long-range coupling constants for allylic ($J_{He'}$ = −0.5 Hz, $J_{Ha'}$ = −2.1 Hz) and homoallylic (J = 1−3 Hz) protons have been determined[122-124] and interaction via four saturated bonds (about 0.5−2 Hz) has been observed.

3. Cyclobutane

In the crystalline phase certain cyclobutane derivatives (tetraphenylcyclobutane[126] and *trans*-1,3-cyclobutanedicarboxylic acid[127]) have a planar ring structure but, according to electron diffraction, cyclobutane itself is non-planar[128]. NMR spectroscopic studies have shown[129] that the cyclobutane molecule undergoes interconversion between two equivalent forms (Fig. 6), in which the orientation of the substituent may be referred to as axial or equatorial by analogy with the nomenclature for six-membered rings; the structure with a pseudoaxial substituent is more planar. According to the estimates of Meiboom and Snyder[129], the dihedral angle θ is 18°.

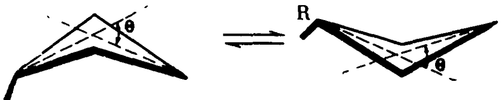

Figure 6. Ring inversion in cyclobutane.

The barrier in the ring inversion of cyclobutane is probably low, but has not been estimated experimentally at present¶. However, the chemical shift and the coupling constants of the signals due to geminal fluorine-19 nuclei[130] in the NMR spectra of certain fluorinated cyclobutane derivatives, used to calculate the free energy differences between the two conformers, were found to vary with temperature. For R = C_6H_5, this difference is about 1 kcal mole^{-1}, which is consistent, as regards order of magnitude, with the value calculated by Allinger et al.[102] Allinger's calculations also showed that the buckled form is more favourable than the planar form to the extent of about 1 kcal mole^{-1} and yields the angle θ = 20°.

The NMR spectra of 3-isopropylcyclobutanols and 3-isopropylcyclobutylamines[131] are also consistent with the non-planar structure of the cyclobutane ring.

4. Cycloheptane

The cycloheptane molecule does not have a highly symmetrical form analogous to the chair form of cyclohexane. The four conformations of cycloheptane with the minimum energy, the geometry of which was calculated by Hendrickson[104], are shown in Fig. 7. The most stable is the twist-chair form. As in the boat form of cyclohexane, which can be converted into a series of twist-boat forms by pseudorotation, in cycloheptanes pseudorotation can take place for the chair−twist-chair and boat−twist-boat conformations. The boat and chair conformations can be interconverted by symmetrical inversion. The barrier to pseudorotation is represented by a simple sinusoidal curve, the symmetrical forms corresponding to its maxima and minima. The energy differences in pseudorotation are small and cannot be estimated from the NMR spectra.

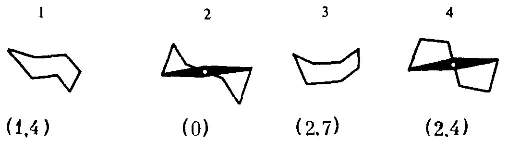

Figure 7. Stable conformations of cycloheptane: 1) chair; 2) twist-chair; 3) boat; 4) twist-boat; the relative energies are indicated in brackets[104].

The ring inversions in a number of substituted cycloheptanes were investigated by Roberts using the resonance of the fluorine-19 nuclei[62]. The fact that the spectra of 1,1-difluorocycloheptane and 1,1,3,3-tetrafluorocycloheptane do not show a temperature variation up to −180°C agrees best with the existence of cycloheptane in the twist-chair form, which undergoes rapid pseudorotation. At the same time the spectrum of 1,1-difluoro-4,4-dimethylcycloheptane does alter significantly as the temperature is reduced. On the basis of these changes, one may conclude that fluorine atoms are present in positions resembling equatorial and axial positions. The barrier to the interconversion of the two forms (or two sets of equivalent forms) is low and amounts to 6 kcal mole^{-1} according to preliminary estimates[62].

5. Cyclo-octane

The ring inversion of cyclo-octane was investigated by Meiboom[47], Harris and Sheppard[46], and Anet and coworkers[68,133]. On lowering the temperature, the proton signal in the $C_8D_{15}H$ spectrum broadens and at −111 °C two

---

¶ In oxetan, where as a result of the replacement of a methylene group by a heteroatom in the four-membered ring several 1,2- and 1,3-interactions are eliminated, the barrier in the ring inversion process is only 35 cm^{-1} according to the estimate of Chan et al.[132]

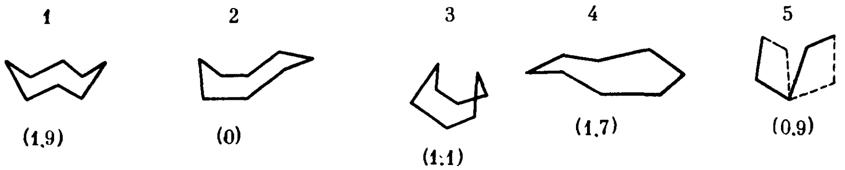

Figure 8. Cyclo-octane conformations with minimum energies: 1) chair–chair; 2) boat–chair; 3) boat–boat; 4) twist-chair–chair; 5) S_4; the relative energies are indicated in brackets[104].

sharp lines separated by about 19 Hz are observed[133]. The activation parameters for the inversion process were calculated from the temperature variation of the band outline (Table 1, Nos. 41 and 42). However, it is impossible to arrive at unambiguous conclusions concerning the nature of the conformations undergoing interconversion. From the conformational standpoint, cyclo-octane is probably the most complex cyclic molecule. Theoretical analysis shows[100,104] that there exist a large number of conformations of cyclo-octane with approximately the same energy. The boat-chair form (C_s symmetry) is probably the most favourable on energy grounds[100,104]. However, the energies of five other symmetrical forms are in the range of 2 kcal mole^{-1}: chair–chair (extended crown), boat–boat (saddle, symmetry D_{2d}), twist-chair–chair (D_2), twist-chair–boat, and the form with symmetry S_4 (Fig. 8). The regular crown form of cyclo-octane, in contrast to the "crown" of cyclohexane (chair), does not correspond to an energy minimum; according to Hendrickson's calculations[104], its energy is higher by 2.8 kcal mole^{-1} than the energy of the boat–chair form. The transitions between the cyclo-octane conformations can take place, apart from the interconversion of symmetrical forms, via a pseudorotation, the barriers to which are not high. Thus the signals in the NMR spectrum at a low temperature may correspond to a whole set of conformations, provided that pseudorotation is sufficiently rapid. By studying the temperature variation of the NMR spectra of three deutero-derivatives of cyclo-octane ($C_8D_{14}H_2$) and alkyl-substituted cyclo-octanes, Anet and St. Jacques[133] concluded that they agree best with the boat–chair form. X-Ray diffraction studies showed that many cyclo-octane derivatives have the same conformation[134]. However, in order to interpret the NMR spectra of fluorinated cyclo-octanes, Roberts[62] chose the S_4 form (twist-boat). Since the energy of the S_4 form differs only by 1 kcal mole^{-1} from that of the boat–chair form[104], the replacement of a hydrogen atom by a fluorine atom can shift the conformational equilibrium towards the S_4 form.

The cyclo-octane conformations were examined theoretically also by Bixon and Lifson[103] and Allinger et al.[102] In all these studies the energy minimum was obtained for the boat–chair form.

Recently ring inversion in eight-membered unsaturated systems was investigated by NMR spectroscopy: cyclo-octatetraene[64,66], fluorocyclo-octatetraene[65], cyclo-octatrienone[68], and substituted cyclo-octatriene[67].

In cyclo-octatetraene derivatives[64-66] bond displacement may occur as well as the interconversion of two boat forms (*t* and *b*, symmetry D_{2d}) (Fig. 9). The transition state for both processes is probably a planar form. Calculation of the barrier to the inversion of cyclo-octraene, taking into account the σ-strain of the system[69], yielded results in good agreement with experiment.

6. Decalin

An interesting example of complex systems undergoing ring inversion is provided by *cis*-decalin derivatives. While the NMR spectrum of *trans*-decalin, which has a fixed conformation, consists of a complex multiplet, in the *cis*-decalin spectrum there is a comparatively narrow singlet even at −120°C.[135,136] On this basis, it was initially suggested that the barrier to the ring inversion of *cis*-decalin is low, not exceeding 6 kcal mole^{-1}; however, recently it was suggested[137] that the low width of the signal may be due not to rapid ring inversion but to the similarity of the chemical shifts of the axial and equatorial protons.

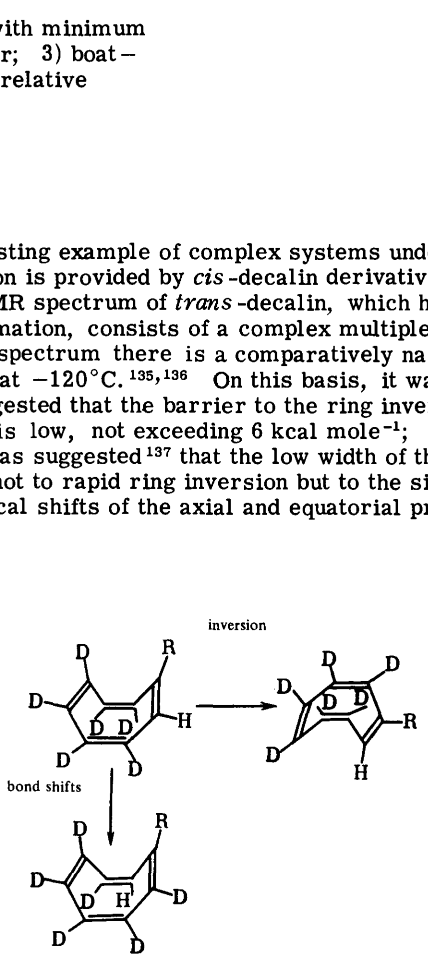

Figure 9. Ring inversion and bond shifts in cyclo-octatetraene[66].

The ring inversion of *cis*-decalin derivatives was investigated by Roberts[62,70] using fluorine-19 resonance. In the spectrum of 2,2-difluoro-*cis*-decalin two AB quartets, corresponding to the axial and equatorial positions of fluorine atoms, appear in place of the average signal when the temperature is reduced. The activation energy for the ring inversion proved to be somewhat higher than for cyclohexane (Table 1, No. 50). Since the bulk of the fluorine atoms is small, it may be supposed that in unsubstituted *cis*-decalin the inversion barrier is approximately the same. The introduction of a methyl group in the 9- or 10-position of 2,2-difluoro-*cis*-decalin results in a lowering of the barrier. This is apparently due to the fact that for both forms undergoing interconversion there is a *syn*-axial interaction of the methyl group with the fluorine atom.

The NMR spectra of 1-methyl-, 3-methyl-, 6-methyl-, and 6,9-dimethyl-*cis*-decalin do not show a temperature variation, in agreement with the existence of a single energetically favourable conformation.

Theoretical calculations have been made for the conformations of decalin[101,102] and show that, in contrast to the earlier hypothesis[138], the double chair conformation is the most favourable for both *cis*-decalin and *trans*-decalin.

7. Heterocycles

Compared with hydrocarbons, in heterocyclic systems there are a number of additional factors which may influence the ring-inversion parameters. Apart from different bond lengths and valence angles, as a result of which the ring geometry and the intensities of interactions between atoms not linked by valence bonds are different from those in the hydrocarbon analogues, electronic effects due to the presence of unshared electron pairs, vacant *d* orbitals, and conjugation may play a major role in heterocycles.

Although the amount of data obtained up to the present time on the ring inversion of heterocyclic compounds is small, it is evident that they cannot be interpreted by simple analogy with the hydrocarbons. In some cases the corresponding parameters are in fact similar but the agreement may be the result of the opposed effects of several factors.

The barriers for pyran (10.7 kcal mole^{-1}) and thiopyran (11.6 kcal mole^{-1})[71] are close to the corresponding value for cyclohexane, but in piperidine the barrier is probably higher[71,72]. On the other hand, about 6 kcal mole^{-1} was obtained for perfluoropiperidine[73]. The barrier in *NN*-dimethylpiperazine, the geometry of which is close to that of the cyclohexane ring[79] according to electron diffraction data[105], is almost the same as in cyclohexane. The barriers in hexahydro-1,3,5-triazines[85], the skeleton of which consists exclusively of C–N bonds, are also close to this value. However, the data obtained for triazines and the mechanisms proposed for ring inversion differ somewhat[85,86]. A decrease of the barrier with increasing dimensions of the substituent of the nitrogen was also noted for 1,3,5-triazines[85]; this can probably be accounted for by a tendency of the pyramidal nitrogen atom to assume a more planar structure with increase of the size of the substituent.

The orientation of unshared electron pairs plays a major role in ring inversion processes in heterocyclic systems incorporating nitrogen, oxygen, and sulphur. For alkyl-substituted piperidines, it has been established with the aid of NMR spectra[72,139] and dipole moment studies[140] that the alkyl group is equatorial. However, there exist at present two opposed views concerning the orientation of the unshared pair in piperidine itself. According to the first view, the dimensions of the unshared pair exceed those of the hydrogen atom[72,139] and accordingly piperidine must be predominantly in the conformation with an axial hydrogen atom; according to the second view, the unshared pair is smaller[141,142]. The recent calculation by Allinger and coworkers[143] for piperidine conformations showed that hydrogen in the axial orientation has a small advantage on energy grounds (0.6 kcal mole^{-1}). Since the difference between the energies is small, evidently in real systems the presence of substituents or small deformations of the ring can displace the equilibrium in the opposite direction.

The available data on the ring inversion of substituted 1,3-dioxanes[77], containing two heteroatoms, show that the decisive factor in these compounds is probably the interaction of atoms not linked by valence bonds. The barrier in unsubstituted 1,3-dioxane is almost identical with that in cyclohexane[77]. As a result of intensive 1,3-*syn*-axial interactions, the energy of the ground state of 2,2-dimethyl-1,3-dioxane is increased, which leads to a decrease of the barrier†. At the same time in 5,5-dimethyl-1,3-dioxane, where such interactions do not occur, the barrier is 10.5 kcal mole^{-1} (Table 1, No. 74). It should also be noted that the conformational energies of the 5-alkyl substituents in 1,3-dioxanes are very much lower than the corresponding values for cyclohexane[145].

Among six-membered rings containing a large number of heteroatoms, acetone diperoxide[55,82], and tetramethyl-*s*-tetrathiane[81] were investigated. The barriers in these compounds are significantly higher than in tetramethylcyclohexane. Here non-valence interactions probably do not play a dominant role and other factors are more important; in particular, ring inversion can involve other intermediate forms than in cyclohexane. It has been suggested that the twist-boat form and not the chair form is the most stable for tetramethyl-*s*-tetrathiane[81,146]. The high barrier in this compound made it possible to isolate a stable conformer at −80°C,[146] as had been done for chlorocyclohexane[147].

The ring inversion of tetramethyl derivatives of 1,2-dithiane and 1,2-dioxane[75] has also been investigated. The difference between the barriers in these compounds has been explained by the absence of intermediate forms in ring inversion; the existence of a symmetrical boat form of tetramethyldioxane is impossible because of the interaction between the methyl groups; at the same time in tetramethyldithiane this form can be realised owing to the greater length of the C–S bonds.

The barriers to the inversion of tetra- and hexa-hydropyridazines are much higher[83] than in the corresponding hydrocarbons. While the barriers in cyclohexane and cyclohexane differ sharply, those in the above compounds are similar (Table 1, Nos. 90–95).

In heterocyclic systems containing nitrogen there is a possibility of yet another conformational transition—inversion at the nitrogen atom. In six-membered rings (piperazines[79] and triazines[85,86]) the rate of this process is still too high to investigate by NMR methods; however, in aziridine (ethyleneimine) derivatives, where the nitrogen atom is incorporated in a strained three-membered ring, the inversion is slower. A number of substituted aziridines have now been investigated[87–90,148–151] and attempts have been made to estimate the role of the various factors influencing the heights of the barriers in these compounds. Thus bulky substituents at the nitrogen atom apparently increase the rate of inversion[148], since they increase the steric strains in the ground state; these strains are removed in the transition state, which has a planar structure. The conjugation effect, which leads to a "flattening" of the pyramidal structure of the nitrogen atom, acts in the same direction: the rates of ring inversion in acetylaziridines[89] are much higher than in alkylaziridines. An "extreme" example in this case is formamide, which has

---

† Since the C–O bond is much shorter (1.43 Å) than the C–C bond (1.53 Å), the conformational energy of 2-alkyl substituents in 1,3-dioxane reaches 3 kcal mole^{-1} [99] (compared with 1.6 kcal mole^{-1} in cyclohexane). Eliel and Knoeler[144] showed that in the *trans–cis* isomerisation of 2-alkyl-5-t-butyl-1,3-dioxane the t-butyl group passes to the axial position. This is apparently the first example of the axial orientation of the t-butyl group in a six-membered ring. In the analogous situation cyclohexane goes over to the boat form[95].

an almost planar structure: here the barrier to the nitrogen inversion is only 1 kcal mole^{-1}.[152] Solvents have a considerable influence on the barriers to ring inversion in aziridines: in hydroxylated solvents the rate of inversion is significantly lower[87,148]. Probably in this case the solvent forms a weak bond of the hydrogen type with the unshared electron pair of the nitrogen atom.

Simultaneous inversion at the nitrogen atoms has also been observed in a series of diazabicycloheptanes and diazabicyclo-octanes[84].

IV. CONFORMATIONAL ENERGIES OF SUBSTITUENTS

It is by no means possible to obtain the absolute values of the thermodynamic parameters of ring inversion in all cyclic systems. However, it is possible to determine by a relatively simple procedure quantities which are sometimes of no less interest. These are the so called conformational energies of substituents, i.e. the differences between the free energies of the conformers with R in the axial and equatorial positions. The equilibrium constant K for this process is defined by the expression:

$$K = N_a/N_e\,, \qquad (20)$$

where N_a and N_e are the mole fractions of the axial and equatorial forms in the equilibrium mixture. The values of K may be determined with the aid of kinetic methods, for example, from the different reactivities of substituted cyclohexanes as a function of the orientation of the substituent. This approach has been developed independently and successfully employed for the determination of conformational energies by Eliel and coworkers[153] and Winstein[154]. Subsequently a number of physical methods were developed for the determination of the content of the conformers in the mixture, among which those based on vibrational and NMR spectra became most widely used. At present the conformational energies of a large number of substituted cyclohexanes have been determined. In this section the scope of the determination of conformational energies of substituents by NMR methods will be briefly discussed. Attention will be concentrated on a comparative estimate of the accuracy of the methods. The effects of various factors on the conformational energies have been discussed in reviews[155,156].

N_a and N_e may be determined most directly by measuring the areas of the signals corresponding to the two conformers in the low-temperature NMR spectra where these signals are completely or partly separated. The conformational energies of chloro- and bromocyclohexane[49,157], iodocyclohexane[157], and fluorocyclohexane[48,157] were determined in this way. In all these studies measurements were made of the intensities of signals due to the tertiary proton, which can be identified without error. However, in principle, one can employ for this purpose other signals, for example those of the hydroxyl and methyl protons[76,158,159].

However, this method for the measurement of conformational energies is not always feasible owing to experimental difficulties. Moreover, in this case one obtains the free energies for temperatures between −60° and −100°C. The use of these values at other temperatures is not always justified, since ΔG may vary with temperature.

In order to determine K from NMR spectra, it is possible to use parameters which differ for conformers with axial and equatorial orientations of the substituents and which become averaged out in the inversion process: chemical shifts, coupling constants, and signal widths. If the corresponding parameters are known for fixed conformations, it is possible to determine the relative concentrations of both forms in the equilibrium mixture and hence the equilibrium constant by Eqn. (20).

1. Determination of Conformational Energy from the Chemical Shift

If ring inversion takes place in a substituted cyclohexane, a chemical shift of the signal (usually of the tertiary proton) is observed in the NMR spectrum:

$$\delta = N_e\delta_e + N_a\delta_a\,, \qquad (21)$$

where δ_a and δ_e are the chemical shifts of the axial and equatorial forms, and N_a and N_e are their mole fractions. The method was proposed by Elial who used it to investigate the equilibrium in bromocyclohexane[160]. The shifts δ_a and δ_e may be determined from the low-temperature NMR spectra with "frozen" inversion. The compositions of the equilibrium mixtures of a number of halogeno-substituted cyclohexanes[49,50,52] and cyclohexyl ethers[161] were determined by this procedure. For substituents with high electronegativities, the difference δ_{a-e} between the chemical shifts of the signals due to the tertiary proton may become considerable (0.7–0.8 p.p.m.).[50]

However, methods in which model compounds with known conformations are used have become most widespread. Usually *cis*- and *trans*-4-t-butyl derivatives of cyclohexane are used as the "fixed" forms. Since the t-butyl group in the cyclohexane rings always occupies an equatorial position[154,162], the *cis*-isomer yields in this case δ_a and the *trans*-isomer δ_e‡. In some studies other 4-alkyl derivatives of cyclohexane[163] or 3-alkyl derivatives[164] were employed as model compounds. The method has been used to determine the conformational energy of the amino-group[163,164] and the nitro-group[165] and also in the investigation of the conformational equilibria in a number of other cyclohexane[166], cyclohexanol[167], and cyclohexanone[168] derivatives. The dependence of the conformational energy on the presence of hydrogen bonds has been established by this method for the amino-group: the relative constants of the conformers differ significantly in neutral, protonated, and proton-donating solvents (Table 2). In most studies the chemical shift of the tertiary proton was determined; however, the chemical shifts of the hydroxyl proton, for which the difference between the axial and equatorial positions amounts to about 30 Hz, were also employed for this purpose.

Evidently fixed models may be used only when the alkyl groups do not have a significant influence on the chemical shifts of the tertiary proton, do not distort the cyclohexane ring, and merely stabilise the conformation. The effect of the diamagnetic anisotropy of alkyl substituents in cyclohexane was studied in a number of investigations[175,180–184]. It has been shown experimentally that the effect of a 4-alkyl substituent is small[175]. However, an axial alkyl group in the 3-position displaces significantly the signal of an axial H_1 proton[175,183,184] and therefore the conformational energies obtained with 3-alkyl substituted model compounds are

---

‡ δ_a refers to the conformer in which the substituent occupies an axial position. This applies also to the coupling constant and signal widths discussed below. Since the chemical shifts of tertiary protons are usually investigated, this nomenclature is not altogether convenient.

probably unreliable. This has been demonstrated experimentally by Eliel and Martin[169] for halogeno-substituted cyclohexanes. Recently Jensen and Beck[171] compared the low-temperature NMR spectra of a number of cyclohexane derivatives with those of model compounds having a 4-t-butyl group. In all the compounds, the chemical shifts of the axial and equatorial α-protons differed at low temperatures from the chemical shifts of the corresponding 4-t-butyl derivatives. In all cases the conformational energies determined by Eliel's method proved to be lower than the result obtained by measuring the areas and by "freezing" the ring inversion with subsequent determination of δ_a and δ_e. Thus the fixed model method probably yields only semiquantitative results.

In addition the chemical shift method involves also a number of factors which may lead to significant errors in the determination of the conformational equilibrium position. Since the tertiary proton signal constitutes the X part of the ABX or A_2B_2X system and is greatly complicated as a result of spin–spin coupling, the chemical shifts cannot be determined with adequate precision. To eliminate this difficulty, the protons in the relevant positions are usually replaced by deuterium[154,173,185]. The accuracy of the determination of the equilibrium constant diminishes if the difference δ_{a-e} between the chemical shifts due to the fixed conformers is small (as in nitrocyclohexane[177,186]) or if the conformational equilibrium is strongly displaced towards one of the forms, in particular when $\delta - \delta_e$ is small[163,166]. The chemical shifts δ_a and δ_e have an "intrinsic" temperature variation and therefore in the extrapolation of the results obtained at low temperatures to other conditions it is necessary to apply corrections[171].

2. Determination of Conformational Energies from Spin–Spin Coupling Constants

The method is based on the difference between the vicinal coupling constant J_{HH} as a function of the axial or equatorial positions of the protons relative to the cyclohexane ring. Numerous experimental data show that J_{aa} varies in the range from 9 to 12.5 Hz and J_{ae} from 3.5 to 6 Hz.[187] The number of available measurements of J_{ee} is smaller; it probably does not exceed 2–3 Hz. The approach to the determination of equilibrium constants based on J_{HH} values was developed for ethane derivatives[6] and was then employed in studies on ring inversion in substituted cyclohexanes[172,173]. If the equilibrium mixture contains x moles of one conformer and $1 - x$ of another, then, as a result of inversion, averaged constants will be obtained:

$$\begin{aligned} J_{12}^{av} &= J_{14}^{av} = xJ_{ae} + (1-x)J_{ea} \simeq J_{ae} \, , \\ J_{13}^{av} &= J_{15}^{av} = xJ_{aa} + (1-x)J_{ee} \simeq J^{*} \, . \end{aligned} \qquad (22)$$

Thus, when the first-order condition $\delta_{12} \gg J_{12}$ holds, (which is usually the case for electronegative substituents), the α-proton signal will be a 1 : 2 : 1 triplet with spacings J^{*}; each component of the triplet will in turn be another triplet with spacings J_{ae}. In practice, however, the signal is rarely fully resolved. In some cases, as a result of the superposition of individual components, a symmetrical quintet[177] or septet is observed, as happens for nitrocyclohexane[176,188]. Usually the signal has an unresolved contour. Nevertheless in many cases it is possible to determine averaged constants either directly or from measurements of signal widths at a specified height[172]. J_{aa}, J_{ae}, and J_{ee} are frequently obtained from the spectra of *cis*- and *trans*-4-t-butylcyclohexyl-R.[173,188]

The method for the determination of the equilibrium positions from the averaged coupling constants becomes extremely approximate for small values of x ($x < 1/5$). Moreover it has a number of additional limitations. In particular, it has been shown that in cyclic systems $J_{ae} \neq J_{ea}$.[189-191] In the analysis of the spectra of the compounds investigated no account was taken also of long-range interaction constants which may reach 2 Hz for equatorial H_1 and H_3 protons[192].

3. Determination of Equilibrium Constants from Signal Widths

When the tertiary proton multiplet is unresolved, the conformational energies may be determined from the signal width. This parameter has been used in the very early studies to determine the configurations and fixed conformations of cyclohexane derivatives[193].

The equilibrium constant for a mixture of conformers is

$$K = \frac{w_a - w}{w_e - w} \, , \qquad (23)$$

where w is the observed signal width, w_e the signal width for the conformer with a fixed equatorial position of the substituent, and w_a the signal width for a fixed axial position of the substituent. As in methods (a) and (b), the signal widths for *trans*- and *cis*-4-t-butylcyclohexyl-R are frequently adopted as w_a and w_e. This method is the most approximate, but in a number of cases it yields conformational energies in satisfactory agreement with the values obtained by other methods[165,177,194-197].

Table 2 lists the conformational energies of substituents in the cyclohexane ring and it is indicated which of the methods discussed above was used to obtain the value. The methods discussed can be arranged in the following sequence in terms of decreasing accuracy: chemical shifts > coupling constants > widths. However, frequently even approximate measurements of band widths yield satisfactory conformational energies and under favourable conditions the determination of K from NMR spectra is not inferior in accuracy to the most precise kinetic and thermodynamic methods.

V. APPLICATION OF FLUORINE-19 RESONANCE

In recent years ^{19}F NMR spectra have been used to investigate the mobile and fixed conformations of cyclic systems[62,198]. Perfluorocyclohexane[57], fluorocyclohexane[48], *gem*-difluorocyclohexane[22,62], substituted *gem*-difluorodecalins[70], cyclobutane derivatives[130], and large-ring systems have been investigated by this method[62,65].

The use of the chemical shifts of fluorine has a number of advantages, since they are more sensitive to the molecular environment and exceed by a factor of several tens the proton chemical shifts. In fluorine-substituted cyclohexanes the difference δ_{a-e} between the signals of the axial and equatorial fluorine atoms is 20 p.p.m., i.e. it exceeds by a factor of almost 50 the corresponding value for protons. The spin–spin coupling constants J_{FF} are of the order of 250–280 Hz and the constants J_{FaHa}§ also exceed the J_{aa} values for protons. The high values of δ_{a-c} permit the investigation of ring inversion in fluoro-substituted cyclic compounds over a wide range of temperatures by high-resolution NMR methods. Moreover, fluoro-substituted cyclohexanes are very convenient for the investigation of ring inversion by spin-echo methods for two reasons: (1) at the resonance frequencies employed in the spin-echo experiments $2\pi J_{FF} \lesssim \delta\omega$ and therefore it is possible to make measurements over a wide range of exchange rates; (2) the vicinal coupling constant J_{HF} is almost independent of the rate of exchange at very high and very low rates and does not affect the echo-signal amplitude, so that it can be disregarded in the determination of the rate[31].

The rates of inversion of fluorinated cyclohexane derivatives were determined by both high-resolution NMR methods[22,48,54] and by the spin-echo method[31,58]. The temperature variation of the chemical shift of fluorine was used to estimate the percentage contents of the conformers of 2,2-difluoro-*cis*-decalin[70] and alkyl derivatives of 1,1-difluorocyclohexane[54,62]. It has been shown[48] that the equatorial position is preferred for the fluorine atom to a much lesser extent than for chlorine and bromine atoms. The conformational energy of fluorine determined from the signal areas and from chemical shifts was found to be 0.153 and 0.242 kcal mole^{-1} respectively, in good agreement with the data derived by other methods[202,203].

For a correlation between the parameters of the fluorine-19 spectra and the structure of substituted cycloalkanes, further accumulation of experimental data is necessary. However, it is already evident that this method may be effective in studies on the conformations of cyclic compounds.

---o0o---

After the manuscript had been sent to the editorial board, a large number of new data on the ring inversion of cyclic compounds were published. Those which are of greatest interest may now be indicated briefly.

With reference to p. 517: Allinger and coworkers calculated theoretically the conformations and energies of a large number of cycloalkanes and cyclic ketones[204]. The predicted barrier to ring inversion in cyclohexanone is 4.8 kcal mole^{-1}, which agrees well with recent experimental data by Gerig[205] and Jensen and Beck[206], who showed that

---

§ The vicinal coupling constants J_{FH} obtained in a number of investigations[130,199-201] show that the same relation applies to them as in the case of J_{HH}: J_{aa} is the maximum, J_{ee} is a minimum, and J_{ae} is intermediate.

the replacement in the cyclohexanone ring of one sp^3-hybridised atom by an sp^2-hybridised atom leads to an appreciable decrease of the barrier. A similar result was obtained for *cis*-decalones[207].

With reference to p. 519: Roberts and coworkers[208] investigated by the resonance of fluorine-19 nuclei the ring inversion in a number of cyclo-octane derivatives. They succeeded in detecting both types of conformational transitions: ring inversion and pseudorotation. For the majority of the compounds investigated, the boat-chair form is the most stable at low temperatures. Its stability has been confirmed recently by X-ray diffraction studies on *trans*-1,2-dichlorocyclo-octane[209]. It is interesting to note that the dihedral angles obtained in this investigation are in excellent agreement with the values predicted by Hendrickson[104].

The bond shift in cyclo-octatetraene was investigated by Anet and Bock[210]; Lack and Roberts[211] determined the barriers for *cis*-hydrindane derivatives.

With reference to p. 521: The conformational transitions in heterocyclic compounds were investigated: in difluoropiperidine[212], 1,3-dithiane derivatives[213], six-membered rings with silicon atoms[214,215], bicyclic diazo-compounds[216,217], and aziridines[218] and at tervalent oxygen[219] and arsenic[220] atoms. Jensen and Bushweller[221] continued their studies on the isolation of "pure" conformers of cyclohexane derivatives.

With reference to p. 524: Recently Jensen, Bushweller, and Beck determined the conformational energies of 22 functional groups in the cyclohexane ring; probably these are the most reliable data obtained hitherto. The conformational energies of ester groups[223] and amino-groups[224] have also been investigated.

Chemiluminescence Excitation Mechanisms

R.F.Vasil'ev

A systematic review of modern views on the factors which favour the formation of chemical reaction products with greater equilibrium excitation is presented. The excitation can be electronic (for reactions in solution) or electronic and vibrational (for gas-phase reactions). In the latter case, fine details can be revealed, and particular features of the excitation process can be related to the electronic structure of the reactants (atoms or simple molecules). With complex molecules (typical of liquid-phase reactions) only a qualitative or semi-quantitative interpretation is possible. Examples are chosen from among those reactions whose chemiluminescence is adequately understood. Although the excitation mechanism is specific for a particular reaction type, excitation is favoured in general by the participation of ions, radical-ions, and charge-transfer states; these species also favour the retention of the reaction energy as internal energy of the products. 119 references.

CONTENTS

I. INTRODUCTION

The number of papers published on chemiluminescence has been steadily rising during the past few years: new chemiluminescent reactions have been discovered, and new methods of utilising chemiluminescence have been proposed. The rate of publication in the field of chemiluminescence has doubled in 5–6 years, which is higher by a factor of 2–3 than the corresponding figure for scientific information as a whole (doubling every 10–15 years[1,2]).

Papers on chemiluminescence can be divided into several categories, depending on the detail in which the given chemiluminescent system is discussed: 1) initial observations and rough description of the system; 2) identification of the emitter of chemiluminescence and of the chemical steps leading to excitation; 3) quantitative study of the excitation and emission steps.

The present review is devoted to the elementary mechanisms by which chemical energy is converted into light, and will deal mainly with papers in the third category.

II. GENERAL PROBLEMS IN CHEMILUMINESCENCE

A. Definition of Chemiluminescence

The term chemiluminescence usually denotes the emission (in excess of equilibrium) of radiation by particles which have gained excitation in a chemical reaction. If the reaction is split into two stages—the formation of excited particles, and the emission (or quenching) of radiation—it is possible to write a simple relationship between the absolute intensity of chemiluminescence I (in quanta per unit volume and per unit time) and the absolute rate of formation of excited particles $w_{\mathrm{P}*}$ (per unit volume and per unit time):

$$I = \eta_{\mathrm{P}} w_{\mathrm{P}}. \tag{1}$$

where η_{P} is the relative probability or quantum yield of light emission by the excited product $\mathrm{P}*$.

The above definition is too general, and the formula is oversimplified: not surprisingly, therefore, its application in real cases gives rise to difficulties and confusion. We shall consider these difficulties in detail.

1. In keeping with the terminology currently accepted in luminescence, the prefix "chemi" relates to the mode of supply of the excitation energy (cf. photoluminescence, radioluminescence, cathodoluminescence, etc.). Strictly speaking, the name chemiluminescence should be reserved for the emission of light which is observed on mixing reactive materials. However, mixtures of reactants are sometimes chemically inert, and an additional agency is needed to activate them (heat, electrical discharge or electrolysis, illumination). Nevertheless, it is not correct in these cases to talk of thermoluminescence[†], electroluminescence, or photoluminescence: the phenomenon should be called chemiluminescence, because the elementary act which gives rise to an excited particle is the chemical reaction between the reactants. In particular, some agencies can give rise to electronically excited particles which react to give an electronically excited product (for example, the reactions of electronically excited $\mathrm{O}(^1D)$ and $\mathrm{N}(^2D)$ atoms produced by an electrical discharge in the gas): in this case the emission from the product should be classified as chemiluminescence, but the emission from the primary particles is (evidently) not chemiluminescence. In the most recent terminology, the mode of activation or of generation of the reactive particles is also stated (e.g., thermochemiluminescence, electrochemiluminescence, photochemiluminescence).

2. Opinions differ as to the nature (chemical, or physical) of processes such as the transfer of an electron from one particle to another. If the process gives rise to excitation, followed by light emission, we shall term it chemiluminescence only if we take the view that the process itself is chemical. A physical process is sometimes defined as one in which the coordinates of the nuclei

---

[†] The term "thermoluminescence" is particularly unfortunate. Literally, it denotes luminescence induced by heating, and some authors actually define it in this way. But this definition is meaningless, since thermal energy by itself cannot give rise to luminescence (i.e. to emission in excess of equilibrium). Thermoluminescence (or thermal de-excitation) is the correct name of an entirely different phenomenon: the emission of light observed on heating solids which have been previously exposed to ionising radiation.

remain unchanged: in this sense, the electron-transfer process is undoubtedly physical. However, the transfer of an electron gives rise to particles with entirely different chemical properties (ions and neutral molecules, or atoms), and there are grounds for treating the process as chemical. In this review, the luminescence arising from processes such as the transfer of an electron from a radical-anion to a radical-cation will be treated as chemiluminescence.

3. In some systems the light is emitted not by the product but by a third particle, excited by energy transferred to it from the excited product. In this case the elementary excitation act is purely physical, but the primary excited particle is formed by a chemical process, and many of the properties of the emission (intensity, time dependence, and spectral composition) are intimately bound up with a chemical mechanism. Hence this type of emission must be classified as chemiluminescence.

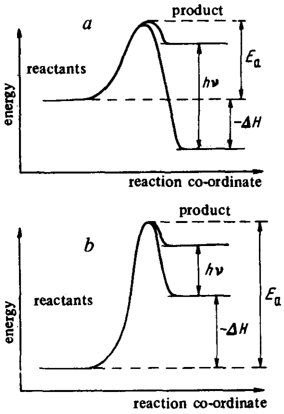

Figure 1. Model of the origin of chemiluminescence in (*a*) exothermic and (*b*) endothermic reactions.

4. Chemiluminescence is not necessarily confined to exothermic reactions. An amount of energy equal to (or not greater than) the sum of the activation energy E_a and the heat of reaction $-\Delta H$ can be converted into excitation energy (Fig. 1). The newly formed reaction products, when chemically activated, contain energy in excess of equilibrium even in the case of endothermic processes. If this excess of energy is lost by radiation, the process is no different from chemiluminescence. Of course, in endothermic reactions rotational and vibrational levels are more likely to be excited than electronic levels, and the radiation will lie in the long-wave (infrared) region of the spectrum.

5. The emission yield η_P is the ratio of the rate of emission (radiative deactivation) from P* to the sum of the rates of all the processes removing P*. The value of η_P for chemical excitation is the same as the emission yield for any other mode of excitation (e.g., photon absorption) under the same conditions (composition, temperature, and other parameters affecting the emission yield). Hence, this quantity is sometimes known from photoluminescence data for the compound P even before the chemiluminescence is measured. However, it is important to remember that the emission yield η_P is equal to the photoluminescence quantum yield only when the same excited state of the particle P is obtained both by chemical excitation and by the absorption of a photon. The situation is illustrated in Fig. 2 for a hypothetical organic molecule. The singlet state S_1 is populated as a result of photoexcitation. If the chemiluminescence is associated with a transition from the singlet state, its emission yield is equal to the photofluorescence quantum yield.

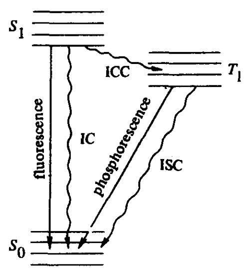

Figure 2. Excited states of a typical organic molecule and optical transitions between states: internal conversion (IC) and intersystem crossing (ISC). *S* and *T* are singlet and triplet states respectively.

However, if a triplet state becomes populated during the chemiluminescent reaction and the emission originates from this state the emission yield becomes equal to the photophosphorescence quantum yield (i.e. the number of quanta of phosphorescence per quantum of light absorbed) divided by the intersystem conversion yield of the triplet state T_1 from the singlet state S_1 (i.e. the ratio of the rate of transitions from S_1 to T_1 to the overall rate of all deactivation paths available to S_1.

In the light of the above, chemiluminescence can be defined as follows: the emission of radiation is termed chemiluminescence if the elementary act by which the emitter is formed consists in a chemical reaction or in the transfer of energy from a chemically excited product formed either spontaneously or as a result of a special energetic interaction.

Chemiluminescence is observed in a particular spectral region if the following conditions apply:

1. The energy of the photon is not less than the sum of the activation energy and the heat of reaction:

$$h\nu \leqslant E_a - \Delta H$$

or

$$\lambda \geqslant 28.6/(E_a - \Delta H)$$

if the wavelength is expressed in μm and the energy in kcal mole^{-1}. (Exceptions to this rule are discussed in section III. A. 5 below.)

2. The lifetime of the excited state of the emitter (with respect to radiation) is small compared to the characteristic relaxation time of the scattering processes for excess energy, or in other words the rate of emission is large compared to the rate of the radiationless deactivation processes, or the emission yield η_P is relatively high.

The overall schemes of chemiluminescence are summarised in Table 1, where the symbol w denotes the total rate of formation of the product P, η_P^{exc} is the excitation efficiency or yield, i.e. the ratio of the number of excited particles to the total number of particles of the same kind produced by the reaction, η_{PA} is the energy transfer efficiency, i.e. the relative contribution of the rate of energy transfer to the overall rate of deactivation of the excited product P*, η_A is the emission yield of the acceptor A, I_P and I_A are the quantum intensities of the emission for the product and the acceptor respectively.

Table 1. Summary of chemiluminescence.

Stage	Particles involved	Rate
Energy interaction	Unreactive components	
	→ Reactive components	
Chemical reactions	→ Non-excited product P	$(1-\eta_P^{exc})w$
	→ Excited product P*	$\eta_P^{exc}\, w$
Physical processes:		
Radiationless deactivation	→ Non-excited product P	
Emission (chemiluminescence)	→ Non-excited product and photon $P + h\nu_P$	$\eta_P\, \eta_P^{exc}\, w = I_P$
Transfer of excitation energy	→ Non-excited product and excited acceptor $P + A^*$	$\eta_{PA}\eta_P^{exc}\, w$
Emission in the acceptor molecule	→ Non-excited acceptor and photon $A + h\nu_A$	$\eta_A\eta_{PA}\eta_P^{exc}\, w = I_P$
Deactivation of the acceptor, energy transfer from A* to another acceptor, etc.	→ Non-excited acceptor and other products	

The proposed scheme leads to the following expression for the total quantum intensity of chemiluminescence I:

$$I = I_P + I_A = (\eta_P\eta_P^{exc} + \eta_A\eta_{PA}\eta_P^{exc})\, w\,. \qquad (2)$$

If energy transfer is negligible, the scheme is simplified and Eqn. (2) reduces to Eqn. (1). However, it may be necessary to consider additional processes, for example parallel reactions giving rise to excited products other than P*, chemical reactions of the excited states leading to new emitters of chemiluminescence, secondary energy transfer from an acceptor A* to another acceptor capable of luminescence, etc. The formula for the intensity then retains the form of Eqn. (2) but becomes more complicated.

B. Chemiluminescence Yield

The most important quantitative parameter of chemiluminescence is the chemiluminescence yield η_{cl}, i.e. the ratio of the absolute chemiluminescence intensity to the rate of the reaction leading to the formation of the excited product‡:

$$\eta_{cl} = I/w\,. \qquad (3)$$

In the light of the above considerations, the chemiluminescence yield is given by the expression in brackets in Eqn. (2):

$$\eta_{cl} = (\eta_P + \eta_A\eta_{PA})\,\eta_P^{exc}\,. \qquad (4)$$

If the scheme is complicated by the presence of additional processes, a more complex expression for the yield is obtained, but in every case it is possible to identify two factors one of which is the excitation yield. These factors have entirely different physical significance, since they stem from different stages in the chemiluminescent process (the chemical excitation stage and the physical energy transfer and emission stage).

We shall not be particularly concerned with the emission stage in the following sections, because light emission from atoms and molecules has been adequately treated in recent monographs[3,4,5], mainly as a result of research on photoluminescence, and also because it tells us very little about the specific features of the chemical excitation mechanism. The excitation stage, on the other hand, will be fully discussed because of the need for quantitative information on the elementary chemical act. This type of information has only just begun to appear in the literature.

In any form of luminescence, the yield reflects the efficiency with which the energy supplied to the system is converted into light. Often the concept of yield is itself far from straightforward, and needs to be discussed specially[6]; this is particularly true of types of luminescence which have not yet been extensively studied (such as chemiluminescence).

It would appear that formula (3) offers a method of determining the yield η_{cl}, but this requires a measurement of the absolute intensity and of the absolute reaction rate. The experimental determination of the intensity involves only practical difficulties (which can, however, be very serious). Much more fundamental difficulties arise in the determination of the reaction rate—we need to know the rate of the particular step which gives rise to excitation. These difficulties become more intractable, the more complicated the reaction. In general, the reaction mechanism must be known, otherwise the problem of measuring the rate of one particular step becomes meaningless. Often, and particularly with complex and with "new" chemiluminescent reactions, the mechanism is not known, and different definitions of the chemiluminescence yield are used in these systems in order to achieve some measure of quantitative description of the phenomenon. For example, the intensity of luminescence is referred to the rate of consumption of one of the reactants, or alternatively the total light emission is referred to the initial concentration. Difficulties in the experimental determination of the yields and in their theoretical interpretation usually arise on going from gas reactions to reactions in a condensed phase, from light particles to polyatomic molecules, and from vibrational to electronic excitation.

---

‡This quantity is sometimes called the chemiluminescence quantum yield, a term derived from photochemistry and luminescence, where it is used to denote the yield of reaction product or of light per quantum absorbed. In chemiluminescence the relevant concept is the yield of quanta per reacting molecule. Hence it is better to avoid the term "chemiluminescence quantum yield".

III. CHEMICAL EXCITATION MECHANISMS

A. Simple Gas Reactions

In the gas phase the medium has no effect on the various elementary acts, and therefore more reliable and unambiguous information on the chemical reaction mechanism can be obtained. Nevertheless, the theoretical treatment of the excitation act meets with serious difficulties even in the simplest systems.

It is difficult to calculate the reaction rate, and it is even harder to determine to what extent and in what form the energy is concentrated in the products.

1. *Reaction rate*

Consider a simple exchange reaction (Fig. 3)

$$\mathrm{A + BC \rightarrow AB + C} \qquad \text{(I)}$$

where A, B, and C are atoms. The molecule BC is taken to be immobile in Fig. 3, and is treated as a target for the impinging A atom.

A simple expression for the reaction rate w can be written by making two assumptions:

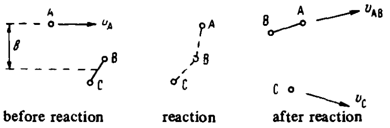
a) the molecule BC approximates to a sphere of radius b_0; the reaction proceeds with probability $p = 1$ if the atom A (treated as a point) collides with the sphere or approaches it tangentially; if the atom does not touch the sphere, $p = 0$.

b) the velocity of all A atoms is the same.

With these assumptions we can write

$$w = \frac{d[\mathrm{AB}]}{dt} = \pi b_0^2 v_\mathrm{A}[\mathrm{A}][\mathrm{BC}] = k[A][\mathrm{BC}] \qquad (5)$$

where $k = \pi b_0^2 v_\mathrm{A}$ is the rate constant for the reaction, and v_A is the velocity of the A atom.



before reaction   reaction   after reaction

Figure 3. Exchange reaction A + BC →AB + C.

In reality, however, the interaction between the particles BC and A is a function of the distance b, and the reaction probability p (per single collision between A and BC) depends on b, on v_A, and on the internal energy state of the reactants and of the products. Therefore, the cross-section πb_0^2 should be replaced by a cross-section for the reaction from the state n_i for the reactants to the state n_j for the products:

$$\int_0^\infty p(v_\mathrm{A}, b, n_i, n_j)\, 2\pi b\, db = \sigma_{ij}(v_\mathrm{A}, n_i, n_j) \qquad (6)$$

where n_i denotes the quantum numbers corresponding to internal energy states (electronic, vibrational, and rotational) of the initial reactants, and n_j those of the products.

Furthermore, since neither v_A (the relative approach velocity of A and BC) nor the state of internal motion of the reactants is constant, a distribution function for the particles among these parameters must be introduced: $F(v_\mathrm{A}, n_\mathrm{i})$. The resulting expression for the rate of production of the product in the quantum state n_j, which is particularly important in chemiluminescence, takes the form

$$\frac{d[AB(n_j)]}{dt} = \sum_{n_i}\int_0^\infty \sigma_{ij} v_\mathrm{A} F(v_\mathrm{A}, n_i)\, dv_\mathrm{A} = w_j\ . \qquad (7)$$

The distribution function F contains the concentrations of the reactants as factors, but (strictly speaking) only in the equilibrium system, and in this case we can write

$$F(v_\mathrm{A}, n_i) = f(v_\mathrm{A}, n_i)[\mathrm{A}][\mathrm{BC}]\ . \qquad (8)$$

Equilibrium implies a lack of reaction, and we can dismiss this case as trivial. However, the assumption is often made that the reaction can proceed with very small departures from equilibrium. In this case, inserting Eqn. (8) into Eqn. (7), we obtain the customary rate law for a bimolecular reaction:

$$w_j = k_j[\mathrm{A}][\mathrm{BC}] \qquad (9)$$

where

$$k_j = \sum_{n_i}\int_0^\infty \sigma_{ij} v_\mathrm{A} f(v_\mathrm{A}, n_i)\, dv_\mathrm{A}\ . \qquad (10)$$

It follows that the rate constant—whose evaluation is the aim of most of the quantitative work in chemical kinetics—is merely an averaged parameter only indirectly related to the real interaction probabilities of the particles and to the mechanism of the reaction.

To a first approximation§, the excitation yield defined above is equal to the ratio

$$\Sigma_2 k_j / \Sigma_1 k_j = \eta_\mathrm{P}^\mathrm{exc} \qquad (11)$$

where the summation 1 is taken over all the states of AB and the summation 2 is taken only over the states which give rise to the experimentally observed chemiluminescent emission.

The exact calculation of the probability p (formula 6) is a quantum-mechanical problem: the result of the interaction between A and BC depends on the properties of the surface (or, more accurately, the hypersurface in multidimensional space) which describes the potential energy for the reaction. The form of the surface must be obtained by a quantum-mechanical calculation. Satisfactory calculations so far have been made[7] only for the simplest of all reactions: $\mathrm{H + H_2 = H_2 + H}$.

Evidently, a complete solution of the problem is not likely to be achieved in the near future, even for relatively simple cases and with the approximation discussed above. Nevertheless, we already have interesting examples of partial solutions, which assist in the qualitative interpretation of experimental results for the more complex systems.

---

§We ignore the rates at which the given state of the product is populated by internal conversion from other states. Strictly speaking, the right-hand side of Eqn. (9) should then include additional terms of the form

$$\sum_l k_{lj}[\mathrm{AB}(n_l)] - \sum_l k_{jl}[\mathrm{AB}(n_j)]\ .$$

2. *Vibrational excitation in exchange reactions*

Vibrational excitation in exchange reactions has been studied in detail. Reactions of the type

$$H + X_2 \xrightarrow{k_v} HX + X \qquad \text{(II)}$$

where X = Cl, Br, or I have been investigated by infrared chemiluminescence[8-13], and reactions of the type

$$M + X_2 \xrightarrow{k_v} MX_v + X \qquad \text{(III)}$$

where M = Na, K, Rb, Cs, in crossed molecular beams[14-17]. In these reactions the energy is insufficient to excite the electronic levels of the product. The rate constants k_V describe the population of the rotational states of the v-th vibrational level.

From recent experimental results, and their theoretical treatment, it has been possible to draw various important conclusions regarding the forces between the reactants which eventually lead to the reaction.

It has been shown that in reaction (II) the probability of forming HX in high vibrational states is low. For example, in the case of HCl the following relative rate constants have been obtained for the population of the vibrational states: $k_6 = 0.004$, $k_5 = 0.04$, $k_4 = 0.3$, $k_3 \simeq k_2 \simeq k_1 = 1$. In other words, only a small fraction of the total energy of the reaction (2 eV) is converted into internal energy, whilst the major part is converted into translational energy.

In reaction (III), on the other hand, the greater part of the energy (also ~ 2 eV) is converted into vibration, and the constant k_V is a maximum for the highest possible quantum number v. Furthermore, the cross-section¶ of reaction (III) is significantly higher than the corresponding value for gas-kinetic reactions, and the molecule MX after the reaction tends to move in the same direction as the atom M before the collision.

These features have been successfully correlated with the properties of the potential energy hypersurface. Polanyi and coworkers[10], without attempting to calculate the equation of the hypersurface, took some "ready-made" surfaces, and integrated the classical equations of motion of the atoms A, B, and C for a representative choice of trajectories, allowing for energy and momentum conservation (Monte Carlo method). The form of the surface was found to determine the point at which most of the energy is evolved: whilst the distance between A and B decreases (i.e. during the approach stage—attractive case), whilst the distance between B and C increases (i.e. during the separation stage—repulsive case), or during the transitional phase.

These workers showed that when A is a light atom and B and C are heavy atoms (as in the case of reaction (II)) the proportion of the energy converted into vibrations decreases as the amount evolved during the approach stage decreases, i.e. as the "repulsive" character of the interaction potential increases.

Attraction between the reactants is more characteristic of reaction (III): an electron can be transferred from M to X_2 even at large separations, and the strong coulombic attraction between M^+ and X^-X favours the evolution of reaction energy during the early stages of the reaction, and hence its conversion into vibrational energy. This "harpoon" mechanism is consistent with the ionic character of the M–X bond and with the large cross-section of the reaction. For a particular set of parameters of the reaction system, the theoretical angular distribution of the receding products agrees with that obtained experimentally.

Undoubtedly, the molecular beam method gives a great deal of valuable information about the elementary chemical act, and also in particular on reactions of interest from the standpoint of their chemiluminescence. Unfortunately, the probability of emission during purely vibrational transitions is very low, and existing infrared detectors are too insensitive to reveal the chemiluminescence of the products of reactions (II) and (III) in a molecular beam.

Even in infrared chemiluminescence experiments involving much larger numbers of excited molecules than the molecular beam experiments it is necessary to use large reaction vessels and multiple passes.

The examples considered above are not exhaustive. Vibrational chemiluminescence in exchange reactions has been observed also in the systems H + O_3, H + O_2, H + NOCl, H + NO, etc. In the reaction

$$H + O_3 \rightarrow O_2 + OH; \quad (-\Delta H = 77 \text{ kcal mole}^{-1})$$

(believed to be responsible for the hydroxyl bands in the luminescence of the night sky[17]) the higher vibrational levels of OH (up to $v = 9$) are populated with a higher probability than the lower levels. This is evidence that attraction is predominant in the interaction potential of the reactants[18]. On the other hand, repulsion is predominant in the reaction between N and NO_2 to give N_2O and O.[19]

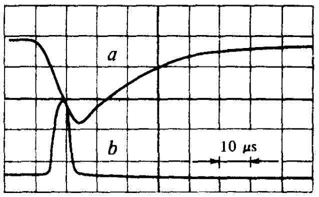


Figure 4. Photolytic pulse (a) and laser pulse (b) in an F_2O + H_2 chemical laser.

As a result of reaction, some of the sublevels can be more densely populated than sublevels situated at lower energies: in other words, a population inversion is established, and this phenomenon can lead to laser action. Thus, Kasper and Pimentel[20] were able to demonstrate chemical laser action with a mixture of Cl_2 + H_2, using flash photolysis to initiate the chain reaction by decomposing the chlorine molecule into atoms. The spectrum of the laser flash consisted of several narrow lines from vibrational-rotational transitions in the HCl molecule (in the region 3.6–3.8 μm), which appeared sequentially with an interval of the order of microseconds. Other examples of chemical lasers are known: the emission from HF (2.7–3.9 μm), produced by secondary reactions in the flash photolysis of UF_6 with H_2 and hydrocarbons[21,22], and of F_2O

¶The main attraction of the molecular beam method is that the cross sections and the angular distribution of the products (rather than the rate constants) are determined directly. Reactions are therefore characterised in greater details than is possible by conventional gas-kinetic methods.

with hydrogen[23]. The following series of reactions takes place in the UF_6 system:

$$UF_6 + h\nu \rightarrow UF_5 + F,$$
$$F + H_2 \rightarrow H + HF, \quad -\Delta H = 32 \text{ kcal mole}^{-1}$$
$$H + UF_6 \rightarrow UF_5 + HF; \quad -\Delta H = 46 \text{ kcal mole}^{-1}$$

The F_2O system has the advantage that a chain reaction takes place and therefore a single photolytic photon can produce many vibrationally excited molecules of hydrogen fluoride:

$$F_2O + h\nu \rightarrow OF + F,$$
$$F + H_2 \rightarrow HF + H,$$
$$OF + H_2 \rightarrow HOF + H,$$
$$H + F_2O \rightarrow HF + OF.$$

The second and last of the above reactions can excite up to the third and the sixth vibrational level respectively. Laser action is observed as a pulse of radiation (Fig. 4) which is much shorter than the flash of photolytic light.

3. *Electronic excitation of atoms in exchange reactions*

As a rule, excitation in exchange reactions is concentrated on the particle in which a new bond is formed as a result of the reaction. Polanyi and coworkers[12,14] have recently pointed out an exception to this rule: the formation of an electronically excited halogen atom X in reactions of type II:

$$H + X_2 \rightarrow HX + X^* ({}^2P_{1/2})$$

(X = Br, I), and also, with even higher probability, in the reaction

$$H + HX \rightarrow H_2 + X^* ({}^2P_{1/2}).$$

The X^* atoms are detected by their emission by the forbidden transition ${}^2P_{1/2} \rightarrow {}^2P_{3/2}$ (10.5 kcal mole^{-1}, 2.7 μm spectral region for the bromine atom).

These processes are much harder to treat theoretically than the processes involving vibrational–rotational excitation. The interpretation involves two potential energy hypersurfaces, one for the electronically excited and one for the non-excited products; at large distances between the reactants these merge into a single surface. The probability of motion of the system over both these surfaces has to be evaluated.

Moulton and Herschbach[25] examined formally analogous reactions (involving also vibrationally excited molecules) in molecular beams. The classical work of Polanyi in the early 1930's had shown (see Ref. 26) that in the chemiluminescent reactions of alkali atoms with halogen molecules the metal atoms are excited by the elementary step (interaction of the metal with the vibrationally excited molecule):

$$M + MX_v \rightarrow MX + M^*.$$

The large cross-sections for this reaction suggest that the interaction is more likely to be chemical ("reactive energy transfer") than a simple vibrational–electronic transfer of energy from MX to M. Moulton and Herschbach gave a direct experimental demonstration of this effect using the "three-beam" method. They observed chemiluminescence from potassium whose electronic levels had been excited by the reactive energy transfer process (V) from the vibrationally excited product of the exchange reaction (IV):

$$\underset{\text{beam 1}}{K} + \underset{\text{beam 2}}{Br_2} \rightarrow KBr_v + Br \qquad (IV)$$
$$\underset{\text{product beam}}{KBr_v} + \underset{\text{beam 3}}{Na} \rightarrow K^* ({}^2P) + NaBr. \qquad (V)$$

The product beam was crossed with a beam of sodium atoms above the photocathode of a photomultiplier with a filter for the 766.5/769.9 nm lines of the radiative transition ${}^2P \rightarrow {}^2S$ in the potassium atom. The heat of reaction (IV) is 45 kcal mole^{-1}. About one-half of the KBr molecules had an energy in excess of the 41 kcal mole^{-1} needed to excite the K atom in reaction (V) (the energy of the potassium ${}^2P$ level plus the difference between the K–Br and Na–Br bond energies). About 40% of these actually followed reaction (V). Because of the high emission probability, the K^* atoms were observed within the reaction zone. Thus, one photon was detected for every 5 KBr molecules entering the reaction zone. (The Na atoms were taken in 10^7-fold excess.) From these results Moulton and Herschbach extimate a cross-section of ~ 150 Å^2 for reaction (V)—at least, well in excess of 10 Å^2—i.e. much larger than the gas-kinetic cross-section. This cross-section is larger by an order of magnitude than the cross-section for "non-reactional" transfer, e.g.

$$NaBr_v + K \rightarrow NaBr + K^*$$

which was also investigated by the same authors[25]. These large cross-sections are consistent with the "harpoon" mechanism envisaged for the process.

4. *Electronic excitation of molecules*

Many instances of visible and u.v. chemiluminescence from molecules have been reported in flames, cold flames, and in pre-ignition reactions (see review articles 26–29).

The mechanism of some of these reactions has been studied in fair detail: the rate constants (but not the cross-sections) of the individual steps have been obtained, as well as their temperature coefficients, and a great deal is known about the electronic states of reactants and products, their nature (multiplicity, symmetry type), vibrational–rotational structure, the form of the potential surfaces (or, more accurately, their cross-sections), and the intersections of the different surfaces. It is relatively easy to obtain, experimentally, well resolved chemiluminescence spectra giving valuable information on these reactions.

The adiabatic correlation rules (see Ref. 5, p. 130, and Ref. 26, p. 185) are of the utmost importance in the formation of electronically excited molecules. These rules set stringent limits to the number and the type of electronic states in the products which can be obtained from the states of the initial reactants and which correlate with these states. The formation of excited products often involves a transition to a "forbidden" potential surface at the point where it intersects an "allowed" surface: such a non-adiabatic transition has a low probability.

a. Exchange reactions. Vibrational–rotational excitation is commonest in exchange reactions. However, if the sum of the activation energy and the heat of reaction is greater than the electronic excitation energy of the product, the latter can be produced in an electronically excited state. Of course, this outcome is most likely when the reactants are chemically very active.

Figs. 5 and 6 show the reaction paths for the two bimolecular reactions $NO + O_3 = NO_2 + O_2$ and $SO + O_3 = SO_3 + O_2$: the pre-exponential factors and activation energies are indicated[28]. In spite of their formal similarity, these reactions show some interesting differences. The pre-exponential factors describing the population of the ground

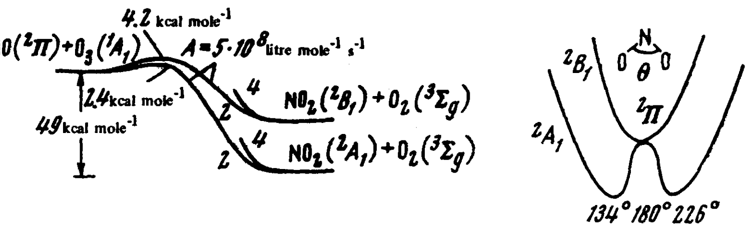

Figure 5. Potential energy diagram for the reaction $NO + O_3 \rightarrow NO_2 + O_2$. The initial state correlates with the doublet but not with the quartet final state.

$^2A_1$ state and the excited $^2B_1$ state of the NO_2 molecule in the reaction $NO + O_3$ have the same value (5×10^8 litre mole^{-1} s^{-1}). On the other hand, in the reaction $SO + O_3$ the ground $^1A_1$ state of the SO_2 molecule is populated with a pre-exponential of 1.5×10^9 litre mole^{-1} s^{-1}, whereas the corresponding values for the excited $^3B_1$ and $^1B_1$ states are 4×10^7 and 1×10^8 respectively. Thrush[28] explains these differences in terms of the adiabatic correlation rules and of the nature of the potential energy surfaces of reactants and products. For $SO + O_3$, one triplet surface for the reactants changes *smoothly* into a triplet surface for the non-excited products of the same symmetry, but it *intersects* two surfaces for the excited products of different symmetry. The probability of reaction to give the excited state is lower, because the probability of the required intersection is low. For the reaction $NO + O_3$, orbital degeneracy (π state) produces two doublet surfaces for the reactants which change *smoothly* into two doublet surfaces for the products.

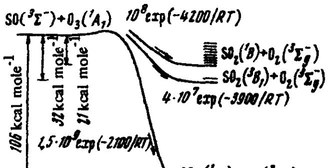

Figure 6. Potential energy diagram for the reaction $SO + O_3 \rightarrow SO_2 + O_2$.

There have been no reports so far of the population of the $^1\Delta g$ (22 kcal mole^{-1}) and the $^1\Sigma g$ (38 kcal mole^{-1}) electronic states of the oxygen molecule in these reactions, although deviations from Wigner's rule can be expected only for reaction paths leading to SO_2 in the $^1A_1$ and $^1B_1$ states. The general rule that excitation is concentrated in the products which contain the newly formed bond may apply also to these reactions.

It is interesting to note that the excited states are populated with high efficiency: although only 70–80% of the reaction energy is converted into electronic excitation, the rate constants are lower than the rate constants for the formation of non-excited molecules by only one to three orders of magnitude. (The excitation energy of NO_2 $^2B_1$ is not accurately known, but it is close to 40 kcal mole^{-1}.)

Like purely vibrational excitation, electronic excitation in exchange reactions gives rise to a non-Boltzmann distribution of the product molecules among the vibrational levels of the upper electronic state. This has been observed, for example, in diffuse flames associated with the reaction of alkali metal vapours with halogenomethanes[30–32]. The emitter of chemiluminescence in these reactions, C_2 in the $A^3\pi_g$ state (55.4 kcal mole^{-1} above the $^3\pi_u$ ground state), is excited during the elementary act

$$C + CX \rightarrow C_2 + X.$$

Table 2. Vibrational levels v' whose population $N(v')$ is a maximum, and relative population $N(v')/N(0)$ of the vibrational levels of the electronically excited $A^3\Pi$ state of the C_2 radical (produced in the reaction between potassium vapour and halogenated methanes).

Halogenated methanes	$CHCl_3$	CCl_4	CBr_4	CI_4
Energy of the C–X* bond, kcal mole^{-1}	77	77	66	50
v'	2	6	1	3
$N(v')/N(0)$	2	55	2	17

*Estimated by Miller and Palmer[31] with an accuracy of 4 kcal mole^{-1}. The uncertainty in these values may be even greater, because the initial data[31] were later shown[32] to be doubtful. However, we may assume that the relative magnitudes of the bond energy are correct.

A definite correlation has been reported[30,31] between the exothermicity of the elementary act, i.e. the energy of the C–X bond, and the energy of the vibrational level which is populated with the highest probability. However, recent work[32] at low pressures and high spectral resolution does not confirm this conclusion. Hence, the maxima in the distribution of the product over the vibrational levels cannot be directly related to the exothermicity of the reaction (see Table 2), and the large difference between the $K + CHCl_3$ and $K + CCl_4$ systems shows that the assumption of a common mechanism for the formation of the emitter for all reactions of a given type is an oversimplification.

b. Addition reactions. Practically all the known chemiluminescent reactions are termolecular:

$$A + B + M \rightarrow AB^* + M \tag{VI}$$

The third body M disposes of some of the energy and thus prevents the immediate decomposition of the newly formed AB molecule. Reaction (VI) can follow several paths and lead to different states of the product AB. If A and B are free atoms, the high degree of degeneracy can lead to correlation between the initial state and a number of stable states of the product (see, for example Fig. 7). The chemiluminescence is not necessarily emitted from these states: their potential energy surfaces may intersect other surfaces, and transitions to new states can take place.

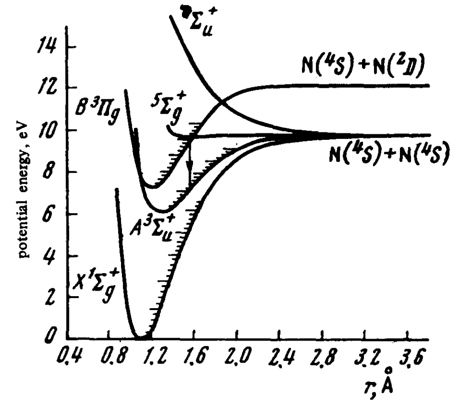

Figure 7. Potential energy curves for the nitrogen molecule.

The yellow "afterglow" of nitrogen in an electrical discharge is an example of chemiluminescence of this type: the emission comes from electronically excited N_2 molecules produced by the recombination of N atoms. Emission occurs after transition of the nitrogen molecule from the states $A^3\Sigma_u^+$ and $^5\Sigma_g^+$ to the state $B^3\Pi_g$, which correlates with a state of the free atoms in which one of them is excited[29].

The third body M also can act as the emitter of chemiluminescence, particularly if it is a metal atom with a low excitation potential, e.g.[33-35]

$$H + H + Na \rightarrow H_2 + Na^* \quad (590\ nm)$$
$$H + H + Tl \rightarrow H_2 + Tl^* \quad (535\ nm)$$
$$H + OH + Pb \rightarrow H_2O + Pb^* \quad (406\ nm)$$
$$H + X + Pb \rightarrow HX + Pb^*$$

(where X is a halogen atom). In the reaction

$$O + O + O \rightarrow O_2 + O(^1S)$$

one of the oxygen atoms acts as the third body, by accepting some of the energy of the reaction (5.1 eV) and going into a ^1S excited state (4.17 eV). This process can occur only at very low pressures, and it has been detected (postulated. Sci. Ed.) in the upper atmosphere. The well known "green atmospheric line" at 557.7 nm is due to the transition of an O atom from a ^1S level to another (also excited ^1D level located 1.96 eV above the ^3P ground state[17,36,37].

Other examples of chemiluminescent addition reactions include NO + O + M ("air afterglow"), N + O + M, H + NO + M, O + SO + M, O + CO + M, O + H + M, and others.

None of these gas-phase chemiluminescent reactions has been investigated as extensively as the air afterglow reaction. But even the latter has not yet been fully interpreted: clearly, its mechanism is very complex. The main difficulty is to account, at the same time, for the influence of the nature of the third body M on the luminescence intensity and for the independence of the luminescence intensity on the concentration of M over a wide range of pressures.

Many workers[38-40] have treated the reaction of NO and O as a bimolecular radiative association, but most workers now incline to the view that this reaction is termolecular (see discussion in Ref. 41); it has also been suggested that vibrational relaxation[42,43] (energy redistribution) and redissociation by collision[43] of the electronically excited nitrogen dioxide play a significant role.

Under some experimental conditions the well known tendency of NO to associate may be important. When the gas is allowed to expand adiabatically into a low-pressure chamber, the equilibrium

$$n\mathrm{NO} \rightleftharpoons (\mathrm{NO})_n$$

is shifted towards the right by the cooling effect[44]. Most of the associated species are dimeric, but clusters with a mass number up to 600 have been detected mass spectrometrically[45]. Excitation is more likely in the reaction $(NO)_n + O \rightarrow NO_2^* + (NO)_{n-1}$ than with the monomer; in the case of the dimer, between 1 and 10 collisions of the dimer with an oxygen atom are needed[45] to form an electronically excited NO_2^* molecule. This explains the anomalously high (by 3–4 orders of magnitude) chemiluminescence intensity of nitric oxide in the upper atmosphere[46,47]. Under normal (non-adiabatic) conditions the excitation probability is low (of the order of 10^{-5} excited molecules[41] per collision between NO and O). However, the probability of the overall reaction $NO + O \rightarrow NO_2$ is also of the same order, and therefore not less than one-half of the molecules of product are formed via an electronically excited state[48], and most of the collisions do not lead to a reaction.

The great importance of chemiluminescent reactions stems from that fact that they occur both in artificial and in natural processes. Many reactive particles are formed in the upper atmosphere under the influence of u.v. radiation from the sun. Their chemiluminescence provides information on the composition of the atmosphere, on the movement of air masses, and on solar activity. An interesting new method of investigation is the slow release of an active material from a rising rocket, and observation of the bright chemiluminescence produced by the reaction between this material (nitric oxide, triethylboron, trimethylaluminium, sodium or aluminium vapour) and atoms present in the atmosphere[46,47,49]. "Air afterglow" is observed in the wake of bodies moving at supersonic speeds: atoms and radicals are produced by thermal dissociation of the oxygen in the compressed layers of air ahead of the moving body, and the resulting chemiluminescence gives information on the streamline properties of the body, on the transition from laminar to turbulent flow, etc.[50,51] Lastly, observations of chemiluminescence can lead to numerical values of chemical bond energies, rate constants, and to spectroscopic information on the structure of molecules and radicals[27].

5. *Excitation of singlet oxygen*

The chemical excitation of molecular oxygen calls for a special discussion, because it has recently been shown to play an important role in some liquid-phase chemiluminescent reactions as well as in the gas phase.

O atoms can be produced by an electrical discharge in O_2. Under favourable conditions up to 10% of the O_2 molecules formed by recombination are obtained in the $^1\Delta_g$ state, and up to 0.1% in the $^1\Sigma_g^+$ state[52]. Emission from singlet states is both spin- and parity-forbidden and has a very low probability. For example, the radiative life time τ_0 for the magnetic-dipole $^1\Delta \rightarrow {}^3\Sigma$ transition (1270 nm band) is 5.3×10^3 s.

It has recently been shown[52-54] that, in addition to isolated singlet molecules, double molecules as a collision pair (but not forming a complex) are able to emit light. Careful study of the emission spectra has revealed bands corresponding to transitions between vibrational sublevels of the electronic states of O_2 molecules and O_4 dimers (Fig. 8).

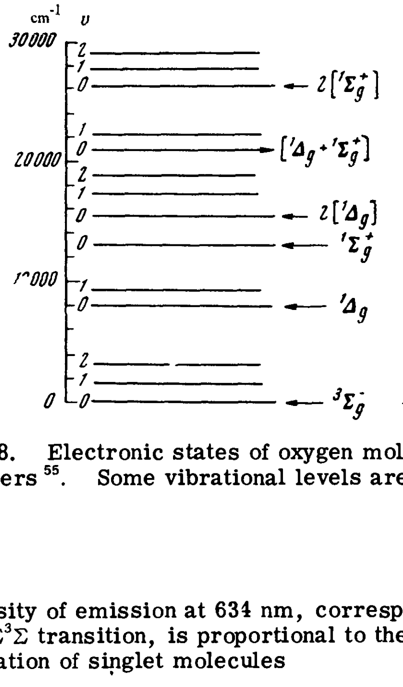

Figure 8. Electronic states of oxygen molecules and dimers[55]. Some vibrational levels are indicated.

The intensity of emission at 634 nm, corresponding to the $^1\Delta{}^1\Delta \rightarrow {}^3\Sigma{}^3\Sigma$ transition, is proportional to the square of the concentration of singlet molecules

$$I_{634} = k[O_2{}^1\Delta]^2$$

where $k = 0.28$ litre mole^{-1} s^{-1}.[54] (According to Falick and Mahan[56], this constant has the value 0.03 litre mole^{-1} s^{-1}.) From the scheme

$$2O_2{}^1\Delta \underset{k_2}{\overset{k_1}{\rightleftharpoons}} (O_2{}^1\Delta)_2 \xrightarrow{k_3} (O_2{}^3\Sigma)_2 + h\nu \qquad \text{(VII)}$$

we easily obtain formula (7), with $k = k_1k_3/k_2$. Hence, taking $k_1 = 10^{11}$ litre mole^{-1} s^{-1} and $k_2 = 10^{13}$ s^{-1}, we obtain $k_3 = 28$ s^{-1}, or $1/k_3 = 3.6 \times 10^{-2}$ s for the lifetime of the radiation, which is 5 orders of magnitude shorter than for the transition in an isolated molecule. Since the pair $O_2^*O_2^*$ exists only as a collision state, $1/k_2 \simeq 10^{-13}$ s, and only one collision between excited oxygen molecules in $k_2/k_3 \simeq 10^{11}$ leads to emission. The $O_2{}^1\Delta$ molecule is fairly stable: collisional deactivation by oxygen and nitrogen molecules occurs with rate constants of 10^3 and 10^1 litre mole^{-1} s^{-1} respectively[57]. Hence, only one in 10^8 collisions between singlet and non-excited O_2 molecules causes deactivation of $O_2{}^1\Delta$, and the concentration of singlet oxygen can reach relatively high values. From the ratio of the emission intensities from dimeric and monomeric O_2 molecules

$$\frac{I_{634}}{I_{1270}} = \frac{k[O_2{}^1\Delta]^2}{\tau_0^{-1}[O_2{}^1\Delta]} = k\tau_0[O_2{}^1\Delta] \qquad (12)$$

combined with the above values of k and τ_0, we conclude that the ratio becomes greater than unity when the pressure of singlet oxygen exceeds a few tens of mmHg. In low-pressure experiments the quantum intensity of the 634 nm emission is always lower than the quantum intensity of the 1270 nm emission, but the former is easier to detect because photoelectric cells are much more sensitive in the visible than in the infrared region.

Evidently, this emission mechanism allows the photon energy to be much greater than the energy evolved in the elementary chemical act. This is the exception to the rule outlined at the beginning of this article.

B. Reactions in the Liquid Phase (Electronic Excitation)

The quantitative study of the elementary excitation acts in solutions is very much harder than the study of chemiluminescent gas-phase reactions.

Most liquid-phase reactions involve polyatomic molecules. The quantum-mechanical description of polyatomic molecules relies on approximate computational methods, in which the transition from the simplest one-electron system to more complex systems is made by various means. There is no exact theory of the elementary act in condensed systems. Neither the transition state theory nor the collision theory is able, in practice, to predict reaction rates from the structure of the reacting species. A direct calculation of the motion of the representative point of the system along the potential energy surface, such as has been done for the H + $H_2 \rightarrow H_2$ + H reaction, is impossible in a more complicated system. The same is true of an exact calculation of the influence of the solvent.

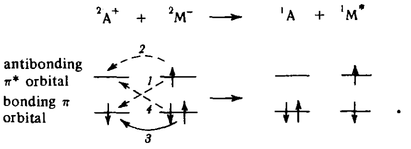
Most chemiluminescent liquid-phase reactions in solutions are complicated processes involving many intermediate steps whose mechanism is as yet far from clear. Both the reactions themselves and their chemiluminescence are characterised by complex kinetics, and quantitative data on chemiluminescence and excitation yields are very difficult to obtain.

For this reason, the standards and the criteria used in liquid-phase chemiluminescence studies are quite different from those used in gas-phase systems. Workers studying simple gas reactions aim to understand every detail of their mechanism—a realistic albeit laborious objective. On the other hand, with the complex molecules involved in liquid-phase reactions one must be content with a simple, qualitative interpretation. Workers rely heavily on analogies: on the one hand, with the simpler gas-phase systems, on the other hand with photochemical and photophysical processes. (Note that chemiluminescence is "photochemistry in reverse".)

Relatively few of the steadily increasing number of papers on liquid-phase chemiluminescence have attempted to study the phenomenon in reactions where the mechanism is known. However, a number of well chosen model systems have been described in recent years, and several types of excitation mechanism have been shown to have wide application. We shall consider a few examples of these mechanisms below. A more detailed description of the specific features of chemiluminescence in solutions can be found in various reviews[57-66] and in Gundermann's monograph[67].

1. *Electron transfer*

Consider the transfer of an electron from an anion-radical M^- (or $^2M^-$, where the left-hand superscript denotes the multiplicity) to a cation-radical A^+ (or $^2A^+$). A^+ has a deficiency of one electron with respect to the molecule A, and M^- has one electron in excess; the last bonding orbital and the first antibonding orbital are filled, as shown below:



$$^2A^+ + {}^2M^- \longrightarrow {}^1A + {}^1M^* \qquad \text{(VIII)}$$

The transition can occur in several ways. Transition *1* gives only non-excited products (not shown). However, if the excitation potential of at least one of the product molecules is less than the difference between the ionisation potential and the electron affinity (or, if M^- and A^+ have the same solvation energy, less than the difference between the oxidation and the reduction potential), it is possible to obtain an excited and a non-excited molecule (path *2* and path *3*, the latter shown in the diagram), or even two electronically excited molecules (path *4*)†.

Excitation by the mechanism of radical-cation and radical-anion annihilation was first demonstrated by Chandross and Sonntag[68]. These workers observed singlet–singlet emission from 9,10-diphenylanthracene (DPA) during the reaction between potassium diphenylanthracene (source of DPA^-) and the 9,10 dichloride of DPA (source of DPA^{2+}). Weller and Zachariasse[69] observed chemiluminescence during the reaction of the anion-radicals (M^-) of chrysene, picene, pyrene, 1,2-benzanthracene, anthracene, perylene, and tetracene with the cation of Würster Blue (D^+). Chemiluminescence had been predicted by the authors before the experiment: since the fluorescent state of the aromatic hydrocarbons M^* is quenched by electron donors D through the formation of a charge-transfer complex M^-D^+, the authors suggest that the opposite process—the interaction of M^- and D^+—can lead to chemical excitation.

The electrochemical production of ion-radicals is an effective way of studying the chemiluminescence associated with electron transfer. Chemiluminescence accompanying electrolysis has been reported by several workers (see review in Ref. 65), but the recent work by Hercules[70] on the chemiluminescent annihilation of aromatic ion-radicals has produced a veritable avalanche of reports of electrochemiluminescence. Electrochemical excitation using a.c. is particularly revealing, because both cations and anions are produced at any one site of the layer adjacent to the electrode during each half cycle (by the reactions $M + e^- \rightarrow M^-$, $M \rightarrow M^+ + e^-$, and $M^- \rightarrow M^+ + 2e^-$). The electrochemiluminescence is particularly intense if the voltage applied to the electrodes is sufficient to produce both types of ion-radical. When one type only is produced, the observed chemiluminescence is weaker by several orders of magnitude. The mechanism of this "pre-annihilation"[71] electrochemiluminescence is still unclear (see discussion in Ref. 72), and so are also many other features of the phenomenon such as the roles of the solvent, of impurities, of the products, etc. (see discussion of Hoytink's paper at a Discussion of the Faraday Society[73]).

Hoytink[73] summarises current views on the thermodynamics and kinetics of electrochemiluminescence by discussing the annihilation of the radical-ions of aromatic hydrocarbons (M). The heat of reaction ΔH does not differ significantly from the difference between the oxidation and the reduction potential of M, which are themselves close to the oxidation and the reduction half-wave potential respectively. It is evident from Table 3 that the exothermicity is sufficient to populate the triplet states, and in some cases also the singlet excited states. The formation of either state during reaction is determined by the relative rates, which can be assessed by considering the intersection of the potential energy surfaces (where the initial and the final state have the same nuclear conformation). The energy change accompanying electron transfer depends mainly on the change in the orientation of the solvent: according to Marcus' theory[74], this change can be characterised by the average distribution of the electron (m) between the participants to the reaction. For example, for the initial state $M^+ + M^-$ the energy minimum corresponds to $m = 0$, whereas for the final state M + M, to $m = 1$. The energy change is proportional to m^2, i.e. it has a parabolic form, which differs for the various combinations of states of the products (singlets, triplets, excimers). The position of the parabolas (Fig. 9) for strongly exothermic reactions shows that the energy barriers separating the initial state ($M^+ + M^-$) from the electronically excited products (curves *3* and *4*) are much lower than the barrier between the initial reactants and the non-excited products (curve *2*). Hence, excitation occurs with 100% probability at the intersection points (to the approximation of the statistical spin factor). On the other hand, the rate of formation of the non-excited product is low, because of tunnelling transition is required (the intersection point is not reached in practice). This transition is similar to the transition involved in the internal conversion from the S_1 state to the S_0 state (see Ref. 4, p. 82–84).

Table 3. Energy balance during cation–anion annihilation[73].

Hydrocarbon	Half-wave potential, V		$-\Delta H$, eV	Energy, eV	
	oxidation	reduction		singlet	triplet
Benzene	2.26	(—3.16)	5.4	4.7	3.6
Naphthalene	1.57	—2.60	4.2	3.9	2.6
Phenanthrene	1.49	—2.48	4.0	3.6	2.7
Pyrene	1.14	—2.10	3.2	3.3	2.1
Anthracene	1.10	—1.98	3.1	3.3	1.8
Perylene	(0.77)	—1.67	2.4	2.9	—
Tetracene	0.80	—1.58	2.4	2.6	1.3

This phenomenon has a clear physical meaning. The elementary act of electron transfer does not involve a change in the nuclear coordinates: therefore, it is fast, and the slower processes of energy dissipation among the bonds cannot compete with the faster processes in which the reaction energy is set free in the form of electronic excitation energy[68]. A somewhat different explanation can also be given[75]: when the product is formed in the ground state the whole of the (electronic!) energy of the reaction must be converted into vibrational energy. This process has a low probability, as shown by the low rate

---

†For examples, see Fig. 9 below.

constant for the internal conversion illustrated in Fig. 2 (of the order of 10^5 s^{-1}). On the other hand, when the electronically excited state is populated the greater part of the electronic energy of the reaction is converted into electronic energy of the product.

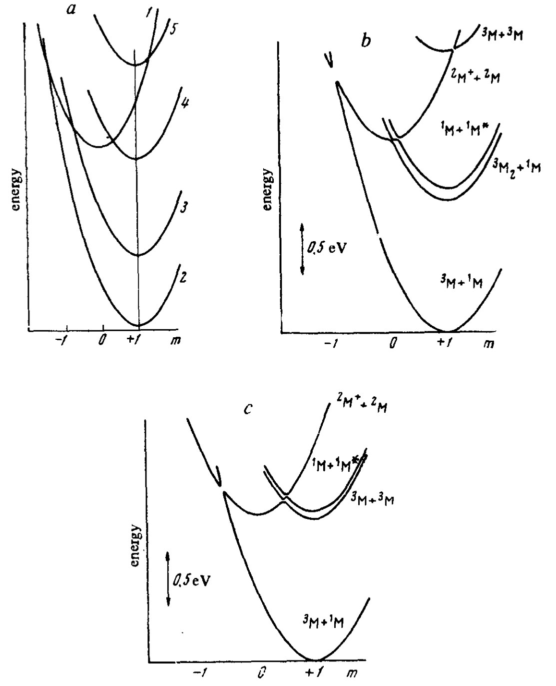


Figure 9. Potential energy curves for a typical radical-ion annihilation (*a*) and for the annihilation of naphthalene (*b*) and tetracene (*c*) radical-ions. Figs. *b* and *c* show the non-intersection ("repulsion") of the curves. *1*) Initial state, *2*) non-excited products, *3*–*5*) electronically excited products.

As regards the emission stage, we can say the following. The life time of the triplets (^3M) is large, and in liquids these species are effectively quenched. Hence, their contribution to the electrochemiluminescence results from triplet–triplet annihilation, yielding a singlet excited molecule $^1M^*$:

$$^3M + {}^3M \rightarrow {}^1M^* + {}^1M\,.$$

Direct emission from the triplet state has a low intensity in solutions, although in principle it can be enhanced by exchange interaction between the triplet molecule and radical-ions or other triplet molecules. The main contribution to the electrochemiluminescence comes from directly excited singlets ($^1M^*$) and singlet excimers ($^1M_2^*$). The electrochemiluminescence spectrum is qualitatively similar to the photofluorescence spectrum[76], but the relative importance of monomers and excimers is different in these two different types of excitation.

It is evident from Fig. 9 that the barrier to the reverse reactions of the type

$$^3M + {}^3M \rightarrow M^- + M^+$$

can be relatively low. Processes of this type have been observed in the photoexcitation of fluorescein[77], eosin[78], and Methylene Blue[79].

The rapid progress made in the study of electrochemiluminescence is largely due to the practical advantages of the method: the particles whose interaction produces the elementary excitation act can be prepared at a known and controllable rate.

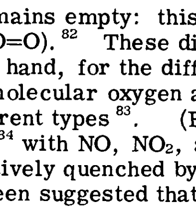
Electrochemiluminescence can be characterised by its yield, defined as the average number of photons emitted per electron transferred from one electrode to the other[71]. Its value can be calculated from the absolute luminescence intensity and the electrolysis current. For example, in the electrolysis of *N*-methyl-1,3-di-*p*-anisyl-4,7-diphenylisoindole in dimethylformamide solution the emission amounts to 3×10^{-3} photon per electron. Allowing for the fluorescence yield, this is equivalent to 0.6% conversion of the electrical energy into excitation.

2. *Excitation of molecular oxygen*

The formation of singlet oxygen molecules in liquid-phase as well as in gas-phase reactions has recently been demonstrated. For example, when a stream of molecular chlorine is passed through an alkaline aqueous solution of hydrogen peroxide, oxygen in the $^1\Delta$ state is obtained in at least 10% yield[80]. The chemiluminescence of reactions of this type has been successfully investigated, mainly because the emitter is a simple molecule in which the nature and the energetics of the excited states are well known. The electronic configuration of the O_2 molecule is obtained by combination of the atomic orbitals of the O atoms:

$$2O\,(1s^22s^22p^4) \rightarrow O_2\,(KK\,(\sigma 2s)^2\,(\sigma^*2s)^2\,(\sigma 2p)^2\,(\pi_y 2p)^2\,(\pi_z 2p)^2\,(\pi_y^* 2p)\,(\pi_z^* 2p));\ {}^3\Sigma_g^-.$$

Thus, we obtain eight bonding and four antibonding orbitals, and the bond order is two. The nature of the $^3\Sigma$, $^1\Delta$, and $^1\Sigma$ states is determined by the occupancy of the upper antibonding orbitals[81]:



(IX)

In the $^1\Sigma$ state the unpaired electrons reside in different orbitals, spatially distinct, and this state (like the $^3\Sigma$ ground state) can be thought to have the properties of a biradical (·O–O·). On the other hand, in the $^1\Delta$ state the two electrons occupy the same antibonding orbital, while the other orbital remains empty: this structure is similar to that of ethylene (O=O).[82] These differences are responsible, on the one hand, for the different reactivities of the three states of molecular oxygen and their participation in reactions of different types[83]. (For example, the $^1\Delta$ state does not react[84] with NO, NO_2, and H_2O, whereas the $^1\Sigma$ state is effectively quenched by water[53].) On the other hand, it has been suggested that the different states of O_2 are produced in reactions of different types[82].

According to McKeown and Waters[82], the production of "biradical" oxygen is most likely in one-electron elementary acts involving free radicals, for example

$$[Fe(CN)_6]^{3-} + {}^{\cdot}O{-}OH \rightarrow [Fe(CN)_6]^{4-} + {}^{\cdot}O{-}O^{\cdot} + H^+\,.$$

The formation of "ethylene-like" singlet oxygen is more likely in heterolytic reactions, i.e. in elementary acts involving the participation of electron pairs, as in the reaction between H_2O_2 and alkaline hypochlorite solutions:

$$^{-}O{-}O{-}H + {}^{-}O{-}Cl \longrightarrow O{=}O + H{-}O^{-} + Cl^{-} \qquad (X)$$

or in the reaction between H_2O_2 and halogens:

$$^{-}O{-}O{-}H + Br{-}Br \longrightarrow O{=}O + HBr + Br^{-}. \qquad (XI)$$

As in the case of gas-phase reactions, the emission spectra of liquid-phase reactions contain bands due to both free molecules and dimers of oxygen.

It follows from Eqn. (12) that the ratio of the photocurrents at 634 and 1270 nm in the chemiluminescence spectrum is proportional to the concentration of singlet oxygen:

$$i_{634}/i_{1270} = a\,[O_2^1\Delta] \qquad (13)$$

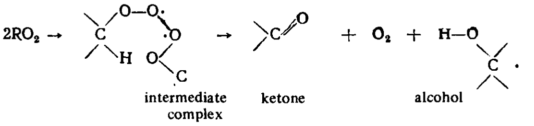
where a is a coefficient depending on the spectral sensitivity of the detector but independent of the geometry of the apparatus and of quenching by collisions. This coefficient can be evaluated by calibrating the apparatus for the 1270 and 634 nm bands using an electrical discharge in gaseous O_2. Hence, the concentration of singlet oxygen and the yield (10%) of $O_2{}^1\Delta$ in the reaction between hydrogen peroxide and chlorine can be determined experimentally[80]. It should be noted, however, that in this liquid-phase reaction the emission occurs from the gas bubbles (chlorine) rising through the solution. In these circumstances the fate of the singlet O_2 molecules is determined by the same rate constants as in the gas-phase reaction (section III.5). The rate constants of processes involving singlet oxygen as a true solute have not yet been measured.

The discovery of chemiluminescence was responsible for the interest in the problem of singlet oxygen and its participation in physical, chemical, and biological processes‡.

The "double" energy of the dimers (from 45 kcal mole^{-1} for $^1\Delta^1\Delta$ to 75 kcal mole^{-1} for $^1\Sigma^1\Sigma$) can facilitate reactions with a large activation energy. Khan and Kasha[55] attempted to formulate a general theory of chemiluminescence in reactions leading to the production of singlet oxygen. They assume that the emitter can be either the O_2O_2 pair or an acceptor species carrying the energy of the excited dimer. However, they were unable to produce a quantitative proof of these views: undoubtedly, this is because the kinetics and the mechanism of the overall reaction are complex, and the elementary excitation act cannot be isolated for study.

3. *Excitation of carbonyl compounds during the oxidation of organic materials*

The oxidation of organic compounds in solution by molecular oxygen is often accompanied by weak chemiluminescence[60,61,88]. Excitation occurs in one of the elementary steps of the complex chain reaction involved: during the disproportionation of peroxidic radicals (RO_2):



(XII)

The emitter of chemiluminescence in the visible region of the spectrum is a ketone in the triplet state.

This reaction can be studied conveniently because its rate w, and therefore also the chemiluminescence intensity I (see Eqn. 2), can be controlled by adding chain oxidation initiators (peroxides or azo compounds). In the presence of strongly luminescent energy acceptors A, formula (2) applies exactly, and the emission yield η_P of the ketone can be determined by varying the concentration of A (and thus varying the efficiency η_{PA} of the energy transfer). The low value of η_P (19^{-5}–10^{-3}) is due to the low probability of triplet–singlet emission and to strong deactivation by molecular collisions with the solvent. The excitation yields can be evaluated by formula (2) once the absolute chemiluminescence intensity I, the rate w, and the yield η_P are known. The values 10^{-3}–10^{-2} were obtained[89,90] for the excitation yield of ketones (acetophenone, cyclohexanone, benzophenone, diacetyl) in the oxidation of the hydrocarbons ethylbenzene, cyclohexane, diphenylmethane, and ethyl methyl ketone respectively.

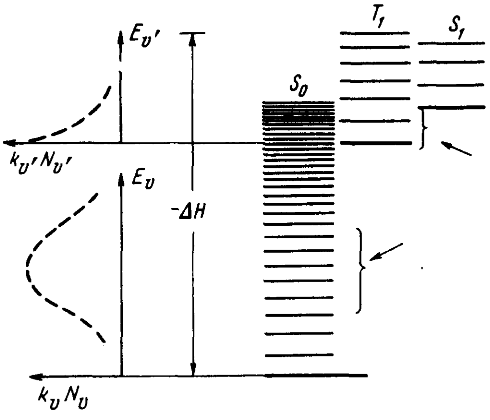


Figure 10. Population of the energy states of a ketone during the disproportionation of peroxide radicals. Probable energy dependences of the rate at which the vibrational levels are populated are shown on the left for the S_0 and T_1 electronic states. The arrows denote the levels with the highest occupancy probability.

Hence, the excitation yields are fairly large, considering that an energy of between 55 and 75 kcal mole^{-1} (depending on the structure), or 60–70% of the heat of reaction (XII), needs to be concentrated on the ketone (one of the three products) in order to excite it. The quantity η_P^{exc} can be treated[88,90] as the ratio of the rates at which the S_0 and T_1 states of the ketone are populated (Fig. 10):

$$\eta_P^{exc} = \left(\sum_{v'=0}^{\infty} k_{v'}N_{v'}\right) \Big/ \left(\sum_{v=0}^{\infty} k_vN_v\right)$$

where $k_{v'}$ and k_v are the rate constants which describe the population of the vibrational levels of the T_1 and S_0 states respectively, and N_v is the number of configurations of the intermediate complex for which the ketone molecule acquires an energy equal to the energy of the vibrational

---

‡These problems attracted lively discussion in the literature of the 1930's and 1940's (see Section 79 and others in Terenin's monograph[3]). More recent reviews can be found in Refs. 85–87.

level v (or v'). Using rate constants averaged over the number of configurations, we arrive at

$$\eta_P^{\mathrm{exc}} = (\bar{k}_{v'}/\bar{k}_v)\left(\sum_{v'=0}^{\infty} N_{v'}\right)\Big/\left(\sum_{\bar{v}=0}^{\infty} N_v\right) = \frac{k_{v'}}{\bar{k}_v} n_T$$

where n_T denotes the fractional number of the states of the intermediate complex for which the energy acquired by the ketone is at least equal to the energy of the triplet state of the ketone. This fraction is evidently very small, since electronic excitation of the ketone requires much more than half the energy of reaction (XII). Yet, the low value of n_T is compensated by the ratio $\bar{k}_{V'}/k_V$; there are grounds for expecting this ratio to be much larger than unity:

1. The energy of the reaction is, essentially, electronic, since the rearrangement of the intermediate complex to give the final products involves a change in the electronic structure of the given combination of atoms. Studies of the radiationless deactivation of electronically excited organic molecules have shown that Franck–Condon factors play an important role in the conversion of electronic energy into vibrational energy. These factors inhibit the conversion to an extent which varies inversely with the energy (see Section 4–3 of Ref. 4). The rate constants $k_{V'}$ and k_V relate, on the average, to processes in which a small and a large fraction respectively of the energy of the reaction are converted into vibrations (Fig. 10).

2. If we accept the analogy with gas-phase exchange reactions (Section III.A.2), and assume that the bonds formed in reaction (XII) are not ionic, and are more similar to those of reaction (II) than to those of reaction (III), we again conclude that the conversion of a large fraction of the energy of reaction (XII) into vibrational energy has a low probability, and hence its rate constant is low.

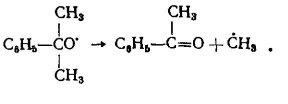
3. Lastly, as was stated above (Section III.B.1), the high yields of electrochemiluminescence are due to the fact that the conversion of large amounts of electronic energy into vibrational energy is unnecessary.

The low occupation probabilities of the upper vibrational levels of the electronic ground state indicate that in the overwhelming majority of elementary acts of type (XII), when the energy acquired by the ketone is insufficient to cause electronic excitation, the reaction does not take place and the peroxide radicals simply separate after an encounter. This may be one of the reasons why the absolute rate constant for the disproportionation of peroxide radicals is much lower than the rate constant for diffusion, even though the radicals experience tens or even hundreds of collisions at each encounter, and the activation energy for disproportionation is equal to the activation energy for diffusion.

It should be noted that detailed studies of chemiluminescence have been made only on hydrocarbons whose oxidation involves secondary peroxide radicals, so that disproportionation takes place in a six-membered complex (reaction XII). With tertiary radicals this complex cannot form, and chain termination is brought about by the reactions

$$2\mathrm{ROO}^{\cdot}\rightarrow\mathrm{ROOOOR}\begin{array}{l}\nearrow \mathrm{ROOR}+\mathrm{O_2}\\ \searrow 2\mathrm{RO}^{\cdot}+\mathrm{O_2}\end{array}. \qquad \mathrm{(XIII)}$$

In the oxidation of cumene, for example, the oxy-radical can dissociate as follows:



$$\mathrm{C_6H_5{-}\overset{\overset{\displaystyle CH_3}{|}}{\underset{\underset{\displaystyle CH_3}{|}}{C}}O^{\cdot}} \rightarrow \mathrm{C_6H_5{-}\overset{\overset{\displaystyle CH_3}{|}}{C}{=}O + \dot{C}H_3}\,.$$

This reaction is exothermic by about 10 kcal mole^{-1}, and the suggestion[91] that it is the source of excitation of acetophenone at 150° is clearly untenable. In this temperature region the decomposition products of tertiary peroxides have been shown to contain ethers, whose presence is ascribed[92] to the disproportionation of oxy-radicals e.g.

$$2\,(\mathrm{CH_3})_3\mathrm{CO}^{\cdot} \rightarrow (\mathrm{CH_3})_2\mathrm{C{=}O} + \mathrm{CH_3{-}O{-}C\,(CH_3)_3}\ .$$

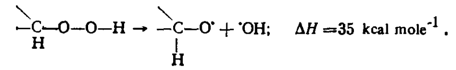
If a reaction of this type is possible in the case of cumyl oxy-radicals, it may indeed give rise to excitation of acetophenone, since its enthalpy change is at least 80 kcal mole^{-1}.

Alternative excitation mechanisms are suggested in the current literature for the chemiluminescence of oxidation reactions. Bowen and Lloyd[93-95] and Reich and Stivala[96] assume that the ketone is excited by the molecular decomposition of a hydroperoxide (a reaction product):

 (XIV)

$$\mathrm{{-}\overset{|}{\underset{\underset{\displaystyle H}{|}}{C}}{-}O{-}O{-}H \rightarrow {-}\underset{|}{C}{=}O + H_2O}; \quad -\Delta H = 70{-}80\ \mathrm{kcal\ mole^{-1}}. \qquad \mathrm{(XIV)}$$

Reaction (XIV) has a relatively large activation energy, and could be significant at high temperatures. However, there is no direct proof that it takes place as a single elementary act[97]. Many peroxides decompose by a radical mechanism rather than by the molecular mechanism (XIV):



$$\mathrm{{\setminus}\!\!{-}\underset{H}{C}{-}O{-}O{-}H \rightarrow {\setminus}\!\!{-}\underset{\underset{\displaystyle H}{|}}{C}{-}O^{\cdot} + {}^{\cdot}OH}; \quad \Delta H = 35\ \mathrm{kcal\ mole^{-1}}.$$

Disproportionation of the radicals produced by this reaction gives the same final products as reaction (XIV):

$$\mathrm{{-}\underset{\underset{\displaystyle H}{|}}{C}{-}O^{\cdot} + {}^{\cdot}OH \rightarrow {-}C{=}O + H_2O}; \quad -\Delta H = 110\ \mathrm{kcal\ mole^{-1}}.$$

The radicals can also behave as oxidation initiators, and the observed chemiluminescence could simply be the result of the disproportionation of peroxide radicals.

Two more mechanisms are noteworthy. Stauff and coworkers[98] described the reaction

$$2\mathrm{RO_2} \rightarrow \mathrm{R_2} + \mathrm{O_2^*{-}O_2^*} \qquad \mathrm{(XV)}$$

and Lloyd[95] postulated the reaction

$$\mathrm{ROOH} \rightarrow \mathrm{RH} + \mathrm{O_2^*} \qquad \mathrm{(XVI)}$$

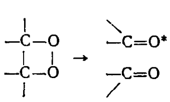
as paths for the formation of singlet oxygen. Unfortunately, no evidence whatever is quoted of the reality of these processes. It is hard to believe that deeply oxygenated compounds can lose the whole of their oxygen in elementary processes of the type of (XV) or (XVI). Reaction (XVI) could conceivably take place at high temperatures and in the presence of a powerful catalyst, but not on a glass wall at 80°.

Partial excitation of molecular oxygen in reactions of type (XII) has been proposed[60,61], and more recently Howard and Ingold[99] have confirmed this view by a chemical argument. The initial spin state in reactions (XII) and (XIII) is singlet or triplet (combination of two doublet states of free radicals), and the spin conservation rule predicts the formation of products in both the singlet and the triplet state, although the final system is profoundly affected by the energy distribution factors.

---o0o---

In spite of the uncertainties still present in chemiluminescence problems, particularly as regards liquid-phase reactions, there are indications that the generality (or, conversely, the specificity) of the factors leading to efficient excitation in various reactions will become better understood during the next few years. We may assume that one of these factors will be shown to be the participation of ions, radical-ions, or charge-transfer complexes: as the data discussed in this review suggest, these species favour the retention of the reaction energy as internal energy of the products.

Whilst this paper was in press, new calculations of the energy distribution of the products of exchange reactions have been published[100,101], and also a review[102] and new work on chemical lasers including the first report of purely chemical laser action[103,104] and of continuously operating chemical lasers[105,106]. Luminescence of nitrogen dioxide has been observed in crossed molecular beams[107]. In addition to the fully characterised electronic and vibrational excitation, chemical reactions can also generate non-equilibrium occupancy of nuclear spin states: studies of chemical pumping of this type were started[108] in 1967 and are attracting considerable attention at the moment[109]. Many of the recent results point to the decomposition of a cyclic peroxide group, e.g.



as the commonest elementary excitation act in liquid-phase chemiluminescence.

A process of this type is characteristic of the chemiluminescence produced by the oxidation of the light-emitting substance found in the firefly and its analogues (e.g. lophine),[110-114] of organic anhydrides and amides[115] (in this case the strongly fluorescent molecule acts as "catalyst" and as emitter by gaining electronic energy from the products which are not amenable to excitation), and other reactions. The high excitation efficiency accompanying the decomposition of the peroxide ring follows from the rule of orbital symmetry conservation[116]. Different views on the mechanism of the chemiluminescence attending the oxidation of organic compounds have been critically discussed[117], and Kellogg[118] comes to the surprising conclusion that the excitation yield of the ketone approaches 100%, with quenching by oxygen retained in the solvent cage. Interesting new data are presented in a review of the physical aspects of chemiluminescence[119].

Reaction of Fluorine and Non-metal Fluorides in an Electric Discharge

I.V.Nikitin and V.Ya.Rosolovskii

Fluorine reacts readily with the majority of substances at room or moderately elevated temperatures. Only in a few cases is special activation of the reactants necessary. An electric discharge may be used for this purpose. This review deals with studies of reactions involving elemental fluorine and fluorides in a gas discharge. Reactions which may be of preparative value are mainly considered.
The bibliography includes 113 references.

CONTENTS

I. INTRODUCTION

The use of electrical discharges in gases for preparative purposes in inorganic chemistry is generally known. The activating effect of the discharge makes possible reactions which cannot be achieved by thermal activation of the starting material or in the absence of a discharge by high temperatures and pressures alone.

Fluorine readily interacts with the majority of substances at room or moderately elevated temperatures. An exception are the reactions of fluorine with its nearest neighbours in the Periodic System: nitrogen, oxygen, and noble gases. In those cases where thermal activation of the starting materials does not lead to reaction or the expected products are unstable at high temperatures and therefore cannot be isolated, factors acting upon the reactant, such as an electric discharge or irradiation, become particularly important.

At low pressures and currents the plasma of a glow discharge is characterised by a low molecular temperature, amounting usually to several hundred degrees Kelvin, and a considerably higher electronic temperature. When the reaction is carried out in a discharge, the walls of the reactor may be cooled to very low temperature. Thus in syntheses in a discharge two conditions necessary for the formation of thermally unstable compounds are immediately fulfilled; in a low-temperature discharge plasma high concentrations of active species are established and the possibility of rapid quenching prevents the decomposition of the compounds formed.

The present review deals with studies on the reactions of fluorine with nitrogen, oxygen, krypton, xenon, and chlorine in an electric discharge. At normal temperatures and pressures molecular fluorine does not react with the above elements. In a discharge fluorine becomes more active due to its dissociation into atoms. The excited $^1\Pi_u$ state of the F_2 molecule has a repulsive potential curve[1]. The transition $^1\Sigma_g^+ \rightarrow {}^1\Pi_u$ leads to the dissociation of F_2 into two non-excited fluorine atoms (in the $^3P_{3/2}$ state). One cannot exclude the possibility that ionised atoms and fluorine molecules present in the discharge participate in the reaction. For example, the emission spectrum of fluorine excited by an electric discharge[2] shows emission bands which were assigned to the F_2^+ ion.

The inclusion in the review of a section dealing with the reactions of nitrogen fluorides was dictated by the considerable interest which the reactions of this group of fluorides have attracted in recent years.

II. INTERACTION OF FLUORINE WITH NITROGEN

Many reactions leading to the formation of both binary† nitrogen fluorides and those containing other elements have been investigated. A characteristic feature of these reactions is the synthesis of nitrogen fluorides from nitrogen-containing compounds[3-5]. This review deals with the reactions of fluorine with elemental nitrogen.

The synthesis of nitrogen fluorides from the elements is thermodynamically possible. A mixture of fluorine and nitrogen constitutes a system in a state of metastable equilibrium which must overcome a high activation barrier for reaction to occur. If the reaction between fluorine and nitrogen occurs then, in accordance with the large negative free energy of nitrogen trifluoride ($\Delta G^\circ_{298} = -21.38$ kcal mole^{-1}) [6], a stoichiometric mixture of fluorine and nitrogen will be fully converted at room temperature into nitrogen trifluoride. The equilibrium constants[6] for the reaction $\frac{1}{2}N_2 + \frac{3}{2}F_2 \rightleftharpoons NF_3$ at a pressure of 1 atm at 298°K is of the order of 10^{14}. The absence of an appreciable reaction between fluorine and nitrogen is evidently due to kinetic factors.

Attempts were made as early as the beginning of the century to obtain nitrogen fluoride in a discharge[7]. A study was made of the effect of an arc on a mixture of gaseous fluorine and nitrogen and also of a spark discharge on a liquid mixture of the same substances. However, the formation of nitrogen fluoride in these experiments could not be established[7].

The synthesis of nitrogen trifluoride in a glow discharge with a yield of about 30% was reported in 1964 [8]. Mixtures of fluorine and nitrogen were passed through the discharge at a pressure of 20–40 mmHg, the walls of the tube being cooled with liquid nitrogen. Variation of the ratio $F_2:N_2$ in the initial mixture did not lead to the synthesis of nitrogen fluorides other than NF_3. The compound was obtained also in a discharge at a current of 10–15 mA and a pressure of 10–17 mmHg, the reactor being maintained at temperatures ranging from –150 to –196°C.[9]

The synthesis of nitrogen fluoride in a discharge-flow apparatus at a pressure of 15 mmHg has been described[10]. The volume flow rate of the fluorine–nitrogen mixtures was varied from 0.09 to 1.20 litre h^{-1} (the volumes of the gases at s.t.p. are indicated). The nitrogen trifluoride formed in the discharge condensed on the walls of the discharge tube immersed in liquid nitrogen. The conversion of the fluorine–nitrogen mixture rises to 60–70% as the volume flow rate is reduced to about 0.1 litre h^{-1} at a current of 10 or 25 mA. The conversion is almost independent of the composition of the initial fluorine–nitrogen mixtures.

The authors of the review[11] carried out experiments with a stoichiometric mixture ($F_2:N_2 = 3:1$). The gases were passed through a discharge tube and the NF_3 formed was condensed in a trap at –196°C at a distance of 12 cm from the discharge zone. After the removal of the cold trap from the discharge, the yield of NF_3 fell. An increase of the current from 4 to 12 mA entails an increase of conversion, which, however, falls as the current is raised further to 25 or 40 mA. This phenomenon may be explained by an increase in the importance of the reverse reaction with increasing power of the discharge[11].

Since a high conversion of fluorine–nitrogen mixtures in a glow discharge is attained at low flow rates, the absolute yield of NF_3 per unit time is low. The synthesis of nitrogen trifluoride in a discharge is scarcely practicable for the preparation of the substance in large amounts. Usually the compound is obtained by the electrolysis of an ammonium hydrogen fluoride melt. Nitrogen fluoride was in fact, first synthesised in this way[12]. The electric discharge method has a certain advantage in that the compound obtained in a glow discharge is free from impurities, which are present in the substance synthesised electrolytically.

Nitrogen trifluoride is formed in very low yields (1.5–2%) in a silent (electrodeless) discharge when a mixture of fluorine and nitrogen is circulated through an ozoniser[13].

$\Delta G^\circ_{298} = 18.72$ kcal mole^{-1} for the formation of tetrafluorohydrazine from the elements, ΔG°_T becoming negative only at temperatures below –243°C [6]. However, when the experiments in a gas discharge are carried out under conditions of rapid flow, it is possible to obtain a low yield of tetrafluorohydrazine from the elements. The NF_2 radicals formed as an intermediate in the reaction between fluorine and nitrogen are stabilised to N_2F_4 as a result of the rapid cooling of the reaction mixture on quenching. Thus a stream of nitrogen was passed[14] through an arc discharge (300 A, 40 V) at a rate of 15 litre min^{-1} and mixed with gaseous fluorine. The reaction products entered a trap cooled with liquid nitrogen. The yield of nitrogen trifluoride and tetrafluorohydrazine did not exceed 1%.

About 1% of bound nitrogen was obtained on mixing carbon tetrafluoride with nitrogen plasma[15]. The quenching products contained nitrogen trifluoride, tetrafluorohydrazine, and traces of difluorodiazines. The reaction of sulphur hexafluoride with a nitrogen plasma also gives about 1% of bound nitrogen, largely in the form of the trifluoride[15]. The synthesis of nitrogen trifluoride under the action of an arc rotated by a magnetic field in a mixture of carbon tetrafluoride and nitrogen has been described[16]. The syntheses of nitrogen fluorides in plasma devices are considered in detail in the book edited by Baddour and Timmins[17].

The energy losses per unit volume of the reacting gases in the synthesis of NF_3 in a discharge are very large. Thus a conversion of 54% was achieved[11] at a specific energy[18] of 325 W h litre^{-1}. The high energy losses are evidently due to the need to activate the nitrogen molecules. The published data are as yet insufficient to decide which active forms of nitrogen participate in the synthesis of nitrogen trifluoride. The intermediates in the reaction of fluorine with nitrogen may be the radicals NF and NF_2. NF radicals have been detected both in the emission spectrum of nitrogen fluoride which has passed through a microwave discharge[19,20] and in the emission spectrum of the flame formed when hydrogen burns in nitrogen trifluoride[21]. However, it is difficult to state definitely as a result of which process NF radicals might have been generated in the synthesis of NF_3 in a discharge.

---

† Binary nitrogen fluorides are defined as those which consist only of fluorine and nitrogen: NF_3, N_2F_4, N_2F_2, FN_3.

To determine the mechanism of the synthesis of nitrogen trifluoride from the elements, spectroscopic studies on the interaction between fluorine and nitrogen in a discharge would be useful. The reaction of active nitrogen and molecular fluorine has not apparently been investigated[22].

In an electric discharge it is possible to obtain substances in greater yields than those corresponding to thermodynamic equilibrium[18]. For example, nitric oxide synthesised from the elements is formed in amounts greatly exceeding the thermodynamic equilibrium value[18,23]. As already mentioned, at low temperatures the equilibrium $\frac{1}{2}N_2 + \frac{3}{2}F_2 \rightleftharpoons NF_3$ is fully displaced to the right. Electric discharge in a mixture of fluorine and nitrogen displaces the system from a state of metastable equilibrium and brings it closer to thermodynamic equilibrium, i.e., the effect of the discharge is in this case comparable to that of a catalyst.

III. REACTIONS OF NITROGEN FLUORIDES IN A DISCHARGE

Nitrogen trifluoride is decomposed into its elements in a glow discharge. At low flow rates a steady-state degree of decomposition is attained, amounting to about 80% at a current of 15 or 25 mA. [10] The dissociation of NF_3 may be represented by the following sequence of reactions:

$$NF_3 \rightleftarrows F + NF_2 \rightleftarrows 2F + NF \rightleftarrows {}^3/_2F_2 + {}^1/_2N_2.$$

Tetrafluorohydrazine was not detected in the NF_3 decomposition products[10]. The NF_2 radicals, which are suggested by this decomposition mechanism, either undergo further defluorination or combine with a fluorine atom regenerating the nitrogen trifluoride. When the fluorine formed in the decomposition of NF_3 is removed, for example by reaction with mercury vapour, it is possible to obtain tetrafluorohydrazine and difluorodiazines from nitrogen trifluoride[24]. According to the literature[24], the yields of N_2F_4 and N_2F_2 relative to the unreacted nitrogen trifluoride were respectively 51–67 and 12–16%. The discharge tube was maintained at a temperature of about 200°C. At a higher temperature (320–330°C) the reaction

$$2NF_3 + 2Hg = N_2F_4 + Hg_2F_2$$

also takes place without an electric discharge. [25]

The synthesis of tetrafluorohydrazine in the decomposition of nitrogen trifluoride in a discharge may be compared with the synthesis of hydrazine from ammonia in a discharge[26-29]. One of the reasons for the low yield of hydrazine in its synthesis from ammonia is the breakdown of the N_2H_4 formed by hydrogen atoms. Acceleration of the recombination of atomic hydrogen leads to an increased yield of hydrazine. Tetrafluorohydrazine is obtained from nitrogen trifluoride in a discharge provided that the fluorine formed reacts with mercury, which is a fluorine acceptor.

The synthesis of hydrazine from ammonia and of tetrafluorohydrazine from nitrogen trifluoride is described by the following general equation:

$$2AX_3 = A_2X_4 + X_2.$$

Other reactions described by the same general equation occur in an electric discharge: the synthesis of P_2Cl_4 from phosphorus trichloride[30] and of B_2Cl_4 from boron trichloride[31,32]. However, B_2F_4 has not been obtained in a discharge from boron trifluoride[33].

Tetrafluorohydrazine is obtained by heating nitrogen trifluoride in the presence of fluorine acceptors, for example metals[34]. The possibility of synthesising N_2F_4 from NF_3 arises because of the relative stability of NF_2 radicals and the absence of high concentrations of fluorine atoms. On the other hand, in a glow discharge tetrafluorohydrazine is unstable in relation to its decomposition products – nitrogen trifluoride and nitrogen. Tetrafluorohydrazine readily decomposes, with a small expenditure of energy, forming nitrogen trifluoride[11]:

$$N_2F_4 = {}^4/_3NF_3 + {}^1/_3N_2.$$

With increase in the energy density, more far-reaching breakdown takes place:

$$N_2F_4 \rightarrow NF_3;\ NF_3 \rightleftarrows {}^1/_2N_2 + {}^3/_2F_2.$$

The low stability of tetrafluorohydrazine in a glow discharge prevents the occurrence of difluoroamination reactions in a discharge using N_2F_4.

The first reports on the synthesis of the compound F_3NO appeared in 1966.[35-38] The compound is called nitrogen oxytrifluoride or trifluoroamine oxide. The latter name emphasises the formal similarity of F_3NO to the amine oxides $R_3N \rightarrow O$ and is used more often. The possibility of synthesising F_3NO provides evidence as to the valency, coordination unsaturation of the nitrogen atom in nitrogen trifluoride.

Trifluoroamine oxide is formed when a discharge acts upon the following mixtures: fluorine–air[39], fluorine–nitrogen oxides[39], and nitrogen trifluoride–oxygen difluoride[40,41]. The synthesis of F_3NO by the action of a discharge on an equimolar mixture of nitrogen trifluoride and oxygen has been reported and the method has been described in greater detail in a later paper[42]. The mixture of starting materials is passed at a rate of 1.7–3.4 litre h^{-1} through a discharge tube in liquid nitrogen. A pressure of 10–15 mmHg and a current of 30–50 mA are maintained in the apparatus. Under these conditions, about 70% NF_3 reacts, the yield of F_3NO amounting to 10–15%. The reaction products are also nitrogen oxides and dioxygen difluoride. When the discharge tube is thermostatted at –78°C, trifluoroamine oxide is not formed.

The mechanism of the synthesis of F_3NO from nitrogen trifluoride and oxygen in a discharge is obscure. Since nitrogen trifluoride readily dissociates, one cannot exclude the possibility that trifluoroamine oxide is in fact one of the decomposition products of nitrogen trifluoride, formed, for example, in the following way:

$$NF_3 = {}^1/_2N_2 + {}^3/_2F_2;\ {}^1/_2N_2 + {}^1/_2O_2 = NO \qquad NO + F = NOF;\ NOF + 2F = F_3NO.$$

In this case nitrogen trifluoride serves simply as a source of fluorine and nitrogen. One can also imagine a direct synthesis of F_3NO—by the reaction of activated (atomic) oxygen with nitrogen trifluoride activated in a discharge:

$$NF_3 + O = F_3NO.$$

Molecular oxygen and certain other oxidants do not interact with nitrogen trifluoride in the absence of a discharge[42-44]. Other reactions[35-37,45-52] leading to the formation of trifluoroamine oxide do not involve the use of an electric discharge. Although it is at present difficult to state a preference for any one of the methods described for the synthesis of F_3NO, the synthesis in a discharge from nitrogen trifluoride and oxygen appears to be fairly simple and the starting materials are available.

The formation of the cation NF_4^+ also indicates the coordination unsaturation of nitrogen in the NF_3 molecule. In 1966 reports were published[52,53,54] on the preparation of two salts with this hitherto unknown cation: hexafluoroarsenate ($NF_4^+AsF_6^-$) and hexafluoroantimonate ($NF_4^+SbF_6^-$). The first compound has been obtained both in a discharge[53,55] and by heating the same starting materials under pressure[56]. In the electric-discharge synthesis of $NF_4^+AsF_6^-$ a mixture of NF_3, AsF_5, and F_2 in molar proportions of 1 : 1 : 2 was passed into a glass reactor cooled to –78°C. The initial pressure of the gaseous mixture in the reactor was about 80 mmHg. After 35–42 h, about 1 g of $NF_4^+AsF_6^-$ was obtained in the circulation system. The formation of this salt may be represented by the equation

$$NF_3 + F_2 + AsF_5 = NF_4^+AsF_6^-,$$

which postulates a heterolytic dissociation of the fluorine molecule.

IV. SYNTHESIS OF OXYGEN FLUORIDES

Oxygen fluorides with the general formula O_nF_2 (n = 2–6) are extremely reactive. They react with many substances at temperatures as low as –196°C. Polyoxygen difluorides are obtained from fluorine and oxygen in a glow discharge. Since the compounds are stable only at very low temperatures, the discharge reactor must be cooled during the synthesis.

In the preparation of dioxydifluoride O_2F_2, a mixture of gases with a ratio $F_2 : O_2 = 1 : 1$ by volume or containing a small excess of fluorine is admitted into a discharge tube cooled with liquid air or liquid nitrogen[57–60]. A current of several tens of milliamperes is maintained in the discharge. The O_2F_2 produced is condensed on the walls of the discharge tube in the form of a solid, the vapour pressure of which is 0.01 mmHg at –168°C [44]. The yield of O_2F_2 falls with increasing flow rate of the fluorine–oxygen mixture but more than half of the mixture passed through the discharge is converted into dioxygen difluoride even at specific energies of 5–7 W h litre^{-1} [11]. The synthesis of dioxygendifluoride in a glow discharge may be accompanied by the formation of ozone[44,58]. It has been shown[61] that ozone is formed in an appreciable amount only at high specific energies.

Dioxygendifluoride is not formed solely by the reaction of fluorine with oxygen in a glow discharge. The photochemical reaction of fluorine with ozone on irradiation with light of wavelength 3650 Å at –153°C yields dioxygendifluoride and oxygen difluoride[62]. On the other hand, when a mixture of fluorine and ozone is irradiated at a higher temperature (0° and 20°C), ozone decomposes with formation of oxygen[63]:

$$F_2 + O_3 + h\nu\ (3650\,\text{Å}) \rightarrow F_2 + {}^3/_2O_2.$$

Trace amounts of O_2F_2 are formed when a mixture of F_2 and O_2 is irradiated with light from a mercury lamp at a temperature of –42°C [64].

The compound with the formula O_3F_2 was apparently obtained for the first time in 1938. [65] The synthesis of O_3F_2 in a glow discharge was described in 1959. [66] The conditions for the preparation of trioxygen difluoride ("ozone fluoride") did not essentially differ in any way from the conditions for the synthesis of O_2F_2 with the exception that the initial mixture of gases for the synthesis of O_3F_2 contained three volumes of oxygen and two volumes of fluorine. Trioxygendifluoride frozen at –196°C was converted into O_2F_2 under the action of fluorine activated in the discharge. Trioxygendifluoride did not react with molecular fluorine at –196°. [66]

In 1961 the synthesis of the oxygen fluoride O_4F_2 was described[67]. To prepare this compound, a mixture of two volumes of oxygen and one volume of fluorine was introduced into a discharge tube cooled to –196°C. Tetraoxygendifluoride is a reddish-brown substance melting at –191° ± 2°C and a vapour pressure of 0.25 mmHg at –183°C. [68] On increase in temperature to –163°C, O_4F_2 decomposes into oxygen and dioxygendifluoride; rapid heating results in the explosion of tetraoxygendifluoride. An improved method for the synthesis of O_4F_2 has been described[68]. In a discharge tube, made partly of copper to improve the removal of heat, a yield of 180 mg of O_4F_2 per hour was achieved. The discharge tube was maintained at temperatures between –203 and –213°C.

The oxygen fluorides O_5F_2 and O_6F_2 were obtained from fluorine–oxygen mixtures with the reactant ratios $O_2 : F_2$ = 5 : 2 (for O_5F_2) and 3 : 1 (for O_6F_2). The discharge tube was cooled to –213°C and the power of the discharge was varied in the range 1.6–6 W. [69] Apart from fluorine–oxygen mixtures, a mixture of oxygen difluoride and oxygen was employed for the synthesis of O_2F_2, O_3F_2, and O_4F_2 in a discharge[70].

Thus the results published up till 1967 show that fluorine and oxygen react in an electric discharge with formation of oxygen fluorides O_nF_2 (n = 2–6). The preparation of a particular compound is determined by the composition of the initial fluorine–oxygen mixture and the conditions of the synthesis. Higher members of the family of polyoxygendifluorides are formed at a low current and a low discharge power, a low reactor wall temperature, and a low flow rate of the starting materials into the discharge. Subsequent investigations altered somewhat the postulates established by 1967.

The existence of the compound with the formula O_3F_2 and the possibility of its synthesis in a glow discharge were questioned. Nebgen et al.[71] concluded that trioxygendifluoride is dioxygendifluoride with "intermediate" oxygen, which is retained in dioxygendifluoride too tenaciously to be regarded as dissolved but at the same time too weakly to postulate the formation of a chemical bond. Malone and McGee[72] regarded O_3F_2 as a mixture of weakly bound radicals FO and O_2F. In his review Turner[73] expressed well founded doubts concerning the existence of trioxygendifluoride and substances with the empirical formulae O_5F_2 and O_6F_2.

It has been shown[74] that the so-called trioxygendifluoride is a mixture of O_2F_2 and O_4F_2 in equilibrium with the radicals O_2F, which decompose on raising the temperature:

$$\begin{array}{l} [O_2F_2,\quad O_4F_2] \\ \qquad\quad \downarrow\downarrow \\ \qquad\quad 2OOF \rightarrow O_2F_2 + O_2 \cdot \end{array}$$

An additional study[75] on the existence of the species O_3F_2 by ^{19}F and ^{17}O NMR spectroscopy and also the study of the formation of dioxygenyl tetrafluoroborate from boron trifluoride and trioxygendifluoride confirmed these conclusions of Solomon et al.[74] It was shown[75] that the models[71,72] proposed for O_3F_2 are incorrect.

Another important result obtained recently is a development of a method for the synthesis of dioxygendifluoride not involving an electric discharge. The preparation of O_2F_2 by the radiolysis of a mixture of liquid fluorine and oxygen at –196°C was reported[76]. The synthesis was described in detail in a later communication[77]. The starting materials were subjected to the action of 3 Mev bremsstrahlung. Goetschel et al.[77] were probably the first to obtain pure dioxygendifluoride. The pure compound in the solid state is coloured yellow and not orange as usually stated in earlier communications. The melting point of O_2F_2 (–154.1°C) [76,77] differs appreciably from the value found previously (–163.5°C) [56]. Dioxygendifluoride without an admixture of O_2F radicals is diamagnetic. Data have been presented[77] indicating the possible existence of the radical O_4F.

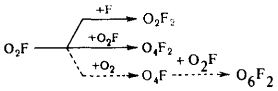
The synthesis of dioxygendifluoride in a glow discharge in large amounts does not require any special equipment apart from a single-phase high-voltage transformer. The synthesis in an electric discharge has the advantage of simplicity over the radiolysis of liquid fluorine and oxygen.

The synthesis of oxygen fluorides in an electric discharge involves the intermediate formation of the O_2F radical. The existence of the O_2F radical (dioxygenmonofluoride) has now been reliably established[78–87]. The radical is relatively long-lived at –180°C [82], its average lifetime at temperatures between –180 and –160°C has been estimated[85] as 20 min. The study where it was shown that the O_2F radical exists in the gas phase at room temperature is of great interest[88]:

$$O_2BF_4(\text{solid}) \rightleftharpoons O_2F(\text{gas}) + BF_3(\text{gas}).$$

The available data[61,75,77–79] can be rationalised in general terms by the following mechanism for the synthesis of oxygen fluorides:

$$F_2 + \text{energy} \longrightarrow 2F;\ \ F + O_2 \longrightarrow O_2F$$



The energy necessary for the dissociation of fluorine is imparted to the F_2 molecule by photolysis, radiolysis, or in a discharge. The reaction pathway indicated by a dashed line is regarded as probable.

The synthesis in a discharge of OF_2, which is thermally stable up to 200–250°C, has not been described. The action of a glow discharge on fluorine–oxygen mixtures at a low pressure with the reactor cooled in liquid nitrogen does not apparently lead to success. The synthesis of O_2F_2, which has the advantage that its occurrence does not require the dissociation of molecular oxygen, competes with the synthesis of OF_2, which does require such dissociation.

V. SYNTHESIS OF NOBLE GAS FLUORIDES

In 1962 the existence of noble gas compounds was discovered[89]. Certain noble gas fluorides were obtained in an electric discharge soon after this discovery. In the synthesis of xenon fluorides the walls of the discharge reactor or an insert introduced into the reactor are cooled to –78°C. The compounds obtained are synthesised on the cold surface in the reaction zone.

In the synthesis of XeF_2 using a discharge produced by an induction coil, mixtures of gases with $Xe : F_2$ ratios ranging from 1 : 1 to 1 : 3 were employed. The yield of the product reached 0.1 g h^{-1}. [90,91] XeF_2 is obtained in higher yields from a mixture with $Xe : F_2 = 1 : 1$ (by volume) in a glow discharge[92]. For a mixture flow rate of about 1 litre h^{-1} and a current of 30–90 mA, 3.4–3.7 g of xenon difluoride may be obtained after 1 h in the discharge[92]. Xenon difluoride has been obtained[93] by passing mixtures containing approximately equal volumes of Xe and CF_4 through a glow discharge. In this case the yield of XeF_2 was 0.05–0.15 g h^{-1} for a gas flow rate of 1–2 litre h^{-1}.

In the synthesis of xenon tetrafluoride a mixture with $Xe : F_2 = 1 : 2$ (by volume) was introduced into the discharge at a rate of about 0.14 litre h^{-1}. [94] The yield of XeF_4 reached 1.5 g after 3.5 h in the discharge at a current of 12–31 mA. Xenon hexafluoride has been synthesised from a mixture with $Xe : F_2 = 1 : 3$ (by volume)[94]. The mixture was passed into the discharge at a rate of 0.016 litre h^{-1}. [95] The possibility of synthesising xenon oxide fluorides by reacting xenon with oxygen difluoride in a discharge has been reported[44,95].

Apparently in the synthesis of xenon fluorides in a discharge the composition of the product is determined to some extent by that of the initial mixture of reactants, since in the synthesis of XeF_2, XeF_4, and XeF_6, mixtures with $Xe : F_2 = 1 : 1$, 1 : 2, and 1 : 3 respectively were employed. Probably the xenon difluoride formed initially is fluorinated to XeF_4 or XeF_6 if the fluorine content in the initial mixture exceeds 50 vol.% and the gases are passed into the discharge at a sufficiently low rate.

In the synthesis of xenon fluoride the dissociation of fluorine is a process requiring activation. The excitation of xenon atoms in the discharge[96] is not an essential condition for the synthesis of the fluorides.

Xenon difluoride may be synthesised photochemically by irradiating mixtures of xenon and fluorine or oxygen difluoride with sunlight or ultraviolet light[97–101]. Gaseous fluorine begins to absorb in the visible region, and this absorption reaches a maximum in the near ultraviolet at 2845 ± 5 Å. [102] The excitation of noble gas atoms requires a very high expenditure of energy. For example, the energies required to excite xenon atoms to metastable and resonance states are respectively 8.32 and 8.45 eV, [103] i.e. in order to excite 1 g-atom of xenon into either of these states more than 190 kcal would be required. Radiation with an energy of about 190 kcal per einstein has a wavelength of about 1500 Å, corresponding to the Schumann ultraviolet region, which is difficult to attain experimentally. The synthesis of XeF_2 by irradiating with daylight mixtures of fluorine and xenon in Pyrex reaction vessels[98,99,101] confirms the possibility of the reaction of fluorine atoms with unexcited xenon atoms. The fluorination of xenon at low temperatures with the aid of O_2F_2 [104,105] or O_4F_2 [68] in all probability also constitutes a reaction of atomic fluorine, formed as a result of the breakdown of oxygen fluorides, with unexcited xenon atoms.

When a high-frequency (25 MHz) discharge acts on mixtures of xenon, fluorine, and silicon or carbon tetrachloride, xenon difluoride, identified by mass spectrometry, is formed[106]. According to Meinert[106], the XeF_2 formed initially exchanges halogen atoms with $SiCl_4$ or CCl_4. When a mixture of xenon with chlorine and fluorine is exposed to a high-frequency (25 MHz) discharge or ultraviolet light, chlorine tri- and penta-fluorides are formed and not xenon halides[107].

In the fluorination of krypton the discharge reactor must be cooled to –183° or –196°C. Krypton fluoride was obtained in a discharge at a current of 24–37 mA and a pressure of 7–12 mmHg [95,108]. A mixture with $Kr : F_2 = 1 : 2$ (by volume) was employed for the synthesis and it was thought[95,108] that the product was krypton tetrafluoride. It soon became known[109] that, under conditions corresponding to those described above[108], krypton difluoride and not tetrafluoride is obtained. Krypton difluoride was synthesised in a circulation apparatus with a Pyrex discharge tube[109]. A mixture of fluorine and krypton with $Kr : F_2 = 1 : 2$ or 1 : 1.1 was admitted into the apparatus, the current being 15–20 mA. The yield of

KrF_2 reached 75% relative to the krypton taken for the synthesis, 0.25 g of KrF_2 being obtained after 1 h. To avoid the contamination of krypton tetrafluoride by silicon tetrafluoride, it has been suggested that KrF_2 be synthesised in a metallic discharge reactor[110].

The synthesis of krypton difluoride in a glow discharge is the only convenient method for the preparation of this compound. The photochemical reaction of krypton and fluorine[111] is very slow: after 1 day 2–3 mg of KrF_2 is formed from a mixture of the gases in a 2 litre vessel at atmospheric pressure.

VI. SYNTHESIS OF CHLORINE PENTAFLUORIDE.

The halogen derivatives of fluorine are obtained from the appropriate elements in the cold or with moderate heating. During the search for methods of synthesising higher chlorine fluorides, the possibility of preparing chlorine pentafluoride in a discharge was investigated. Chlorine pentafluoride is formed when a mixture of chlorine and fluorine or certain chlorine- or fluorine-containing compounds are exposed to an electric discharge (an a.c. or d.c. discharge or a discharge produced by a radiofrequency oscillator)[112]. In the synthesis of ClF_5 from fluorine and chlorine, mixtures were employed in which the fluorine content exceeded the stoichiometric proportion. An example of the synthesis of ClF_5 in a glow discharge where the initial mixture contained 10 volumes of fluorine for one volume of chlorine has been described[112,113]. The mixture of gases was passed at a rate of 1.5 litre h^{-1} through a discharge tube cooled to −78°C. A pressure of 30 mmHg was maintained in the apparatus. The reaction products—chlorine mono-, tri-, and penta-fluoride—were condensed in a trap at −196°C. The yield of ClF_5 was approximately 1 cm^3 (probably 1 cm^3 of gaseous ClF_5 is meant) in 4 litres of the initial mixture of gases[113]. The synthesis of ClF_5 in a discharge is interesting only as yet another example of reactions with participation of fluorine.

---o0o---

The literature available on gas-discharge reactions deals mainly with traditional problems in gas electrochemistry, such as the synthesis of ozone, oxidation of nitrogen, and the cracking of hydrocarbons. The number of studies dealing with the reactions of halogens and halogen-containing compounds in a discharge has increased considerably in the last decade, but these reactions nevertheless still remain relatively little investigated.

Little attention has been devoted to the kinetics of the reactions of fluorine and fluorides in a discharge. The description in certain papers of "typical" experiments frequently illustrates only the reaction occurring in the discharge, providing information about the results of an individual experiment but not about the course of the reaction under conditions other than "typical". Non-metal fluorides are obtained mainly in a.c. glow discharges at mains frequency. The preparative scope of discharges of other types is virtually unknown.

Autocondensation of Cyclic Ketones

S.V.Svetozarskii and E.N.Zil'berman

The reactions of cyclohexanone and 2-, 3-, and 4-methylcyclohexanones, cyclopentanone, and cycloheptanone, mainly under the action of acid and alkaline reagents, have been examined. The conditions governing the formation and the structures of the dimeric, trimeric, and polymeric autocondensation products—αβ-, βγ-, and other unsaturated ketones, hydroxyketones, compounds with furan or hydrogenated furan rings, dihydropyrans, hydrocarbons such as dodecahydrotriphenylene, and other compounds—have been discussed.
The bibliography includes 102 references.

CONTENTS

I. INTRODUCTION

Cyclohexanone is the starting material in the manufacture of ϵ-caprolactam. Under the conditions of the synthesis[1] of cyclohexanone by catalytic dehydrogenation of cyclohexanol[2] or the oxidation of cyclohexane, and during storage[3], and in subsequent conversion of cyclohexanone into ϵ-caprolactam[4], side reactions occur, including autocondensation reactions. As a result impurities appear in the ϵ-caprolactam which impair its quality[5] as a monomer for the manufacture of polyamide resins. Moreover, cyclohexanone has found wide applications in organic synthesis as a solvent in the processing of polymers. Here too, when cyclohexanone is heated or comes into contact with various chemical reagents, side autocondensation reactions are possible.

The cyclohexanone autocondensation products have also found some applications. For example, it has been suggested that they be used for the stabilisation of poly(vinyl chloride)[6] and as intermediates[7] or starting materials[8] in the manufacture of plastics, herbicides[9,10], insecticides[11], and polystyrene plasticisers[12].

In the present review an attempt is made to give a general account of the conditions governing the formation and structure of the cyclohexanone autocondensation products. The autocondensation of other cyclic ketones, many of which have found practical application although on a more restricted scale than cyclohexanone, is also considered.

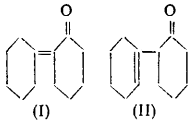
Among cycloalkanones, cyclohexanone is the most reactive, as can be seen, for example, from the rate of formation of oximes or cyanohydrins in the reactions of these cyclic ketones with hydroxylamine and hydrogen cyanide respectively. The differences in the reactivities of cycloalkanones with 5,6, and 7 carbon atoms are associated with their stereochemical structures. While cyclohexanone exists predominantly in the unstrained chair form, cyclopentanone and cycloheptanone molecules are extremely strained systems which in the case of rings with 7 and more members is due to the interaction between hydrogen atoms and the carbonyl oxygen (not linked directly) and in 5-membered rings there is classical (Baeyer) ring strain. The characteristics of the structure of cycloalkanones are reflected in their behaviour in autocondensation reactions. Indeed the autocondensation reactions of cyclohexanone are more varied than those of cyclopentanone and cycloheptanone. There are no literature data on the autocondensation of cyclic ketones with higher molecular weights.

II. DIMERIC AUTOCONDENSATION PRODUCTS

The autocondensation of cycloalkanones takes place predominantly under the influence of condensing agents. Those employed are substances with acid or basic properties.

I. Ketones

Cyclohexanone. In the autocondensation of cyclohexanone a liquid unsaturated product A with the composition $C_{12}H_{18}O$ is formed most readily. The unsaturated ketone A was obtained for the first time by Wallach[13] in 1896 by allowing cyclohexanone to stand for a long time with sodium ethoxide. Since the ketone A can have the structure of either 2-cyclohexylidenecyclohexanone (I) or 2-Δ^1-cyclohexenylcyclohexanone (II), the structure of the liquid ketone A began to be investigated from that time and a search was made for other methods of its synthesis.



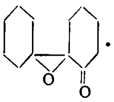
(I) (II)

The liquid ketone A is obtained by the autocondensation of cyclohexanone in the presence of sodamide[14,15], by heating with potassium hydroxide[16-19], on prolonged standing with sodium methoxide in methanol[20], on refluxing with concentrated sulphuric acid[17,21] and *p*-toluenesulphonic acid, and by reaction with 60% sulphuric acid[22] or 70% perchloric acid[23]. It is also formed from cyclohexanone on prolonged refluxing[24], on heating under pressure[25], on heating with lithium phosphate[26], calcium hydride[27,28], zinc chloride[29], lead dioxide[30], alumina (under pressure)[31], aluminium chloride[32], boron chloride[33], boron trioxide[34], aluminium phenoxide[35], tri-isobutylaluminium[36], acetoxydi-isobutylaluminium[37], and phosphorus pentoxide[16], by interaction with titanium tetraisopropoxide[38], dibromogermane, or polymeric dichlorogermane[39], by heating with cyclohexanone azomethines[8] and ion-exchange resins[7,40-42], by ultraviolet irradiation (in the presence or absence of hydrogen chloride) in monochloroacetone solution[43], etc.

The ketone A is also formed as a side product in various reactions of cyclohexanone, for example in the condensation with methanol[44], trichlorogermane[38], acrylonitrile[45], 4-vinyl pyridine[46], etc.

Either structure (I) or (II) has been attributed to the liquid ketone A or it was regarded as a mixture of ketones (I) and (II). Various reactions have been employed to establish the structure. In the hydrogenation in the presence of solid catalysts[47], reaction with benzaldehyde[29], condensation with ethyl sodiocyanoacetate[48], and in the Wolf–Kishner reaction[49], the liquid ketone A reacts as an $\alpha\beta$-unsaturated ketone (I). In the reaction with nascent hydrogen[47,50], in oxidation with ozone[48] or potassium permanganate[51], and in methylation with methyl iodide[48], the ketone A reacts as a $\beta\gamma$-unsaturated ketone (II). The absence of appreciable exaltation of molecular refraction[42,51] was regarded as proof of the endocyclic position of the double bond in the ketone.

In 1942 Reese[51] obtained a solid ketone B (m.p. 57°C) with the same composition as the liquid ketone A. There is no doubt about the position of the double bond in the $\alpha\beta$-position in the ketone B and therefore Reese believed that the liquid ketone A is a $\beta\gamma$-unsaturated compound; however, when the ketone A was oxidised with hydrogen peroxide, a small amount of compound (III), which is a product of the addition of oxygen to the exocyclic double bond, was isolated. The same compound is formed in a quantitative yield when the ketone B is oxidised with hydrogen peroxide[51]:



(III)

Kon and Nutland[48] showed that the products of the reaction of the liquid ketone A with semicarbazide is a mixture of two semicarbazones with high (main substance) and low (small amount) melting points, which they believe to differ in the position of the double bond. However, these investigators[48] did not succeed in obtaining the ketone in any one form from the high-melting semicarbazone: on reaction with semicarbazide, the regenerated liquid ketone again gave a mixture of semicarbazones. The product of the reaction of the liquid ketone A with 2,4-dinitrophenylhydrazine is also a mixture[52] of two hydrazones: orange (a colour characteristic of a ketone with an endocyclic double bond) and red (corresponding to an $\alpha\beta$-unsaturated carbonyl compound). When this mixture of hydrazones is allowed to stand with a solution of sodium hydroxide in methanol, the red form of the hydrazone is completely converted into the orange form.

Spectroscopic studies on the ketones A and B showed that their ultraviolet spectra have the same absorption maximum at 254.0–257.5 nm,[53–58] which is characteristic of $\alpha\beta\beta$-trisubstituted $\alpha\beta$-unsaturated carbonyl compounds[59]. However, the extinction coefficients of the two ketones differ—the value for the solid ketone B [56] is 6500 and that for the liquid ketone A is smaller[19,55,58], amounting to 680–800.

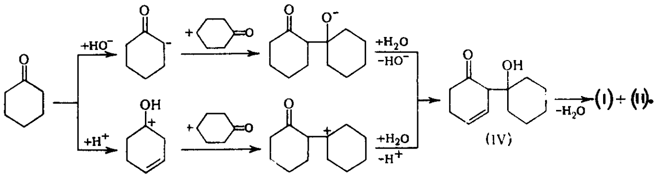
The infrared spectrum of the solid ketone B shows only one maximum[56,57] at 1670–1680 cm^{-1}, corresponding to the $\alpha\beta$-unsaturated ketone (I). At the same time the infrared spectrum[57] of the liquid ketone A has an intense band at 1710 cm^{-1}, characteristic of the $\beta\gamma$-unsaturated ketone (II), and a weak band at 1680 cm^{-1}.

The NMR study of the ketones A and B showed[57] that the spectrum of the solid ketone B contains no signals due to vinylic protons, which the spectrum of the liquid ketone A revealed the presence of a vinylic proton.

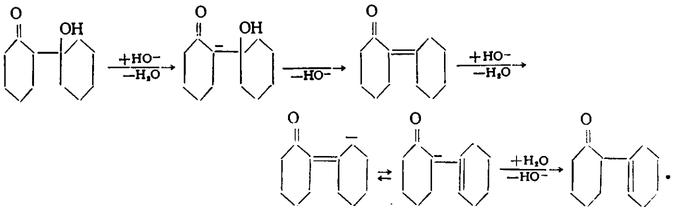
Thus the available data on the chemical and physicochemical properties of the liquid ketone A lead to the conclusion that it is a mixture not of two stereoisomers[54] but of two structural isomers with structures (I) and (II). The content of the solid ketone in this mixture is various—55% according to some data[52] and 7–20% according to others[19,57,60], which can be explained by the use of different methods of synthesis and identification. The variable composition of the liquid ketone A is evidently responsible for the wide variation of the published literature values of the constants for the product: b.p. [8,33], 142–150°C at 15 mmHg, refractive index[16,45] n_{D}^{20} = 1.5048–1.5112, and specific gravity[32,61] d_4^{20} = 1.0010–1.0072.

The fact that the liquid ketone A behaves in many reactions as a ketone with structures (I) or (II) can probably be accounted for by the migration of the double bond in the course of the reaction.

The formation of a mixture of ketones (I) and (II) in the autocondensation of cyclohexanone under the influence of bases and acids can be represented by the following mechanism:

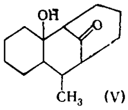


The $\alpha\beta$-unsaturated ketone (I) formed initially by the dehydration of the hydroxyketone (IV) isomerises[19] to the $\beta\gamma$-ketone (II):



Owing to the similarity of the boiling points of ketones (I) and (II), they cannot be separated by vacuum distillation. Bibo[19] subjected the liquid product A to low-temperature crystallisation and isolated a compound with m.p. 9°C and an ultraviolet absorption maximum at 291 nm ($\epsilon_{\max}$ = 46), which is characteristic of an isolated C=O group. The ultraviolet spectrum of this compound did not show the presence of bands corresponding to the C=C–C=O group and the product is probably the pure $\beta\gamma$-unsaturated ketone (II).

The autocondensation of aliphatic ketones is known to give rise together with unsaturated carbonyl compounds also to stable hydroxyketones, for example, acetone gives the diacetone alcohol[62] and triacetone dialcohol[38], which can be readily converted into $\alpha\beta$-unsaturated ketones—mesityl oxide and phorone. It might have been expected that, under the cyclohexanone autocondensation conditions, the hydroxyketone (IV) forms as an intermediate in the synthesis of ketones (I) and (II). However, until recently the hydroxyketone (IV) could not be isolated from the cyclohexanone autocondensation products. The first mention of the hydroxyketone (IV) appeared in 1934 when the reaction of cyclohexanone with Grignard reagents (phenylmethyl aminomagnesium bromide[63] and t-butylmagnesium bromide[64]) was achieved. The compound isolated from the reaction products melted at 56°C and on reaction with semicarbazide yielded the semicarbazone[63] of the hydroxyketone (IV) or the liquid product A. In 1952 Stanek[16] reported that, in the autocondensation of cyclohexanone in the presence of alcoholic potassium hydroxide, he isolated a solid hydroxyketone (m.p. 160°C)—2-(1-hydroxycyclohexyl)cyclohexanone (IV). However, Plešek and Munk[65] showed convincingly that this compound is in fact 2-hydroxy-4-methyl-2,3-cyclohexanobicyclo [1,3,3] nonan-9-one (V)--the product of the interaction of two cyclohexanone molecules with one acetaldehyde molecule formed from ethanol under the reaction conditions:

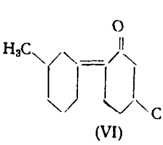


(V) .

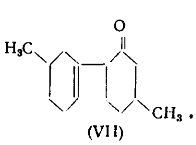
Bibo[19] isolated from the products of the reaction of cyclohexanone with powdered potassium hydroxide (20°C) a crystalline compound (m.p. 32–33°C) with the composition $C_{12}H_{20}O_2$, which may be vacuum-distilled (0.1 mmHg) almost without decomposition. An isolated carbonyl group (λ_{max} = 290 nm, ϵ_{max} = 21), a hydrogen-bonded OH group (3528 cm^{-1} band in the infrared spectrum), and a hydrogen-bonded C=O group (1695 cm^{-1} band) were found in this compound. On the basis of these data, the structure of the hydroxyketone (IV) was attributed to the compound $C_{12}H_{20}O_2$. In addition, Bibo[19] repeated the reaction of cyclohexanone with t-butylmagnesium bromide described by Ivanoff and Spassoff[64] and isolated from the reaction mixture a compound $C_{12}H_{20}O_2$ with m.p. 32–33°C, which did not depress the melting point when mixed with the compound having the same composition synthesised by the action of powdered potassium hydroxide on cyclohexanone.

Bibo showed[19] by thin-layer chromatography that in the autocondensation of cyclohexanone in the presence of potassium hydroxide at 20°C the reaction mixture contained the hydroxyketone (IV), while in the autocondensation of cyclohexanone in the presence of the same condensing agent but in boiling toluene solution with continuous removal of the water formed in the reaction the hydroxyketone (IV) was already absent from the reaction product in the very early stages and only the ketones (I) and (II) could be detected.

Alkylcyclohexanones can also undergo autocondensation with formation of dimeric products. When 3-methylcyclohexanone was allowed to stand with sodium ethoxide, on heating with calcium hydride[27] and potassium hydroxide[66], and on irradiation of 3-methylcyclohexanone in the presence of hydrogen chloride in chloroacetone solution[43], a liquid ketone with the composition $C_{14}H_{22}O$ was obtained, to which the structure of either the αβ-unsaturated carbonyl compound (VI) [27,67] or the βγ-unsaturated carbonyl compound (VII) [51,66,68] was attributed. At the same time Reese[51] synthesised a solid (m.p. 71°C) ketone with the composition $C_{14}H_{20}O$, in which the carbon–carbon double bond is in the αβ-position relative to the carbonyl group [compound (VI)]:

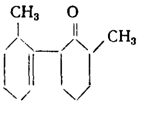


(VI)

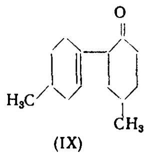


(VII)

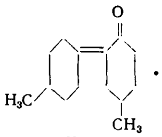
The corresponding liquid ketones, to which structures (VIII) and (IX) were attributed, were synthesised by heating 2-methylcyclohexanone with potassium hydroxide[66] and 4-methylcyclohexanone with barium hydroxide[66] or when the ketones were exposed to ultraviolet light and hydrogen chloride in monochloroacetone solution[43]:



(VIII)



(IX)

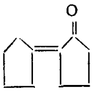


(X)

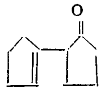
It has been stated[36] that the dimeric product of the autocondensation of 4-methylcyclohexanone has the structure of the αβ-unsaturated ketone (X). However, it should be noted that the liquid dimeric products of the autocondensation of 2-, 3-, and 4-methylcyclohexanones as well as the liquid product A of the autocondensation of cyclohexanone are mixtures of ketones with αβ- and βγ-double bonds. The infrared spectra of these compounds have bands at 1718–1720 and 1692–1695 cm^{-1} characteristic of the C=O and C=C–C=O groups respectively.

Cyclopentanone. One dimeric product of the autocondensation of the ketone is known. The liquid dimeric autocondensation product C with the composition $C_{10}H_{14}O$ is formed from cyclopentanone on heating under the conditions of its synthesis from adipic acid[69], in the presence of sodium ethoxide[13,70,71] and methoxide[72], potassium t-butoxide[73,74], potassium hydroxide[16,71,75-77], and alcoholic potassium hydroxide[16], on prolonged standing with sodium hydroxide[78], on reaction with aqueous alcoholic sodium hydroxide[79], on heating with a complex of n-butyllithium and trimethylboron[72], on saturating cyclopentanone with hydrogen chloride[71,80], on heating with sulphuric acid[81], calcium hydride[27] or carbide[27,82], lithium phosphate[26], and tri-isobutylaluminium[36], and on passing cyclopentanone vapour over alumina[75,77]. The liquid product C is obtained also by the reaction of cyclopentanone with aluminium chloride[83], t-butylmagnesium chloride[84], isopropylmagnesium halides[85,86], aluminium and magnesium amalgam[87], phosphorus pentoxide or polyphosphoric acid[70], etc. The product C is formed when cyclopentanone is reduced with aluminium isopropoxide[88], under the conditions of the reaction with acetone[89], etc.

The exaltation of the molar refraction of the liquid product C, calculated for 2-cyclopentylidenecyclopentanone (XI) [48,82] has the normal value. Nevertheless on ethylation the product C behaves as a βγ-unsaturated carbonyl compound (XII),[48] while the reaction with ethyl sodiocyanoacetate and oxidation with oxone lead to the formation of compounds characteristic of the αβ-unsaturated ketone (XI):[48]



(XI)



(XII)

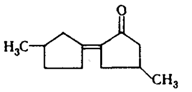
Moreover, Kon and Nutland[48] showed that, when the product C interacts with semicarbazide, a mixture of high-melting and low-melting semicarbazones in proportions of 20 : 1 is formed, and they suggest that the semicarbazones differ in the position of the double bond. The liquid carbonyl compound isolated from the high-melting semicarbazone was converted on treatment with semicarbazide into the same mixture of semicarbazones in the same proportions.

The ultraviolet spectrum of the liquid product C has an absorption maximum (at 254–259 nm)[53,56,79], characteristic of $\alpha\beta\beta$-trisubstituted $\alpha\beta$-unsaturated carbonyl compounds[59]. The extinction coefficient is high[53,56,79] ($\epsilon_{\max}$ = 10 700–12 600) and corresponds to $\alpha\beta$-unsaturated ketones[59]. The infrared spectrum shows an intense band[56] (1700 cm^{-1}) due to an $\alpha\beta$-unsaturated ketone. At the same time the literature values of the specific gravity[75,76] d_4^{20} vary in the range 1.0172–1.0217 and the refractive indices[75,76] n_D^{20} vary in the range 1.5098–1.5211.

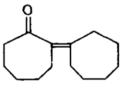
With rare exceptions[26], the structure of 2-cyclopentylidenecyclopentanone (XI) is attributed to product C. However, on the basis of the data quoted one cannot exclude the possibility that it contains also a small amount of 2-Δ'-cyclopentenylcyclopentanone (XII).

It has been stated that in the interaction of cyclopentanones with phenylmethyl aminomagnesium bromide[63], t-butylmagnesium bromide, or isopropylmagnesium bromide[64], the primary autocondensation product is a dimeric hydroxyketone. However, there are no reliable analytical data confirming the structure of this hydroxyketone.

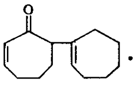
Under the action of hydrochloric acid[13] or on heating with calcium hydride[27], 3-methylcyclopentanone is converted into the unsaturated ketone (XIII):



(XIII)



(XIV)

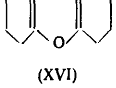


(XV)

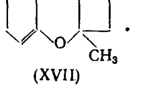
When cycloheptanone is heated with lithium phosphate[26], potassium t-butoxide[73], or potassium hydroxide[90], an autocondensation product with the composition $C_{14}H_{22}O$ is obtained, which is regarded as a mixture of 2-cycloheptylidenecycloheptanone (XIV) and 2-Δ'-cycloheptenylcycloheptanone (XV), since the infrared spectrum showed absorption bands at frequencies of 1720 and 1692 cm^{-1} (see p. 555).

2. Oxygen-containing Heterocyclic Compounds

In 1964 Svetozarskii et al.[90] showed that oxygen-containing heterocycles may be formed in the autocondensation of cyclohexanone. 1,2,3,4,5,6,7,8-Octahydrodibenzofuran (XVI) and 2-methyl-2,3-cyclopentano-4,5-cyclohexeno-(Δ^5)-2,3,4,5-tetrahydrofuran (XVII) were isolated from the products of the reactions of cyclohexanone, the ketone (I),[91] or the liquid mixture[66] of the ketones (I) and (II) (product A) with a large amount of concentrated sulphuric acid in the absence of a solvent[90] or in the presence of benzene[66]:



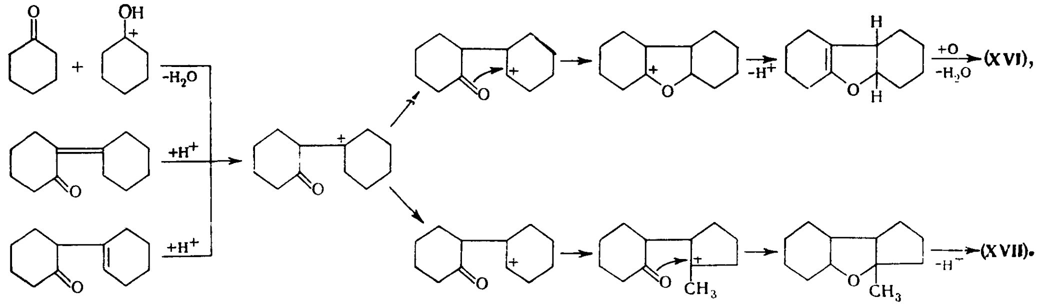
(XVI)



(XVII)

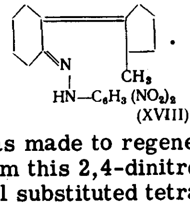
The substituted tetrahydrofuran (XVII) and octahydrodibenzofuran (XVI) are formed in small amounts as side products under conditions of the Beckmann rearrangement of cyclohexanone oxime under the influence of oleum and when the product of the rearrangement comes into contact subsequently with cyclohexanone[4]. Compound (XVI) is obtained in small amounts[92] also when a mixture of the $\alpha\beta$- and $\beta\gamma$-unsaturated ketones (I) and (II) is passed over a zinc–iron catalyst at 450°C.

The formation of compounds (XVI) and (XVII) under the conditions of the autocondensation of cyclohexanone under the influence of concentrated sulphuric acid can be explained by the following mechanism[90,91]:



In this reaction the oxidising agent is probably sulphuric acid.

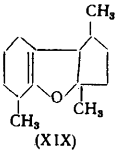
On reaction with 2,4-dinitrophenylhydrazine, compound (XVII) gives rise[90] to the hydrazone of an $\alpha\beta$-unsaturated ketone (XVIII):



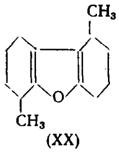
(XVIII)

When an attempt was made to regenerate the $\alpha\beta$-unsaturated ketone from this 2,4-dinitrophenylhydrazone (XVIII), only the initial substituted tetrahydrofuran (XVII) was isolated[90]. Probably the steric positions of the groups in 2-(2-methylcyclopentylidene)cyclohexanone are so unfavourable that ring closure to the more stable tetrahydrofuran derivative (XVII) takes place readily. The instability of this ketone is in all probability due to the powerful interaction of the carbonyl oxygen with the methyl group, which entails a considerable deformation of the $\pi-\pi$ conjugated system leading to the migration of the double bond with simultaneous cyclisation to the substituted tetrahydrofuran (XVII).

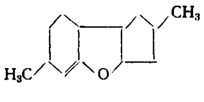
2-, 3-, and 4-Methylcyclohexanones undergo similar reactions. Two compounds (XIX) and (XX) were isolated[66] from the products of the reaction of 2-methylcyclohexanone with concentrated sulphuric acid[66], while in the case of 3-methylcyclohexanone[66,91] and 4-methylcyclohexanone[66], only the substituted tetrahydrofurans (XXI) and (XXII) respectively were obtained:



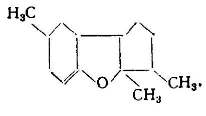
(XIX)



(XX)



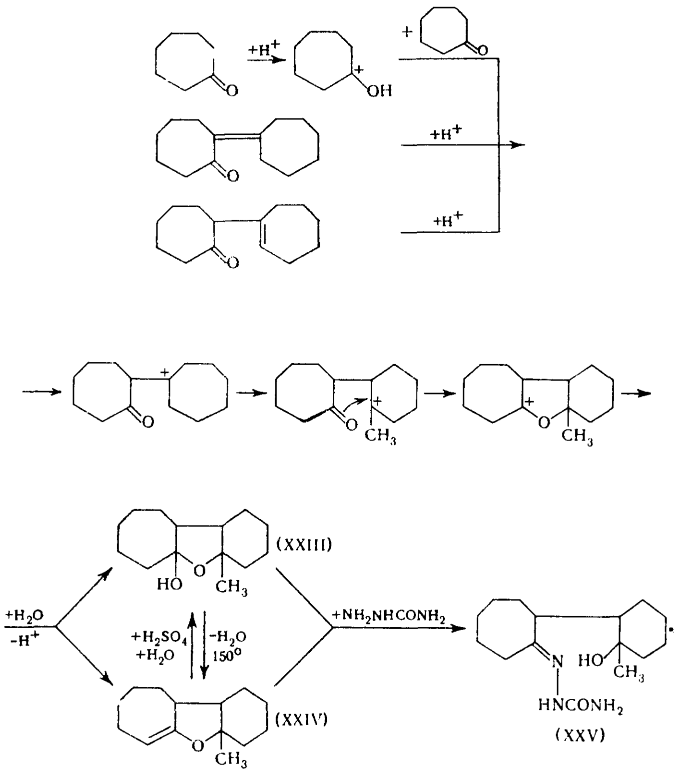
(XXI)



(XXII)

When cycloheptanone or the dimeric product of its autocondensation in the presence of sulphuric acid is allowed to stand[93], rearrangement with intramolecular cyclisation also takes place. A distinctive feature of this reaction is the formation together with the liquid unsaturated tetrahydrofuran derivative (XXIII) of a solid substituted tetrahydrofuran derivative (XXIV) without a double bond but containing an associated hydroxy-group.

The scheme below shows that compounds (XXIII) and (XXIV) can be interconverted and yield the same semicarbazone (XXV) on reaction with semicarbazide:



It is noteworthy that the contraction of one of these rings on autocondensation of cycloheptanone may lead to the formation not of a six-membered ring, as shown in the mechanism [compounds (XXIII) and (XXIV)], but a five-membered ring[93]. To determine more accurately the structure of compounds (XXIII) and (XXIV), additional studies are necessary.

Thus the common reaction of the cycloalkanones considered in this section is autocondensation with formation of dimeric unsaturated carbonyl compounds, which are mixtures of ketones with endocyclic and exocyclic carbon–carbon double bonds.

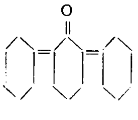
Cycloalkanones behave differently in reactions with concentrated sulphuric acid: cyclohexanone, 2-, 3-, and 4-methylcyclohexanones, and cycloheptanone are converted into tetrahydrofuran derivatives, while cyclopentanone and 2-ethylcyclohexanone do not enter into this reaction[66]. The inertness of cyclopentanone is probably due to the fact that the conversion of five-membered rings into four-membered rings is unfavourable owing to energy factors. A product of type A also was not obtained from 2-ethylcyclohexanone, probably because of the hindrance of the carbonyl oxygen by the ethyl group[66] in the 2-position.

III. TRIMERIC AND POLYMERIC AUTOCONDENSATION PRODUCTS

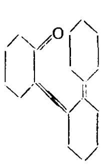
1. Ketones

As early as 1896 Wallach[13] isolated from the products of the reaction of cyclohexanone with sodium ethoxide a steam-involatile liquid substance, which set on standing into a yellow crystalline mass. Wallach suggested that the substance is an unsaturated ketone with the formula $C_{18}H_{26}O$ formed by the condensation of three cyclohexanone molecules with evolution of two water molecules. On heating cyclohexanone in methanol solution with concentrated sulphuric acid, Mannich[21] obtained a liquid product D with the composition $C_{18}H_{26}O$, from which no solid compound of any kind could be obtained even after prolonged standing. The product D was also synthesised by the autocondensation of cyclohexanone under the influence of zinc chloride[29], alumina[31], titanium tetraisopropoxide[38], ion-exchange resins[40], 60% sulphuric acid[91], etc.

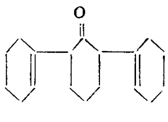
The liquid product D has been regarded[21,31,38] as an unsaturated ketone—2,6-dicyclo hexylidenecyclohexanone (XXVI):



(XXVI)

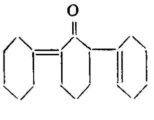


(XXVII)

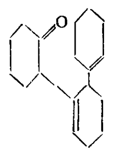


(XXVIII)

The structures of the $\alpha\beta$- $\gamma\delta$-unsaturated ketone[29] (XXVII) and 2,6-dicyclohexenylcyclohexanone (XXVIII)[16] have also been attributed to the trimeric autocondensation product of cyclohexanone. It has been stated[18,36] that the product D is a mixture of the ketones (XXVI) and (XXIX):



(XXIX)



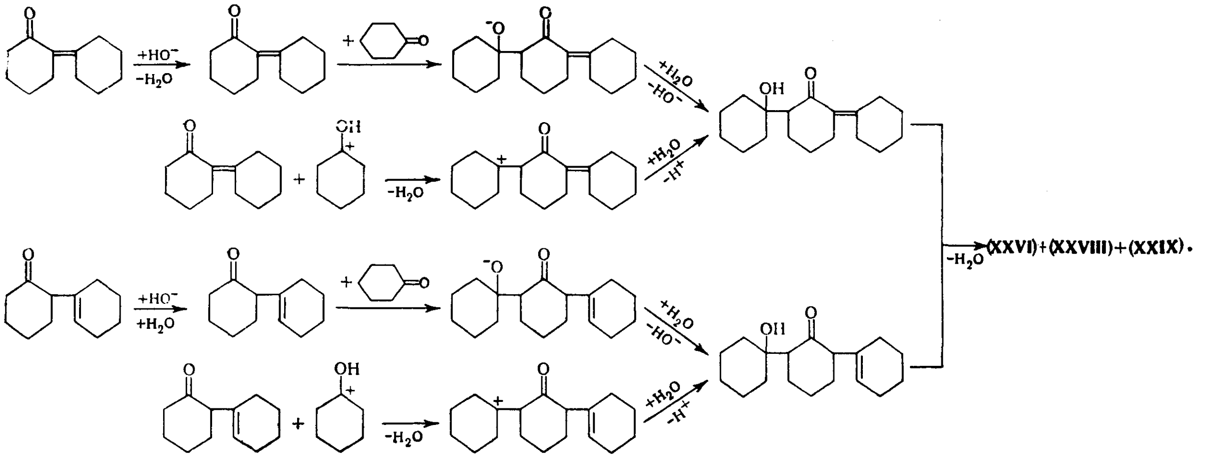
(XXX)

Among the structures quoted, that of compound (XXVII) is quite unacceptable, since this ketone cannot exist owing to steric hindrance[94]. The other hypothesis also proved to be incorrect. The most correct appears to be the view of Munk and coworkers[56,95], who showed that the liquid product D is a mixture of the ketones (XXVIII) and (XXIX). The infrared spectrum of this product does not show a band at 1662 cm^{-1}, which would have been characteristic of the ketone (XXVI), but bands at 1716 cm^{-1} (isolated C=O group) and 1685 cm^{-1} (C=C–C=O group) have been found.

Further studies on the composition of the liquid product D, obtained by refluxing cyclohexanone in toluene solution with sodium hydroxide, with continuous removal of the water formed, showed[19] that it is a mixture of three ketones: *cis*-(XXVIII) (m.p. 79°C), *trans*-(XXVIII) (colourless liquid), and (XXIX) with a very small amount of the ketone (XXVI).

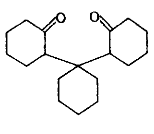
The *cis*-isomer of the ketone (XXVIII) was obtained as a pure solid compound also by other investigators[17,18]. It is noteworthy that Mleziva[17], who was the first to isolate this ketone, erroneously attributed to it the structure of compound (XXX). 2,6-Dicyclohexylidenecyclohexanone (XXVI) (m.p. 144.5–146.5 °C) was synthesised[95] by eliminating hydrogen chloride from the products of the addition of hydrogen chloride to a liquid mixture of ketones D or to 2,6-dicyclohexenylcyclohexanone (XXVIII).

The liquid trimeric product D is also formed[17,29] on heating a mixture of cyclohexanone with the mixed dimeric ketones (I) and (II) or the product A alone[18] in the presence of condensing agents. Therefore, one may assume[17,29] that in the synthesis of a mixture of trimeric ketones D directly from cyclohexanone the intermediates are the dimeric ketones (I) and (II). On the other hand, the formation of the product D from the liquid mixture of ketones (I) and (II) alone[18] must be preceded by their hydrolysis[96]. The formation of a liquid mixture of trimeric ketones in the autocondensation of cyclohexanone or its condensation with the liquid product A may be represented by the following mechanisms:

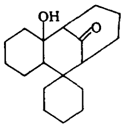


The interaction of 4-methylcyclohexanone with tri-isobutylaluminium gives a mixture[36] of trimeric autocondensation products, the structure of which was not investigated.

Prolonged standing of cyclohexanone with sodium methoxide in methanol or heating the ketone with sodium hydroxide in methanol lead to the formation of a solid product (m.p. 182°C), to which the structure of compound (XXXI) was attributed[20]. However, more detailed studies showed[97] that the 1,5-diketone formed initially readily cyclises and exists as a tetracyclic hydroxyketone with the structure (XXXII):



(XXXI)

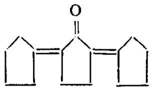


(XXXII)

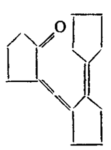
The reaction of cyclohexanone or the liquid mixture of ketones (I) and (II) with concentrated sulphuric acid in the presence of water, methanol, or butanol leads to a product of the autocondensation of six cyclohexanone molecules with the composition $C_{36}H_{52}O_2$, which is a diketone with three double bonds, two of which are conjugated with the carbonyl group and one is isolated[98].

Cyclopentanone. When cyclopentanone is heated with potassium hydroxide[16,71,75-77], sodium methoxide, or a complex of butyl-lithium with trimethylboron[72], potassium t-butoxide[73], potassium n-butoxide[74], and tri-isobutylaluminium[36], when it reacts with sodium ethoxide[13,70] and solid sodium hydroxide[78], or when its vapour is passed over alumina[75,77], an unsaturated trimeric autocondensation product E with the composition $C_{15}H_{20}O$ is obtained as a yellow solid[56,78] with m.p. 83–84°C.

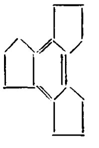
The structure of 2,5-dicyclopentylidenecyclopentanone (XXXIII) has been attributed to product E.[13,16,70-74,78] It has been suggested[76,77] that the product E (m.p. 83–84°C) is a ketone with the structure (XXXIV). However, Mayer[70] and Plešek[71] disproved this hypothesis on the basis of numerous observations and in particular the following findings: (a) the saturated ketone 2,5-dicyclopentylcyclopentanone obtained in the reduction of the ketone (XXXIII) does not react with benzaldehyde[70], while the product of the reduction of the unsaturated ketone (XXXIV), which has an active methylene group, does react with this reagent; (b) heating of the ketone (XXXIII) in acids or alkalis does not lead to the formation of the hydrocarbon 1,2,3,4,5,6-tricyclotrimethylenebenzene (XXXV), which should have formed from the ketone with the structure (XXXIV):



(XXXIII)



(XXXIV)



(XXXV)

The infrared spectrum of 2,5-dicyclopentylidenecyclopentanone (XXXIII) has a band at 1692 cm⁻¹ and the ultraviolet spectrum has an absorption maximum at 300 nm $(\epsilon_{max} = 20900)$[56].

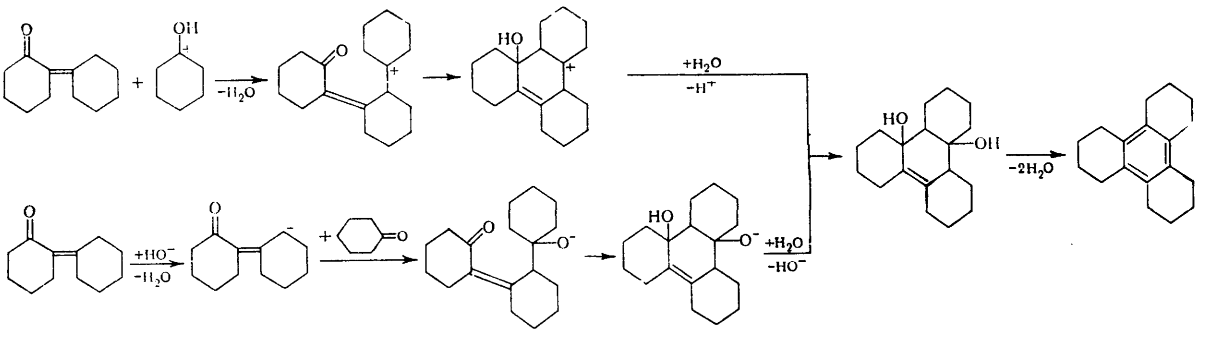
The ketone (XXXIII) is also formed[71] when the unsaturated ketone (XI) is heated with potassium hydroxide in toluene, as a result of a reversible aldol condensation (hydrolysis of 2-cyclopentylidenecyclopentanone).

2. Hydrocarbons

Cyclohexanone. When cyclohexanone is allowed to stand with concentrated sulphuric acid in methanol[98] and with 60% sulphuric acid[91], on heating cyclohexanone with concentrated sulphuric acid[17], *p*-toluenesulphonic acid[18], zinc chloride[29], polymeric dichlorogermane[39], polyphosphoric acid[99], activated aluminosilicate[100], alumina (under pressure)[31], thorium oxide, and a mixture of calcium, aluminium, and cerium (or thorium) oxides[101], or simply on heating under pressure without any condensing agent[27], a hydrocarbon—1,2,3,4,5,6,7,8,9,10,11,12-dodecahydrotriphenylene (XXXVI)—is obtained in a yield not exceeding[101] 13%. This hydrocarbon (m.p. 232°C) is formed as a side product in the reaction of cyclohexanone with acetic anhydride in nitromethane in the presence of perchloric acid[23].

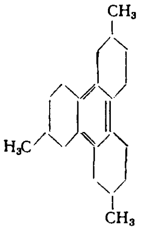
It has been shown[96] that dodecahydrotriphenylene (XXXVI) can be obtained in a low yield by heating under pressure a mixture of the dimeric ketones (I) and (II) with aqueous potassium hydroxide. The formation of the hydrocarbon (XXXVI) is probably preceded by the hydrolysis of the ketones (I) and (II). Compound (XXXVI) is also formed on heating a mixture of the ketones (I) and (II) with cyclohexanone in the presence of zinc chloride[29] or when a mixture of the ketones (I) and (II) is allowed to stand with sulphuric acid in methanol[96].

As in the synthesis of the mixture of the trimeric ketones (product D), in the synthesis of dodecahydrotriphenylene (XXXVI) the intermediates are probably the ketones (I) and (II):

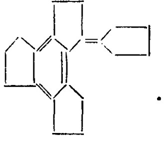


(XXXVI)

On heating with sulphuric acid in methanol or with a mixture of thorium and aluminium oxides, 4-methylcyclohexanone is converted into 2,6,10-trimethyl-1,2,3,4,5,6-7,8,9,10,11,12-dodecahydrotriphenylene (XXXVII):[101]



(XXXVII)



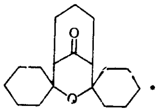
(XXXVIII)

When hydrogen chloride is passed into cyclopentanone[70,71,80] and when the latter is heated with potassium hydroxide[76] or with concentrated sulphuric acid[81], triscyclotrimethylenebenzene (XXXV) is obtained (m.p. 97.5–98.0°C). It is also formed when a mixture of cyclopentanone and 2-cyclopentylidenecyclopentanone (XI) is saturated with hydrogen chloride[70,71].

When the ketone (XI) is heated with *p*-toluenesulphonic acid, a hydrocarbon with the composition $C_{20}H_{24}$ is formed, to which the structure (XXXVIII) is attributed[71].

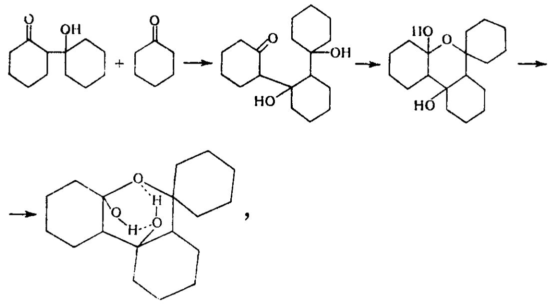
3. Oxygen-containing Heterocyclic Compounds

After the reaction of cyclohexanone with sodamide[14], a compound with the composition $C_{18}H_{28}O_2$ (m.p. 186°C) was isolated and was assigned the structure of the saturated heterocyclic ketone (XXXIX):

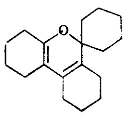


(XXXIX)

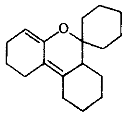
It was shown[94] that, when cyclohexanone is kept for a long time in contact with powdered sodium hydroxide, a solid compound with the composition $C_{18}H_{30}O_3$ (m.p. 175°C), having the structure of an internal cyclic hydrogen-bonded hemiacetal (XL)[102], is formed. The maximum yield (75%) of compound (XL) was achieved[102] at 10°C when the duration of the reaction was 24 h. Under the influence of catalytic amounts of sulphuric acid[102], this cyclohexanone trimer (see the mechanism below) splits off two molecules of water and is converted into a mixture[19] of the pyran (XLI) and the dihydropyrans (XLII) and (XLIII) which are its isomers:



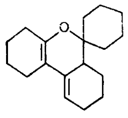
(XL)



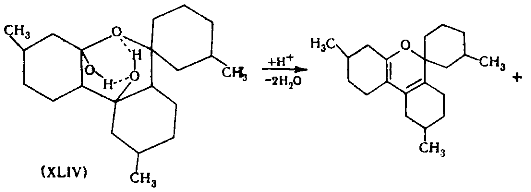
(XLI)



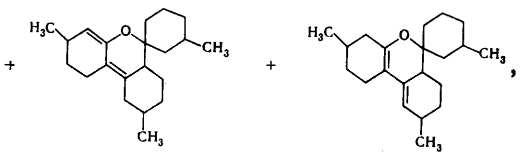
(XLII)

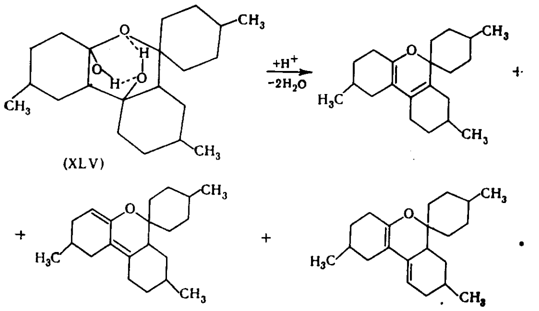


(XLIII)



(XLIV)





(XLV)

Compound (XL) and also the mixture of (XLI), (XLII), and (XLIII), are converted on heating into dodecahydrotriphenylene (XXXVI) in high yields.

It is noteworthy that initially the structure of an $\alpha\beta$–$\delta\epsilon$-unsaturated ketone, and not the pyran (XLI) or the dihydropyrans (XLII) and (XLIII), was attributed to the product formed on elimination of two water molecules from compound (XL).

It has been shown[78] that the interaction of 3- and 4-methylcyclohexanones with solid sodium hydroxide leads to the formation of the analogous trimeric products (XLIV) and (XLV). 2-Methylcyclohexanone does not trimerise owing to steric hindrance. In the presence of sulphuric acid the trimeric compounds (XLIV) and (XLV) are dehydrated to compounds which on heating yield the same hydrocarbon—2,6,10-trimethyl-1,2,3,4,5,6,7,8,9,10-11,12-dodecahydrotriphenylene (XXXVII). By analogy with the products formed in the reaction of cyclohexanone with sodium hydroxide[102], the trimeric compounds (XLIV) and (XLV) should also be internal cyclic hemiacetals and the products of their dehydration by sulphuric acid should consist of a mixture of the corresponding pyrans and dihydropyrans.

Organophosphorus Compounds with an Active Methylene Group

A.N.Pudovik and G.E.Yastrebova

The review deals with the present state of the chemistry of organophosphorus compounds with an active methylene group: esters and nitriles of phosphonoacetic acids, phosphonoacetone, and other compounds in which the methylene group is linked directly to the P=O and any other electronegative group. Compounds of this type are analogues of acetoacetic, malonic, cyanoacetic, and phenylacetic esters, the importance of which for theoretical and synthetic organic chemistry is well known. The methods for the synthesis of phosphorus-containing compounds with an active methylene group are considered in the first part of the review, while their chemical properties associated with the mobility of the hydrogen atoms of the methylene group (alkylation, addition, condensation, P(O)-activated olefin formation, and certain other reactions) are dealt with in the second part.

The bibliography includes 292 references.

CONTENTS

I. INTRODUCTION

The chemistry of organophosphorus compounds has been developing very rapidly recently. This is primarily due to the considerable theoretical and especially practical importance which organophosphorus compounds have acquired in various branches of the national economy and modern engineering. The applications of organophosphorus compounds as insecticides in agriculture, medicinal preparations (particularly for eye infections), extractants, flotation agents in mining, plasticisers and stabilisers for polymers, and antioxidants for lubricating oils and the manufacture of non-combustible fabrics and materials are well known. The range of practical uses of organophosphorus compounds increases every year. Among the numerous types of organophosphorus compounds those with an active methylene group are of great interest. The first representative of this class of compound—ethyl diethoxyphosphonoacetate—was obtained by A. E. Arbuzov and Dunin in 1914 by the Arbuzov rearrangement. They established for the first time that the hydrogen atoms of the methylene group may be substituted by sodium and the reaction of the sodio-derivative of the diethoxyphosphonoacetate ester with alkyl halides can yield alkyl derivatives. Since then a number of organophosphorus compounds with an active methylene group have been obtained by the Arbuzov and Michaelis–Becker reactions and other methods.

The hydrogen atoms of the methylene group linked to the phosphorus atom and any other electron-accepting group exhibit considerable mobility which is responsible for the capacity of these compounds to undergo alkylation, acylation, addition, condensation, P(O)-activated olefin formation, and halogenation reactions. Thus we see an analogy between these organophosphorus compounds and esters of ketoacids and dicarboxylic acids such as the acetoacetic and malonic esters, which have played an extremely important role in theoretical and synthetic organic chemistry. Problems associated with the structure and tautomerism of this type of organophosphorus compounds are also of definite interest. The present review is a first attempt at a general account of the extensive and interesting data available in world chemical literature on the synthesis, structure, and reactivity of organophosphorus compounds with an active methylene group. Soviet chemists have made a very large contribution to the development of this branch of the chemistry of organophosphorus compounds.

II. SYNTHESIS OF ORGANOPHOSPHORUS COMPOUNDS WITH AN ACTIVE METHYLENE GROUP

1. Derivatives of Phosphorylated Acetic Acid and Its Nitrile

Ethyl diethoxyphosphonoacetate was obtained for the first time by A. E. Arbuzov and Dunin more than half a century ago by the reaction of ethyl bromoacetate with triethyl phosphite[1]:

$$(C_2H_5O)_3P + BrCH_2COOC_2H_5 \rightarrow (C_2H_5O)_2P(O)CH_2COOC_2H_5 + C_2H_5Br.$$

Subsequently the Arbuzov–Dunin method was successfully used for the synthesis of the ethyl esters of higher dialkoxyphosphonoacetic acids[2-7] and phosphonoacetic esters containing unsaturated substituents both at the phosphorus atom and in the carboxy-group[8-10].

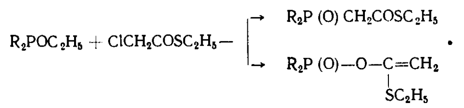
The fully esterified alkylphosphonous and dialkylphosphinous acids enter into the Arbuzov rearrangement with esters of halogenoacetic acids more vigorously than trialkyl phosphites[11-15]. After the reaction of the ethyl esters of dialkylphosphinous acids with iodoacetic ester, Razumov and Zabusova isolated crystalline intermediates of the quasiphosphonium type, in accordance with the first step of the Arbuzov reaction[16]:

$$R_2POC_2H_5 + ICH_2COOC_2H_5 \rightarrow \left[R_2P\begin{matrix} \diagup OC_2H_5 \\ \diagdown CH_2COOC_2H_5 \end{matrix}\right]^+ I^-.$$

Their stability depends on the nature of the groups joined to the phosphorus atom. On storage and on heating, the products decompose in accordance with the second step of the Arbuzov reaction, forming ethyl iodide and dialkylethoxycarbonylmethylphosphine oxide[17,18]:

$$\left[R_2P\begin{matrix} \diagup OC_2H_5 \\ \diagdown CH_2COOC_2H_5 \end{matrix}\right]^+ I^- \rightarrow R_2P(O)CH_2COOC_2H_5 + C_2H_5I.$$

The reactions of phosphorus and dialkylphosphinous acids with alkyl- and aryl chlorothioloacetic acids follow two pathways: via the classical mechanism of the Arbuzov rearrangement and with formation of alkenyl esters of phosphorus acids, i.e. via the Perkow mechanism[19-22]:



$$R_2POC_2H_5 + ClCH_2COSC_2H_5 - \left[\begin{array}{l} \rightarrow R_2P(O)CH_2COSC_2H_5 \\ \rightarrow R_2P(O){-}O{-}\underset{SC_2H_5}{\underset{|}{C}}{=}CH_2 \end{array}\right. .$$

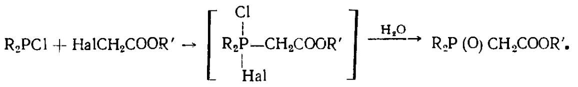
Nylen successfully used the Michaelis–Becker method for the preparation of phosphonoacetic esters. Thus ethyl diethoxyphosphonoacetate was obtained in high yield by the reaction of sodium diethyl phosphite with ethyl chloroacetate[23,24]:

$$(C_2H_5O)_2PONa + ClCH_2COOC_2H_5 \rightarrow (C_2H_5O)_2P(O)CH_2COOC_2H_5 + NaCl\,.$$

A large number of various phosphonoacetic acid esters[25-31] and dialkylcarboxymethylphosphine oxides[32] were obtained by this method, usually referred to as the Michaelis–Becker–Nylen method. Phosphonoacetic acid esters can be obtained by the reaction of dialkylphosphorous acids themselves with diazoacetic ester[33,34]:

$$(C_2H_5O)_2POH + N_2CHCOOC_2H_5 \rightarrow (C_2H_5O)_2P(O)CH_2COOC_2H_5.$$

Apart from the above general methods, a number of specific reactions leading to the formation of phosphorylated derivatives of carboxylic acids of the type of tertiary phosphine oxides have been described. The starting materials in these reactions are the chlorides of phosphinous acids. Dialkylalkoxycarbonylmethylphosphine oxides have been obtained by the addition of α-halogeno-substituted acid esters to dialkylchlorophosphines with subsequent hydrolysis of the addition products[35,36]:



$$R_2PCl + HalCH_2COOR' \rightarrow \left[R_2\overset{Cl}{\underset{Hal}{P}}{-}CH_2COOR'\right] \xrightarrow{H_2O} R_2P(O)CH_2COOR'.$$

In the method proposed by Lutsenko and coworkers dialkylchlorophosphines, alkyldichlorophosphines, and aryldichlorophosphines are allowed to react with trichlorostannylacetic acid[37,38]:

$$\rangle P{-}X + R'_3SnCH_2COOR \rightarrow \rangle P{-}CH_2COOR + R'_3SnX.$$

The alkoxycarbonylmethylphosphines and di(alkoxycarbonylmethyl)phosphines are oxidised further by atmospheric oxygen with formation of the corresponding phosphine oxides.

Phosphorylated acids may be obtained also by the oxidation of the corresponding phosphorylated aldehydes by peracetic acid[39]:

$$\begin{matrix}R\\R'\end{matrix}\!\!>P(O)CH_2CHO \xrightarrow{CH_3COOOH} \begin{matrix}R\\R'\end{matrix}\!\!>P(O)CH_2COOH\,.$$

They are converted by esterification into esters of dialkylphosphonoacetic acids.

The first example of phosphonoacetonitriles was obtained in 1952 by Dawson and Burger[40] as a result of the reaction between chloroacetonitrile and triethyl phosphite[40]:

$$(C_2H_5O)_3P + ClCH_2CN \rightarrow (C_2H_5O)_2P(O)CH_2CN + C_2H_5Cl\,.$$

The method based on the Arbuzov rearrangement was successfully employed subsequently also for the synthesis of phosphorylated acetonitriles[19,41-43]. The reactions of trialkyl phosphites with chloroacetamide and its substituted derivatives leads to the formation of phosphonoacetamide or its *N*-alkyl and *N*-aryl derivatives[2,3,19,21,44-52]:

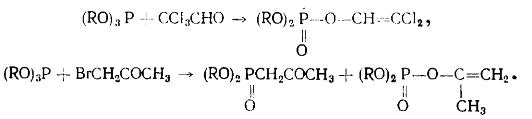
$$(RO)_3P + ClCH_2CON\begin{matrix}R'\\R''\end{matrix} \rightarrow (RO)_2P(O)CH_2CON\begin{matrix}R'\\R''\end{matrix} + RCl\,.$$

Apart from phosphites, phosphoroamidites and esters of phenylphosphonous acid were employed in these reactions[49].

2. Phosphorylated Ketones

The Arbuzov rearrangement was used as the first synthetic procedure for esters and other derivatives of β-ketophosphonic acids, which are phosphorus analogues of the corresponding derivatives of β-ketocarboxylic acids. A. E. Arbuzov and Razumov obtained diethoxyphosphonoacetophenone in 1934 by the reaction of triethyl phosphite with ω-bromoacetophenone[25]. In a similar reaction with bromoacetone Razumov and Petrov established that two products are then formed, which they suggested are tautomers of diethoxyphosphonoacetone[54].

This problem was elucidated much later when Perkow[55] showed for α-halogenoaldehydes and then Pudovik[56,57] and Allen and Jonson[58] for α-halogenoketones that the reactions of esters of phosphorus(III) acids with α-halogenocarbonyl compounds can take place in two ways: with formation of ketophosphonates, unsaturated phosphoric acid esters, or both simultaneously; diethyl isopropenyl phosphate was isolated by one of the authors of this review[57]:



$$(RO)_3P + CCl_3CHO \rightarrow (RO)_2\underset{O}{\underset{\|}{P}}{-}O{-}CH{=}CCl_2,$$

$$(RO)_3P + BrCH_2COCH_3 \rightarrow (RO)_2\underset{O}{\underset{\|}{P}}CH_2COCH_3 + (RO)_2\underset{O}{\underset{\|}{P}}{-}O{-}\underset{CH_3}{\underset{|}{C}}{=}CH_2\,.$$

The relative amounts of the ketophosphonic esters and unsaturated phosphates or phosphonates formed by the reaction of phosphites or phosphinites with α-halogenoketones are significantly influenced by the nature and amounts of halogen atoms and also by the structure of the halogenoketones and the reaction conditions. Pudovik and Aver'yanova showed that the relative yield of ketophosphonic esters increases appreciably on going from chloro- to bromo- and iodo-acetone[59].

With increase in the number of halogen atoms in the halogenoketone, the formation of ketophosphonates becomes more difficult and the yield of unsaturated phosphates increases. The reactions with asymmetric dichloro- and dibromo-acetones[56,60,61] and tribromoacetone[62] lead to the formation of unsaturated phosphates only.

Ketophosphonic esters are formed in high yields from primary monobromo-[62,64] and iodo-ketones[59,63]. When secondary and particularly tertiary[64] halogenoketones are employed, their yield is considerably reduced or they are not formed at all.

The yield of ketophosphonic esters is significantly affected also by the reaction temperature and the solvent. An increase of temperature favours the formation of the ketophosphonate[56,59]. When iodoacetone is allowed to react with triethyl phosphite in ethyl ether as solvent[59], the ketophosphonic ester is formed with a higher yield than, for example, in aqueous alcohol[63].

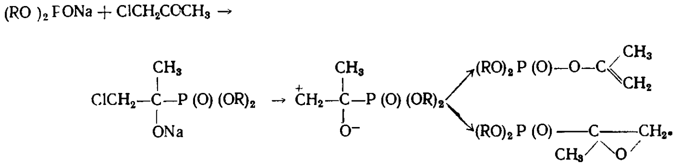
Mixed esters of phosphorous acid[61], phosphoroamidites[61], and esters of phenylphosphonous[59] and diphenylphosphinous[53,65] acids have been allowed to react with halogenocarbonyl compounds in order to synthesise various derivatives of ketophosphonic acids. The reactions of α-halogenoacetophenones with phosphites[25,66-69], mixed phosphites[70,72], and diphenylphosphinous acid esters[53,65] take place similarly. In all cases both products—the phosphonate and vinyl phosphate—are formed in different proportions:

$$(RO)_3P + BrCH_2COC_6H_5 \rightarrow (RO)_2P(O)CH_2COC_6H_5 + (RO)_2P(O){-}O{-}C(C_6H_5){=}CH_2.$$

The Michaelis–Becker reaction has been used for the synthesis of ketophosphonic esters. Nylen, who was the first to investigate the reactions of α-chloro- and α-bromo-acetones with sodium diethyl phosphite, concluded that they take place in a complex manner and did not obtain the ketophosphonic esters[24]. Subsequently B. A. Arbuzov and coworkers showed that this reaction leads to a mixture of products consisting of esters of β-ketophosphonic acids and epoxyphosphonic acids and unsaturated esters of phosphoric acid[64,67,73–83]. They suggest[78] that the reactions can involve both the α-carbon atom and the carbonyl group. In the first case the ester of a β-ketophosphonic acid is formed:

$$(RO)_2PONa + HalCH_2COR' \rightarrow (RO)_2P(O)CH_2COR' + NaHal.$$

The reaction via the carbonyl group leads to the formation of a dipolar ion, which rearranges to an unsaturated phosphate or is stabilised as an epoxyphosphonic ester[78,84]:

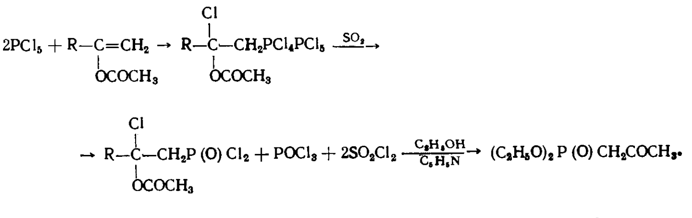


While α-chloro- and α-bromo-cyclohexanones and α-bromoacetophenone form with sodium diethyl phosphite mixtures of phosphoric and epoxyphosphonic acids[78], the reaction with chloro- and bromo-acetones leads to a mixture of esters of β-keto- and epoxy-phosphonic acids[76,79,85].

The esters of chloro- and trichloro-acetylphosphonic acids and diethoxyphosphonoacetyl- and diethoxyphosphonodichloroacetyl-phosphonic acids have been obtained by the reaction of sodium dialkyl phosphites with chloro- and trichloro-acetyl chlorides [86,87]:

$$(RO)_2PONa + ClCH_2COCl \rightarrow (RO)_2P(O)COCH_2Cl + (RO)_2P(O)CH_2C(O)P(O)(OR)_2 + NaCl.$$

The above results show that esters of β-ketophosphonic acids are formed by the Michaelis–Becker reaction either in very low yields or not at all. Among other reactions leading to the formation of esters of β-ketophosphonic acids, the interaction of phosphorus pentachloride with enol acetates is of considerable interest. This reaction, developed by Lutsenko and Kirillov, leads to the formation initially of the chlorides of β-acetoxy- β-chloroalkylphosphonic acids, which are converted into diethoxyphosphonoacetone by treatment with alcohol[88]:



$$2PCl_5 + R{-}C(OCOCH_3){=}CH_2 \rightarrow R{-}CCl(OCOCH_3){-}CH_2PCl_4PCl_5 \xrightarrow{SO_2}$$
$$\rightarrow R{-}CCl(OCOCH_3){-}CH_2P(O)Cl_2 + POCl_3 + 2SO_2Cl_2 \xrightarrow[C_5H_5N]{C_2H_5OH} (C_2H_5O)_2P(O)CH_2COCH_3.$$

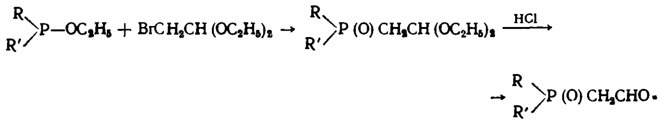
Diethoxyphosphonoacetaldehyde[88,89] and diethoxyphosphonoacetophenone[90] were obtained by the same method. The latter is also formed in the reaction between diazomethane and benzoylphosphonic ester[90]:

$$(C_2H_5O)_2P(O)COC_6H_5 + CH_2N_2 \rightarrow (C_2H_5O)_2P(O)CH_2COC_6H_5.$$

The reaction of trialkylstannylacetone with dialkylchlorophosphines gave dialkylacetonylphosphines, the oxidation of which leads to dialkylacetylmethylphosphines[91]:

$$R_2PCl + R'_3SnCH_2COCH_3 \rightarrow R_2PCH_2COCH_3 \xrightarrow{H_2O_2} R_2P(O)CH_2COCH_3.$$

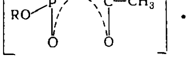
Phosphorylated acetals have been obtained by the action of halogeno-substituted acetals on phosphorus(III) acid esters; their hydrolysis leads to phosphorylated aldehydes[40 92–94]:



$$RR'P{-}OC_2H_5 + BrCH_2CH(OC_2H_5)_2 \rightarrow RR'P(O)CH_2CH(OC_2H_5)_2 \xrightarrow{HCl} RR'P(O)CH_2CHO.$$

In order to investigate the tautomerism of the keto–enol type of β-ketophosphonic esters, B. A. Arbuzov and Vinogradova employed methods involving titration with bromine and ultraviolet, infrared, and Raman spectroscopy[64,74–76,95,96]. Phosphonoacetone and methylphosphonoacetone, which are the phosphorus analogues of acetoacetic and methylacetoacetic esters, contain a small amount of the enolic form[96]. They undergo appreciable enolisation only in an alkaline medium[97]. Titration with bromine of cyclohexanone-2-phosphonic acid in alcoholic solution revealed the presence of 9% of the enolic form and in hexane solution 60% of the enolic form was found[98,99]. Comparison of the effects of the carboxy- and phosphono-groups on the capacity for the formation of the enolic form led to the conclusion that there is a definite analogy in the behaviour of β-keto acids and their phosphorus analogues, with the difference that the β-ketophosphonic esters are less enolised. A complete parallelism is not, however, observed.

The structure of metal derivatives in the molecules of which the methylene group is located between the P = O and carbonyl groups was investigated by infrared, ultraviolet, and NMR spectroscopy[100]. The results indicate the presence in the anion of phosphonoacetone of an extended π-orbital system, which is also characteristic of the acetylacetone anion:



3. Phosphorylated Alkanes

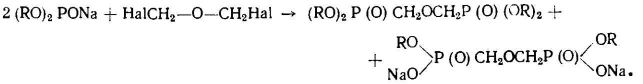
The first example of this class of compound—tetraethyl methylenediphosphonate—was obtained by Ford-Moore and Williams[101] by the reaction of methylene iodide with triethyl phosphite[101]. The yield of the diphosphonate in this reaction was, however, very low, since considerable amounts of diethyl iodomethyl- and ethyl-phosphonates are formed at the same time:

$$(C_2H_5O)_3P + CH_2I_2 \rightarrow (C_2H_5O)_2P(O){-}CH_2{-}P(O)(OC_2H_5)_2 + (C_2H_5O)_2P(O)CH_2I + (C_2H_5O)_2P(O)C_2H_5 + C_2H_5I.$$

The yield of the diphosphonate may be increased somewhat by using in the reaction an excess of trialkyl phosphite[102–104]. The yield of tetra-alkyl methylenediphosphonates is improved still further when the reaction is carried out in two consecutive stages[105]:

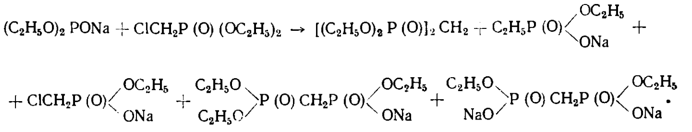
$$(C_2H_5O)_3P + CH_2I_2 \rightarrow (C_2H_5O)_2P(O)CH_2I + C_2H_5I,$$
$$(C_2H_5O)_2P(O)CH_2I + (C_2H_5O)_3P \rightarrow [(C_2H_5O)_2P(O)]_2CH_2 + C_2H_5I.$$

When an attempt was made to obtain tetra-alkyl methylenediphosphonates by the Michaelis–Becker reaction between methylene iodide or chloride and sodium diethyl or diallyl phosphite, instead of the neutral esters only the corresponding disodium salts were isolated[105–107]. The formation of salts of the acid esters is observed also in the reactions of sodium dialkyl phosphite with di-(α-bromomethyl) and di-(α-chloro methyl) esters[108–110]:



$$2(RO)_2PONa + HalCH_2{-}O{-}CH_2Hal \rightarrow (RO)_2P(O)CH_2OCH_2P(O)(OR)_2 + \frac{RO}{NaO}{>}P(O)CH_2OCH_2P(O){<}\frac{OR}{ONa}.$$

The formation of salts of acid esters is due to the alkylation of sodium dialkyl phosphite by the phosphonates[111]. When sodium dialkyl phosphite is alkylated by alkyl halides, the neutral alkylphosphonic esters are formed initially in all cases. The salts of the acid esters are formed as a result of secondary processes due to the high reactivity of the neutral alkylphosphonic esters. It has been shown for the reaction of sodium diethyl phosphite with diethyl chloromethylphosphonate that the salt-like product is a mixture of sodium chloride and salts of the acid esters of ethyl- and chloromethyl-phosphonic and methylenediphosphonic acids[112]:



$$(C_2H_5O)_2PONa + ClCH_2P(O)(OC_2H_5)_2 \rightarrow [(C_2H_5O)_2P(O)]_2CH_2 + C_2H_5P(O){<}\frac{OC_2H_5}{ONa} +$$
$$+ ClCH_2P(O){<}\frac{OC_2H_5}{ONa} + \frac{C_2H_5O}{C_2H_5O}{>}P(O)CH_2P(O){<}\frac{OC_2H_5}{ONa} + \frac{C_2H_5O}{NaO}{>}P(O)CH_2P(O){<}\frac{OC_2H_5}{ONa}.$$

Nevertheless, despite the complexity of these reactions[112–114], tetra-alkyl methylenediphosphonates are formed in high yields compared with the analogous reactions of phosphites. Until recently, methylenediphosphine dioxides were very difficult to obtain. A number of methods using organometallic compounds have been proposed for their synthesis. Thus, reactions of methylenediphosphonic dichloride with Grignard reagents have been described[114,115]:

$$[Cl_2P(O)]_2CH_2 + 4RMgX \rightarrow [R_2P(O)]_2CH_2 + 4MgXCl,$$

and also reactions of dialkylchloromethylphosphines with halogenomagnesium derivatives of dialkylphosphinous acids[116]:

$$R_2P(O)CH_2Cl + R_2POMgX \rightarrow R_2P(O)CH_2P(O)R_2 + MgXCl,$$

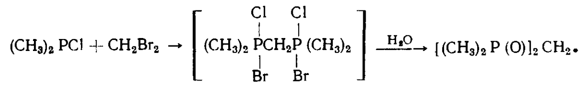
and reactions of diphenylphosphinic chloride with the lithio-derivative of methyldiphenylphosphine oxide[117]:

$$(C_6H_5)_2P(O)CH_3 \xrightarrow{n\text{-}C_4H_9Li} (C_6H_5)_2P(O)CH_2Li \rightarrow$$
$$\xrightarrow{(C_6H_5)_2P(O)Cl} (C_6H_5)_2P(O){-}CH_2{-}P(O)(C_6H_5)_2.$$

Methylenediphosphine dioxides may be obtained by the oxidation of the corresponding methylenediphosphines, which are formed in the reaction between methylene chloride or bromide with sodium diphenyl phosphite[118] or dialkylhydroxymethylphosphine[119]:

$$2(C_6H_5)_2PNa + CH_2Cl_2 \rightarrow (C_6H_5)_2PCH_2P(C_6H_5)_2 +$$
$$+ 2NaCl \xrightarrow{O_2} (C_6H_5)_2P(O)CH_2P(O)(C_6H_5)_2,$$
$$2R_2PCH_2OH + CH_2Br_2 \rightarrow R_2PCH_2PR_2 \xrightarrow{O_2} R_2P(O)CH_2P(O)R_2.$$

Among other methods for the synthesis of methylenediphosphine dioxides, the addition of chlorodimethylphosphine to methylene bromide with subsequent hydrolysis of the addition product is interesting[36]:



$$(CH_3)_2PCl + CH_2Br_2 \rightarrow \left[(CH_3)_2\overset{Cl}{\underset{Br}{P}}CH_2\overset{Cl}{\underset{Br}{P}}(CH_3)_2\right] \xrightarrow{H_2O} [(CH_3)_2P(O)]_2CH_2.$$

as well as the reaction of chlorodiphenylphosphine with diazomethane, which leads ultimately to tetraphenylmethylenediphosphine dioxide[120]:

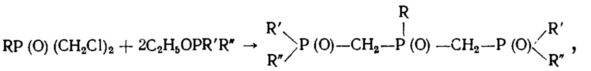
$$(C_6H_5)_2PCl + CH_2N_2 \xrightarrow[-N_2,\,-2HCl]{H_2O} (C_6H_5)_2P(O)CH_2P(C_6H_5)_2 \rightarrow$$
$$\xrightarrow{KMnO_4} (C_6H_5)_2P(O)CH_2P(O)(C_6H_5)_2.$$

However, all the methods enumerated above have not found wide practical application because of the difficulty of obtaining the reactants employed in them and the low yields of the desired products. In 1962 Kabachnik and Medved' proposed a simpler method for the synthesis of methylenediphosphine dioxides by the condensation of chloromethyldiphenylphosphine oxide with ethyl diphenylphosphinite[121]:

$$(C_6H_5)_2P(O)CH_2Cl + C_2H_5OP(C_6H_5)_2 \xrightarrow[-C_2H_5Cl]{} (C_6H_5)_2P(O)CH_2P(O)(C_6H_5)_2.$$

Subsequently this method was successfully employed for the synthesis of a number of methylenediphosphine dioxides with alkyl and substituted aromatic groups[122,123] and also methylenediphosphonic acids[124].

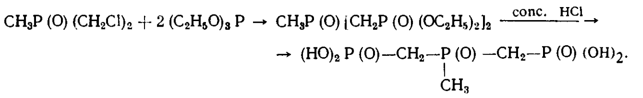
Similarly di(chloromethyl)phosphine and tri(chloromethyl)phosphine oxides and phosphorus(III) esters gave the corresponding phosphine oxides and phosphorus acid esters containing in the molecule several $>P(O){-}CH_2$ groups[125–127]:



$$RP(O)(CH_2Cl)_2 + 2C_2H_5OPR'R'' \rightarrow \frac{R'}{R''}{>}P(O){-}CH_2{-}\overset{R}{P}(O){-}CH_2{-}P(O){<}\frac{R'}{R''},$$

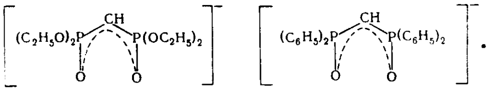
$$(ClCH_2)_3P(O) + 3R_2POC_2H_5 \rightarrow [R_2P(O)CH_2]_3P(O).$$

Certain compounds of this type, containing dialkoxyphosphono-groups, were hydrolysed to the corresponding acids[127], which proved to be extremely interesting and promising as complexones[128]:



$$CH_3P(O)(CH_2Cl)_2 + 2(C_2H_5O)_3P \rightarrow CH_3P(O)[CH_2P(O)(OC_2H_5)_2]_2 \xrightarrow{\text{conc. HCl}}$$
$$\rightarrow (HO)_2P(O){-}CH_2{-}\underset{CH_3}{P}(O){-}CH_2{-}P(O)(OH)_2.$$

In the study of the structure of sodio- and potassio-derivatives of tetraethoxydiphosphonomethane and tetraphenylmethylenediphosphine dioxide by infrared and NMR spectroscopy, Cotton and coworkers[129] in the first case and Kabachnik and coworkers[130] in the second showed that the anions of these compounds have a structure with delocalised π bonds:



4. Phosphorylated Alkenes

The esters of allylphosphonic acid are readily obtained by the Arbuzov rearrangement when allyl chloride or bromide reacts with trialkyl[131] and triallyl[132] esters of phosphorous acid:

$$(RO)_3P + BrCH_2CH{=}CH_2 \rightarrow (RO)_2P(O)CH_2CH{=}CH_2 + RBr.$$

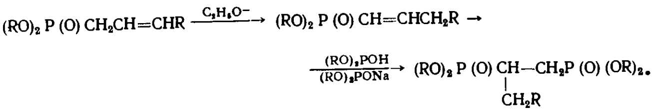
The reaction of alkyl halides with esters of allylphosphonous acid gives esters of alkylallylphosphinic acids[132,134]:

$$(RO)_2PCH_2CH{=}CH_2 + R'X \rightarrow \begin{matrix} RO \\ R' \end{matrix}\!\!>\!P(O)CH_2CH{=}CH_2 + RX.$$

Phosphonic esters can also be synthesised by the Michaelis–Becker reaction. However, Pudovik's investigation showed that the reactions of salts of dialkylphosphorous acids with halogenoallyl compounds do not always take place unambiguously. The reactions of allyl bromide, crotyl chloride[135,136], cinnamyl chloride[137,138], and 1-chloro-5-methoxypent-2-ene with sodium diethyl phosphite in benzene solutions and in the presence of an excess of diethylphosphorous acid leads to the formation of diethyl alkenylphosphonates[131,139,140]. The reactions with secondary halogenoallyl isomers take place with the allyl rearrangement[135,139,141–143]:

$$\left.\begin{matrix} (C_2H_5O)_2PONa + RCH{=}CHCH_2Cl \\ (C_2H_5O)_2PONa + RCHClCH{=}CH_2 \end{matrix}\right\rangle \rightarrow (C_2H_5O)_2P(O)CH_2CH{=}CHR.$$

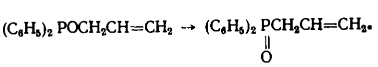
When stoichiometric proportions of the reactants are used and the reaction is carried out without a solvent, the allylphosphonic esters undergo prototropic isomerisation to thermodynamically more stable substituted vinylphosphonic esters, to which diethylphosphorous acid adds subsequently. This results in a mixture of esters of phosphonic and diphosphonic acids[139]:



$$(RO)_2P(O)CH_2CH{=}CHR \xrightarrow{C_2H_5O^-} (RO)_2P(O)CH{=}CHCH_2R \rightarrow$$
$$\xrightarrow[(RO)_2PONa]{(RO)_2POH} (RO)_2P(O)\underset{\displaystyle CH_2R}{\underset{|}{C}H}{-}CH_2P(O)(OR)_2.$$

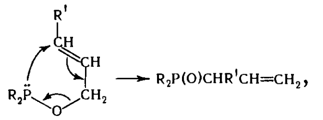
The thermal rearrangement of allyl esters of phosphorous acid[144–146] leading to allylphosphonic esters and the similar rearrangements of alkyl-, dialkyl-, aryl-, and diaryl-phosphinous acids are very interesting reactions[147]. When the diallyl ester of ethylphosphonous acid is replaced by the allyl ester of diethylphosphinous acid, the rate of thermal rearrangement increases.

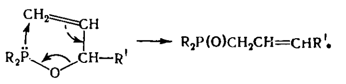
The isomerisation of the allyl esters of phenylphosphonous and diphenylphosphinous acids takes place much more readily. On vacuum distillation alone, the allyl ester of diphenylphosphinous acid isomerises to allyldiphenylphosphine oxide[147,148]:



$$(C_6H_5)_2POCH_2CH{=}CH_2 \rightarrow (C_6H_5)_2\underset{\displaystyle O}{\underset{\|}{P}}CH_2CH{=}CH_2.$$

The thermal isomerisation of α- and γ-substituted allyl esters takes place with inversion of the allyl radicals[145]. For these reactions, Pudovik and Aladzheva proposed an intramolecular mechanism with intermediate formation of five-membered cyclic transition states[145]:





Esters of propargylphosphonic acids with similar structures are difficult to obtain[149]. Gordon and Griffin showed that the reaction of propargyl bromide with sodium diethyl phosphite leads to the formation of a mixture of 1-propynylphosphonate, 2-propynylphosphonate, and allenylphosphonate[150]:

$$(C_2H_5O)_2PONa + BrCH_2C{\equiv}CH \rightarrow (C_2H_5O)_2P(O)C{\equiv}C{-}CH_3 +$$
$$+ (C_2H_5O)_2P(O)CH_2C{\equiv}CH + (C_2H_5O)_2P(O)CH{=}C{=}CH_2.$$

The content of 2-propynylphosphonate in the mixture is less than 1% according to NMR data. Similar results were obtained when an attempt was made to prepare 2-propynylphosphonate by the Arbuzov rearrangement[150,151].

5. Derivatives of Substituted Methylphosphonic Acids containing Aryl, Carbocyclic, and Heterocyclic Groups

Methods based on the Arbuzov rearrangement and the Michaelis–Becker reaction have been successfully employed to synthesise the esters of unsubstituted and ring-substituted benzylphosphonic acids[84,152–154] and alkyl(aryl)benzylphosphinic acids[155,156]:

$$\left.\begin{matrix} (C_2H_5O)_3P + ClCH_2C_6H_4{-}R \xrightarrow{-C_2H_5Cl} \\ (C_2H_5O)_2PONa + ClCH_2C_6H_4{-}R \xrightarrow[-NaCl]{} \end{matrix}\right] \rightarrow (C_2H_5O)_2P(O)CH_2C_6H_4{-}R.$$

The second method was used to prepare unsubstituted benzylphosphonates[156–159] and benzylphosphonates with alkyl[157], ethoxycarbonyl, and cyano-groups[154] in the benzene ring. The sodium salts of ethylphosphonous[160], benzylphosphonous[161], and diphenylphosphinous acids[162] can also be successfully employed in these reactions. Sodium diethylphosphorothioite reacts with benzyl chloride to form diethyl benzylphosphonothionate[163]. When it was heated with ethyl bromide, *OS*-diethyl benzylphosphonothiolate was obtained[164]:

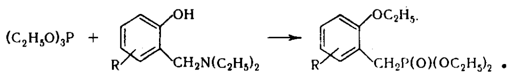
$$(C_2H_5O)_2PSNa + ClCH_2C_6H_5 \rightarrow (C_2H_5O)_2P(S)CH_2C_6H_5 + NaCl,$$

$$(C_2H_5O)_2P(S)CH_2C_6H_5 + C_2H_5Br \rightarrow \begin{matrix} C_2H_5O \\ C_2H_5S \end{matrix}\!\!>\!P(O)CH_2C_6H_5.$$

A modified Michaelis–Becker method, in which benzyl acetate is used in the reaction with sodium diallyl phosphite instead of benzyl chloride, has been successfully employed for the synthesis of diallyl benzylphosphonate[165]:

$$(CH_2{=}CHCH_2O)_2PONa + CH_3COOCH_2C_6H_5 \rightarrow (CH_2{=}CHCH_2O)_2P(O)CH_2C_6H_5 + CH_3COONa.$$

Esters of ethoxybenzylphosphonic acids are formed in the reaction between diethylaminomethylphenols and triethyl phosphites[166]:



An interesting method for the synthesis of substituted tribenzylphosphine oxides has been developed by Kirsanov and coworkers; it is based on the reaction of substituted benzyl chlorides with red phosphorus and iodine with subsequent treatment of the reaction products with sodium sulphite. Dibenzylphosphinic and benzylphosphonic acids are formed in these reactions in small amounts in addition to substituted tribenzylphosphine oxides[167]:

$$P + ClCH_2C_6H_4{-}R + I_2 \xrightarrow{Na_2SO_3} (R{-}C_6H_4CH_2)_3P(O) +$$
$$+ RC_6H_4CH_2P(O)(OH)_2 + (R{-}C_6H_4CH_2)_2P(O)OH.$$

The synthesis of methylphosphonic acids with carbocyclic and heterocyclic substituents has been achieved by the reaction of trialkyl phosphites and sodium dialkyl phosphites with a wide variety of carbocyclic[168] and heterocyclic derivatives of methyl halides[169–174]. α-Furyl-[169], α-tetrahydrofuryl-[169,170], α-thienyl-[171], α-pyridyl-[172], and phthalimidomethyl-phosphonates[173,174], and phosphonates containing polycyclic substituents[157,168,175] were obtained.

6. Esters of Halogenomethyl-, Aminomethyl-, Hydroxymethyl-, and Alkoxymethyl-Phosphonic Acids

Esters of chloromethylphosphonic acids can be readily obtained by the reaction of chloromethylphosphonic dichloride with alcohols[112,176,177]. The dichlorides themselves became available after the discovery and development by Kabachnik and Shepeleva of the reaction between phosphorus trichloride and paraformaldehyde[176]:

$$PCl_3 + CH_2O \rightarrow ClCH_2P(O)Cl_2,$$
$$ClCH_2P(O)Cl_2 + 2\,ROH \rightarrow (RO)_2P(O)CH_2Cl + 2\,HCl.$$

A number of diarylchloromethylphosphine oxides[122,123] and the chlorides of alkyl- and aryl- chloromethylphosphinic acids were obtained similarly by the reaction of diarylchlorophosphines and alkyl- and aryl-dichlorophosphines with paraformaldehyde:

$$(R{-}C_6H_4)_2PCl + CH_2O \rightarrow (R{-}C_6H_4)_2P(O)CH_2Cl.$$

While the esters of bromomethyl-[101,179,180] and iodomethyl-phosphonic acids[30,101,105,180] and the free acids themselves[180] have been described in fair detail, the esters of fluoromethylphosphonic acid were difficult to obtain until recently. The reactions of the fluorides of dialkylphosphorous acids with diazomethane[158] or of the sodium salts of dialkylphosphorous with bromofluoromethane have been suggested for their synthesis[181]:

$$(RO)_2P(O)F + CH_2N_2 \rightarrow (RO)_2P(O)CH_2F + N_2\,,$$
$$(RO)_2PONa + BrCH_2F \rightarrow (RO)_2P(O)CH_2F + NaBr.$$

A simple method for the preparation of the chloride of di(chloromethyl)phosphinic acid, consisting in the reaction of phosphorus pentachloride with di(hydroxymethyl)phosphinic acid, was recently developed by Ivanov and coworkers[182]:

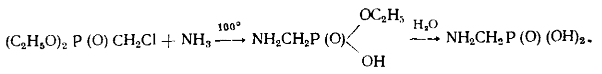
$$(HOCH_2)_2P(O)OH + 3\,PCl_5 \rightarrow (ClCH_2)_2P(O)Cl + 3\,HCl + 3\,POCl_3.$$

Numerous derivatives of di(chloromethyl)phosphinic[183] and di(chloromethyl)phosphinothionic acids[184-187] have been obtained from this acid chloride by substituting the chlorine at the phosphorus atom. These reactions may be represented by the following general equation:

$$(ClCH_2)_2P(O)Cl + RX \rightarrow (ClCH_2)_2P(O)X + RCl,$$

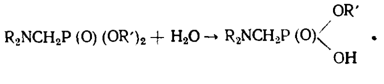
where X = OH, OAlk, OAr, $N(Alk)_2$, and others.

A number of methods have been proposed for the synthesis of aminomethylphosphonic acids and their various derivatives. When aqueous ammonia acts upon the esters of chloro- or iodo-methylphosphonic acids under severe conditions, the monoester of aminomethylphosphonic acid is formed. Its hydrolysis yielded the free aminomethylphosphonic acid[177]:



$$(C_2H_5O)_2P(O)CH_2Cl + NH_3 \xrightarrow{100^\circ} NH_2CH_2P(O)\begin{matrix} OC_2H_5 \\ OH \end{matrix} \xrightarrow{H_2O} NH_2CH_2P(O)(OH)_2.$$

Acid esters of dialkylaminomethylphosphonic acids may be obtained also as a result of the partial hydrolysis of the diesters[188]:



$$R_2NCH_2P(O)(OR')_2 + H_2O \rightarrow R_2NCH_2P(O)\begin{matrix} OR' \\ OH \end{matrix}\,.$$

An *N*-substituted aminomethylphosphonic acid was obtained by the reaction of benzoyl chloride with aminomethylphosphonic acid[177]:

$$NH_2CH_2P(O)(OH)_2 + C_6H_5COCl \rightarrow C_6H_5CONHCH_2P(O)(OH)_2.$$

In 1952 Kabachnik and Medved'[189,190] and somewhat later Fields[191] developed a simple method for the preparation of esters of α-aminoalkylphosphonic acids by the condensation of aldehydes and ketones with dialkylphosphorous acids and ammonia or amines[189-191]:

$$(RO)_2P(O)H + {>}C{=}O + H{-}N{<} \rightarrow (RO)_2P(O){-}\overset{|}{\underset{|}{C}}{-}N{<} + H_2O.$$

The reactions of dialkylphosphorous acids with formaldehyde and primary amines or ammonia give, depending on the proportions of the initial reactants, mono-, di-, and tri-(dialkylphosphonomethyl)amines[191-193]. Tertiary aminomethylphosphine oxides were obtained from secondary phosphine oxides, formaldehyde, and the amines[194,195]:

$$(CNCH_2CH_2)_2P(O)H + CH_2O + (C_4H_9)_2NH \rightarrow (CNCH_2CH_2)_2P(O)CH_2N(C_4H_9)_2.$$

Also in 1952 Pudovik found that substituted aminophosphinic esters can be readily obtained in high yields by the addition of partially esterified phosphorus acids to Schiff bases[196-198]:

$$(RO)_2P(O)H + X{-}C_6H_4CH{=}NC_6H_4Y \rightarrow (RO)_2P(O)\underset{\displaystyle C_6H_4X}{\underset{|}{C}}HNHC_6H_4Y.$$

This reaction was subsequently extended to carbodiimides, dibenzylidenediamines, and polymeric Schiff bases[199,200].

Esters of aminomethylphosphonic and di(aminomethyl)phosphinic acids are also formed by the reaction of alkyl hypophosphites with diethylaminomethyl esters and di(diethylamino)methane[201]:

$$ROP(O)H_2 + (C_2H_5)_2N{-}CH_2{-}N(C_2H_5)_2 \rightarrow ROP(O)[CH_2N(C_2H_5)_2]_2.$$

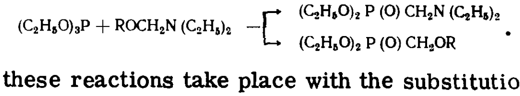
The reactions of trialkyl phosphites, diethyl phosphoroamidites, and phosphorous triamides with esters and ethers of aminomethanol and diethylaminoacetylnitrile give rise to esters and other derivatives of dialkylaminomethylphosphonic acids[202]:

$$(C_2H_5O)_3P + CNCH_2N(C_2H_5)_2 \rightarrow (C_2H_5O)_2P(O)CH_2N(C_2H_5)_2.$$

Böme and coworkers[203] showed that the reactions of aminoacetates with triethyl phosphite and diethyl phosphoroamidite take place even at room temperature forming the diethyl ester of dimethylaminomethylphosphonic acids and the ethyl ester of dimethylaminomethylphosphonoamidic acid:

$$(C_2H_5O)_3P + (CH_3)_2NCH_2OCOCH_3 \rightarrow (C_2H_5O)_2P(O)CH_2N(CH_3)_2.$$

The reactions of aminomethyl ethers with triethyl phosphite are not unambiguous. In the presence of acetic acid the C–O bond in the aminomethyl ether is broken and diethyl diethylaminomethylphosphonate is formed, while alkyl halides lead to the formation of diethylalkoxymethylphosphonates[204]:



$$(C_2H_5O)_3P + ROCH_2N(C_2H_5)_2 \rightarrow \begin{cases} (C_2H_5O)_2P(O)CH_2N(C_2H_5)_2 \\ (C_2H_5O)_2P(O)CH_2OR \end{cases}.$$

All these reactions take place with the substitution of amino-, acetate, and alkoxy-groups by a phosphono-group and have a common mechanism based on the Arbuzov rearrangement.

Similar reactions of *N*-hydroxymethylamides of acetic and benzoic acids with trialkyl phosphites lead to esters of acetamido- and benzamido- methylphosphonic acids[208]:

$$(RO)_3P + R'CONHCH_2OH \rightarrow (RO)_2P(O)CH_2NHCOR' + ROH.$$

The reaction of the *N*-hydroxymethylamide of chloroacetic acid with triethyl phosphite is much more complicated, forming a mixture of products consisting of the ester, amide, and nitrile of diethoxyphosphonoacetic acid[51]:

$$(C_2H_5O)_3P + ClCH_2CONHCH_2OH \rightarrow (C_2H_5O)_2P(O)CH_2COOC_2H_5 + \\ + (C_2H_5O)_2P(O)CH_2CONH_2 + (C_2H_5O)_2P(O)CH_2CN.$$

The reaction of phosphorus trichloride with an *N*-hydroxymethylamide followed by hydrolysis of the products gave *N*-alkylaminomethylphosphonic acid[206,207]:

$$PCl_3 + RCONR'CH_2OH \rightarrow RCONR'CH_2OPCl_2 \rightarrow RCONR'CH_2P(O)Cl_2 \rightarrow \\ \rightarrow RCONR'P(O)(OH)_2 \rightarrow NHR'CH_2P(O)(OH)_2.$$

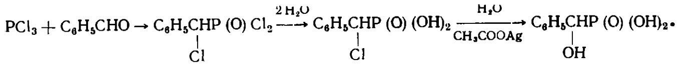
When aminomethylphosphonic acid was acted upon by nitrous acid, hydroxymethylphosphonic acid was obtained[177]:

$$NH_2CH_2P(O)(OH)_2 + HNO_2 \xrightarrow{H_2O} HOCH_2P(O)(OH)_2.$$

Earlier hydroxymethylphosphonic acid had been synthesised by the hydrolysis of the intermediate formed in the reaction between phosphorus trichloride and paraformaldehyde[208]:

$$PCl_3 + (CH_2O)_3 \xrightarrow{H_2O} HOCH_2P(O)(OH)_2.$$

Similarly the reaction of phosphorus trichloride and benzaldehyde gave the dichloride of α-chlorobenzylphosphonic acid, the hydrolysis of which can yield both α-chlorobenzylphosphonic and α-hydroxybenzylphosphonic acids, depending on the conditions[209]:



$$PCl_3 + C_6H_5CHO \rightarrow C_6H_5\underset{\mid \atop Cl}{C}HP(O)Cl_2 \xrightarrow{2H_2O} C_6H_5\underset{\mid \atop Cl}{C}HP(O)(OH)_2 \xrightarrow[CH_3COOAg]{H_2O} C_6H_5\underset{\mid \atop OH}{C}HP(O)(OH)_2.$$

Abramov[210] showed for the first time that esters of hydroxymethylphosphonic acid are formed as a result of the addition of dialkylphosphorous acid to formaldehyde[211]. A large number of derivatives of both hydroxymethyl- and hydroxyalkyl-phosphonic acids have been obtained by the addition of partially esterified phosphorus acids to various carbonyl compounds.

Esters of alkoxymethylphosphonic[212], methylthiomethylphosphonic[213], and alkoxymethylphenylphosphinic[214] acids are formed in high yields when alkylchloromethyl and chloromethylthiomethyl ethers react with trialkyl phosphites and diethyl phenylphosphonite:

$$(RO)_3P + ClCH_2OR' \rightarrow (RO)_2P(O)CH_2OR' + RCl.$$

Depending on the conditions, the reaction of α-chloro- or α-bromo-methyl ethers with sodium dialkylphosphites gives rise either to esters of alkoxymethylphosphonic or an involatile mixture of ester salts[109,215,216]:

$$(RO)_2PONa + HalCH_2OCH_3 \rightarrow (RO)_2P(O)CH_2OCH_3 + {RO \atop NaO}\rangle P(O)-CH_2-OCH_3.$$

The sodium salt of diethylphosphinous acid reacts similarly with butyl chloromethyl ether[217].

III. REACTIONS OF ORGANOPHOSPHORUS COMPOUNDS WITH AN ACTIVE METHYLENE GROUP BASED ON THE MOBILITY OF ITS HYDROGEN ATOMS

The hydrogen atoms of the methylene group in organophosphorus compounds, located between two electron-accepting groups, become so mobile that the proton is readily eliminated with formation of carbanions even in reactions with weak organic bases.

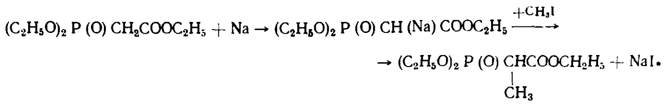
A method has been proposed recently for a quantitative determination of mobile hydrogen atoms in compounds of this type[218]. It is a modification of the standard Chugaev–Tserevitinov method for the determination of mobile hydrogen and consists in the reaction of methylmagnesium iodide with the test compound. It was shown that, when the substituent X in the compound $\rangle P(O)-CH_2-X^-$ is an electron-accepting group, both hydrogen atoms in the methylene group become mobile (esters and nitrile of diethoxyphosphonoacetic acid, diethoxyphosphonoacetone, and diethoxyphosphonoacetophenone). When the substituents X are various hydrocarbon residues or other groups without electron-accepting properties or with weak properties of this kind, only one hydrogen atom is mobile (esters of ethyl-, benzyl-, and propoxymethyl-phosphonic acids). Mobile hydrogen is found also in phosphonium salts of the type[219] $[(C_6H_5)_3\overset{+}{P}CH_2COAr]X^-$.

According to the data of Kabachnik and coworkers, the hydrogen atoms of the methylene group located between two diphenylphosphine oxide groups exhibit distinct proton mobility[220]. Thus tetraphenylmethylenediphosphine dioxide in aniline solution enriched with deuterium undergoes hydrogen isotope exchange at an appreciable rate even at room temperature. It has been confirmed by ^{1}H NMR that only the hydrogen atoms of the methylene group are involved in the isotope exchange.

Among the reactions of organophosphorus compounds with an active methylene group based on the mobility of the hydrogen atoms, the most important and the most interesting are the alkylation and acylation reactions, reactions involving addition to αβ-unsaturated compounds with activated multiple bonds, and reactions with carbonyl compounds.

1. Alkylation and Acylation Reactions

A. E. Arbuzov and Dunin[221-223] were the first to show that the reaction of alkyl halides with the sodio-derivative of diethoxyphosphonoacetic ester results in the formation of alkyl-substituted ethyl diethoxyphosphonoacetates[25,30 224-232]:



$$(C_2H_5O)_2P(O)CH_2COOC_2H_5 + Na \rightarrow (C_2H_5O)_2P(O)CH(Na)COOC_2H_5 \xrightarrow{+CH_3I} \\ \rightarrow (C_2H_5O)_2P(O)\underset{\mid \atop CH_3}{C}HCOOCH_2H_5 + NaI.$$

Alkyl halides, esters of α-halogenocarboxylic acids, α-halogenoethers, and α-halogenoketones have been used as alkylating agents in the alkylation of esters of diethoxyphosphonoacetic acid[230]. Pudovik and coworkers[233] showed that the alkylation of diethoxyphosphonoacetic ester with isomeric butadiene hydrochlorides gives in both cases the same product, corresponding to the structure of the primary chloride—the ester of but-2-enyldiethoxyphosphonoacetic acid. The reaction with the secondary chloride takes place with complete allyl rearrangement:

$$(C_2H_5O)_2P(O)\underset{\mid \atop COOC_2H_5}{C}H-Na + \underset{(CH_3CHClCH=CH_2)}{ClCH_2CH=CHCH_3} \rightarrow (C_2H_5O)_2P(O)\underset{\mid \atop COOC_2H_5}{C}HCH_2CH=\underset{\mid \atop CH_3}{C}H.$$

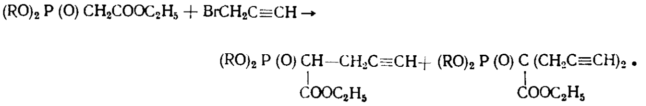
Apart from the alkylation of diethoxyphosphonoacetic esters, the alkylation of diethoxyphosphonoacetone[74,76,97, 231,232] and diethoxyphosphonoacetonitrile[41,230] has been investigated in fair detail. The alkylation of diethoxyphosphonoacetone can be achieved fairly readily when its sodio-derivative is acted upon both by alkyl halides[74,76,231] and the ethyl esters of bromoacetic and α-bromo-propionic acids and bromoacetone[230]:

$$(C_2H_5O)_2P(O)CH(Na)COCH_3 + BrCH_2COCH_3 \rightarrow (C_2H_5O)_2P(O)\underset{\displaystyle COCH_3}{CH}CH_2COCH_3 + NaBr.$$

The alkylation of diethoxyphosphonoacetonitrile with alkyl halides takes place most readily when its potassio-derivative in ether–dioxane solution is employed. In this case alkyl iodides are the most effective[41]:

$$(C_2H_5O)_2P(O)CH_2CN + K + RI \rightarrow (C_2H_5O)_2P(O)-\underset{\displaystyle CN}{CH}-R + KI.$$

In the alkylation of the esters and nitrile of diethoxyphosphonoacetic acid and of diethoxyphosphonoacetone with equimolar amounts of alkylating agents, monoalkylation products were obtained in all cases. However, when propargyl bromide acts upon sodio- or potassio-derivatives of the ethyl ester or nitrile of diethoxyphosphonoacetic acid, a mixture of products of the substitution of one and two hydrogen atoms for a propargyl group is formed[234]. Evidently the introduction of a third electron-accepting group increases the mobility of the remaining hydrogen atom to such an extent that even with an equimolar ratio of the initial reactants the dialkylation product is formed preferentially:

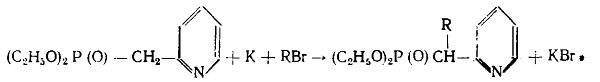


$$(RO)_2P(O)CH_2COOC_2H_5 + BrCH_2C{\equiv}CH \rightarrow$$
$$(RO)_2P(O)\underset{\displaystyle COOC_2H_5}{CH}-CH_2C{\equiv}CH + (RO)_2P(O)\underset{\displaystyle COOC_2H_5}{C}(CH_2C{\equiv}CH)_2.$$

The dialkylation products of esters of diethoxy-[225], diethyl-[16], and diphenyl-phosphonoacetic acids[16] were obtained by the action of alkyl halides on the sodio- or potassio-derivatives of the corresponding monoalkylated products:

$$R_2P(O)\underset{\displaystyle COOC_2H_5}{C}R'(Na) + R''Hal \rightarrow R_2P(O)\underset{\displaystyle COOC_2H_5}{C}(R')(R'') + NaHal.$$

Among other organophosphorus compounds with an active methylene group, diethyl 2-pyridylmethylphosphonate[235] and tetraethyl methylenediphosphonate[100,102] were alkylated with alkyl bromides:

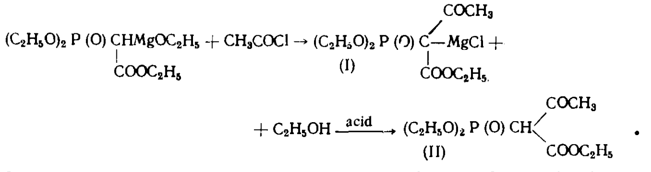


The alkylation of the diphosphonate takes place with much more difficulty[236]. The reaction of butyl bromide with the potassio-derivative of tetraethoxydiphosphonomethane gave butyl(tetraethoxydiphosphono)methane in a yield of only about 15%[102]:

$$(C_2H_5O)_2P(O)CH_2P(O)(OC_2H_5)_2 + K + C_4H_9Br \xrightarrow[-KBr]{} [(C_2H_5O)_2P(O)]_2CH-C_4H_9.$$

In the alkylation of metallated derivatives of methylenediphosphine dioxides with alkyl iodides, it was shown that sodium iodide is firmly retained by the alkylated dioxide[237-239]. A tetrasubstituted product was obtained in the alkylation with allyl bromide of ethyl dimethylenetriphosphonate, which has two active methylene groups, as a result of the successive substitution of their mobile hydrogen atoms[125].

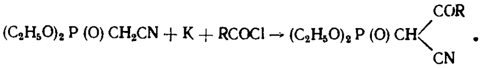
The acylation of organophosphorus compounds with an active methylene group has been investigated in less detail. It has not proved possible to obtain *C*-acylated products from diethoxyphosphonoacetic ester by the action of acetyl chloride on the alkali metal salts[240]. However, when the ethoxymagnesium salt of diethoxyphosphonoacetic ester was employed, ethyl diethoxyphosphonoacetoacetate (II) was obtained in a good yield:



$$(C_2H_5O)_2P(O)\underset{\displaystyle COOC_2H_5}{CH}MgOC_2H_5 + CH_3COCl \rightarrow \underset{(I)}{(C_2H_5O)_2P(O)\overset{\displaystyle COCH_3}{\underset{\displaystyle COOC_2H_5}{C}}-MgCl} +$$
$$+ C_2H_5OH \xrightarrow{acid} \underset{(II)}{(C_2H_5O)_2P(O)CH}\begin{matrix}COCH_3\\COOC_2H_5\end{matrix}.$$

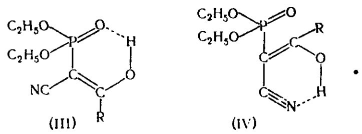
Diethoxyphosphonomalonic ester is obtained similarly.

The acylation of diethoxyphosphonoacetonitrile is achieved by the reaction of its potassio-derivative with the chlorides of acetic, propionic, n-butyric, and benzoic acids[241]:



$$(C_2H_5O)_2P(O)CH_2CN + K + RCOCl \rightarrow (C_2H_5O)_2P(O)CH\begin{matrix}COR\\CN\end{matrix}.$$

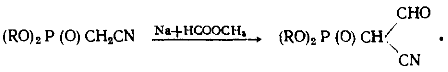
The authors suggest on the basis of infrared spectroscopy that the *C*-acyl derivatives of diethoxyphosphonoacetonitrile can have structures (III) or (IV):



(III) (IV)

The preferred structure is (III), in which the formation of a hydrogen bond involving the P=O group is postulated, since the displacement of the P=O absorption band is much greater (by 90 cm^{-1}) compared with the band due to the CN-group (by 50 cm^{-1}).

Recently it proved possible to formylate dialkoxyphosphonoacetonitriles[242]:

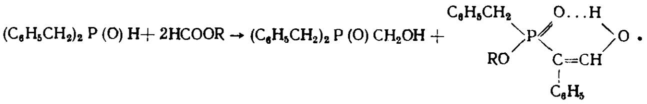


$$(RO)_2P(O)CH_2CN \xrightarrow{Na+HCOOCH_3} (RO)_2P(O)CH\begin{matrix}CHO\\CN\end{matrix}.$$

The formylation of the esters of dialkoxyphosphonoacetic[243], benzylphosphonic[244], and dibenzylphosphinous[245] acids has also been described:

$$(C_2H_5O)_2P(O)CH_2C_6H_5 + HCOOCH_3 \rightarrow (C_2H_5O)_2P(O)\underset{\displaystyle CHO}{CH}-C_6H_5 + CH_3OH.$$

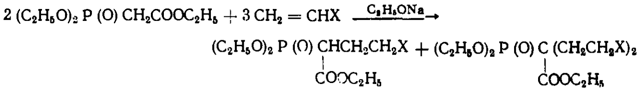
However, in the last case the reaction takes place in a more complex manner: instead of the expected product, dibenzylhydroxymethylphosphine oxide and an enol are formed[245]:



2. Addition Reactions

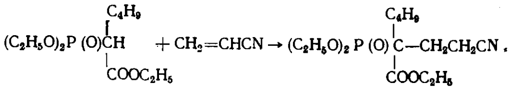
Reactions involving the addition of partially esterified phosphorus acids and organophosphorous compounds with an active methylene group to unsaturated electrophilic compounds, which were first achieved by Pudovik, serve as the basis of a new method for the synthesis of various derivatives of phosphonic and phosphinic acids[246].

The addition of diethoxyphosphonoacetic ester to the nitrile and the methyl ester of acrylic acid takes place readily in the presence of a small amount of sodium ethoxide. Products of addition to one and two molecules of the unsaturated compound have been isolated[224,231,247]:



$$2(C_2H_5O)_2P(O)CH_2COOC_2H_5 + 3CH_2=CHX \xrightarrow{C_2H_5ONa} (C_2H_5O)_2P(O)\underset{COOC_2H_5}{C}HCH_2CH_2X + (C_2H_5O)_2P(O)\underset{COOC_2H_5}{C}(CH_2CH_2X)_2,$$

where X = CN or $COOCH_3$. The addition of homologues of diethoxyphosphonoacetic ester—methyl and butyl diethoxyphosphonoacetates—to electrophilic compounds—acrylonitrile, methyl acrylate, and methyl methacrylate—also takes place readily[224,247]:



$$(C_2H_5O)_2P(O)\overset{C_4H_9}{\underset{COOC_2H_5}{C}}H + CH_2=CHCN \rightarrow (C_2H_5O)_2P(O)\overset{C_4H_9}{\underset{COOC_2H_5}{C}}-CH_2CH_2CN.$$

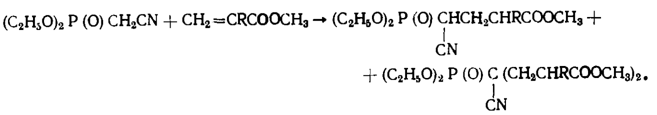
When alkylalkoxy-, dialkyl-, and diphenyl-phosphonoacetic acids and their homologues, in which the methylene group is less reactive, were added to unsaturated compounds, the potassio-derivatives of the esters were employed[248]:

$$R_2P(O)CH_2COOC_2H_5 + CHR'=CR''X \xrightarrow{R_2P(O)CH(K)COOC_2H_5} R_2P(O)\underset{COO_2H_5}{C}HCHR'CHR''X,$$

Later the addition of phosphonoacetic esters to nitroisopentene, ethyl vinyl sulphone[249], divinyl sulphone, and *p*-di-(β-nitrovinyl)benzene[250] to esters of maleic[251], cinnamic[231], crotonic[252], and propynylphosphonic[253] acids, and also unsaturated polyesters[254] was achieved. The esters of αβ-unsaturated carboxylic acids can be arranged in the following sequence in terms of their reactivity in reactions involving the addition of diethoxyphosphonoacetic ester: acrylates > crotonates > methacrylates > cinnamates[247].

The addition of diethoxyphosphonoacetone and its homologues to acrylonitrile[255], methyl acrylate, diethyl maleate, diethyl acetylenedicarboxylate, and ethylideneacetone[231] has been achieved. In most cases these reactions take place with greater difficulty and are accompanied by very small heat change. In order to drive the reactions to completion, the reaction mixtures must be heated for a long time.

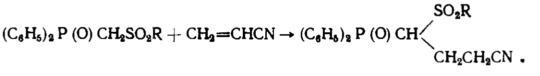
The addition of diethoxyphosphonoacetonitrile and its homologues[41,247,256] takes place much more readily compared with that of diethoxyphosphonoacetic ester and diethoxyphosphonoacetone:



$$(C_2H_5O)_2P(O)CH_2CN + CH_2=CRCOOCH_3 \rightarrow (C_2H_5O)_2P(O)\underset{CN}{C}HCH_2CHRCOOCH_3 + (C_2H_5O)_2P(O)\underset{CN}{C}(CH_2CHRCOOCH_3)_2.$$

Diethoxyphosphonoacetonitrile is somewhat more reactive and ethyl diethoxyphosphonoacetate somewhat less reactive than dibutylphosphorous acid, as shown by experiments on "competing addition" and confirmed by the results of a kinetic study of the addition of a number of organophosphorus compounds with a mobile hydrogen atom to acrylonitrile. The introduction of an alkyl residue into the methylene group of diethoxyphosphonoacetic ester results in a lowering of its reactivity in addition reactions[257].

The addition of (alkylsulphonyl)methyldiphenylphosphine oxide[258] and butyl (ethylsulphonyl)methylphenylphosphinate[259] to acrylonitrile has also been achieved:

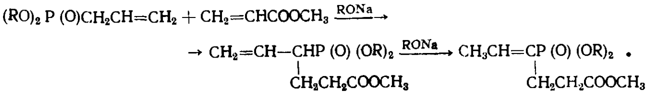


$$(C_6H_5)_2P(O)CH_2SO_2R + CH_2=CHCN \rightarrow (C_6H_5)_2P(O)CH\begin{matrix} SO_2R \\ CH_2CH_2CN \end{matrix}.$$

When benzylphosphonic ester was added to acrylonitrile and ethyl acrylate, it proved impossible to isolate the addition product in a pure form[260]; in the reaction with ethyl cinnamate the addition product was isolated and characterised[261]:

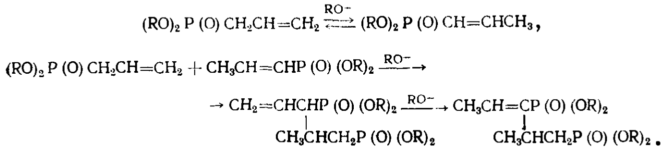
$$(C_2H_5O)_2P(O)CH_2C_6H_5 + C_6H_5CH=CHCOOC_2H_5 \xrightarrow[70^\circ,\ 1.5\ h]{C_2H_5ONa} (C_2H_5O)_2P(O)\underset{C_2H_5OOC-CH_2-\underset{}{C}H-C_6H_5}{CH}-C_6H_5.$$

The addition of dialkyl esters of allylphosphonic acid to methyl acrylate yields the methyl esters of 3-(dialkoxyphosphono)pentene-3-carboxylic acid. The addition products formed initially, in the presence of sodium alkoxide, undergo prototropic isomerisation[262]:



$$(RO)_2P(O)CH_2CH=CH_2 + CH_2=CHCOOCH_3 \xrightarrow{RONa} \rightarrow CH_2=CH-\underset{CH_2CH_2COOCH_3}{C}HP(O)(OR)_2 \xrightarrow{RONa} CH_3CH=\underset{CH_2CH_2COOCH_3}{C}P(O)(OR)_2.$$

In the presence of sodium ethoxide, diethyl allylphosphonate is converted into a dimeric product—1,3-di(diethoxyphosphono)-2-methylpent-3-ene[263]. Evidently the first stage in this reaction is prototropic isomerisation of the allylphosphonic ester to the diethyl ester of propenylphosphonic acid, which then adds on a second molecule of the allylphosphonic ester at the double bond. In the presence of alkoxide anions, the addition products undergo further prototropic isomerisation with formation of the final products[262]:



$$(RO)_2P(O)CH_2CH=CH_2 \overset{RO^-}{\rightleftarrows} (RO)_2P(O)CH=CHCH_3,$$

$$(RO)_2P(O)CH_2CH=CH_2 + CH_3CH=CHP(O)(OR)_2 \xrightarrow{RO^-} \rightarrow CH_2=CH\underset{CH_3CHCH_2P(O)(OR)_2}{C}HP(O)(OR)_2 \xrightarrow{RO^-} CH_3CH=\underset{CH_3CHCH_2P(O)(OR)_2}{C}P(O)(OR)_2.$$

The possibility of the prototropic isomerisation of allylphosphonic esters to the propenyl isomers has been demonstrated by Ionin and Petrov for diethyl allylphosphonate and its methyl-, chloromethyl-, and phenyl-substituted derivatives[137]:

$$R-\overset{R'}{C}=CHCH_2P(O)(OC_2H_5)_2 \rightleftarrows R-\overset{R'}{C}H-CH=CHP(O)(OC_2H_5)_2.$$

Analysis of infrared, ultraviolet, and NMR (^1H and ^{31}P) spectroscopic data established that the isomerisation goes to completion only in the case of the allylphosphonic ester. Crotylphosphonic ester isomerises to the extent of 25% and cinnamylphosphonic ester does not isomerise at all. In the case of γ-chlorocrotylphosphonic ester the chlorine is replaced by an ethoxy-group without isomerisation. The above data led to the conclusion that the diethoxyphosphono-group interacts very weakly with a double bond. Conjugation with this group is less stable than hyperconjugation between a methyl group and a double bond. The conjugation between a double bond and a benzene ring is incomparably more favourable than the possible conjugation of this bond with a diethoxyphosphono-group[137].

Recently Kirilov and coworkers found that the ethyl esters of diethoxy- and di-isopropoxy-phosphonoacetic acids and diethoxyphosphonoacetonitrile add to the C=N double bonds of Schiff bases—benzylideneaniline, benzylidene-*p*-chloroaniline, etc.[264] The reactions take place in the presence of aluminium chloride, sodamide, and sodium alkoxides. The yields of the addition products are 30–60% and depend on the catalyst; the highest yields were obtained with aluminium chloride[265]:

$$(RO)_2P(O)CH_2X + C_6H_5CH=N-C_6H_4-R \rightarrow (RO)_2P(O)CH(X)CH(C_6H_5)NHC_6H_4-R,$$

where X = $COOC_2H_5$ or CN.

3. Condensation and P(O)-activated Olefin Synthesis

Condensation reactions. The possibility of the condensation of organophosphorus compounds having an active methylene group with aldehydes was demonstrated for the first time by Pudovik and Lebedeva in 1953. By heating diethoxyphosphonoacetic ester with benzaldehyde in acetic anhydride solution, they obtained the diethyl ester of α-ethoxycarbonyl-β-phenylvinylphosphonic acid[255]:

$$(C_2H_5O)_2P(O)\underset{\displaystyle COOC_2H_5}{\underset{|}{CH_2}} + C_6H_5CHO \xrightarrow{(CH_3CO)_2O} (C_2H_5O)_2P(O)\underset{\displaystyle COOC_2H_5}{\underset{|}{C}}{=}CHC_6H_5 + 2\,CH_3COOH\,.$$

Later in the condensation of diethoxyphosphonoacetic ester with benzaldehyde under somewhat different conditions and in the presence of piperidine the yield of the condensation product was greatly increased[266,267]. The product of the condensation of benzaldehyde with two moles of diethoxyphosphonoacetic ester was also obtained in low yield[266].

Diethoxyphosphonoacetic ester reacts with aliphatic aldehydes and in particular formaldehyde under milder conditions, in methanol solution in the presence of piperidine. The esters of α-ethoxycarbonylvinylphosphonic acid have been obtained by this method[268]:

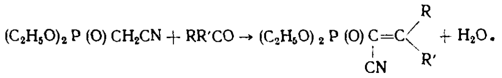
$$(C_2H_5O)_2P(O)\underset{\displaystyle COOC_2H_5}{\underset{|}{CH_2}} + CH_2O \rightarrow (C_2H_5O)_2P(O)\underset{\displaystyle COOC_2H_5}{\underset{|}{C}}{=}CH_2 + H_2O\,.$$

The synthesis of esters of α-alkoxycarbonyl- and α-cyanovinylphosphonic acids by the condensation reaction has significant advantages both as regards yields and the availability of the starting materials over the methods for the preparation of these compounds described previously[264,270].

In the presence of piperidine, diethoxyphosphonoacetonitrile readily condenses with both aliphatic[271-273] and aromatic aldehydes[42,274]:

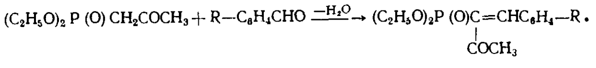
$$(C_2H_5O)_2P(O)CH_2CN + CH_2O \rightarrow (C_2H_5O)_2P(O)\underset{\displaystyle CN}{\underset{|}{C}}{=}CH_2 + H_2O\,.$$

In the presence of ammonium acetate and acetic acid, reaction with ketones also take place[275]:



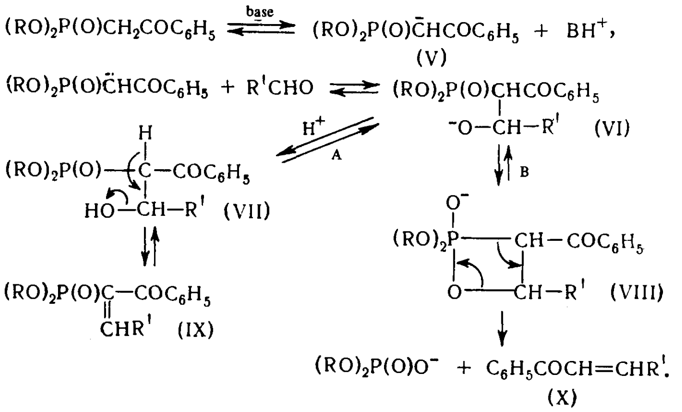
$$(C_2H_5O)_2P(O)CH_2CN + RR'CO \rightarrow (C_2H_5O)_2P(O)\underset{\displaystyle CN}{\underset{|}{C}}{=}C\begin{matrix} R \\ R' \end{matrix} + H_2O\,.$$

Recently we showed that diethoxyphosphonoacetone[274,276,277] and diethoxyphosphonoacetophenone[278,279] are also capable of condensing with aliphatic and aromatic aldehydes. The reactions occur in benzene or toluene solutions in the presence of piperidine with simultaneous azeotropic distillation of the water formed:



$$(C_2H_5O)_2P(O)CH_2COCH_3 + R{-}C_6H_4CHO \xrightarrow{-H_2O} (C_2H_5O)_2P(O)\underset{\displaystyle COCH_3}{\underset{|}{C}}{=}CHC_6H_4{-}R\,.$$

The reactions of aldehydes with dialkoxyphosphonoacetophenones are of considerable theoretical interest[279]. We established that the reaction with p-nitrobenzaldehyde can involve simultaneously either condensation or P(O)-activated olefin formation:



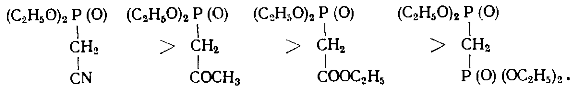
The carbonion (V), formed when a basic reagent acts upon the organophosphorus compound with an active methylene group, interacts further with the carbonyl compound and is converted into the anion (VI). Both stages are common to the condensation and P(O)-activated olefin formation reactions. By combining with a proton, the anion (VI) is converted into the alcohol (VII) and its dehydration gives the condensation product (IX) (pathway *A*). The P(O)-activated olefin formation reaction (pathway *B*) probably takes place via the intermediate formation of an unstable four-membered cyclic product or transition state (VIII) (by analogy with the Wittig reaction); the bond redistribution in (VIII) leads to a phosphoric acid and an unsaturated ketone.

The rate and mode of this complex and multistage reaction depend both on the nature and amount of the catalysts and solvents employed and on the structure of the organophosphorus compounds and aldehydes[279].

Tetraethoxydiphosphonomethane, which has a less active methylene group, condenses with benzaldehyde only after prolonged heating of the reactants in xylene with simultaneous azeotropic distillation of the water formed[280]:

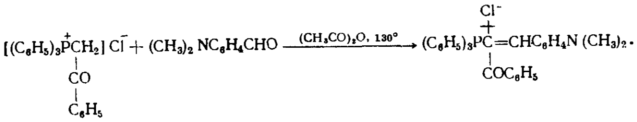
$$[(C_2H_5O)_2P(O)]_2CH_2 + C_6H_5CHO \rightarrow C_6H_5CH{=}C[P(O)(OC_2H_5)_2]_2 + H_2O\,.$$

Organophosphorus compounds with an active methylene group can be arranged in the following sequence in terms of their relative reactivities in condensation reactions with aldehydes[274]:



$$\underset{\displaystyle CN}{\underset{|}{\overset{\displaystyle (C_2H_5O)_2P(O)}{\overset{|}{CH_2}}}} > \underset{\displaystyle COCH_3}{\underset{|}{\overset{\displaystyle (C_2H_5O)_2P(O)}{\overset{|}{CH_2}}}} > \underset{\displaystyle COOC_2H_5}{\underset{|}{\overset{\displaystyle (C_2H_5O)_2P(O)}{\overset{|}{CH_2}}}} > \underset{\displaystyle P(O)(OC_2H_5)_2\,.}{\underset{|}{\overset{\displaystyle (C_2H_5O)_2P(O)}{\overset{|}{CH_2}}}}$$

Phosphonium salts also condense with aldehydes; thus dyes analogous to styryl dyes have been obtained by the condensation of phosphonium salts with p-dimethylaminobenzaldehyde[281]:



$$[(C_6H_5)_3\overset{+}{P}\underset{\displaystyle \underset{\displaystyle C_6H_5}{\underset{|}{CO}}}{\underset{|}{CH_2}}]\,\overset{-}{Cl} + (CH_3)_2NC_6H_4CHO \xrightarrow{(CH_3CO)_2O,\ 130^\circ} (C_6H_5)_3\overset{\displaystyle \overset{Cl^-}{+}}{P}\underset{\displaystyle COC_6H_5}{\underset{|}{C}}{=}CHC_6H_4N(CH_3)_2\,.$$

The P(O)-activated olefin formation reaction. The P(O)-activated olefin formation reaction, discovered by Horner in 1958, is characteristic of and specific to organophosphorus compounds with an active methylene group. It is of great preparative importance in organic chemistry, since it permits the syntheses of a wide variety of unsaturated hydrocarbons and their various derivatives.

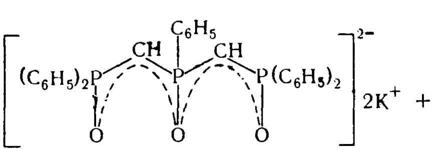
The use of reagents for the P(O)-activated synthesis of olefins is more effective than the Wittig reaction involving various phosphoranes. In relation to carbonyl compounds and in particular to ketones, reagents for P(O)-activated olefin synthesis are more reactive by virtue of their more pronounced nucleophilic properties compared with phosphoranes. The isolation of olefins is greatly facilitated when the P(O)-activated olefin formation method is employed. The unsaturated compounds obtained can be readily separated from the readily water-soluble alkali metal salts of alkylphosphoric acids, while in the Wittig reactions it is necessary to resort to special procedures for the separation of the olefin from triphenylphosphine oxide. Moreover, reagents for P(O)-activated olefin synthesis are more readily available than the Wittig reagents.

A detailed review has been published on the P(O)-activated olefin formation reaction in organic synthesis[282]. Here we shall confine ourselves to a discussion of studies which have been published recently and in which diphosphono-derivatives were used as for P(O)-activated olefin synthesis reagents. Reactions of this type are of considerable interest also because they permit a fairly simple synthesis of various unsaturated organophosphorus compounds.

The possibility of synthesising vinylphosphonates by the P(O)-activated olefin formation reaction was first demonstrated by Wadsworth and Emmons[283]. They obtained the diethyl ester of β-phenylvinylphosphonic acid by the reaction of tetraethoxydiphosphonomethane with benzaldehyde in the presence of sodium hydride[283]:

$$[(C_2H_5O)_2P(O)]_2CH_2 + C_6H_5CHO \xrightarrow{NaH} (C_2H_5O)_2P(O)CH{=}CHC_6H_5 .$$

Similarly, even with the potassio-derivative of tetraphenylmethylenediphosphinedioxide, Kabachnik and coworkers obtained also unsaturated phosphine oxides[130]. Phosphine oxides with two unsaturated substituents may be obtained by using in the reaction with aldehydes the dipotassio-derivative of pentaphenyldimethylenetriphosphine trioxide[127]:



$$+\ 2C_6H_5CHO \xrightarrow{-2(C_6H_5)_2P(O)OK} (C_6H_5CH{=}CH)_2P(O)C_6H_5 .$$

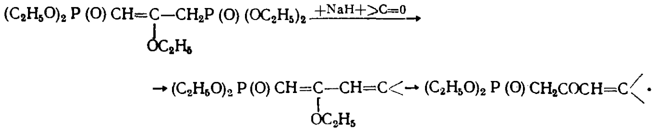
The P(O)-activated olefin formation reaction permits the synthesis of organophosphorus compounds with a substituent at the phosphorus atom containing several conjugated double bonds. For example, cinnamaldehyde is allowed to react for this purpose with the potassio-derivative of tetraethoxydiphosphonomethane[284]:

$$[(C_2H_5O)_2P(O)]_2CHK + C_6H_5CH{=}CHCHO \rightarrow (C_2H_5O)_2P(O)CH{=}CHCH{=}CHC_6H_5 .$$

Diphosphonomethane derivatives in which the hydrogen has been replaced by another group readily enter into the P(O)-activated olefin formation reaction. Thus esters of unsaturated phosphonic acids containing the dimethylamino-group at the α-carbon atom have been obtained from di(diethoxyphosphono)dimethylaminomethane[285]:

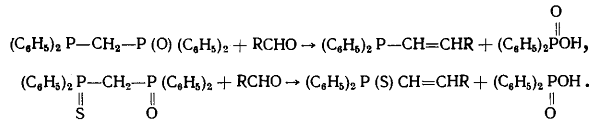
$$[(C_2H_5O)_2P(O)]_2CHN(CH_3)_2 + RCHO \rightarrow (C_2H_5O)_2P(O)C(N(CH_3)_2){=}CHR .$$

Unsaturated ketophosphonic esters were obtained by Normant by the reaction of carbonyl compounds with the sodio-derivative of 2-ethoxy-1,3-diphosphonopropene[265]:



$$(C_2H_5O)_2P(O)CH{=}C(OC_2H_5){-}CH_2P(O)(OC_2H_5)_2 \xrightarrow{+NaH+{>}C{=}0} (C_2H_5O)_2P(O)CH{=}C(OC_2H_5){-}CH{=}C{<} \rightarrow (C_2H_5O)_2P(O)CH_2COCH{=}C{<} .$$

$\alpha\beta$-Unsaturated phosphines and phosphine sulphides have been obtained with the aid of the P(O)-activated olefin formation reaction[286]. In this case compounds containing simultaneously ter- and quinque-valent phosphorus atoms or diphenylphosphine oxide and diphenylphosphine sulphide groups were used in this case as reagents for P(O)-activated olefin synthesis:



$$(C_6H_5)_2P{-}CH_2{-}P(O)(C_6H_5)_2 + RCHO \rightarrow (C_6H_5)_2P{-}CH{=}CHR + (C_6H_5)_2P(O)OH,$$
$$(C_6H_5)_2P(S){-}CH_2{-}P(O)(C_6H_5)_2 + RCHO \rightarrow (C_6H_5)_2P(S)CH{=}CHR + (C_6H_5)_2P(O)OH .$$

4. Reactions of Other Types

Among other reactions of organophosphorus compounds with an active methylene group in which the methylene hydrogen atoms are involved, bromination, chlorination, and azo-coupling reactions are known.

The bromination of diethoxyphosphonoacetone and diethoxyphosphonoacetaldehyde with elemental bromine takes place readily and rapidly in ethereal solution[40]:

$$(C_2H_5O)_2P(O)CH_2COCH_3 + Br_2 \rightarrow (C_2H_5O)_2P(O)CH(Br)COCH_3 + HBr .$$

Chlorination of diethoxyphosphonoacetone with sulphuryl chloride gave a high yield of α-chlorodiethoxyphosphonoacetone[287]. When an excess of chlorine is allowed to react with dialkoxyphosphonoacetonitriles with simultaneous ultraviolet irradiation of the reaction mixture, both hydrogen atoms are substituted[288]:

$$(RO)_2P(O)CH_2CN + 2Cl_2 \xrightarrow[25-30^\circ]{h\nu} (RO)_2P(O)CCl_2CN + 2HCl .$$

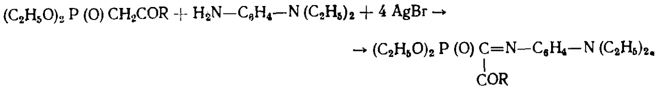
Without ultraviolet irradiation, the chlorination does not take place but at a higher temperature not only the methylene group but also the alkoxy-group and the phosphorous atoms are chlorinated.

The azo-coupling of aromatic diazo-compounds with diethoxyphosphonoacetic ester, diethoxyphosphonoacetone, and diethoxyphosphonoacetonitrile has been achieved. The reactions were carried out under mild conditions in the absence of catalysts[289]:

$$(C_2H_5O)_2P(O)CH_2X + ClN_2C_6H_4R \rightarrow (C_2H_5O)_2P(O)CH(X){-}N{=}NC_6H_4R + HCl,$$

where X = $COOC_2H_5$, $COCH_3$, or CN.

There are data showing that the reaction of diethylaminoaniline with organophosphorus compounds having an active methylene group in the presence of silver bromide leads to the formation of azomethylene dyes containing the phosphono-group[290]:



$$(C_2H_5O)_2P(O)CH_2COR + H_2N{-}C_6H_4{-}N(C_2H_5)_2 + 4\,AgBr \rightarrow$$

$$\rightarrow (C_2H_5O)_2P(O)\underset{\displaystyle COR}{\underset{|}{C}}{=}N{-}C_6H_4{-}N(C_2H_5)_2.$$

However, later it was shown that in the case of diethoxyphosphonoacetophenone the yields of dyes in this reaction are very low and they cannot be isolated in a pure form[291,292].

Organosilicon Ketones

N.V.Komarov and V.K.Roman

One of the most important fields in the chemistry of organosilicon compounds at the present time is the chemistry of organic silanes and siloxanes with carbon-containing functional groups[1-6]. Polysiloxanes with vinyl, nitrile, hydroxy- and other functional groups in the silane exhibit enhanced mechanical strength compared with alkylsiloxanes, are satisfactorily compatible with many materials, and have already found industrial application. Organic silanes and siloxanes with carbonyl groups in the organic substituents are also used in the manufacture of new products[7-11]. Patent data show that polyketoalkylsiloxanes exhibit improved adhesion to metallic surfaces[12]. The aim of the review is to describe methods for the preparation and the properties of silicon-containing ketones. In earlier monographs[3,13] and a review[14] on organic silanes with carbon-containing functional groups, the sections dealing with organosilicon ketones are very fragmentary and incomplete.
The bibliography includes 180 references.

CONTENTS

I. INTRODUCTION

The first information about organosilicon compounds with carbonyl groups appeared in 1903.[15] However, vigorous studies in this field were begun only after 1950 by Sommer, Andrianov, Petrov, Brook, Gilman, and many other investigators. The names of these compounds are usually derived from the name of the organic ketone with an indication of the position of the silyl group. For example, the compound $(CH_3)_3SiCH_2COCH_3$ is called 1-trimethylsilyl-2-propanone or trimethylsilylacetone. Sometimes the silane serves as a basis for the name, for example, benzoyltrimethylsilane $(CH_3)_3SiCOC_6H_5$.

Depending on the relative positions of silicon and the carbonyl group, silyl-substituted ketones of the type R_3SiCOR', R_3SiCH_2COR', $R_3Si(CH_2)_2COR'$, $R_3Si(CH_2)_3COR'$, $R_3Si(CH_2)_4COR'$, etc. are called respectively α-, β-, γ-, δ-, ϵ-, etc. organosilicon ketones. An aromatic or a heterocyclic group may also be interposed between the silyl and keto-groups, for example:

$R_3Si(CH_2)_nC_6H_4COR'$, $n = 0, 1, 2 \ldots$ or 
Silicon-containing β-diketones and ketoesters of the type

$$R_nSi[OC(R')=CHCOR']_{4-n} \text{ and } R_nSi[CH(COCH_3)COOR']_{4-n}, n = 1, 2, 3.$$

are also known.

II. METHODS OF SYNTHESIS OF ORGANOSILICON KETONES

The majority of the synthetic methods do not differ fundamentally from those for the preparation of organic ketones, although the presence of a silicon atom undoubtedly influences the type of reaction. The only general method, whereby organosilicon ketones with a wide variety of structures may be obtained, is organometallic synthesis. Among other methods, the Friedel–Crafts reaction, the acetoacetic ester synthesis, the Kharasch reaction, and the oxidation of silicon-containing alcohols and hydrocarbons have been widely employed.

1. Organometallic Synthesis

Organosilicon ketones are obtained with the aid of organolithium, organosodium, organopotassium, organocadmium, and organomagnesium compounds, the organomagnesium synthesis being most widely used.

As early as 1947 Whitmore et al.[16] attempted to prepare trimethylsilylacetone by the reaction of acetyl chloride with trimethylsilylmethylmagnesium chloride. However, only the decomposition products, including acetone, were obtained. The compound was later prepared by Hauser and Hance[17] by the reaction of acetic anhydride with trimethylsilylmethylmagnesium bromide under milder conditions:

$$(CH_3)_3SiCH_2MgBr \xrightarrow[2.\ H_2O,\ NH_4Cl]{1.\ (CH_3CO)_2O,\ -70^\circ} (CH_3)_3SiCH_2COCH_3.$$

4-Trimethylsilyl-2-butanone was synthesised from the chloride of trimethylsilylpropionic acid and methylmagnesium bromide in the presence of ferric chloride[18]:

$$(CH_3)_3SiCH_2CH_2COCl \xrightarrow[FeCl_3]{CH_3MgBr} (CH_3)_3SiCH_2CH_2COCH_3.$$

This ketone was also obtained using an organocadmium compound[19]:

$$(CH_3)_3SiCH_2CH_2COCl \xrightarrow{(CH_3)_2Cd} (CH_3)_3SiCH_2CH_2COCH_3.$$

γ-Silylketones are also obtained in high yields by the action of organomagnesium compounds on the nitriles of silicon-containing carboxylic acids[20-23]:

$$Cl_3SiCH_2CH_2CN \xrightarrow{RMgHal} R_3SiCH_2CH_2COR,$$

where R = CH_3 and C_6H_5.

δ- and ϵ-Silyl-substituted ketones[24,25], silicon-containing ethynyl ketones[26,27], and aromatic and heterocyclic silyl-substituted ketones[28,29] have been obtained similarly. At the same time the reaction of chloro-α-cyanoisopropopoxydimethylsilane $(CH_3)_2ClSiOC(CH_3)_2CN$ with Grignard reagents involves not only the CN group but also the Si–Cl and Si–O bonds and leads to the formation of a complex mixture of substances from which it is impossible to isolate the individual products[30]. Komarov and Yarosh[31,32] obtained α-silylethynyl ketones by the reaction of trialkylsilylethynylmagnesium bromides with acetic anhydride:

$$R_3SiC{\equiv}CMgBr + (CH_3CO)_2O \rightarrow R_3SiC{\equiv}CCOCH_3,$$

where R = CH_3 or C_2H_5.

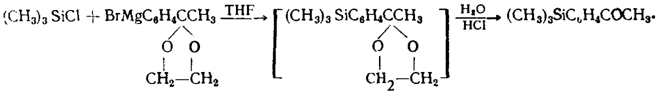
The same reaction with acetyl and benzoyl chlorides leads to the exclusive formation of tertiary diethynylsilylalcohols.

The reactions of *p*-triethylsilylphenylmagnesium bromide with acid anhydrides gave alkyl(aryl) *p*-triethylsilylphenyl ketones[33]:

$$p\text{-}(C_2H_5)_3SiC_6H_4MgBr + (RCO)_2O \rightarrow p\text{-}(C_2H_5)_3SiC_6H_4COR,$$

where R = CH_3, C_2H_5, n-C_3H_7, or C_6H_5.

p-Trimethylsilylacetophenone is formed in high yield by the reaction between the magnesium derivative of the ethyleneketal of 4-bromoacetophenone and trimethylchlorosilane in tetrahydrofuran (THF)[34]:



$$(CH_3)_3SiCl + BrMgC_6H_4C(OCH_2CH_2O)CH_3 \xrightarrow{THF} \left[(CH_3)_3SiC_6H_4C(OCH_2CH_2O)CH_3\right] \xrightarrow[HCl]{H_2O} (CH_3)_3SiC_6H_4COCH_3.$$

Silicon-containing ketoalcohols are obtained by the addition of benzil to an ethereal solution of trimethylsilylmethylmagnesium chloride[35]:

$$(CH_3)_3SiCH_2MgCl + C_6H_5COCOC_6H_5 \rightarrow (CH_3)_3SiCH_2C(OH)(C_6H_5)COC_6H_5.$$

Treatment of benzoyl chloride with a suspension of triphenylsilylpotassium in ether leads to the synthesis of benzoyltriphenylsilane in 4% yield[36]:

$$C_6H_5COCl + (C_6H_5)_3SiK \rightarrow (C_6H_5)_3SiCOC_6H_5 + KCl.$$

When triphenylsilyl-lithium reacts with an excess of acetyl chloride, acetyltriphenylsilane is also formed in a low yield[37]:

$$(C_6H_5)_3SiLi + CH_3COCl \rightarrow (C_6H_5)_3SiCOCH_3 + LiCl.$$

On the other hand, the reaction of triphenylsilyl-lithium with acetic anhydride does not yield the expected ketone[38]. A di-ϵ-silylketone was obtained unexpectedly as a side product in the synthesis of an ϵ-silylcarboxylic acid by the following reaction[39]:

$$(C_6H_5)_3Si(CH_2)_4Li \xrightarrow[-25°]{CO_2} \xrightarrow{H_2O} (C_6H_5)_3Si(CH_2)_4COOH + [(C_6H_5)_3Si(CH_2)_4]_2CO.$$

2. Synthesis with the Aid of Acetoacetic Ester

The first information about the sodioacetoacetic synthesis of organosilicon ketones was obtained in 1947 when Gilman[40] attempted to prepare triethylsilylacetoacetate by the reaction of sodioacetoacetic ester with triethylchlorosilane according to the following scheme:

$$(CH_3COCHCOOC_2H_5)^- Na^+ + (C_2H_5)_3SiCl \rightarrow (C_2H_5)_3SiCH(COCH_3)COOC_2H_5.$$

However, the only product isolated under these conditions proved to be ethyl β-triethylsiloxyorotonate $(C_2H_5)_3SiOC(CH_3){=}CHCOOC_2H_5$.

Andrianov[41], who achieved a similar reaction with chlorodiethoxymethylsilane, succeeded in obtaining silylacetoacetate:

$$CH_3(C_2H_5O)_2SiCl + NaCH(COCH_3)COOC_2H_5 \rightarrow CH_3(C_2H_5O)_2SiCH(COCH_3)COOC_2H_5 + NaCl.$$

When this compound is hydrolysed in an alkaline medium, the ester group is not split off from silicon and there is only partial hydrolysis of the ethoxy-groups linked to silicon. On the other hand, in an acid medium the ester group is almost completely split off and an infusible, insoluble powder is formed.

Later it was shown that silylacetoacetates can be more conveniently obtained by the condensation under mild conditions of organochlorosilanes with acetoacetic ester in the presence of triethylamine:[11]

$$(CH_3)_3SiCl + CH_2(COCH_3)COOC_2H_5 \xrightarrow[C_6H_6,\,-5°]{(C_2H_5)_3N} (CH_3)_3SiCH(COCH_3)COOC_2H_5.$$

Acetoacetic ester reacts with $SiCl_4$ in the cold with formation of the hydrochloride of tri(acetylethoxycarbonylmethyl)chlorosilane as prisms[42,43]:

$$3\,CH_3COCH_2COOC_2H_5 + SiCl_4 \rightarrow (CH_3COCHCOOC_2H_5)_3SiCl \cdot HCl + 2HCl.$$

On the other hand, when the mixture is heated to 100°C and at the same time dry air is passed through it the reaction leads to the formation of the yellow crystals of di(acetyl ethoxycarbonylmethyl)dichlorosilane[44].

Organosilanes containing a halogen in the organic substituent proved to be more suitable for the sodioacetoacetic ester synthesis of organosilicon ketones. Thus Sommer[19,45] obtained 4-trimethylsilyl-2-butanone by the following reaction:

$$(CH_3)_3SiCH_2I + CH_3COCH_2COOC_2H_5 + Na \rightarrow (CH_3)_3SiCH_2CH(COCH_3)COOC_2H_5 \rightarrow$$

$$\xrightarrow[\text{or 10\% NaOH}]{HCl} (CH_3)_3SiCH_2CH_2COCH_3.$$

The reaction of monobromohexamethyldisiloxane with sodioacetoacetic ester and subsequent hydrolysis of the ketoester produced gave a mixture of ketosiloxanes[46]:

$$(CH_3)_3SiOSi(CH_3)_2CH_2Br \xrightarrow[Na]{CH_3COCH_2COOC_2H_5} (CH_3)_3SiOSi(CH_3)_2CH_2CH(COCH_3)COOC_2H_5 \rightarrow$$

$$\xrightarrow[8\ h]{10\%\ NaOH} (CH_3)_3SiOSi(CH_3)_2CH_2CH_2COCH_3 + O[Si(CH_3)_2CH_2CH_2COCH_3]_2.$$

The ϵ-silylketone[24] $(CH_3)_3Si(CH_2)_4COCH_3$ and the aliphatic-aromatic organosilicon ketoester[47] $(CH_3)_3SiC_6H_4CH_2CH(COCH_3)COOCH_3$ were synthesised similarly.

In the reaction with sodioacetoacetic ester primary γ-silyl-substituted ethynyl chlorides also form organosilicon ketoesters[48]. When the latter are heated with 10% hydrochloric acid, silylethynylketoacids are formed. More prolonged refluxing leads to the rupture of the Si–C bond with formation of hexaethyldisiloxane as the principal product:

$$(C_2H_5)_3SiC{\equiv}CCH_2Cl + CH_3COCHNaCOOC_2H_5 \rightarrow (C_2H_5)_3SiC{\equiv}CCH_2CH(COCH_3)COOC_2H_5 \rightarrow$$

$$\xrightarrow[C_2H_5OH]{HCl} (C_2H_5)_3SiC{\equiv}CCH_2CH(COCH_3)COOH \xrightarrow[90°]{HCl} (C_2H_5)_3SiOSi(C_2H_5)_3 + CO_2 + \text{resin}.$$

The expected silylethynyl ketones $R_3SiC{\equiv}CCH_2COCH_3$ could not be isolated.

Secondary γ-silylethynyl chlorides behave similarly in sodioacetoacetic ester synthesis[27].

3. The Friedel–Crafts Reaction

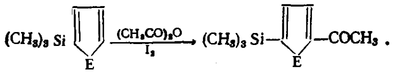
The Friedel–Crafts reaction constitutes a convenient method for the preparation of aromatic and heterocyclic organosilicon ketones, although it does not always take place successfully in consequence of the instability of the Si–Caryl bond in relation to acid reagents[49]. For example, the reaction of triethylphenylsilane[50] and also arylhalogenosilanes[51] with acid chlorides in the presence of aluminium chloride usually yields organic ketones and hexa-alkyldisiloxane instead of the expected organosilicon ketones:

$$R_3SiC_6H_5 + R'COCl \xrightarrow{AlCl_3} C_6H_5COR' + R_3SiOSiR_3.$$

Successful acylation of phenylsilanes by the Friedel–Crafts reaction[52] was achieved under mild conditions by the action of acetyl and benzoyl fluorides on trimethylphenylsilane in the presence of boron trifluoride:

$$(CH_3)_3SiC_6H_5 + RCOF \xrightarrow{BF_3} (CH_3)_3SiC_6H_4COR \quad (R{=}CH_3C_6H_5).$$

Acylation of 2-thienyltrimethylsilane and 2-furyltrimethylsilane with acetic anhydride takes place readily in the presence of iodine[53]:



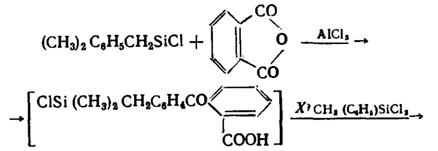
In contrast to phenylsilanes, the acylation of benzylsilanes[54] and trialkyl-β-phenylethylsilanes[55] with acyl chlorides using aluminium chloride takes place without the dissociation of the Si–C bond:

$$R_3Si(CH_2)_nC_6H_5 + R'COCl \xrightarrow{AlCl_3} R_3Si(CH_2)_nC_6H_4COR' \quad (n = 1,\ 2).$$

It has been established that, because of the conjugation of the Si–C bond with the aromatic ring, benzyltrimethylsilane is approximately 24 times more reactive than benzene in the acylation reaction and trimethyl-β-phenylethylsilane is 16 times more reactive.

The Friedel–Crafts reaction has been successfully used by Andrianov for the synthesis of various benzylsiloxane derivatives[10,56–59]:

$$(CH_3)_2C_6H_5CH_2SiCl + (CH_3CO)_2O \xrightarrow{AlCl_3} \xrightarrow{H_2O} [CH_3COC_6H_4CH_2(CH_3)_2Si]_2O,$$



$$\rightarrow HOOCC_6H_4COC_6H_4CH_2Si(CH_3)_2O[Si(CH_3)(C_6H_5)O]_xSi(CH_3)_2CH_2C_6H_5COC_6H_4COOH.$$
$$(x = 1-5,10)$$

Organosilicon ketones are also obtained by the Friedel–Crafts reaction from the chlorides of organosilicon carboxylic acids. Thus toluene and anisole are acylated in the *p*-position with *m*- and *p*-trimethylsilylbenzoyl chlorides[60]:

$$(CH_3)_3SiC_6H_4COCl + C_6H_5R \xrightarrow{SnCl_4} (CH_3)_3SiC_6H_4R,$$

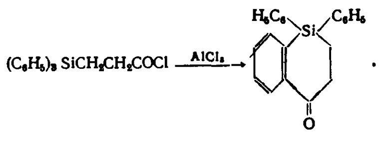
where R = CH_3 or OCH_3.

The chlorides of organosilicon carboxylic acids with alkoxy-groups at the silicon atom may be used as acylating agents. For example, the condensation of trimethoxysilylundecanoyl chloride with benzene in the presence of aluminium chloride leads to the formation of the corresponding ketone[61]:

$$(CH_3O)_3Si(CH_2)_{10}COCl + C_6H_6 \xrightarrow{AlCl_3} (CH_3O)_3Si(CH_2)_{10}COC_6H_5.$$

Ketosilanes with the composition $X_mR_{3-m}Si(CH_2)_nCOR'$, where $m = 0-3$ and $n = 2-10$, are obtained similarly[62].

It is interesting to note[63] that 3-triphenylsilylpropionyl chloride cyclises under the action of aluminium chloride to 2,3-benzo-1,1-diphenyl-1-silacyclohex-2-en-4-one:



A similar cyclisation is observed also with 4-triphenylsilylbutyryl chloride.

The condensation of β-trimethylsilylpropionyl chloride with ferrocene in the presence of aluminium chloride led to the isolation of a 76% yield of β-trimethylsilylpropionylferrocene[64]:

$$(CH_3)_3SiCH_2CH_2COCl + C_5H_5FeC_5H_5 \xrightarrow{AlCl_3} (CH_3)_3SiCH_2CH_2COC_5H_4FeC_5H_5.$$

A very interesting reaction was discovered by Birkofer et al.[65], who observed that the reaction of acid chlorides or anhydrides with di(trimethylsilyl)acetylene in the presence of aluminium chloride results in the formation of silylated alkynones:

$$(CH_3)_3SiC{\equiv}CSi(CH_3)_3 + RCOCl \xrightarrow{AlCl_3} (CH_3)_3SiC{\equiv}CCOR + (CH_3)_3SiCl,$$

where R = CH_3, C_2H_5, $C_6H_4NO_2$, or CH_2Cl. The yields of the ketones reached 90%.

The following reaction takes place similarly:

$$C_6H_5C{\equiv}CSi(CH_3)_3 + CH_2ClCOCl \xrightarrow{AlCl_3} C_6H_5CCl{=}C\begin{matrix} \diagup Si(CH_3)_3 \\ \diagdown COCH_2Cl \end{matrix}.$$

4. The Kharasch Reaction[66]

Sommer[67] and then Petrov and Chernyshev[68,69] obtained silicon-containing ketones by the addition of butyraldehyde and benzaldehyde to vinyl- and γ-butenyl-silanes in the presence of diacetyl and benzoyl peroxides:

$$R_3SiCH{=}CH_2 + R'CHO \xrightarrow{\text{peroxide}} R_3SiCH_2CH_2COR',$$

where R = CH_3 or C_2H_5 and R^1 = C_3H_7 or C_6H_5.

Organosilicon ketones are also formed in low yields on heating equimolar mixtures of tri(trimethylsiloxy)vinylsilane with aldehydes in an autoclave in the presence of t-butyl peroxide[70]:

$$[(CH_3)_3SiO]_3SiCH{=}CH_2 + RCHO \xrightarrow[185°,\ 4\ h]{\text{peroxide}} [(CH_3)_3SiO]_3SiCH_2CH_2COR,$$

where R = CH_3, C_6H_5, or *o*-HOC_6H_4.

Brook[71] added benzaldehyde to triphenylvinylsilane with ultraviolet irradiation and obtained a corresponding ketone in 12% yield. We showed that the photochemical reaction of aldehydes with alkylvinyl- and alkoxyvinyl-silanes is general and may serve as a convenient method for the synthesis of γ-silyl-substituted ketones with various structures, including ketones containing readily hydrolysable alkoxy-groups at the silicon atom[72–73]:

$$R_3SiCH{=}CH_2 + R'CHO \xrightarrow{h\nu} R_3SiCH_2CH_2COR',$$

where R = CH_3, C_2H_5, or C_2H_5O and R′ = CH_3, C_2H_5, C_3H_7, iso-C_4H_9, C_6H_5, etc. The yields of ketones reach 90%. On the other hand, the reaction involving the radical addition of aldehydes to allylsilanes could not be achieved.

5. Interaction of Silanes Containing Unsubstituted Hydrogen Atoms with Unsaturated Ketones

Petrov and Sadykh-Zade[74,75] showed that the addition of partially substituted silanes bearing organic substituents to αβ-unsaturated ketones in the presence of a Speier catalyst does not yield the expected organosilicon ketone. The reaction involves the 1,4-position with formation of silicon-containing vinyl ethers:

$$\equiv SiH + -\overset{|}{C}{=}\overset{|}{C}-\overset{|}{C}{=}O \xrightarrow{H_2PtCl_6} -CH-\overset{|}{C}{=}\overset{|}{C}-O-Si\equiv.$$

Calas[76] investigated the reaction between silanes with free hydrogen atoms and unsaturated ketones having an isolated double bond. The reaction of triethylsilane with 2-methylhept-2-en-6-one in the presence of zinc chloride as a catalyst does not lead to the formation of a ketone:

$$(CH_3)_2C{=}CHCH_2CH_2COCH_3 + (C_2H_5)_3SiH \xrightarrow[100°,\ 24\ h]{ZnCl_2} (CH_3)_2C{=}CHCH_2CH_2\overset{\overset{CH_3}{|}}{C}HOSi(C_2H_5)_3.$$

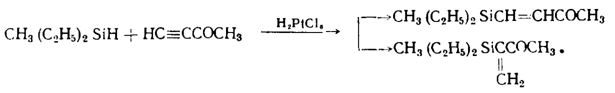
We investigated[77,78] the reaction between silanes with free hydrogen atoms and allylacetone under the influence of chloroplatinic acid and showed that it is suitable for the synthesis of ϵ-silyl-substituted ketones:

$$\mathrm{R_3SiH + CH_2{=}CHCH_2CH_2COCH_3 \xrightarrow{H_2PtCl_6} R_3Si\,(CH_2)_4\,COCH_3}.$$

The yields of ketones reached 75–85%. Recently Khudobin and Kharitonov[79] obtained ϵ-silyl-substituted ketones by the addition of trisubstituted silanes to unsaturated ketones with an isolated double bond, the mixture being heated in the presence of colloidal nickel. Klotz and Kuckertz[12] synthesised siloxanes with two keto-groups in the ϵ-positions in 42% yield by the reaction of *sym*-tetramethyldisiloxane with allylacetonylacetone in the presence of platinum in an autoclave:

$$\mathrm{2H(CH_3)_2\,SiOSi\,(CH_3)_2\,H + 2CH_2{=}CHCH_2CH\,(COCH_3)_2 \xrightarrow[160^\circ]{Pt}}$$
$$\mathrm{\rightarrow (CH_3CO)_2\,CH\,(CH_2)_3\,Si\,(CH_3)_2\,OSi\,(CH_3)_2\,(CH_2)_3\,CH\,(COCH_3)_2}.$$

Mashlyakovskii and Chelpanova[80] investigated the reaction of 2-butynone with diethylmethylsilane and established that, in contrast to methyl vinyl ketone, the reaction involves the 1,2-position with formation of a mixture of the *cis*- and *trans*-isomers. On the basis of infrared and PMR-spectroscopic studies, gas–liquid and thin-layer chromatography, and also by synthesis, Komarov and Pukhnarevich[81] showed that, under the conditions of this reaction, a mixture of β- and γ-silylvinyl ketones is in fact obtained:



$$\mathrm{CH_3\,(C_2H_5)_2\,SiH + HC{\equiv}CCOCH_3 \xrightarrow{H_2PtCl_6}} \begin{cases} \mathrm{\rightarrow CH_3\,(C_2H_5)_2\,SiCH{=}CHCOCH_3} \\ \mathrm{\rightarrow CH_3\,(C_2H_5)_2\,SiC({=}CH_2)COCH_3}. \end{cases}$$

The use of polar aprotic solvents (tetrahydrofuran, dioxane) permits the selective hydroxylation of ethyl methyl ketone and the isolation of chromatographically pure γ-substituted ketone derivatives[82].

6. Oxidation of Silicon-containing Alcohols and Hydrocarbons

Organosilicon ketones may be obtained by the oxidation of silicon-containing secondary alcohols and aliphatic-aromatic silicon-containing hydrocarbons. Potassium permanganate, the chromic acid mixture, anddicyclohexylcarbodi-imide are used as oxidising agents. α-Silyl-substituted ketones[83-87] $\mathrm{R_3SiCOR'}$ and β-silyl-substituted ketones[71,87] $\mathrm{R_3SiCH_2COR'}$ have been obtained in this way. By oxidising secondary silicon-containing ethynyl- and vinyl-alcohols with chromium trioxide, one of the present authors[88,89] synthesised for the first time organosilicon ethynyl ketones:

$$\mathrm{(CH_3)_3\,SiC{\equiv}CCHOHR \xrightarrow{CrO_3} (CH_3)_3\,SiC{\equiv}CCOR},$$

where $\mathrm{R = CH_3}$, $\mathrm{C_2H_5}$, or $\mathrm{CH{=}CH_2}$. Organosilicon ketones of the ethylene series $\mathrm{R_3SiCH{=}CHCOR^1}$ were obtained similarly[90].

The oxidation of *o*-, *m*-, and *p*-trimethylsilylethylbenzenes with oxygen in the presence of chromium trioxide and calcium carbonate gives a mixture of trimethylsilylacetophenones with trimethylsilylbenzoic acids[91]:

$$\mathrm{(CH_3)_3\,SiC_6H_4C_2H_5 \xrightarrow[200^\circ]{O_2/CrO_3+CaCO_3} (CH_3)_3\,SiC_6H_4COCH_3 + (CH_3)_3\,SiC_6H_4COOH}.$$

The yields of ketones are 15–20%.

When secondary silicon-containing aromatic alcohols were heated with an excess of acetone in the presence of aluminium t-butoxide, the corresponding ketones were isolated in yields of 19–42% (Oppenauer reaction)[33]:

$$p\text{-}\mathrm{R_3SiC_6H_4CHOHR' + CH_3COCH_3 \underset{200^\circ}{\overset{Al(OC_4H_9\text{-}t)_3}{\rightleftarrows}}} p\text{-}\mathrm{R_3SiC_6H_4COR' + CH_3CHOHCH_3},$$

where $\mathrm{R = CH_3}$ or $\mathrm{C_2H_5}$ and $\mathrm{R' = CH_3}$, $\mathrm{C_2H_5}$, $\mathrm{C_3H_7}$, or $\mathrm{C_6H_5}$.

7. Hydrolysis of Organosilicon Dihalogeno-derivatives

The hydrolysis of silicon-containing dihalogeno-derivatives of hydrocarbons is an important method for the synthesis of α-silyl-substituted ketones. The first α-silyl-substituted ketones was obtained in 1957 by Brook[36] from benzyltriphenylsilane by the reaction

$$\mathrm{(C_6H_5)_3\,SiCH_2C_6H_5 \xrightarrow{2\,(CH_2CO)_2NBr} (C_6H_5)_3\,SiCBr_2C_6H_5 \xrightarrow[CH_3COOAg]{H_2O} (C_6H_5)_3\,SiCOC_6H_5}.$$

Benzoylhydroxy- and benzoylmethoxy-silanes $\mathrm{C_6H_5COSi(C_6H_5)_2OR}$ ($\mathrm{R = H}$ or $\mathrm{CH_3}$), benzoyl(halogenobenzyl)silanes $\mathrm{C_6H_5COSi(C_6H_5)_2CXYC_6H_5}$ ($\mathrm{Y = Cl}$ or Br: $\mathrm{X = H}$, Cl, or Br), dibenzoylsilanes $\mathrm{(C_6H_5CO)_2SiR_2}$ ($\mathrm{R = CH_3}$ or $\mathrm{C_6H_5}$), and benzoylmethyl-α-naphthylphenylsilane $\mathrm{CH_3(C_6H_5)(C_{10}H_7)SiCOC_6H_5}$ were synthesised analogously[92,93]. All the reactions take place with satisfactory yields. The synthesis of a γ-silyl-substituted ketone was achieved similarly[71]:

$$\mathrm{(C_6H_5)_3\,SiCl + Li\,(CH_2)_3\,C_6H_5 \rightarrow (C_6H_5)_3\,Si\,(CH_2)_3\,C_6H_5 \xrightarrow[H_2O]{Br_2} (C_6H_5)_3\,SiCH_2CH_2COC_6H_5}.$$

A β-silyl-substituted ketone could not be obtained by this method, only the decomposition products being isolated.

8. Hydration of Silylacetylenes

The attempts to hydrate trialkylsilylacetylenes and di(trialkylsilyl)acetylenes proved unsuccessful. The reaction apparently leads to the formation of silyl-substituted ketones with the carbonyl group in the β-position, which decompose according to the mechanism[94,95]:

$$\mathrm{R_3SiC{\equiv}CR' + H_2O \rightarrow [R_3SiCH_2COR'] \rightarrow 2R_3SiOH + CH_3COR'},$$

where $\mathrm{R = CH_3}$ or $\mathrm{C_2H_5}$ and $\mathrm{R' = C_6H_5}$, $\mathrm{(CH_3)_3Si}$, etc.

The attempt at the Kucherov hydration of the triple bond in trialkylvinylethynylsilanes $\mathrm{R_3SiC{\equiv}CCH{=}CH_2}$ and dialkyldi(vinylethynyl)silanes $\mathrm{R_2Si(C{\equiv}CCH{=}CH_2)_2}$ was also unsuccessful: under mild conditions there was only partial polymerisation of the compound and under severe conditions the Si–C bond was broken[96,97]. The corresponding ketones were obtained only from monosubstituted alkynylsilanes with the triple bond in the γ-position relative to the silicon atom:

$$\mathrm{R_3SiCH_2CH_2C{\equiv}CH \xrightarrow[HgSO_4]{H_2O} R_3SiCH_2CH_2COCH_3},$$

where $\mathrm{R = CH_3}$ or $\mathrm{C_2H_5}$.

Silyl-substituted α-ketoalcohols[99] and alkenyl alkoxyalkyl ketones[100] were also synthesised from the corresponding silyl-substituted ethynyl and vinylethynyl-alcohols:

$$\mathrm{R_3Si\,(CH_2)_{\mathit{n}}\,COH\,(CH_3)\,C{\equiv}CH \xrightarrow[HgSO_4]{H_2O} R_3Si\,(CH_2)_{\mathit{n}}\,COH\,(CH_3)\,COCH_3},$$
$$\mathrm{R_3Si\,(CH_2)_{\mathit{n}}\,COH\,(CH_3)\,C{\equiv}CCH{=}CH_2 \xrightarrow[HgSO_4+H_2SO_4]{CH_3OH} R_3Si(CH_2)_{\mathit{n}}C(CH_3){=}CHCOCH_2CH_2OCH_3},$$

where $n = 2$–4 and R is an alkyl group.

9. Condensation of Silanes Containing Functional Groups with β-Diketones

Dilthey[15] found in 1903 that acetylacetone readily reacts with silicon tetrachloride to form a crystalline hydrochloride. The reaction usually results in the substitution of three chlorine atoms according to the mechanism:

$$3\,(CH_3CO)_2CH_2 + SiCl_4 \rightarrow [(CH_3CO)_2CH]_3SiCl\cdot HCl + 2HCl.$$

The fourth chlorine atom is not substituted even in the presence of an excess of the diketone. Subsequently this reaction was extended to benzoylacetone and dibenzoylmethane[101] and also silicon tetrabromide[102].

The condensation of tetra-acetoxysilane with acetylacetone in molar proportions of 1 : 2 leads to the formation of diacetoxydi-(2,4-dioxopentyl)silane $[CH_2(CH_3CO)_2]_2.$ $.Si(OCOCH_3)_2$.[103,104] West[105] obtained a number of mono-, di-, and tri-alkylsilyl derivatives of acetylacetone:

$$R_nSiCl_{4-n} + (4-n)\,CH_3COCH_2COCH_3 \rightarrow R_nSi\,[CH\,(COCH_3)_2]_{4-n} + (4-n)\,HCl,$$

where n = 1–3 and R = CH_3, C_2H_5, or C_6H_5. The trimethylsilyl derivative of acetylacetone is also obtained by the following reaction[106]:

$$R_3SiN\,(C_6H_5)\,CONHC_6H_5 + CH_3COCH_2COCH_3 \rightarrow R_3Si\,[CH(COCH_3)_2] + C_6H_5NHCONHC_6H_5.$$

The reaction of chlorodiethylmethoxysilane with sodium acetylacetonate gave a silyl ether of the enolic form of acetylacetone[107]:

$$(C_2H_5)_2\,(CH_3O)\,SiCl + CH_3COCHNaCOCH_3 \rightarrow (C_2H_5)_2\,(CH_3O)\,SiOC\,(CH_3){=}CHCOCH_3.$$

10. Ester, Crotonic, and Benzoin Condensations

Esters of the type $R(CH_3)_2Si(CH_2)_nCOOR'$ condense in the presence of sodamide, sodium alkoxides[108], di-isopropylaminomagnesium bromide[108,109], and $(CH_3)_2NMgBr$[110] to silicon-containing β-ketoesters. The latter are hydrolysed to ketones on treatment with a strong inorganic acid[108-111,180]:

$$2R\,(CH_3)_2Si(CH_2)_nCOOR' \xrightarrow{C_2H_5ONa}$$
$$\rightarrow R\,(CH_3)_2\,Si\,(CH_2)_{n-1}CH(COOR')CO\,(CH_2)_nSiR\,(CH_3)_2 \xrightarrow{H_2SO_4} [R(CH_3)_2Si(CH_2)_n]_2\,CO.$$

Ethyl trimethylsilylpropionate condenses with acetone in the presence of sodamide to the corresponding β-diketone[18]:

$$(CH_3)_3\,SiCH_2CH_2COOC_2H_5 + CH_3COCH_3 \xrightarrow{NaNH_2} (CH_3)_3\,SiCH_2CH_2COCH_2COCH_3.$$

The condensation of *p*-trimethylsilylbenzaldehyde with acetone, pinacol, acetophenone, and cyclohexanone has been achieved[28,112]. When the ketone contains one active methylene group, the reaction takes place unambiguously according to the mechanism:

$$p\text{-}(CH_3)_3SiC_6H_4CHO + CH_3COR \xrightarrow{-H_2O} p\text{-}(CH_3)_3\,SiC_6H_4CH{=}CHCOR,$$

where R = C_6H_5 or $C(CH_3)_3$. In the presence of two active methylene groups, further condensation involving this group is possible.

When an alcoholic solution of *p*-trimethylsilylbenzaldehyde is heated with potassium cyanide, benzoin condensation takes place and leads to the formation of a disilyl-substituted aromatic ketoalcohol[28]:

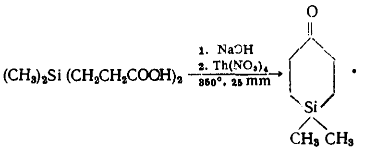
$$(CH_3)_3SiC_6H_4CHO + OHCC_6H_4Si(CH_3)_3 \xrightarrow{CN^-} (CH_3)_3SiC_6H_4COCH(OH)C_6H_4Si(CH_3)_3.$$

11. Pyrolysis of Salts of Organosilicon Acids

Dry distillation of the calcium salts of organosilicon acids and their mixtures with organic acid salts leads to the formation of silicon-containing ketones with symmetrical and asymmetric structures[113]:

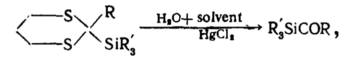
$$(R_3SiCH_2CH_2COO)_2\,Ca \rightarrow (R_3SiCH_2CH_2)_2\,CO + CaCO_3,$$
$$(R_3SiCH_2CH_2COO)_2\,Ca + (R'COO)_2\,Ca \rightarrow R_3SiCH_2CH_2COR' + CaCO_3,$$

where R = CH_3 or C_2H_5 and R′ = $(CH_3)_2CH$. The yields of ketones amount to 13–28%. Dimethylsilacyclohexanone was obtained in 35% yield by the pyrolysis of the thorium salt of a dibasic organosilicon acid[114]:



12. Other Methods

Many α-silyl-substituted ketones have been prepared by the hydrolysis of 2-silyl-1,3-dithianes[84,115]:

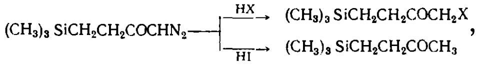


where R = R′ = CH_3, C_6H_5, etc.

The reaction of the chloride of β-(trimethylsilyl)propionic acid with diazomethane results in the formation of diazomethyl β-(trimethylsilyl)ethyl ketone[116,117]:

$$(CH_3)_3SiCH_2CH_2COCl + CH_2N_2 \rightarrow (CH_3)_3SiCH_2CH_2COCHN_2.$$

The latter reacts with hydrogen halides and acetic acid to form halogeno- and acetoxy-substituted organosilicon ketones and these can be converted into 4-trimethylsilyl-2-butanone:



$$(CH_3)_3\,SiCH_2CH_2COCHN_2 \begin{cases} \xrightarrow{HX} (CH_3)_3\,SiCH_2CH_2COCH_2X \\ \xrightarrow[HI]{} (CH_3)_3\,SiCH_2CH_2COCH_3 \end{cases},$$

where X = Cl, Br, or $OCOCH_3$.

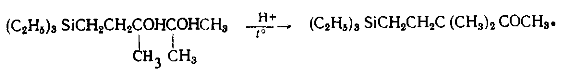
The diazo-method can also be used to synthesise a di[oxoalkyl(alkyl)]siloxane by the reaction

$$ClSi\,(CH_3)_2CH_2CH_2COCl \xrightarrow{CH_2N_2} ClSi\,(CH_3)_2CH_2CH_2COCHN_2 \xrightarrow[H_2O]{HI}$$
$$\rightarrow O[Si(CH_3)_2CH_2CH_2COCH_3]_2.$$

The synthesis of 2-benzoyl-1-(*p*-trimethylsilylphenyl)-epoxyethane by the Darzens condensation has been reported[118]:

$$(CH_3)_3\,SiC_6H_4CHO + ClCH_2COC_6H_5 \xrightarrow{C_2H_5ONa} (CH_3)_3SiC_6H_4\overset{O}{CH{-}CH}COC_6H_5.$$

The present authors synthesised a δ-silyl-substituted ketone by the pinacol rearrangement of an organosilicon glycol[99]:



$$(C_2H_5)_3\,SiCH_2CH_2\underset{CH_3}{C}OH\underset{CH_3}{C}OHCH_3 \xrightarrow[t^\circ]{H^+} (C_2H_5)_3\,SiCH_2CH_2C\,(CH_3)_2\,COCH_3.$$

Silicon-containing ketones can also be obtained by the silylation of hydroxyketones[119]:

$$(CH_3)_3\,SiCl + C_2H_5CHOHCOC_2H_5 \xrightarrow{C_5H_5N} (CH_3)_3\,SiOCH\,(C_2H_5)\,COC_2H_5.$$

III. PROPERTIES OF ORGANOSILICON KETONES

The properties of organosilicon ketones depend to a large degree on the relative positions of the silicon atom and the carbonyl group. A characteristic feature of α- and β-silyl-substituted ketones is the instability of the Si–C bond in relation to the majority of the nucleophilic and electrophilic reagents. Silicon-containing ketones in which the silicon atom is further away from the C=O group enter into various reactions involving the carbonyl group without the dissociation of the silicon–carbon bond.

These features of organosilicon ketones are reflected in their ultraviolet and infrared spectra. The study of the spectra showed that the characteristic absorption of the carbonyl group in these compounds is determined, on the one hand, by the structure of the molecule as a whole and, on the other hand, depends on the relative positions of the carbonyl group and the silicon atom. The carbonyl groups of α-silyl-substituted ketones exhibit an anomalous polarity, resembling that of a carboxylate ion rather than a β-diketone (6.2–6.45 μm).[120]

Polarity of C=O bond, μm (infrared spectra)

CH_3COCH_3—5.81

$C_6H_5COC_6H_5$—6.01

$(C_6H_5)_3SiCOCH_3$—6.08

$\left.\begin{matrix}(C_6H_5)_3SiCOC_6H_5\\(CH_3)_3SiCOCH_3\end{matrix}\right\}$—6.18

It has been suggested[71,121] that the anomalous spectroscopic effects of α-silyl-substituted ketones can be explained by the interaction of the unpaired electron of the oxygen atom in the carbonyl group with the vacant *d*-orbitals of silicon. As the silicon atom is removed further away from the carbonyl group, the effect of the silyl group diminishes and the absorption band associated with the carbonyl group in α-silyl-substituted ketones (1618 cm^{-1} for benzoylsilanes and 1645 cm^{-1} for acetyl- and propionylsilanes) rises to 1667 cm^{-1} in the spectra of β-silyl-substituted ketones and reaches 1716 cm^{-1} in the case of γ-silyl-substituted ketones, a value which is usual for aliphatic ketones[116,122–124]. Yates and Agolini[125] believe that the fundamental cause of the lower absorption frequency of the carbonyl group in α-silyl-substituted ketones is the inductive effect of the silicon atom, which increases the electron density at the carbonyl oxygen, thereby enhancing the basicity of the carbonyl group in ketones of the $R_3SiCOC_6H_5$ series compared with their hydrocarbon analogues.

Since the properties of α- and β-silyl-substituted ketones differ appreciably from those of ketones with the silicon atom more remote from the carbonyl group, we combined them into separate classes. Aromatic silyl-substituted ketones, silylethynylketones with the formula $R_3SiC{\equiv}CCOR'$, and complexes of silicon halides with β-diketones and β-ketoesters also exhibit a number of characteristic features because of the mutual effects of the silicon atom and the carbonyl group.

1. α-Silyl-substituted Ketones

In contrast to their hydrocarbon analogous, α-silyl-substituted ketones are coloured yellow, orange, or red[36,83]. Evidently the silicon atom behaves as a chromophore[120]. These ketones are thermally stable. For example, benzoyltriphenylsilane scarcely changes on heating to 250°C. At 365°C there is some decomposition, but 70% of the initial compound is recovered[36]. Alkylsilyl ketones and alkylarylsilyl ketones are liquid, while arylsilyl ketones are solid crystalline substances.

The chemical properties of α-silyl-substituted ketones were investigated Brook. The principal characteristic feature is high lability in relation to chemical reagents. The majority of benzoylsilanes are readily hydrolysed in air[92]. In consequence of the interaction of the unshared electrons of the oxygen atoms in the carbonyl group with the vacant *d*-orbitals of silicon, nucleophilic reagents usually cause the decomposition of the ketone molecule at the Si–C bond. Similar decomposition takes place also when benzoylsilanes are irradiated with ultraviolet light. Only hydrogenation and reactions with phenylhydrazine and certain Grignard reagents take place without the rupture of the carbon–silicon bond.

When α-silyl-substituted ketones are treated with ethanol in the presence of aqueous alkali, the yellow colour of the ketone disappears after several minutes and silanol and an aldehyde are formed[36,126]:

$$(C_6H_5)_3SiCOC_6H_5 \xrightarrow[H_2O]{\bar{O}H} (C_6H_5)_3SiOH + C_6H_5CHO.$$

A similar reaction takes place in the chromatographic separation of α-silyl-substituted ketones on activated alumina.

When sodium ethoxide is allowed to act upon benzoyltriphenylsilane, the main product is ethoxydiphenyl(diphenylmethoxy)silane $(C_6H_5)_2CHOSi(OC_2H_5)(C_6H_5)_2$ together with small amounts of cleavage products—diphenylmethanol and diethoxydiphenylsilane[126,127].

Treatment of benzoyltriphenylsilane with phenyl-lithium does not lead to the expected alcohol: only the decomposition products, including triphenylsilanol and tetraphenylsilane, were isolated[36]. Methyl–magnesium iodide and benzylmagnesium chloride interact with benzoyltriphenylsilane in a normal manner with formation of alcohols[120,128]:

$$(C_6H_5)_3SiCOC_6H_5 \xrightarrow{CH_3MgI} (C_6H_5)_3SiC(OH)(CH_3)C_6H_5.$$

At the same time Grignard reagents with β-hydrogen atoms (C_2H_5MgBr, C_3H_7MgBr) behave mainly as reducing agents. There is no reaction between benzoyltriphenylsilane and t-butylmagnesium chloride and only cleavage at the Si–C bond takes place when this ketone interacts with phenylmagnesium bromide.

The attempts to prepare the oxime of benzoyltriphenylsilane were unsuccessful because of its decomposition into triphenylsilanol and benzaldehyde[36]. However, benzoyltriphenylsilane does form crystalline hydrazones[129]. It is readily reduced by lithium aluminium hydride[120] to the carbinol $(C_6H_5)_3SiCHOHC_6H_5$. On being irradiated with ultraviolet light in methanol solution for 2 h, benzoyltriphenylsilane is converted into methoxytriphenylsilane[130,131]:

$$(C_6H_5)_3SiCOC_6H_5 \xrightarrow[CH_3OH]{h\nu} (C_6H_5)_3SiOCH_3 + C_6H_5CH(OCH_3)_2.$$

The treatment of α-silyl-substituted ketones with diazomethane leads to the formation of a mixture of β-silyl-substituted ketones with isomeric siloxyalkenes[132]:

$$R_3SiCOR' + CH_2N_2 \rightarrow R_3SiCH_2COR' + R_3SiOCR'{=}CH_2.$$

The Wittig reaction with α-silyl-substituted ketones has been investigated[133]. Benzoylsilanes form siloxyalkenes and alkyl silyl ketones undergo the normal Wittig reaction.

2. β-Silyl-substituted Ketones

A distinctive feature of β-silyl-substituted ketones is also chemical instability. They decompose under the action of both nucleophilic and electrophilic reagents[18]. β-Silyl-substituted ketones formed on hydration of trialkylsilylacetylenes cannot be isolated because of their decomposition into trialkylsilanol and a non-silylated ketone[95]:

$$R_3SiC{\equiv}CR' \xrightarrow{H_2O} [R_3SiCH_2COR'] \xrightarrow{H_2O} R_3SiOH + CH_3COR'.$$

β-Ketosilanes isomerise to siloxyalkenes on heating to 80–175°C and also in the presence of mercuric iodide[134–137]:

$$R_3SiCH_2COR' \rightarrow R_3SiOCR'{=}CH_2.$$

When trimethylsilylacetone is treated with 2,4-dinitrophenylhydrazine in 85% ethanol containing sulphuric acid, the Si–C bond is ruptured and a 2,4-dinitrophenylhydrazone of acetone is formed[17]. This ketone also decomposes on being refluxed with ethanol:

$$(CH_3)_3SiCH_2COCH_3 \xrightarrow[t^\circ]{C_2H_5OH} (CH_3)_3SiOC_2H_5 + CH_3COCH_3\ .$$

Trimethylsilylphenylacetone $(CH_3)_3SiCH(C_6H_5)COCH_3$ is more stable and does form a 2,4-dinitrophenylhydrazone. Triphenyl(phenylacetyl)silane $(C_6H_5)_3SiCH_2COC_6H_5$, obtained by the oxidation of the corresponding carbinol with a mixture of chromium trioxide and sulphuric acid, is even more stable[71].

3. γ-, δ-, and ε-Silyl-substituted Ketones

The Si–C bonds in γ-, δ-, and ε-silyl-substituted ketones are stable in relation to nucleophilic and electrophilic reagents, in contrast to the α- and β-substituted ketones. In oxidation, reduction, and condensation reactions they behave similarly to non-silylated ketones. In addition they undergo certain specific reactions due to the presence of the silicon atom.

The reduction of γ-silyl-substituted ketones with lithium aluminium hydride leads to the formation of silicon-containing secondary alcohols[71,138–140]. The oxidation of 4-trimethylsilyl-2-butanone[19] and 5-trimethylsilyl-2-pentanone[24] with sodium hypobromite yields organosilicon acids:

$$(CH_3)_3Si(CH_2)_nCOCH_3 \xrightarrow{NaBrO} (CH_3)_3Si(CH_2)_nCOOH\ (n = 2\text{–}3).$$

The reaction with alkylmagnesium bromides results in the formation of tertiary organosilicon alcohols[19,20,22,24,140]:

$$(CH_3)_3Si(CH_2)_nCOR \xrightarrow{R'MgBr} (CH_3)_3Si(CH_2)_nCR'(OH)R',$$

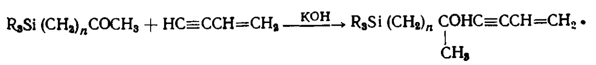
where R = CH_3 or C_6H_5, R′ = CH_3, C_2H_5, or C_6H_5, and n = 2 and 4.

The reaction of vinylethynylmagnesium bromide with γ-, δ-, and ε-silyl-substituted ketones takes place normally with formation of silicon-containing vinylethynylalcohols[100]:

$$R_3Si(CH_2)_nCOCH_3 + BrMgC{\equiv}CCH{=}CH_2 \rightarrow R_3Si(CH_2)_n\underset{\displaystyle CH_3}{\underset{|}{C}}OHC{\equiv}CCH{=}CH_2\ ,$$

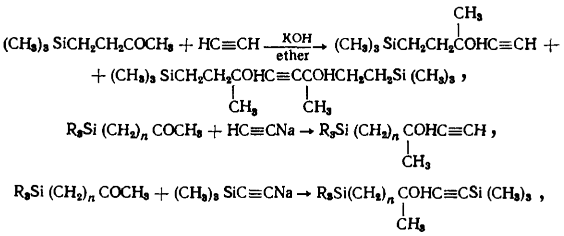
where R = CH_3 or C_2H_5 and n = 2–4.

These alcohols have also been synthesised in yields up to 80% by the reaction of organosilicon ketones with vinylacetylene in the presence of potassium hydroxide:



$$R_3Si(CH_2)_nCOCH_3 + HC{\equiv}CCH{=}CH_2 \xrightarrow{KOH} R_3Si(CH_2)_n\underset{\displaystyle CH_3}{\underset{|}{C}}OHC{\equiv}CCH{=}CH_2\ .$$

γ-, δ-, and ε-Silyl-substituted ketones enter into the Favorskii reaction with acetylene and also react with sodioacetylene and its derivatives to form silylethynylmethanols and silylethynylglycols[99,141–142] in high yields:



$$(CH_3)_3SiCH_2CH_2COCH_3 + HC{\equiv}CH \xrightarrow[ether]{KOH} (CH_3)_3SiCH_2CH_2\overset{\displaystyle CH_3}{\overset{|}{C}}OHC{\equiv}CH\ +$$

$$+\ (CH_3)_3SiCH_2CH_2\underset{\displaystyle CH_3}{\underset{|}{C}}OHC{\equiv}\underset{\displaystyle CH_3}{\underset{|}{C}}COHCH_2CH_2Si(CH_3)_3\ ,$$

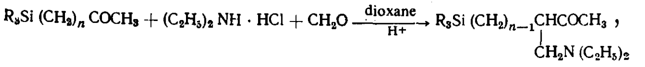
$$R_3Si(CH_2)_nCOCH_3 + HC{\equiv}CNa \rightarrow R_3Si(CH_2)_n\underset{\displaystyle CH_3}{\underset{|}{C}}OHC{\equiv}CH\ ,$$

$$R_3Si(CH_2)_nCOCH_3 + (CH_3)_3SiC{\equiv}CNa \rightarrow R_3Si(CH_2)_n\underset{\displaystyle CH_3}{\underset{|}{C}}OHC{\equiv}CSi(CH_3)_3\ ,$$

where R = CH_3 or C_2H_5 and n = 2–4.

The reaction with 2,4-dinitrophenylhydrazine[20,22,24,68,98,113,140], 3,5-dinitrobenzoylhydrazide[143], hydroxylamine[20,108,144,145], and semicarbazide[67,68,140] leads to the formation of crystalline silicon-containing hydrazones, oximes, and semicarbazones.

The condensation of silicon-containing ketones with secondary amines and formaldehyde by the Mannich reaction requires comparatively severe conditions and the use of a solvent—dioxane or alcohol—is obligatory[146,147]:

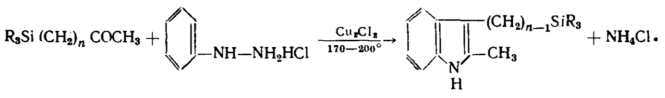


$$R_3Si(CH_2)_nCOCH_3 + (C_2H_5)_2NH\cdot HCl + CH_2O \xrightarrow[H+]{dioxane} R_3Si(CH_2)_{n-1}\underset{\displaystyle CH_2N(C_2H_5)_2}{\underset{|}{C}}HCOCH_3\ ,$$

where R = CH_3 or C_2H_5 and n = 2–4.

The yields of organosilicon aminoketones amount to 40–45%. Their water-soluble hydrochlorides are physiologically active: they reduce blood pressure, stimulate respiration, and exhibit a spasmolytic activity. Their toxicity is in the range 250–320 mg kg^{-1}.

The Fischer reaction between phenylhydrazine hydrochloride and γ-, δ-, and ε-silyl-substituted ketones leads to the formation of indole derivatives with a silyl substituent in the β-position[148]:



γ-Silyl-substituted ketones are capable of condensation with esters in the presence of sodamide, whereby they are converted into silicon-containing β-diketones[18,149,150]:

$$(CH_3)_3SiCH_2CH_2COCH_3 + RCOOC_2H_5 \xrightarrow{NaNH_2} (CH_3)_3SiCH_2CH_2COCH_2COR,$$

where R = CH_3 or $(CH_3)_3SiCH_2CH_2$.

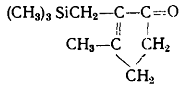
According to their dissociation constants, organosilicon β-diketones are weaker acids than acetylacetone because of the inductive effect of the trimethylsilyl group. Like their non-silylalated analogues, they are effective chelating agents and readily form complexes with copper(II), nickel, and barium salts[18,149,151,152]. The chelates usually contain two molecules of the ketone per metal ion.

When 4-trimethylsilyl-2-butanone is heated with diethyl carbonate in the presence of sodium hydride, the product is a β-ketoester the subsequent treatment of which with bromoacetone and sodium gives a silicon-containing diketoester[18,153,154]:

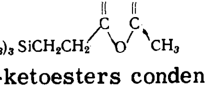
$$(CH_3)_3SiCH_2CH_2COCH_3 + (C_2H_5O)_2CO \xrightarrow{NaH} (CH_3)_3SiCH_2CH_2COCH_2COOC_2H_5 \rightarrow$$

$$\xrightarrow[Na]{BrCH_2COCH_3} (CH_3)_3SiCH_2CH_2COCH(COOC_2H_5)CH_2COCH_3\ .$$

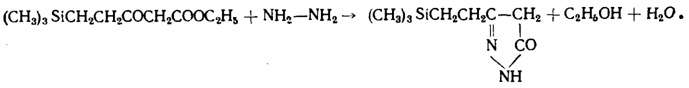
The latter, on being refluxed with aqueous sodium hydroxide, cyclises to 3-methyl-[2-(trimethylsilyl)methyl]cyclopent-2-enone:



and on treatment with a mixture of sulphuric and acetic acids gives rise to a mixture of silicon-containing furan derivative:



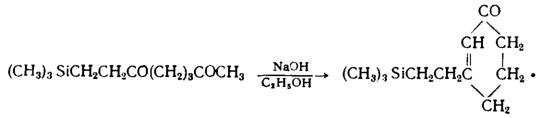
Organosilicon β-ketoesters condense with hydrazine hydrate to crystalline pyrazolones[18]:



The sodio-derivative of a silicon-containing β-ketoester adds to methyl vinyl ketone with formation of a δ-diketone (the Michael reaction):[18,155]

$$(CH_3)_3SiCH_2CH_2COCH_2COOC_2H_5 + CH_3COCH{=}CH_2 \xrightarrow{NaOC_2H_5} \rightarrow (CH_3)_3SiCH_2CH_2CO(CH_2)_3COCH_3.$$

The diketone thus obtained cyclises on treatment with alcoholic alkali to 3-[2-(trimethylsilyl)ethyl]cyclohex-2-enone:



When concentrated sulphuric acid is allowed to act upon γ- or ϵ-silyl-substituted ketones, one methyl group is split off from the silicon atom and the corresponding ketosiloxanes are formed[7-9,19,109,156-160]:

$$2(CH_3)_3SiCH_2CH_2COCH_3 \xrightarrow{H_2SO_4} \xrightarrow{H_2O} O[Si(CH_3)_2CH_2CH_2COCH_3] + 2CH_4,$$

$$n[(CH_3)_3Si(CH_2)_2]_2CO \xrightarrow{H_2SO_4} \xrightarrow{H_2O} [(CH_3)_3Si(CH_2)_2CO(CH_2)_2Si(CH_3)_2O]_n + 2n\,CH_4.$$

γ- and ϵ-Oxoalkylsiloxanes with linear and cyclic structures are readily obtained by the hydrolysis of mono-, di-, and tri-ethoxy- and mono-, di-, and tri-chloro-oxoalkylsilanes[159,160]:

$$(C_2H_5O)_n(CH_3)_{3-n}SiCH_2CH_2COCH_3 \xrightarrow[H+]{H_2O} [O_{n/2}(CH_3)_{3-n}SiCH_2CH_2COCH_3]_x,$$

$$Cl_nR_{3-n}Si(CH_2)_4COCH_3 \xrightarrow{H_2O} [O_{n/2}R_{3-n}Si(CH_2)_4COCH_3]_x.$$

When the oxoalkylsiloxanes are refluxed with dilute alkali, water-soluble oxoalkylsiliconates (monosodium salts of oxoalkylsilanetriols) are formed:

$$[CH_3CO(CH_2)_nSiO_{1.5}]_x \xrightarrow{NaOH} x[CH_3CO(CH_2)_nSi(OH)_2]ONa,$$

where $n = 2$ and 4.

The photolysis of organosilicon ketones leads to mainly cleavage[161].

4. Silylethynyl ketones with the General Formula $R_3SiC{\equiv}CCOR'$

The chemistry of these ketones was investigated by Komarov and Pukhnarevich[89,162-171]. Their characteristic feature is reduced reactivity of the triple bond in reactions with nucleophilic reagents. It is due to the conjugation of the triple bond with the 3*d*-orbitals of the silicon atom and also due to influence of the silicon and carbonyl groups. The addition of electrophilic agents and reactions involving the carbonyl group take place according to the usual mechanism characteristic of non-silylated analogues[163].

a. Reactions involving the carbonyl group. The reaction of 4-trimethylsilylbut-3-yn-2-one with methylmagnesium iodide leads to the formation of a tertiary alcohol:

$$(CH_3)_3SiC{\equiv}CCOCH_3 \xrightarrow{CH_3MgI} (CH_3)_3SiC{\equiv}CC(OH)(CH_3)_2.$$

The reaction with vinylethynylmagnesium bromide results in the formation of silylethynyl homologues of Nazarov's carbinol and those with phenylethynylmagnesium bromide give organosilicon diethynylalcohols with isolated triple bonds[164,165]:

$$R_3SiC{\equiv}CCOCH_3 + BrMgC{\equiv}CR' \rightarrow R_3SiC{\equiv}CC(OH)(CH_3)C{\equiv}CR',$$

where R = CH_3 or C_2H_5 and R′ = C_6H_5 or CH=CH_2.

Triethynyldisilylglycols with isolated triple bonds were synthesised by reaction with ethynylenedimagnesium dibromide[166]:

$$2R_3SiC{\equiv}CCOCH_3 + BrMgC{\equiv}CMgBr \rightarrow R_3SiC{\equiv}CC(OH)(CH_3)C{\equiv}CC(OH)(CH_3)C{\equiv}CSiR_3,$$

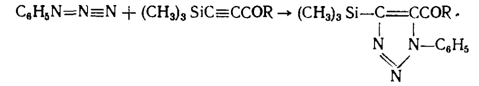
where R = CH_3 or C_2H_5.

The reaction of silyl-αβ-ethynyl ketones with magnesium derivatives of ethynylalcohols leads to the synthesis of organosilicon diethynylglycols[167]:

$$R_3SiC{\equiv}CCOCH_3 + BrMgC{\equiv}CCH_2OMgBr \rightarrow R_3SiC{\equiv}CC(OH)(CH_3)C{\equiv}CCH_2OH.$$

Silyl-α-ethynyl ketones react with 2,4-dinitrophenylhydrazine, semicarbazide, 3,5-dinitrobenzoylhydrazide, and hydrazine hydrate, forming the corresponding hydrazones[143].

The addition of phenyl azide to trimethylsilylalkynones gave silyl-substituted triazoles[65]:



b. Reactions involving the triple bond. When hydrogen chloride is passed through a solution of a silyl-α-ethynyl ketone in glacial acetic acid, silyl-substituted β-chlorovinyl ketones are formed[168,169]:

$$R_3SiC{\equiv}CCOCH_3 + HCl \rightarrow R_3SiCCl{=}CHCOCH_3,$$

where R = CH_3 or C_2H_5. They are thick oily liquids, which rapidly darken in the light with formation of viscous polymers. Chemically they are less reactive than their non-silylated analogues. They do not enter into the Diels–Alder reaction with cyclopentadiene and hexachlorocyclopentadiene and do not exchange the chlorine atom for an alkoxy-, acetoxy-, and hydroxy-group under normal conditions. When silicon-containing β-chlorovinyl ketones were allowed to react with Grignard reagents, tertiary chloroallyl alcohols were obtained in high yields[170]:

$$R_3SiCCl{\equiv}CHCOR' + R''MgX \rightarrow R_3SiCCl{=}CHCOHR'R'',$$

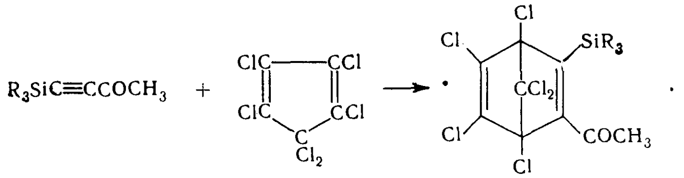
where R = R′ = CH_3 or C_2H_5, R″ = CH_3 or C_6H_5, and X = Br or I.

Silyl-α-ethynyl ketones can combine with both one and two bromine molecules at the multiple bond, but the addition of a second molecule takes place with considerable difficulty[89]:

$$R_3SiC{\equiv}CCOR' \xrightarrow{Br_2} R_3SiCBr{=}CBrCOR' \xrightarrow{Br_2} R_3SiCBr_2CBr_2COR'.$$

In contrast to their non-silylated analogues, silyl-substituted ketones do not combine with hydrogen under the usual conditions in the presence of Raney nickel and Lindlar's catalyst. Hydrogenation in an autoclave at 25 atm leads to the formation of saturated ketones without a silicon atom.

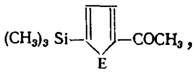
In reactions with cyclopentadiene and hexachlorocyclopentadiene adducts could be isolated only in the case of the latter and even then severe conditions were required and the yields were low, while non-silylated α-ethynyl ketones react with cyclopentadiene even at room temperature[171]:



The reaction of silyl-α-ethynyl ketones with alcohols and phenols in the presence of sodium ethoxide and with diethylamine is usually accompanied by the cleavage of the Si–C bond. They do not react with acetic and chloroacetic acids in the presence of $BF_3.O(C_2H_5)_2$–HgO and on irradiation with ultraviolet light. The reaction with mercaptans in the presence of sodium methoxide or on prolonged ultraviolet irradiation also does not occur, while non-silylated ethynyl ketones readily combine with one or two mercaptan molecules. The attempts to hydrate silyl-α-ethynyl ketones in the presence of mercuric salts led only to the formation of products of decomposition at the silicon-carbon bond.

5. Aromatic and Heterocyclic Silyl-substituted Ketones

A characteristic feature of silicon-containing aromatic ketones of the type $(CH_3)_3SiC_6H_4COR$ is the instability of the Si–C_{aryl} bond in relation to electrophilic agents such as $AlCl_3$ [50,51] and that of ketones of the type $(CH_3)_3SiCH_2C_6H_4COR$ is instability to the action of oxidising agents [56]. At the same time oxidation of heterocyclic ketones takes place without the cleavage of the Si–C bond [53,172]:



where E = O or S.

When acted upon by reducing agents, organomagnesium compounds, 2,4-dinitrophenylhydrazine, hydroxylamine, and semicarbazide and in the Mannich reaction, ketones of this class behave like their non-silylated analogues. The reduction of 4-trimethylsilylacetophenone with sodium borohydride takes place according to the usual mechanism [173]:

$$(CH_3)_3SiC_6H_4COCH_3 \xrightarrow{2H} (CH_3)_3SiC_6H_4CHOHCH_3.$$

A glycol is obtained in 91% yield by a similar procedure from the diketone $(CH_3)_2Si(C_6H_4COCH_3)_2$. The hydrogenation of the hydrochlorides of organosilicon aminoketones over Raney nickel yielded secondary aminoalcohols, the reduction being accompanied by the degradation of the aminoketones [174]:

$$(CH_3)_3SiCH_2C_6H_4COCH_2CH_2N(CH_3)_2\,HCl \xrightarrow[Ni]{H_2} (CH_3)_3SiCH_2C_6H_4CHOHCH_2CH_2N(CH_3)_2 + HCl.$$

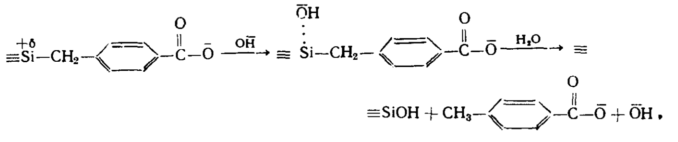
The hydrochlorides of organosilicon aminoketones react with ethylmagnesium bromide to form silicon-containing tertiary aminoalcohols. Organosilicon tertiary alcohols have also been obtained by Grignard reaction from trialkylsilylmethylphenyl and trialkylsilylethylphenyl ketones [55]:

$$R_3Si(CH_2)_nC_6H_4COCH_3 \xrightarrow{CH_3MgCl} R_3Si(CH_2)_nC_6H_4C(OH)(CH_3)_2.$$

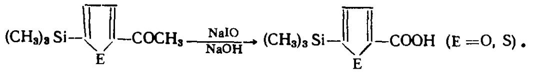
The oxidation of di(acetylbenzyl)tetramethyldisiloxane with sodium hypobromite in an alkaline medium is accompanied by the decomposition of the molecule at the silicon-carbon bond [56]:

$$[CH_3COC_6H_4CH_2(CH_3)_2Si]_2O + 6NaBrO \rightarrow 2CH_3C_6H_4COONa + [(CH_3)_2SiO]_x + 4NaOH + 2CHBr_3.$$

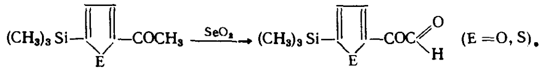
The comparatively ready elimination of the benzylcarboxy-group is probably associated with the migration of the reaction centre in a system of conjugated multiple bonds, as a result of which the electron density at the silicon atom is reduced, whereupon the Si–C bond dissociates under the action of a nucleophilic agent:



The oxidation of 2-acetyl-5-trimethylsilylfuran and 2-acetyl-5-trimethylsilylthiophen with hypoiodite takes place without the rupture of the Si–C bond and yields the corresponding acids [53]:



Selenium dioxide oxidises the above compounds to silicon-containing glyoxals in 40–70% yield [172]:



The Mannich condensation of alkyl trimethylsilylmethylphenyl ketones with dimethylamine and paraformaldehyde leads to the formation of organosilicon aminoketones [174]. However, the aminoketones were not isolated in a pure form:

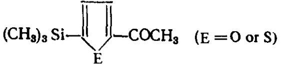
$$(CH_3)_3SiCH_2C_6H_4COR + CH_2O + (CH_3)_2NH \cdot HCl \xrightarrow[C_2H_5OH]{HCl} \rightarrow (CH_3)_3SiCH_2C_6H_4COCHR'CH_2N(CH_3) \cdot HCl,$$

where R = CH_3 or C_2H_5 and R′ = CH_3.

The aromatic silicon-containing ketones $R_3Si(CH_2)_nC_6H_4COR'$, where R = CH_3 or C_2H_5, R′ = CH_3, C_6H_5, C_5H_{11}, $C_6H_4OCH_3$, or $C_6H_4CH_3$, and $n = 0–2$, react with 2,4-dinitrophenylhydrazine to form crystalline 2,4-dinitrophenylhydrazones [33,34,52,55,60,91]. The reaction of 2,4-dinitrophenylhydrazine with the ketodisiloxanes $O[Si(CH_3)_2CH_2C_6H_4COR]_2$ may involve both carbonyl groups [56,57].

When semicarbazide is allowed to react with silicon-containing aromatic ketones, crystalline semicarbazones are obtained [34,60,91].

Heterocyclic ketones of the type



also readily form semicarbazones. A crystalline oxime has been obtained from *p*-trimethylsilylacetophenone $(CH_3)_3SiC_6H_4COCH_3$. [34]

The polycondensation of organosilicon ketodicarboxylic acids with glycol at 170–190°C in an atmosphere of nitrogen has been reported [58]:

$$HOOCC_6H_4COC_6H_4CH_2Si(CH_3)_2OSi(CH_3)_2CH_2C_6H_4COC_6H_4COOH + n\,HOCH_2CH_2OH \rightarrow$$
$$\rightarrow [OCOC_6H_4COC_6H_4CH_2Si(CH_3)_2OSi(CH_3)_2CH_2C_6H_4COC_6H_4COOCH_2CH_2]_nOH + (n-1)\,H_2O.$$

The polycondensation of organosilicon ketoacids with more than two dimethylsiloxane rings may involve a rearrangement into cyclic polydimethylsiloxanes and polyesters with a disiloxane unit:

$$m\,HOOCC_6H_4COC_6H_4CH_2Si(CH_3)_2O[Si(CH_3)_2O]_nSi(CH_3)_2CH_2C_6H_4COC_6H_4COOH +$$
$$+ m\,HOCH_2CH_2OH \rightarrow H_2O + m[-Si(CH_3)_2O-]_n +$$
$$+ n[OCH_2CH_2OCOC_6H_4COC_6H_4CH_2Si(CH_3)_2OSi(CH_3)_2CH_2C_6H_4COC_6H_4CO]_mOH.$$

These polyesters are vitreous low-melting products readily soluble in organic solvents.

The polycondensation of silicon-containing diketodicarboxylic acids with di-(β-hydroxyethoxymethyl)tetramethyldisiloxane takes place according to the mechanism [10]:

$$x\,HOOCC_6H_4COC_6H_4CH_2Si(CH_3)_2O[Si(CH_3)_2O]_nSi(CH_3)_2CH_2C_6H_4COC_6H_4COOH +$$
$$+ x\,HOCH_2CH_2OCH_2Si(CH_3)_2OSi(CH_3)_2CH_2OCH_2CH_2OH \rightarrow (x-1)\,H_2O +$$
$$+ x\,H\{OOCC_6H_4COC_6H_4CH_2Si(CH_3)_2O[Si(CH_3)_2O]_nSi(CH_3)_2CH_2C_6H_4COC_6H_4COOCH_2-$$
$$-CH_2OCH_2Si(CH_3)_2OSi(CH_3)_2CH_2OCH_2CH_2\}OH^{\cdot\cdot}.$$

6. Complexes of Silicon Halides with β-Diketones and β-Ketoesters

West[105], Andrianov[107], and Hester[175] established by infrared and NMR spectroscopy that the complexes of acetylacetone with silicon halides have the structure of *o*-silyl derivatives:

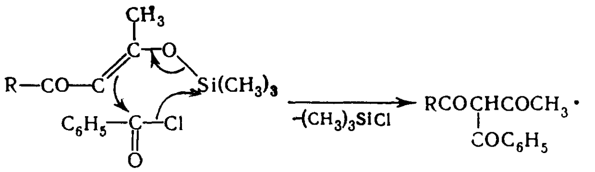
$$R_nSi[OC(CH_3){=}CHCOCH_3]_{4-n},$$

where $n = 1-3$ and R = alkyl, aryl, or a halogen. For the triethylsilyl derivative of ethyl acetoacetate, Andrianov[41] proposed a structure with a C-silyl bond, i.e. $R_3Si[CH(COCH_3)COOC_2H_5]$, and Gilman[40] and West[176] suggested an enolic structure: $R_3SiOC(CH_3){=}CHCOOC_2H_5$.

A characteristic property of compounds of this class is instability in both acid and alkaline media. In aqueous hydrochloric acid solutions they are slowly hydrolysed, while in an alkaline medium the hydrolysis is instantaneous[105,107,177,178]:

$$[CH_3COCH{=}C(CH_3)O]_3SiCl \cdot HCl \xrightarrow{H_2O} (CH_3CO)_2CH_2 + Si(OH)_4 + HCl.$$

When benzoyl chloride is allowed to act upon 2-trimethylsiloxypent-2-en-4-one, the molecule decomposes, possibly as a result of the interaction between the 3*d*-orbitals of silicon and the free electron pairs of the chlorine atom in benzoyl chloride[179]:



The interaction of complexes with heavy metal chlorides leads to the formation of crystalline double salts[15,43,102,105]:

$$[RCOCH{=}C(R)O]_3SiCl \cdot HCl + MCl_n \rightarrow [RCOCH{=}C(R)O]_3SiCl \cdot MCl_n,$$

where R = CH_3 or C_6H_5, M = Rb, Cu, Zn, Fe, Au, Pt, or Sn, and *n* is the valence of the metal.

When $[C_6H_5COCH{=}C(C_6H_5)O]_3SiCl.HCl$ is acted upon by sulphuric acid or silver nitrate, the crystalline sulphate $[C_6H_5COCH{=}C(C_6H_5)O]_3Si(HSO_4)$ and the nitrate $[C_6H_5COCH{=}C(C_6H_5)O]_3SiNO_3$ are formed respectively[101].

The Electronic Structure of Radical-anions

S.P.Solodovnikov and A.I.Prokof'ev

The ESR spectroscopic data relating to studies on the chemical and electronic structures of radical-anions derived from organic compounds have been examined. These studies include those on the distribution of unpaired electron density in radical-anions, the effect of substituents on such distribution, the hindered motion of groups and fragments in radical-anions, the effect of the solvent on the distribution of unpaired electron density, and the nature of the association of radical-anions with metal cations. Among problems of the chemical behaviour of radical-anions, electron-exchange reactions between the radical-anions and the initial molecules have been considered.
The bibliography includes 124 references.

CONTENTS

I. INTRODUCTION

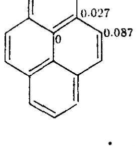
Electron-transfer hypotheses are nowadays widely used to account for the mechanisms of certain chemical reactions. These include the metallation, Wurtz, Grignard, hydrogenation, and certain other reactions [1]. In these reactions radical-anions (RA) are either detected experimentally or are postulated as intermediates. Although the true role of radical-anions in these processes has not been always completely established, their very presence necessitates a careful study of their chemical behaviour.

The application of radiospectroscopic, optical polarographic, quantum-chemical, and other methods yielded extensive data on the physicochemical properties of these species. These techniques have greatly expanded our knowledge of the electronic structure of molecules capable of being reduced with the formation of radical-anions.

The formation of ionic species in the interaction between liquid potassium and naphthalene was noted as early as 1867 by Berthelot [2]. However, systematic studies in this field began with the work of Schlenk [3] in the first quarter of the twentieth century. Schlenk observed that aromatic ketones and hydrocarbons react with alkali metals in ethereal solutions forming coloured free-radical products. The free-radical nature of metal ketyls was confirmed in 1934 by Sugden [4], who showed them to be paramagnetic. In the nineteen-thirties, studies on the reactions of alkali metals with aromatic hydrocarbons were continued by Scott [5], who began the general use of 1,2-dimethoxyethane (DME) as a solvent and demonstrated its exceptional effectiveness in the reaction between aromatic hydrocarbons and alkali metals. A number of studies have been made [6-8] to elucidate the composition of complexes of aromatic hydrocarbons with alkali metals. It has been shown for complexes of anthracene with lithium, sodium, and potassium that, depending on the amount of metal M introduced into the reaction, the composition of the complex with anthracene (A) varies from AM to AM_2. An important property of solutions of these complexes is their high electrical conductivity.

The electronic structure of the products of the reaction of aromatic hydrocarbons with alkali metals has been established by electron spin resonance (ESR) and electronic spectroscopy. Analysis of these data showed that one of the first products of the interaction in solution between aromatic compounds and alkali metals are mono- and di-anions of these compounds linked to some extent to the metal cations. The hyperfine structure (HFS) of the ESR spectra indicates complete transfer of the unpaired electron from the alkali metal to the aromatic hydrocarbon molecule and a high degree of delocalisation of the electron. The simple approximation of the molecular orbital (MO) method is frequently sufficient to describe the nature of the delocalisation of the unpaired electron. Analysis of ESR spectra of numerous hydrocarbon π-electron radicals shows that the magnitude of hyperfine coupling (HFC) to protons (a_H) is proportional to the density of the unpaired electron at the corresponding hydrogen nucleus [9]. Fig. 1 shows the variation of a_H with the unpaired electron density at the carbon atom (ρ_C) in the lowest non-bonding orbital of the radical-anion calculated by the simple MO method. This linear relation constitutes the basis of the familiar McConnell formula [10]: $a_H = Q\rho_C$ ($-Q = 22.5$–30 gauss).

However, there are cases where the simple molecular orbital theory predicts zero unpaired electron densities at carbon atoms, while the ESR spectra show a hyperfine structure due to hydrogen atoms bound to these carbon atoms. As an example, the diagram below shows the distribution of unpaired electron density in the pyrene radical-anion [9,11] based on the simple molecular orbital theory:



.

The diagram shows that zero unpaired electron densities occur at the terminal protons of pyrene. Nevertheless the ESR spectra of this radical-anion show a hyperfine structure due to these protons with hyperfine coupling constants of 1 gauss.

This discrepancy between the simple molecular theory and the ESR data is due to the fact that the molecular orbital theory yields charge densities of the unpaired electron, while the hyperfine structure of the ESR spectra is due to the interaction of the unpaired electron spin density (SD) with the paramagnetic nuclei in the radical.

Practical methods for the calculation of spin density in π-electron radicals were proposed by McLachlan[11]. Since a detailed description of the essential features of these methods is outside the scope of this review, we shall only mention that they allow for the interaction of the unpaired electron with the filled π-electron shells. This interaction leads to partial "unpairing" of the electrons with α- and β-spins in filled electron shells, as a result of which they move in orbitals which differ from those predicted by the molecular orbital theory. In this case the spin density at the carbon atom is the sum of the unpaired electron density calculated by the simple molecular orbital theory and the spin densities of electrons corresponding to the α- and β-spins. When the molecular orbital theory yields zero unpaired electron densities, the overall spin density may have a "negative" sign relative to the direction of the spin of the unpaired electron.

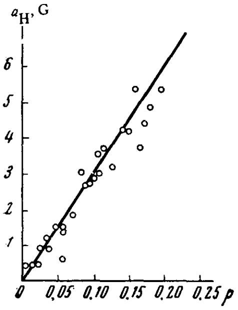


Figure 1. Variation of the proton hyperfine coupling constants in the ESR spectra of the radical-anions of benzene, cyclo-octatetraene, naphthalene, anthracene, naphthacene, pentacene, perylene, coronene, phenanthrene, and biphenyl with unshared electron density at a given carbon atom calculated by the molecular orbital method.

Further studies showed that there exists also a relation between the hyperfine coupling to the carbon-13 and nitrogen-14 nuclei and the distribution of spin density[12]. These relations are more complex but are nevertheless satisfactorily consistent with the concepts of the delocalisation of the unpaired electron in the lowest non-bonding orbital of the radical-anion.

The electronic absorption spectra of anions and dianions may be treated from this standpoint[13-15]. The electronic spectra of these species have characteristic bands in the visible region and the ultraviolet absorption is analogous to that of the initial hydrocarbon. Absorption in the visible region is due to transitions of the unpaired electron in the lowest non-bonding orbital.

An enormous amount of work has been done in the last decade on radical-anions, mostly using the ESR method. One of the most important results of the application of this method in the chemistry of free radicals has been the detection of radical-anions in polarographic reduction carried out directly in an ESR spectrometer[16]. This method, developed by Maki and Geske, greatly extended the possibilities of the synthesis of radical-anions. While reduction with alkali metals is carried out mainly in ethereal solutions, electrochemical reduction allows the use of a larger number of solvents. In many cases it proved possible to employ solvents such as alcohol and water[17], in addition to aprotic solvents such as dimethylformamide (DMF), dimethyl sulphoxide (DMSO), and acetonitrile (AC).

The range of problems solved with the aid of ESR is very wide: the distribution of spin density in various radical-anions, the effect of substituents on the distribution of spin density, the effect of solvent and the hindered rotation of individual groups on hyperfine coupling, electron-exchange reactions, ion association, stability of radical-anions and the way it is influenced by the nature of the metal and the solvent, and chemical reactions involving radical anions.

We decided to isolate only a few main trends in studies on radical-anions without attempting a complete description of the enormous scientific literature which has accumulated recently. One may include here the electronic structure of radical-anions of various classes of chemical compounds, the effect of substituents and medium on the electronic structure of radical-anions, and the formation of ionic association complexes. Among problems related to the chemistry of radical-anions, only electron-exchange reactions will be considered in detail, since extensive and interesting data have accumulated in this field. Until recently there have been no reviews or monographs on this problem in the Soviet literature. Among the reviews published outside the Soviet Union, particular mention should be made of those of Geske[18] and Szwarc[19] and the compilation on radical-ions[20].

II. ELECTRONIC STRUCTURE OF RADICAL-ANIONS

The ESR spectra of the radical-anions derived from an enormous number of organic compounds have now been investigated: polyenes, aromatic compounds with various functional groups, heterocyclic compounds, and organic derivatives of the elements. In describing these extensive experimental data, we decided to separate the most important classes of chemical compounds whose radical-anions have been investigated in detail and also certain trends in this field.

The review of the experimental data should be begun with butadiene as the simplest example. The radical-anion from butadiene was obtained electrochemically in liquid ammonia by Levy and Myers[21]. The ESR spectrum of this radical-ion is presented in Fig. 2 and consists of a quintet of triplets with the following hyperfine proton coupling constants (a_i) in the 1- and 4-positions and 2- and 3-positions: $a_1 = a_4 = 7.617$ gauss and $a_2 = a_3 = 2.791$ gauss.

$$^{\bullet}H_2\overset{1}{C}{=}\overset{2}{C}H{-}\overset{3}{C}H{=}\overset{4}{C}H_2 .$$

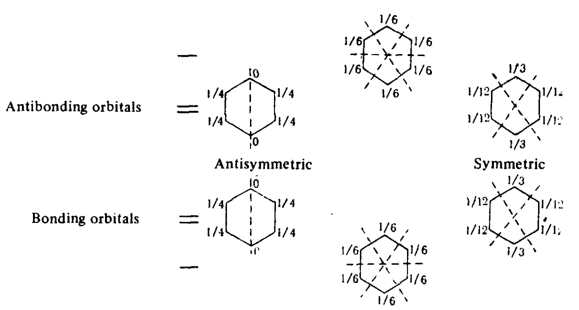
The distribution of spin density is described satisfactorily by the wave function $\Psi_3 = 0.600\ \varphi_1 - 0.371\ \varphi_2 - 0.371\ \varphi_3 + 0.600\ \varphi_4$ obtained by Hückel's simple molecular orbital method. The ratio of the coupling constants is $a_1/a_2 = 2.729$ and that of the spin densities is $\rho_1/\rho_2 = 0.600^2 : 0.371^2 = 2.615$. The distribution of spin density in the butadiene radical-anion is confirmed by the analysis of the spectra of the radical-anions obtained from butadiene derivatives[22]: $(CH_3)_2C{=}CH{-}CH{=}(CH_3)_2$ and $H_2C{=}C(CH_3){-}C(CH_3){=}CH_2$.

Numerous studies have been made on the radical-anions of benzene derivatives. These include alkyl, cyano-, carbonyl, nitro-, and also certain organometallic derivatives. The distribution of spin density in some of these radical-anions may be interpreted using the properties of the molecular orbitals of benzene [9]. Six molecular orbitals may be formed from the six $2p_z$ atomic orbitals of carbon: three bonding and three antibonding orbitals.

Figure 2. ESR spectrum of the butadiene radical-anion in liquid ammonia at −78°C.

The relative energies of these orbitals and the electron densities are presented in Scheme 1.

Scheme 1



The dashed lines indicate the positions of the nodes of the π-orbitals. The highest bonding and the lowest antibonding orbitals are degenerate. In the benzene radical-anion the unshared electron is equally distributed between two degenerate orbitals. The distribution of the electron in the degenerate orbitals is indicated in the Scheme. These two orbitals may be classified as symmetric and antisymmetric according to their behaviour on reflection in a plane perpendicular to the benzene ring and passing through opposite atoms. The spin density at each carbon atom in the benzene radical-anion is 1/6 and the ESR spectrum consists of 7 lines with binomial intensity ratios and with spacings of 3.75 gauss.[23] In the radical-anions of substituted benzene where the symmetry is less than threefold the degeneracy is removed. If the perturbation introduced by the substitutent is not too great, then the distribution of the unshared electron proves to be similar to the distribution in one of the degenerate benzene orbitals. The effect of substituents may be examined most simply when the perturbation is purely inductive [9]. If the substituent is electropositive, the unshared electron will occupy the antisymmetric orbital and the ESR spectrum of the radical-anion will consist of a quintet due to the interaction of the unshared electron with the *ortho*- and *meta*-protons with a coupling constant of about 5 gauss. The Scheme shows that the spin density in the antisymmetric antibonding orbital is distributed equally between the four carbon atoms. The hyperfine coupling to the proton in the *para*-position and the nuclei of the substituent should be small.

When the substituent is electronegative, the unshared electron will occupy the symmetric orbital. Here the ESR spectrum will be complex, since it must involve considerable doublet splitting (about 8 gauss) due to the proton in the *para*-position with additional splitting of the doublet components due to the *ortho*- and *meta*-protons. The application of these simple concepts to certain mono- and di-*para*-substituted benzenes gives a good agreement with experiment. Similar concepts were developed for *ortho*- and *meta*-derivatives of benzene [9].

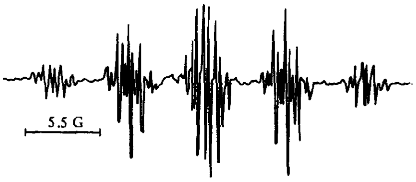


Figure 3. ESR spectrum of the toluene radical-anion in dimethoxyethane containing potassium.

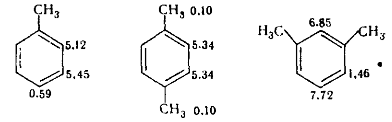
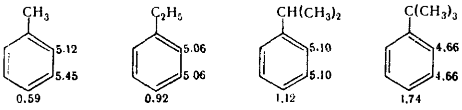
The experimental data on the ESR spectra of the radical-anions of alkylbenzenes clearly illustrate these ideas. Fig. 3 presents as an example the ESR spectrum of the toluene radical-anion. The coupling constants for the toluene and *p*-xylene radical-anions [23-26] indicated in the Scheme below proved to be similar to those predicted by considering the antisymmetric orbital, while in the *m*-xylene radical-anion the distribution of spin density agrees better with the symmetric orbital [24-26]:

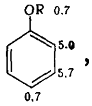


Interesting features are revealed when the ESR spectra of the following radical-anions are compared:



It is seen that, on transition from toluene to t-butylbenzene, there is an appreciable increase of the coupling constant for protons in the *para*-position and a decrease of the constants for the *ortho*- and *meta*-protons [9]. Three causes responsible for this change in the distribution of spin density may be indicated: configuration interaction, vibrational interaction, and thermal equilibrium between two states close to degeneracy. These mechanisms should lead to an admixture of a symmetric wave function with the antisymmetric wave function in the wave function of the unpaired electron. The high value of the coupling constant for the *para*-hydrogen in the radical-anion of t-butylbenzene is regarded as a result of the mixing of two states. The role of the vibrational interaction between the antisymmetric and symmetric states decreases with increasing distance between these two states. If the distance between the levels become comparable to *kT*, thermal population of the highest vacant orbital at room temperature becomes possible. When this condition applies, the coupling constants should depend on temperature. Such a variation has been observed by Tuttle[27] and de Boer and Colpa[28]. The sum of the coupling constants $a_H(para) + a_H(CH_3)$ diminishes as the temperature is lowered, while the sum $a_H(ortho) + a_H(meta)$ increases by the same amount. The hyperfine coupling constants for the *p*-xylene radical-anion are independent of temperature, which may be accounted for by long distances between the levels[28]. Estimates of the distance between the two states yield 384 cm^{-1} for toluene and 868 cm^{-1} for *p*-xylene.

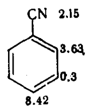
Another example illustrating the effect of electropositive substituents on the degenerate benzene orbitals is the ESR spectra of the radical-anions of alkoxybenzenes investigated by Grandberg et al.[29]:

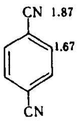


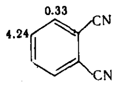
,

where R = CH_3 or C_2H_5.

The cyano-group has a filled π-bonding and a vacant antibonding orbital the interaction of which with the π-orbitals of benzene must be considered in the analysis of the ESR spectra of the radical-anions of cyanobenzenes. However, here too the concepts developed above are applicable to the analysis of the ESR data for the radical-anions of benzonitrile, terephthalonitrile, and phthalonitrile:



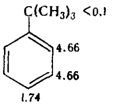


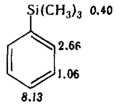


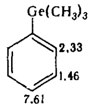
.

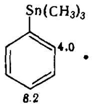
The cyano-group in the radical-anion of benzonitrile and terephthalonitrile lowers the energy of the symmetric orbital and in the radical-anion of phthalonitrile the energy of the antisymmetric orbital is reduced[9].

The concept of the orbital degeneracy of the benzene levels proved useful in the examination of a number of other substituted benzenes[30,31]:









.

Above it was shown that the unshared electron in the radical-anions of monoalkylbenzenes occupies the antisymmetric orbital. Analysis of the hyperfine structures of the ESR spectra of the radical-anions of benzene derivatives containing silicon, germanium[30], and tin[31] shows that in these radical-anions the symmetric orbital lies below the antisymmetric orbital. The simple concepts developed above permit the classification of these substituents as electronegative. However, one must not disregard certain features in the ESR spectra which may be associated with conjugation. Thus the high values of the hyperfine coupling constants for methyl protons in the radical-anion of trimethylsilylbenzene may reflect the occurrence of some interaction between the vacant *d*-orbitals of silicon and the π-electrons in the benzene ring.

The examples examined illustrate the removal of degeneracy in cases where the unshared electron is located either in the symmetric or the antisymmetric orbital. However, weak perturbation by a substituent may lead to only a slight redistribution of spin density between these orbitals. Such a situation was observed by Fraenkel and coworkers[32] in the radical-anion of monodeuterobenzene in which one hydrogen atom was replaced by deuterium. In contrast to the benzene radical-anion for which a hyperfine coupling constant of 3.75 gauss was found, the following hyperfine coupling constants were obtained for monodeuterobenzene: $a_H^2 = a_H^3 = a_H^5 = a_H^6 = 3.92 \pm 0.01$ gauss, $a_H^4 = 3.41$ gauss, and $a_D^1 = 0.55 \pm 0.01$ gauss. The introduction of deuterium leads to a somewhat greater population of the antisymmetric orbital compared with the symmetric orbital. Köhnlein et al.[33] succeeded in removing the degeneracy in the benzene radical-anion itself by a suitable choice of conditions. The ESR spectrum of the benzene radical-anion in a 2 : 1 tetrahydrofuran (THF)—dimethoxyethane mixture changes on raising the temperature above −20°C—the seven lines with a binomial distribution of intensities are replaced by a main triplet ($a_H^1 = 6.5$ gauss) with further splitting of each triplet component into a quintet ($a_H^2 = 1.75$ gauss). The authors suggest that the removal of degeneracy is due to exchange interaction with the metal cation, as a result of which the unshared electron occupies the symmetric orbital.

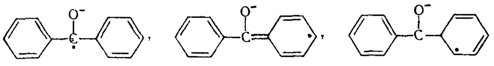
Apart from benzene, the radical-anions of a number of compounds with D_{3h}, D_{6h}, and D_{8h} symmetries having degenerate electronic states have been investigated: triphenylene, *sym*-tricyanotriazole[34], *sym*-trimethylsilylbenzene[35], trinitrobenzene[36], coronene[37], and cyclo-octatetraene[38]. When the radical-anions of *sym*-tricyanotriazole, *sym*-trimethylsilylbenzene, and trinitrobenzene are generated chemically, the distribution of spin density shows a deviation from the symmetry of the initial molecules. These deviations are attributed to the removal of orbital degeneracy and to the distribution of spin density in each of the degenerate orbitals. The interaction of the metal cation with one of the functional groups is regarded as a possible cause of the removal of degeneracy[36].

Cyclo-octatetraene (COT) readily accepts two electrons and is converted into a dianion. The ESR spectrum of the cyclo-octatetraene radical-anion consists of nine lines with a binomial intensity distribution and a hyperfine coupling constant of 3.2 gauss.[38] It has been suggested that the addition of one electron results in a flattening of cyclo-octatetraene, so that the radical-anion has a planar structure with D_{8h} symmetry. The electronic structure of planar COT$^{\dot{-}}$ should exhibit orbital degeneracy. However, the study of the ESR spectrum of the radical-anion of monodeuterated cyclo-octatetraene does not show any signs of the removal of degeneracy[39]. McLachlan[39] explains the absence of such signs by the fact that the vibrations of the C–C bonds, which leads to the extension or compression of the molecule, interact more effectively with the motion of electrons than do other types of vibrations. These interactions lead to the appearance of orbitals corresponding to a fully symmetrical distribution of spin density.

The above concepts proved unsatisfactory in the study of the ESR spectra of the radical-anions of substituted benzenes with substituents having their own π electrons. In these radical-anions the unshared electron orbitals differ markedly from the benzene orbitals and an independent calculation is necessary for the interpretation of the ESR spectra. Such substituents include the carbonyl, nitroso-, nitro-, and certain other complex functional groups. A satisfactory description of the distribution of spin density in the radical-anions of the above compounds may be achieved by the McLachlan method[11] with a suitable choice of parameters for the Coulombic and exchange integrals (MO parameters).

The ESR spectra of *p*-benzosemiquinone[40], *o*-benzosemiquinone[41], 1,4-naphthosemiquinone, 9,10-anthrasemiquinone, *o*-phenanthraquinone, etc.[42] can be satisfactorily described within the framework of the McLachlan method when the following values are adopted for the MO parameters: $\alpha_0 = \alpha_C + 1.2\beta$ and $\beta_{CO} = 1.56\beta$.

The principal features of the distribution of spin density in the radical-anions of the carbonyl compounds may be examined on the basis of the following valence bond schemes for the benzophenone radical-anion:



from which it follows that in the ESR spectrum of the benzophenone radical-anion there should be a main hyperfine structure due to the protons in the *ortho*- and *para*-position with subsidiary hyperfine structure due to the *meta*-protons. Indeed, Kazakova and Syrkin[43] obtained hyperfine coupling constants of 2.1 gauss for the *ortho*- and *para*-protons and 0.7 gauss for the *meta*-protons.

Table 1. Hyperfine coupling constants and spin densities in the radical-anions of carbonyl compounds.

Radical-anion	Position	a_H, G	Spin density (expt.)	Spin density (calc.)

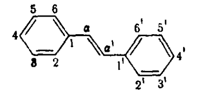
	1	—	—	0.1444
	2	2.08	0.0878	0.0799
	3	0.70	0.0295	0.0298

The ESR spectra of the radical-anions of certain carbonyl compounds show interesting features. A breakdown of the symmetry of the hyperfine interaction relative to the axis passing through the carbonyl carbon atom and the carbon atom in the *para*-position has been observed in the radical-anions of acetophenone, benzaldehyde[44], terephthalic aldehyde[45,46], and 1,4-diacetylbenzene[46]. Table 1 lists the hyperfine coupling constants for the ESR spectra of certain carbonyl radical-anions.

Such non-equivalence of the hyperfine coupling constants for the *ortho*- and *meta*-positions is caused by the interaction of the benzene ring protons with the carbonyl groups. The rotation of the carbonyl group is hindered and its frequency is probably less than the characteristic frequency for relaxation of the ESR spectra (10^7–10^6 Hz). The retardation of the rotation of the carbonyl group results in the existence of *cis*- and *trans*-forms of the radical-anion of terephthalic aldehyde and 1,4-diacetylbenzene[46]. The free energy of the conversion of the *cis*-form into the *trans*-form is $\Delta F_{293^\circ} = -200 \pm 25$ cal mole^{-1} for the terephthalic aldehyde radical-anion and $\Delta F_{293^\circ} = 210 \pm 90$ cal mole^{-1} for the 1,4-diacetylbenzene radical-anion with $N_{cis}/N_{trans} = 1/4$. A satisfactory agreement between the experimental and theoretical spin densities was achieved with the following choice of MO parameters: $\alpha_0 = \alpha_C + 1.55\beta$, $\beta_{CO} = 1.5\beta$, and $\beta_{CC^*} = 1.1\beta$, where β_{CC^*} is the exchange integral between the carbonyl carbon atom and the carbon atom in the benzene ring. The asymmetry in the distribution of spin density was achieved by introducing a negative correction to the Coulombic integral for the carbon atom in the 6-position [$\delta = (-0.05)$–(-0.15)].

A similar asymmetry in the hyperfine coupling constant was observed in the ESR spectra of the *trans*-stilbene[47] and *trans*-azobenzene[48] radical-anions:



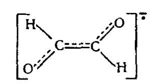
.

	2	3	4	5	6	α	
Stilbene	3.03	0.83	4.00	0.80	1.94	4.51	gauss
Azobenzene	2.81	0.78	2.81	0.78	2.03	4.84	gauss

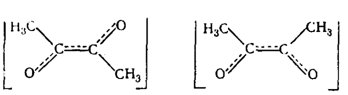
When account is taken of the interaction between the atoms in the 2- and α-positions and also in the 2′- and α′-positions, which alters the Coulombic integrals for the atoms in the 2- and 2′-positions, it is possible to obtain agreement between the theoretical and experimental spin densities. However, as for the carbonyl radical-anions, the physical significance of this interaction remains unexplained. Maki[45] suggested that the asymmetry may be due to the polarisation of the π-electron cloud by the electrical dipole of the carbonyl group.

Rieger and Fraenkel[46] described the ESR spectra of a series of radical-anions containing the carbonyl group. These radical-anions are aromatic resonance-stabilised paramagnetic species. However, the less stable aliphatic ketyls, obtained in particular from hexamethylacetone, pentamethylacetone[49], and diethylpinacol[50], have also been investigated.

Recently Russell and coworkers[20] made a large-scale study of the paramagnetic species formed on reduction of conjugated diketones, which have been called semidiones. The reduction of conjugated tri- and tetra-ketones leads to the corresponding radical-anions: semitriones and semitetraones. The simplest representative of semidiones is the radical-anion formed on reduction of glyoxal[51]:

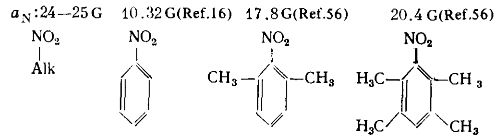


The spectrum of this radical-anion consists of a triplet due to the interaction of the unshared electron with two hydrogen atoms. Analysis of the spectrum permits an estimation of the spin density distribution, according to which the maximum spin density is located at the carbonyl carbon atoms. ESR spectra revealed the formation of two paramagnetic species in the reduction of diacetyl[52]:



with a signal intensity ratio of 20:1. The study of the temperature variation of these signals made it possible to determine the difference between the stabilities of the isometric semidiones. It was found that the *trans*-isomer is more stable than the *cis*-isomer. The higher values of the hyperfine interaction constants for the *cis*-isomer can be accounted for by the formation of a "more compact" ion pair and the consequent increase of spin density at the carbonyl carbon atoms. The introduction of bulky substituents (isopropyl, t-butyl) leads to the formation of *trans*-isomers only[53]. The study of numerous derivatives of semidiones shows clearly how the hyperfine coupling constants for β-protons depend on the conformation, bond angles, and other factors. These problems will be discussed in greater detail in the next section.

The ease of the electrochemical generation of radical-anions containing the nitro-group permitted a detailed study of the ESR spectra of the radical-anions of a large number of nitro-compounds. The localisation of the unshared electron at the nitro-group is caused by its high electronegativity. The diagrams quoted below show how the structure of the nitro-compounds affects the hyperfine coupling to the nitrogen nucleus in the nitro-group:



where Alk = CH_3,[54] C_2H_5, C_3H_7, or C_4H_9.[55]

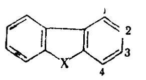
While in the radical-anions of aliphatic nitro-compounds the spin density is wholly localised at the nitro-group, in the nitrobenzene radical-anions approximately half the spin density is withdrawn into the benzene ring as a result of conjugation. The decrease of this conjugation caused by the displacement of the nitro-group from the plane of the benzene ring in the radical-anions of *o*-dimethylnitrobenzene and nitrodurene leads to greater localisation of the unshared electron at the nitrogroup as compared with nitrobenzene. Satisfactory agreement between the theoretical spin densities in the radical-anions of nitro-compounds and the experimental values was achieved with the following parameters found by Rieger and Fraenkel[57]: $\alpha_N = \alpha + 2.2\beta$, $\beta_{CN} = 1.2\beta$, $\alpha_0 = \alpha + 1.7\beta$, and $\beta_{NO} = 1.67\beta$. The hyperfine coupling constant for the nitrogen atom (a_N) is described by the expression $a_N = A\rho_N^\pi + 2B_0\rho_O^\pi$, where A = 99 ± 10 gauss, $B_0 = -35.8 \pm 5.9$ gauss, and ρ_N^π and ρ_O^π are the spin densities at the nitrogen and oxygen atoms.

Aliphatic nitro- and polynitro-compounds behave differently on reduction. While mononitroalkanes yield relatively stable primary radical-anions, polynitro-compounds are capable of forming paramagnetic dianions on reduction. Thus in the reduction of tetranitromethane with dithionite in an alkaline medium, Lagercrantz[58] observed the formation of the nitroform radical-dianion $[C(NO_2)_3^{\cdot}]^{2-}$. The formation of such a dianion was confirmed by the reduction of the potassium salt of nitroform. The ESR spectrum of the nitroform dianion consists of seven lines with a hyperfine coupling constant for the nitrogen nuclei of 8.4 gauss and intensity ratios corresponding to the interaction of the unshared electron with 3 equivalent nitrogen nuclei. In the reduction of the potassium salt of nitroform the formation of a new radical-dianion $[CH(NO_2)_2^{\cdot}]^{2-}$ with the hyperfine coupling constants a_N = 9.6 gauss and a_H = 4.1 gauss is observed in addition to $[C(NO_2)_3^{\cdot}]^{2-}$. The dissociation of the C–C or C–X bonds with formation of the corresponding radical-dianions is observed in the electrochemical reduction of various derivatives of dinitroalkanes[59]. Syrkin and coworkers observed the formation of paramagnetic dianions in the reduction of *p*-dinitrodiphenylmethane[60].

A number of studies have been made on the radical-anions of diaryl systems of the type Ar–Ar and Ar–X–Ar. One of the problems associated with the structure of these compounds is the degree of breakdown of the conjugation between the aromatic rings joined by a single C–C bond. Such breakdown is possible due to the repulsion of the hydrogen atoms and the displacement of the aryl groups from the planes for conjugation. The study of biphenyl[61], 1,1′-binaphthyl[62], and 9,9′-bianthryl[63], in which the angle between the arene planes is ~30°, ~70°, and ~90° respectively, showed that in the biphenyl and binaphthyl radical-anions the unshared electron is delocalised over both aromatic fragments, while in the bianthryl radical-anion it is delocalised over only one fragment.

The study of bridged radical-anions is interesting from the standpoint of the transmission of effects via various –X– groups. The radical-anions of diphenylmethane[64–66], diphenylethane[64–66], phenyl ether[66], *p*-cyclophanes[66,67], di-(*p*-nitrophenyl)methane[68,69], *p*-nitrophenyl ester[68], and di-(*p*-nitrophenyl) sulphide[68] were studied for this purpose. Syrkin and coworkers[65] showed that the initial conclusion[64] that the unshared electron in the radical-anions of diphenylmethane and diphenylethane may be delocalised was based on erroneous experimental data obtained in the measurement of the ESR spectra of secondary radical-anions. The data on *p*-cyclophanes and di-(*p*-nitrophenyl)methane are not unambiguous. The differences in the spectra of the radical-anions obtained from di-(*p*-nitrophenyl)methane are due to the mobility of the hydrogen atoms in the $-CH_2-$ group. Syrkin and coworkers[69] state that, depending on the conditions, it is possible to observe the ESR spectrum of a radical-monoanion in which, according to their data, there is no conjugation, and of the radical-dianion of di-(*p*-nitrophenyl)methane in which the unshared electron is fully delocalised over the entire molecule. An unambiguous conclusion may be arrived at concerning the delocalisation of the unshared electron between the nitro-groups via the $-CF_2-$ group in the radical-anion of difluorodinitromethane on the basis of an analysis of a simple ESR spectrum[70], which consists of a triplet of quintets due to the interaction of the unshared electron with two nitrogen nuclei (a_N = 12.9 gauss) and two fluorine nuclei (a_F = 14.8 gauss). The delocalisation of the unshared electron was observed in the radical-anion of diphenyl sulphone by Kaiser et al.[71] and also by Gerdil and Lucken[72]. The distribution of spin density in the phenyl rings of this radical-anion is similar to that in the radical-anion of biphenyl.

The intensive studies on the radical-anions of aromatic hydrocarbons and aromatic compounds containing oxygen and nitrogen atoms are largely due to the simplicity of the theoretical analysis of their ESR spectra. The inclusion in the aromatic systems of many-electron atoms such as those of sulphur, phosphorus, and selenium leads to certain difficulties in the interpretation of the spectra. One of the few approaches whereby account can be taken of the effect of these atoms on the electronic structure of organic derivatives of elements of this kind involves the consideration of the *d* orbitals. The quantum-mechanical method for taking into account the interaction of *d* electrons with *p* electrons proposed by Longuet-Higgins[73] permits the treatment of the sulphur atom as an analogue of the double bond in ethylene. According to Longuet-Higgins, such treatment makes it possible to understand the aromatic nature of thiophen. Since thiophen itself is not reduced, dibenzothiophen and related compounds were chosen to test these hypotheses. The hyperfine coupling constants for protons in benzene rings are presented below[74]:



X	a_1	a_2	a_3	a_4, gauss
O	4.87	0.98	4.87	1.96
S	4.48	0.86	5.16	1.46
Se	4.27	1.02	5.27	1.02
$-CH=CH-$	0.32	2.88	0.72	3.60 .

The calculation of the hyperfine coupling constants within the framework of the Longuet-Higgins scheme, which takes into account the interaction of *p* and *d* electrons, gave the following values for benzothiophen: $a_1 =$ 1.36 gauss; $a_2 =$ 2.30 gauss; $a_3 =$ 0.02 gauss; $a_4 =$ 2.63 gauss (*d* model). At the same time a second calculation was made including the interaction of the π electrons of the aromatic part of the molecule with the lone pair of *p* electrons of sulphur and oxygen. The hyperfine interaction constants obtained agree with experiment better than in the case where account is taken of *d* electrons:

	a_1	a_2	a_3	a_4, gauss	
Dibenzothiophen	3.99	−1.23	5.03	0.75	(*p*-model).
Dibenzofuran	4.78	−1.41	4.80	1.86	

On the basis of these results, Gerdil and Lucken concluded that the interaction of the *d* orbitals of the sulphur atom with the π orbitals of the aromatic system is slight.

Urberg and Kaiser[20] compared the involvement of various valence states of sulphur in conjugation using as an example thioxanthone and its sulphone. The data show that in both cases the sulphur atom is only weakly involved in conjugation compared with the carbonyl group. Analysis of the ESR spectra of the radical-anions of di-(*p*-nitrophenyl) sulphide, sulphoxide, and sulphone led to the conclusion that the distribution of unshared electron density in these compounds depends little on the valence state of sulphur.

The problem of the $d-\pi$ conjugation was discussed in the study of the radical-anions of 2,1,3-benzothiadiazole and 2,1,3-benzoselenadiazole by Strom and Russell[75] and by Solodovnikov and Todres[76]. However, data in favour of $d-\pi$ interaction were not obtained. This problem also arises in the study of the radical-anions containing a phosphorus atom, such as aromatic and aliphatic phosphines and phosphine oxides[77]. The search for more distinctive effects of the involvement of *d* orbitals in conjugation led to the study of the ESR spectra of non-aromatic radical-anions[78,79] such as $[R_2Si]_n$. The ESR spectra of the radical-anions of the cyclic compounds $[(CH_3)_2Si]_6$ and $[(C_2H_5)_2Si]_6$ provide evidence of the interaction of the unshared electron with six silicon atoms and 12 carbon atoms. This delocalisation is attributed[78] to the interaction of the silicon *d* orbitals, which the authors believe to contain the unshared electron.

III. EFFECT OF SUBSTITUENTS AND THE MEDIUM ON THE ELECTRONIC STRUCTURE OF RADICAL-ANIONS

The review of studies on the effect of substituents, the solvent, and the hindered motion of the functional groups in radical-anions on their ESR spectra requires special consideration. Some of these problems were considered for a number of examples in the preceding section. In particular, it was shown that semiempirical quantum-chemical methods permit a satisfactory description of the effect of substituents on the distribution of spin density. In this section we shall consider certain special methods for the treatment of the effect of substituents.

Rieger and Fraenkel[80] showed that the ratio of the spin densities in the *ortho*- and *para*-positions of the radical-anions is associated with the π energy of the unshared electron:

$$\rho^{\pi}_{\text{ortho}}/\rho^{\pi}_{\text{para}} = 1/4\,(x_0^2-2)^2$$

where x_0 is the root of the secular equation. In the case of a weak interaction between the substituent and the ring $x_0 \to 1$ and the ratio $\rho^{\pi}_{\text{ortho}}/\rho^{\pi}_{\text{para}}$ approaches 1/4, i.e. the orbital of the unshared electron comes close to the symmetrical benzene orbital. For powerful electron-accepting groups, x_0 tends to zero and the ratio $\rho^{\pi}_{\text{ortho}}/\rho^{\pi}_{\text{para}}$ tends to unity. For nitrobenzene and the benzonitrile radical-anions, this ratio is 0.83 and 0.43 respectively. Thus the ratio of the spin densities in the *ortho*- and *para*-positions is a quantitative characteristic of the electronegativity of the substituent. However, this method does not seem to be widely used.

Table 2. Nitrogen hyperfine coupling constants and Hammett's σ_p constants for the radical-anions of *p*-substituted nitrobenzenes.

Substituent	a_N, G	σ_p	Substituent	a_N, G	σ_p
NH_2	12.18	−0.172	Br	9.70	0.238
OCH_3	11.57	−0.111	$CONH_2$	8.37	—
CH_3	10.79	−0.129	$COOCH_3$	7.73	0.385
F	10.76	−0.056	CN	7.15	0.674
H	10.32	0.00	$COCH_3$	7.02	0.502
C_6H_5	9.84	—	SO_3CH_3	6.90	—
Cl	9.83	0.238	CHO	5.83	0.50
			NO_2	1.74	0.778

Attempts have been made to take into account the effect of substituents on the hyperfine coupling constants using the Hammett equation. Table 2 lists the hyperfine coupling constants for nitrogen nuclei (a_N) in the radical-anions of *para*-substituted nitrobenzenes[81] and Hammett's σ_p constants (after Van Bekkum[82]).

The analysis of such data carried out by Bowers[20] yielded the following values of ρ in the Hammett equation $\lg\,(a^X_N/a^H_N) = \rho\sigma_n$ for different solvents: −0.833 in dimethylformamide, 0.888 in dimethyl sulphoxide, and −0.750 in acetonitrile. The correlation between a_N and σ_n is not adequate, but is nevertheless a definite correspondence between these quantities.

Brokskii and coworkers[83,84] found that the relation between a_N and σ_n for the radical-anions of *para*-substituted nitrobiphenyls is described satisfactorily by the equation

$$a^H_N - a^X_N = \Delta a^X_N = 3.60\,\sigma - 0.3$$

where a correlation coefficient $r = 0.958$. Having expressed a_N for the radical-anions of nitrobiphenyls as a function of a'_N for the radical-anions of *p*-nitrobenzene using the results of Maki and Geske[81], these investigators estimated the weakening of the effect of the substituent on a_N when a second benzene ring is introduced:

$$a_N = 5.61 + 0.424\,a'_N,$$

whence it follows that the ratio of the slopes (ρ) of the plots based on the Hammett equations for these two series of compounds is about 0.4. This corresponds to a weakening by a factor of 2.5 of the effect of the substituent in the radical-anions when a second benzene ring is introduced.

Certain examples of the effect of the hindered rotation of functional groups on the ESR spectra of radical-anions were considered in the first section of the review. The asymmetry of the spectra of the carbonyl compounds of azobenzene and stilbene is evidence that there is no free interconversion of the *cis*- and *trans*-forms. These examples relate to "static" cases where the barrier between two conformations is fairly high and the transitions take place at a low frequency and do not affect the ESR spectra. However, there exist examples where in the analysis of ESR spectra it is necessary to take into account the nature of the motion of different groups in the radical-anions. This has been clearly shown by Stone and Maki[85] in the analysis of the hyperfine coupling constants for the radical-anions of nitroalkanes $RR'CHNO_2$.[17,18,85]

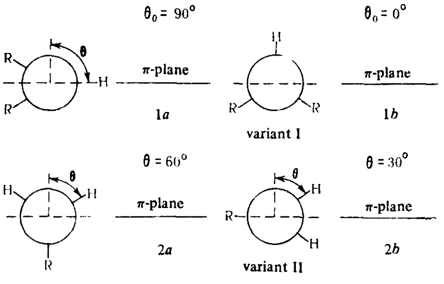
Table 3. Hyperfine coupling constants for the radical-anions of certain nitroalkanes.

R	R′	a_N, G	a_H^β, G	Variant
CH_3	H	25.5	9.75	II
C_2H_5	H	24.8	9.98	II
n-C_3H_7	H	24.2	9.76	II
n-C_5H_{11}	H	25.1	10.1	II
CH_3	CH_3	25.2	4.6	I
C_2H_5	CH_3	24.7	3.19	I
C_2H_5	CH_2OH	24.7	3.26	I

Table 3 shows that the hyperfine coupling constants for the nitrogen nucleus (a_N) are almost independent of the substituents R and R′. In those cases where R′ = H, $a_H^\beta = 9.9 \pm 0.14$ gauss and is independent of R. In radical-anions with one β-proton, a_H^β is much smaller than in the case of two β-protons. The sharp change in the hyperfine coupling constants for the β-proton on transition from RCH_2NO_2 to $RR'CHNO_2$, where R and R′ are alkyl substituents, is attributed to the effect of the hindered rotation of the RR′CH group about the C–N bond. The dependence of the hyperfine coupling constant for β-hydrogen atoms in RR′CH–X on the angle θ is described by the expression $a_H^\beta = Q(\theta)\rho_X^\pi$,[86] where $Q(\theta) = B_0 + B_2\cos^2\theta$, ρ_X^π is the spin density in the $2p_z$-orbital, and θ is the angle between the $2p_z$-orbital and the CH bond projected on a plane perpendicular to the C–X bond. Horsfield et al.[87] determined the constants B_0 and B_2 for the radical $CH_3CHCOOH$ and found them to be 3.2 and 43.5 gauss respectively. Since $B_0 \ll B_2$, it follows that $Q(\theta) \simeq B\cos^2\theta$. In the liquid phase the alkyl groups are not rigidly fixed and Q varies with their rotation. In this case the equation describing the dependence of the hyperfine coupling constants for β-protons on the angle θ must be modified: $a_H^\beta = \langle Q(\theta)\rangle \rho_X^\pi$, where $\langle Q(\theta)\rangle$ is the average value of Q. In the general case $\langle Q(\theta)\rangle$ is the quantum-mechanical average of $\cos^2\theta$ with respect to the rotational wave functions $\Psi(\theta)$. In the limit corresponding to free rotation, $\langle Q(\theta)\rangle = \frac{1}{2}B$ and $a_H^\beta = \frac{1}{2}B\rho_C^\pi$.

It is possible to distinguish several equilibrium conformations (Scheme 2):

Scheme 2



Qualitative examination of these conformations showed that $a_H^\beta(1b) > a_H^\beta(1a)$ and $a_H^\beta(2b) > a_H^\beta(2a)$.

The differences in the hyperfine coupling constants are probably associated with the existence of different equilibrium conformations and with different effects of hindered rotation on $\langle Q(\theta)\rangle$. Averaging in the classical quantum-mechanical approximation leads to qualitatively identical results. An increase in the amplitude of vibrations in the classical case causes a decrease of $\langle Q(\theta)\rangle$ for equilibrium positions in the vicinity of 0° and 30°C and an increase for angles of 60° and 90°. A similar effect causes the barrier height to be reduced in a quantum-mechanical treatment.

Table 4. Splitting constants for the radical-anions of certain organic fluoronitro-compounds.

R	R′	a_N, G	a_F^β, G	Variant
H	F	20.05	28.8	II
CF_3	F	19.25	24.85	II
CF_2OCH_3	F	19.7	49.0	II
		15.9	93.3	I
CF_3	Cl	21.6	42.1	I

Analysis of the data in Table 3 shows that for variant I $a_H^\beta \neq 0$ and $\theta \neq 90°$, which leads to conformation 1*b*. It follows from the conformations quoted that $a_H^\beta(1b) > a_H^\beta(2a)$, but this is inconsistent with experiment, i.e. it is necessary to suppose that β-protons are not fixed but possess a certain freedom of rotation.

Hindered rotation probably has a significant effect on the hyperfine coupling constants in the ESR spectra of the radical-anions of organic fluoronitro-compounds[88] $RR'CFNO_2$. It may be supposed that the following expression is valid for such anions:

$$a_F^\beta \simeq (B_0 + B\cos^2\theta)\rho_N^\pi + Q_F\rho_F^\pi.$$

For the majority of the radical-anions quoted in Table 4, a_N is constant within the limits of 2 gauss; it is therefore probable that the term $Q_F\rho_F^\pi$ makes a constant contribution to the splitting by β-fluorine atoms in CF_2.

An interesting example of the conformational differences in the structural of the radical-anions of 2,3,5,6-tetraisopropylnitrobenzene was observed by McKinney and Geske[89].

Hyperfine lines corresponding to two different "rotational isomers" A and B appear in the ESR spectrum of this radical-anion. Fig. 4 shows the ESR spectrum which arises when tetraisopropylnitrobenzene is reduced in acetonitrile. The species A and B are characterised by a nitrogen nucleus hyperfine coupling constant of 23.6 and 22.0 gauss respectively. Since the g-factors of A and B are identical, the central components of their spectra merge. The equilibrium constant $K = B/A = 2.3$ and $\Delta G_{298°} = -500 \pm 100$ cal mole^{-1}.

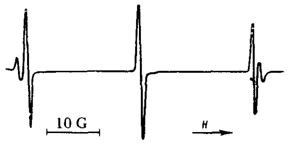


Figure 4. ESR spectrum of the tetraisopropylnitrobenzene radical-anion in acetonitrile.

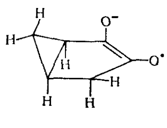
The hindered motion of portions of cyclohexane-1,2-semidione was observed by Lown[90]. At 25°C the ESR spectrum of this radical-anion contains five lines due to the interaction of the unshared electron with four equivalent α-protons ($a_H = 10.34$ gauss is dimethoxyethane). However, on cooling to −96°C, a spectrum consisting of seven lines and corresponding to the two pairs of equivalent protons with $a_H = 14.2$ gauss and $a_H = 6.9$ gauss appears. Hence it follows that a reduction of temperature entails a retardation of inversion and the equatorial and axial protons become distinguishable. At 25°C the inversion frequency is $(14.2 - 6.9) \times 2.8 \times 10.6 = 2 \times 10^7$ Hz, i.e. the lifetime of the radical-anion in one conformation is less than 5×10^{-8} s. Russell and Strom[91] showed that in the ESR spectra of the radical-anions in the series ranging from cycloheptane-1,2-semidione to cyclopentadecane-1,2-semidione at 25°C the signals due to both conformations are present. This is evidence that at this temperature the lifetime of one conformation is $> 10^{-7}$ s.

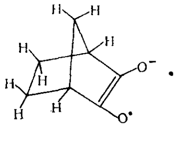
Talaty and Russell[92] found that the introduction of substituents into cyclohexane-1,2-semidione alters significantly the hyperfine coupling constant for equatorial and axial protons. However, the sum of these constants is virtually invariant (Table 5). These data lead to the conclusion that the observed hyperfine coupling constants (a_{eq} and a_{ax}) are correlated with the true constants ($a^0_{ax} = 13.18$ gauss and $a^0_{eq} = 6.59$ gauss) by the simple equation

$$a_{ax} = 13.18f + 6.69(1 - f),$$
$$a_{eq} = 6.59f + 13.18(1 - f),$$

where f is the fraction of molecules in one of the stable conformations. Calculation with the aid of these equations showed that, with increase in the size of the substituents, an increasing proportion of the molecules are in a stable state and the fraction undergoing ring inversion falls.

Semidiones obtained from bicyclic diketones are of particular interest:





The hyperfine structure of the ESR spectra of these radical-anions contains components due to all the protons present. The assignments of the hyperfine coupling constants are based on a study of the corresponding alkyl-substituted semidiones[20,93,94]. The problems of the mechanism of the transfer of spin density to more remote protons has not been elucidated in detail, but it is suggested that homohyperconjugation takes place in this case.

Table 5. Hyperfine coupling constants (gauss) for 4-substituted cycloalkane-1,2-semidiones at 25°C in dimethyl sulphoxide.

4-Substituent	a_{ax}	a_{eq}	$a_{ax} + a_{eq}$
H	9.83	9.83	19.66
CH_3	12.33	7.34	19.67
$(CH_3)_2CH$	12.63	7.02	19.65
t-Butyl	13.02	6.64	19.66
trans-4,5-$(CH_2)_4$	13.18	6.59	19.77

Analogous effects of the steric positions of atoms on ESR spectra were observed by Russell[20] for semidiones obtained from derivatives of decalin, steroid ketones, bicyclic hydrocarbons, etc.

The hyperfine coupling constants of the radical-anions measured in the ESR spectra refer, strictly speaking, to a definite solvent and depend on its nature. Ludwig et al.[95] observed a change in the hyperfine coupling constant for the nitrogen nucleus in the radical-anion of nitrobenzene from 10.32 gauss in acetonitrile to 9.7 gauss in dimethylformamide. The radical-anions of substituted nitrobenzenes behave similarly[96]. We may note that the changes of the hyperfine coupling constants for protons in the aromatic nucleus are small. However, in the radical-anions of semiquinones the proton hyperfine coupling constants change by 1–45% on transition from dimethyl sulphoxide to aqueous alcoholic solutions[97].

One of the causes responsible for the change in the hyperfine coupling constants is probably a redistribution of spin density in the radical-anions due to the specific solvation of functional groups and the formation of hydrogen bonds. Gendell et al.[98], who suggested the existence of an equilibrium between various types of radical-anion complexes with solvents, succeeded in describing satisfactorily the relation between the hyperfine coupling constants and solution composition. In pure solvents S_A and S_B the complexes R_XS_A and R_XS_B of the radical R_X with one molecule of S_A and S_B exist. In a mixture of solvents there is the equilibrium.

$$R_XS_A + S_B \underset{k_B}{\overset{k_A}{\rightleftarrows}} R_XS_B + S_A$$

It may prove that the hyperfine coupling constant a_A for the nucleus under consideration in the complex R_XS_A differs from the value of a_B for the complex R_XS_B. The observed ESR spectra will depend on the rate of the exchange reaction. For slow exchange, the lifetime of the radical complexes $\tau \gg |\gamma(a_A - a_B)|^{-1}$ (γ is the gyromagnetic ratio for two electrons) and the spectrum will show components referring to both complex R_XS_A and R_XS_B. A case of this kind was observed by Corvaja and Giacometti[99] for the radical-anion of m-nitrophenol in water–dimethyl formamide mixtures. In the case of a rapid exchange, only a single spectrum will be observed with a hyperfine coupling constant having the mean value

$$\tilde{a} = p_A a_A + p_B a_B,$$

where p_A and p_B are the fractions of the complexes R_XS_A and R_XS_B:

$$p_A = \frac{\tau_A}{\tau_A + \tau_B} = \frac{1}{1 + K\alpha}; \qquad p_B = \frac{\tau_B}{\tau_A + \tau_B} = \frac{K\alpha}{1 + K\alpha}.$$

The lifetimes τ_A and τ_B of the complexes R_XS_A and R_XS_B depend on the rate constants and the concentrations:

$$\tau_A = \frac{1}{k_A[S_B]}; \qquad \tau_B = \frac{1}{k_B[S_A]}; \qquad \alpha = \frac{[S_B]}{[S_A]}.$$

The equilibrium constant is

$$K = \frac{k_A}{k_B} = \frac{[R_XS_B][S_A]}{[R_XS_A][S_B]}.$$

The observed mean hyperfine coupling constant $\tilde{a}$ for rapid exchange may be expressed by the somewhat rearranged formula

$$\tilde{a} = {}^1/_2(a_A + a_B) + {}^1/_2[(K\alpha - 1)/(K\alpha + 1)]\Delta,$$

where $\Delta = a_B - a_A$. A plot, based on this equation, of α against $2\delta\tilde{a}/\Delta$, where $2\delta\tilde{a} = 2[\tilde{a} - \frac{1}{2}(a_A + a_B)]$, yields for $K = 10$ the curve in Fig. 5. The value of K was chosen arbitrarily to illustrate the form of the expression[98]. It corresponds to the case where the complex with the solvent S_B is much more stable than the complex with S_A.

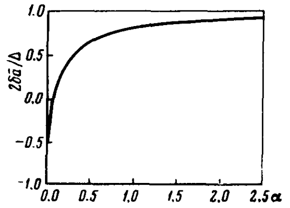


Figure 5. Variation of the hyperfine coupling constant with solvent composition (see text).

The value of $\tilde{a}$ varies rapidly from a_A in the pure solvent to S_A ($\alpha = 0$), since on addition of small amounts of a strongly complexing solvent we have for low values of K a linear relation between $\tilde{a}$ and the hyperfine coupling constants in the pure solvents:

$$\tilde{a} = a_A K\alpha(a_B - a_A).$$

When large amounts of S_B are added, $\tilde{a}$ tends asymptotically to a_B. This type of situation is observed in the variation of the hyperfine coupling constants for the nitrogen nucleus of the nitro-group in the radical-anions of nitrobenzene and *p*-nitroaniline in aqueous acetonitrile mixtures[98]. The addition of small amounts of water leads to an appreciable increase of the hyperfine coupling constant for the nitrogen nucleus. With increase in percentage content of water, this quantity changes little and at a fairly high concentration remains invariant, which is evidence of complete "solvation" of the radical-anion by water molecules.

IV. ION PAIRS

The formation of ion pairs has been investigated hitherto by electrochemical and ultraviolet spectroscopic methods and only recently radioscopic methods began to be used in this field: Symons[100] analysed different ESR spectroscopic data which provide direct or indirect information about the formation of ion pairs in solution: (1) analysis of the dependence of the hyperfine coupling constants on the diamagnetic gegenion; (2) the variation of the properties of the radical-anion, in particular the variation in the symmetry of the spin density distribution; (3) the variation of the ESR line shape; (4) analysis of the ESR spectra of paramagnetic dimers in a triplet state.

We shall consider these data separately. The hyperfine interaction with alkali metal ions is frequently reflected in the ESR spectra of radical-anions in ethereal solutions. This effect was observed by Adam and Weissman[101]. In a study of the ESR spectrum of the sodioketyl of benzophenone they noted the splitting of each component of the spectrum into four lines as a result of the interaction between the unshared electron and the magnetic moment of the ^{23}Na nucleus which has a spin of 3/2. Subsequently such interaction was observed in the ESR spectra of many radical-anions obtained by reduction with alkali metals. In all cases the spin density at the cation is low, but the detection of a small splitting nevertheless permits the conclusion that an ion pair is formed. The data on the hyperfine interaction constants for the nuclei of metal cations (a_M) in various solvents and the calculated spin densities at these nuclei (ρ_{ns}) are compiled in Table 6 taken from Symons' paper.

It was assumed that $\rho_{ns} = a_M/a_{atom}$, i.e. the ratio of the hyperfine coupling constants for the metal cation and the free metal in the gas phase. Analysis of the hyperfine coupling constants for the cations shows that the solvent plays a decisive role in the formation of ion pairs. This is associated with the particular solvating capacity of the ions. Unfortunately, this problem has not been investigated adequately on a quantitative basis, and at present one can only note, for example, that the hyperfine coupling constants for the Na^+ cations in the ion pairs with the radical-anions of naphthalene increase on going from dimethoxyethane to tetrahydrofuran and to ethyl ether.

The structure of the radical-anions also plays a significant role. The magnetic interaction depends on the overlapping of the *s* orbital of the cation with the orbital of the unshared electron of the anion. Symons noted that the preferred sites for the localisation of the cation are positions with maximum negative charges.

Atherton and Weissman[102] found an appreciable increase of the hyperfine coupling constant for sodium-23 in sodionaphthalene dissolved in various ethers when the temperature was raised. On lowering the temperature, this quantity tends to zero in tetrahydrofuran solution. The authors suggest that, when the temperature is reduced, the cation is located at the node of the wave function of the unshared electron between the 9- and 10-positions, so that the overlapping of the wave function of the unshared electron in the radical-anion with the *s* orbital of the cation is zero. On raising the temperature, the cation begins to vibrate about its equilibrium position, which leads to an increase of the overlapping and of the hyperfine coupling constants.

Another explanation of this effect is that a decrease of temperature entails an increase of the solvation of the cation and an increase of the distance between the cation and the paramagnetic ion[103]. This type of variation is regarded as a result of the equilibrium $A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} B$, where A is an ion pair with a hyperfine coupling constant for the sodium nucleus $a_{Na} = 1.5$ gauss and B an ion pair with $a_{Na} = 0$. For higher values of k_1 and k_{-1}, an averaged spectrum will be observed. If two different ion pairs have different hyperfine coupling constants a_A^{Na} and a_B^{Na} and the probabilities of the existence of forms A and B are p_A and p_B, the equilibrium constant K may be expressed in terms of these quantities:

$$K = \frac{p_B}{p_A} = \frac{\tau_B}{\tau_A} = \frac{k_1}{k_{-1}},$$

where τ_A and τ_B are the lifetimes of forms A and B. In the case of rapid exchange between the two forms, a_{Na} will depend on temperature in accordance with the formula

$$a_{Na} = p_A a_A^{Na} + p_B a_B^{Na} = \frac{a_A^{Na} + K a_B^{Na}}{1+K}.$$

The heats and entropies of reaction have been determined for a number of systems using this expression (Table 7).

Table 6. Cation hyperfine coupling constants (a_M) for ion pairs including paramagnetic anions (M^+A^-).

Anion	Cation	Solvent	a_M, G	ρ_{as}
Naphthalene	Li	THP	0.37	0.26
	Na	THP	1.26	0.40
	Rb	THP	0.09	0.026
	Cs	THP	1.81	0.14
	Na	THF	1.05	0.32
Biphenyl	Li	THP	0.136	0.095
	Na	THP	0.079	0.025
	K	THP	0.083	0.101
	Rb	THP	0.33	0.091

	Cs	THF (-100°)	−0.2	−0.024
	Cs	THF (-20°)	−0.7	+0.085
Duroquinone	Li	t-PeOH	0.22	0.15
	Na	t-PeOH	0.85	0.27
p-Benzoquinone	Na	t-BuOH	0.2	0.06
o-Benzoquinone	Li	t-BuOH	0.3	0.21
	Na	t-BuOH	0.2	0.06
Hexamethylacetone	$(Na)_2$	THF (-70°)	1.7	0.54
Benzophenone	Li	DME	0.67	0.47
	$(Li)_2$	DME	1.125	0.79
m-Dinitrobenzene	Na	THF	0.26	0.082
	K	THF	0.2	0.24
	Rb	THF	0.9	0.25
	Cs	THF	2.45	0.30

Note. THP = tetrahydropyran, EE = ethyl ether, TMED = tetramethylethylenediamine, MeTHF = 2-methyltetrahydrofuran, DME = dimethoxyethane, THF = tetrahydrofuran, t-PeOH = t-pentyl alcohol, and t-BuOH = t-butyl alcohol. The temperature of the measurement is indicated in brackets in the second column; in all other cases the experiments were performed at room temperature.

The constants k_1 and k_{-1} and the activation energies for the formation of ion pairs have been determined from the temperature variation of the ESR line widths (Table 8).

Table 7.

	Sodioanthracene in MeTHF	Sodioanthracene in 1:1 THF-MeTHF	Sodionaphthalene in THF	Sodionaphthalene in 1:1 THF-EE
a_A^{Na}, G	1.55	1.55	1.15	1.00
a_B^{Na}, G	0	1.15	0	0
$\Delta H°$, kcal mole^{-1}	−4.6±0.3	−6.2±0.5	−4.8±0.5	−6.4±0.8
$\Delta S°$, e.u.	−23±3	−25±3	−20±4	−33±4

The condition for rapid exchange between ion pairs does not always hold. Thus the ESR spectrum of sodionaphthalene in ethyl ether at low temperatures (below −80°C) corresponds to two different ion pairs with different hyperfine coupling constants for the sodium nucleus: $a_{Na} = 0.8$ gauss and $a_{Na} = 0.06$ gauss. Hirota[103] attributes the higher hyperfine coupling constants to contact ion pairs and the lower values to ion pairs separated by solvent molecules.

Table 8.

	Sodioanthracene in MeTHF	Sodionaphthalene in 1:3 THF-EE
k_1, s^{-1}	$5 \cdot 10^7$ (−60°)	$1 \cdot 10^8$ (−80°)
k_{-1}, s^{-1}	$4 \cdot 10^8$ (−80°)	$7 \cdot 10^8$ (−80°)
ΔE_1, kcal mole^{-1}	3·0	6·0
ΔH_{-1}, kcal mole^{-1}	7.4	11.5

The formation of ion pairs is also reflected in a variation of the hyperfine coupling constants for the radical-anion nuclei as a function of the nature of the cation and the solvent or in relation to the free ion. The free anion is understood to be the paramagnetic species obtained by electrochemical reduction using tetra-alkylammonium salts as a supporting electrolyte. In this case one can neglect the formation of ion pairs with a considerable degree of justification. In some cases, for example, for protons in the 9- and 10-positions of the anthracene anion (the Na^+ and K^+ cations, tetrahydrofuran and tetramethylethylenediamine as solvents) the variation of the hyperfine coupling constant amounts to only a few per cent[100]. In other cases these changes may be much greater. The ESR spectrum of the lithium salt of durosemiquinone in t-pentyl alcohol is characterised by two different hyperfine coupling constants for methyl protons. Thus one may suppose that the lithium cation resides for a relatively long time at one oxygen atom[104]. A similar situation arises in the radical-anion of *m*-dinitrobenzene on formation of an ion pair with the alkali metal cation. As a result of the perturbation introduced by the cation, the hyperfine coupling constant for one nitrogen nucleus is about 10 gauss, while for the other it is about 0.2 gauss.[100]

Interesting information about the kinetic characteristics of ionic association complexes may be obtained by studying the specific broadening of their hyperfine structure lines. We shall examine separately the broadening associated with the change in the hyperfine coupling constants for the alkali metal and radical-anion nuclei. The changes in the hyperfine coupling constants for the metal nuclei may be caused by the reaction[100]

$$(M^+A^-) \rightleftarrows M^+ + A^-,$$
$$(M^+A^-) + M^+ \rightleftarrows M^+ + (A^-M^+),$$
$$(M^+A^-)_1 \rightleftarrows (M^+A^-)_2.$$

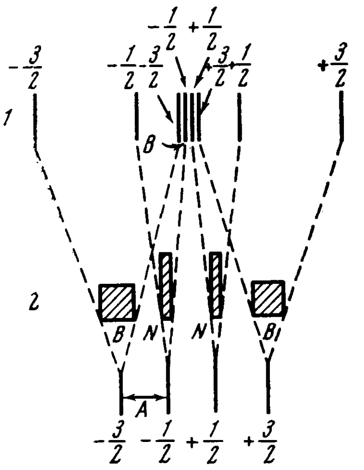

Figure 6. Splitting due to the metal cation ($I = 3/2$) in the ESR spectra of two ion pairs with hyperfine coupling constants A_1 and A_2: 1) slow exchange; 2) intermediate case; 3) rapid exchange.

These reactions affect the lifetime of the paramagnetic species in a definite spin state, which in turn leads to line broadening. The first two reactions cause uniform broadening of all the lines. Hirota and Weissman[105] found that the addition of sodium iodide to the sodioketyl of xanthone leads to an appreciable line broadening. The third reaction represents the conversion of ion pair 1 with a hyperfine coupling constant A_1 into ion pair 2 with a constant A_2. Here the significant factor is that the transition from one type of ion pair to another takes place with participation of one cation. The splitting due to the metal does not disappear in this process. Fig. 6 illustrates the broadening of the lines caused by the third reaction for ion pairs which are in equilibrium and which have metal hyperfine coupling constants a_1 and a_2.[100] In the case of a slow exchange two sets of lines will be observed, as can be seen in Fig. 6 (lines *1*). With increase in the rate of exchange, each pair of lines will become wider until they overlap, and as a result we obtain a single broad line corresponding to each spin state. Since the ±3/2 lines (Fig. 6) are separated in the field considerably more than the ±1/2 lines, the widening of the ±3/2 lines will be much greater compared with the ±1/2 lines (lines *2*). In rapid exchange only a quartet of narrow lines will be observed (lines *3*). Fig. 7 (Hirota[103]) illustrates clearly this type of broadening of the components of the sodium hyperfine structure in sodionaphthalene in a mixed tetrahydrofuran–ethyl ether solvent at different temperatures. It is clearly seen that the two extreme components due to sodium undergo marked broadening at −100°C.

The dynamic nature of solvation is indicated by the specific broadening in the hyperfine structure of the radical-anion itself. It is expressed in an alternation of the hyperfine structure line widths. One of the reasons for the alternation may be the migration of the cation between two equivalent functional groups in the anion. The steady-state pattern associated with this process is determined by the non-equivalence of the hyperfine coupling constants for the nuclei in these functional groups. For example, in the ion pairs of the radical-anions of *m*-dinitrobenzene with alkali metal cations the hyperfine coupling constant for one nitrogen nucleus is 10 gauss and that for the other is 0.2 gauss.[100] Here the situation is complicated by the fact that the same effects can be produced either by the fluctuation of the solvation shell or by conformational transitions in the molecule[106].

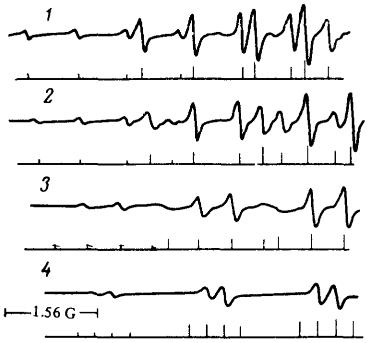

Figure 7. Temperature variation of the line width in the ESR spectrum of the naphthalene radical-anion in the presence of potassium in the mixed solvent tetrahydrofuran (25%)–ethyl ether (75%); the expected relative line intensities in the absence of broadening effects associated with exchange processes are indicated under the spectra: temperature (°C): 1) −60; 2) −75; 3) −85; 4) −95.

Another ionic association process is the formation of paramagnetic dimers observed by Weissman and coworkers[107,108]. A clear example of such structures is the formation of the complexes of the radical-anions of 2,2′-bipyridyl and related ligands with divalent cations (Be^{2+}, Ba^{2+}, and Zn^{2+}). The ESR spectra of these systems in the solid phase at −196°C are characterised by the presence of triplet states corresponding to the structure of the chelate complexes of two radical-anions with a divalent metal cation. The determination of the zero splitting constants from the ESR spectra of the paramagnetic dimers permitted the estimation of the average distance between the anions in the dimers. In the complexes of the radical-anion dimers of 4,7-biphenyl-1,10-phenanthroline, 2,2′-biquinoline, and 2,2′-bipyridyl with the cations Be^{2+}, Mg^{2+}, Zn^{2+}, Ca^{2+}, Ba^{2+}, and Sr^{2+} this distance is approximately 7 Å.[108] The distance between the radical-anions of hexamethylacetone in the complex with sodium cations is 5.6 Å.[107] Comparison of these distances with the radii of the cations suggests that the dimers have either the structure $A^-M^{2+}A^-$ or $A^-M_2^+A^-$.

V. ELECTRON EXCHANGE REACTIONS

Ward and Weissman[109] observed a pronounced broadening of the hyperfine structure components in the ESR spectrum of the naphthalene radical-anion on addition of free naphthalene to the solution of the radical-anion.

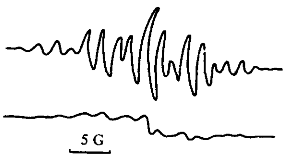

Figure 8. ESR spectrum of the naphthalene radical-anion in the presence of potassium in dimethoxyethane; concentration of radical-anion 1.4 × 10^{-3} M; upper spectrum recorded in the absence of neutral naphthalene; lower spectrum recorded after the addition of naphthalene to a concentration of 0.218 M.

Fig. 8 presents the original ESR spectra of the naphthalene radical-anions obtained by these investigators before and after the addition of free naphthalene. They attributed this phenomenon to the exchange of an electron between the radical-anion and the naphthalene molecule:

$$C_{10}H_8^{\overset{\cdot}{-}} + C_{10}H_8 \rightleftarrows C_{10}H_8 + C_{10}H_8^{\overset{\cdot}{-}}.$$

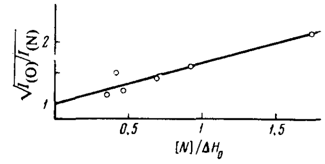

Figure 9. Variation of $I(O)/I(N)$ with $[N]/\Delta H_0$ for naphthalene in the presence of sodium in tetrahydrofuran.

The position of the hyperfine line in the spectrum is determined by the spin quantum numbers of the protons m_α and m_β in the α- and β-positions in the molecule. The transition of an electron from the radical-anion to the neutral molecule alters m_α and m_β to m'_α and m'_β. This process is accompanied by a shift of the resonance line in accordance with the new values m'_α and m'_β. According to Anderson's theory[110], the contribution of such an exchange process to line width is given by the expression $1/\tau = 2\pi\delta\nu$, where $\delta\nu$ is the contribution to line width by the exchange and τ the period between the exchange steps. It is suggested that the line has the Lorentzian shape and the frequency of the exchange is small compared with the difference $\nu_i - \nu_j$ between the frequencies of adjacent hyperfine lines. On the other hand, when $1/\tau > \nu_i - \nu_j$, the exchange results in narrowing of the line.

In practice it proved more convenient to measure not the line width but the intensity, since the two are related:

$$\frac{I_{(N)}}{I_{(O)}} = \left(\frac{\Delta H_0}{\Delta H_0 + \Delta H_N}\right)^2; \quad \sqrt{\frac{I_{(O)}}{I_{(N)}}} = 1 + \frac{\Delta H_N}{\Delta H_0},$$

where $I_{(O)}$ and ΔH_0 are the intensity and line width before the addition of neutral molecules, $I_{(N)}$ is the intensity after the addition, and ΔH_N is the contribution to line width by electron exchange. Simple rearrangement leads to an expression relating k_{exch} (the rate constant for the bimolecular exchange reaction) to line intensity and naphthalene concentration $[N]$:

$$\sqrt{\frac{I_{(O)}}{I_{(N)}}} = 1 + \frac{k_{exch}[N]}{\sqrt{3}\pi\, 2.83 \cdot 10^6 \Delta H_0},$$

where ΔH_0 is the width of the ESR line between the points of maximum slope. Fig. 9 shows the variation of $\sqrt{I_{(O)}/I_{(N)}}$ with $N/\Delta H_0$ for sodionaphthalene in tetrahydrofuran. Table 9 lists the exchange rate constants (k_{exch}) in various solvents with different counterions. The data in this Table confirms that the nature of the solvent and the metal have a significant influence on the rate of exchange reactions[109].

Table 9. Rate constants for the exchange between metal-naphthalene and naphthalene.

Cation	Solvent	k_{exch}, litre mole^{-1} s^{-1}
K^+	DME	$(7.6 \pm 3)10^7$
K^+	THF	$(5.7 \pm 1)10^7$
Na^+	DME	$\sim 10^9$
Na^+	THF	$\sim 10^7$
Li^+	THF	$(4.6 \pm 3)10^8$

Further studies by Zandstra and Weissman[111] showed that the rate of the exchange reaction is very different for free ions and ion pairs. Their studies of the reactions

$$C_{10}H_8^{\overset{\cdot}{-}} + C_{10}H_8 \rightleftarrows C_{10}H_8 + C_{10}H_8^{\overset{\cdot}{-}}, \qquad (A)$$

$$C_{10}H_8^{\overline{\cdot}}Na^+ + C_{10}H_8 \rightleftarrows C_{10}H_8 + Na^+C_{10}H_8^{\overline{\cdot}}, \qquad (B)$$

in tetrahydrofuran, tetrahydropyran, and 2-methyltetrahydrofuran show that reaction (A) is much faster than reaction (B). Table 10 lists the rate constants and activation energies for these reactions. Remarkable changes in the rate of reaction (B) in tetrahydrofuran are observed when the temperature is reduced. On lowering the temperature below 300°K, the rate of reaction begins to increase and then at 280°K it becomes higher than reaction (A) at the same temperature. To account for this effect, the association of ion pairs with naphthalene is postulated. According to Szwarc[19], the activation energies in Table 10 are too high, the explanation of the anomalous behaviour of the rate constant for the exchange reaction (B) in tetrahydrofuran at a low temperature is not satisfactory, and the effect requires further study.

A similar situation was observed by Hirota[103] in the study of the rates of exchange in sodioanthracene in dimethoxyethane, 2-methyltetrahydrofuran, and in 2-methyltetrahydrofuran–tetrahydrofuran mixtures. To determine the rates of reactions (A) and (B) in the same solvent with the same gegenion, there must be equilibrium between the free ions and ion pairs and the rate of exchange between these species must be sufficiently low to preclude the formation of an average pattern.

Table 10. Rate constants and activation energies for the exchange reaction between sodionaphthalene and naphthalene.

Solvent	Species	Activation energy, kcal $mole^{-1}$	Temp., °C	$10^{-6}k$, litre $mole^{-1}$ s^{-1}
Tetrahydropyran	ion pairs	17.7±0.9	21	4.4±0.1
	free pairs	18.5±2.2	—23	9.7±4.5
Methyltetrahydrofuran	ion pairs	12.8±3.2	—23	2.8±0.7
	free pairs	12.4±3.6	21	4.5±0.1
Tetrahydrofuran	ion pairs	4.6±0.5	50	34.0±0.8
		—6.8±0.5	—16	71.0±15
	free ions	13.2±1.5	13	38.0±14

Chang and Johnston[112] found that the difference in the rates may be observed with the aid of ESR also when it is impossible to distinguish between the ESR spectra of the ion pairs and free ions. Using the conditions for the so called "rapid exchange" when $1/\tau > \nu_i - \nu_j$ and the exchange leads to the narrowing of the lines, these investigators found a sharp difference in line narrowing in the spectra of free radical-anions and ion pairs. In Fig. 10 the narrow line corresponds to the free radical-anions and the broad line to the ion pairs. The exchange constants obtained from these spectra agree satisfactorily with the data of Zandstra and Weissman[111].

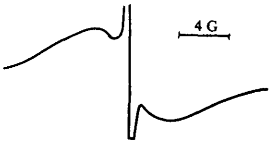

Figure 10. ESR spectrum of the naphthalene radical-anion in the presence of potassium in tetrahydrofuran after the addition of naphthalene to a concentration of 1.4 M.

The study of the rates of exchange in a wider class of compounds showed that molecular structure and the type of interaction between the radical-anion and the solvent have a marked influence on the rate of exchange in different aromatic systems[113]. Table 11 presents data illustrating the effect of the structure of the species undergoing exchange on the electron exchange rate constant.

Adams and coworkers made an interesting comparison of the splitting by nitrogen nuclei in the spectra of the radical-anions of aromatic nitro-compounds and the rates of electron exchange[113]. With increase of the hyperfine coupling constants, there is an appreciable decrease of k_{exch}. This comparison may be followed on the basis of the data in Table 12.

Table 11. k_{exch} in dimethylformamide measured for various aromatic systems.

A/$A^{\dot{-}}$ systems undergoing exchange	k_{exch}, litre $mole^{-1}$ s^{-1}
Anthracene	$4.8 \cdot 10^8$
p-Benzoquinone	$3.8 \cdot 10^8$
Duroquinone	$6.2 \cdot 10^7$
1,4-Naphthoquinone	$4.2 \cdot 10^8$
Nitrobenzene	$3.0 \cdot 10^7$
Benzonitrile	$2.9 \cdot 10^8$
m-Nitrobenzonitrile	$1.6 \cdot 10^8$
Benzophenone	10^8

The same effect on k_{exch} is observed when water is added to dimethylformamide. The increase of a_N on addition of water is accompanied by a decrease of k_{exch}. The data are presented in Table 13.

Table 12. k_{exch} in dimethylformamide for aromatic nitro-compounds.

A/$A^{\dot{-}}$ systems undergoing exchange	a_N, G	k_{exch}
Nitrobenzene	9.83	$3.0 \cdot 10^7$
p-Dinitrobenzene	1.47	$6.0 \cdot 10^8$
m-Dinitrobenzene	4.68	$5.2 \cdot 10^8$
p-Chloronitrobenzene	9.18	$7.9 \cdot 10^7$
m-Chlorodinitrobenzene	8.75	$8.8 \cdot 10^7$
3,5-Dichloronitrobenzene	7.63	$1.6 \cdot 10^8$

Interesting details of the mechanism of the electron transfer reactions were obtained by Adam and Weissman[101] in the study of the exchange between the sodium ketyl of benzophenone and benzophenone in dimethoxyethane. Two pathways may be postulated for the exchange reaction:

1. Transfer of an electron from the ion pair to the ketone molecule:

$$Na^+OC(C_6H_5)_2^{\dot{-}} + OC(C_6H_5)_2 \rightarrow Na^+ + OC(C_6H_5)_2 + OC(C_6H_5)_2^{\dot{-}},$$

$$Na^+ \text{(free ion in solution)} + OC(C_6H_5)_2^{\dot{-}} \rightarrow Na^+OC(C_6H_5)_2^{\dot{-}}.$$

2. Transfer of a sodium atom:

$$Na^+OC(C_6H_5)_2^{\dot{-}} + OC(C_6H_5)_2 \rightarrow OC(C_6H_5)_2 + Na^+OC(C_6H_5)_2^{\dot{-}}.$$

If the reaction takes place via the first pathway, then at high benzophenone concentrations a singlet line should be observed; if the reaction follows the second pathway, a quartet due to the sodium nucleus should be found. The observation of a quartet due to the sodium atom with a hyperfine coupling constant of 1.1 gauss (instead of 1.0 gauss in dilute solution of the benzophenone ketyl) is evidence of the transfer of a sodium atom and of increased spin density at the sodium nucleus as a result of the exchange.

Data on the rates of exchange between different species are of considerable interest:

$$A^{\overline{\cdot}} + B \rightarrow B^{\overline{\cdot}} + A \,.$$

The application of ESR yielded only qualitative data, since the rates of such processes are very high and direct kinetic study is extremely difficult[114]. Reactions of this kind were investigated by Arai et al.[115] using pulse radiolysis. The measured rate constants for electron transfer from the biphenyl radical-anion to naphthalene, phenanthrene, *p*-terphenyl, pyrene, and anthracene are very high and lie in the range $(0.26–6.4) \times 10^9$ litre mole^{-1} s^{-1}.

Table 13. Effect of solvation on k_{exch} for exchange between the nitrobenzene radical-anion and nitrobenzene.

Solvent	a_N, G	k_{exch}
DMF-1.6% H_2O	10.17	$9\ 9\cdot10^6$
DMF-4.8% H_2O	10.82	$2.7\cdot10^6$
DMF-8.0% H_2O	11.26	$2.7\cdot10^6$
DMF-10% H_2O	11.35	$3.2\cdot10^5$
DMF-32% ethyl acetate	9.8	$3.1\cdot10^7$

From the standpoint of the theory of electron transfer reactions, the comparison of the rate constants for the exchange between A and B (k_{AB}) with the rate constants for the exchange reactions

$$A^{\overline{\cdot}} + A \rightarrow A + A^{\overline{\cdot}}, \quad (k_A)$$

$$B^{\overline{\cdot}} + B \rightarrow B^{\overline{\cdot}} + B\,, \quad (k_B)$$

is of considerable interest. According to the theory of Marcus[116], there is a definite relation between these quantities:

$$k_{AB} = (k_A\, k_B\, K_{AB}\, f)^{1/2},$$

where K_{AB} is the equilibrium constant for the exchange reaction A and B and $f = 1$ when $K_{AB} = 1$. The applicability of this theory to the electron exchange reaction was tested by Bruning and Weissman[117] on optically pure 1-(naphthyl)-1-phenylethane and the corresponding radical-anion and also the racemic mixture. The first system yields identical rate constants for the exchange between the optical isomers and their radical-anions ($k_d = k_l$) and the second yields rate constants for the exchange between the radical-anion of one isomer and the neutral molecule of the other (k_{dl}): $A_d^{\overline{\cdot}} + A_l \rightarrow A_d + A_l^{\overline{\cdot}}$.

If the Marcus theory is correct, then $k_d = k_l = k_{dl}$. The rate constants were determined for the potassium salt: $k_d = 0.7 \times 10^8$ litre mole^{-1} s^{-1} and $k_{dl} = 1.1 \times 10^8$ litre mole^{-1} s^{-1} in dimethoxyethane and $k_d = 0.2 \times 10^8$ litre mole^{-1} s^{-1} and $k_{dl} = 0.2 \times 10^8$ litre mole^{-1} s^{-1} in tetrahydrofuran. These data show that the theory, developed largely for electron transfer reactions between variable-valence ions, is indeed applicable to electron transfer reactions between organic compounds.

It is striking that rapid exchange is observed between identical species. Electron exchange is strongly retarded when structural changes are produced by transfer of an electron to a neutral molecule. This is the situation in the radical-anion of cyclo-octatetraene (COT). The experiments of Katz and Strauss[38] showed that after the addition of small amounts of potassium to a solution of 0.7 M COT, a well resolved ESR spectrum of the COT radical-anion is observed. The low rate of exchange between the COT radical-anion and the neutral molecule,

$$\text{COT}^{\overline{\cdot}} + \text{COT} \rightleftarrows \text{COT} + \text{COT}^{\overline{\cdot}}, \tag{1}$$

is due to the fact that the radical-anion has a planar structure, in contrast to the non-planar neutral molecule. Further addition of potassium leads to the obliteration of the hyperfine structure by the reaction

$$\text{COT}^{\overline{\cdot}} + \text{COT}^{=} \rightleftarrows \text{COT}^{=} + \text{COT}^{\overline{\cdot}}. \tag{2}$$

The estimated rate constants for reactions (1) and (2) are about 10^4 litre mole^{-1} s^{-1} and about 10^9 litre mole^{-1} s^{-1} respectively. Since the radical-anion and the dianion of COT have the same planar structure, the rate constants for the exchange between them are much higher than for the exchange between the radical-anion and the neutral molecule[118].

ESR is not the only method for the measurement of rate constants for electron exchange. In many cases the NMR method has been used successfully. The application of NMR is based on the study of the effect of electron exchange on proton line width in NMR spectra. The contribution to the NMR line width (ΔT_2^{-1}) by electron exchange is described by the expression[119]

$$\Delta T_2^{-1} = \frac{f_P \tau_P a^2/4}{1 + f_D \tau_P^2 a^2/4 + 2\,\tau_P T_{1e}^{-1}},$$

where τ_P and τ_D are the lifetimes in the paramagnetic and diamagnetic states, $\tau_P = 1/k[D]$, $\tau_D = 1/k[P]$, k is the exchange rate constant, $[P]$ and $[D]$ are the concentrations of the molecules in the paramagnetic and diamagnetic states, a is the proton hyperfine coupling constant, f_P and f_D are the fractions of paramagnetic and of diamagnetic molecules, and T_{1e} is the spin–lattice electronic relaxation time. Two limiting cases of slow and rapid exchange are distinguished: slow exchange when $f_D \tau_P^2 a^2/4 \gg 1 + 2\tau_P T_{1e}^{-1}$ and rapid exchange when $f_D \tau_P^2 a^2/4 + 2\tau_P T_{1e}^{-1} \ll 1$. The formulae corresponding to these limiting cases are greatly simplified: for slow exchange $\Delta T_2^{-1} = \tau_D^{-1} = k[P]$ and for rapid exchange $\Delta T_2^{-1} = f_P \tau_P a^2/4 = [P]a^2/4[D]^2 k$. These two limiting cases should differ in the temperature variation of the line width. In the case of slow exchange an increase of temperature should entail a considerable widening of the lines, while in the case of rapid exchange the NMR line should become narrower.

Both these cases were observed by de Boer and McLean[119] in a study of the NMR spectra of *p*-xylene in the presence of the *p*-xylene radical-anions. The lines due to the ring protons became broader on raising the temperature and those due to the methyl protons became narrower. Since the hyperfine coupling constant for the methyl proton is more then ten times higher than for the benzene ring protons in the ESR spectrum of the *p*-xylene radical-anion, the condition of rapid exchange obtained for protons of the first type and the condition of slow exchange obtains for protons of the second type. Studies on the temperature variation of the line width led to the determination of the pre-exponential factor and the activation energy for electron exchange between the *p*-xylene radical-anion and the neutral molecule: $k = 10^{12.0} \exp(-6200/RT)$ litre mole^{-1} s^{-1}.

Williams[120] showed that the rate constants for electron exchange involving the *p*-benzosemiquinone and durosemiquinone radical-anions measured by the NMR method agree satisfactorily with the constants determined by the ESR method.

---o0o---

One may conclude that considerable progress has been achieved in the study of the electronic and chemical structure of radical-anions. However, at present this progress is to some extent isolated from the development of the chemistry of radical-anions[1,19,121,122]. This is because the reactivity of radical-anions has still been little investigated. Nevertheless a brief survey of the few available data on the reactions of radical-anions leads to the conclusion that factors such as the distribution of the unshared electron[123], association between the anion and cation[124], and the effect of the solvent on the electronic structure and reactions of radical-anions play an important role in their chemistry. Comparison of the kinetic data for electron exchange reactions and reactions involving electron transfer from a radical-anion to a molecule with a different structure are also of considerable interest. The elucidation of the effect of these factors on the kinetic behaviour of radical-anions is undoubtedly one of the essential stages in the study of the role of electron transfer in organic reactions and the extensive data now available on the chemical and electronic structure of radical-anions should in the future make a positive contribution to the solution of this urgent chemical problem.

Application of Mössbauer Spectroscopy in the Study of Surface Phenomena

V.I.Gol'danskii and I.P.Suzdalev

Recently there has been a considerable growth of interest in the elementary processes occurring on the surface of a solid or associated with the effect of the surface on the properties of atoms and molecules within the bulk of the solid. Mössbauer spectroscopy yields unique information about the electronic structure and the nature of the motion of atoms and therefore the use of this method is extremely effective in fundamental investigations of surface phenomena.

This review deals with the theoretical concepts of Mössbauer spectroscopy and the experimental data on its application in the physical chemistry of surface phenomena. A systematic account is given of new experimental results, which are compared with data obtained by other procedures.

The bibliography includes 70 references.

CONTENTS

I. INTRODUCTION

The development of the theory and technique of Mössbauer spectroscopy has revealed fields of research where its application is extremely effective. One such field, where the characteristics of the method give rise to a particularly large number of new possibilities, concerns surface phenomena[1,2]. During the several years of the application of the Mössbauer effect in the study of surface phenomena, many interesting and important results have been obtained in studies on the dynamics of the motion of atoms on the surface, their electronic state, the elementary steps in adsorption and catalysis, and also the physics of the highly dispersed state of matter.

Bearing in mind the differences between the types of surface effects, the surface phenomena investigated with the aid of Mössbauer spectroscopy may be conventionally divided into two classes. The first class is associated with the study of the state of atoms present directly on the surface of the solid. Here one investigates (1) the atomic vibrations on the surface, (2) surface diffusion, (3) the electronic states of atoms on the surface, (4) the magnetic properties of atoms on the surface, (5) the elementary steps in adsorption and the chemistry of surface compounds, and (6) catalysis.

The second class of phenomena is associated with the effects of the boundaries of the solid on the properties of its internal atoms. These include, for example, (1) the change in the phonon spectrum and the type of atomic vibrations in highly dispersed particles, (2) the variation of the magnetic properties of the particles (the phenomenon of superparamagnetism), and (3) topochemical reactions.

The study of all these processes involves a definite characteristic associated with the method, consisting in the fact that, in order to ensure a sufficiently large number of resonating nuclei on the surface of the solid (it is necessary to have at least 10^{17} nuclei per cm^2 when the probability of the Mössbauer effect $f' \simeq 0 - 0.3$), it is necessary to choose systems with high surface areas, amounting to hundreds of square metres per gramme. The surface density of atoms in a monomolecular layer is about 10^{15} nuclei per cm^2. However, it is possible to observe the effect for surface densities smaller by a factor of tens and hundreds (10^{13}–10^{14} nuclei per cm^2) if one uses as the test object a surface source of resonance γ-radiation, for example by depositing cobalt-57 nuclei on the test surfaces. Then the measurement of the spectra with the required statistical accuracy is determined solely by the duration of the experiment. Experiments where the test substance is employed as an absorber are simpler to perform and are more widely carried out. However, in many cases, for example in the study of the properties of atoms located on crystal boundaries, it is necessary to deposit radioactive nuclei on the surface investigated.

The necessity for the presence on the surface of a sufficiently large number of resonating nuclei in order that the Mössbauer effect may be observed naturally imposes limitations on the application of Mössbauer spectroscopy, particularly in the study of adsorption and catalysis at low surface coverages and also in the study of the surface of single crystals.

The characteristics of the results in the fields enumerated above are dealt with below.

II. PHENOMENA ON THE SURFACE OF SOLIDS

1. Atomic Vibrations on the Surface

The first theoretical calculations of Rich[3] and Maradudin[4] showed that the type of vibrations of atoms on the surface differs from that in the bulk of the solid. It was to be expected that the average of the square of the displacement of the atoms on the surface $\langle r^2 \rangle$ will be higher compared with the internal atoms and that the difference should increase with temperature. According to Rich[3], in a model comprising a cubic lattice extending to infinity at one end and in which account is taken only of the nearest neighbours, the probability of the Mössbauer effect at 90°K for the internal atoms is higher by 26% and at 284°K by 60% than for the surface atoms. Maradudin[4] drew attention to the fact that the vibrations of surface atoms are anisotropic. Thus, for the model with a cubic lattice of a central type taking into account the interactions with the nearest neighbours and the neighbours following immediately beyond them, the average of the square of displacement in a direction perpendicular to the surface exceeds by a factor of two the corresponding values for the internal atoms, while along the surface $< x^2 >$ is greater by 30% than $< x^2 >$ for internal atoms. Calculations showed that the effect of the surface extends only over five layers. Kothari[5] found by calculating the ratio of the Debye temperatures for the surface and internal layers of the cubic lattice ($\theta_{\text{eff}}/\theta_0 \simeq 0.7$) that $< r^2 >_s$ for surface atoms exceeds by a factor of two $< r^2 >_i$ for internal atoms and is almost independent of the model. Analogous results were obtained by Corciovei[6]. Clark et al.[7] calculated $< r^2 >$ as a function of the distance from the free surface of the single crystal for a face-centred cubic lattice of nickel at a high temperature. The calculations were made for (100), (110), and (111) surfaces using a model of the central type taking into account the interactions with nearest neighbours in a crystal having a thickness of 20 layers. It was esablished that $< r^2 >$ increases monotonically from the centre of the crystal to its edges.

Burton and Godwin[8] and also Suzdalev[9] noted that the nature of the anisotropy of the atomic vibrations depends significantly on whether the atoms form part of the surface layer itself, i.e. on whether they are located within the surface or whether they are distributed on top of the surface under investigation (Fig. 1).

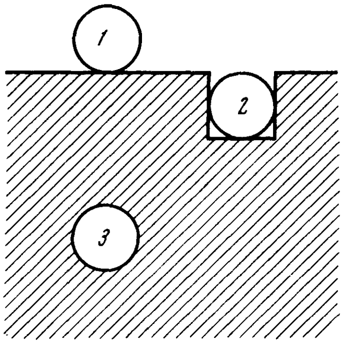

Figure 1. Atoms *on* the surface of the solid (*1*), *within* the surface (*2*), and within the solid (*3*).

Subsequently we shall use the following terminology: unless it is specified where the atoms are located, the term atoms *in* the surface will imply atoms within the surface when they are located in the interior of the surface layer and the term atoms *on* the surface will imply atoms distributed on top of the surface layer. The values of $< x^2 >$ and $< z^2 >$ on the surface have been estimated with the aid of a very simple model developed by Clark et al.[7] (Fig. 2) in which the force constants are proportional to the number of bonds between a given atom and the nearest neighbours and the next nearest neighbours (all the bonds are assumed to be of equal length and the bonds directed at right angles to the direction of the γ-radiation are disregarded). Fig. 2 presents three cases of bond location: *a* and *b*—atoms on the surface of the solid; *c* and *d*—atoms in the surface; *e*—atoms within the solid. The arrows indicate two different directions of γ-radiation. Under these conditions the force constants κ are as follows:

(*a*) $\kappa \propto 1 + 4 = 5$ bonds
(*b*) $\kappa \propto 0 + 2 = 0$ bonds
(*c*) $\kappa \propto 1 + 4 = 5$ bonds
(*d*) $\kappa \propto 2 + 6 = 8$ bonds
(*e*) $\kappa \propto 2 + 8 = 10$ bonds.

Apart from showing a general increase of $< r^2 >$ on the surface, the model permits the estimation of the anisotropic vibration of the surface atoms. For atoms *within* the surface (*c* and *d*), the amplitude of the atomic vibrations at right angles to the surface is higher than along the surface:

$$\frac{\langle z^2\rangle}{\langle x^2\rangle} = \frac{8}{5} = \frac{\varkappa_x}{\varkappa_z}.$$

On the other hand, for atoms over the surface of the solid (*a* and *b*), the amplitude of the atomic vibrations along the surface is higher than at right angles to the surface:

$$\frac{\langle z^2\rangle}{\langle x^2\rangle} = \frac{2}{5} = \frac{\varkappa_x}{\varkappa_z}.$$

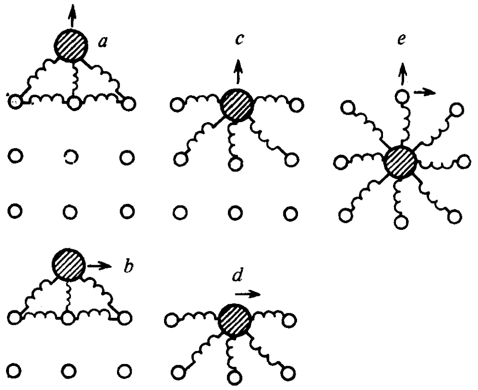

Figure 2. A model diagram illustrating the location of the atoms *on* the surface (*a*, *b*), *within* the surface (*c*, *d*), and within the solid (*e*) taking into account the interactions with nearest and next nearest neighbours.

Wallis[10] analysed the problem of the mean square velocities $< v^2 >$ of atoms on the surface of a solid and showed that on the surface these velocities are reduced, which leads to a decrease of the temperature shift of the Mössbauer spectral lines: $\delta E_D = E_\gamma < v^2 >/c^2$, where E_γ is the energy of the resonance transition.

A number of experiments have been performed to investigate the nature of the atomic vibrations on different surfaces. The type of vibrations of radioactive atoms in a planar surface of the usual kind was investigated by the surface emitter–bulk phase absorber method.

Allen[11] deposited 0.01 of a monolayer of cobalt-57 on the (100) and (111) silicon surfaces previously evacuated to 10^{-9} mmHg. The spectrum had two lines, which "merged" into one when the cobalt diffused into the silicon. For 300° and 800°K, the second-order Doppler effect resulted in a relative temperature shift $\delta E_D/E_D = 10^{-15}(-2.05 \pm 0.16)$ deg^{-1} for atoms on the surface and $\delta E_D/E_D = 10^{-15}(-2.17 \pm 0.16)$ deg^{-1} for internal atoms, which confirms the decrease of $< v^2 >$ on the surface. On the other hand, analysis of the temperature variation of the probability of the Mössbauer effect $f(T)$ for cobalt-57 atoms on the surface of silicon and within the bulk of the crystal yielded the Debye temperatures $\theta_T = 555°K$ on the surface and $\theta_T = 588°K$ within the bulk of silicon.

Results contrary to the calculations[5-9], i.e. a decrease of $< r^2 >$ on the surface relative to the bulk phase of the solid, were obtained by Bowles and Cranshaw[12], who deposited electrolytically radioactive tin on platinum. They observed an increase in the probability of the effect (a decrease of $< r^2 >$) for tin monolayers compared with individual, even very small particles. However, one should bear in mind that this type of effect might have been caused by the diffusion of tin into the bulk of platinum.

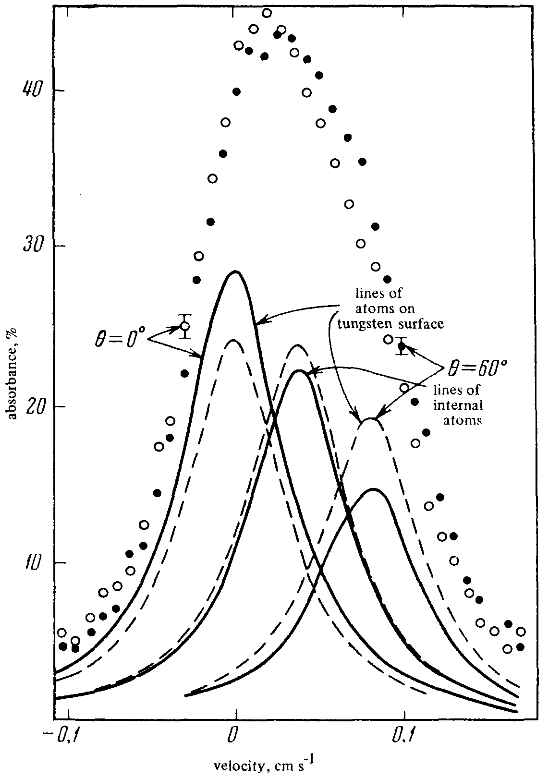

Figure 3. Spectrum of cobalt-57 on tungsten (300°K) with potassium hexacyanoferrate(II) as an absorber.

Burton and Godwin[8] investigated the cobalt-57 vibrations on single crystal and polycrystalline surfaces of tungsten and silver. Cobalt-57 was deposited on the metal by vacuum-evaporation (10^{-10} mmHg) in an amount corresponding to 0.1 of a monolayer (Fig. 3 shows the spectrum of cobalt-57 on tungsten). It is suggested that the spectrum consists of three lines—a doublet and a singlet—and that the asymmetric (due to the anisotropy of the thermal vibrations of cobalt-57 atoms) doublet is caused by cobalt-57 atoms on the surface of tungsten (as on silicon[11]), while the singlet corresponds to the cobalt which had diffused into the bulk of tungsten. Later it was found that $< r^2 >$ for atoms on the surface of tungsten increases relative to $< r^2 >$ for internal atoms and that the cobalt-57 vibrations on the surface are anisotropic:

$$\frac{\langle x^2\rangle_s}{\langle z^2\rangle_s} = 1.9 \pm 0.4 \quad \text{and} \quad \frac{\langle x^2\rangle_s}{\langle z^2\rangle_i} = 2.5 \pm 0.5.$$

Since $< x^2 > \; > \; < z^2 >$, here the cobalt atoms are located on the tungsten surface and not *within* the surface. For cobalt-57 atoms on the surface of silver, it was found[8] that $< r^2 >_s \; < \; < r^2 >_i$. The result is contrary to the usual increase of $< r^2 >$ on the surface. It is also contrary to the measurements of the Debye temperatures of the surface and internal silver atoms by diffraction of slow electrons[13] with the electron energy varied from 40 to 240 eV. Jones et al. obtained a value for $< z^2 >$ on the surface of silver twice as high as for internal atoms. Therefore the results of Burton and Godwin[8] are probably associated with the formation on the surface of silver of highly dispersed cobalt-57 and the effect of its intrinsic properties and not that of the surface of silver.

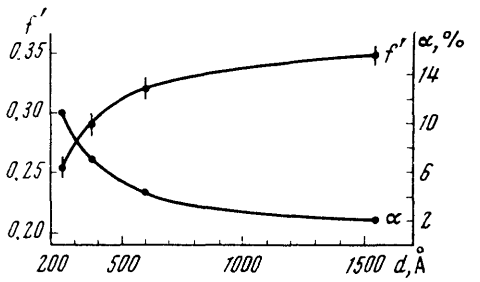

Figure 4. Variation with particle size of the probability of the Mössbauer effect f' and the specific surface α of particles of highly dispersed β-tin (77°K).

The use of large surface areas permits the study of atomic vibrations on the surface also with the aid of the bulk-phase emitter–surface absorber method. Thus the vibrations of atoms in tin dioxide on the surface of highly dispersed tin with a particle size of 300 Å were investigated[14] and a marked decrease of the probability of the Mössbauer effect compared with the probability for the usual tin dioxide was observed. The probability f' approached the normal value when the particles were fully oxidised. In another experiment[15] a study was made of the variation of f' and correspondingly of $< r^2 >$ for non-oxidised β-tin particles with $d = 250$ and 370 Å and $d = 650$ and 1550 Å. A decrease of f' with decrease of particle size was observed. Fig. 4 presents the function $f' = f'(d)$ and the variation of the specific surface $\alpha = f(d)$. The Debye temperature θ_D decreases from 140°K for $d = 1550$ and massive specimens to 120°K for $d = 250$ Å. For five surface layers, estimates yield $\theta_D = 100°K$. A decrease of f' was also observed for small tungsten particles by Roth and Hörl[16], although it was much smaller than might have been expected: $f' = 0.57$ for particles with a diameter of 30 Å and $f' = 0.61$ for particles with a diameter of 1 μm.

Van-Wieringen[17] noted that the vibrations of surface atoms are influenced by the matrix in which the dispersed particles are distributed. Thus, depending on the matrix,

f' ranging from 0.43 after incorporation in a matrix to 0.31 after preparation of a suspension in acetone and compression between two plates was obtained for Fe_2O_3 with a particle size of 30 Å.

In experiments with particles dispersed to an even greater extent, the nature of the vibrations of atoms on the surface is of course obscured by the vibrations of atoms within the particles.

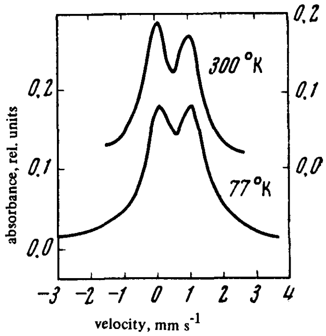

Figure 5. Spectrum of iron on the surface of η-Al_2O_3 at different temperatures.

A number of studies on the dynamics of the motion of surface atoms have been made under conditions where the Mössbauer atoms were sorbed on a large surface area. Such investigations were begun by Flinn et al.[18] with iron atoms on the surface of η-alumina and were followed by the present authors' experiments with tin on the surface of silica gel[19].

Spectra of iron, which is probably present in the form of Fe_2O_3 on the surface of alumina, are presented in Fig. 5. A striking feature is the asymmetry of the quadrupolar spectrum of Fe^{3+} on alumina, which is particularly pronounced at 300°K: $A = 0.94 = I_{3/2}/I_{1/2}$, where A is the ratio of the intensity of the doublet lines. This asymmetry, as well as the asymmetry observed in the study by Burton and Godwin[8] already noted above, is due to the anisotropy of the atomic vibrations on the surface. Assuming that the asymmetry of the components of the quadrupolar splitting is caused by the anisotropy of the probability of the Mössbauer effect (the Gol'danskii–Karyagin effect), Suzdalev et al.[18] found that $< z^2 > - < x^2 > = 10^{-18}$ cm². It was suggested that the electric field gradient is positive, i.e. the iron atoms are incorporated in the surface layer of the alumina lattice ($< z^2 > > < x^2 >$), in contrast to cobalt-57 on the surface of tungsten[8]. Generally speaking, in order to determine the sign of the electric field gradient, it is necessary to employ a single-crystal surface. Then, knowing the angle between the crystal field gradient (perpendicular to the surface) and the direction of the γ-beam, it is possible to determine unambiguously the sign of the crystal field gradient from the quadrupolar spectrum and hence the nature of the asymmetric vibrations.

The quadrupolar spectrum observed in studies[19,20] on tin (in the form of SnO) on the surface of a zeolite or silica gel with a pore diameter of 120 Å was also found to be asymmetric (Fig. 6). The asymmetry increased with temperature. Since in these experiments absolute values of f' were obtained, it proved possible to determine not only the difference $< z^{-2} > - < x^2 >$ but also each component separately: $< x^2 > = 0.46 \times 10^{-18}$ cm² and $< z^2 > = 1.76 \times 10^{-18}$ cm² at 210°K. Thus tin atoms are located within the surface layer of silica gel and the mean square of the displacement in a direction perpendicular to the surface of the globule exceeds by a factor of four the mean square of the displacement along the surface of the globule.

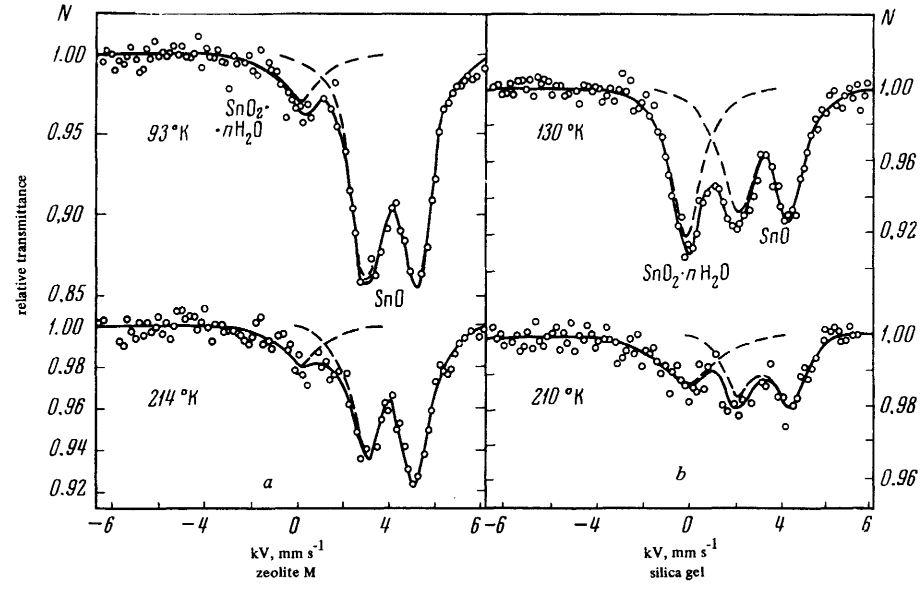

Figure 6. Spectrum of tin on the surface of a type M zeolite (mordenite) (*a*) and coarsely porous silica gel (*b*) at different temperatures. The left-hand line corresponds to $SnO_2.nH_2O$ and the two right-hand lines to SnO.

The temperature variation of the anisotropy of the atomic vibrations on the surface has been investigated theoretically and experimentally[20]. Silica gel and a zeolite with tin atoms on the surface were studied. When the Sn^{2+} ion on the surface was treated as a harmonic oscillator, a relation $A = f(T, \gamma)$ (γ is a parameter associated with the difference between the squares of the vibration frequencies of tin atoms in two directions at right angles) suitable for calculations was obtained:

$$A(T) = \frac{\int_0^1 (1+u^2)\exp(-\gamma T u^2)\,du}{\int_0^1 (^5/_3 - u^2)\exp(-\gamma T u^2)\,du}\,(u^2 = \cos^2\theta);\quad \gamma = \frac{\varkappa^2 k}{M}\left(\frac{1}{\omega_1^2} - \frac{1}{\omega_2^2}\right),$$

where κ is the wave number, M the mass of the particle, and θ the angle between the normal to the surface and the direction of the γ-ray beam. Fig. 7 presents the calculated values of $A = f(T)$ for different γ and shows satisfactory agreement between the experimental points and the calculated curve corresponding to $\gamma = 0.0045$ and $1/\omega_1^2$ and $1/\omega_2^2 = 4.5 \times 10^{-27}$ s^{-2}. This shows that the Sn^{2+} ion vibrates "along" the surface as a harmonic oscillator weakly interacting with its neighbours.

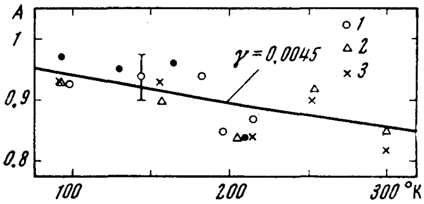

Figure 7. Temperature variation of the asymmetry of the quadrupole splitting lines of SnO on the surface of coarsely porous silica gels (*1*), a silica gel with fine pores (*2*), and a zeolite (*3*).

An important problem is also the elucidation of the effect of pore dimensions on the type of atomic vibrations, i.e. whether there are differences within the type of atomic vibrations on a surface close to the usual planar type and on a surface with an appreciable curvature. The vibrations of tin atoms on the surface of coarsely porous silica gel with pore dimensions of 120 and 250 Å, which is almost planar a relation to the tin atom and in silica gels with fine pores and a zeolite with nearly molecular pore dimensions were compared in the present authors' investigation[20].

Experiments on the temperature variation of the asymmetry of the vibrations showed that this kind of difference in pore dimensions does not affect the nature of the anisotropy of the vibrations but does influence the absolute values of $< r^2 >$. Probably $< r^2 >$ increases uniformly in all directions in the coarsely porous silica gels. In systems with pores having molecular radii, smaller values of $< r^2 >$ were observed for tin atoms on the surface than in coarsely porous systems, particularly at high temperatures.

However, the principal differences between the coarsely porous specimens and those having fine pores are shown in the diffusion pattern of tin atoms along the surface.

In conclusion and summarising the results obtained in this section, we may note that all the theoretical calculations associated with the increase of $< r^2 >$ and the anisotropy of the vibrations of atoms on the surface are largely consistent with the experimental data. An exception is the decrease of $< r^2 >$ and the corresponding increase of the probability of the Mössbauer effect for tin atoms on the surface of platinum[12] and for cobalt atoms on the surface of silver[8] (see in addition the remarks on pp. 610–611). We shall return to the discussion of this anomaly in the section dealing with the effect of the surface on the phonon spectrum of small particles.

2. Surface Diffusion

The diffusion of Mössbauer atoms may lead to an appreciable broadening of the observed lines in the γ-resonance spectra compared with their natural width. In solids the diffusion coefficients of atoms do not exceed 10^{-12} cm^2 s^{-1}, which gives rise to a widening significantly smaller than the natural line width. At the same time in liquids the diffusion coefficient is of the order of 10^{-5} cm^2 s^{-1} and therefore the experimental width exceeds by many powers of ten the natural width. However, in liquids there is no Mössbauer effect and therefore the widening of the experimental line cannot be observed. On the surface cases probably occur where the diffusion coefficients are in the intermediate range and therefore diffusion has a marked effect on line width in the Mössbauer spectra. The most probable mechanism of surface diffusion involves abrupt transition of atoms from one position to another. Then the widening of the line is determined by the Singwi–Sjolonder formula[21]: $\Delta\Gamma = 2h/\tau$ (h is the Planck constant, $\tau = l^2/6D_1$ the localisation time, l the distance between the localisation centres, and D_1 the coefficient of diffusion by "jumps"). For example in the case of iron τ must be less than 10^{-7} s^{-1} (for $l = 3 \times 10^{-8}$ cm) and D_1 must be greater than 10^{-9} cm^2 s^{-1} for appreciable widening to be observed. There exists yet another mechanism which operates, for example, in polymolecular adsorption, mainly continuous diffusion which leads to a widening

$$\Delta\Gamma = \frac{2E_\gamma^2 D_2}{\hbar c^2},$$

where E_γ is energy of the nuclear order of magnitude and D_2 the coefficient of continuous diffusion. The widening of the Mössbauer line is more sensitive to this type of diffusion; here it is sufficient for D_2 to exceed 10^{-11} cm^2 s^{-1}.

In a number of studies the surface diffusion of tin and iron atoms on the surfaces of silica gel[19,20], zeolites[22], and ion-exchange resins[23] was investigated. Tin was physically sorbed on the surface of silica gels and zeolites in the form of $SnO_2.nH_2O$. The temperature variation of line half-width was investigated. It was shown that in coarsely porous silica gels there is a phase transition in the adsorption layer at 200°K involving "jumps" by $SnO_2.nH_2O$ groups from one localised position to another, which leads to a marked line widening and a decrease of the probability of the Mössbauer effect. In silica gels with fine pores and in zeolites a phenomenon of this kind was not observed (with the exception of a slight widening at a higher temperature) probably because of the stronger bonds formed by $SnO_2.nH_2O$ with the surface in pores of molecular dimensions (Fig. 8). It was of interest to estimate the activation energy for the diffusion of the $SnO_2.nH_2O$ groups. Using the expression $\tau = \tau_0 \exp(Q/RT)$, the activation energies were found to be $Q \simeq 3.5$ kcal $mole^{-1}$ for coarsely porous silica gel and 7.5 kcal mole^{-1} for silica gels with fine pores[19]. A study was also made of the diffusion of Fe^{2+} ions in the pores of zeolites of type Y and M and in KU-2 ion-exchange resin[22-24]. An increase of temperature resulted in a widening of the Fe^{2+} line, which led to the estimates $\tau = 3.9 \times 10^{-8}$ s and $D = 0.7 \times 10^{-8}$ cm^2 s^{-1} at 213°K and $\tau = 2.2 \times 10^{-8}$ s and $D = 10^{-8}$ cm^2 s^{-1} at 300°K for the diffusion of Fe^{2+} in the channels of zeolite M (mordenite) in the presence of n-hexane molecules. The numerical values of τ and D are consistent with the data of Barrer et al.[25]

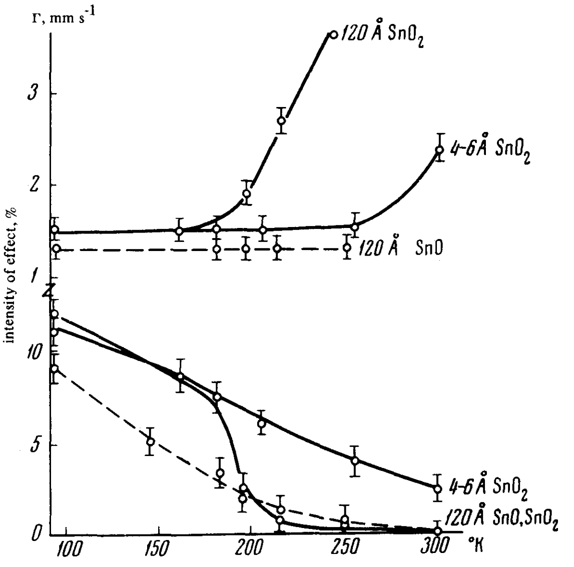

Figure 8. Temperature variation of the effect (%) and line width (Γ, mm s^{-1}) for tin on the surface of silica gels with pore diameters of 120 and 4–6 Å.

The diffusion of Fe^{2+} cations in the ion-exchange resin with sorbed hexane and water was investigated in greater detail (Fig. 9). The activation energy for diffusion in hexane was found to be 5 kcal mole^{-1} and for diffusion in water only about 1 kcal mole^{-1}, the diffusion of hexane occurring after its fusion (190°K). The lower activation energy for the diffusion of Fe^{2+} in KU-2 resin when water is present in the pores is probably due to the polarity of water molecules, which weakens the bond between the iron(II) cation and the resin lattice.

3. Electronic State of Atoms on the Surface

In this section we shall consider the problems of the type of electronic bonds involving the atoms on the surface compared with the bonds for atoms within the solid. It is difficult to expect that the valence of atoms will change on transfer to the surface. However, one may expect changes in the ionic character of the bond or in the mutual screening of the *s*, *p*, and *d* electrons. This might lead to a change of the isomer shift in the Mössbauer spectra of surface atoms. Such changes have not, however, been observed so far. Zeolites, where the pore dimensions are nearly molecular, appear to be an exception. Thus the isomer shift δE_I for Sn^{2+} in the type M zeolite[20] relative to SnO_2 increased from 2.7 mm s^{-1} (a value characteristic of the usual polycrystalline SnO) to 3.2 mm s^{-1} [henceforth the isomer shifts (IS) for tin will be reckoned relative to IS for tin dioxide and for iron relative to IS for sodium nitroprusside]. The above increase in isomer shift may be attributed, according to Donaldson and Senior[26], to a decrease of the contribution of the crystal field, which is very powerful in the normal compound SnO and leads to the mixing of the *s* and *p* electronic orbitals, thereby diminishing the isomer shift [i.e. the signal $|\Psi(0)|^2$]. Moreover, the atoms on the surface should be subject to the crystal field of lower symmetry compared with atoms within the bulk of the solid. This must lead to high electric field gradients the direction of which may be reasonably assumed to be perpendicular to the surface.

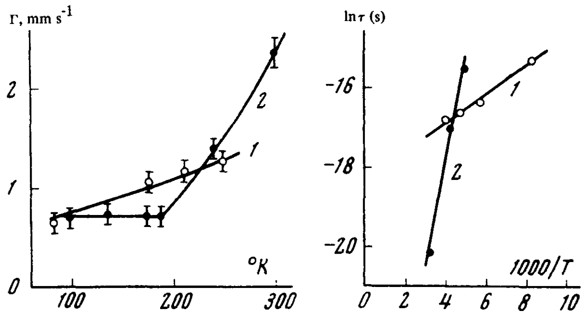

Figure 9. Increase in line width Γ for Fe^{3+} in an ion-exchange resin with increasing rate of diffusion of iron and the variation of the logarithm of the ion localisation time (ln τ) with temperature: *1*) water; *2*) n-hexane.

This may result in an increased quadrupole splitting in the Mössbauer spectra in the vicinity of the surface. Indeed in all the experiments the quadrupole splitting (QS) for surface atoms ΔE_Q increased and sometimes appeared even when the atoms within the bulk of the solid gave rise to no splitting at all. Thus Burton and Godwin[8] obtained $\Delta E_Q = 0$ for cobalt-57 atoms within a tungsten support and $\Delta E_Q = 0.78$ mm s^{-1} for cobalt-57 atoms on the surface of tungsten. For iron on the surface of η-alumina in the form of Fe_2O_3, Flinn et al.[18] observed an increase of QS from 0.3 mm s^{-1}, characteristic of the normal state of Fe_2O_3, to 1.06 mm s^{-1}. A similar increase of QS in consequence of the more important role of the surface was observed by Rumbic et al.[27] for highly dispersed Fe_2O_3 particles with dimensions of about 100 Å. Fig. 10 shows an increase of ΔE_Q as the particle size diminishes. Similar calibrations may be employed to estimate the particle size. An increase of QS for SnO on the surface to 2.1 mm s^{-1} compared with the normal value $\Delta E_Q = 1.3$ mm s^{-1} has been observed[19,20]. Finally the most striking feature is the occurrence of quadrupole splitting (ΔE_Q = 0.6 mm s^{-1}) in the Mössbauer spectrum of a metallic iron film 4.6 Å thick[28].

Continuing the discussion of the electronic state of atoms on the surface, we shall now deal with the magnetic properties.

4. Magnetic Properties of Atoms on the Surface

According to classical concepts, ferromagnetism is essentially a three-dimensional effect associated with the finite volume of matter[29]. Therefore magnetic ordering should not be expected for surface atoms. It is now known, however, that a hyperfine structure in Mössbauer spectra may arise not only in magnetically ordered systems but also in paramagnetic materials, provided that the relaxation time of electron spin is comparable to the precession time of the nuclear spin of the resonating atom[30,31]. Both spin–spin and spin–lattice relaxation is involved. At low concentrations of paramagnetic ions it is possible to ensure that the relaxation is wholly of the spin–lattice type. Since the paramagnetic ion on the surface is linked to the lattice less strongly than within the bulk of the solid, an increase in the spin–lattice relaxation time may be expected for surface atoms together with the appearance of a hyperfine structure in the Mössbauer spectra for such atoms, while those in the bulk phase do not give rise to a hyperfine structure.

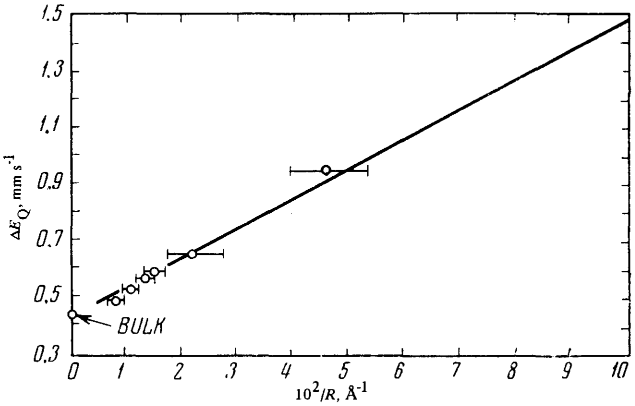

Figure 10. Variation of ΔE_Q with the reciprocal of the radius of highly dispersed Fe_2O_3.

The first result of this kind was obtained in the study of the relaxation of electron spin in ion-exchange resins[32]. The concentration of iron was extremely low (1.6 wt.%). A sharp increase in spin–lattice relaxation time was observed after the adsorption of water by this type of system. Fig. 11 presents the spectra of Fe^{3+} in a sulphonated ion-exchange resin before and after the adsorption of water. Water weakens the bond between Fe^{3+} and the resin lattice and increases the spin–lattice relaxation time τ. It was also noted that the increase of τ is accompanied by a decrease of the electric field gradient whenever it is caused by the withdrawal of the ion from the resin lattice and an increase in the symmetry in charge distribution occurring when the Fe^{3+} ion is surrounded by water molecules. We may note that, although the bond between the surface ion and the lattice is weakened, which leads to an increase of τ, the presence of high gradients may lower it (for two-phonon processes, which are responsible for relaxation in the case under discussion[32], the probability of spin–lattice relaxation is proportional to the square of the distance between the Stark levels, i.e. as a result of the increase of the electric field gradient and of the distance between the Stark doublets, the probability of relaxation increases and the relaxation time falls). Therefore Fe^{3+} ions in an ion-exchange resin exist under conditions more favourable for high relaxation times than in the case where Fe^{3+} is located on the usual type of surface, because the bond with the lattice is weak as on a normal surface but the electric field gradient is much weaker.

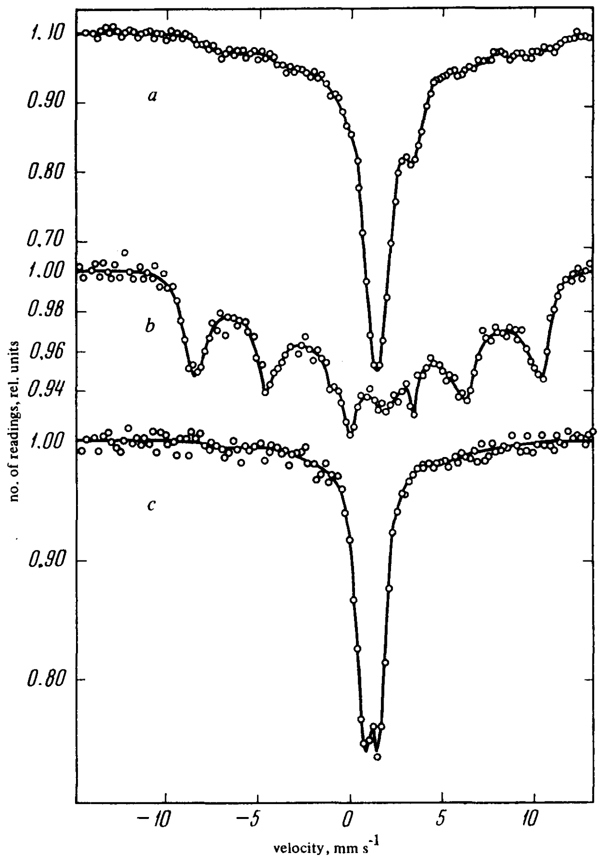

Figure 11. Spectra of a sulphonated resin with Fe^{3+} before (*a*) and after the adsorption of water (*b*) and of a phosphorylated resin after the adsorption of water (*c*) at 80°K.

Fig. 12 shows the temperature variation of the spin–lattice relaxation time for the Stark doublet $S_Z = \pm 5/2$ obtained experimentally and calculated using the Debye and Einstein approximations for $\theta_F = 325$°K and $\theta_D = 400$°K respectively[32]. θ_D determined in the usual way from the temperature variation of the probability of the Mössbauer effect is approximately the same. The vibration frequencies ($k\theta/\hbar$) of the lattice with Fe^{3+} obtained in this way are very high. Probably such high-frequency vibrations tend to average out the electric field at the Fe^{3+} ions and thereby retard the relaxation.

The effect of the immediate environment of the paramagnetic ion on the nature of spin–lattice relaxation has been investigated[33]. By sorbing different amounts of water molecules in an ion-exchange resin, it has been shown that the hyperfine structure is fully formed and the maximum relaxation time $\tau = 2.4 \times 10^{-8}$ s is observed when there are six molecules of water for each iron ion. Then each spectrum corresponding to an intermediate average number of water molecules (n_{av}) per Fe^{3+} ion does not arise by a simple superposition of spectra with different values of n (for example the hyperfine structure due to four water molecules is not a result of the superposition of spectra with zero, 1, 2, 3, 4, 5, and 6 water molecules for each Fe^{3+} ion). This is evidence that the spectra of partly hydrated resin are observed. It was found that under certain conditions it is possible to observe the hyperfine structure due to Fe^{2+} in the ice lattice, for example in a strongly acid medium with an excess of chlorine atoms relative to iron (0.02 M $FeCl_3$ in 4.5 M hydrochloric acid). Since in the presence of between one and six water molecules per Fe^{2+} ion the ice lattice is not as yet observed in the ion-exchange resin (the distance between the ion-exchange centres is about 20–30 Å), one may conclude that the spin–lattice relaxation time is determined by the nearest environment of Fe^{3+}, i.e. the water molecules and not the entire ice lattice. Thus ion-exchange resins are very suitable for the investigation of the effect of various ligands on the relaxation of electron spin of the Fe^{2+} ion.

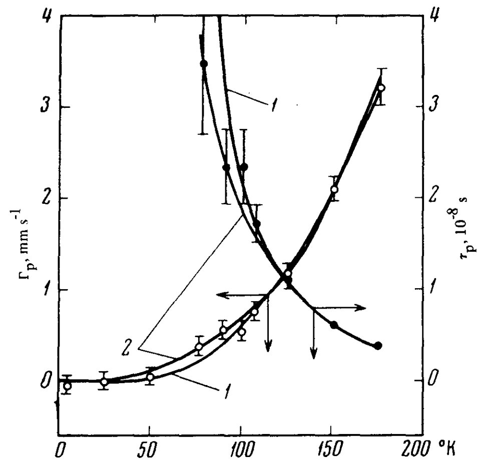

Figure 12. Temperature variation of the spin–lattice relaxation time of the Fe^{3+} ion and the width of the extreme spectral lines. The continuous curves were calculated using the Einstein (curve *1*) and Debye (curve *2*) approximations.

Widely occurring phenomena, such as adsorption and catalysis, are directly associated with the electronic and magnetic properties of atoms on the surface.

5. Elementary Steps in Adsorption. The Chemistry of Surface Compounds

The interaction of atoms or molecules with the surface of a solid leads, on the one hand, to a change in the state of the adsorbent atoms on the surface and, on the other hand, also in the properties of the sorbed groups themselves, i.e. the properties of the adsorbate. This entails a change in both the dynamic and electronic properties of atoms, which should be reflected in the Mössbauer spectra. The method employed in such experiments involves the use of an absorber of resonance γ-quanta as the adsorbate or the adsorbent. In order to obtain the Mössbauer spectra, it is necessary to have an adsorbent or adsorbate with atoms containing resonating nuclei and to follow the changes in the state of either the surface of the solid or of the sorbed substances. In some cases it is possible to follow both provided that the adsorbent and the adsorbate contain resonating nuclei. The application of Mössbauer spectroscopy makes it possible to distinguish physical sorption and chemisorption.

Since the bond between the surface atoms and the adsorbate is weaker in physical sorption than in chemisorption, the probability of the Mössbauer effect should be lower in physical sorption and the temperature variation more pronounced than in chemisorption, particularly at high temperatures. A distinction of this type was made[19] for $SnO_2.nH_2O$ physically sorbed on the surface of silica gel and Sn^{2+} chemisorbed as SnO. For physical sorption (Fig. 8), a more pronounced temperature variation of the probability of the effect was observed than in the case of chemisorption.

Moreover, since chemisorption entails a change in the electronic structure of both the adsorbent and the adsorbate, a radical rearrangement of the Mössbauer spectrum can be observed—with a change in the isomeric shift and quadrupole splitting, which is not a characteristic feature of physical sorption.

Physical sorption was investigated as a function of the number of monolayers of sorbed tin tetrachloride molecules on silica gel and a study was made of systems with pores whose size ranged from several hundred of angstroms to nearly molecular dimensions[20].

After the adsorption of $SnCl_4$ on silica gel, the form of the spectra hardly changed; the smallest decrease of the isomeric shift was observed in sorption on silica gel with nearly molecular pore dimensions.

A significantly different temperature variation of f' was observed on silica gels with fine pores for $SnCl_4$ sorbed in amounts less than one monolayer and in amounts corresponding to about five layers. The temperature variation of f' was much more pronounced for a large number of $SnCl_4$ layers than for a small amount, which is evidence that in physical sorption the $SnCl_4$ molecules are much more strongly bound to the surface of silica gel than to one another. For systems with fine pores, such a difference between the characteristics of the spectra with different numbers of sorbed layers is less marked.

The adsorption of water in ion-exchange resins was also investigated on the basis of changes in the probability of the Mössbauer effect[23]. The adsorption of water is known to lead to swelling of the resins and to a change in the state of the ion. KU-2 and KB-4 cation-exchange resins with the cations Fe^{3+} and Fe^{2+} and AV-16 and AV-17 anion-exchange resins with the anions $[Fe(CN)_6]^{3-}$ and $[Fe(CN)_6]^{4-}$ were investigated. All the ion-exchange resins were organic polymers or copolymers with functional groups capable of ion exchange. In KU-2 and KB-4 cation exchangers these are $R{-}SO_3^-$ and $R{-}COO^-$ groups respectively, in AV-16 anion exchangers these are the R_2NH, R_3N, and R_4N^+ groups, while AV-17 anion-exchange resins contain R_4N^+ groups. Whereas in KU-2 sulphonated resin the Mössbauer effect disappeared as a result of the adsorption of water, in KB-4 resin it persisted after such adsorption. This result is associated with the dissociation of water molecules and Fe^{3+} ions from the lattice of KU-2 sulphonated resin. Analysis shows that[24] (Fig. 13) three water molecules for each Fe^{2+} ion are required for complete dissociation of the iron cation from the SO_3 group in the resin and the disappearance of the Mössbauer effect. It has also been shown that the Mössbauer effect does not decrease because part of the ions are dissociated while others are not. For small amounts of water (up to three molecules per ion), $\langle r^2 \rangle$ increases and f' falls but Fe^{3+} ions remain localised (undissociated), while in the presence of a large amount of water Fe^{3+} ions cease to be localised, which leads to their diffusion by abrupt transitions ("jumps") from one localised position to another and the complete disappearance of the Mössbauer effect with simultaneous widening of the line due to diffusion. On the basis of the literature data[24,33] and the finding that the lines in the Mössbauer spectrum do not become wider when the average amount of water increases up to three molecules per Fe^{3+} ion while in the case of more pronounced hydration the lines do widen with increase of temperature owing to diffusion, one may conclude that the variance of the number of water molecules per metal ion is small.

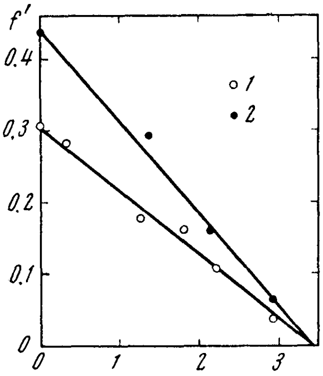

Figure 13. Decrease of the probability f for Fe^{3+} in a sulphonated ion-exchange resin after the adsorption of different numbers of water molecules per sulpho-group (300°K): *1*) resin with 12% of divinylbenzene as a cross-linking agent; *2*) non-swelling resin.

The effect of the degree of cross-linking of the sulphonated resin on the melting point of ice in the resin, at which the Mössbauer effect disappears, has been investigated[24]. It was found that an increase in the degree of cross-linking entails a shift of the point of disappearance of f' towards higher temperatures, probably due to the concentration of Fe^{3+} ions in the vicinity of the exchange centres. In the carboxylic acid KB-4 resin and in a phosphonic acid resin[32] there is probably an increase of $\langle r^2 \rangle$ for Fe^{3+} ions and a decrease of f' but not complete dissociation of Fe^{3+} from the COO^- and CO_2^- groups.

Krizhanskii and coworkers[34] and Mackey and Collins[35] studied ion-exchange resins with the anions $[SnCl_6]^{2-}$ and iron cations respectively. Mackey and Collins found that in sulphonated cation exchangers there are two types of Fe^{3+} cations, with normal and anomalously high values of ΔE_Q ($\Delta E_Q = 1.6$ mm s^{-1}). They suggested that lines with high quadrupole splitting arise as a result of the hydrolysis of Fe^{3+} and the formation of hydrated dimers with an excess electron. However, one should bear in mind that the adsorption of water results in the appearance of a magnetic hyperfine structure in the spectrum[32], which covers a wider range of velocities than was examined by Mackey and Collins[35] and therefore the lines attributed to anomalous quadrupole splitting might have been simply part of a magnetic hyperfine structure, which had not been detected. Delgass and Boudart[36] observed a change in the probability of the Mössbauer effect in a type Y zeolite after the adsorption of water. Probably the decrease of f' is associated in this case with the increase of $\langle r^2 \rangle$ for Fe^{3+} ions, as in ion-exchange resins[24], and not with the fact that part of the ions are dissociated and others are not, as suggested by Delgass and Boudart[36]. The adsorption of water can lead to an increase in the spin–lattice relaxation time too, as noted earlier[32,33] for Fe^{3+} in a sulphonated ion-exchange resin. An increase in spin–lattice relaxation time for Fe^{3+} ions was also observed after the adsorption of water, methanol, n-hexane, and tetramethyltin in zeolites of types Y and M containing Fe^{3+}, with a consequent asymmetry in quadrupole splitting of the Blume type[22,37], associated with the effect of electron spin relaxation on the Mössbauer spectra. Moreover, the adsorption of the substances enumerated above also led to the appearance of new lines in the spectrum, corresponding to divalent ions[22]. Since it is difficult to suppose that the adsorption of substances such as, for example, n-hexane leads to the reduction of iron in the zeolite, the appearance of the new lines may be attributed to the localisation in the zeolite channels of divalent iron ions which had been non-localised before adsorption and which had not given rise to a Mössbauer spectrum. The hypothesis of the presence of two types of cations in zeolites has been put forward previously by Dubinin[38] and Neimark[39]. The weak bond between Fe^{2+} and zeolite is characterised by the diffusion of the cation along the zeolite channel, which is reflected in a strong temperature-induced widening of the Fe^{2+} line.

All the previous experiments were related in one way or another to physical sorption, i.e. did not lead to a radical change in the spectrum. It is extremely interesting to investigate chemisorption by following the changes in Mössbauer spectra. When iron-containing zeolites were studied[22], the spectra of the $(CH_3)_4^{119}Sn$ adsorbate were also obtained and the presence of a bond between tetramethyltin molecules and $[AlO_4]^-$ was demonstrated. Similar spectra were obtained by Karasev et al.[40] in a study of the chemisorption of $(CH_3)_4Sn$ on alumina.

Morice and Rees[41] studied the adsorption of water and methanol on zeolites of types Y and M evacuated at 360°C. The adsorption of water or methanol resulted in a marked change in the spectra, the disappearance of certain forms of iron from the zeolite, and the appearance of others. It is at present difficult to identify all the forms of iron in the zeolites in experiments of this kind before and after adsorption.

The adsorption of polar solvents in zeolites alters the quadrupole splitting, the change being different for the Fe^{3+} and Fe^{2+} ions (see, for example, Refs. 22–24)—the quadrupole splitting increases for Fe^{2+} and decreases for Fe^{3+}. The results for Fe^{2+} probably indicate the formation of new chemical bonds, i.e. refer to chemisorption, while those for Fe^{3+} are related to water molecules surrounding the hydrated Fe^{3+} ion and diminishing the electric field gradient.

The experimental results for the chemisorption of iron(III) oxide on SiO_2 or Al_2O_3 carriers are easier to interpret. In this connection, we shall consider the studies of the oxidation and reduction of surface atoms. Hobson et al.[42,43] investigated the reduction of iron(III) oxide (Fe_2O_3) with different particle sizes on alumina and silica. The initial spectrum corresponds to highly dispersed Fe_2O_3 and reveals the very high value $\Delta E_Q = 1.87$ mm s^{-1}, which constitutes a record. Using the variation of the quadrupole splitting with particle size (Fig. 10) and extrapolating it to smaller particle sizes, Hobson and coworkers[42,43] estimated the dimensions of their own particles (about 20 Å). After the chemisorption of hydrogen, the spectra changed sharply. The authors postulate the presence of two forms of iron—the reduced, divalent iron with $\delta E_I = 1.35$ mm s^{-1} and $\Delta E_Q = 1.65$ mm s^{-1} corresponding to the usual ionic iron compounds and trivalent iron with $\delta E_I = 1.02$ mm s^{-1} and $\Delta E_Q = 0.98$ mm s^{-1}. For these particle sizes, reduction to metallic iron does not take place. The reduction of larger Fe_2O_3 particles on alumina[43] gave a mixture of metallic and divalent iron. The authors conclude that the smaller particles of silica gel cannot be reduced to metallic iron at all.

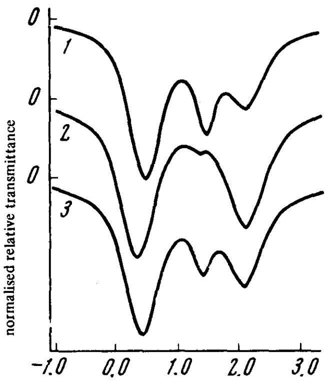

Figure 14. Spectra of iron on silica before (curve *1*) and after (curve *2*) chemisorption of ammonia.

Hobson studied the chemisorption of ammonia on iron(III) oxide obtained by preliminary heat treatment of silica gel impregnated with iron(III) nitrate[44]. Fig. 14 shows the spectra before chemisorption (curve *1*), after chemisorption (curve *2*), and after repeated degassing (curve *3*). The kinetic data indicate dissociative adsorption of ammonia in this system. Spectrum *3* shows the reduction of trivalent iron by ammonia, since the amine radical formed can supply electrons to the iron *d* orbital and thereby facilitate the formation of a high-spin iron(II) complex.

After the desorption of ammonia, the initial spectrum is restored[3]. These experiments characterise the change in the state of the adsorbents after chemisorption.

A series of experiments on the chemisorption of $(CH_3)_4Sn$ on silica gel and alumina were made by Karasev and coworkers[40,45], who showed that the form of the spectrum depends significantly on adsorption temperature. The spectra of freshly prepared specimens at 30°C differed sharply from those of specimens kept for 24 hours and longer in air. Fig. 15 shows the spectra of the initial $(CH_3)_4Sn$ adsorbed at 30°C on alumina and kept in air for 20 and 35 h. At an adsorption temperature of 30°C two additional peaks (curve *2*), which were attributed to the doublet of chemisorbed $(CH_3)_4Sn$, were observed in addition to the initial spectrum of tetramethyltin. The chemisorption centres are either oxygen or hydroxy-groups.

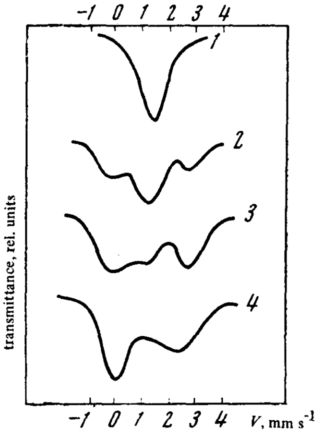

Figure 15. Spectra of $(CH_3)_4Sn$ chemisorbed on γ-Al_2O_3: *1*) initial spectrum of $(CH_3)_4Sn$ before chemisorption; *2*) after chemisorption; *3*) and *4*) after exposure to air.

The authors attribute the presence of the initial substance to physically sorbed $(CH_3)_4Sn$. When the specimen is kept for 20 h at room temperature (curve *3*), the intensity of the doublet increases. Further exposure to air leads to a radical alteration to the spectrum. Two lines appear, one of them (with $\delta E_I = 0$) is assigned to the chemisorption of $(CH_3)_4Sn$ involving the dissociation of tin–methyl bonds and the formation of a bond between the tin and oxygen atoms at the site of the aluminium vacancies; the second line is due to the bond between tin and aluminium and the surface dissociation of $(CH_3)_4Sn$. Chromatographic analysis of the gas phase over γ-alumina with adsorbed $(CH_3)_4Sn$ reveals the presence of ethane and methane, which may be attributed to the dissociative chemisorption of $(CH_3)_4Sn$.

To conclude this section, we emphasise yet again the principal results obtained in the study of the elementary adsorption steps. For physical sorption, these are (a) the observation of a more pronounced interaction of sorbed $SnCl_4$ molecules with the adsorbent than with one another; (b) the determination of the type of interaction between water molecules and iron cations in ion-exchange resins (the weakening of the bond between the cation and the lattice, dissociation in two stages, the presence of a definite number of water molecules per metal ion in the dissociation process, an increase in the spin–lattice relaxation time); (c) localisation of cations after the adsorption of molecules in the zeolite.

For chemisorption the following results were obtained: (a) the demonstration of the presence of two types of iron ions on the surface of silica gel after the chemisorption of hydrogen and the presence of a variety of forms of iron in zeolites; (b) demonstration of the adsorption of ammonia with formation of an iron(II) complex; (c) the existence of two types of active centres for the chemisorption of tetramethyltin.

6. Heterogeneous Catalysis

Two aspects of the application of Mössbauer spectroscopy in this field must be distinguished: (1) the determination of the relation between the rate and selectivity of catalytic reactions on the one hand and the electronic state of the catalyst atoms on the other; (2) the observation of intermediate complexes in catalysis.

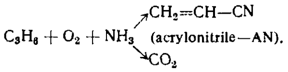
For the first aspect, it is sufficient to obtain the Mössbauer spectra of the catalysts before or after the catalytic reaction and to compare the parameters of these spectra with catalytic activity.

In order to investigate the second range of problems, it is necessary to have at one's disposal a Mössbauer proton spectrometer in which the reaction takes place directly in the zone where the spectra are recorded. Experiments of the second type have not as yet been achieved.

It is of considerable interest to investigate the relation between catalytic activity in any one reaction with parameters such as the isomeric shift and the quadrupole splitting in the Mössbauer spectrum. Probably catalytic activity should be related to both parameters and therefore in order to investigate correlations of this kind separately, it is necessary to have catalysts with variable catalytic activities and variable isomeric shifts for constant quadrupole splitting or conversely. It is simpler to vary the quadrupole splitting in a series of solid solutions for a constant isomeric shift.

The catalytic activities and selectivities of a number of iron- and tin-containing mixed oxide catalysts of the type of $X_aO_bM_cO_d$ solid solutions, where M is a Mössbauer atom and X a non-Mössbauer atom, have been compared[46]. For Fe^{3+} or Sn^{4+}, which have the symmetrical configurations $3d^5$ and $4d^{10}$, it is possible to alter the quadrupole splitting by varying X without changing the isomeric shift. The quadrupole splittings for these configurations are associated solely with the effect of the crystal field on these ions.

The oxidative ammonolysis of propene on catalysts of this kind has been investigated in this way. The reaction may take place via two pathways:



$$C_3H_6 + O_2 + NH_3 \begin{cases} \nearrow CH_2{=}CH{-}CN \text{ (acrylonitrile—AN).} \\ \searrow CO_2 \end{cases}$$

The curves relating the rate of formation of acrylonitrile to quadrupole splitting for a constant isomeric shift have a maximum. Similar "bell-shaped" curves are observed for the relation between the rate of reaction and the heat of formation Q of the surface compounds. An increase in the crystal field gradient and in the distortion of the lattice leads to an increase of Q and therefore at a certain value of the quadrupole splitting the rate of formation of acrylonitrile should be a maximum.

In order to investigate the possible mechanism of the catalysis, it is, however, necessary to choose simpler reactions involving one pathway only, such as for example, the classical catalytic oxidation of carbon monoxide to carbon dioxide on iron(III) oxide. An investigation of this kind was made[47] on a highly dispersed iron(III) oxide, the results of the Mössbauer experiment being compared with the kinetic data. In order to increase the fraction of surface ions, a highly dispersed iron(III) oxide with a particle size of about 80 Å and less was employed. The Mössbauer spectrum of such particles consisted of a paramagnetic component and a component with a magnetic hyperfine structure (Fig. 16). Several modifications of this experiment have been performed: (a) catalytic oxidation of carbon monoxide to carbon dioxide with and without freezing out the reaction product (carbon dioxide); (b) chemisorption of carbon monoxide on the specimen; (c) interaction of carbon monoxide with the specimen in the absence of oxygen with carbon dioxide frozen out; (d) heat treatment of the specimen with carbon monoxide and subsequent chemisorption of oxygen. The experiments were carried out at 100°C. The spectra and the kinetic measurements lead to definite conclusions concerning the mechanism of the catalytic oxidation of carbon monoxide to carbon dioxide, in agreement with Hauffe's data[48]. After the reaction of carbon monoxide with the catalyst surface, iron(II) cations bound firmly to the surface of Fe_2O_3 appear, the state of the iron remaining unchanged after heating to 100°C. The kinetic results show that there is a complete correspondence between the amount of carbon monoxide which has reacted with Fe_2O_3 and the amount of carbon dioxide frozen out.

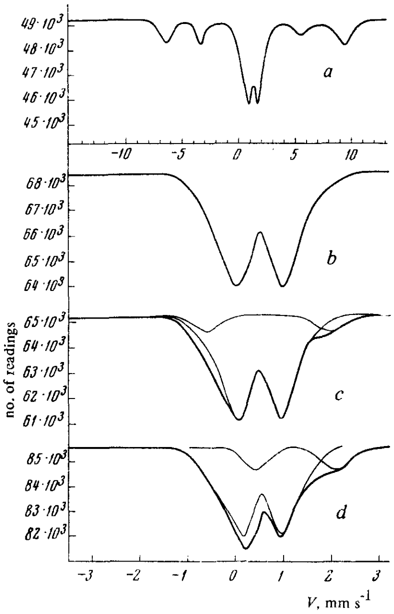


Figure 16. Spectra of iron(III) oxide in the catalytic oxidation of carbon monoxide to carbon dioxide: *a*) before oxidation; *b*) before oxidation at relatively low velocities of the source and absorber (the "paramagnetic" component of the spectrum is shown); *c*) after chemisorption of carbon dioxide; *d*) after chemisorption of carbon monoxide for measurements at room temperature.

This finding shows that the role of carbon monoxide involves in this case simply the reduction of Fe^{3+} to Fe^{2+} on the surface of the Fe_2O_3 particles without the formation of any surface compounds of carbon monoxide with iron(III) oxide. As a result, divalent iron ions appear on the surface of the particles and form a compound of the type of FeO. Indeed, the value $\delta E_I = 1.29 \pm 0.08$ mm s^{-1}, determined from the spectra, agrees with the value $\delta E = 1.32 \pm 0.06$ mm s^{-1} for the usual polycrystalline state of FeO.

However, the value $\Delta E_Q = 1.67 \pm 0.08$ mm s^{-1}, obtained for the surface compound FeO, greatly exceeds $\Delta E_Q = 0.77 \pm 0.03$ mm s^{-1} for the usual polycrystalline state of FeO. The observed increase of quadrupole splitting on the surface of iron(III) oxide may be attributed to the breakdown of symmetry in the distribution of atoms on the surface of the solid. The carbon monoxide molecules chemisorbed on the surface of Fe_2O_3 bind the oxygen of the catalyst and are desorbed in the form of CO_2 from the surface, leaving behind the Fe^{2+} ions. After the chemisorption of oxygen, the initial state of Fe_2O_3 is restored. A somewhat different process takes place after the adsorption of carbon monoxide on Fe_2O_3 (Fig. 16)—a surface compound with a fairly asymmetric configuration is formed. A similar surface compound arises when the catalytic oxidation of carbon monoxide is carried out without freezing out the carbon dioxide. When carbon dioxide is frozen out, the spectrum does not change. Probably the catalytic oxidation of carbon monoxide on Fe_2O_3 involves alternate reduction and oxidation of the catalyst. In the chemisorption of carbon monoxide the active part of the Fe_2O_3 surface is reduced to FeO, as a result of which carbon dioxide is formed. Oxygen in the gaseous mixture reoxidises FeO to Fe_2O_3.

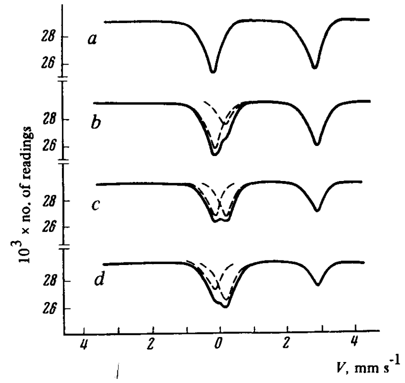

Figure 17. Spectra of Fe^{2+} on the surface of quartz before the pyrolysis of acetylene (*a*) and 0.5, 2, and 5 min (*c*, *b*, and *d*) after the start of the reaction (T_{exp} = 300°K).

In another study dealing with the pyrolysis of acetylene over an iron-containing quartz surface[49] an anomalous transparency of a film of pyrocarbon produced in the course of the reaction of acetylene with the iron atoms on the surface was observed. By evaporating Fe_2O_3 enriched with the iron-57 isotope to the extent of 91%, iron was deposited on the surface of quartz in the form of a divalent compound, probably iron(II) silicate ($FeSiO_3$) and also in the form of metallic iron and Fe_2O_3. After the pyrolysis of acetylene over this type of catalyst, there appears in the spectrum a line corresponding to a symmetrical surface compound, the amount of which increases with the duration of pyrolysis to a definite value, which is probably associated with the attainment of equilibrium between the complex formed in the reaction and the amount of iron(II) silicate present on the surface (Fig. 17). A layer of pyrocarbon with a thickness of several hundred angstroms, which is permeable in further penetration by acetylene to the quartz surface, is formed in the pyrolytic process on quartz. A control experiment was performed in which quartz with pyrocarbon on its surface was placed in a reactor with an argon atmosphere; under these conditions, iron was not bound in a surface complex, i.e. acetylene is essential for the formation of the complex. When the pyrocarbon was burnt off, the complex did not disappear either, which shows that the complex is located on the surface and is not bound to the bulk phase of the pyrocarbon. A similar conversion of metallic iron into the same complex has been observed.

In conclusion of the discussion of this class of phenomena, mention must be made of a new field in the chemistry of the solid state—the application of Mössbauer spectroscopy to surface phenomena, which permits the study of elementary processes on the surface taking into account the electronic and vibrational states of the atoms.

III. PHENOMENA ASSOCIATED WITH THE EFFECT OF THE BOUNDARIES OF THE SOLID ON THE PROPERTIES OF INTERNAL ATOMS

1. The Change in the Phonon Spectrum of a Substance in a Highly Dispersed State

In this section we shall consider the characteristic vibrations of atoms in small particles of a substance obtained by observing the changes in the probability of the Mössbauer effect. The changes in f for highly dispersed particles are associated with two effects: the first is the influence of the surface already mentioned above, which should lead to an increase of $\langle r^2 \rangle$. Since a decrease of particle size entails an increase in specific surface, f falls for this reason alone.

The second effect is associated with the change in the nature of the phonon spectrum itself for such particles and may act in the opposite sense, i.e. lead to an increase of f as the particle size is reduced. Marshall and Wilenzik[50], who assumed that for small particles the Debye approximation is applicable, concluded that the phonon spectrum must be displaced towards shorter wavelengths, which leads to an increase of f as the particle size is reduced. In fact, there is an upper limit to the wavelengths of phonons due to the dimensions of the particles themselves and therefore the phonon spectrum for small particles shows a more marked "cut off" on the long wavelength side (low frequency side) and, since the probability of the Mössbauer effect increases very markedly as the ratio $R/\hbar\omega$ falls (R is the recoil energy and ω the effective average vibration frequency), the low-frequency "cut off", which increases $\overline{\omega}$, results in a marked increase of f. Marshall and Wilenzik's reasoning is based, however, on the assumption that the Debye approximation is applicable to small particles. Actually, the phonon spectrum of small particles differs sharply from the usual spectrum by a set of discrete frequencies due to the presence of a finite number of atoms in such particles, which may lead to a change in $\overline{\omega}$ such that f will fall as the particle size is reduced. When account is taken of the decrease of the wavelength of the real phonon spectrum as a result of the effect of the surface, it is possible to predict the changes of f for particles of different kinds. The following in many ways contradictory results have been obtained experimentally. For β-tin particles, f falls with particle size (from 1550 to 250 Å)[15], while for gold particles it actually increases[50]. For small tungsten particles, f is also smaller than for foil[16].

For platinum[36], the probability of the effect hardly changes with particle size. Apart from these experiments, we investigated the changes in f for particles of FeNi (31% Ni) and FeCo (49% Co) alloys (particle size 800, 500, 300, and 160 Å), for which the probability of the effect fell with decreasing particle size, and for SnO_2 with a particle size of about 60 Å, for which f was also smaller than in macroscopic SnO_2. The literature data[15-17,36,50] and also our latest measurements are given in the Table.

Mössbauer effects in different substances

Substance	References	Size, Å	T, °K	f'_{exp}	Method of preparation
β-Sn	15	250	80	0.25	aerosol
		250	300	0.022	
		foil	80	0.35	
		foil	300	0.06	
FeNi (31% Ni)		160	80	0.7 rel. units	aerosol
		160	300	0.5 rel. units	
		800	80	1.4 rel. units	
		800	300	1.1 rel. units	
FeCo (49% Co)		160	80	0.7	aerosol
		160	300	0.5 rel. units	
		800	80	1.4 rel. units	
		800	300	1.3 rel. units	
W	16	30	4	0.57	hydrolysis of tungsten hexacarbonate
		1 μm	4	0.61	
Au	50	60	25	0.16	hydrosol
		60	60	0.07	
		200	25	0.14	
		200	60	0.05

		60	300	0.11	
		powder	80	0.9	
		powder	300	0.6	
Fe_2O_3	17	20—30	300	0.31—0.43	hydrosol
			100	0.37—0.51	
Pt	37	100	4	2-8 rel. units	platinum in silica gel pores
		foil	4	2-8 rel. units	

It follows from the Table that in almost all cases, with the exception of gold and platinum, the probability of the effect falls with decrease of particle size. However, the absolute values of f may oscillate somewhat, depending on the method of preparation of the particles[17] and therefore it is desirable to perform experiments of this kind for particles of 3-4 different dimensions, prepared by the same method (the aerosol method is apparently preferable, since under these conditions more nearly spherical particles are obtained). The increase of f for individual tin-119 atoms on the surface of platinum compared with polyatomic tin particles on platinum[12] and also the constancy of f for platinum in the pores of silica gel compared with platinum foil[34] can be included among the effects related to the increase of f with decreasing particle size. The results obtained for tin on the surface of platinum may, however, be attributed to the diffusion of tin into the bulk of platinum.

The most probable explanation of the increase of f with decreasing particle size is that the effect of the "compacting" of the phonon spectrum (as a result of the long wavelength cut off) predominates over surface effects. Unfortunately the influence of the surface can diminish f in different ways, depending on the method of preparation of the specimen. This makes it difficult to assess quantitatively the decrease of f taking into account the increase caused by the "compacting" of the phonon spectrum. Nevertheless experiments show that for gold and platinum the effect of the low-frequency component of the phonon spectrum on f is more significant than for the other substances investigated. This makes it possible to characterise the contribution of the long-wavelength part of the spectrum to the overall phonon spectrum by investigating very small particles of the substance.

2. Magnetic Properties of Small Particles. Superparamagnetic Phenomena

Thermal fluctuations of magnetisation do not occur in massive specimens which remain magnetically ordered up to the Curie (T_C) and Néel (T_N) points. As a result, whenever $T < T_C$, T_N, magnetic fields are found at the nuclei and the specimen shows macroscopic magnetisation. However, as the dimensions of the specimens decrease, thermal fluctuations in the magnetisation of the entire particle begin to occur, which leads to an averaging of the macroscopic magnetisation to values characteristic of the paramagnetic state of matter and the disappearance of magnetic fields at the nuclei, although the substance is still in the magnetically ordered state. Such behaviour of matter in a highly dispersed state in fact characterises the phenomenon of superparamagnetism. Indeed, for finite volumes of the substance, the frequency of the fluctuations in magnetisation may be described by the formula

$$\nu = \nu_0 \exp\left(-\frac{Kv}{kT}\right),$$

where ν_0 is usually of the order of 10^{10} s^{-1}, K(erg cm^{-3}) is the constant of anisotropy characterising the energy necessary to "overturn" the magnetisation vector and v is the volume of the particle. With increase of temperature, the fluctuation frequency ν increases, and, depending on the method used to investigate small particles of this kind, the latter will exhibit at a given temperature the properties either of magnetically ordered or magnetically disordered substances. This leads to an effective lowering of the Curie and Néel points as the particle size is reduced. By superimposing an external magnetic field of several kilo-oersteds, it is possible to increase artificially the constant of anisotropy by an amount μH:

$$\nu = \nu_0 \exp[(-Kv + \mu Hv)/kT],$$

where μ is the magnetic moment of the atom and H the external magnetic field. This provides an additional equation for the determination of the unknown volume of the particles. Mössbauer spectroscopy is the only method available for the investigation of superparamagnetism, since, in contrast to usual procedures, it permits the investigation of the relaxation of magnetisation during a period of 10^{-8} s. The frequency of thermal fluctuations and the relaxation time of magnetisation τ are determined from the widening of the Mössbauer line[32]:

$$\tau = \frac{\hbar}{\Delta\Gamma}.$$

A second feature of small particles is the absence of phase transition points associated with the change in the direction of the magnetisation of the spin relative to the axis of the crystal field, for example the absence of the Morin point in haematite.

The first experiment on superparamagnetism by the γ-resonance method was performed by Nakamura et al.[51], who found that, for Fe_2O_3 particles 50 Å in diameter, the Néel point is markedly reduced compared with large particles and lies between 120° and 300°K ($T_N \simeq 1000$°K for the usual Fe_2O_3). At 120°K there is the usual six-line hyperfine structure characteristic of an antiferromagnetic material and at 300°K the spectrum consists of a doublet corresponding to the superparamagnetic state of Fe_2O_3. Subsequently similar experiments were performed to investigate the effective changes in the behaviour of the Curie and Néel points and to determine the constants of anisotropy. Two methods may be employed to determine the constants. Kündig et al.[27] suggested that the frequency of the precession of the nuclear spin in the magnetic field acting upon the nucleus be used as a characteristic for which the contribution by the hyperfine structure amounts to approximately 50% of the entire spectrum under conditions where the frequency of the thermal fluctuations of the magnetisation is equal to the frequency of the precession of the nuclear spin. By determining the average volume of the particles at a specified temperature or the temperature for a specified column, for which the above condition holds, and by substituting these values in the exponential equation, the constant of anisotropy is found. The volume of the particles is determined by some other procedure, for example from X-ray diffraction data.

It is possible to suggest another method, associated with the possibility of the determination of τ from Mössbauer spectra, as was done by Suzdalev et al.[32] or by Wickman et al.[52] In this case one observes the experimental relation between $\ln\tau = \ln\tau_0 - Kv/kT$ and $1/T$, from which it is possible to determine the values of $\ln\tau_0$ and Kv/k. Kündig et al.[27] investigated highly dispersed Fe_2O_3 with a particle size of about 100 Å prepared by impregnating silica gel with a solution of $FeCl_3$ and subsequent thermal decomposition to iron(III) oxide. They also observed a decrease of the Curie point below 300°K. By analysing the change in the spacings between the hyperfine lines, the authors showed that in such Fe_2O_3 particles there is no Morin transition in which the magnetisation becomes parallel to the crystal field gradient when the temperature is reduced. The constant of anisotropy for Fe_2O_3 is $K = 4 \times 10^4$ erg cm^{-3} according to experimental data.

Shinjo[53] and Van der Kraan and van Loef[54] investigated the highly dispersed state of the antiferromagnetic material hetite (α-FeOOH) with a particle size between 60 and 500 Å. Here $K = 1 \times 10^4$ erg cm^{-2} and therefore the lowering of the Néel point and the appearance of superparamagnetism are already appreciable for larger particles than in the case of Fe_2O_3. When the particle size is reduced, the anisotropy constant may diminish somewhat[27]. Ando et al.[55] investigated the antiferromagnetic material NiO by introducing cobalt-57 into this oxide. The Néel point for NiO is 523°K. For 100 Å particles, obtained by impregnating with a mixture of $Ni(NO_3)_3$ and cobalt-57 with subsequent heat treatment at 500°C in air, the Néel point fell to 200°K. The investigators were able to demonstrate, using the characteristics of the structure of the highly dispersed initial oxide (with an excess of oxygen relative to the stoichiometric composition), that the Fe^{2+} spectrum observed previously by Bhide and Shenoy[56] and Triftshäuser and Craig[57], disappears for small particles and only the Fe^{3+} spectrum remains, owing to the presence of oxygen in excess of stoichiometry.

Schuele et al.[58] investigated highly dispersed ferrites ($NiFe_2O_4$ and $CoFe_2O_4$) with a particle size between 100 and 200 Å. Since the anisotropy constant for cobalt compounds is higher, superparamagnetism appears for smaller particles than in the case of nickel.

Another branch of studies of this kind involves the determination of particle distribution with respect to dimensions by comparing two parts of a complex spectrum: (1) component corresponding at a given temperature to the non-magnetic state without a magnetic hyperfine structure which arises from small particles; (2) component corresponding to the magnetic state with a hyperfine structure which arises for larger particles.

A study of this kind was made by Gonser et al.[59] for particles of the $MgFe_2O_4$ ferrite deposited on MgO. The particle size varied both with temperature and with the duration of heat treatment of the $MgO-Fe^{3+}$ system in which the ferrite particles were deposited. The form of the spectra suggested that particles with a volume $v = 0.5 \times 10^{-18}$ cm^3 (deposition temperature 700°C, time 15 min), 1.4×10^{-18} cm^3 (800°C, 20 min), and 9.7×10^{-18} cm^3 (800°C, 90 min) were obtained, the relaxation times of the magnetisation being respectively $\tau = 0.18 \times 10^{-9}$, 0.31×10^{-9}, and 14×10^{-9} s. The authors used the following expressions for the calculation:

$$\tau = \frac{a}{\omega}\exp\left(\frac{|K_1|\,v}{12\,kT}\right), \quad \omega = \frac{4}{3}\gamma\frac{|K_1|}{M_s},$$

where $a \simeq 1$, γ is the gyromagnetic ratio, K_1 the constant of anisotropy along the light magnetisation axis, M_S the spontaneous magnetisation, and v the volume of the particle. Cobalt-57 particles were deposited in copper and investigated by the same procedure[60].

Assuming that the magnetic structure of the spectrum disappears when $\tau = 3 \times 10^{-9}$ s[52] and that $K = 2 \times 10^5$ erg cm^{-3} for the face-centred cobalt lattice, Masu et al.[60] found the critical volume of the particles at different temperatures. The average particle size was 100 Å and at 335°K a paramagnetic spectrum was already observed ($T_C \simeq 1000$°K for cobalt).

Lindquist et al.[61] investigated highly dispersed nickel with a small admixture of cobalt-57 obtained in silica gel pores. The particle size was about 30 Å. The relaxation time at 300°K was found to be $\tau = 2 \times 10^{-9}$ s by comparing with the calculations of Wickman et al.[52] the form of the hyperfine structure for the paramagnetic Fe^{3+} ions in the Ferrichrome A lattice. Lindquist et al.[61] observed that, when an external magnetic field is applied, the hyperfine structure of the spectrum of the paramagnetic component of the superparamagnetic material appears.

Gen et al.[62] studied the magnetic properties of the FeNi (13% Ni) alloy and found that in particles 100 and 500 Å in diameter a magnetic α-phase and a non-magnetic γ-phase are present, while macroscopic specimens contain only the α-phase. The α-phase is magnetically ordered for particles with diameters < 100 and 500 Å. The study of the oxidation of such highly dispersed particles showed that, depending on the size, the relative proportions of the FeO, Fe_2O_3, and Fe_3O_4 phases change; the α-Fe_2O_3 and Fe_3O_4 phases are present in a highly dispersed state and have a reduced Néel point. The oxidation of the highly dispersed particles begins at 150°C, while that of macroscopic specimens takes place only at 500°C.

The study of the oxidation of highly dispersed systems permits the observation of the early stages in the oxidation, as was shown in the oxidation of highly dispersed β-tin[13]. The lowering of the Curie point to 600°K for the highly dispersed FeCo alloy (49% Co) with a particle size of 160 Å was observed. These particles were obtained by the aerosol method, which probably yields the purest specimens for the investigation of the magnetic properties of particles, since the effect of another phase (metal, oxide, silica gel), which probably operated in all other investigations, is excluded. Despite the fact that for ferromagnetic materials superparamagnetism begins to have an effect for particle sizes of about 200 Å, the critical thickness of the film for which the hyperfine structure of the spectrum vanishes at a given temperature is much smaller. Lee et al.[28] investigated ultrathin iron films with a thickness of 1.2–15 Å deposited on a silicon support. The magnetic field had the usual value for 15 Å and thicker films but began to diminish as the thickness was reduced further. The results show that T_C and K vary sharply when the dimensions of the film become equal to twice the lattice constant.

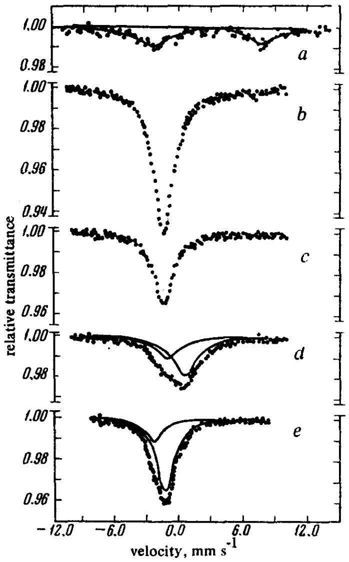

Figure 18. Spectra of gold-197 in the thermal decomposition of gold salts on η-Al_2O_3: *a*) $KAu(CN)_2$; *b*) and *c*) after high-temperature heat treatment; *d*) spectrum of $HAuCl_4$ after heat treatment at 140°K; *e*) spectrum after high-temperature heat treatment of $HAuCl_4$.

3. Topochemical Reactions

In the thermal or radiation-induced decomposition of a solid, the various phases interact and new substances are formed in a highly dispersed state and particles grow and become sintered. All these phenomena can be investigated very effectively by Mössbauer spectroscopy. Naturally, the results which we shall now discuss are directly related to the two fields dealt with previously, particularly to the preceding section. We shall divide topochemical reactions into two classes: (1) reactions in which the surface of the solid, which behaves as a carrier (for example silica gel or alumina), is involved and (2) reactions without a carrier.

Interesting studies of reactions of the first type were made by Delgass et al.[36] using the gold salts $KAu(CN)_2$ and $HAuCl_2$ on η-Al_2O_3 and MgO. The results of these investigations are presented in Fig. 18. The initial spectrum (*a*) of $KAu(CN)_2$ shows that, on drying at 140°C, the gold compound is not decomposed and spectra (*b*) and (*c*) demonstrate that, when the system is heat-treated in air, it is reduced to metallic gold. The spectra (*d*) for $HAuCl_4$ and η-Al_2O_3 at 140°C reveal the presence of metallic gold and a symmetrical gold complex and the spectrum (*e*) reveals, after heat treatment, yet another line, in addition to the line due to metallic gold.

An even more significant role of the carrier was noted in the studies of Hobson[42], Dunken et al.[63], and Arnold and Hobert[64]. Hobson[42] obtained iron(III) oxide by thermal decomposition of iron(III) nitrate and silica gel and alumina and the oxide was then reduced to hydrogen. He found that the distribution of Fe_2O_3 in η-Al_2O_3 with respect to particle size is wider than in the case of silica gel. Dunken et al.[63] observed that, after the thermal decomposition of $FeCl_3$ in alumina pores, only the superparamagnetic Fe_2O_3 phase is obtained when the percentage content of iron in alumina is varied from 0.125 to 9%, while Fe_2O_3 consisting of various phases (superparamagnetic and antiferromagnetic) was obtained in silica gel pores.

Among investigations of the second type, we may mention the studies on iron oxalates and hexacyanoferrates(III). Gallagher and Kurkijan[65] studied the thermal decomposition of the oxalates $Fe_2(C_2O_4)_3.5H_2O$, $Ba_3[Fe(C_2O_4)_3]_2.8H_2O$, and $Sr_3[Fe(C_2O_4)_3]_2.2H_2O$. With increase of temperature, divalent iron appears in all three compounds. The authors[65] found that at 300°C the highly dispersed Fe_2O_3 phase appears. Further increase of temperature leads to the appearance of the usual Fe_2O_3 phase. Heat treatment of strontium oxalate at 700°C and above resulted in the formation of an iron(IV) complex, while barium oxalate did not form such a complex.

Suzdalev and coworkers[66,67] investigated by Mössbauer spectroscopy and derivative plot analysis the thermal decomposition of iron(II) and iron(III) oxalates in an atmosphere of nitrogen. Fig. 19 shows differential plots and Mössbauer spectra for the decomposition of these oxalates. Iron(III) oxalate has three phase transitions at 200°, 280°, and 400°C, while iron(II) oxalate has only two: at 200° and 400°C. The first phase transition corresponds to the appearance of iron(II) oxalate with simultaneous dehydration. The third transition of iron(III) oxalate and the second transition of iron(II) oxalate correspond to the appearance of the Fe_3O_4 phase in the usual polycrystalline phase. The second phase transition in iron(III) oxalate corresponds to the formation of highly dispersed Fe_2O_4 with a particle size of about 100 Å.

The radiolysis of iron(III) oxalates[68] also indicates the formation of iron(II) oxalate. The spectrum of the latter does not alter on radiolysis. Probably the energy of the bond between iron and the lattice is higher in the divalent iron oxalate than in the trivalent iron salt. At a dose of 200 Mrad equilibrium is established between iron(II) and iron(III) oxalates. The growth of Fe_2O_3 particles in the second phase transition in the thermal decomposition of iron(III) oxalate was also investigated as a function of temperature as well as the kinetics of particle growth at a constant temperature[69].

The change in particle size was estimated from the change of the ratio of the area under the hyperfine structure to the area under the paramagnetic component corresponding to smaller particles. It was shown that, with increase of temperature from 240 to 280°C, the particle size increases and the contribution by the hyperfine structure rises also.

The results of the kinetic experiments show that at 240°C there is a slight increase in the contribution by the hyperfine structure over a period of 2–3 h and then no further changes are observed.

Probably heat treatment of the test substance at the same temperature leads to the establishment of a quasiequilibrium state, since equilibrium is established only as a result of the coalescence of smaller particles. At 240°C the growth of Fe_2O_3 particles begins, which, however, differ markedly in their dimensions and initially their system is not in equilibrium. In a study of the kinetics of particle growth, measurements were made of the relaxation times associated with the establishment of an average particle size. At higher temperatures equilibrium is established faster. As a result, the quasiequilibrium average particle size is related to a definite temperature and the actual particle size depends on the duration of the heat treatment.

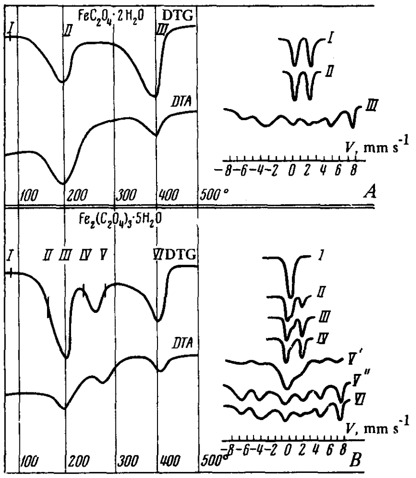

Figure 19. Differential plots (left-hand figure) and Mössbauer spectra (right-hand figure) obtained for the specimens at different temperatures: *A*) iron(II) oxalate; *B*) iron(III) oxalate.

The thermal decomposition of hexacyanoferrates was studied by Borshchagovskii et al.[70] using the compounds $LiY_8[Fe(CN)_6]_7.34H_2O$, $Sc_4[Fe(CN)_6]_3.xH_2O$, $Mn_2[Fe(CN)_6].6H_2O$, and $Sr_2[Fe(CN)_6].6H_2O$. All these compounds decompose by the same mechanism. At 160°C they are dehydrated and their spectra become somewhat wider, at 360°C iron atoms pass to the outer sphere, and at 760°C iron carbide (Fe_3C) is formed. By studying the kinetics, Borshchagovskii et al.[70] found that, after heat treatment for 2 h, metallic iron is formed from iron carbide.

In conclusion we shall consider the oxidation of highly dispersed tin (with particle sizes of 300 and 1000 Å).[14] It was shown that, up to the melting point of highly dispersed tin, its oxidation is hindered by the SnO_2 formed on the surface, but above the melting point the nature of the oxidation alters sharply. There is rapid formation of SnO, the proportion of which in material with a particle size of 300 Å becomes much greater than that of β-tin. However, up to 400 Å the spectra show the presence of unoxidised tin and for 1000 Å particles the amount of β-tin at an oxidation temperature of 300°C is greater than that of SnO.

These results show that up to 400°C the oxidation probably involves the reactions

$$2\,Sn + O_2 \rightarrow 2\,SnO,$$
$$2\,SnO \rightarrow SnO_2 + Sn,$$

and the reaction $2SnO + O_2 \rightarrow 2SnO_2$, a characteristic feature of which is the disappearance of SnO without the formation of β-tin, plays a very small role. About 400°C, this reaction begins to take place at a high rate and the entire tin is oxidised to SnO_2.

Electrophilic Substitution in the Series of Six-membered Nitrogen-containing Heteroaromatic Compounds and Their *N*-Oxides

Zh.I.Aksel'rod and V.M.Berezovskii

This review deals with the present state of the problem of electrophilic substitution in the series of six-membered nitrogen-containing heterocycles using as an example simple derivatives of neutral monoazines and diazines, their *N*-oxides, and certain condensed structures containing not more than 2 nitrogen atoms in one ring. Much attention has been devoted to problems of the comparison of the reactivities of heteroaromatic compounds with the results of theoretical calculations by the molecular orbital method and also the application of kinetic methods to the determination of the nature of the reactants. The bibliography includes 199 references.

CONTENTS

1. INTRODUCTION

The extensive data on the reactivities of various nitrogen-containing heterocycles have been comprehensively described in the literature. The problems of the chemistry and in particular the electrophilic substitution of heterocyclic compounds which are extremely important both theoretically and in practice, such as mono- and diazines (pyridine, pyrazine, pyrimidine, etc.), their benzo-derivatives (quinoline, quinoxaline, etc.), and also more complex condensed structures, containing together with nitrogen atoms also other heteroatoms (phenoxazine, phenothiazine, and others), have been discussed in detail in reviews edited by Elderfield[1], Weissberger[2], and Katritzky[3] and in a number of monographs[4-6].

Studies by Soviet scientists have made a valuable contribution to the development of the chemistry of nitrogen-containing heterocyclic compounds. In this connection, mention should be made of the work of Yur'ev[7,8], Rubtsov[9], Nesmeyanov and Kochetkov[10,11], Postovskii[12], and many others[13,14]. In recent years, considerable advances, associated primarily with the study of the mechanism of heteroaromatic substitution, have been made in research on the reactivities of nitrogen-containing heterocyclic compounds. These advances have been reviewed recently by Katritzky[15] and Ridd[16,17] and also in monographs by Schofield[18] and Palmer[19] based on data from both experimental and theoretical studies of the mechanisms of these reactions.

In the present review an attempt is made to examine in detail the results of investigations of electrophilic substitution in the series of six-membered aromatic nitrogen-containing heterocycles from the standpoint of modern concepts of reaction mechanisms and also to compare these results with the calculated indices of the reactivity of the compounds. Neutral model systems are chosen for discussion: pyridine and also pyridazine, pyrimidine, and pyrazine (i.e. heterocycles containing not more than two nitrogen atoms in the ring) and some of their condensed systems and *N*-oxides.

The electrophilic substitution reaction in the series of nitrogen-containing six-membered heteroaromatic compounds takes place under much more severe conditions than those involving the corresponding hydrocarbons, i.e. the replacement of a =CH group by the more electronegative nitrogen atoms leads to a decrease of reactivity in both the heterocyclic and the fused aromatic ring. Thus the ring nitrogen atom plays the role of an electron-accepting *meta*-directing substituent.

On the whole, electrophilic substitution in the heterocyclic series has much in common with substitution in the series of aromatic-hydrocarbons. The directive influence of substituents on electrophilic attack in the series of six-membered nitrogen-containing heteroaromatic compounds is qualitatively the same as for aromatic hydrocarbons. Thus powerful electron-accepting groups (NO_2, SO_3H, COOH) hinder electrophilic substitution of pyridine derivatives, while powerful electron-donating groups (OH, NH_2, OR, NR_2) greatly facilitate such reactions.

Quantitatively the effect of substituents is different for heterocyclic and aromatic systems. For example, comparison of the rates of nitration of chloro- and methoxypyridines and the corresponding substituted benzene derivatives shows that the same substituents exhibit greater conjugative effects in pyridine than in benzene[15].

The principal characteristic of electrophilic substitution reactions in the heteroaromatic series is that the attack by electrophilic agents may be directed to the nitrogen atom, by virtue of its *p*-electron pair (an analogous situation is encountered in the series of amino-derivatives of aromatic compounds). The ease of this reaction depends on the electron density at the nitrogen atom and also on steric factors.

As a result of electrophilic attack, the nitrogen atom acquires a positive charge, which strongly deactivates the carbon atoms in the ring. Calculation of the partial rate factors for the nitration and hydrogen isotope exchange reactions of substituted pyridine derivatives in neutral and protonated forms shows that the replacement of a =CH group in benzene by the $=\overset{+}{N}H-$ group deactivates the ring in the *meta*-position much more than the replacement by =N– (the rate constants for these reactions in the case of the protonated and neutral forms are reduced relative to the rate constants for the reactions of benzene by a factor of 10^{12}–10^{18} and 10^6–10^7 respectively)[20,21].

The effect of the nitrogen atom and the $=\overset{+}{N}H-$ group in pyridine on the reactivity of the ring carbon atoms can also be estimated quantitatively with the aid of Hammett's σ constants, with =N– and $=\overset{+}{N}H-$ regarded as ring substituents introduced into the benzene molecule[22].

	α	β	γ
$\sigma_{=N-}$	0.8	0.6	0.9
$\sigma_{=\overset{+}{N}H-}$	—	2.1	2.3

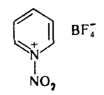
The constants quoted are smallest for the β-position, which is consistent with the *meta*-directing effect of the substituting groups in electrophilic substitution reactions. Moreover, all the $\sigma_{=N-}$ are smaller than $\sigma_{=\overset{+}{H}-}$, which is evidence of the greater reactivity of the neutral pyridine molecule compared with its cations. This is consistent with the conclusion based on the calculation of the partial rate factors for substitution in the pyridine series.

Experimental studies of the mechanism of electrophilic substitution in the heteroaromatic series permits solution of the problem of the nature of the reactive species—whether it is the free base or the species resulting from preliminary addition of a proton or the attacking agent to the nitrogen atom. These processes are frequently reversible and therefore even in weakly acid solutions there is a low equilibrium concentration of the free base. Furthermore, the predominant species present in solution is not always active, so that the nature of the reactive form of the compound may be established only by kinetic methods.

Since the mode of electrophilic substitution reactions in heterocyclic compounds, as well as in aromatic compounds, is determined by the state of the electron cloud in the molecule, the application of the molecular orbital theory permits the prediction of the preferred location of the substituent. For this purpose, one uses as the indices of reactivity the π-electron density, boundary π-electron density, localisation energy, etc.

2. SUBSTITUTION IN THE PYRIDINE SERIES

Electrophilic attack on unsubstituted pyridine is directed to the carbon atom in the 3-position. Pyridine is nitrated under very severe conditions—in oleum at 300°C—with a low yield (4.5%).[23] The kinetics of this process cannot be studied, since it has still not been established whether the result of this type of nitration is a consequence of the low reactivity of the positively charged pyridinium ion or whether the reaction involves the very small amount of the free base in the highly acid medium. The nitration of pyridine in a homogeneous aprotic medium at 30°C, using a solution of nitronium tetrafluoroborate (NO_2BF_4) in sulpholane (tetrahydrothiophen 1,1-dioxide), results in the formation of an *N*-nitropyridinium ion, as shown by ultraviolet and NMR spectroscopy[24]:



The sulphonation of pyridine also takes place in the 3-position under severe conditions (H_2SO_4–SO_3, 350°C).[25] Many electrophilic substitution reactions of pyridine derivatives are catalysed by salts of di- and ter-valent metals [$Hg(CH_3COO)_2$, $AlCl_3$, etc.], which can probably be accounted for by partial transfer of electron density from the coordinated metal atom to the nitrogen atom. This tends to decrease the formal positive charge of the nitrogen atom and consequently of the ring as a whole[26]. The use of optimum conditions for the sulphonation of pyridine—heating for 24 h in 20% oleum at 220–230°C in the presence of catalytic amounts of mercury(II) sulphate—leads to the formation of pyridine-3-sulphonic acid in 71% yield[27].

Gas-phase halogenation of pyridine at 300°C leads to the formation of 3-mono- and 3,5-di-halogeno-derivatives, while at 500°C 2-mono- and 2,6-di-halogeno-substituted compounds are formed[28]; probably in the latter case the reaction takes place not by an electrophilic but by a radical mechanism. Recently a method was described for the direct halogenation of pyridine in sulphuryl chloride or phosphorus oxychloride[29]. Thus bromination in the presence of one equivalent of sulphuryl chloride at 160–170°C gives a 45% yield of 3,5-dibromopyridine, while in phosphorus oxychloride the yield is about 20%. It is interesting to note that sulphuryl chloride is itself an electrophilic agent as a result of ionisation of the type $\overset{\delta+}{Cl}-\overset{\delta-}{SO_2Cl}$.[30]

Pyridine readily combines with mercury(II) acetate at 155°C, giving a 35% yield of 3-pyridylmercury acetate[31].

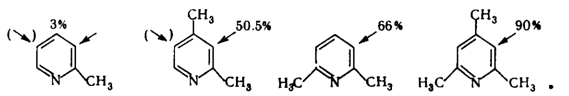
According to the LCAO-MO calculation[32,33], the electron densities q_r at the C_3 atom of pyridine and its cation is greater and the localisation energy for electrophilic substitution A_e smaller than the corresponding values for C_2 and C_4 (Table 1). Consequently electrophilic substitution of pyridine, both as a neutral molecule and in the protonated form, should be directed to the 3-position, in agreement with experiment.

Table 1. Indices of the reactivity of pyridine[32,33].

Structure	q_r, charge units	A_e $(-\beta)$	position of carbon atoms	A_e $(-\beta)$	q_r, charge units	Structure
	0.923 1.004 0.950	2.672 2.538 2.701	2- 3- 4-	2.709 2.560 3.071	0.759 1.012 0.835	
Note. This and other Tables present the results obtained by the simple Hückel method without taking into account adjacent orbital overlap, using the parameters $h = 0.5$ and $h' = 0$ for the tertiary nitrogen atom and $h = 2$ and $h' = 0.2$ for the secondary nitrogen atom[34]. It should be noted that the predicted positions of highest reactivity for a given heterocyclic compound obtained by this method and also by the more accurate self-consistent field calculations agree[33].

On the other hand, the correlation between the calculated data and the observed relative reactivities in the series benzene–pyridine–pyridinium cation is unsatisfactory. While the capacity for electrophilic substitution decreases on going from benzene to pyridine, the electron density at the C_3 carbon atom of pyridine is higher than for benzene ($q_r = 1$) and the localisation energy for the pyridine C_3 atom is lower than for benzene ($A_e = 2.540$); moreover, the electron density at the carbon atom in the 3-position increases on transition from pyridine to its cation.

Depending on the position of the activating group, substituted pyridine derivatives can undergo electrophilic attack in the $\alpha\alpha'$- or $\beta\beta'$-positions. The nitration of alkylpyridines takes place more readily than that of unsubstituted pyridine. Thus 2-mono-, 2,4-, and 2,6-di- and 2,4,6-tri-methylpyridines interact with potassium nitrate or nitric acid in sulphuric acid at 100–160°C with formation of 3-mononitro-derivatives (in the case of 2-picoline and 2,4-lutidine, as a result of the concerted directing effects of the CH_3 groups and the nitrogen atom, an equimolar mixture of 3- and 5-mono-nitrocompounds is obtained), the yield in these reactions increasing with the number of methyl groups in the pyridine molecule[35–37]:

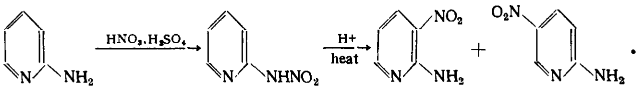


Nitration of the cation of 1,2,4,6-tetramethylpyridine in the 3-position takes place under the same conditions as the nitration of 2,4,6-trimethylpyridine and therefore the latter compound reacts in the protonated form[38]. This conclusion has also been confirmed by kinetic investigations.

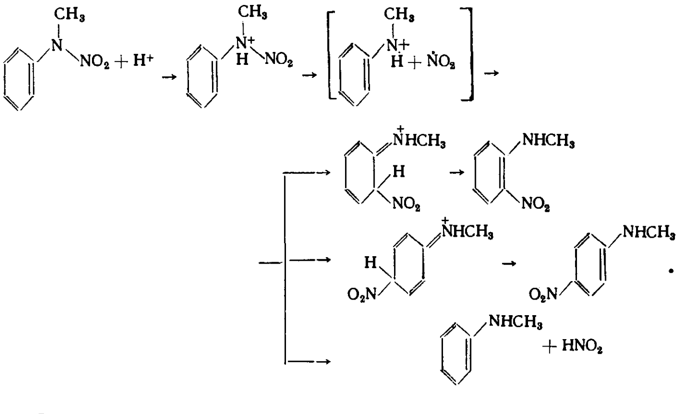
Katritzky and coworkers[21] established that the variation of the nitration rate constant with the acidity of the medium is similar for collidine and its N-methyl cation; the maximum possible rate constant for the reaction with participation of the free base, calculated on the basis of the transition state theory (2.26×10^9 litre $mole^{-1}$ s^{-1}), is much less than the experimental rate constant (1.6×10^{11} litre $mole^{-1}$ s^{-1}); finally, the entropy of activation for this reaction is −26.7 e.u. The theoretical entropy of activation should be higher for a reaction between two charged species (about −20 e.u.) than between a neutral molecule and a monocation[39]. All these data show that 2,4,6-trimethylpyridine enters into the nitration reaction in the protonated form.

Nitration of 3-bromopyridine as well as nitration of unsubstituted pyridine takes place under very severe conditions—with potassium nitrate in 10% oleum at 270°C in the presence of iron as a catalyst—and leads to the formation of 3-bromo-5-nitropyridine in 7% yield[40]. Thus the *ortho-para*-directing effect of the halogen atom in the pyridine series is less than the *meta*-directing effect of the ring nitrogen (or the $=\overset{+}{N}H$ group).

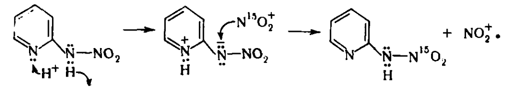
The presence in pyridine of the powerful electron-donating amino-group greatly facilitates electrophilic attack on the ring of the molecule. Nitration of 2-aminopyridine with nitric acid and sulphuric acid takes place in two stages: at 20°C and below 2-aminonitropyridine is formed initially and then at 40°C it undergoes endothermic rearrangement to a mixture of 2-amino-3-nitro- and 2-amino-5-nitropyridines in proportions of 1 : 8[41,42]:



The preferential substitution in the *para*-position relative to the amino-group in this reaction is evidence of an intermolecular or a partially intermolecular nature of the rearrangement. On the basis of a spectrophotometric determination of the amount of nitrous acid formed in the rearrangement of N-methyl-N-nitroaniline, it has been suggested[43] that the acid-catalysed rearrangement of the nitroamines takes place with dissociation of the $N{-}NO_2$ bond and the intermediate formation of two free radicals and therefore further reaction takes place not by an electrophilic but by a radical mechanism:



On the other hand, there are data supporting an intramolecular mechanism of the rearrangement. In a study of the rearrangement of α-nitroaminopyridine in sulphuric acid in the presence of sodium nitrate containing nitrogen-15, it was found that the labelled nitrogen enters into α-amino-β-nitro- and α-amino-β′-nitro-pyridines in a smaller amount than that remaining in the nitrate. The exchange of nitro-groups under these conditions probably involves a mechanism with electrophilic substitution at the amino-nitrogen, where a negative charge appears in consequence of the removal of a proton under the influence of two strongly electron-accepting groups[44]:



4-Aminopyridine is nitrated in the 3-position; the reaction also proceeds via a stage with rearrangement of the *N*-nitroamine but at a higher temperature (160°C). It is interesting to note that 3-nitroaminopyridine does not rearrange to the aminonitro-compound, while 3-(*N*-methyl-*N*-nitroamino)pyridine is readily converted into 3-methylamino-2-nitropyridine[45].

Table 2. Nitration of alkoxy- and hydroxy-pyridines with nitric acid.

		Reaction conditions		Position of entry of NO_2 group	Yield, %	Refs.
R	R′	medium	temp., °C

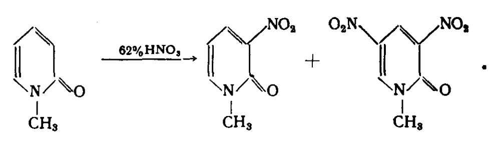
4-OH	3-CH_2CH_2Cl 6-OH	HNO_3(33%)	20	5-	48	60

For alkoxy- and hydroxy-pyridines, as for aminopyridines, the mode of the electrophilic substitution reaction is determined by the *ortho*-*para*-directing effect of the substituents present in the molecule. Table 2 presents data on the nitration of various alkoxy- and hydroxypyridines.

It is striking that in the nitration of 2-alkoxypyridines *para*-substitution takes place, while in the analogous reaction of 2-hydroxypyridines *ortho*-substitution is preferred. This difference in the mode of the nitration reactions of alkoxy- and hydroxy-derivatives of pyridine may be attributed to the tautomeric equilibrium of the hydroxy-compounds. Since 2-hydroxypyridine is present in solutions mainly in the oxo-form[61], it may also participate in the reaction in this form. This conclusion is confirmed by the preferred *ortho*-substitution in *N*-methyl-2-pyridone, which has a fixed lactam structure[51]:



Moreover, it has been established by kinetic methods that 4-hydroxypyridine, which like 2-hydroxypyridine is present in solutions in the pyridone form[61], enters into hydrogen isotope exchange in an acid medium in the oxo-form[62].

Another explanation of the *ortho*-nitration of 2-hydroxypyridine, namely that the substance reacts in the hydroxy-form and in the transition complex the NO_2 and OH groups are coordinated[63], appears to be unlikely.

The possibility in principle of the nitration of substituted pyridine in the γ-position relative to the heteroatom when the α-position is blocked was recently demonstrated by Dyumaev and coworkers[57] for 2-mono- and 2,6-di-alkyl-3-hydroxypyridines and then independently by De Selms[58] for 3-hydroxy-2-methylpyridine and 2-chloro-3-hydroxypyridine.

A systematic study of the kinetics of the nitration of a number of substituted pyridines in sulphuric acid enabled Katritzky and coworkers[64] to establish the following facts. In the nitration of more basic pyridines ($pK_a > +1$) containing electron-donating groups, the compounds react in the protonated form. Weakly basic pyridines ($pK_a < -2.5$) are nitrated as free bases. The behaviour of compounds with intermediate pK_a values has not as yet been investigated. The ring position occupied by nitro-groups is consistent with the general dependence on the type of substituents in the molecule.

Thus 2,6-dichloropyridine ($pK_a = -2.86$) is smoothly nitrated in the 3-position at 100°C.[21] At first sight this result is unexpected, since the chlorine atom in the benzene ring has a deactivating effect, but in the case of 2,6-dichloropyridine the reaction takes place via the free base, which is more reactive than the corresponding pyridinium cation[21]. In the case of 2,6- and 3,5-dimethoxypyridines, which are nitrated in the protonated form ($pK_a = 1.60$ and 4.44 respectively), the introduction of the first nitro-group reduces the basicity of substituted pyridines to such an extent that the mononitro-compounds formed ($pK_a = -3.86$ and -2.52) react further as free bases[21,64]:

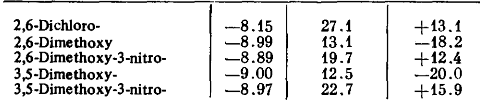


Table 3. Activation parameters for the nitration of substituted pyridine derivatives[21,64].

Substituted pyridine	H_0	E_a, kcal mole^{-1}	$\Delta S^{\neq}$, e.u.
2,6-Dichloro-	—8.15	27.1	+13.1
2,6-Dimethoxy	—8.99	13.1	—18.2
2,6-Dimethoxy-3-nitro-	—8.89	19.7	+12.4
3,5-Dimethoxy-	—9.00	12.5	—20.0
3,5-Dimethoxy-3-nitro-	—8.97	22.7	+15.9

The conclusions concerning the form in which chloro- and methoxy-pyridines are nitrated were based on a study of the kinetics of the processes, and in particular on the estimation of the activation parameters of these reactions (Table 3).

It follows from the data in Table 3 that all the above compounds may be divided into two groups with $\Delta S^{\neq}$ from +12 to +16 e.u. and from −18 to −20 e.u. This difference in activation entropy is evidence that they react by different mechanisms[39], namely that the compounds of the first group react as free bases and those of the second group in the protonated form.

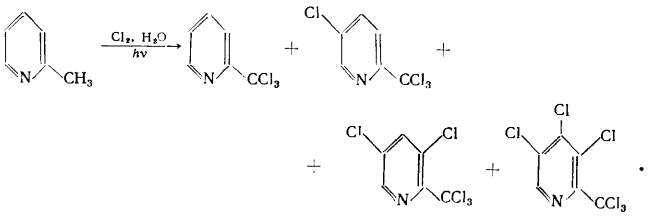
Comparison of the dependence of the nitration rate constants of substituted pyridines on the acidity of the medium with the theoretical dependence calculated for each of the possible reacting species on the basis that substituted pyridines are Hammett bases leads to the same conclusion[65].

The determination by kinetic methods of the form in which unsubstituted pyridine is nitrated is impossible. Most probably the reaction takes place as for methylpyridines, with participation of the pyridinium cation, since the pyridine nitrogen is fairly basic (for pyridine, pK_a = 5.23).[64]

A kinetic study of the mechanism of electrophilic substitution in the series of substituted pyridines has also been made in acid-catalysed hydrogen isotope exchange.

On heating, the tritilation of 2,6-lutidine and 2,4,6-collidine in a sulphuric acid–trityl ether mixture takes place in the 3- and 5-positions[20]. The study of the kinetics of these reactions showed that the protonated species are subjected to electrophilic attack; the reaction was shown to be pseudomonomolecular and to have an AS_E2 mechanism[20].

The halogenation of alkylpyridines as well as their nitration takes place under milder conditions than the halogenation of unsubstituted pyridine. Thus 2- and 4-picolines are readily brominated in the 3- and 5-positions at 80°C in the presence of aluminium chloride[26]. The chlorination of 2-picoline with chlorine water in the light involves homolytic substitution of the side chain and subsequent electrophilic substitution of the ring; under the same conditions, 3- and 4-picolines do not react[66]:



Bromination of monohalogenopyridines as well as their nitration requires more severe conditions. 2-Bromopyridine reacts with bromine in the gas phase at 300°C in the presence of an iron salt with formation of a mixture of 2,5-dibromo- and 2,3,5-tribromo-derivatives[28].

Halogenation of 2-aminopyridines takes place readily under mild conditions in the 5-position with formation of aminomonohalogenopyridines. Halogenation under severe conditions leads to 3,5-dihalogeno-derivatives. Thus *para*-substitution relative to the amino-group is preferred for 2-aminopyridines both in halogenation and in nitration (Table 4). 4-Aminopyridines are also halogenated in the 3- and 5-positions[68] and 3-aminopyridines in the 2- and 6-positions[69].

Halogenation of hydroxypyridines takes place under mild conditions. 2- and 4-Hydroxypyridines are readily brominated with bromine water, forming 3,5-dibromo-derivatives[70]. Bromination of 2,4-dihydroxypyridines under the same conditions leads only to the 3-monobromo-substituted compound. Analogous results were obtained in a study of the bromination of 2-ethoxy-4-pyridone and 4-ethoxy-2-pyridone—in these compounds the carbon atom between the carbonyl and ether groups is most reactive[71]. On the other hand, 2,4-diethoxypyridine is brominated in the 5-position, which may be associated with the steric screening of the carbon atom in the 3-position by the two ethoxy-groups[71].

In contrast to nitration, bromination of 3-hydroxypyridine takes place readily in aqueous solution at 20°C in the 2-, 4-, and 6-positions with formation of a tribromo-derivative (yield 50%).[72]

Table 4. Bromination of 2-aminopyridines with free bromine[67].

		Reaction conditions		Position of entry of bromide
R′	R″	medium	temp., °C	
CH_3	H	—		5-
H	CH_3	20 % H_2SO_4	0	5-
H	CH_3	20 % H_2SO_4	35	3,5-
CH_3	CH_3	—		5-
Br	H	CH_3COOH	0	5-
Br	H	CH_3COOH	20	3,5-
H	Br	CH_3COOH	0	5-; 3,5-
Br	Br	CH_3COOH	0	5-; 3,5-
C_2H_5	H	H_2SO_4	100	3,5-

Sulphonation of alkylpyridines takes place under the same conditions (20% oleum, 220°C, $HgSO_4$ catalyst) as that of unsubstituted pyridine but with a lower yield (for example, the yields of monosulphonic acids for 2-, 3-, and 4-picolines are 60, 23, and 40% respectively[37]), owing to a side reaction involving the oxidation of the alkyl groups in concentrated sulphuric acid. The position of the sulpho-group is determined by the *meta*-directing effect of the ring nitrogen atom, since only the 5-sulphonic acid is obtained from 3-picoline on sulphonation. In contrast to nitration, sulphonation of 2-picoline also takes place only in the 5-position. In all probability, under the above sulphonation conditions, picoline reacts in the protonated form. If one excludes the possibility of protonation, then substitution of the hydrogen atom takes place under much milder conditions. Thus 2,6-di-t-butylpyridine with a sterically screened nitrogen atom is readily sulphonated with sulphur trioxide in the 3-position at −10°C.[73]

In the sulphonation of aminopyridines substituted in different positions the location of the sulpho-groups is the same as in halogenation, but only monosulphonic acids are formed[74].

3. SUBSTITUTION IN THE DIAZINE SERIES

Diazines are more inert in electrophilic substitution reactions than monoazines let alone benzene. In the pyrimidine molecule the 5-position is most aromatic, which is consistent with the calculations of electron densities q_r and localisation energy A_e for this compound in both neutral and protonated form. In pyrazine and pyridazine molecules, where the nitrogen atoms are in the *para*- and *ortho*-positions relative to one another, the electronegative effects of both are not concerted and their resultant effect is much weakened. According to calculations, the electron charge q_r at any carbon atom in pyrazine and pyridazine, in both the neutral molecule and the cation, is higher than in the 2- and 4-positions but lower than in the 5-position of pyrimidine (Table 5).

The reactivity of unsubstituted pyrimidine is extremely low; for successful nitration, nitrosation, and sulphonation, the pyrimidine molecule must contain at least two activating electron-donating groups[77]. Thus 2- or 4-hydroxypyridine is not nitrated. 2,4-Dihydroxypyrimidine (uracil) is nitrated in boiling fuming nitric acid in the 5-position[78]. 4,6-Dihydroxypyrimidine and its derivatives are also nitrated in the 5-position but under milder conditions—in acetic acid at 20°C. This difference may be associated with the state of tautomeric equilibrium involving these dihydroxypyrimidines—it has been established by numerous spectroscopic studies that, while 2,4-dihydroxypyrimidine exists preferentially in the diketo-form, 4,6-dihydroxypyrimidine has one phenolic and one oxo-group[79]:

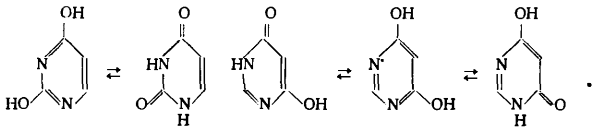


Table 5. Indices of the reactivities of pyrimidine, pyrazine, and pyridazine[32,33,75,76].

Neutral form	q_r, charge units	A_e (−β)	Position of carbon atom	A_e (−β)	q_r, charge units	Protonated form
	0.845 0.874 1.009	2.865 2.691 2.539	2- 4- 5-	3.456 3.146 2.579	0.467 0.632 1.029		0.926	2.664	2-	2.667	0.735		0.970 0.982	—	3- 4-	—	0.866 0.922	
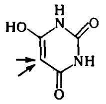
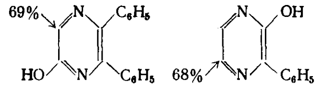
When the pyrimidine molecule contains together with the hydroxy-group also an amino- or alkylamino-group, nitration takes place in the 5-position at 50–60°C (nitric acid in sulphuric acid)[80,81].

For successful halogenation of pyrimidine derivatives, it is sufficient if one hydroxy or amino-group or two alkoxy-groups are present in the 2-, 4-, or 6-positions[82]. Halogenation takes place readily in the 5-position on heating with halogenosuccinimide in acetic acid or chloroform[82].

The halogenation of 2,4-dihydroxypyrimidine (uracil) and 2,4,6-dihydroxypyrimidine (barbituric acid) takes place in a more complex manner. On halogenation, barbituric acid gives rise initially to 5-mono- and then 5,5-di-halogeno-substituted compounds. The mechanism of this reaction has not been completely elucidated—it may involve the addition of HOHal to the double bond between the C_4 and C_5 atoms with subsequent dehydration[77]. Uracil usually yields monohalogeno-derivatives, but bromination in an aqueous medium yields 5,5-dibromo-2,4,6-trihydroxy-4,5-dihydropyrimidine[83], i.e. initially there is substitution in the 5-position accompanied by 4,5-addition[84]. This reaction differs fundamentally from the halogenation of barbituric acid:

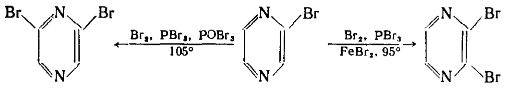


Electrophilic substitution in the pyrazine series, as in the pyrimidine series, usually requires the presence in the molecule of activating hydroxy- or amino-groups[85]. Thus arylpyrazines are nitrated in the benzene ring while the nitration of 2-hydroxy-5,6-diphenylpyrazine with fuming nitric acid in acetic acid at 25°C takes place in high yield in the 3-position of the pyrazine ring[86]. 2-Hydroxy-3-phenylpyrazine is nitrated under the same conditions in the *para*-position relative to the hydroxy-group[87]:



The halogenation of pyrazine can take place also in the absence of activating groups in the molecule, but under very severe conditions—in the vapour phase at 400°C.[88] Bromopyrazine is obtained also when pyrazine hydrobromide is treated with bromine in an inert solvent: the reaction results initially in the formation of a perbromide, which on heating to 200–250°C rearranges to 2-bromopyrazine[89].

Depending on the reaction conditions, the bromination of monobromopyrazine takes place in different positions in the molecule and leads to 2,3-[90] or 2,6-dibromo-derivatives[91]:



The mode of halogenation of hydroxypyrazines is determined by the *ortho–para*-directing effect of the hydroxy-group. Thus 2-hydroxy-3-methylpyrazine is brominated with bromine in chloroform in the 5-position (yield 20%); under the same conditions, 2-hydroxy-5,6-dimethylpyrazine gives the 3-bromo-derivatives (yield 61%), while 2-hydroxy-3,5-dimethylpyrazine is not brominated at all[87].

Substitution in the pyridazine series has been inadequately investigated. The pyridazine ring is very resistant to electrophilic substitution reactions. Powerful nitrating agents either have no effect at all on pyridazine or cause it to char[92]. 3-Pyridazinone also does not change under the action of the nitrating mixture, probably because of the low reactivity of the cation formed[93]. The introduction of a nitro-group into the pyridazine molecule takes place successfully only when amino-derivatives are employed and involves the rearrangement of the corresponding nitroamines. Thus nitration of 4-amino-3-methoxy-6-methylpyridazine with potassium nitrate in sulphuric acid at 20°C takes place in the 5-position[93], while 3,5-diaminopyridazine is nitrated in the 4-position[94].

Chlorination of 6-methyl-2-phenyl-3-pyridazinone with phosphorus pentachloride at 160°C leads mainly to the 4-chloro-derivative[95], while 3,6-dichloropyridazine forms with phosphorus pentachloride the 3,4,5,6-tetrachloro-derivative[96]. Under these conditions, 2,6-dimethyl-3-pyridazinone is not chlorinated and on reaction with chlorine at 100°C is substituted in the 5-position[97].

4. SUBSTITUTION IN THE BENZOMONOAZINE (QUINOLINE, ISOQUINOLINE, ACRIDINE) SERIES

In heteroatomic compounds containing a condensed benzene ring electrophilic substitution may take place both in the benzene and in the heterocyclic ring, depending on the reaction conditions.

In sulphuric acid quinoline is substituted in the 5- and 8-position. Nitration of quinoline with fuming nitric acid in concentrated sulphuric acid at 0°C yields a mixture of almost equal amounts of the 5- and 8-mononitro-derivatives[98].

Quinoline is nitrated faster than pyridine because of the presence of the condensed benzene ring; the rate of this process can be readily measured. The considerable rate of reaction (higher by a factor of 10^2 than expected for a diffusion-dependent process with participation of the free base) and the variation of the reaction rate constant with the acidity of the medium in the range 85–98% sulphuric acid are evidence that the nitronium cation reacts with the protonated species—the quinolinium cation[99]. The participation of quinoline in the nitration reaction as a protonated species is consistent also with the calculated entropy of activation for this reaction (−9.3 e.u; see p. 629) and is confirmed by a comparison of the rates of nitration of quinoline and the methylquinolinium ion[100].

Table 6. Indices of the reactivity of quinoline[98,101,102].

Neutral form	q_r, charge units	A_e * $(-\beta)$	Position of carbon atom	A_e ** $(-\beta)$	q_r, charge units	Protonated form
	0.896	2.725	2-	4.75	0.690		1.008	2.487	3-	1.97	1.267	
	0.932	2.500	4-	3.63	0.787	
	0.988	2.350	5-	1.82	0.967	
	1.003	2.475	6-	1.97	1.078	
	0.984	2.544	7-	2.26	0.950	
	1.012	2.306	8-	1.60	1.346	

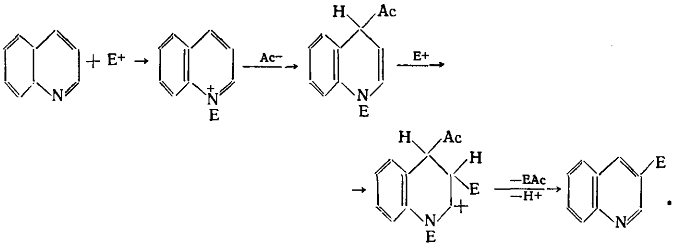
* Data presented in a graphical form.

** The energy data (in kcal mole^{-1}) have been expressed in units of $-\beta$, assuming that $\beta = 6$ kcal mole^{-1}.

It is noteworthy that the location of electrophilic substituents in the quinolinium cation is in good agreement with the calculated localisation energies for electrophilic substitution (A_e is a minimum for the 5- and 8-positions) but is in much worse agreement with the distribution of electron densities in this system (Table 6).

Calculation of the partial rates of nitration of quinoline and naphthalene in an acid medium shows that the 5- and 8-positions of the quinolinium ion are deactivated compared with the 1-position of naphthalene by a factor of 10^{10}. This result differs from the data obtained by the calculation of the localisation energy, which shows that the 5- and 8-positions of the quinolinium ion are less reactive than the 1-position of naphthalene by a factor of 5 and 100 respectively[99]. Probably the methods employed to calculate the localisation energy to a large extent underestimate the effects of the heteroatom of the aromatic system.

In the nitration of quinoline with nitric acid in acetic anhydride a low yield (about 6%) is obtained of 3-nitroquinoline and traces (0.7%) of the 6- and 8-isomers[103]. Probably under these conditions the non-protonated form mainly reacts; then the distribution of π-electron densities in the neutral quinoline molecule correctly indicates the location of the substituent in the 3-, 6-, and 8-positions but is inconsistent with the relative amounts of the isomers (3 > 6 and 8). This finding can be readily explained if one assumes that the reaction involves an addition–elimination mechanism, i.e. initially there is 1,2- or 1,4-addition of a weak nucleophilic agent (acetyl anion) and then substitution in the dihydroquinoline system[103]. Since this system does not have a positive charge, one may expect on substitution a correlation between the reactivity and the distribution of π-electron density. Calculations for 1,2-dihydroquinoline yields the following sequence of the decrease of π-electron density: 8 > 6 > 3, and for 1,4-dihydroquinoline: 3 > 6 > 8.[101] Thus the proposed mechanism for electrophilic substitution in the neutral quinoline molecule involves a preliminary 1,4-addition stage:



In the halogenation of quinoline the location of the substituent depends on the acidity of the medium, as happens in the nitration reaction. Thus, in the bromination of quinoline in sulphuric acid substitution takes place in the 5- and 8-positions[104] and in acetic acid in the 3-, 6-, and 8-positions[105]. Hence by varying the experimental conditions for the electrophilic substitution reaction, it is possible to obtain a number of quinoline derivatives differing in the positions of the substituents (Table 7).

Table 7. Bromination of quinoline[106].

Position of substituent	Yield, %	Reaction conditions
2-Bromo-	(50—60)	Br_2, 500°C, vapour phase
3-Bromo-	(91)	Br_2, CCl_4, pyridine, heat
6-Bromo-	(~2)	
4-Bromo-		heat treatment of 3-bromoquinoline hydrobromide, 300°C
5-Bromo-	(28)	Br_2, Ag_2SO_4, H_2SO_4
8-Bromo-	(29)	
1,1-Dibromo-	(~100)	Br_2, CCl_4, in the cold
3,6-Dibromo-	(35)	Br_2, glacial CH_3COOH
3,6,8-Tribromo-		
5,8-Dibromo	(43)	$2Br_2$, Ag_2SO_4, H_2SO_4
5,6,8-Tribromo-		$3Br_2$, Ag_2SO_4, H_2SO_4

Depending on temperature, the sulphonation of quinoline (200–300°C) yields quinoline-5-, quinoline-6-, quinoline-7-, and quinoline-8-sulphonic acids or their mixture[107], the formation of these derivatives being probably determined by the stability of the quinolinium ion.

Quinoline substituted in the benzene ring usually directs electrophilic agents to the 5- or 8-position in an acid medium regardless of the nature of the substituent already present. Thus, electrophilic substitution of 8-hydroxyquinoline—halogenation, sulphonation, nitrosation, and mercuration—takes place preferentially in the 5-position, while under more severe conditions 5,7-disubstitution takes place. It is interesting that in the direct nitration of 8-hydroxyquinoline with 37% nitric acid in sulphuric acid at 20°C it is impossible to isolate the mononitro-compound, only 8-hydroxy-5,7-dinitroquinoline being obtained in 57% yield[108].

The presence of substituents in the pyridine ring of quinoline can alter significantly the position of the reaction centre relative to unsubstituted quinoline. Thus 4-hydroxyquinoline is nitrated in sulphuric acid as the protonated species, largely with formation of the 6-nitro-derivative[109].

Electrophilic substitution in two different positions has been observed for isoquinoline, as for quinoline. Nitration of isoquinoline by fuming nitric acid in concentrated sulphuric acid at 0°C gives a mixture of 5- and 8-mononitroisoquinolines, the 5-nitro-isomer predominating considerably (90.4%)[98], while under more severe conditions only the 5,7-dinitro-compound is formed. In the study of the kinetics of the nitration of isoquinoline it has been established that the reaction takes place with participation of the protonated form of isoquinoline, as in the nitration of quinoline. The simultaneous nitration of a quinoline–isoquinoline mixture shows that the ratio of the reactivities of these compounds is 1 : 24.5. [98]

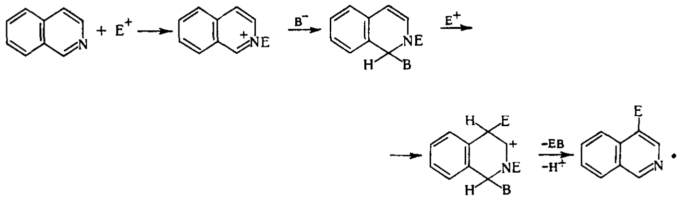
The fact that the reactivity of isoquinoline in electrophilic substitution reactions is higher than that of quinoline follows also from a comparison of the conditions for the sulphonation of these compounds. Isoquinoline is sulphonated under milder conditions (40% oleum, 180–200°C) than quinoline, and only isoquinoline-5-sulphonic acid is formed[110].

The location of the nitro- and sulpho-groups in the 5-position in the nitration and sulphonation of isoquinoline in a strong acid is in good agreement with the calculated localisation energies A_e for electrophilic substitution (Table 8).

Table 8. Indices of the reactivity of isoquinoline[98,111].

Position	 q_r, charge units	 A_e, kcal mole^{-1}
1-	0.844	—21.8
3-	0.943	—13.5
4-	0.973	—13.0
5-	1.001	—9.5
6-	0.968	—13.5
7-	0.992	—11.8
8-	0.971	—10.9

The mercuration of isoquinoline with mercury(II) acetate at 150–160°C takes place smoothly in the 4-position[112]; bromination takes place in the same position when isoquinolinium perbromide or its salts are heated[113]. Substitution in the 4-position is inconsistent with the distribution of electron densities q_r in the neutral isoquinoline molecule—calculation shows that the electron densities decrease in the sequence $5 > 7 > 4 \simeq 8$ (Table 8). The experimentally observed mode of reaction can be accounted for by a 1,2-addition mechanism:



Calculation of the distribution of π-electron density in the 1,2-dihydrocation yields a higher value for the 4-position[34].

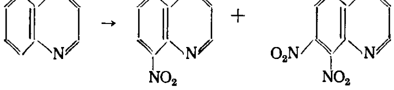
Table 9. Indices of the reactivity of acridine[98,115].

Position	 q_r, charge units	 A_e, kcal mole^{-1}
1-	0.984	—12.4
2-	1.005	—9.0
3-	0.979	—16.4
4-	1.016	—7.3
9-	0.915	—21.1

Substitution in the acridine series has been investigated in less detail. Nitration of acridine in sulphuric acid gives a mixture of 13% of the 4- and 68% of the 2-mononitro-derivative and a certain amount of 1- (3%) and 3-isomers (< 1%)[114]. This ratio of the 2- and 4-substituted compounds is unexpected, since it is inconsistent either with the distribution of π-electron density or with the localisation energies (Table 9). The reaction probably proceeds via the protonated form of the acridine molecule[98]. Evidently the above calculations fail to take adequate account of the inductive effect of the nitrogen atom in the α-position of the acridine molecule.

5. SUBSTITUTION IN THE BENZODIAZINE (QUINOXALINE, PHENAZINE, CINNOLINE, QUINAZOLINE) SERIES

Quinoxaline is resistant to nitration under mild conditions; when it is treated with fuming nitric acid in oleum at 90°C for 24 h, 1.5% of 5-mononitroquinoxaline and 24% of 5,6-dinitroquinoxaline are obtained[116]. The location of the electrophilic agent in the 5-position agrees well with calculated data (Table 10). It is interesting to note that the second nitro-group enters the *ortho*-position and not the *meta*-position relative to the first:



The presence of polar substituents in both the pyrazine and the benzene ring of quinoxaline favours electrophilic substitution. Nitration of 6-methoxyquinoxaline with potassium nitrate in sulphuric acid at 0°C takes place readily in the 5-position; 5-methoxyquinoxaline yields on nitration the 6,8-dinitro-derivative, and it is impossible to isolate the mononitro-compound[117].

The location of the substituent in the nitration of 2-hydroxyquinoxaline, which is a very weak base ($pK_a = 1.37$), depends on the acidity of the medium; in acetic acid the 7-nitro-derivative is obtained[117], while in sulphuric acid the product is the 6-isomer[118]. Possibly the neutral molecule is nitrated in acetic acid and the monocation in sulphuric acid:

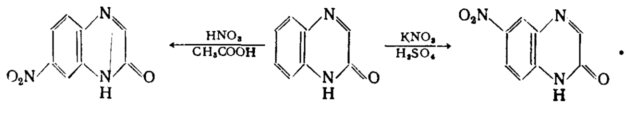


Table 10. Indices of the reactivities of quinoxaline and phenazine[98,102,111].

Structure	Neutral form q_r, charge units	Dication A_e, kcal mole^{-1}	Position of carbon atom	Dication A_e, kcal mole^{-1}	Neutral form q_r, charge units	Structure
			1-	—13.5	0.991		0.902	—31.8	2-	—17.9	0.955	
	1.002	—13.3	5-			
	0.987	—16.8	6-			

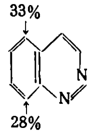
Substitution in the 6-position is observed also when quinoxaline-2,3-dione is treated with potassium nitrate in sulphuric acid; in the presence of an excess of the nitrate, the 6,7-dinitro-derivative is formed[119]. When quinoxaline is refluxed in aqueous nitric acid, the product is 6-nitroquinoxaline-2,3-dione, probably in consequence of the oxidation of quinoxaline and subsequent nitration of quinoxaline-2,3-dione[120].

Like quinoxaline, phenazine (Table 10) reacts with electrophilic agents only under very severe conditions. The α-carbon atoms are reactive in this case, in full agreement with calculation. Probably both quinoxaline and phenazine interact in the protonated form with electrophilic agents in an acid medium.

The nitration of phenazine with a mixture of nitric acid ($d = 1.42$) and sulphuric acid at 130°C gives 1-nitrophenazine in 1.5% yield. It is striking that in the nitration of phenazine under conditions corresponding to the synthesis of dinitro-derivatives, the nitro-groups enter into different benzene rings. Thus in the reaction with sulphuric acid with a tenfold excess of nitric acid ($d = 1.48$) at 70°C, a mixture of 1,5- and 1,8-dinitrophenazines is formed in 80% yield[121].

When phenazine derivatives with electron-donating substituents in the β-position are nitrated, the nitro-group enters the α-position adjacent to the substituent already present; in the nitration of substituted phenazines with electron-donating substituents in the α-position, the nitro-group enters the *para*-position relative to the substituent already present, with formation of 1,4-substituted phenazine derivatives[121].

Substitution reactions in the cinnoline and quinazoline series have been investigated much less than in the quinoxaline series and in the phthalazine series they are altogether unknown. Nitration of cinnoline with fuming nitric acid in concentrated sulphuric acid between −5° and 20°C yields a mixture of almost equal amounts of the 5- and 8-nitrocinnolines:



Under the same conditions, 4-methylcinnoline gives only the 8-nitro-derivative in 49% yield[122].

By comparing the rates of nitration of the 2-methylcinnolinium, 2-methylisoquinolinium, and isoquinolinium cations, it has been shown that in 76–83% sulphuric acid cinnoline is nitrated as the cation[123]. It is known that the cinnolinium monocation is formed with the positive charge in the 2-position[124]. The non-protonated nitrogen atom (N_1) deactivates the system of the cinnolinium cation to a greater extent than that of the isoquinolinium cation by a factor of 2×10^2 and the carbon atom in the 5-position is deactivated more than in the 8-position[123]. This leads to an increase in the amount of the 8-nitro-isomer in the nitration of cinnoline compared with the amount of the nitro-derivative formed in the nitration of isoquinoline.

The location of nitro-groups in the nitration of cinnoline agrees well with the distribution of π-electron density in the neutral molecule of this compound and the localisation energy of its cation (Table 11).

Table 11. Indices of the reactivities of cinnoline and quinazoline[98,102].

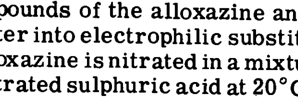
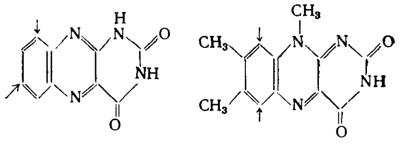
In contrast to the nitration of quinoline and isoquinoline, quinazoline is nitrated in an acid medium in the 6-position[125], which agrees poorly with theoretical calculations (Table 11). However, in a study of ultraviolet spectra of quinazoline solutions in sulphuric acid it has been established that the quinazolinium cation readily undergoes covalent hydration[126] and consequently electrophilic substitution in the hydrated cation takes place in the *para*-position relative to the NH group:



It is noteworthy that, among more complex condensed structures, compounds of the alloxazine and isoalloxazine series readily enter into electrophilic substitution reactions. Unsubstituted alloxazine is nitrated in a mixture of fuming nitric and concentrated sulphuric acid at 20°C with formation of the 6- and 8-mononitro-derivatives in proportions of 2 : 3, while in the nitration in oleum at 70°C 6,8-dinitroalloxazine is obtained[127]. This mode of the alloxazine nitration reaction corresponds to the distribution of π-electron density in the neutral alloxazine molecule[128]: there are no calculated data available in the literature for protonated structures of this series.

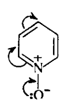


6,7-Dimethyl-substituted alloxazines and isoalloxazines are nitrated in the 5- and 8-positions under mild conditions[129].

6. ELECTROPHILIC SUBSTITUTION OF HETEROAROMATIC *N*-OXIDES

Substitution reactions in the series of *N*-oxides of nitrogen-containing heterocyclic bases, which are unusually reactive, are of particular interest. Linton[130], Jaffé[131], and Katritzky et al.[132] demonstrated the presence in heterocyclic *N*-oxides of two opposed electronic effects due to the electron-accepting properties of the positively charged nitrogen atom on the one hand and the conjugation of the free electron pair of the oxygen atom in the N→O group with the π-electrons of the ring on the other. By virtue of the dual effect of the *N*-oxide group on the electronic structure of the heteroaromatic ring, electrophilic and nucleophilic substitution in this series may involve the same position in the molecule[133,134].

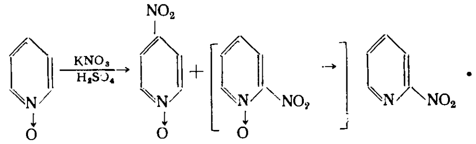
At the instant of the electrophilic substitution reaction, the *N*-oxide group in the neutral molecule is readily polarised and exhibits at the same time electron-donating properties and a *para*-orienting effect. An electrophilic agent may attack the ring of the *N*-oxide in the α- or γ-position, where, by virtue of the positive effect of conjugation, an enhanced electron density is created. However, the reaction in the γ-position should take place particularly readily, since the effect of conjugation in the α-position is partially compensated by the opposed inductive effect of the neighbouring nitrogen atom:



The presence of the N→O group in the molecule not only alters the mode of substitution in the initial heterocycle but also facilitates electrophilic substitution.

Tupitsyn and coworkers[135] investigated the kinetics of base-catalysed deuterium exchange involving methyl groups in isomeric picolines, quinaldines and their *N*-oxides, reactions which simulate electrophilic substitution in a side-chain of heterocycles, and showed that the *N*-oxides undergo exchange much faster than the non-oxidised bases. The authors discovered the main features of the mechanism of the transmission of the electronic effects of the heteroatoms on the reaction centre[136,137]. Similarly reactions involving substitution of the ring hydrogen atoms are faster with the *N*-oxides than with the initial heterocycles.

Indeed, in contrast to the nitration of pyridine, the nitration of pyridine *N*-oxide with potassium nitrate in sulphuric acid at 100°C takes place in the 4-position in 94% yield[138]. It is noteworthy that this involves the formation also of a small amount (1.5–4%) of 2-nitropyridine, probably in consequence of the reduction of its *N*-oxide[139]:

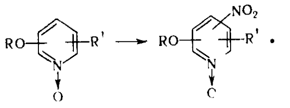


The *N*-oxides of alkyl- and halogeno-substituted pyridines are smoothly nitrated in the 4-position. Thus the *N*-oxides of 2-mono- and 2,6-di-methyl-[138], chloro[140,141], and bromo-pyridines[142,143] are nitrated with nitric acid in sulphuric acid at 90–100°C with formation of 4-nitro-derivatives as the sole reaction products. The same mode of substitution is noted also in the nitration of the *N*-oxides of 3-alkyl-, 3,5- or 2,5-dialkyl-[144–146], or 3-halogeno-pyridines[147,148] under identical conditions. Thus the strong *para*-directing effect of the *N*-oxide group is shown in these reactions.

The *N*-oxides of 2,4-lutidine and 2,4,6-collidine, where the 4-position is blocked by an alkyl group, are resistant to nitration under similar conditions[149].

It is interesting to note that, in the presence of the bulky t-butyl group in the 3-position of pyridine *N*-oxide, nitration takes place not in the γ-position but in the α-position and subsequent reduction leads to 3-t-butyl-2-nitro- or 3-t-butyl-6-nitro-pyridines; the isopropyl group does not show this type of effect[150].

Table 12. Nitration of the *N*-oxides of alkoxy- and hydroxy-pyridines with nitric acid



OR	R′	Reaction conditions		Position of entry of NO_2 group	Yield, %	Refs.

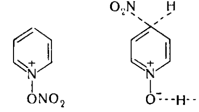
* With simultaneous de-oxidation of the *N*-oxide.

In electrophilic substitution reactions in the series of pyridine *N*-oxides the directing effect of the N→O group is greater than that of the alkoxy-group but smaller than the effect of the hydroxy-group. This is consistent with substitution in the 4-position in the *N*-oxides of alkoxy-pyridines and in the 2- or 3- and 5-positions of the *N*-oxides of hydroxy-derivatives of pyridine (Table 12).

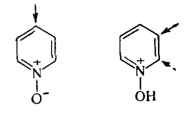
It is striking that in the presence of two alkoxy-groups in the 3- and 5-positions, substitution takes place at the C_2 and C_6 carbon atoms[157,158], the authors explaining this effect by the steric hindrance arising when the substitution reaction involves the 4-position. However, subsequently, using kinetic methods, it was shown that the difference in the location of the nitro-group in the *N*-oxides of 2- [2–6? (Ed. of Translation)] and 3,5-dialkoxypyridines is due to the fact that they undergo nitration in different forms[159].

It should, however, be noted that the mechanism of electrophilic substitution reactions in the series of pyridine *N*-oxides cannot be regarded as finally elucidated. The conclusions drawn from the study of the kinetics of the reactions may be contradictory when they are based on different kinetic criteria for the determination of the nature of the reactant. Thus Schofield and coworkers[160] showed that the *N*-methoxypyridinium cation does not react with nitric acid in 88% sulphuric acid at 95–125°C, i.e. under conditions where the *N*-oxide of pyridine is readily substituted in the γ-position. Probably the neutral molecule of the *N*-oxide participates in the latter reaction.

Subsequently, on the basis of a study of the dependence of the rate constant for the nitration of the *N*-oxide of 2,6-dimethylpyridine in the 4-position on the acidity of the medium, it was shown that the *N*-oxide of 2,6-lutidine is also nitrated as the neutral molecule[161]. The following activation parameters are quoted for these reactions: $E = 23.9$ kcal mole^{-1} and $\lg A = 10.7$ at 25°C in 81.4% sulphuric acid[161]. However, subsequently the same authors' calculations showed that the theoretical value is $\lg A = 4$ for this process and is even smaller when the *N*-oxide reacts in the protonated form[162]. Therefore it is possible that the reaction takes place either with formation of a pre-equilibrium *O*-nitro-complex, which then slowly rearranges to the 4-nitro-compound, or the nitronium cation is bound to the C_4 carbon atom of the pyridine ring and the proton is removed synchronously from the *N*-oxide group[162]:



On the other hand, in a study of the kinetics of the nitration of a number of substituted *N*-oxides of pyridine, Katritzky and coworkers[159] concluded that in the case of substitution in the 4-position *N*-oxides react as the free bases and in the case of 2- or 3-substitution as the protonated species:



The conclusion that in the nitration in the 4-position the *N*-oxides of substituted pyridines react as the free bases is confirmed also by the finding that the entropy of activation for these compounds (Table 13) is much lower than −20 e.u., i.e. the theoretical entropy of activation for the reaction of two charged species[39]. The estimation of the absolute reaction rates leads to the same conclusion: the experimental rate of nitration of the above *N*-oxides (10^{-1}–10^{-5} litre mole s^{-1}) is much lower than the limiting rate of the diffusion process with participation of the free bases (8.5×10^8 litre mole s^{-1}).

The kinetics of the nitration of the *N*-oxides of substituted pyridines in the β-position have been investigated for the *N*-oxides of 2,4,6-trimethoxy-, 2,6-dimethoxy-, and 4-methoxy-2,6-dimethylpyridines and the kinetics of α-nitration have been studied for the *N*-oxides of 3,5-dimethoxy- and 3,5-dimethoxy-2-nitropyridines[159].

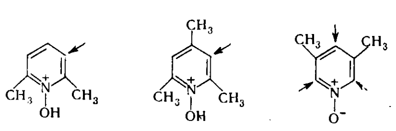
Examination of the dependence of the rate constants for α- and β-nitration on the acidity of the medium established that in all the examples quoted *N*-oxides react in the protonated form. For substitution in the α-position, this is also confirmed by a comparison of the rates of nitration of the *N*-oxides of 3,5-dimethoxypyridine and the 1,3,5-trimethoxypyridinium cation (this method has not been used for β-substitution).

The activation parameters have been determined for the nitration of substituted pyridine *N*-oxides in the α- or β-positions, as for γ-nitration (see above) (Table 13). The entropies of activation in the β-position ($\Delta S^{\neq}$ between −17 and −26 e.u.) agree well with the expected value of $\Delta S^{\neq}$ for a reaction with participation of the protonated form of the *N*-oxide. However, the entropy of activation for α-nitration (−12.3 e.u.) is lower than the expected value (−20 e.u.)[39].

Table 13. Activation parameters for the nitration of substituted pyridine *N*-oxides[159].

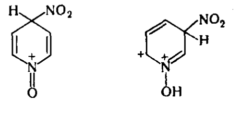
 Position of substituent	Position of entry of NO_2 group	H_2SO_4, %	E_a, kcal mole^{-1}	lg*A*	$\Delta S^{\neq}$
—	4-	87.9	23.5		
3.5-$(CH_3)_2$	4-	91.8	25.3	19.0	+26.3
2.6-Cl_2	4-	82.4	26.9	13.5	+1.5
3.5-Cl_2	4-	90.0	27.8	14.0	+15.1
2.4,6-$(OCH_3)_3$	3-	81.0	16.9	9.5	−17.2
2.6-$(OCH_3)_2$	3-	84.8	14.5	6.9	−26.1
2.6-$(CH_3)_2$-4-OCH_3	3-	90.3	16.6	9.1	−18.5
3.5-$(OCH_3)_2$	2-	82.3	20.3	10.5	−12.3
3.5-$(OCH_3)_2$-2-NO_2	6-	82.0	23.8	10.4	−13.0
1,3,5-Trimethoxypyridinium perchlorate	2-	82.3	14.5	6.9	−29.0

Conclusions analogous to those obtained as a result of the study of the kinetics of the nitration of substituted pyridine *N*-oxides were arrived at also in a study of the kinetics of acid-catalysed isotope exchange of hydrogen involving the same compounds. Katritzky and coworkers[163] established that the deuteration of 2,6-lutidine and 2,4,6-collidine *N*-oxides at 200–250°C and an acidity $H_0 = 8.7$ takes place in the 3-position in the protonated form, while the exchange of hydrogen in the *N*-oxide of 3,5-dimethylpyridine is observed in the 2-, 4-, and 6-positions with participation of the free base:



Under the same conditions, the rate of exchange of hydrogen in the β-position of pyridine *N*-oxide is only one-quarter of the rate of exchange in unoxidised pyridine, i.e. the $\overset{+}{N}$–OH group has a more deactivating effect than $\overset{+}{N}$H, in consequence of the negative inductive effect of the OH groups[164].

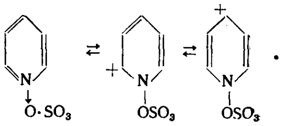
Comparison of the nitration and hydrogen isotope exchange reactions of the *N*-oxides of substituted pyridines reveals an interesting feature: the nitration takes place preferentially in the 4-position in the free base of the *N*-oxide, while the slower and consequently more selective hydrogen exchange reaction involves the 3-position of the cation of the *N*-oxide, which is present in excess but is less reactive (for example, in the case of the *N*-oxide of 2,6-lutidine). This result is unexpected because of the high reactivity of the nitronium cation. The proposed explanation of this difference in the location of electrophilic agents is associated with the difference in the stabilities of the transition states in 4- and 3-nitration; possibly the electron-accepting effect of the NO_2 group in the case of β-substitution leads to a marked destabilisation of the doubly charged intermediate structure[163]:



Nevertheless sulphonation of *N*-oxides takes place preferentially in the 3-position, which makes this explanation less convincing, since the sulpho-group is also a powerful electron acceptor.

The appreciable conjugation effect of the N→O group in the nitration of pyridine *N*-oxide becomes very slight in the sulphonation reaction. Pyridine *N*-oxide is sulphonated under severe conditions (in 20% oleum at 220°C in the presence of mercuric sulphate) with formation of the 3-sulphonic acid (yield 67%).[165] Probably the *N*-hydroxypyridinium cation is sulphonated; substitution in the 3-position of the cations is in good agreement with the calculated localisation energies for electrophilic substitution (the values of A_e for the 2-, 3-, and 4-positions are respectively 2.70, 2.58, and 2.67 – β units)[166].

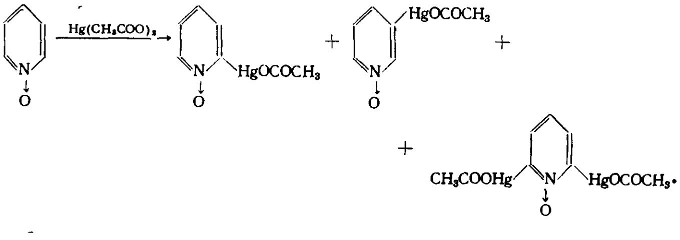
den Hertog et al. [167] showed that the bromination of pyridine *N*-oxide also takes place under severe conditions: with an excess of bromine in 90% sulphuric acid with heating to 200°C in the presence of catalytic amounts of silver sulphate—and leads to the formation of 2- and 4-monobromo-derivatives in proportions of 1 : 2 with an overall yield of about 10%. Bromination in 65% oleum at 120°C gives only the 3-bromo-compound and it is possible that an adduct of sulphur trioxide and pyridine *N*-oxide reacts[168]:



Nor can one exclude the possibility that in this case the reaction involves the protonated form of the *N*-oxide.

When the pyridine ring contains powerful electron-donating groups, the mode of halogenation of the *N*-oxide is determined by the conjugation effects of these groups and substitution takes place under milder conditions. Bromination of 2-hydroxypyridine *N*-oxide with bromine in acetic acid takes place in the 3-position[169], while iodination of 3-hydroxypyridine *N*-oxide gives the 4,6-di-iodo-derivative[170].

The mercuration of pyridine *N*-oxide with mercury(II) acetate in acetic acid at 100°C gives a mixture of 2-, 2,6-, and 3-substituted compounds in proportions of 8 : 1 : 2[171]:



The predominance of the α- and not the γ-derivative in this reaction may be attributed to a difference in the mechanism of the nitration and mercuration of *N*-oxides.

Mercuration with mercury(II) sulphate in sulphuric acid at 170°C yields only the 3-, and 2-monomercuri-derivatives in proportions of 2 : 1.[171] The higher amount of the β-isomer is probably associated with the protonation of the *N*-oxide.

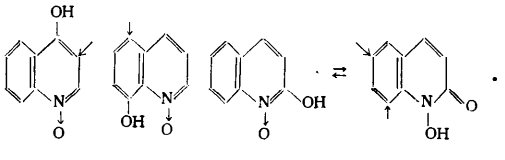
Quinoline *N*-oxide undergoes electrophilic substitution more readily than pyridine *N*-oxide. In the nitration of quinoline *N*-oxide in sulphuric acid, Ochiai[172] observed an interesting temperature variation: at 10°C a mixture of the 5- and 8-isomers is formed but on raising the temperature the formation of 4-nitroquinoline *N*-oxide becomes appreciable and this nitro-derivative constitutes the main reaction product at 70°C. Above 100°C reduction begins, and the amount of the 4-nitro-compound falls.

Later it was found for the *N*-oxides of 6-substituted quinoline derivatives that the directing effect of the N→O group in the nitration reaction depends to an even greater extent on the concentration of sulphuric acid than on temperature[173]. At the same temperature the amount of the 4-nitro-derivative diminishes and that of the 5- and 8-nitro-derivatives increases with the acidity of the medium. The use of the usual kinetic criteria enabled Schofield and coworkers[162] to establish that the 1-hydroxyquinolinium cation undergoes 5- and 8-nitration and the free base of quinoline *N*-oxide undergoes 4-nitration.

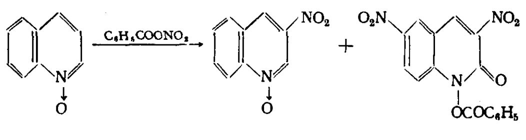
It is striking that the rate constant for the nitration of the 1-hydroxyquinolinium cation is lower than that for the quinolinium cation (0.78×10^4 and 1.67×10^4 litre $mole^{-1}$ s^{-1} respectively[162]); consequently in the protonated form the *N*-oxide group plays the role of a deactivating electron-accepting substituent. The same effect is shown also in the electrophilic deuteration of quinoline and quinoline *N*-oxide in an acid medium, where both compounds react in the protonated form. Substitution involves the same positions (the 3-position in the benzene ring) but in the case of the *N*-oxide the yield of the reaction is lower[174].

In the series of quinoline *N*-oxide derivatives the usual direction to the *para*-position relative to the N→O group occurs when methyl[175] and halogeno-derivatives[176] are nitrated in concentrated sulphuric acid at 40–70°C. At the same time the alkoxy-group, in contrast to alkoxypyridine *N*-oxides, is a more powerful directing agent in this series than the N→O group[177].

Hydroxyquinoline *N*-oxides are nitrated in the *ortho*- and *para*-positions relative to the hydroxy-group under milder conditions—with nitric acid in glacial acetic acid[178–180]:

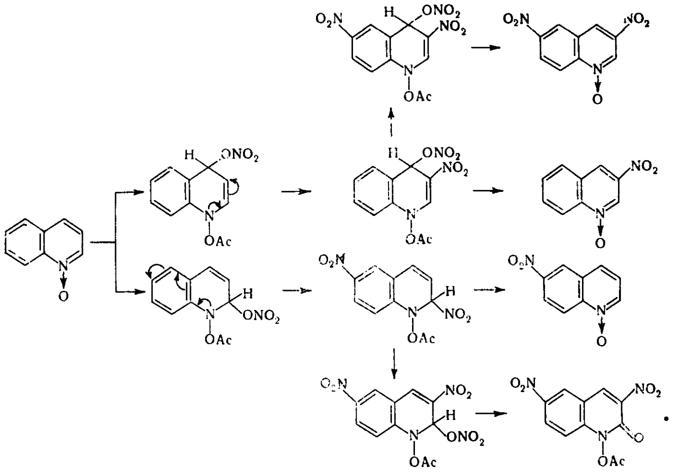


In the nitration of quinoline *N*-oxide with benzoyl nitrate in a neutral medium (in chloroform or dioxan) at 20°C, the *N*-oxide of 3-nitro-quinoline is formed in 40% yield together with some *N*-benzoyloxy-3,6-dinitro-2-oxoquinoline[181]:

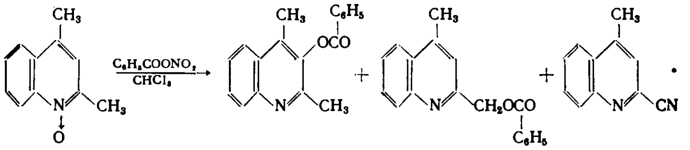


The use of a mixture of acetyl chloride with silver or potassium nitrate as a nitrating agent avoids the formation of 2-hydroxyquinoline and leads to the synthesis of 3- and 6-mono- and 3,6-di-nitro-compounds in yields of 32, 1.4, and 100% respectively[181].

Ochiai and Kaneko[181] suggested that in nitration with acyl nitrates in a neutral medium the reaction does not involve a simple electrophilic substitution mechanism but includes a stage with addition and subsequent elimination:

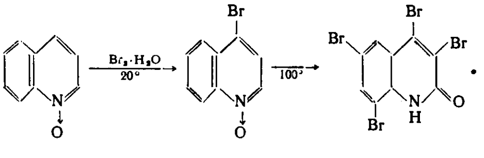


One may adduce in favour of this hypothesis data showing that 2- and (or) 4-substituted quinoline *N*-oxides do not give rise to nitration products on treatment with acyl nitrates, as shown for 2,4-dimethylquinoline *N*-oxide[182]:



Moreover, Ochiai and Ohta[183] showed that the *N*-methoxyquinolinium cation and also the adduct of quinoline *N*-oxide and boron trifluoride are nitrated with potassium nitrate in dimethyl sulphoxide at 140°C in the 3-position, which is likewise evidence of the validity of the above mechanism.

Hamana and Jamazaki[184] observed that, when quinoline *N*-oxide is brominated in a neutral medium, substitution also takes place in the 3-position: on refluxing quinoline *N*-oxide with bromine and chloroform in acetic anhydride, 3,6-dibromoquinoline *N*-oxide is formed in 60% yield (under the same conditions, pyridine *N*-oxide gives a 35% yield of the 3,5-dibromo-derivative). When quinoline *N*-oxide is brominated with bromine water at 20°C, initially normal substitution takes place in the *para*-position relative to the N→O group, but on heating to 100°C the *N*-oxide of 4-bromoquinoline formed may undergo further reaction, resulting in the formation of 3,4,6,8-tetrabromo-2-oxoquinoline[185]:

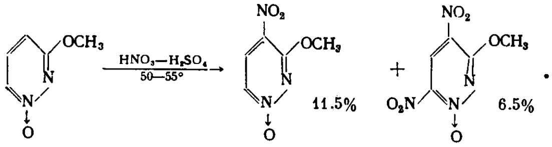


Electrophilic substitution of acridine *N*-oxide—nitration in sulphuric acid at 0°C and also bromination in glacial acetic acid at 100°C—takes place in the *para*-position relative to the N→O group and leads to the formation of 9-substituted acridine *N*-oxides[186].

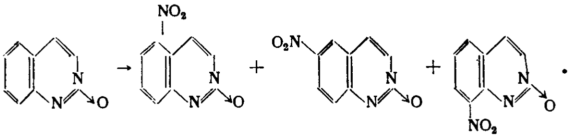
In isoquinoline *N*-oxide, where the *para*-position relative to the N→O group is occupied, the polar directing effect of the *N*-oxide group is not shown and, as in the case of isoquinoline, nitration takes place only in the 5-position (95%) and to a much lesser extent in the 8-position (1.5%)[187]. The study of the dependence of the rate of nitration of isoquinoline *N*-oxide and the *N*-methoxyisoquinolinium ion on the acidity of the medium by Schofield and coworkers[160] established that isoquinoline *N*-oxide reacts in the protonated form.

In the series of diazine *N*-oxides electrophilic substitution reactions have been studied only for the *N*-oxides of pyridazines, phthalazines, and cinnolines. While unsubstituted pyridazine is resistant to nitration under fairly severe conditions[92], the 1-*N*-oxide of pyridazine is nitrated in the *para*-position relative to the N→O group in a mixture of nitric and sulphuric acid at 130–140°C with a yield of 22%;[188] the same location of the new substituent is observed for the *N*-oxides of methylpyridazines[189].

In consequence of the competing directing effects of the substituents, nitration of 3-methoxypyridazine *N*-oxide results in the formation only of a mixture of 4-mono- and 4,6-dinitro-derivatives[190]:



When cinnoline 2-*N*-oxide is heated in a mixture of nitric and sulphuric acids at 90°C, 5-, 6-, and 8-mononitro-derivatives are formed in yields of 3, 15 and 23% respectively together with the unreacted initial *N*-oxide[193]:



The authors believe that these proportions of the isomers can be accounted for by the fact that the directing effect of the 2-N→O group favours substitution in the 6- and 8-positions, while the effect of the cinnoline ring favours 5- and 8-substitution, so that both effects reinforce one another in the 8-position. However, this explanation cannot be regarded as satisfactory, since isoquinoline *N*-oxide is substituted only in the 5-position[187]. The study of the kinetics of the nitration of cinnoline 2-*N*-oxide in 64.4–90.0% sulphuric acid suggests that 5- and 8-nitro-derivatives are formed entirely or largely in the nitration of the cation, while 6-substitution takes place in the free base of cinnoline 2-*N*-oxide[162].

Nitration of cinnoline 1-*N*-oxide with a mixture of nitric and sulphuric acids leads only to the 4-substituted compound[194], i.e. in this case the usual *para*-directing effect of the N→O group is shown.

Quinoxaline *N*-oxide is resistant to nitration with fuming nitric acid in concentrated sulphuric acid even at 100°C[117].

Phenazine 10-*N*-oxide behaves differently—it is readily nitrated even at 0°C with formation largely of 3- and small amounts of 1-nitro-compounds[191]; when the reaction is carried out at 100°C, the 10-*N*-oxides of 3,6- and 1,6-dinitrophenazines are formed[192]:

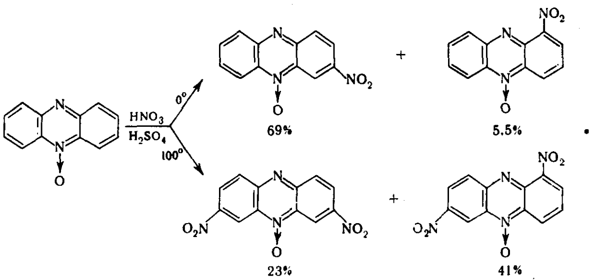


Table 14. Indices of the reactivities of pyridine and pyridazine *N*-oxides[131,166,195].

Structure	q_r, charge units	$A_e(-\beta)$	Position of carbon atom	q_r, charge units	Structure
	0.976	2.36	2-			1.003	2.58	3-	0.922	
	0.994	2.44	4-	1.001	
			5-	0.955	
			6-	0.978	

Table 15. Indices of the reactivities of quinoline, isoquinoline, and acridine *N*-oxides[196–199].

Position of carbon atom					q_r, charge units	A_e $(-\beta)$	q_r, charge units	q_r, charge units
1-	—	—	1.184	0.992
2-	0.975	2.30	—	0.959
3-	1.003	2.50	1.139	0.984
4-	0.994	2.21	0.896	1.012
5-	1.000	2.29	0.968	—
6-	1.000	2.48	0.990	—
7-	0.998	2.45	0.958	—
8-	1.004	2.32	1.022	—
9-				1.004

Note. The application of computational methods to the *N*-oxides requires the introduction of additional parameters for the Coulombic integral of the oxygen atom and the resonance integral of the N–O bond; usually the required values are found to be within the ranges $\alpha_{O^-} + (0.8 - 1.2)\beta$ and $\beta_{N^+-O^-} = (0.5 - 1)\beta$.

According to preliminary kinetic data, the monocation of the *N*-oxide formed by the addition of a proton to the unoxidised nitrogen atom is nitrated[15].

In the series of phenazine *N*-oxides the N→O group is a more powerful directing agent than halogens but weaker than alkoxy-groups and therefore the nitration of the 10-*N*-oxides of 1-, 2-, and 3-chlorophenazines takes place in the 6-position[193] and the nitration of the 10-*N*-oxide of 1-methoxyphenazine involves the *para*-position relative to the methoxy-group[121].

It is at present impossible to make a far-reaching analysis of the correlation between the experimental reactivities of the *N*-oxides of heteroaromatic compounds in electrophilic substitution reactions and the theoretical values obtained by the LCAO-MO method, because of the limited amount of calculated data. In particular, a calculation for the cationic form of the *N*-oxides has been made only in the case of pyridine *N*-oxide[166]. Tables 14 and 15 list the indices of the reactivities of certain *N*-oxides calculated by the simple LCAO-MO method. Comparison of these values with the experimental data shows that more successful correlations with the reactivities of the *N*-oxides are observed by considering the localisation energies A_e rather than the distribution of electron density q_r.

Influence of Steric Factors on the Structure and Physicochemical Properties of Monohydric Phenols

G.A.Nikiforov and V.V.Ershov

The specificity of a series of chemical properties of sterically hindered phenols depends greatly on their structure. In the series of 2,6-di-t-alkylphenols in which conjugation of the aromatic ring and hydroxyl group is retained (insignificant departure from coplanarity) the C–O–H bond system is subjected to some deformation due to the bulky *o*-alkyl groups (a steric effect), which is reflected in the energy of homolytic breaking of the O–H bond and the physicochemical parameters of these phenols. The unusual nature of the spectral characteristics (ultraviolet, infrared, and NMR) of sterically hindered phenols is due to the steric effect of the ortho-substituent. For the same reason these compounds do not form self-associates; the hydrogen bond is somewhat stretched and weaker. Steric effects also play a decisive part in the reduction of acidity of sterically hindered phenols, preventing the solvation of the anion formed. For all the examples considered data are given on the effect of a para-substituent on the physicochemical parameters of the phenols. 98 references.

CONTENTS

I. INTRODUCTION

Sterically hindered phenols have found wide application as additives to prevent the oxidation of fats, oils, fuels, and various polymeric materials. The ability of sterically hindered phenols to retard (inhibit) radical-chain processes of oxidation of organic substances led to a very intense study of various practical and theoretical aspects of the chemistry of these compounds. The large number of studies in this field show distinctly that in many instances sterically hindered phenols show specific properties due to peculiarities in their structure. The physicochemical properties of sterically hindered phenols are largely responsible for their behaviour as oxidation inhibitors. In this connection the effect of the steric factor on the change in one or another property of phenolic compounds has frequently been investigated and a large body of experimental results on this problem has now accumulated, allowing certain generalisations to be made. In both the Russian and foreign literature there have been reviews dealing solely with the oxidation of sterically hindered phenols[1,2], their participiation in inhibited oxidation[3-6] and the properties of the phenoxyl radicals formed from them[7-10].

2,6-Dialkyl substituted phenols and their numerous derivatives are usually associated with the idea of sterically hindered (screened) phenols in the Soviet and foreign literature. Even in the first stages (1945–1950) of the intensive study of the 2,6-dialkylphenols it was observed that their properties depend on the effective volumes of the alkyl substituents. In this connection it was proposed[11,12] to classify such phenols in a separate group, termed sterically hindered phenols. To this period belong also the first attempts to evaluate the steric influence exerted by alkyl groups on the properties of the phenols. Thus Coggenshall[13,14], who used ultraviolet and infrared spectroscopy to study the ability of phenols to form hydrogen bonds (self-association), divided the phenols into three groups: non-screened, semiscreened, and screened. Naturally, the most pronounced steric influence is shown by phenols containing tertiary alkyl groups in the ortho-positions, and therefore specific properties of sterically hindered phenols were studied mainly for examples of compounds of this type.

II. STRUCTURE AND ENERGY OF THE O–H BOND OF STERICALLY HINDERED PHENOLS

The problem of the structure of sterically hindered phenols mainly reduces to a consideration of the relative arrangement in space of the aromatic ring, and the hydroxyl and alkyl groups. It is well known[15], that many physical and chemical properties of ordinary phenols are determined by the electron-withdrawing properties of the aromatic ring. Hence their enhanced acidity (in comparison with aliphatic alcohols), corresponding position of the signal of the hydroxyl proton in the NMR spectra, tendency to participate in radical processes, peculiarities of the mechanism of electrophilic substitution, etc. Evidently, the most characteristic properties of a phenol correspond to a structure in which the hydroxyl group (the C–O bond) is coplanar with the aromatic ring. The departure of the hydroxyl group from the plane of the ring will decrease the conjugation of the lone pair of electrons of the oxygen atom with the π-electrons of the aromatic ring, and consequently the properties of the phenol will approximate on the one hand to the properties of benzene, and on the other to the properties of aliphatic alcohols. Such a departure of the hydroxyl group most probably occurs in sterically hindered phenols containing t-alkyl groups, since it should be facilitated by the effect of bulky alkyl groups in the ortho-positions relative to the phenolic hydroxyl. Even a simple comparison of the effective radii of the hydroxyl and t-butyl groups shows the possibility of the destruction of the coplanarity of the hydroxyl group and aromatic ring in compounds of the series of sterically hindered phenols. Many investigators working in this field were primarily interested in this very question. And since a breakdown in the conjugation of the *p*-electrons of the oxygen atom with the aromatic system in sterically hindered phenols should lead to a marked change in the physicochemical properties of the phenol, that possibility and the nature of the departure of the hydroxyl group from the plane of the ring were usually investigated with the aid of various physical methods[16-27]. The first studies in this field were made by Ingold, using infrared spectroscopy[22-25]. He showed[22] that the increase in the hydroxyl group frequency in the infrared spectra observalbe in 2,6-di-t-butyl-4-substituted phenols in comparison with the corresponding 4-substituted phenols is too great to be the result of only electronic effects of the t-butyl groups. Evidently, in this instance the steric effect of the alkyl groups is considerable. However, the changes in the frequencies of the O–H bond vibrations in a series of 4-substituted phenols and in a series of 4-substituted 2,6-di-t-butylphenols with change in substituent obey the same law. Fig. 1 shows the variation of ν_{OH} with σ_p for 4-substituted phenols and their sterically hindered analogues. The parallelism of the straight lines on the graph shows that both groups of phenols have similar spatial structure.

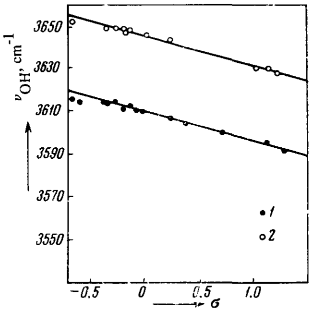

Figure 1. Variation of ν_{OH} with σ_p of para-substituents in the series of 4-X-phenol (*1*) and 4-X-2,6-di-t-butylphenol (*2*).

A similar conclusion can also be reached on the basis of the following discussion. The displacement of the hydroxyl group from the plane of the ring should sharply reduce its resonance interaction with strongly accepting substituents in the para-position, that is, σ_p, for example, for the nitro-group should have a value intermediate between the maximal (1.27, characteristic for *p*-nitrophenol) and the minimal (0.78, characteristic for other nitroderivatives of benzene in which direct conjugation of the substituents is absent). However, the best correlation in the series of sterically hindered phenols in coordinates ν_{OH} against σ_p is observed on using the maximal values of σ_p. The picture is analogous when maximal values of σ_p for the formyl and nitrile groups are used.

The coplanarity of the aromatic ring and hydroxyl group is also shown by the following calculation, given by Ingold[22,25]. It is known that the fundamental frequency of the carbonyl group in various substituted benzaldehydes is linearly dependent on σ_p for the *p*-substituent. If the hydroxyl group is coplanar with the aromatic ring for 2,6-di-t-butyl-4-formylphenol, then:

$$\sigma_{eth} = \sigma_p^{OH} + 2\sigma_m\text{-t-butyl} = -0.36 + 2\cdot(-0{,}12) = -0.60.$$

When there is a linear relation between ν_{CHO} and σ_p, the shift in frequencies on going from 4-formylphenol to 2,6-di-t-butyl-4-formylphenol should be in the ratio 0.36 : 0.60 (3 : 5), which agrees with the experimental results.

On the basis of the above facts it could have been suggested that in 2,6-di-t-butylphenols the hydroxyl group lies in the plane of the aromatic ring or close to this position. However, it must be borne in mind that the infrared spectroscopic results do not permit the electronic influence of the substituents on the nature of the absorption by the hydroxyl group to be evaluated with sufficient accuracy, and consequently the above discussion is approximate, since at small angles of departure from coplanarity the resonance energy and electron density hardly change because these quantities are approximately proportional to the square of the cosine of the dihedral angle[28].

The electronic spectra can be a more sensitive characteristic of the electronic interaction of the hydroxyl group and the aromatic ring. Ultraviolet spectroscopy is interesting because the position of the absorption bands of the benzenoid system is determined mainly by the resonance effect of the substituent and therefore is more sensitive to a change in coplanarity than ν_{OH} in the infrared region.

For example, having obtained a series of resonance parameters for para-substituents ($\sigma_{R'} = \sigma_{\bar{p}} - \frac{2}{3}\sigma_m$), Cohen and Jones[18] showed that in a plot of $\sigma_{R'}$ against $\Delta\bar{\nu}$ there is satisfactory correlation for any substituents. It is characteristic that the straight lines for 4-X-phenols and 4-X-2,6-di-t-butylphenols are only approximately parallel. The presence of two t-butyl groups increases the value of ρ both for phenols and for the phenolate ions by 11%. This shows the insignificant departure of the C–O bond from the plane of the aromatic ring.

Finally, data on the molecular polarisability of phenols have been used to find the coplanarity of the hydroxyl group and the aromatic ring[21]. Unlike dipole moments, which depend weakly on the volume of the replacing groups[19], the molar polarisability of the compounds allows the spatial position of the individual fragments of the molecule to be calculated rather precisely. A comparison of the observed Kerr constants with the values calculated theoretically for various conformations of 2,4,6-tri-t-butylphenol showed that here the hydroxyl group is displaced ~ 14° out of the plane of the aromatic ring.

It is noteworthy that the observed departure from coplanarity is increased significantly when the hydroxyl group in 2,6-di-t-butylphenyl is replaced by methoxyl. In this instance, as spectroscopic investigations have shown[26,29,30] the angle made by the C–O bond at the ring plane approaches 90°.

The departure (although insignificant) of the hydroxyl group from coplanarity in 2,6-di-t-butylphenol is due to the interaction of the electron clouds of the hydroxyl and t-butyl groups. As an investigation of molecular models showed[31], the overlap of the effective radii of the phenol hydrogen and each of the equivalent hydrogen atoms of the neighbouring t-butyl groups found in the most convenient conformation is approximately 0.25 Å. This suggests that the total bond strain energy is within the range 0.1–0.2 kcal mole^{-1}, appreciably less than the energy of conjugation which is gained by the hydroxyl group being in the plane of the ring (~ 7.0 kcal mole^{-1}).

The steric hindrances created by the t-butyl groups also prevents the normal rotation of the hydroxyl group around the C–O bond, increasing the rotational barrier. This barrier calculated on the basis of dielectric measurements is 2.2–2.8 kcal mole^{-1} for 2,4,6-tri-t-butylphenol[32,33]. It is interesting to note that this value is lower than for the unsubstituted phenol (4.4 kcal mole^{-1}). The high value of the rotational barrier in unsubstituted phenol is due to its self-association, whereas in 2,6-di-t-butylphenol this is completely absent and consequently, the presence in it of a rotational barrier is due solely to the existence of steric hindrances created by the bulky *o*-alkyl groups.

Hence, the general features of the structure of the sterically hindered phenols are that when the conjugation of the aromatic ring with the hydroxyl group is retained (insignificant departure from coplanarity) the system of C–O–H bonds is subjected to certain deformations, in addition to which there is a rather high rotation barrier (restricted rotation) of the hydroxyl group around the C–O bond. All this leads to the specificity of certain physicochemical properties in a series of sterically hindered phenols.

The strains which arise in a system of C–O–H bonds of a phenol on the introduction in the ortho-position of t-butyl groups should evidently cause some change in the bond energy in this system, particularly the dissociation energy of the O–H bond. However, the direct determination of the dissociation energy of the O–H bond is extemely difficult and has been done only in the simplest instances.

To the first approximation the dissociation energy of the O–H bond in phenol ($D_{O...H}$) is proportional to the energy of the highest filled molecular orbital (E_{hfmo}),[34-36] and in this connection quantum-mechanical investigations of the activity of the phenolic compounds in oxidations yield a satisfactory correlation between the inhibiting activity of phenols and E_{hfmo}.[37] An extremely successful version of the estimation of the strength of the O–H bond is a combination of Fiesser's experimental method[38] used for the determination of the redox potential of unstable systems (E_C) and quantum-mechanical calculations of the dissociation energy of the O–H bond ($D_{O...H}$).[34] By combining these methods the dissociation energies of the O–H bond were calculated for a series of the simplest phenols, particularly unsubstituted phenol $D_{O...H}$ = 84 kcal mole^{-1}.

In the series of sterically hindered phenols the strength of the O–H bond was calculated on the basis of results obtained in investigating the equilibrium reactions of substituted 2,6-t-butylphenols with one of the nitrogenous radicals (2,2,6,6-tetramethyl-4-ketopiperidyl-1-oxyl) with the aid of the EPR method[39]. It has been shown that the strength of the O–H bond of certain sterically hindered phenols varies within the limits 76 ± 3 kcal mole^{-1}.

As the data show, the introduction of two t-butyl substituents into the ortho-positions to the hydroxyl group causes some weakening of the O–H bond, which agrees with results on the structure of sterically hindered phenols.

III. SPECTROSCOPIC CHARACTERISTICS OF STERICALLY HINDERED PHENOLS

1. Electronic Spectra

The first spectroscopic investigations of sterically hindered phenols were in 1948, when Coggenshall[14], on the basis of shifts in the absorption maxima of these phenols in the range 265–275 mμm, produced on replacing octane by alcohol as solvent, attempted to estimate the steric effect of *o*-alkyl substituents. However, the more detailed ultraviolet characteristics and their change with the structure of the phenol and medium were investigated much later[18,40-43].

Like their unscreened analogues, sterically hindered phenols exhibit two characteristic absorption bands in the ultraviolet range: 210–220 mμm (the B-band with high absorptivity) and 260–280 mμm (the C-band with low absorptivity). Table 1 gives the ultraviolet spectra of ortho-substituted phenols with gradual increase in the volume of the ortho-alkyl substituents. As Table 1 shows, the change in the size of the alkyl groups does not affect the characteristics of the ultraviolet spectra strongly, but the following two facts must be considered. The first is the low sensitivity of the position of the B-band to increase in the volume of the ortho-substituent. Dearden[40] considers that this anomaly is explained by the considerable contribution to the ground state of the phenol of the bipolar structure of the type:

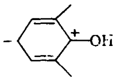

Table 1. The ultraviolet spectra of *o*-alkylphenols[40].

Compound	Cyclohexane				Ethanol			
	B-band		C-band		B-band		C-band	
	λ_{max}, mμm	E_{max}	λ_{max}, mμm	E_{max}	λ_{max}, mμm	E_{max}	λ_{max}, mμm	E_{max}
Phenol	210	6000	269	2200	218	6000	271	1900
o-Cresol	213	7000	270	1850	213	7100	272	2050
o-Isopropylphenol	211	7500	270	2100	215	6200	271	2250
o-t-Butylphenol	213	5900	268	2050	216	5100	271	2300
2,6-Dimethylphenol	211	7900	275	1600	214	8500	271	1550
2,6-Di-isopropylphenol	211	9200	275	1950	214	8000	270	1850
2,6-Di-t-butylphenol	211	7500	275	1800	212	7600	268	1550

The second fact is the shift of the B-band to longer wavelengths on going from a non-polar solvent to a polar one. It is suggested[14,40] that this effect is connected with steric hindrances which arise during the formation of associates with the solvent. The most pronounced change in form and position of the maxima in the spectrum are observed on increasing the pH of the medium. Thus, when an alcoholic solution of phenols is made alkaline there is a displacement of both bands to longer wavelengths and simultaneously there is an increase in the absorptivity. These facts are evidently due to an increase in the fraction of quinonoidal structure in the ground state of the ionised form of the phenol, which in the reactivity scheme leads to an increase in the ambidentate properties of the phenoxide anion.

The introduction of various substituents into the para-position of sterically hindered phenols also has a considerable effect on the parameters of the ultraviolet spectra. As might be expected, the presence of electron-withdrawing substituents brings about a shift of B- and C-bands to longer wavelengths, the shift increasing with the electronegativity of the substituent (Table 2). Since the parameters of the ultraviolet spectrum are extremely sensitive to changes in the effects of conjugation of the hydroxyl group with the para-substituents[44,45], they should be correlated with the constants of the para-substituent. Such a relation is observed sufficiently well in using σ_R' constants[18], which reflect the resonance constituent in the total value of σ_p^- on allowing for the regular change in the inductive effect with distance, that is,

$$\sigma_{R'} = \sigma_p^- - {}^2/_3\sigma_m.$$

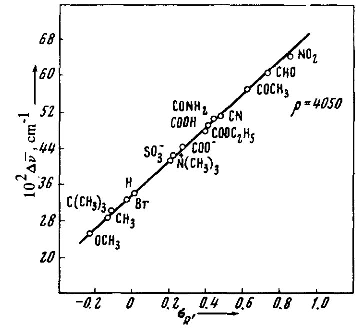

Figure 2. Correlation of $\Delta\bar{\nu}$ and $\sigma_{R'}$ in the 4-X-2,6-di-t-butylphenol series.

This correlation is made in the coordinates $\Delta\bar{\nu}$ against $\sigma_{R'}$ (Fig. 2). The shift in frequencies is calculated from the equation

$$\Delta\bar{\nu} = \bar{\nu}_a - \bar{\nu}_b,$$

where $\bar{\nu}_a$ is the frequency of the B-band of 4-X-2,6-di-t-butylphenol, and $\bar{\nu}_b$ that of the band for the corresponding substituted benzene. Table 2 gives the results for the ultraviolet spectra of 4-X-2,6-di-t-butylphenols in neutral and alkaline solutions. The shift in the bands observable on going from a neutral medium to an alkaline one increases with the electronegativity of the substituent and also depends linearly on $\sigma_{R'}$. The marked shift of the B-band in an alkaline medium in comparison with a neutral one with strongly electron-withdrawing substituents (CHO, CN, COOR, $COCH_3$, NO, and NO_2) is due to the considerable contribution of the quinonoid structure to the ground state of the ionised form[18,46].

2. Infrared Spectroscopy of 2,4-Dialkylphenols

The infrared spectra of sterically hindered phenols has been investigated in considerable detail[13,16,20,22-26,47-59]. The studies made in this field deal mainly with two problems: finding the spatial structure of the phenols of this series and their ability to form a hydrogen bond.

Table 3. Frequencies (ν_{OH}, cm^{-1}) of the hydroxyl group in the alkylphenol series (CCl_4).

Alkylphenol	ν_{OH}	Reference
Phenol	3612	16, 23, 25, 50, 51, 61, 62
2,6-Dimethylphenol	3622	20, 61, 62
2,6-Diethylphenol	3623	20, 53
2,6-Di-isopropylphenol	3623	20, 50, 53, 61, 62
2,6-Di-t-butylphenol	3651	20, 23, 25, 50, 51, 53, 61, 62
2,6-Di-t-pentylphenol	3646	59
p-Cresol	3617	51
2,4,6-Trimethylphenol	3626	51
2,6-Di-isopropyl-4-methylphenol	3628	23, 25, 51
2,6-Di-t-butyl-4-methylphenol	3650	16, 20, 23, 25, 51, 53, 54
4-Methyl-2,6-di-t-pentylphenol	3642.5	23, 25
4-Methyl-2,6-bis(triethylmethyl)phenol	3635	23, 25

In examing the infrared spectra of sterically hindered phenols the most noteworthy effect is that the band of the hydroxyl group is a narrow signal strongly displaced to shorter wavelengths in comparison with unsubstituted phenol (in KBr and CCl_4). The observed increase in the frequency of the hydroxyl group is evidently due to the interaction of the electron clouds of the hydroxyl and *o*-t-butyl groups[22,25]. Such an explanation was given in the interpretation of the results of an investigation of the chemical shifts in the PMR signal from the hydrogen atom of the hydroxyl group for a series of di-*o*-alkylphenols[60]. Table 3 gives results on the change in frequency of the hydroxyl group with the effective volume of the ortho-substituent for certain di-*o*-alkylphenols. It can be seen that the frequency of the hydroxyl group reaches maximal value when t-butyl groups are present.

Table 4. Frequencies (ν_{OH}, cm^{-1}) of the hydroxyl group in a series of 4-X-2,6-di-t-butylphenols in CCl_4.[18,22]

X	ν_{OH}	σ_p	X	ν_{OH}	σ_p
NO_2	3626.5	1.24	Cl	3643.5	0.23
CHO	3630.0	1.04	H	3647.0	0.00
CN	3632.5	0.88	OCH_3	3649.0	−0.13
$COCH_3$	3633.0	0.84	CH_3	3649.0	−0.15
COOH	3634.0	0.77	$C(CH_3)_3$	3649.0	−0.14
$COOC_2H_5$	3636.5	0.64	OH	3649.0	−0.37
Br	3643.0	0.25	NH_2	3650.5	−0.66

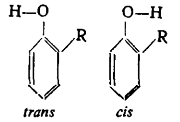
An increase in the lengths of the alkyl chains at the tertiary carbon atom in the ortho-substituents leads to a decrease in the frequency, which is evidently due to a decrease in the steric hindrances resulting from the breakdown of spherical symmetry of the substituents as a whole owing to the large number of possible conformations.

The results of an investigation of the variation of the frequency of the hydroxyl group with the electronegativity of the para-substituent in the 4-X-2,6-di-t-butylphenols is given in Table 4, from which clearly the frequency of the hydroxyl group decreases as the electronegativity of the para-substituent, which affects the polarisation of the O–H bond, is increased. There is good correlation of the data in Table 4 with one another (Fig. 1).

It is noteworthy that the hydroxyl group band for sterically hindered phenols in CCl_4, which is a narrow isolated signal, does not change when the solution is diluted. This is possible only if self-association is absent[47,51,53,57]. A rise in temperature decreases the intensity of the absorption band of the hydroxyl group of sterically hindered phenols[55,56].

There is another interesting, but not completely strict, correlation based on the infrared spectra of sterically hindered phenols, which can yield additional information about the structure of this series of compounds. This is the correlation of the difference in free energy (ΔG) between the *cis*- and *trans*-isomers of mono-*o*-t-alkylphenols with $\Delta\nu_M$ and the change in the band intensity (ΔA) for 2,6-di-t-alkylphenols[24,25].

Careful study of the infrared spectra of *o*-alkylphenols in the range of absorption of the hydroxyl group led to the observation of a group of bands consisting of a band of high intensity with approximately the same frequency as for the unsubstituted phenol, and an incompletely resolved band with intensity and position close to the band of 2,6-di-t-alkylphenols[16,23,24]. The more intense band at the lower frequency was assigned to the so-called *trans*-isomer of the *o*-t-alkylphenol, and the second band to the *cis*-isomer:



The properties of these isomers are different. When the polarity of the medium is varied, the *trans*-isomer behaves like phenol (ν_{OH} decreases as the polarity is raised) but the *cis*-isomer exhibits all the spectroscopic properties of 2,6-di-t-alkylphenols. It is characteristic that for *o*-t-alkylphenols the *trans*-form is more stable than the *cis* form. This again shows the existence of a steric repulsion between the hydroxyl group and the alkyl residues. As Ingold has shown[24,25], the ratio of the intensities of the bands of the isomers can be used to calculate the difference in free energy (ΔG) between these isomers. When from these results ν_{OH} and ΔA are plotted against ΔG for the corresponding 2,6-dialkyl phenols, curves with a maximum or minimum are obtained, showing a sharp difference between the 2,6-dialkylphenols. However, it is noteworthy that the increase in ΔG with the effective volume of the *o*-alkyl substituents is slower than expected. This is evidently because of the decrease in energy as the angle C–H–O is increased.

3. Nuclear Magnetic Resonance Spectra

With the development of the NMR method a more detailed study of the electronic interaction in sterically hindered phenols arising as a result of the steric effect of the alkyl groups became possible. Measurement of the chemical shift of the hydroxyl group proton signal for a series of mono- and di-*o*-alkylphenols showed that as the volume of the substituent is increased there is a successive displacement of the signal to weaker fields, owing to the decrease in the magnetic screening of the hydroxyl group. This behaviour could be due solely to the steric influence of the *o*-alkyl groups, since the other possible factors affecting the position of the signal (appreciable departure from coplanarity, influence of the inductive effect, dipole moment, and magnetic anisotropy) should here result in a displacement to stronger fields. Table 5 shows the values of the chemical signals (τ_{OH} and $\Delta\tau_{OH}$) of the hydroxyl group proton in *o*-alkylated phenols. Clearly, from these results[31,60] the magnetic screening of the hydroxyl group proton decreases in the following order of substituents:

$$H > CH_3 > CH(CH_3)_2 > C(CH_3)_3 \ .$$

In addition, there is a decrease in screening on going from monoalkylphenols to dialkylphenols.

Table 5. Chemical shifts of the signal of the proton of the hydroxyl group in *o*-alkylphenols[31].

Compound	τ_{OH}	$\Delta\tau_{OH}$	ν_{OH}
Phenol	5.77	—	3612
o-Cresol	5.62	—0.15	3615
o-Isopropylphenol	5.54	—0.23	3614.5
o-t-Butylphenol	5.36	—0.41	3607; 3647
2,6-Dimethylphenol	5.56	—0.21	3622
2,6-Di-isopropylphenol	5.48	—0.29	3623
2,6-Di-t-butylphenol	5.13	—0.64	3648

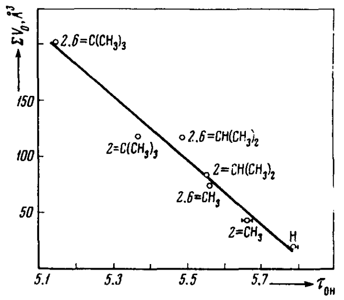


Figure 3. Correlation of the chemical shift of the hydroxyl-group proton and the total volume of the *o*-alkyl substituents in a series of alkylphenols.

It is characteristic that the values of ν_{OH}, also given in Table 5, follow the same relation but in the reverse order. Evidently the reason for this change in the two parameters is the same. In the examples considered the mutual repulsion of the electron clouds of the hydroxyl-group hydrogen and *o*-alkyl substituents leads to a decrease in the electron density at the hydroxyl proton, and consequently to a decrease in its diamagnetic screening. Furthermore, in this there is a definite decrease in the symmetry of the cloud of *S*-electrons of the hydroxyl-group hydrogen, which should lead to an increase in the paramagnetic contribution in the screening and a shift of the signal to weaker fields. The facts examined are illustrated well by the linear dependence of the chemical shift of the hydroxyl proton on the total volume of the *o*-alkyl substituent (Fig. 3). The screening of the hydroxyl proton is also altered by the introduction of a para-substituent into the 2,6-dialkylphenol[19,60]. With increase in the electronegativity of the para-substituent there is a shift of the signal from the hydroxyl-group proton to weaker fields and this shift is correlated with the $\sigma\bar{p}$-values of the substituents. This once again agrees with Ingold's results[22,23,25] on the investigation of the vibrations of the O–H bond in a series of 2,6-di-t-butylphenols. Direct confirmation of the correctness of the conclusions drawn is given by the linear dependence of τ_{OH} on ν_{OH}.

The above results suggest that the para-substituent brings about a redistribution of the electron density not only in the benzene ring but also at the oxygen atom of the hydroxyl group. In this connection, there is also a linear relation between the chemical shift of the signal of the hydroxyl proton and the charge on the oxygen atom (q_0).[31]

IV. THE HYDROGEN BOND OF 2,6-DIALKYLPHENOLS

Usually, hydroxyaromatic compounds are capable of forming a hydrogen bond and for many of them the formation of self-associates is also characteristic. It is noteworthy that all the spectroscopic methods considered above allow us to estimate in some measure the ability of alkylphenols to form associates with the solvent or self-associates. And since the hydrogen bond is especially sensitive to steric hindrances, the observable spectroscopic effects are often criteria of the steric hindrances created by the *o*-alkyl substituents. Most of the information on the influence of steric factors on the formation and strength of the hydrogen bond in a series of sterically-hindered phenols has been given by use of infrared[13,47–51,53,57,63,64] and NMR[31,65–69] spectroscopy.

It is known that many *o*-alkylphenols form self-associates in inert solvents at appreciable concentrations, whereas at a sufficiently great dilution they exist as monomers. In this connection, during the dilution of the solution with an inert solvent (for example, CCl_4) there is a displacement, the stronger the tendency of the phenol to form a hydrogen bond and consequently the hydroxyl group is less sterically screened. This change in the frequency of the hydroxyl group during the dilution of the solutions ($\Delta\lambda = \lambda^{OH}_{conc} - \lambda^{OH}_{dil}$) was also suggested by Coggenshall[13] for use in evaluating the steric effect of alkyl substituents in the formation of a hydrogen bond in the alkylphenol series. By using this parameter, which characterises the strength of the hydrogen bond, he divided the phenols into three groups: $\Delta\lambda > 0.15$ mμm, unscreened phenols; 0.04 mμm $< \Delta\lambda < 0.15$ mμm, semiscreened phenols; $\Delta\lambda < 0.04$ mμm, screened phenols. However, later[47] an empirical index of the hydrogen bond was introduced, which correlated with the screening effect of the alkyl substituents, and it was shown[51] that 2,6-di-t-butyl-4-methylphenol generally does not form self-associates.

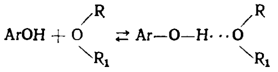
More rigorous results can be obtained by investigating the association of 2,6-dialkylphenols with various substituents. Thus Bellamy[57] found that the relative strength of the hydrogen bond formed between solvents and di-*o*-alkylphenols is independent of the effective volume of the ortho-substituent. An exception is 2,6-di-t-butylphenol for which the steric hindrance is so great that during the formation of its associates with the solvent the volume of the solvent molecules (acceptor) starts to play a decisive role. Careful analysis of the frequencies[63] of the hydroxyl group of 2,6-di-t-butyl-4-methylphenol showed that the associates of this phenol with the solvent can exist in two forms: in the first the hydroxyl-group proton lies in the plane of the ring (or close to it), and in the second it is perpendicular to the plane. In the second form resonance stabilisation of the hydrogen bond is assumed to be absent but there is also a decrease in the steric hindrances of solvation.

The existence of two forms of associates is confirmed by the results of Borod'ko's work[65], who observed, in an investigation of complex formation between 2,6-di-t-butylphenol and tetrahydrofuran, two bands from an associated hydroxyl group (3560–3390 cm^{-1}). On the basis of the thermodynamic parameters of the equilibrium:

he calculated the length of the hydrogen bond for each form: 2.85 and 3.05 Å. It is noteworthy that the length of the hydrogen bond for the unsubstituted phenol is ~ 2.7 Å. There is also a noticeable difference in the energy of the hydrogen bond. Thus for the unsubstituted phenol it is 6 kcal $mole^{-1}$, but for 2,6-di-t-butylphenol it is only 2 kcal $mole^{-1}$.

Spectroscopic results[63] have also been used to calculate the fraction of non-bonded hydroxyl groups of sterically hindered phenols in various solvents. However, the correlation between the basicity of the solvent and the fraction of non-bonded hydroxyl groups could not be deduced. Evidently, the reason for this lies in the geometry of the solvent molecules.

The change in the frequency of the hydroxyl group during association and the equilibrium constants of the reaction



$$ArOH + O\begin{matrix}R\\ R_1\end{matrix} \rightleftarrows Ar{-}O{-}H\cdots O\begin{matrix}R\\ R_1\end{matrix}$$

have been used for a quantitative estimation of the steric factor in the series of sterically hindered phenols[53].

Table 6. Equilibrium constants and shift of the frequencies of the hydroxyl group in the formation of associates of alkylphenols with ethers[51].

Phenol	Ethers											
	di-t-butyl		di-iso-propyl		tetra-hydrofuran		di-n-butyl		diethyl		$[(CH_3)_3Si]_2O$	
	K_{equil}	Δν	K_{equil}	Δν	K_{equil}	Δν	K_{equil}	Δν	K_{equil}	Δν	K_{equil}	Δν
Phenol	3.90	325	7.20	308	10.4	301	4.90	292	6.00	288	0.40	168
o-Cresol	1.70	309	3.20	301	5.5	294	2.60	288	3.40	283	0.00	159
o-Isopropylphenol	2.00	300	3.90	300	6.7	296	3.00	289	3.90	285	0.06	163
o-t-Butylphenol	2.30	280	4.10	291	5.7	284	2.90	280	3.70	278	0.00	169
2,6-Dimethylphenol	0.22	205	0.62	234	2.0	229	0.63	228	0.67	220	0.03	—
2,6-Di-isopropyl-phenol	0.19	197	0.48	215	1.7	201	0.23	201	0.51	191	0.06	—
2,6-Di-t-butylphenol	0.00	—	0.00	—	0.0	—	0.00	—	0.00	—	0.00	—

It was assumed here that the equilibrium constants are a measure of the overall effect and the frequency shift reflects the change in the strength of the hydrogen bond since it is determined by the changes in the force constant of the O–H bond. Table 6 gives the results obtained in this work.

As Table 6 shows, the value of $\Delta\nu$ changes symbathically with the basicity of the ether and increase in the steric effect of the alkyl substituents. An exception is 2,6-di-t-butylphenol, for which the steric hindrances during solvation are too great. On the other hand, the equilibrium constants for the association are not correlated with the basicity of the ether but are arranged in the order of an increase in the steric effects of the ethers. The small difference in the value of $\Delta\nu$ shows that the contributions of the hydrogen bond to the free energy of the system are approximately the same and the significant differences in the equilibrium constants are evidently due to the entropy factor, which is especially sensitive to steric effects. Similar results were obtained by Singh and Rao[50]. They noted that despite the decrease in the equilibrium constant for the association as the volume of the substituent is increased there is an increase in the enthalpy of the reaction. The decrease in $\Delta\nu$ accompanying the increase in the enthalpy of the reaction is evidently the result of an increase in the activation energy during the change of a proton into a hydrogen bond. If the conclusions drawn are correct then a direct relation between $\Delta\nu$ and the change in free energy of the system (ΔF_0) is to be expected. Actually, such a correlation between $\Delta\nu$ and ΔF_0 was observed. Subsequently Singh and Rao investigated the structure of the associate formed. They obtained equilibrium constants in the association of 4-X-2,6-di-t-butylphenols with tetrahydrofuran and the absence of a correlation of these constants with σ_p for the X substituent.

The observed behaviour is explained by certain breakdowns in coplanarity of the hydroxyl group, which leads to a non-planar hydrogen complex. The latter brings about a hindrance to the transfer of electronic effects of the para-substituent to the reaction centre and consequently to the destruction of the linearity between σ_p and K_{equil}. It should be noted that the relief of steric hindrances created by alkyl groups leads to a linear relation between these quantities, which occurs with an unsubstituted phenol[70].

The NMR method played a great part in the investigation of the hydrogen bond of sterically hindered phenols. The main parameter in studying a hydrogen bond by this method is the chemical shift of the proton participating in the formation of the hydrogen bond and also the dependence of this quantity on the concentration of the test substance in various solvents. The change in the position of the signal is due to the fact that with dilution or rise in temperature there is breaking of hydrogen bonds and the signal is shifted to higher fields. The existence of a hydrogen bond, on the other hand, shifts the signal to weaker fields, that is, there is a decrease in the magnetic screening of the proton. Theoretical analysis[71] of the causes of the change in the magnetic screening of the proton showed that the principal ones are the change in polarity of the O–H bond (displacement of the centre of gravity of the electron cloud to the side of oxygen) and the formation of a donor–acceptor bond ArO–H...X (shift of the lone pair of electrons of atom X to the side of the hydrogen atom).

In investigating the hydrogen bond arising in the self-association of alkylphenols and the nature of the complexes formed there have been several studies[31,67,68,72] of the concentration dependence of the parameters of the PMR spectra. In these studies it was found that the position of the signals for the protons of the alkyl groups and benzene ring are almost independent of the concentration of the substance whereas the signal from the proton of the hydroxyl group is usually shifted to higher fields on dilution. Consequently, the change in position of the signal of the hydroxyl proton is the result of the formation of self-associates. With increase in the volume of the alkyl substituents the chemical shift corresponding to the undiluted solution increases; the difference in the chemical shifts also changes on going from a dilute solution to a concentrated one. Both these facts are due to the increase in the length of the hydrogen bond during self-association owing to the increase in the volume of the substituents, that is, with decrease in the possibility of self-association. Table 7 gives the parameters of the self-association process:

$$n \cdot \text{ArOH}_{\text{monomer}} \rightleftarrows n\text{—ArOH}$$

showing the effect of the volumes of the *o*-alkyl substituents. Evidently the equilibrium constants (K_n) and chemical shift (δ_n) in the associated state gradually drop as the steric hindrances increase. The nature of the associate also changes. 2,6-Di-t-butylphenol does not give self-associates ($n = 1$), 2,6-dimethylphenol and 2,6-di-isopropylphenol form cyclic tetrameric associates ($n = 4$), and in the self-association of unsubstituted phenol a cyclic trimer is formed ($n = 3$).

Table 7. Comparison of the self-association parameters with the effective volume of the ortho-substituents[31].

Compound	Total volume, A^3	δ_n	K_n	n
Phenol	14.4	—3.11	4.78	3
2,6-Dimethylphenol	67.0	—0.82	$5.7 \cdot 10^{-2}$	4
2,6-Di-isopropylphenol	131.0	—0.44	$1.25 \cdot 10^{-2}$	4
2,6-Di-t-butylphenol	226.2	0.00	0.00	1

Interesting results were obtained in investigating the associates of phenols with proton-withdrawing solvents[31,72]. The ease of formation of such associates and their stability are determined not only by steric hindrances in the phenol molecule, but also by the volume and proton-acceptor properties of the solvent molecule. These investigations were made with the following solvents: acetone[31], diethyl-ether[31], triethylamine[31], dioxan[72], and ethanol[72]. With decrease in the concentration of phenols in ether, acetone, ethanol, and dioxan the chemical shift of the signal of the hydroxyl proton decreases. This shows that associates with these solvents are more stable that self-associates. When solutions of dialkylphenols in triethylamine are diluted the concentration dependence observed has a characteristic minimum. This anomaly can evidently be explained by the existence of two processes:

$$\text{ArOH} + \text{N}(\text{C}_2\text{H}_5)_3 \rightleftarrows \text{ArOH}\cdots\text{N}(\text{C}_2\text{H}_6);\ \text{ArOH} + \text{N}(\text{C}_2\text{H}_5)_3 \rightleftarrows \text{ArO}^{\ominus} + \text{H}\overset{+}{\text{N}}(\text{C}_2\text{H}_5)_3\,.$$

The concentration dependences of phenols in proton-withdrawing solvents usually reflect the competition of two processes: the dissociation of the self-associates and complex formation with the solvent. With 2,6-di-iso-propyl-, 6-t-butyl-2-methyl-, and 2,6-di-t-butyl-phenols the first process can be neglected, which allows the equilibrium constant of the reaction

$$\text{ArOH} + \text{X} \rightleftarrows \text{ArOH}\cdots\text{X}$$

to be estimated.

The results in Table 8 show that with increase in the steric factor in the phenol the stability of the complexes decreases. An increase in the volumes of the solvent molecules also affects their stability in the same direction.

Investigation of the association of 4-X-2,6-di-t-butyl-phenols with t-butyl alcohol showed that the nature of a para-substituent in the nucleus of the phenol has an effect on the nature of the association[69]. Unlike the results of Singh and Rao[50], obtained by infrared spectroscopy, the value of the chemical shift (τ_{OH}) of the phenol in the presence of t-butyl alcohol is correlated with the σ constants of substituent X (see Fig. 4, straight line *3*). The parallelism of straight lines *2* (in the absence of an alcohol) and *3* (in the presence of an alcohol) shows that the hydroxyl group of the 4-substituted 2,6-di-t-butylphenol in a complex with t-butyl alcohol is subjected to the same effect of the para-substituent as it is for a phenol unsubstituted in the ortho-positions.

Table 8. Equilibrium constants for the complex formation by alkylphenols[31,72].

Compound	Solvent and K_{equil}		
	ether	acetone	dioxan
2,6-Di-isopropylphenol	—	—	7.1
6-t-Butyl-2-methylphenol	3.0	4.2	5.6
2,6-Di-t-butylphenol	0.6	1.9	0.7

It is interesting to note the effect of substituent X in the phenol nucleus on τ_{OH} for t-butyl alcohol (see Fig. 4, straight line *1*). It can be seen that the increase in the degree of association of the phenol with the alcohol brings about the destruction of the alcohol–alcohol associates (shift of the signal of the proton of the hydroxyl group of the alcohol to a stronger field). The shift increases with increase in the electronegativity of the substituent. The latter is evidently due to the polarisation of the O–H bond of the phenol, which brings about an increase in the acidity of the phenol, that is, its proton-donating properties.

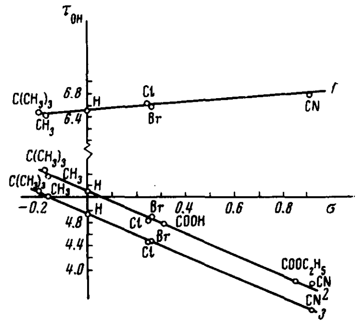


Figure 4. Correlation of τ_{OH} for 4-X-2,6-di-t-butylphenols (*2*, in the presence of t-butyl alcohol; *3*, in its absence) and τ_{OH} of t-butyl alcohol (*1*) with the σ^--factors of the para-substituent.

Bearing in mind the symbathic nature of the strength and bond order, an increase in the order ($P_{O...O}$) and polarisability ($\pi_{O...O}$) of the hydrogen bond with increase in the electronegativity of the para-substituent in the series of phenols must be expected. Such relations are actually observed[69]. They confirm the conclusion that the hydrogen bond in the associate is influenced by the nature of the para-substituent.

Generalising the above results, the following conclusions can be drawn: (*a*) all the 2,6-dialkylphenols are capable of forming hydrogen bonds; (*b*) the increase in the volume of the ortho-substituent reduces the capability of phenols for self-association; (*c*) 2,6-di-t-butylphenols do not give self-associates but can form a hydrogen bond with proton-withdrawing solvents, the nature of which depends on the nature of the substituent in the para-position of the phenol and the geometry of the solvent molecule.

V. ACIDITY OF STERICALLY HINDERED PHENOLS

The increased acidity of phenols in comparison with aliphatic alcohols is a characteristic feature of hydroxyaromatic compounds. This is due to the electron-withdrawing properties of the aromatic ring. Naturally, the change in the conjugation of the π-electrons of the nucleus with the p-electrons of the oxygen atom of the hydroxyl group should be reflected in the ease of heterolytic splitting of the O–H bond.

The introduction into the ortho-position to the hydroxyl group of alkyl substituents usually brings about a marked drop in the acidity of the phenol[73-85]. The reasons for the drop in acidity can be as follows: a positive inductive effect of the alkyl substituents, leading to electronic saturation of the O–H bond (however, as Table 9 shows, its contribution is small), the breakdown of the coplanarity of the aromatic ring and hydroxyl group, which decreases the effect of the electron-withdrawing properties of the ring, and finally the steric hindrances of the solvation of the anion formed.

Table 9. Dissociation constants of alkylphenols[43,73,82].

Compound	pK, 25°	pK, 25°
	water	methanol
Phenol	10.02	14.20
o-Cresol	10.33	14.80
o-Propylphenol	10.55	15.07
o-t-Butylphenol	11.35	16.25
2,6-Dimethylphenol	10.63	15.27
2,6-Di-isopropylphenol	11.08	15.11
2,6-Di-t-butylphenol	11.70	17.08
p-Cresol	10.27	14.55
2,4,6-Tri-t-butylphenol	12.19	—
2,6-t-Butyl-4-methylphenol	12.23	17.51

It has already been shown above that the introduction of even two t-butyl groups into ortho-positions displaces the OH group from the plane of the aromatic ring by ⊁ 14°, which is almost without effect on the conjugation of the p-electrons of the oxygen atom with the aromatic ring. This shows that the contribution of this effect to the decrease in acidity of the derivatives of 2,6-di-t-butylphenols is very small. Therefore the main reason for the drop in acidity is the steric hindrances of the solvation which is clear from Table 9, which gives the dissociation constants of the phenols in water and methanol for the three groups of compounds. It is suggested[42,43,80,81,86,87] that voluminous alkyl groups hinder the solvation of the anion formed as a result of dissociation and decrease its stability. Furthermore, the alkyl groups in the phenol molecule decrease the effective dielectric constant around the hydroxyl group, which increases the electrostatic energy of the anion and leads to a decrease in the dissociation constant. This conclusion is confirmed also by an investigation of the electrical conductivity of solutions of alkylphenols[88], which drops sharply with increase in the volume of the *o*-alkyl substituents.

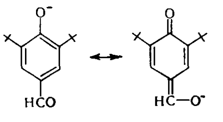
In considering the effect of the nature of the para-substituent on the acidity of the phenol it must be borne in mind that for some para-substituted phenols there is the possibility of tautomeric conversions (for example, quinoxime ⇌ nitrosophenol). This leads to rather complex dependences, especially for sterically hindered phenols, which generally tend to be converted into compounds with quinolide or quinonoid system of bonds. Problems of the tautomerism of phenols have been discussed in detail in a review[85].

From the example of unsubstituted phenol[43,89] and 2,6-dichlorophenol[74,90], it was repeatedly noted that the introduction of electron-withdrawing substituents into the para-position markedly increases the acidity of the phenol and it increases with the electronegativity of the substituent. A similar picture is observed for sterically hindered phenols[42,46,79,84,91,92]. Table 10 gives results on acidities for two series of 4-substituted phenols, which are correlated well with the σ_p constants of the para-substituents.

Table 10. Dissociation constants of 4-X-phenols at 25°C (water).[43]

X	pK_a		σ_p	X	pK_a		σ_p
	unsubstituted phenol	2,6-di-t-butyl phenol			unsubstituted phenol	2,6-di-t-butyl phenol	
CH_3	10.26	12.23	—0.15	$COOC_2H_5$	8.50	9.50	0.64
$C(CH_3)_3$	10.23	12.19	—0.14	$(CH_3)_3N^+$	8.21	9.84	0.77
OCH_3	10.21	12.15	—0.13	$COCH_3$	8.05	8.68	0.84
H	9.99	11.70	0.00	CN	7.97	8.70	0.88
COO^-	9.39	10.80	0.24	CHO	7.60	8.05	1.04
Br	9.36	10.83	0.25	NO_2	7.15	6.65	1.24
SO_3^-	9.03	10.40	0.40	NO	6.36	8.18	1.60
$CONH_2$	8.56	9.53	0.61				

It should be noted that for some 4-X-2,6-di-t-butylphenols with strongly electron-withdrawing substituents, (for example, CHO) the changes in p*K*a on going from the corresponding 4-X-phenol is not so great and can be satisfactorily explained by the inductive effect of the *o*-t-butyl groups without allowance for their steric factor. Values of p*K*a for a series of sterically hindered phenols in various solvents were found experimentally and calculated with allowance only for electronic effects of the two t-butyl groups; these values of p*K*a agreed satisfactorily for 2,6-di-t-butyl-4-formylphenol. When X is an alkyl residue, there is no such agreement, that is, in addition to the inductive effect of the para-substituent there is also the steric effect of the *o*-t-butyl groups. The observed anomaly can be explained by assuming delocalisation of the negative charge in the phenoxide ion with participation of the para-substituent.



If the requirements for solvation of both oxygen atoms in the anion formed are the same, then the total solvation of the 4-formylphenoxide and 2,6-di-t-butyl-4-formylphenoxide anions should be approximately the same. This suggests that although the steric effect of t-butyl groups greatly reduces the solvation of the phenol oxygen, it simultaneously facilitates the redistribution of the electron density at the oxygen atom of the formyl group and increases its degree of solvation, that is, the total change in the solvation of the anions as a whole is probably extremely small.

Hence the steric hindrances created by bulky alkyl groups show the twofold action on the ionisation of sterically hindered phenols. On the one hand, the strain in the O—H bond produced in the screening of the hydroxyl group facilitates the heterolytic breaking of the O—H bond, and on the other hand the phenoxide anion formed loses its stability due to the hindered solvation. The introduction of a para-substituent changes the value of some effect and leads to a marked change in the acidity of sterically hindered phenols.

VI. DIPOLE MOMENTS AND SORPTION PROPERTIES OF STERICALLY HINDERED PHENOLS

The steric effect of *o*-alkyl substituents is also decisive for certain other physicochemical parameters of sterically hindered phenols. First of all there are the dipole moments and the related sorption properties of phenols. These aspects have been discussed in a series of studies, in which the importance of steric hindrances is stressed to some extent. Thus, it was noted[19,93,94] that the introduction of t-butyl groups brings about a change in conjugation. This is expressed in an increase in the moment of the C—O bond from 0.66 D in phenol to 1.53 D in 2,4,6-tri-t-butylphenol. However, it must be remembered that the dipole moment is less sensitive to different steric effects than the physicochemical characteristics discussed above.

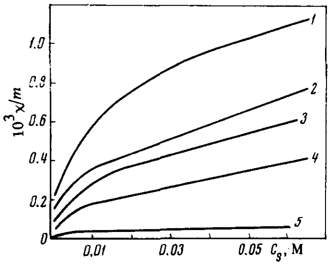


Figure 5. Freundlich isotherms in the adsorption of alkylphenols from cyclohexane on carbon: *1*) H; *2*) CH_3; *3*) *p*-t-C_4H_9 phenol; *4*) $CH(CH_3)_2$; *5*) $C(CH_3)_3$.

The more pronouned dependences on the values for the *o*-alkyl substituents were obtained in investigating the sorption properties of phenols[95-98]. The study of the sorption on carbon[97] and aluminium oxide[96] shows a decrease in the degree of sorption with increase in the volume of the *o*-alkyl substituents. Fig. 5 shows the Freundlich isotherms for several di-*o*-alkylphenols, where X is the amount of working adsorbent, *m* the total amount of adsorbent, and *C* the equilibrium concentration of adsorbent.

Fig. 5 shows there is a sharp difference in the sorption properties of phenols. Similar results were obtained in studying the chromatographic behaviour of phenols[95] (Table 11).

Table 11. Sorption of alkylphenols on silicic acid[95].

Alkyl	R_f		
	o-alkyl-phenol	*p*-alkyl-phenol	2,6-dialkyl-phenol
H	0.26	0.26	0.26
CH_3	0.37	0.28	0.55
C_2H_5	0.43	0.30	—
$CH(CH_3)_2$	0.52	0.30	0.95
$C(CH_3)_3$	0.74	0.31	1.00

Table 11 gives the R_f values obtained in the adsorption of phenols on silicic acid. A comparison of the change in frequency of the adsorption of the hydroxyl group of the phenol in the infrared range with the K_a values, where $K_a = 1/(R_f - 1)$, depending on the value of the *o*-alkyl substituents, obeys a first-order equation[98]. Evidently, the observed increase in the value of R_f with increase in the volume of the *o*-alkyl substituents also shows the decisive role of the steric screening of the hydroxyl group.

---o0o---

The above features of the structure and certain physicochemical properties of sterically hindered phenols greatly determine the behaviour of compounds of similar type in various chemical changes. Thus a very characteristic property of these phenols is the ease with which they lose the hydrogen atom of the hydroxyl group as a proton or radical in ionic or radical processes. At the same time the considerable steric hindrances ensure that this oxygen is a not very accessible reaction centre of the molecule. These very properties agree well with the structure of sterically hindered phenols and are responsible for many interesting features of their behaviour: the inhibition of radical reactions, the formation of stable phenoxide radicals, the change into cyclohexadienones and methylenequinones, etc.

Nuclear Magnetic Resonance Spectroscopy of Organometallic Allyl Compounds

L.A.Fedorov

The NMR spectroscopic data for organometallic allyl and related derivatives have been examined. It is suggested that allyl compounds of transition metals be classified solely as σ- and π-derivatives and NMR spectroscopic criteria for the assignment of the test compounds to one of these types have been formulated. The effects of the structural non-equivalence of allyl ligands in a series of compounds, certain types of isomerism of allyl derivatives and also their possible lack of stereochemical rigidity have been considered. The validity, from the standpoint of NMR experiments, of the hypothesis of the σ-π transformations of allyl derivatives of transition metals in the presence of bases has been discussed. Hypotheses have been put forward concerning the geometry of the allyl compounds of certain non-transition metals.
The bibliography includes 171 references.

CONTENTS

I. INTRODUCTION

Depending on the geometry of the allyl−metal (a transition or non-transition metal) bond, allyl derivatives can be divided into two basic types: (1) compounds with the usual localised σ-bond [structure (I)]; (2) compounds with a non-classical delocalised bond [structure (II)].

(I)

σ-Bond

(II)

Delocalised bond

Allyl derivatives of the σ-type (I) are more characteristic of the chemistry of non-transition metals, while compounds with a delocalised bond (II), usually referred to as the π-bond[1], are typical with transition metals. There is no rigorous correspondence between the nature of the metal (transition or non-transition) and the bond type [(I) and (II)]. A fair number of transition metal derivatives with an allyl−metal σ-bond have been synthesised. On the other hand, structures with a delocalised bond (II) are known for non-transition metals, but, in order to regard them as π-complexes, a group-theoretical justification is necessary. Together with organometallic compounds containing an unsubstituted or substituted allyl group, it is natural to consider also compounds of certain other classes in which the allyl fragment is part of an open or closed carbon chain. In the discussion on derivatives with a delocalised bond, such grouping permits the consideration from one standpoint of all compounds where this bond is formally formed by three electrons from the three carbon atoms of the ligands.

Nuclear magnetic resonance (NMR) spectroscopy has proved to be the most important physicochemical instrument for the discovery and comprehensive investigation of complexes of the π-allyl type. For example, the non-classical structure of certain allyl (and also π-benzyl and trimethylenemethane) transition metal derivatives was initially proposed on the basis of NMR studies[2-4] and only subsequently confirmed by diffraction methods[5-7]. The isomerism in the series of allyl derivatives, various rearrangements, and many other structural and chemical problems have been successfully investigated by NMR spectroscopy. During the last decade, numerous spectroscopic data have accumulated and probably in the immediate future the NMR method will provide much information about compounds of this type.

However, for a number of reasons the data obtained are not always interpreted with sufficient rigour. As a result, certain conclusions which "follow from NMR data" and which have been widely adopted in the literature, actually proved to be incorrect. Apart from other reasons, this was because in studies of organometallic allyl compounds the entire "arsenal" of the NMR method was not employed. For example, until now no studies have been made of such important characteristics as $^{13}C-^{1}H$ spin−spin coupling, although the constants $J_{^{13}C-^{1}H}$ provide information about the valence state of the carbon atoms in the allyl ligand. Moreover, in the discussion of the screening of the proton in the π-allyl ligand the effect of the magnetic anisotropy of other ligands, for example triphenylphosphine, is as yet rarely taken into account.

All these considerations led us to undertake the present review. We must stipulate that the method chosen for the treatment of the subject, namely the use of data based on only one physicochemical procedure, dictated both the principles governing the selection of facts and the manner of their presentation. As a result, we have to concentrate attention only on the conclusions which follow unambiguously from NMR spectroscopic data. Clearly, the final answer to the majority of the problems considered can be obtained only by considering together results obtained by several physicochemical methods.

II. COMPOUNDS WITH A LOCALISED σ-BOND

NMR spectroscopic studies have been made on a number of organometallic σ-allyl derivatives[1, 8–17] and related compounds containing the σ-allyl fragment—cyclopentadienyl[18–24], benzyl[3, 25–28], and indenyl[19, 29–32] derivatives. In almost all cases NMR spectroscopy permits fairly reliable identification of the σ-allyl type. The relevant spectroscopic characteristics are presented in Table 1. For comparison, data for certain other organometallic allyl compounds are also included.

The ^{1}H NMR (PMR) spectra of σ-allyl derivatives (Fig. 1) show at least three groups of signals (intensity ratios 1 : 2 : 2) characteristic of the normal allyl system ($AKLX_2$, in the limiting case $ABCX_2$):

=CH—	CH_2=	—CH_2M
δ 6.0—6.6 p.p.m.	δ 3.5—5.0 p.p.m.	δ 1.5—2.8 p.p.m.

The lines due to the most screened aliphatic CH_2 protons (X_2) are split by CH vinyl protons, which to a first approximation gives rise to a doublet in the spectrum. The vinyl protons of the =CH_2 (KL) group are non-equivalent and therefore produce a poorly resolved multiplet in the spectrum. As a result of splitting by all the remaining protons in the allyl fragment, the vinyl =CH proton (A) gives rise in the spectrum to a distinct asymmetric multiplet, typical for vinyl compounds, located in the region of the weakest fields.

It follows from the data in Table 1 that the screening of individual groups of protons in each compound differs somewhat from the corresponding values in propene.

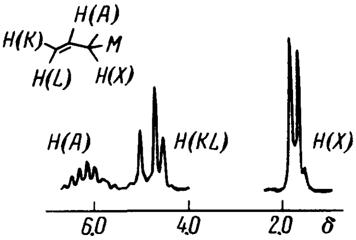

Figure 1. NMR spectrum of the compound σ-$C_3H_5Mn(CO)_5$ ($AKLX_2$ spin system)[1].

* Tetramethylsilane (Ed. of Translation)

However, these differences do not make it necessary to take into account additional factors apart from those already known: the electronegativity of the metal, the magnetic anisotropy of the C – M bond, and the anisotropies of the individual fragments of the molecule. The coupling constants J_{HH} (*cis*) and J_{HH} (*trans*) of the compounds under considerations, including transition metal derivatives, in fact agree with the corresponding constants for propene. Nor are any other spectroscopic differences observed between σ-allyl derivatives of transition and non-transition metals. Furthermore, one may conclude that, under the conditions (temperature, solvent) where NMR spectroscopy indicates a σ-allyl structure of the compounds considered, no signs of coordination of the double bond of the allyl fragment to the metal atom are observed.

The available data permit the formulation of the principal spectroscopic characteristics of organometallic allyl compounds with a localised σ-bond: (1) the non-equivalence of the CH_2 groups; (2) the equivalence of the protons in the aliphatic CH_2 group and their non-equivalence in the olefin group; (3) the agreement of the vicinal coupling constants J_{HH} (*cis*) $\simeq$ 9 – 10 Hz and J_{HH} (*trans*) = 17 Hz with the corresponding constants for propene and other allyl derivatives.

The PMR spectra of σ-benzyl, σ-indenyl, and σ-cyclopentadienyl derivatives of transition and non-transition metals are also very similar to the spectra of the corresponding hydrocarbons (toluene, indene, and cyclopentadiene). In all cases the aliphatic protons are the most screened and the observed spectrum fully agrees with expectation for a spin system with a C – M σ-bond. It should also be noted that the signals due to aliphatic protons, geminal relative to the metal atoms, are located in a fairly narrow region of the spectrum for each of the above classes of compounds:

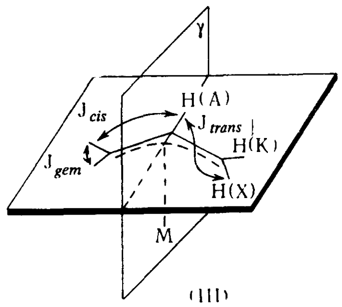
$CH_2{=}CH{-}CH_2M$	$C_6H_5CH_2M$	C_5H_5M	C_9H_7M
δ 1.5—2.8 p.p.m.	δ 2.2—3.0 p.p.m.	δ 3.2—3.5 p.p.m.	δ 2.9—4.0 p.p.m.

This evidently can be used as a test for the formation of a localised bond.

III. DERIVATIVES WITH A DELOCALISED BOND

The PMR spectra of the compound π-$C_3H_5Co(CO)_3$ with a delocalised bond were investigated for the first time in 1960 by Heck and Breslow[2]. The PMR spectra of allyl derivatives of transition metals with a delocalised C_3H_5 – M bond were investigated in greater detail by McClellan et al[1]. The number of studies which in one form or another relate to the NMR spectroscopy of π-allyl compounds increases steadily. Spectroscopic data are now available both for compounds containing allyl groups only [$(C_3H_5)_nM$, M = Ni, Pd, Zr, Hf, Th, Rh, Ir, Pt, U, etc.)] [36–44] and for mixed compounds containing, apart from the π-allyl ligands, one or several other groups: a halogen[1,45–47], carbonyl[1,2,48–50], π-cyclopentadienyl[1,47,54,55], a halogen and carbonyl[56–60], a halogen and π-cyclopentadienyl[54,61], carbonyl and π-cyclopentadienyl [8–10,51–53], etc. Spectroscopic data are also being quoted for π-allyl complexes in which the transition metal atom is coordinated to phosphines, pyridine, dimethyl sulphoxide, the acetylacetonate ion, and similar basic ligands [11,12,46,62–73,82].

Historically the NMR spectra of non-transition metal derivatives with a postulated delocalised bone [structure (II)] were investigated earlier than those of the π-allyl complexes of transition metals. Thus, as early as 1959, Nordlander and Roberts[74] observed in the PMR spectrum of C_3H_5MgBr characteristics the interpretation of which did not exclude the possible existence in this compound of one of the forms of the delocalised C_3H_5 – Mg bond:



(III)

Table 2 lists certain spectroscopic characteristics of the π-allyl derivatives of transition metals. In the PMR spectra of compounds with an unsubstituted ligand, as in the case of σ-complexes, there are as a rule three groups of signals with intensity ratios of 1 : 2 : 2 (Fig. 2). However, the spin system of the AK_2X_2 spectrum indicates a greater symmetry of the allyl – M group in compounds of the π-type. In particular, it follows from the spectrum that each of the two signals in a strong field (K_2X_2) no longer refers to an individual CH_2 group, as in the σ-structure, but to an individual type of proton from each CH_2 group—*cis* or *trans*†.

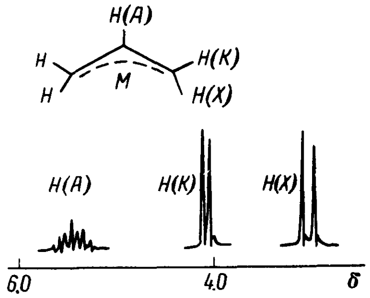


Figure 2. NMR spectrum of the compound $(\pi\text{-}C_3H_5PdCl)_2$ (AK_2X_2 spin system)[66].

The results led to the conclusion that in derivatives of π-type [structure (III)] a delocalised bond is formed and all the carbon atoms of the allyl fragment are in a state of sp^2-hybridisation (strictly speaking, in order to assess the valence state of the carbon atoms of the π-allyl ligand, it is also necessary to have data on $^{13}C-{}^1H$ spin – spin coupling). Then both C – C bonds of the ligands prove to

---

† Here and subsequently we are considering the position of the terminal protons relative to the central proton or the group replacing it [structure (III)]. The terms *"cis"* and *"trans"* were introduced for these compounds in 1959 by Nordlander and Roberts[74] and are used in the discussion of both allyl and π-olefin, π-butadiene, π-pentadienyl, and similar complexes. Two years later[1] the terms *"syn"* and *"anti"* were introduced, but have not been widely adopted by investigators of π-complexes (with the exception of allyl complexes).

be equivalent and the metal is located symmetrically relative to the terminal carbon atoms. Subsequently these conclusions were confirmed by diffraction data (see, for example, Refs. 5, 80, 87, and 88).

The H(A) proton bound to the central carbon atom proves to be least screened in all cases. Its signal consists of a complex symmetrical multiplet due to splitting by the two pairs of terminal protons. Two other signals are due to the *cis*-protons H(K) and *trans*-protons H(X). To a first approximation, each of them consists of a doublet due to splitting by the central atom. In a more detailed investigation of these "doublets" it is possible to observe a fine structure due to the interaction of the non-equivalent geminal protons H(K) and H(X). The corresponding coupling constant J_{HH} (*gem*) usually does not exceed 1.5 Hz [36,41,62,66] but in the case of substituted compounds of the allyl type higher splittings for geminal protons are also known: 2 Hz for $2\text{-}ClC_3H_4$Pdacac[68] and

3 Hz for π-$C_6H_5CH_2Mo(CO)_2C_5H_5$.[3] We may note that for the compound $(CH_2)_3CFe(CO)_3$ this value reaches up to 5 Hz.[4]

As in π-complexes of other types, the proton spin–spin coupling constants for π-allyl complexes J_{HH} (*cis*) = 3–8 Hz and J_{HH} (*trans*) = 10–15 Hz (Table 2) are much lower than for the initial olefins [for example in the case of ethylene J_{HH} (*cis*) = 11.5 Hz and J_{HH} (*trans*) = 19.1 Hz[89]] and the corresponding σ-allyl derivatives. Complex formation is the evident explanation of this effect.

However, it should be emphasised that, despite the lowering of the absolute values of the constants J_{HH} of all three types, the sequence of their relative values established previously[34,90] in the olefin series is strictly maintained:

$$J_{HH}\,(trans) > J_{HH}\,(cis) > J_{HH}\,(gem).$$

This finding permits an unambiguous assignment of the signals due to *cis*- and *trans*-protons in the spectroscopic study of each new π-complex.

The experimental data so far accumulated (Table 2) show that in π-allyl complexes the *cis*-protons H(K) are less screened than the *trans*-protons H(X). The range of variation of the screening of the individual groups of protons in π-complexes is much wider than in derivatives of the σ-type.

$$\begin{array}{ccc} \mathrm{H(A)} & \mathrm{H(K)} & \mathrm{H(X)} \\ 5.68 \geqslant \delta \geqslant 3.5 & 4.4 \geqslant \delta \geqslant 2.7 & 3.2 \geqslant \delta \geqslant 1.3 \end{array}$$

This can probably be accounted for by the greater sensitivity of the π-allyl ligand to the characteristics of the complex-forming metal. Differences in experimental conditions can also play a decisive role: Table 2 includes for certain compounds data for screening in benzene solutions, although the use of this solvent can seriously distort the results. Evidently, as information accumulates on the spectra of the π-allyl derivatives of an increasing number of metals, the range of variation of the screening of protons of each type may become extended. At the same time, there is also a possibility that the range of variation will be found to be narrower in repeated NMR measurements under standard conditions, particularly when NMR spectroscopic data for the compounds in solvents such as benzene, toluene, etc. are excluded. We may also note that, although the ranges of variation of the chemical shifts of the individual groups of protons overlap to a considerable degree, for each specific π-complex the sequence of increasing screening is as a rule maintained: H(A) < H(K) < H(X).

Thus, using as an example compounds containing an unsubstituted π-allyl group, it is possible to formulate a number of criteria for the π-coordination of the transition metal atom to the ligand: (1) the equivalence of both CH_2 groups and the non-equivalence of the protons in each; (2) the shift of the signals of all the protons towards stronger fields compared with the σ-allyl complexes, particularly for *trans*-protons; (3) a sharp reduction of the J_{HH} (*cis*) and J_{HH} (*trans*) constants.

At a fairly low temperature, the PMR spectrum[91] of C_3H_5Li resembles the spectra of the π-allyl complexes of transition metals (Table 3). It consists of three signals and corresponds to the AK_2X_2 spin system. All the necessary spectroscopic criteria of the delocalised bonds were observed: the equivalence of the CH_2 groups, the non-equivalence of the *cis*- and *trans*-protons, and the lowering of the constants J_{HH} (*cis*) and J_{HH} (*trans*). The only difference between the spectra of C_3H_5Li and the π-allyl complexes, for example $(C_3H_5)_4Zr$, consists in the reversal of the positions in the spectrum of the signals due to the *cis*- and *trans*-protons: in contrast to transition metal π-complexes, the *cis*-protons in allyl-lithium are the most screened. Thus one may conclude that, under conditions where the spectrum of allyl-lithium was measured (Table 3), a delocalised bond of type II and not a σ-bond is formed, the metal atom being located symmetrically relative to both CH_2 groups.

Table 3. Comparison of the spectroscopic parameters of zirconium and lithium derivatives with a delocalised allyl–M bond.

The NMR spectrum of the π-allyl complex becomes significantly simplified after symmetrical substitution in the ligand: substitution of the central proton[1,11,46,47,68,82], substitution of both *cis*-protons by identical groups[80,81,92,93], and substitution of both *trans*-protons with formation of a π-enyl ring[47,51,78,83,84,94-96]. The chemical shifts and the spin–spin coupling constants of the remaining protons in general differ little from the corresponding values for π-complexes with an unsubstituted ligand.

Table 4. Chemical shifts of cycloheptatrienyl protons.

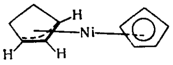
We may note a characteristic feature of the π-enyl complexes associated with the sensitivity of the spin–spin coupling constants to ring size[97-99]. The J_{HH} (*cis*) constants for π-enyl rings are lower than those for the non-complex molecules, as can be seen from a comparison of the corresponding values, for example, for compounds (IV) and (V). However, the absolute values of these constants are significantly lower for both types of compounds than in the case of open-chain systems—π-allyl complexes and olefins[78,96]. Thus the J_{HH} (*cis*) constants for the π-enyl complexes may not fall in the range of values found for the π-allyl compounds:

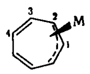


(IV)

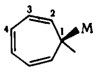
(V)

$J_{HH}(cis)$ = 2.7 Hz (Ref.96) $J_{HH}(cis)$ = 5.4 Hz (Ref.97)

For certain stereochemically non-rigid cycloheptatrienyl molybdenum and cobalt compounds (Table 4), the existence of a π-allyl bond has been postulated [structure (VI)] [104-106]:



(VI)



(VII)

However, recent studies[101,102], including one on the corresponding iron derivative[100], show that at fairly low temperatures the NMR spectra of these compounds agree better with the instantaneous formation of a C_7H_7-M σ-bond [structure (VII)]: the aliphatic proton proves to be most highly screened and the chemical shifts of each of the three pairs of olefinic protons are similar to the corresponding values for cycloheptatriene. To resolve this contradiction, it is evidently necessary to carry out structural studies. However, it should be emphasised that discrepancies between the actual structures of organometallic compounds and those expected on the basis of the effective atomic number rule are being increasingly observed. This can be illustrated, for example, by the structure of the indenyl compound of samarium for which NMR data indicate a localised C–Sm σ-bond[31], although a delocalised π-bond had been suggested, by analogy with the corresponding cyclopentadienyl derivatives of the lanthanides.

IV. PROTON SCREENING IN π-ALLYL COMPLEXES

A shift of the PMR signals to the "aliphatic" region of the spectrum is observed on formation of π-complexes by aromatic and olefinic ligands of a wide variety of types[107]. Since the effect itself has not so far been fully interpreted quantitatively, its discussion for π-allyl compounds must be restricted to certain qualitative considerations. As usual[34,90], it is natural to assume that the magnetic screening of protons is determined mainly by the relation between two factors: the simultaneous effect of the anisotropy of the magnetic susceptibility of the adjacent atoms and bonds and the changes in electron density at the given hydrogen atom.

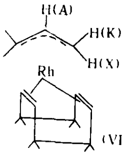
The effect of the anisotropy of the magnetic susceptibility on the screening of protons in the π-allyl ligand may include both the effect of the magnetic anisotropy of the ligand itself and the effect of the transition metal atom and other groups bound to it. One of the main causes of the shift towards stronger fields of the signals due to the protons in olefinic derivatives on formation of π-allyl compounds is the change in the magnetic anisotropy of the multiple bonds on complex formation[108].

The magnetic anisotropy of the double bond, which leads to a shift of the proton signal towards weaker fields compared with its "true" position (i.e. when only local screening is taken into account), is known[34,90] to make a considerable contribution to the screening of olefin protons. On formation of the π-allyl complex the contribution of this effect diminishes, which is shown in the spectra by a shift of the signals of the protons investigated towards stronger fields, although their screening then merely approaches the "true" value.

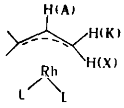
The magnetic anisotropy of the transition metal, particularly the presence in the latter of filled *d* levels, can have a significant effect on the screening of the protons of the coordinated ligand. This effect is clearly revealed by the fact that in all π-allyl complexes the *trans*-protons located close to the transition metal atom are screened more than the *cis*-protons. This type of feature is not characteristic only of allyl-lithium (Table 3), where a non-transition metal is involved in the formation of a delocalised bond[91].

The magnetic anisotropy of other ligands bound to the transition metal atom can also influence the screening of the protons. For example, when the chemical shifts of the protons in two allylrhodium derivatives [(VIII) and (IX), Table 5] are compared, it is evident that the replacement of cyclo-octa-1,5-diene by two triphenylphosphine groups alters the screening of the allyl protons in different ways. Then the central proton is screened to a greater extent, while the terminal protons are in fact descreened, a particularly pronounced effect being observed for *trans*-protons located closest to the source of perturbation. One cause of this behaviour is probably the fact that the effect of the magnetic anisotropy of the triphenylphosphine groups is greater than the effect of cyclo-octa-1,5-diene.

Table 5. Changes in the screening of the protons in the π-allyl derivatives of rhodium as a function of the structure of the compound.



(VIII)



(IX)

$L = P(C_6H_5)_3$

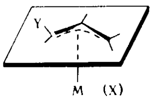
Type of proton	δ_H, p.p.m.rel. to TMS		Δδ
	(VIII)(Ref.109)	(IX)(Ref.78)	
H (A)	5.17	4.95	0.22
H (K)	2.65	2.74	–0.09
H (X)	1.67	2.19	–0.42

It follows from the data in Table 2 that in certain cases a shift of the signal due to the protons in the π-allyl ligand towards strong fields, relative to that of the protons of the non-coordinated olefin, reaches 3–4 p.p.m. Such a shift cannot be explained without postulating that, apart from the influence of the magnetic anisotropy of neighbouring atoms and bonds, the change in the local screening of the ligand protons, caused by the partial transfer of electron density from the metal atom to the ligand (M → L), also has a definite effect. This is evidently a reflection of the electropositive nature of the metal compared with carbon atoms. Unfortunately, it is very difficult to isolate this factor against the background of the experimentally observed overall effect.

It is quite likely that the displacement of electron density from the metal to the ligand is accompanied by its non-uniform distribution in the π-allyl group. Possibly this is why in the complexes examined the central proton proves to be least screened compared with others. A more pronounced screening of the terminal protons may be evidence of an enhanced electron density at the corresponding carbon atoms. Consequently, if electrophilic substitution reactions involving a π-allyl ligand are discovered, the point of attack in such reactions will be primarily the terminal carbon atoms. However, in choosing model systems for such reactions, it is necessary to observe certain conditions. Such models must evidently be characterised not only by the presence of an excess electron density in the ligand but also by a fairly pronounced inertness of the molecule towards possible competing reactions (a strong allyl–M bond, the absence of labile M–halogen bonds, etc.). It may be that in fact an unsuitable choice of models is the reason why all known attempts to achieve electrophilic substitution in a π-allyl ligand (see, for example, Rubezhov[110]) have so far proved unsuccessful.

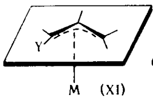
V. ASYMMETRIC ALLYL COMPOUNDS WITH A DELOCALISED BOND

Like any other symmetrical system, a π-allyl complex may lose, as a result of some perturbation, the plane of symmetry γ passing through the metal and the central carbon atom [structure (III)]. As a result, the two "arms" of the π-allyl ligand may become non-equivalent. One may point to several sources of perturbation, which lead to a non-uniform distribution of electron density in a π-allyl ligand. In the simplest case this is a substituent Y joined to one of the terminal carbon atoms [structures (X) and (XI)].



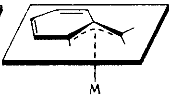
(X)

cis-isomer



(XI)

trans-isomer



(XII)

An asymmetric π-complex of this type, crotylcobalt tricarbonyl, was investigated by the NMR method earlier than others[111]. Subsequently many other asymmetric π-allyl complexes were described[41,55,66,76,112-116]. Some of them are listed in Table 6. Lithium derivatives with asymmetric allyl ligands are also known[117].

It follows from the data in Table 6 that in the complexes under consideration the *trans*- (and *cis*-) protons of the same ligands can have different chemical shifts and somewhat different constants for spin–spin coupling to the central proton (Fig. 3).

The π-benzyl and π-thienyl derivatives of a number of transition metals constitute an interesting class of asymmetric π-allyl complexes[3,25,118,119]. In these compounds asymmetry is an inseparable property of the molecules: three carbon atoms of the ligand form with the metal a delocalised π-allyl bond in such a way that one of its "arms" belongs to the ring [structure (XII)]. At a low temperature, when the geometry of these compounds is fixed, the protons of the CH_2 group are non-equivalent. In particular in $\pi\text{-}C_6H_5CH_2Mo(CO)_2\text{-}\pi\text{-}C_5H_5$ the chemical shifts of these protons at −30°C differ approximately by 1 p.p.m. The proton on the part of the ring involved in the π-allyl bond becomes much more screened than the others and acquires a chemical shift uncharacteristic of aromatic protons [$\delta = 5.2$ p.p.m. for $\pi\text{-}C_6H_5CH_2Mo(CO)_2C_5H_5$]. Because of the structural characteristics of molecules of this class, there is only one piece of spectroscopic evidence for the asymmetry—the difference between the screening of the two *trans*-protons.

Groups external to the allyl ligand and also the low symmetry of the entire molecule can also give rise to the asymmetry of the π-allyl ligand. However, in compounds where these factors may operate, the possibility or impossibility of asymmetry is not evident in all cases. We shall examine two examples of the occurrence of asymmetry of this type in π-allyl complexes of two classes—planar square and octahedral complexes.

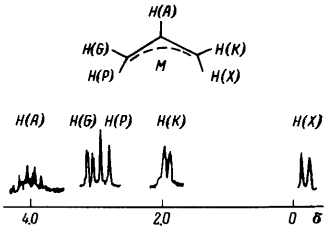


Figure 3. NMR spectrum of the compound $(\pi\text{-}C_3H_5)_4Mo$; four equivalent asymmetric π-allyl ligands (AGKPX spin system)[41].

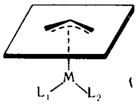
Complexes of the platinum group metals (XIII) have been investigated fairly comprehensively. When $L_1 = L_2$ [for example, $(C_3H_5PdCl)_2$, [46,47,66,93] $(C_3H_5NiBr)_2$, [75] etc.], they have a spectrum of the AK_2X_2 type, characteristic of a symmetrical π-allyl ligand. Evidently asymmetry may arise only when the substituents are non-equivalent ($L_1 \neq L_2$), which leads to the corresponding non-equivalence of the *cis* and *trans*-protons and the appearance in the spectrum of five signals of equal intensity (AGKPX spin system).



(XIII)

However, the possibility of asymmetry is not realised in all cases (Table 6). For example, when the groups L_1 and L_2 do not differ very much in their electronic effects, the spectrum characteristic of symmetrical complexes is maintained. As already stated, the chemical shifts of protons may be influenced not only by changes in electron density but also by the magnetic anisotropy of adjacent groups. In many cases the asymmetry of the allyl group is due precisely to this factor. For example, the spectra of compounds C_3H_5PdClL correspond to the symmetrical allyl group (AK_2X_2) [66] when L = dimethyl sulphoxide (DMSO) and to an asymmetric ligand (AGKPX, Table 6) when $L = E(C_6H_5)_3$ (E = P, As, or Sb), whose basicity is close to that of dimethyl sulphoxide. Probably in this case the magnetic anisotropy of the aromatic rings of the substituents is in fact of decisive importance.

When the π-complexes have an octahedral structure, the number of situations favouring asymmetry is much greater.

For example, we shall consider the conditions under which the π-ligand in derivatives of the type $(\pi\text{-}C_3H_5)_2ML_1L_2$ (Table 7) may become asymmetric.

If the compound has the *trans*-configuration and the ligands L_1 and L_2 are identical or different, then both allyl groups must be symmetrical and equivalent. Correspondingly the NMR spectrum should show only one set of signals associated with the spin system AK_2X_2. For the *cis*-configuration of the molecule and identical ligands L_1 and L_2, the terminal CH_2 groups of both equivalent allyl ligands become non-equivalent. In consequence, the NMR spectrum should show a group of signals of the system AGKPX, characteristic of an asymmetric π-allyl ligand. Such a spectrum was observed, for example, in the study

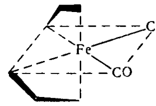
	$L_1 \neq L_2$	two non-equivalent asymmetric allyl ligands: H(A) ≠ H (A') H(G) ≠ H (G') H(K) ≠ H (K') H(P) ≠ H (P') H(X) ≠ H (X')	AGKPX + +A'G'K'P'X'

of $(\pi\text{-}C_3H_5)_2Ru\text{-}\pi\text{-}$cyclo-octa-1,5-diene[123] and $[(\pi\text{-}C_3H_5)_2RhCl]_2$ at a temperature below −20°C.[113]

In turn the observation of the spin system AGKPX in the spectrum of the compound $(\pi\text{-}C_3H_5)_2ML_1L_2$ with $L_1 = L_2$ may be regarded as evidence for the *cis*-arrangement of the allyl group. Such a case probably occurs in the $(\pi\text{-}C_3H_5)_2Fe(CO)_2$ molecule[49]: at −67°C the spectrum corresponds to the system AGKPX (the alternative description of the spectrum by two AK$_2$X$_2$ sets in which the screening of the central protons of two types of allyl groups is fortuitously identical is less likely) which permits the assignment to the compound of the *cis*-structure (XIV):



(XIV)

The spectrum is most complex for the *cis*-configuration with $L_1 \neq L_2$, since in this structure both asymmetric π-allyl groups become non-equivalent. In the spectra of such compounds two sets of signals of the AGKPX system should be observed. This type of situation has indeed been observed in a spectroscopic study of $(\pi\text{-}C_3H_5)_2RhClAs(C_6H_5)_3$ and similar compounds[41].

The number of examples may be increased. Thus the application of the double resonance technique makes it possible to establish[41] that in $(C_3H_5)_4Mo$ there are four asymmetric and equivalent π-allyl ligands (Fig. 3). However, it is much more difficult to arrive at a conclusion concerning the structure of this compound.

Examination of the spectroscopic data for allyl derivatives with asymmetric ligands shows that, despite the appreciable differences in screening, these complexes retain all the spectroscopic features of the π-structure: the screening of the central proton does not alter significantly; the signals of the *trans*-protons are as a rule located in the region of stronger fields than those of *cis*-protons; the constants J_{HH} (*cis*) and J_{HH} (*trans*) differ significantly from one another and are of the same order of magnitude as for asymmetric π-complexes.

The idea of the possible formation of asymmetric π-allyl compounds has been most clearly formulated only in the last two or three years[41,66,67,76,62,113,124,125]. At one time these derivatives were classified as compounds with a mixed bond type – the so called π, σ-complexes [structure (XV)] [58,68,112,126]. However, subsequently this view met certain objections[48,113,125].

(XV)

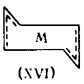
In this connection, it is necessary to emphasise that the available NMR spectroscopic data indicate only a certain asymmetry in the distribution of electron density in a delocalised allyl – M bond, while the π-structure is retained. There are no data indicating a more far-reaching rearrangement of these compounds, including the formation of complexes of the π, σ-type.

VI. ISOMERISM OF π-ALLYL COMPLEXES

The characteristics of the π-allyl bonds, the considerable coordinating capacity of transition metals, and finally the retention under certain conditions of a stable steric orientation of the π-allyl ligand relative to the coordination centre are all factors which give rise to a great variety of π-allyl complexes. In recent years quite a number of examples of different types of isomerism and non-equivalence of allyl ligands have been found with the aid of NMR spectroscopy.

The simplest type is the *cis – trans* isomerism in complexes with asymmetric π-allyl ligands [structures (X) and (XI)]. Isomers of this kind are known for many metals and may be successfully identified by NMR methods even in mixtures[78,81,111,114,121].

An interesting type of isomerism was observed in the study of the derivatives (π-allyl)$_2$M (M = Pd, Ni, or Pt, i.e. metals capable of forming planar square complexes). Two sets of signals (due to the AK_2X_2 spin system for the unsubstituted ligand and K_2X_2 for the ligand substituted at the central carbon atom) have been found in the NMR spectra of these compounds in proportions depending on the metal, temperature, the nature of the medium, and the substituent at the central carbon atom[36,42,53,127–130]. This phenomenon was explained by the fact that such compounds may exist in solution not only in form (XVI), characteristic of the solid state[88], but also in the isomeric form (XVII)[127]:

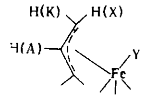


(XVI)

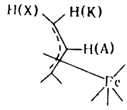
(XVII)

The rotational isomers of the compounds $C_3H_5Fe(CO)_3Y$ (Y = Cl, Br, I, or NO_2) have been investigated[59]. In the crystal such molecules have the structure (XVIII)[131]. Therefore the NMR study of their solutions shows, with increasing electronegativity of Y (I < Br < Cl < NO_2), a shift towards weaker fields of the signals due to the H(A) and H(K) protons most remote from the substituent (Table 8). This behaviour is not shown solely in the case of *trans*-protons H(X), the screening of which is determined not only by the electron density at the terminal carbon atoms but also by the influence of the magnetic anisotropy of the nearest substituent. In the spectra of compounds with Y = halogen, less intense signals of another isomer, which according to the authors has the structure (XIX), were found in addition to the signals due to the isomer (XVIII). In the spectra of these isomers a shift towards weaker fields with increasing electronegativity of Y is observed for signals of the *cis*- and *trans*-protons and corresponds, in accordance with structure (XIX), to signals of the central proton H(A). The content of the isomer in the mixture depends appreciably on the steric hindrance due to the substituent Y: for Y = NO_2, the isomer does not exist.

Table 8. Chemical shifts of protons of different types in the compounds $C_3H_5Fe(CO)_3Y$ (according to data of Nesmeyanov et al.[59]).



(XVIII)



(XIX)

Y	δ_H p.p.m. rel. to HMDSO*						Solvent

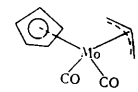
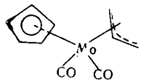
NO_2	5.31	4.70	2.63	—	—	—	$CDCl_3$

An analogous situation was observed in the NMR spectra of the compounds π-allyl – Mo(CO)$_2$ – π-C_5H_5.[13,52] It was found that the relative amounts of the isomers (XX) and (XXI) depend on steric factors determined by the substituent at the central carbon atom of the allyl ligand:



(XX)



(XXI)

An interesting example of the non-equivalence of allyl ligands was observed in the study of triallylrhodium. It was found that at a low temperature (–74°C) the three symmetrical allyl ligands are non-equivalent (in the spectrum there are three groups of AK_2X_2 signals in proportions of 1 : 1 : 1).[38] It was suggested (following Green and Nagy[132]) that each ligand occupies two coordination sites and thus the triallylrhodium molecule may have the form of a trigonal prism or an octahedron[38,40].

VII. STEREOCHEMICAL NON-RIGIDITY OF ORGANOMETALLIC ALLYL COMPOUNDS.

The advances of organometallic chemistry in the last decade led to the synthesis of a multiplicity of compounds of most varied and sometimes unexpected types. Among these, there are quite a few systems where stereochemical non-rigidity was observed or is possible in principle. The terminological aspect of this problem has not yet been clearly resolved. Therefore we shall adopt the convention that the concept "stereochemical non-rigidity" will be applied to two basic types of intramolecular rotation (recognising, of course, the non-rigorous nature of such subdivision in many cases): intramolecular rotation and metallotropy.

For organometallic compounds, including allyl derivatives, it is possible to indicate several types of intramolecular motion, which are analogous to those in the usual organic derivatives, for example rotation about the C–M σ-bond in σ-allyl compounds. However, there is a possibility in principle also of processes specific to organometallic compounds, the nature of which is fairly difficult to predict and the study of which provides much information about the structure and properties of such compounds. In the classification of intramolecular dynamic processes in organometallic allyl compounds it is most natural to use as a basis the spin system of the allyl component of the NMR spectrum.

1. INTRAMOLECULAR ROTATION.

a. Processes with Retention of the AK_2X_2 Spin System.

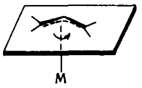
We shall isolate in a separate group those cases where in a certain temperature range the spin system of the allyl part of the spectrum is not simpler than AK_2X_2. One should evidently include here both asymmetric derivatives where the asymmetry of the allyl ligands disappears with increasing temperature (in the sense AGKPX → AK_2X_2) and compounds with a symmetrical C_3H_5-M bond in which the dynamic process is accompanied by the retention of the formal AK_2X_2 spin system.

For example, it is possible to assign to this group the asymmetric complex $[(C_3H_5)_2RhCl]_2$ in the spectrum of which the four separate signals due to each of the four terminal protons merge into two pairs of signals as the temperature is raised from −20° to 90°C. Under these conditions, there is hardly any change either in the position in the spectrum or the form of the signal due to the proton attached to the central carbon atom of the allyl ligand[41]. Apparently an analogous phenomenon is observed in the NMR spectrum of the compound $(C_3H_5)_2Fe(CO)_2$: on raising the temperature from −67° to 20°C, the set of signals of the AGKPX spin system is transformed into the set of signals of the AK_2X_2 system[49].

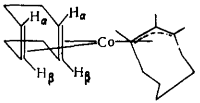
Compounds of the type $2\text{-}RC_3H_5Mo(CO)_2C_5H_5$ (R = H, CH_3, etc.) constitute stereochemically non-rigid systems where the temperature-dependent spectroscopic changes are accompanied by the retention of the spin system. Probably at temperatures exceeding 80–90°C the rate of mutual transformations of the isomers (XX) and (XXI) increases so much that each can no longer be observed spectroscopically as a separate entity. As a result the spectrum contains no longer two but only one set of signals of the AK_2X_2 system[52,53]. Allyl compounds of molybdenum with a more complex structure were examined by Trofimenko[133].

An analogous phenomenon was observed[31] in the study of the spectra of triallylrhodium. The signals of the protons in two of the three nonequivalent π-allyl groups merged into a common system of lines on raising the temperature from −67° to 10°C. In the case of diallylnickel a change in temperature affected the NMR spectrum in such a way that, on transition from −40°C (in $CDCl_3$) to 60°C (in benzene), the ratio of the intensities of the two groups of AK_2X_2 signals associated with the isomers (XVI) and (XVII) gradually changed from 3 : 1 to 2.2 : 1.[36]

The stereochemically non-rigid systems considered have a common characteristic. Neither the removal of the asymmetry of the π-allyl ligand in one isomeric form {in $[(C_3H_5)_2RhCl]_2$ and $(C_3H_5)_2Fe(CO)_2$, etc.} nor the mutual transformation of the isomers [(XX) and (XXI), (XVI) and (XVII), etc.] is accompanied by the equalisation of the chemical shifts of the *cis*- and *trans*-protons. The dynamic process satisfying this condition may be only the rotation of the π-allyl group about the axis joining the metal atom to the central carbon atom of the ligand [structure (XXII)]. This type of process was observed for the first time by Becconsall and O'Brien[38] in a study of the temperature variation of the triallylrhodium spectrum:



(XXII)



(XXIII)

It must be emphasised that this type of dynamic process was observed for derivatives of significantly different transition metals: rhodium, iron, molybdenum, and nickel. It is quite possible that it occurs also in many other π-allyl compounds, but is observed only in those few systems where there are structural factors which retard it and make possible its spectroscopic study. The compounds investigated exhibit in this sense a similarity with complexes where there is a C_nH_n-M π-bond (C_nH_n is a cyclic ligand with n = 4, 5, 6, or 7) and in which the rotation of the ligand about the n-fold axis has been reliably established.

We may quote an opposite example. In the spectrum of π-cyclo-octenyl-π-cyclo-octa-1,5-diene derivative of cobalt (XXIII) the α- and β-protons of the diene ligand are magnetically non-equivalent in the temperature range between −88° and 60°C.[85] The most acceptable explanation of this finding is that there is no rotation about the π-enyl–cobalt bond. However, we may note that in the spectrum of π-C_3H_5–Rh–π-cyclo-octa-1,5-diene the signals of all the diene protons are equivalent[109].

b. Processes with Degeneration of the Spin System to AX_4.

All the compounds in which the allyl component of the NMR spectrum is simplified on raising the temperature to such an extent that the *cis*- and *trans*-protons become indistinguishable ($AK_2X_2 \rightarrow AX_4$) will be assigned to this group of stereochemically non-rigid allyl systems. This type of phenomenon was observed[36,37,44,124], for example, in the NMR spectrum of tetra-allylzirconium. While at a low temperature (−74°C) the spectrum has a form characteristic of a π-allyl complex with symmetrical ligands (AK_2X_2 spin system), on raising the temperature the doublets due to the *cis*- and *trans*-protons initially broaden, then approach one another, and finally merge at −40°C, the width of the signal in the transition region being independent of the concentration of the compound[124]. When the temperature is raised further to −10°C, the signal, which is now associated with all four terminal protons, consists of a distinct doublet, while the signal due to the central proton consists of a quintet (at a low temperature this is a nonet) (Fig. 4). Thus at −10°C the spectrum already belongs to the AX_4 spin system. This shows that under such conditions the terminal protons of all the allyl groups of tetra-allylzirconium are equivalent. The following factors are important for the understanding of the mechanism of this process: (1) when the spectrum changes from AK_2X_2 to AX_4, the screening of the central proton remains unchanged; (2) at −10°C the doublet due to the terminal protons occupies a position in the spectrum intermediate between those of the doublets of the *cis*- and *trans*-protons in the low-temperature spectrum; (3) the

$J_{H(A)-H(X)}$ coupling constant for the AX_4 spectrum is equal to half the sum of the constants J_{HH} (*cis*) and J_{HH} (*trans*) for the AK_2X_2 spectrum.

An analogous spectral pattern was observed in the study of certain other symmetrical allyl derivatives with a delocalised C_3H_5-M bond: tetra-allylthorium (AK_2X_2 at 10°C and AX_4 at 80°C) [37], tetra-allylhafnium (the AX_4 spin system is already observed at −72°C) [36], and allyllithium (the $AK_2X_2 \rightarrow AX_4$ transition occurs at about −87°C) [91]. Above 90°C the $AK_2X_2 \rightarrow AX_4$ transition is also observed in the spectrum of the compound $[(C_3H_5)_2RhCl]_2$ but this is probably a not altogether apt example, since the pattern may be complicated by the dissociation of the Rh−Cl bond[41].

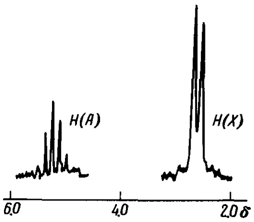


Figure 4. NMR spectrum of the compound $(\pi\text{-}C_3H_5)_4Zr$ at −20°C (AX_4 spin system)[36].

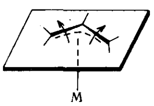
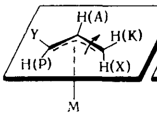
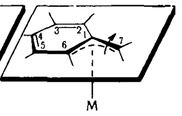
The averaging out of the chemical shifts of the *cis*- and *trans*-protons and of the spin−spin coupling constants has been frequently observed also in the NMR study of asymmetric derivatives with a delocalised allyl−M bond, in particular in the study of the phenylallyl compounds of alkali metals[117]. Thus on raising the temperature the distinct signals associated with the two H(K) and H(X) protons, non-equivalent at 5°C in the $1\text{-}C_6H_5C_3H_4Li$ spectrum, begin to broaden and gradually approach one another and at 90°C become spectroscopically indistinguishable, the process being reversible [structure (XXV)]:



(XXIV)



(XXV)



(XXVI)

Probably the temperature-dependent averaging out of the chemical shifts of the *cis*- and *trans*-protons is determined to some extent by the 1.5 bond order of the delocalised allyl−M bond. It may be supposed that the degree of its double-bond character will be variable and will depend on the nature of the substituent in the ligand and at the metal, on the electron-donating capacity of the metal, and many other factors. Thus under certain conditions the 1.5 order of the delocalised bond can apparently only hinder internal rotation about the $C \overset{...}{-} C$ bonds but cannot prevent it altogether.

Thus the temperature-dependent effects observed in the study of the NMR spectra of the allyl compounds under consideration may be caused entirely by changes in the rate of internal rotation of the CH_2 groups about bonds joining them to the central carbon atom [structures (XXIV) and (XXV)] [36,37,124]. It is useful to note that such effects have so far been observed in compounds of both transition (zirconium and thorium) and non-transition (lithium) metals, where on formation of a delocalised bond the *d* electrons of the metal cannot participate in the formation of dative bonds with the ligand[37], which would favour the fixation of its position in space relative to the metal atom. In the spectra of the derivatives of many other metals, for which the formation of dative bonds is not excluded, the temperature-dependent changes were not observed {the spectra of $C_3H_5Mo(CO)_4$ at 160°C [48], $(C_3H_5PdCl)_2$ at 150°C [48], $(C_3H_5)_4Mo$ at 170°C [41], and $C_3H_5Rh[P(C_6H_5)_3]_2$ at 130°C [78] have been investigated}.

A reversible change in the allyl component of the spectrum was observed in the study of the π-benzyl derivatives of molybdenum, tungsten, and palladium, [3,25,119]. For example, in $\pi\text{-}C_6H_5CH_2Mo(CO)_2\text{-}\pi\text{-}C_5H_5$ the screening of the CH_2 protons is averaged out when the temperature is raised from −30° to 64°C. There are also corresponding changes in the signals of the phenyl protons. Under these conditions, the average chemical shift of each pair of protons [CH_2-, 2−6, and 3−5; structure (XXVI)] is exactly equal to half the sum of the initial shifts[3]. King and Fronzaglia[3] suggested that this effect is caused by the rotation of the benzyl ligand about the 1−7 axis. They did not exclude also alternative mechanisms, in particular a mechanism with a postulated intermediate formation of a σ-type compound. The latter mechanism has been supported by Cotton and Marks[25]. We may note that in the spectra of certain π-thienyl derivatives of molybdenum no changes were observed in the temperature range between −60°C and 105°C [118].

VIII. SPECTRA OF π-ALLYL COMPOUNDS IN THE PRESENCE OF BASES

In 1961 Chien and Dehm[134] observed that, when the solvent is changed (chloroform replaced by dimethyl sulphoxide), the NMR spectrum of $(C_3H_5PdCl)_2$ alters sharply. In the case of an unsubstituted π-allyl ligand this transformation consists of a change of the spin system of the allyl components of the spectrum from AK_2X_2 to AX_4; corresponding changes have also been observed for 1- and 2-substituted allyl groups. Subsequently quite a few papers have been published on these changes, which were observed in the NMR spectra of the π-allyl derivatives of palladium, platinum, rhodium, and other transition metals under the influence of bases (sulphoxides, phosphines, arsines, stibines, etc.)[13,48,62,66,67,69,78,82,112,114,122,124-126,135-139].

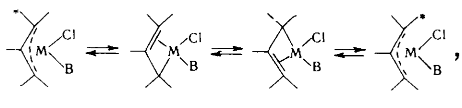
Formally these are the same changes which occur in the spectrum of tetra-allylzirconium on raising the temperature, i.e. the equalisation of the screening of the *cis*- and *trans*-protons is accompanied by a simplification of the spin system of the spectrum ($AK_2X_2 \rightarrow AX_4$ for symmetrical π-allyl derivatives and $AGKPX \rightarrow AK_2X_2 \rightarrow AX_4$ for asymmetric derivatives). In fact the situation is much more complex‡.

---

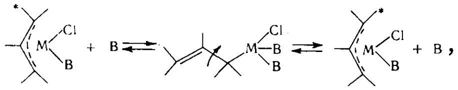
‡ In recent years the term "dynamic allyl"[37] has been frequently used in the literature to designate a new (apart from the σ- and π-allyl derivatives) type of allyl compound. Usually this term designates any situation (associated with the solvent, temperature, etc.) which leads to the appearance in the NMR spectrum of an AX_4 spin system. However, examination of the corresponding data shows that a new "dynamic" type of allyl compound does not exist, just as compounds of the π, σ-type apparently do not exist. In fact there is only a group of phenomena, frequently of a different nature, which have the same spectroscopic effect. Therefore further use of the concept "dynamic allyl" does not appear to be justified.

Chien and Dehm[134] suggested that the π-allyl derivatives of palladium are wholly converted into the σ-form on dissolution in a solvating medium and in this form can in fact undergo the rearrangement (1) put forward by Nordlander and Roberts[74] in the discussion of the spectra of the allyl derivatives of magnesium. However, subsequently it was found that mixed compounds of (π-allyl$-$PdCl)$_2$ with dimethyl sulphoxide and other bases (phosphines, etc.), i.e. compounds of the type C_3H_5PdClB, are, in fact not σ- but π-allyl complexes—symmetrical or asymmetric[48,66,112,137]. Therefore the observed effects were explained not by complete transformation of the compound into the σ-form but by the formation of σ- or π, σ-complexes at a very low concentration, which is, however, sufficient to promote the interchange of the *cis*- and *trans*-protons [Eqns. (2)$-$(4), M = Pd or Ni][48,69,112,125,126]. Moreover, Becconsal and O'Brien[154] pointed out that these effects can be accounted for by rotation about the C$-$C bond.

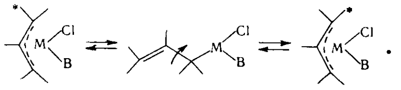
74, 134 (1)



66, 112, 113 (2)

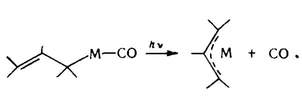


48, 69 (3)



67, 82 (4)

Among the various mechanisms of the rearrangement of the π-allyl derivatives of transition metals to σ- or π, σ-complexes, proposed to account for their spectroscopic behaviour in the presence of bases [Eqns. (1)$-$(4)], the mechanism of type (3) is particularly successful. Essentially this mechanism represents the π-σ transformation of the molecules investigated with retention of the coordination number of the transition metal owing to the simultaneous formation of an M$-$B bond and constitutes a special process, the converse of the transformation of the σ-allyl derivatives of iron, manganese, molybdenum, and tungsten into π-allyl derivatives[1,8-10]:

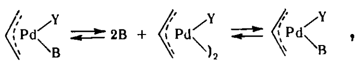


(5)

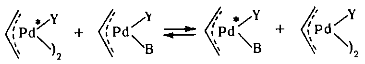
Therefore it might have been expected that the allyl compounds of "pentacoordinate palladium" or nickel isolated in a pure form are in fact σ-complexes. For nickel, such $C_3H_5NiClB_2$ complexes were obtained (B = phosphine or phosphite), but their investigation did not confirm the above hypothesis. It was found that the spectra of derivatives with ligands such as $P(OC_6H_5)_3$ and $P(C_6H_5)_3$ do not differ from those of the corresponding π-allyl derivatives of tetracoordinate nickel: the AK_2X_2 spin system was transformed into AX_4 only in the case where B = $P(C_2H_5)_3$. [62] An analogous conclusion follows from the spectroscopic data for and the structural investigation of other allyl compounds of pentacoordinate nickel[140,141].

Strictly speaking, the spectral spin system AX_4 is too symmetrical to indicate unambiguously any one dynamic process. In principle, several such processes are compatible with a spectrum of type AX_4. Moreover, in solutions of π-allyl derivatives of palladium, nickel, rhodium, and certain other metals in the presence of bases, the exchange reactions (6)$-$(11) occur or can occur (here M = Pd; X = halogen, SCN, etc.; B = DMSO, phosphine, amine, etc.).

These reactions do not relate directly to π-σ rearrangements and in any case can occur without the participation of allyl$-$M bonds. However, they can also cause the merging of the signals due to the *cis*- and *trans*-protons in the NMR spectrum[41,66,69,137,143].

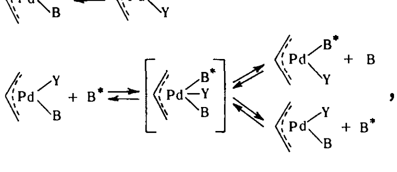


137 (6)

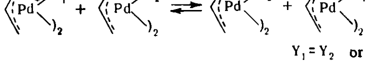


66, 138, 139 (7)

66 (8)

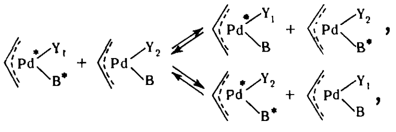


69, 125, 142 (9)



139, 143, 144 (10)

$Y_1 = Y_2$ or $Y_1 \neq Y_2$



125, 139 (11)

$Y_1 = Y_2$ or $Y_1 \neq Y_2$; etc.

It must be emphasised that the structure of the transition state in reactions (6)$-$(11), their stereochemical results, and similar problems associated with their mechanism have only now begun to be seriously investigated by various procedures including the NMR method[143]. For example, it has been found that the rate of exchange depends on temperature, the concentrations of the π-allyl compound and the base, and other factors. A clear similarity of these compounds (lability of the M$-$X bonds, their capacity for exchange reactions, etc.) to organic derivatives of non-transition metals, for which exchange reactions have been investigated fairly thoroughly by the NMR method (see, for example, Brown[145]) has also been observed.

Thus the problem of the causes responsible for the changes observed in the NMR spectra of certain π-allyl derivatives of transition metals under the influence of bases remains at present unresolved. Such a cause may be the internal rotation of the allyl ligand about the C$\overset{\dots}{-}$C bond, which is facilitated by the donor$-$acceptor interaction between the metal and the base. Another cause may be exchange reactions of types (6)$-$(11). Finally the changes may arise also as a result of $\pi$$-$$\sigma$ rearrangement, but so far no evidence has been obtained by the NMR method indicating the formation of a σ-complex under the action of bases which would not be susceptible to some other interpretation.

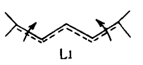
IX. THE NATURE OF THE ALLYL–METAL BOND IN CERTAIN NON-TRANSITION METAL (LITHIUM, MAGNESIUM, ZINC, AND CADMIUM) DERIVATIVES.

According to NMR spectroscopic data, an allyl–Hg σ-bond is formed in allyl derivatives of mercury[17,91,146,147]. Triallylboron below –65°C [14,148] and other allyl compounds of boron[149,150] have similar structures. However, the spectroscopic behaviour of allyl-lithium suggests the formation of a delocalised bond in this compound[91]. In the study of the derivatives of certain other non-transition metals with an allyl–M bond (M = Li, [117,151–153] Mg, [74,154–157] Zn, [158,159] or Cd [160]) it was found that, as in the case of allyl-lithium, close to room temperature the NMR spectrum has an AX_4 spin system for compounds with an unsubstituted ligand and the corresponding spectral pattern for substituted ligands.

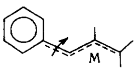
To explain the spectrum of allylmagnesium bromide, Nordlander and Roberts[74] examined three possibilities: (1) the establishment of rapid equilibrium between two σ-structures [Eqn. (1)]; (2) the formation of a structure with a delocalised allyl–M bond in which there is rapid rotation about C–C bonds [structure (XXIV)]; (3) the formation of an ionic bond.

In principle, neither Roberts[161] nor other investigators (see, for example, Lanpher[162]) excluded the possibility of the formation of a delocalised bond of type (II) by non-transition metals. However, since the bond order in such compounds should be greater than unity, Nordlander and Roberts[74] disregarded the second and third possibilities and subsequently interpreted their experimental data only from the standpoint of the formation of a σ-structure undergoing rapid 1,3-transformations [Eqn. (1)]. This view was also adopted by many other investigators[151,153], although in recent years it encountered objections from supporters of the formation of an ionic bond[91,117,158,160].

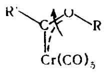
During the last decade extensive data have accumulated in the literature on the NMR spectra of allyl derivatives of transition and non-transition metals. The hypotheses concerning the structures of these compounds have also undergone a definite change. Moreover, experimental spectroscopic studies on organic and organometallic compounds showed that, when the order of the bond under consideration is greater than unity and less than 2, rotation about it is not precluded, for example in the compounds (XXVII), [163] (XXVIII, M = Li), [117] (XXIX) [164], and even in classical olefinic derivatives[165]:



(XXVII)



(XXVIII)



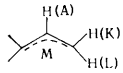
(XXIX)

Therefore it appears necessary to reconsider the possibilities proposed by Nordlander and Roberts[74] and to determine which of them is most acceptable in the light of the available facts.

It has been suggested[91] that in C_3H_5Li the delocalised bond is ionic. Probably this involves some exaggeration. It is known that organic derivatives of lithium do not dissociate into ions. For example, the C_5H_5Li molecule, like C_5H_5Na, has the C_{5v} symmetry and not D_{5h} as might have been expected if it dissociated into ions (a D_{5h} symmetry has been established for C_5H_5M with M = K, Rb, or Cs) [166]. An analogous result was obtained in a study of the Li-NMR spectra of fluorenyl-lithium[167]. In certain organolithium derivatives the metal–carbon bond may be significantly covalent [for example, in a study of the tetramer $(CH_3Li)_4$ it proved possible to observe $^{13}C-^{7}Li$ spin–spin coupling [168,169]. Thus it is probably more justifiable to speak not of an ionic but of a fairly polarised bond (in the sense allyl$^{\delta-}$–M$^{\delta+}$). Then the allyl derivatives of the metals considered may be discussed from a single standpoint. We shall assume that magnesium, zinc, cadmium, and similar metals, as well as lithium, are capable of forming a delocalised allyl–M bond. We shall also postulate that the delocalised bond in any real compound is always polar to some extent and the degree of its polarity depends on the electropositivity of the metal, the nature of the substituents in the ligand and the metal, the nature of the medium, and other factors.

Apart from the effect of other factors, the steric stability of the allyl–M fragment in transition metal derivatives can be achieved also as a result of the participation of the metal *d* electrons in a dative interaction. For allyl compounds of non-transition metals, such a stabilising factor may be the amount of double-bond character of the C⩦C bonds of the ligand, which in turn is a function of the electropositive properties of the metal.

Table 9. Chemical shifts of the methylene protons in certain allyl compounds of non-transition metals.



Compound	Solvent	$\delta_{H(K, L)}$	Electronegativity of metal E_M [170]
C_3H_5Li	THF	2.17[91]	1.0
$(C_3H_5)_2Mg$	THF	2.45[157]	1.2
$(C_3H_5)_2Zn$	C_6D_6	2.96[158]	1.6
$(C_3H_5)_2Cd$	THF	2.86[160]	1.7

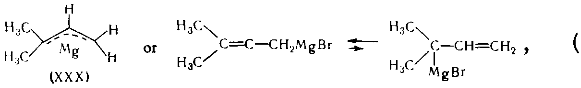
Table 9 shows that the screening of the terminal protons in non-transition metal derivatives varies in parallel with their electropositivity:

$$\xleftarrow[\text{enhancement of screening and the electropositivity of the metal}]{\text{Li} > \text{Mg} > \text{Zn} \sim \text{Cd}}$$

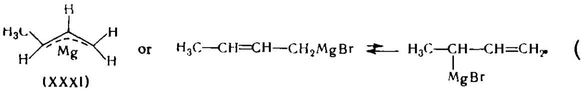
Consequently, the amount of double-bond character in the allyl group should decrease from lithium to zinc and cadmium with a corresponding increase in the rate of internal rotation. The experimental data do not contradict this conclusion. On lowering the temperature to –87°C, "freezing" of internal rotation [structure (XXIV)] is observed in the spectrum of allyl-lithium. Spectroscopically this is shown by a separation of the signals due to the *cis*- and *trans*-protons and in a change of the spin system of the spectrum ($AX_4 \rightarrow AK_2X_2$) [91]. For cadmium and magnesium derivatives, such "freezing" has not so far been achieved even at a lower temperature (diallylmagnesium at –120°C in tetrahydrofuran[157], allylmagnesium bromide at –80°C in ethyl ether[156], and diallylcadmium at –100°C in tetrahydrofuran[160] have been investigated).

Over a wider range of variation of the amount of double-bond character, observations are also consistent with predictions. Thus, while for allyl derivatives of lithium, including asymmetric derivatives[117], internal rotation may be "frozen" by varying the temperature, in studies on asymmetric allyl derivatives of more electropositive metals [potassium and sodium—structure (XXV)] internal rotation was not observed even at a fairly high temperature[117].

We may note that for allyl compounds of magnesium and cadmium it is possible to raise the "freezing temperature" of the spectral pattern, for example by introducing into the ligand electron-donating substituents capable of increasing the amount of double-bond character of the C⋯C bonds. This phenomenon was observed, in particular, by Roberts and coworkers[155] in a spectroscopic study of 1,1-dimethylallylmagnesium bromide (XXX): when the temperature is reduced to only −26°C, the splitting of the signal due to the methyl protons into two components, associated with the *cis*- and *trans*-groups, is already observed:

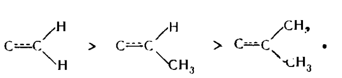


(XXX) (12)



(XXXI) (13)

The molecular structures of 1-$CH_3C_3H_4MgBr$ and 1,1-$(CH_3)_2C_3H_3MgBr$ merit special examination. The spectra, investigated by Roberts and coworkers[154,155], are fully consistent with the structures (XXXI) and (XXX) with a delocalised allyl−M bond if it is assumed that the rate of rotation about the bond of order 1.5 varies in the sequence



Roberts and coworkers interpreted the spectra obtained in a different way. They suggested that each of the compounds considered constitutes one of two possible non-equivalent σ-structures, which are interconverted at a high rate. To reconcile this possibility with the observed spectral patterns, it was suggested that equilibria (12) and (13) are almost entirely displaced to the left.

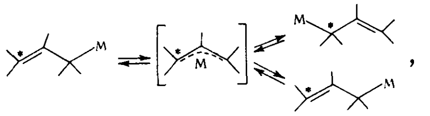
However, whereas previously both possibilities [delocalised structures (XXX) and (XXXI) or equilibria (12) and (13)] might have been regarded as at least equally probable, although only one of them had been considered, further investigations[91,117,163-165] show that there is no justification for rejecting the very possibility of rotation about a C⋯C bond of order 1.5. There are no other objections to the formation of a delocalised bond. On the other hand, equilibria (12) and (13) are not altogether consistent with the spectroscopic and chemical features of the compounds examined. For example, the NMR spectra undergo hardly any changes when the temperature is reduced [if one disregards the splitting of the signal due to the methyl groups in the spectrum of 1,1-$(CH_3)_2C_3H_3MgBr$], although the screening of the CH_2 protons cannot fail to change under these conditions. The assumption that equilibria (12) and (13) are almost completely displaced to the left over the entire temperature range investigated is inconsistent with the results of the analysis of the decomposition products, for example, butenylmagnesium bromide[161].

Investigations in the next few years, in particular structural studies by diffraction methods, will show which view is closer to the truth. However, even if the hypothesis of the formation of a delocalised bond in the allyl compounds of lithium, magnesium, zinc, and cadmium is confirmed, there will remain many other problems the solution of which is at present not evident: association of the compounds considered, the role of the solvent in the formation of a σ- or delocalised structure, the relation between the intramolecular and intermolecular bonds, etc.

X. METALLOTROPY IN ALLYL DERIVATIVES OF NON-TRANSITION METALS

It is not claimed that the view put forward in the preceding section is of completely general validity. It merely shows how the possibility of two interpretations (on the basis of the published NMR data) of the structures of the allyl derivatives of magnesium, zinc, and cadmium—with a localised or a delocalised bond—gives rise as a consequence to two interpretations of the dynamic behaviour of these compounds—a metallotropic 1,3-transition [Eqn. (1)] or rotation about the C⋯C bond of order 1.5 [structures (XXIV) and (XXV)].

Continuing this analysis, we also find it necessary to conclude that the mechanism of metallotropic transformations of those derivatives for which a σ-structure could be reliably demonstrated§ is not also not unambiguous. There are at least two possibilities;



(14)

(15)

The only difference between them is in fact that in one case the formation of a delocalised bond is suggested in the transition state and in the other in the ground state [Eqns. (14) and (15)].

As a rule the mechanism represented by Eqn. (14) is considered, in particular in the discussion of the NMR spectra of the allyl derivatives of boron[14,150]. It was found that below −65°C the spectrum of triallylboron has an $AKLX_2$ spin system corresponding to the allyl−boron σ-bond. On raising the temperature to room temperature, the signals of both methylene groups become broader and on further increase to 135°C two symmetrical signals of the AX_4 spin system appear. In the high-temperature spectrum the chemical shift of the methylidyne proton H(A) remains virtually unchanged but the form of the signal becomes simplified. The chemical shift of the protons H(X) amounts to approximately half the sum of the shifts of the methylene protons of both types in the low-temperature spectrum ($KLX_2 \rightarrow X_4$). In the study of other allyl derivatives of boron similar changes in the NMR spectrum were found.

Certain characteristics of the rearrangement of the allyl compounds of boron have been elucidated[14,150]. In particular, it has been found that the rate of rearrangement of triallylboron in carbon tetrachloride or cyclohexane is independent of concentration, which indicates that the

---

§ For example the allyl derivatives of boron[14,148-150], diallylzinc in solvating media at a low temperature[37,171], indenyl derivatives of mercury at −41°C [29] and of tin(IV) at −37°C [30], etc.

rearrangement is intramolecular. Solvating solvents (tetrahydrofuran and in particular pyridine), which are capable of being coordinated to a vacant orbital of boron, appreciably retard the rearrangement. The rate of the process depends also on the structural characteristics of the compound:

These data lead to the suggestion[14] that the 1,3-transition (it can hardly be called metallotropic because boron is not a metal) in allyl derivatives of boron takes place via a transition state with a delocalised allyl–boron bond [Eqn. (14)]. However, it must be emphasised that the available NMR spectroscopic data do not yet allow a distinction to be drawn between a rearrangement of this type and the interconversions of the two forms of the compound considered in which there is a localised or a delocalised bond [Eqn. (15)]. This applies also to the rearrangement of the indenyl derivatives of tin[30], mercury[29], and similar systems. Probably future spectroscopic investigations will demonstrate the reality of both processes or it will be possible to choose between them.

The Changes in the Luminescent Properties of the Lanthanides in Consequence of Their Interaction

L.I.Anikina and A.V.Karyakin

Information about the changes in the luminescent properties of the lanthanide elements in consequence of their interaction and as a function of their relative amounts in the test objects is reviewed together with data on the mechanism of this process in various systems.
The bibliography includes 93 references.

CONTENTS

I. INTRODUCTION

The luminescent properties of crystalline phosphors are determined by the activator. If there are several activators, then, apart from the additive properties due to each activator, there appear non-additive properties resulting from the interaction of the activators. Owing to rearrangement of the system of energy levels, the interaction may be reflected in a change in absorption and emission spectra, the duration of the excited state and the probability of energy transitions, the nature of local levels, and many other properties. Numerous examples of this phenomenon may be quoted. The sensitisation of one activator by another and also the quenching of luminescence by admixtures may be regarded as the most familiar examples of interaction between activators. The interaction between activators may be employed in some cases as a useful property, while in others one attempts to avoid it.

In practice one usually deals with crystals containing several impurities and it is of course very important to know the nature of their interactions in a particular case. Moreover, the problem of the interaction between activators is of theoretical importance, since it is associated with the problem of energy transfer in matter.

The lanthanide elements are widely used at present in engineering, particularly in laser engineering. In the manufacture of high-purity lanthanides, their luminescent properties are used for production quality control[1]. It is then often necessary to determine in one specimen several elements present simultaneously. To avoid errors in the analysis, it is necessary to know to what extent the luminescent properties of a given system may be non-additive.

II. INTERACTION OF LANTHANIDE ACTIVATORS AND SENSITISATION OF THE LUMINESCENCE OF LANTHANIDE IONS BY OTHER SUBSTANCES

The interaction between lanthanides in phosphors has been known for a long time. The sensitisation of one lanthanide by another was observed for the first time by Tomaschek[2] in the excitation of the SrS–Gd,Sm phosphor by cathode rays. The luminescence of samarium in the phosphor increased appreciably in the presence of gadolinium. It is noteworthy that in the very early studies errors might have been made owing to the lack of highly pure lanthanide preparations. Moreover, the majority of investigations dealing directly with the interaction of lanthanides have been published in the last few years. They deal with the behaviour of lanthanides mainly in crystals, both inorganic (crystalline phosphors) and organic (lanthanide complexes).

A comparatively small number of papers deal with the behaviour of lanthanides in solutions, most of them being concerned with the dependence of the luminescence of terbium and europium on other lanthanides present in solution.

Gallagher et al.[3] examined two-stage energy transfer in solutions and showed that only in the presence of terbium ions is the energy of exciting light transferred from 4,4′-di-*m*-hydroxybenzophenone (DMB) to europium. The authors concluded that terbium ions constitute an intermediate link in energy transfer from DMB to europium, sensitising europium. It has also been noted that other lanthanides (praseodymium, neodymium, samarium, holmium, erbium, and thulium) quench the luminescence of a mixture of DMB and terbium. It has been suggested that the quenching involves an exchange–resonance mechanism.

Ballard and Edwards[4] made a detailed study of energy transfer from an organic substance to a lanthanide ion as a function of the concentration of the latter and also the self-quenching by the lanthanide ion in solution. The transfer of the energy of exciting light from the organic substance to the lanthanide ion may be called sensitisation of the ion by the organic substance. This is also of interest for a wider understanding of the interaction between various components of luminescent systems.

Ballard and Edwards[4] studied the luminescence of certain lanthanide (samarium-, dysprosium, terbium, and europium) nitrates in acetophenone. The intense luminescence of certain lanthanide ions is due to intermolecular energy transfer from the triplet state of acetophenone, provided that there is no self-quenching by the lanthanide ions. It has been established that the self-quenching is excluded in those cases where the difference ΔE between the energies of the resonance and lowest levels is high. When ΔE is low, self-quenching is possible.

Since the investigation was carried out at low temperature (frozen solutions), it was essentially concerned with crystalline substances containing lanthanides.

Holloway and Kestigian[5] examined a case of the quenching of terbium by neodymium, holmium, and erbium ions. The experiments were performed on aqueous solutions of the lanthanide chlorides. The degree of quenching was determined from the change in the duration of the luminescence of terbium. It was found that the probability of the quenching of the fluorescence of terbium is proportional to the square of the concentration of the lanthanide or inversely proportional to the sixth power of the distance between the ions. Such a concentration dependence ($\propto 1/R^6$) characterises a dipole–dipole interaction. The authors conclude that the quenching of the luminescence of terbium takes place by resonance energy transfer.

Heller and Wasserman[6] examined intermolecular energy transfer from an excited organic substance (aldehydes and ketones) to lanthanides (europium or terbium) in dilute solutions. The excitation spectra show that the luminescence of europium and terbium appears when ultraviolet light is absorbed by the organic molecules. The constancy of the luminescence spectrum is evidence of the absence of complex formation. It has been suggested that the energy transfer is regulated by diffusion processes, since the intensity of the fluorescence of the lanthanide diminishes with increasing viscosity. As the temperature is reduced, the intensity of the fluorescence of the lanthanide falls and the phosphorescence of the organic substance appears.

Cabezas and De Shazer[7] investigated the possibility of the sensitisation of the lanthanide ion in the europium trihexafluoroacetylacetonate complex in a liquid medium with intermolecular excitation energy transfer from the organic donor to the organic complex. Benzophenone, excited by illumination with light at $\lambda = 3800$ Å, was employed as a donor. Under these conditions, the complex is not excited. The excitation energy transfer from the triplet state of benzophenone to the triplet state of the complex with subsequent intramolecular energy transfer to the Eu^{3+} ions takes place over a period shorter than 10^{-6} s.

A similar phenomenon was described by Charles et al.,[8] who observed the transfer of the energy absorbed by the *p*-benzoylbenzoate ion in solution to the ethylenediaminetetra-acetatoeuropium ion.

Kropp[9] reported the sensitisation of europium ions by the uranyl ion in solutions: aqueous (in particular in D_2O), alcoholic, in acetonitrile, etc. The luminescence of the UO_2^{2+} ions is then quenched and the intensity of the fluorescence of europium increases. The greatest effect is observed in D_2O. It has been noted that gadolinium does not quench the luminescence of the uranyl ion, since its excited level lies relatively higher and therefore there is no energy transfer.

Briskina et al.[10] observed the transfer of the energy of exciting light from organic dyes, in particular fluorescein, to lanthanide ions (europium and terbium). The energy is transferred from metastable levels of the dye.

McCarthy and Winefordner[11] showed how great is the extent of the intermolecular energy transfer in the determination of traces of lanthanides. The sensitivity of their determination in solution may be enhanced by employing an organic energy donor.

The mechanism of energy transfer from aromatic compounds such as ketones to lanthanide ions in solutions has been examined[12] and the hypothesis that the energy transfer takes place from the triplet level of aromatic molecules to the lanthanide ions was confirmed experimentally.

In a number of investigations published in 1964–1968, a study was made of the interaction between lanthanides in glasses (solid solutions). Cabezas and De Shazer[7] reported the occurrence of energy transfer in glasses activated simultaneously by terbium and dysprosium. At high concentrations of the activator (about 3 wt.%) the enhancement of the luminescence of terbium by about 70% is observed. The authors suggest that energy transfer from dysprosium to terbium takes place via the excitation of the resonance level of Tb^{3+} ($^5D_4$) by emission from Dy^{3+} with $\lambda = 485$ nm ($^4F_{9/2} \rightarrow {}^6H_{15/2}$).

The authors also reported a sensitising effect of terbium or europium on the luminescence of neodymium in glasses (the intensity of the luminescence of neodymium increases by about 10%). They suggest that in this case the energy transfer (accompanied by emission) occurs in the region of $\lambda \simeq 580$ nm (the region of absorption by neodymium and of emission by terbium or europium).

The interaction between terbium and neodymium in a glass was studied in detail by Nakazawa and Shionoya[13]. On the basis of experimental data and theoretical calculations, they concluded that the energy transfer from terbium to neodymium takes place preferentially by a resonance mechanism and is of a dipole–quadrupole type.

In a paper by Karapetyan and Mokeeva[14] on energy transfer in glasses activated by terbium and dysprosium, the existence of two energy transfer mechanisms is indicated: with emission (from dysprosium to terbium) and without emission (resonance) (from terbium to dysprosium).

The studies by a number of investigators[15–18] dealing with the sensitisation of the luminescence of ytterbium by neodymium and praseodymium in a glass are of interest. The luminescence of ytterbium in the infrared part of the spectrum arises both on excitation with light at $\lambda = 0.93$ μm and in the ultraviolet region (the $^2F_{5/2} \rightarrow {}^2F_{7/2}$ transition). The intensity and duration of the luminescence of neodymium and praseodymium then diminish. The authors conclude that the quenching takes place in the excited state and that the energy is transferred to the terbium ions by a non-radiative pathway in an inductive interaction. The probability of excited transfer per unit time depends on the degree of overlapping of the spectra, the degree of prohibition of the interacting transitions, and the donor–acceptor distance. It has been shown[16] that praseodymium can also behave as a quenching agent for the luminescence of ytterbium. It has been stated[17] that praseodymium can quench the luminescence not only of ytterbium but also of neodymium, samarium, and dysprosium.

Shionoya and Nakazawa[19] reported the sensitising effect of cerium ions on the emission by terbium or neodymium in glasses. They suggest that the energy transfer takes place via a non-radiative pathway. Gandy et al.[20] observed the sensitisation of ytterbium by cerium in a glass. Pearson and coworkers[21,22] present experimental data confirming the occurrence of non-radiative energy transfer from gadolinium to terbium in a borate glass. In another study dealing with the concentration-dependent quenching of the luminescence of gadolinium and ytterbium in glasses, Pearson and coworkers[23] concluded that the quenching occurs not only as a result of the quenching interaction in the corresponding activators, but that the process includes also quenching by an admixture of europium present in gadolinium.

Woodcock and Smitzer[24,25] investigated the sensitisation of the luminescence of erbium in a silicate glass by ytterbium ions. The mechanism of the energy transfer is represented as follows. Energy from the $^2F_{5/2}$ level of ytterbium is transferred to the $^4I_{11/2}$ level of erbium; then the erbium ion undergoes a non-radiative transition to the $^4I_{13/2}$ state, from which there is a transition accompanied by emission at $\lambda = 1.5$ μm. Under these conditions, the duration of the fluorescence of ytterbium ($\lambda \simeq 1$ μm) and the fluorescence intensity diminish.

Artamonova et al.,[26] who reported the sensitising effect of UO$_2^{2+}$ on the luminescence of lanthanide ions, note that in a glass the transfer of excitation energy takes place via the following chain of ions: $UO_2^{2+} \rightarrow Nd^{3+} \rightarrow Yb^{3+} \rightarrow Er^{3+} \rightarrow Tm^{3+}$. The greatest energy transfer effect is observed in the following links of the system: $UO_2^{2+} \rightarrow Nd^{3+}$ and $Nd^{3+} \rightarrow Yb^{3+}$.

The sensitisation of the luminescence of erbium in glasses by ytterbium ions was investigated in detail by Kudryashov and coworkers[27]. According to their data, in the presence of ytterbium the intensity of the luminescence of erbium ($^4I_{13/2} \rightarrow {}^4I_{15/2}$ transition) increases by a factor greater than 3 and this occurs on excitation of the luminescence by light in the range 0.75–1.1 μm, which includes the absorption bands of both ytterbium and erbium.

It is noteworthy that in the above investigations the concentrations of the lanthanides in the liquid solutions and glasses were in most cases relatively high (several tenths per cent and above). At low lanthanide concentrations in solutions, interaction was hardly observed.

The effect of the interaction of lanthanide activators is shown most distinctly in crystals. This is probably why the number of studies on the interaction of lanthanides in crystalline specimens is much greater.

A series of studies have been made on the interaction between lanthanides in organic crystals (lanthanide complexes). Soden[28] investigated the effect of substitution of certain lanthanides on the fluorescence of hexa-antipyrine-terbium tri-iodide in crystals of the following series: $TR_{1-x}Tb_x(AP)_6I_3$ (TR = Gd, Er, Dy, Y); AP = antipyrine ($C_{11}H_{12}ON_2$), and $x = 1.0$, 0.5, 0.2, 0.1, 10^{-2}, 10^{-3}, or 10^{-6}. He noted that the presence of dysprosium does not influence the fluorescence of terbium; the intensity of the luminescence of terbium ($\lambda = 549$ nm) falls in proportion to the decrease of x. In the presence of gadolinium or yttrium the intensity diminishes more slowly than x, which is attributed to excitation energy transfer from the antipyrine complexes of these elements to the terbium complex. On introduction of erbium, a more rapid decrease of the intensity of the fluorescence of terbium is observed, which is accounted for by energy transfer from the terbium complex to the erbium complex, where non-radiative transitions take place. Thus, the sensitising effect of gadolinium and yttrium and the quenching effect of erbium on the fluorescence of terbium were demonstrated.

Van Uitert and Soden[29] present the results of a more complete investigation of the effect of substitution by other lanthanides on the fluorescence of hexa-antipyrineterbium tri-iodide and sodium–europium tungstate. A study was made of the luminescence of crystals with the composition $Tb_xM_{1-x}(AP)_3I_3$, where M = Y, La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, or Yb and $x = 1.0$, 0.5, 0.25, and 0.1 and also the series $Na_{0.5}M_{0.5-x}Eu_xWO_4$, where x varies from 3×10^{-3} to 0.5. The luminescence was excited by the emission of a mercury lamp at $\lambda = 2537$ and 3660 Å.

Van Uitert and Soden[29] believe that the distribution of excitation energy absorbed by the antipyrine molecule between terbium and M^{3+} ions in the first series of crystals is determined by the ground energy level of the M^{3+} ions. The ease of energy exchange between the antipyrine molecule and lanthanide ions increases with the total orbital angular momentum of the $4f$ electron. If the ground state of these ions is S (Ga, La, Y), a large proportion of the energy absorbed by the antipyrine molecules bound to the above ions is transferred to terbium; for the H- and F-states, the effect of M^{3+} is slight and M^{3+} ions with the ground state I (Nd, Ho, Er) cause pronounced quenching of the luminescence of terbium.

In the case of ions with the same ground state (F) the exchange of excitation energy takes place preferentially for ions with the normal positions of the multiplets (Eu and Ce—ground states $^7F_0$ and $^2F_{5/2}$) than in the case of reverse multiplets (Tb and Yb—ground states $^7F_6$ and $^2F_{7/2}$).

The quenching of the luminescence of europium in sodium tungstates obeys the same rule as in substitution by other lanthanides according to the authors' data. As an exception, cerium in a tungstate environment causes pronounced quenching of the luminescence of europium. The authors believe that this may be caused by the relatively weak attachment of its uncombined electrons to the $4f$ levels ($4d$–$5d$ transitions). It has been shown that terbium slightly sensitises europium.

Peterson and Bridenbaugh[30] observed a change in the duration of the fluorescence of terbium in the antipyrine–terbium complex on substitution by other lanthanides. They note that both the intensity and duration of the luminescence diminish when favourable conditions are created for the resonance transfer of excitation energy to another, neighbouring lanthanide. The presence of erbium, holmium, and neodymium ions greatly diminishes the duration and intensity of the luminescence of terbium.

Poluektov et al.[31] investigated the luminescence of europium in crystals of ternary phenanthroline–acetophane and phenthroline–thenoyltrifluoroacetone complexes in the presence of other lanthanides. According to the data, the intensity of the luminescence of europium depends on the composition of the deposit. They compared the logarithms of the luminescence intensity of europium and the energy difference ΔE between the triplet state of the molecule and the nearest lower energy level of an extraneous lanthanide. There is a parallelism in the form of the $\lg I_{Eu}$ and ΔE curves as a function of the element. The higher the value of ΔE, the higher is I_{Eu} (Gd, Y, La). For low values of ΔE, the luminescence of europium is quenched (Pr, Nd, Ho, Er, Tm)†.

Despite the high value of ΔE, cerium strongly quenches the luminescence of europium. The authors explain this by the characteristics of the $4f$–$5d$ transitions in cerium and also note that the quenching of the luminescence of europium by other lanthanides is observed only in crystalline complexes. In solutions, for example in benzene, the quenching of the luminescence of europium is not observed.

The same investigators[32] made a detailed study of the sensitisation of the luminescence of europium by terbium in complexes with salol, anthranilic acid, and ternary antipyrine–salicylate complexes.

The excitation of the luminescence of lanthanide ions in complexes takes place[33–36] in consequence of the transfer of the energy of the exciting light from the organic base of the complex to the lanthanide ion and energy may be transferred from both triplet and singlet levels. For this, it is necessary that the energy of the triplet or singlet level of the complex should be equal or should exceed that of the resonance level of the lanthanide ions. The redistribution of energy within the molecule takes place very rapidly, over a period less than the duration of the excited state. When the complex contains several lanthanides interacting with one another, during the excitation period there is

---

† It is noteworthy that the upper energy levels of praseodymium, neodymium, erbium, and thulium ions are located below the $^5D_0$ level of europium, which in fact gives rise to energy transfer.

probably a two-stage energy transfer: from the organic substance to the lanthanide ion and then from the latter to another lanthanide ion interacting with it.

The majority of the literature data on the interaction of lanthanides refer to inorganic crystals (crystalline phosphors). As early as the late 1940's, detailed investigations were made in the luminescence laboratory FIAN [Physical Institute of the USSR Academy of Sciences? (Ed. of Translation)] of the mutual effects of activator lanthanides (cerium, samarium, and europium) in crystalline alkaline earth phosphors[37,38]. A study was made of the absorption and luminescence spectra, the temperature-induced glow, the spectral sensitivity of the flash, etc. On the basis of the considerable changes in the luminescence spectra of one activator in the presence of another, the authors[37,38] suggested that the activators are located side by side and that they tend to form "complicated compounds", which constitute the luminescence centres. The probability of a random distribution of activators close to one another is insignificant when the concentrations are low (about 10^{-3}%).

During recent years a number of studies on the interaction of activator lanthanides by Soviet investigators have been published. Levshin et al.,[39] who studied the determination of small amounts of gadolinium, samarium, and europium in thorium by luminescence methods, paid some attention to this problem. They established that the luminescence of gadolinium is strongly quenched by admixtures of samarium, cerium, and neodymium when their concentrations in the specimen are about 10^{-3}% and above. The luminescence of samarium is strongly quenched by admixtures of neodymium and dysprosium. In another study by Levshin et al.,[40] energy transfer from silver to samarium ions in ZnS phosphors was considered. It was emphasised that the interaction of the activators is observed at very low concentrations (about 10^{-3}%), where the relevant species may not be close neighbours. The authors believe that the pronounced temperature dependence of the interaction is related to a change in the transfer of charge carriers through different bands. However, they do not reject the possibility of resonance energy transfer between activators as well.

Voronov and Levshin[41] investigated the interaction of the silver, samarium, thulium, and europium activators in the cathodoluminescence of ZnS-based phosphors. Samarium was chosen as the principal activator, since it is most sensitive to changes in the immediate environment. The effect of a second activator reduces to a marked redistribution of energy in the spectrum and to a change in the overall luminescence yield. At a low temperature the integral luminescence of samarium in the presence of a second activator hardly changes. Partial quenching of the luminescence of samarium is observed at room temperature. The authors believe that the quenching of the luminescence of samarium involves an electron–hole mechanism. The necessity to compensate charges, suggests a great likelihood of the formation of lanthanide ion pairs, occupying adjacent lattice sites and replacing three Zn^{2+} ions. This is indicated by the formation of deep localisation levels (about 0.5 eV) and a redistribution of energy in the spectrum.

Cherepnev and Pakhomycheva[42] and Leonov[43] investigated the sensitising effect of cerium on the luminescence of samarium in the $SrSO_4$ [42] and $3MgO.B_2O_3$ phosphors[43]. Bozhevol'nov and Fakeeva[44] used the sensitising effect of cerium on the luminescence of samarium in the $PbSO_4$–Ce,Sm phosphor to increase the sensitivity of the determination of samarium by a luminescence method.

O'Connor and Hargreaves[45] reported the excitation energy transfer from cerium to neodymium in CeF_3. Blasse and Bril[46] studied the energy transfer from cerium to samarium, europium, terbium, and dysprosium.

A number of non-Soviet and Soviet investigators studied the luminescence of crystalline phosphors activated by europium in the presence of other lanthanides[47-61]. Van Uitert and coworkers published a series of papers[47-49,55] on the interaction between lanthanide activators, attention being concentrated on the luminescence of europium. In one of their papers[47] they present data on the sensitising effect of terbium on the luminescence of europium. The experiments were performed with tungstates having the composition $M_{0.5}Tb_{0.5-x}Eu_xWO_4$ and $M_{0.5}Y_{0.5-x}Eu_xWO_4$, where M = Na, K, Rb, or Cs and $x = 10^{-4}$, 10^{-3}, 10^{-2}, 10^{-1}, or 0.5. It was shown that the intensity of the luminescence of europium in alkaline earth metal tungstates increases in the presence of terbium in proportion to its concentration. Up to 90% of the energy absorbed by terbium ions is transmitted to europium ions. When terbium is replaced by yttrium, the intensity of the luminescence of europium diminishes. It was also established that the relative intensity of the luminescence of terbium and europium diminishes with increasing radius of the alkali metal ions in the crystal lattice.

In other studies[48], the authors investigated the mechanism of energy transfer from terbium to samarium in the $Na_{0.5}Y_{0.5(x+y)}Tb_ySm_xWO_4$ system, from europium to neodymium in $Na_{0.5}(Y, Eu, Nd)_{0.5}WO_4$ and $(Y, Eu, Nd)_2O_3$, and from dysprosium to terbium in $Na_{0.5}(Y, Tb, Dy)_{0.5}WO_4$.

The quenching of the luminescence of terbium by samarium is characterised by a dipole–quadrupole interaction, but the luminescence of samarium was not observed under these conditions. Energy transfer from europium to neodymium takes place mainly via a dipole–dipole interaction. Energy may be transferred from the $^4F_{9/2}$ level of dysprosium to the $^5D_4$ level of terbium in the above system at 295.77° and 4.2°K. At 295°K the reverse transfer may occur.

In the next study by Van Uitert and coworkers[49], the problem of energy transfer from the main component of the crystal to lanthanide ions and also the concentration-dependent quenching of the luminescence of lanthanide is considered. The authors conclude that the energy of the exciting light is transmitted to the activator more effectively when it is close to the absorption limit of the main component. At frequencies below the absorption limit but not in the region of absorption by the lanthanide ions, excitation via the main lattice is relatively ineffective. At frequencies in excess of the absorption limit the energy is strongly absorbed and is distributed in the lattice. Energy transfer from the main component of the crystal to the lanthanide ions may be regarded as an independent problem.

Levshin and coworkers[50] studied the energy transfer from ZnS to a lanthanide activator and concluded that in this system, following excitation via the main component, the lanthanides receive energy predominantly by an electron–hole mechanism. The process depends markedly on the nature of the activators and the relative positions of their levels.

Two studies[51,52] on the luminescence of lanthanide ions in $Cs_2(NO_2Cl_4)$ crystals also demonstrate the sensitisation of the luminescence of lanthanide ions by the main component of the crystal. It has been shown that the migration of excitation energy of uranyl ions in the crystal lattice plays a significant role in energy transfer.

Mooney and Toma[53], who studied the system YVO_4–Eu suggest a mechanism for energy transfer from VO^{3-} to Eu^{3+} in which the colinearity of the positions of the V–O–Eu ions is not obligatory, as suggested by Blasse[54]. On the basis of structural data, it is concluded that in YVO_4 the π-bonding orbitals of the VO_4^{3-} ions have a maximum electron density in the direction of Y^{3+}. Therefore, in the substitution of yttrium by europium there is maximum overlapping of these π bonding orbitals with the f orbitals of the lanthanide ions. The authors explain in this way the high effectiveness of the luminescence of europium in YVO_4. The vanadium, oxygen, and europium ions do not lie on a single straight line under these conditions.

Blasse and Bril[54] investigated the energy transfer from the main component to lanthanide ions in Ln_2WO_6, Ln_2MoO_6, and $Y_2W_{1-x}Mo_xO_6$ ($0 \leq x \leq 0.1$) activated by europium. The authors suggest that the following conditions are necessary for the effective luminescence of europium: (1) the absorbing group must be a nearest neighbour; (2) the emission and absorption spectra of these groups must overlap; (3) the centre of the absorbing group, the intermediate oxygen ion, and the europium ion must be colinear; (4) the oxygen ions surrounding europium must respond to a high-potential field.

Bril and Wanmaker[56] observed the luminescent properties of phosphors activated by europium with a base incorporating lanthanides: Gd_2O_3, Y_2O_3, La_2O_3, $GdPO_4$, $LaPO_4$, etc. The phosphors exhibited the luminescence of europium. On the basis of the excitation spectra, the authors concluded that the energy absorbed by the main lanthanide ions is transferred to the impurity europium ions.

The study by Van Uitert and Jida[55] on the interaction of lanthanide ions in crystals of different compositions is of great interest. They investigated the single crystals of sodium and potassium tungstates and aluminates containing lanthanides ranging from yttrium and cerium to ytterbium. The cases of identical (concentration-dependent quenching) and different lanthanides (their mutual influence) were examined. Identical ions in immediate proximity quench each other's luminescence. The authors believe that the interactions between the lanthanides may be direct or via oxygen (in the presence of oxygen the quenching is more pronounced). Attention was concentrated on the luminescence of europium and terbium.

When europium and terbium ions interact with those of other lanthanides, the intensity of their luminescence diminishes exponentially with decrease of the spacing between the "fluoresceing" levels of the europium and terbium ions and the nearest lower levels of other lanthanide ions.

Holloway et al.[57] obtained direct proof of energy transfer from terbium to europium. They studied compounds with the composition $(Tb_{1-x}Eu_x)_2(WO_4)_3$. The luminescence of europium (λ = 6150 Å) and terbium (5460 Å) was observed.

The luminescence of europium in the presence of terbium appears both on excitation with ultraviolet light and on excitation with light at λ = 4950 Å (λ corresponding to the excitation of the terbium ion). On the other hand, if the phosphor does not contain terbium $[(Gd, Eu)_2(WO_4)_3]$, then, on excitation with light at λ = 4950 Å, the luminescence of europium is not observed. According to the authors, energy transfer from terbium to europium ions takes place by a non-radiative pathway (sensitisation of europium by terbium). The authors regard the process mechanism as obscure.

In another paper Holloway and Kestigian[58] quote data on the sensitisation of the luminescence of europium by terbium in the $Y_{3-x}Tb_xAl_5O_{12}$ system. The same study dealt with the concentration-dependent quenching of the fluorescence of terbium at 300° and 77°K. It was shown that the probability of quenching varies exponentially with the concentration of terbium.

Ropp[59] studied energy transfer from terbium to europium in Y_2O_3. Holloway and Kestigian[60] made an interesting study on energy transfer between samarium, europium, terbium, and dysprosium in sodium tungstate. They compared the experimental energy transfer data with the relative compositions of the energy levels in the interacting ions. There should be energy transfer of ions with higher excited levels to those with lower fluorescence levels (possibly via an excited state intermediate between the fluorescence levels of the acceptor ion).

Axe and Weller[61] presented experimental data on energy transfer between europium and other lanthanide ions in Y_2O_3. They reported that the addition of lanthanides such as holmium, erbium, thulium, and particularly neodymium strongly quenches the fluorescence of europium. It is suggested that the quenching is caused mainly by non-radiative resonance energy transfer from one lanthanide ion to another. The authors assert that the overlapping of adjacent zones in quadrupolar fields is of great importance in this process.

The interaction between lanthanide ions has been demonstrated also in a number of studies by other investigators. For example, Margolis et al.[62] note that the luminescence of praseodymium in $CeCl_3$ is readily excited by light at $\lambda \simeq 350$ nm (cerium absorption band). The authors wished to demonstrate experimentally that collective absorption of photons, when the energy of the exciting quantum is consumed in the simultaneous excitation of two ions‡, may be observed not only for identical ions, as shown by Varsanyi and Dieke[64], but also for different ions. Possibly in this case there is the usual transfer of energy absorbed by cerium ions to praseodymium ions.

The sensitisation of the luminescence of lanthanides by cerium has been frequently noted[42-44]. Linares[65] investigated the luminescence and excitation spectra and fluorescence lifetimes τ of europium and other lanthanide ions in CeO_2 and ThO_2. Regions corresponding to energy transfer from CeO_2 to europium, samarium, and erbium were observed in the excitation spectrum.

Scott et al.[66] considered the problem of energy transfer from praseodymium to neodymium. They made a theoretical calculation of the width of the spectral lines on the basis of a dipole interaction modulated by phonons.

Rast et al.[67] and Ewanizky et al.[68] investigated the interaction of neodymium and ytterbium in LaF_3 and CaF_2 crystals. In consequence of the transfer of excitation energy from neodymium to ytterbium, the intensity of the luminescence of ytterbium in the region of 0.97 μm increases by two powers of 10 according to Ewanizky et al.[68] In the case of divalent ytterbium, energy transfer from Yb^{2+} and Nd^{3+} is observed.

Brown[69] studied the energy transfer from thulium to holmium in Y_2O_3. The luminescence of holmium was observed on excitation with light corresponding to the absorption bands of thulium ($\lambda \simeq 590$–820 nm). A non-radiative energy transfer is suggested.

---

‡ Collective or cooperative absorption may occur also in the excitation of an acceptor ion as a result of the summation of the energies of two donor ions[63]. For example, the excitation of Tm^{3+} (470 nm) by two quanta capable of exciting Yb^{3+} (960 nm).

Brown and Whiting[70] studied the interaction of lanthanides in LaF_3 and determined the quantum yield and duration of the visible fluorescence of praseodymium in an LaF_3 single crystal in the presence of other lanthanide admixtures: cerium, neodymium, europium, gadolinium, terbium, dysprosium, holmium, erbium, thulium, and ytterbium. The system with praseodymium and cerium was studied in detail. The concentration-dependent quenching of the luminescence of praseodymium in LaF_3 and CeF_2 was examined as a function of temperature. To interpret the experimental data, calculations were made for two simple models; (1) isolated praseodymium; (2) praseodymium adjoining another ion. It was found that the sphere of interaction extends from nearest neighbours up to about 300 atomic distances. It was shown that quadrupole interaction predominates.

In a later study by Van Uitert[71] on the concentration-dependent quenching of the fluorescence of samarium, europium, terbium, erbium, and neodymium in solid matrices, it was established that the quenching of the luminescence of samarium, terbium, and erbium ions occurs as a result of dipole–dipole interaction. The authors believe that the quenching of the fluorescence of europium is influenced by the crystal structure of the matrix.

Blasse's study[72] dealt with the concentration-dependent quenching of the luminescence of europium in $Ba_2Gd_{1-x}Eu_xM^{5+}O_6$ (M = Nd or Ta) and $Gd_{1-x}Eu_xAl_3B_4O_{12}$ with different crystal structures. The extent of the influence of the crystal structure on the concentration-dependent quenching was demonstrated.

Peterson and Bridenbaugh[73] analysed the duration of the luminescence of terbium in the presence of other lanthanide ions to investigate the interaction between pairs of lanthanides. A study was made of the duration of the excited state $(\tau)/{}^5D_4$ of terbium ions in a series of mixed crystals $Tb_{0.9}TR_{0.1}Cl_3.6H_2O$. It was established that the lanthanide ions which absorb light in the region corresponding to emission by terbium (europium, thulium, praseodymium, samarium, neodymium, erbium, and holmium) reduce τ, while lanthanum, gadolinium, ytterbium, yttrium, lutetium, dysprosium, and cerium, which do not absorb in the range 4875–6800 Å, hardly change τ. Erbium, holmium, and neodymium ions have the greatest effect. The intensity of luminescence varies approximately in parallel with τ. This phenomenon is explained by the resonance transfer of excitation energy from terbium to other lanthanide ions, which leads to quenching and decrease of τ.

In another study by the same investigators[73], the problem of self-quenching by neodymium in $Na_{0.5}Gd_{0.5-c}Nd_cWO_4$ was examined and it was shown that the probability of quenching is proportional to $1/r^6$, where r is the distance between the interacting ions.

Osiko and Voron'ko[74], who investigated the concentration-dependent quenching of the luminescence of neodymium in CaF_2, concluded that the resonance Nd–Nd interaction accompanied by quenching takes place only at distances of about 4 Å, corresponding to the distance between the neodymium ions in an ion pair centre (3.8 Å). On the other hand, the probability of a non-radiative energy transfer between single centres at a distance greater than 4 Å is low, as shown by the weak dependence of τ for single centres on the concentration of neodymium. Thus, according to the authors, the concentration-dependence of the quenching of the luminescence of neodymium is due to the association of neodymium ions. In consequence of the increase in the number of ion pair centres, an increase of concentration entails an increase of inactive absorption, which lowers the overall luminescence yield.

In another paper by the same investigators[75] experimental data are quoted for excitation energy transfer from erbium to holmium and thulium in CaF_2 crystals.

Porter and Moos[76] reported ion pair interaction in the $LaCl_3$–holmium system. On the basis of the relative luminescence intensities in transitions from the ${}^5S_2$, ${}^5I_4$, and ${}^5I_7$ levels, it was concluded that the ${}^5S_2 \rightarrow {}^5I_4$ transition takes place via the interaction between a pair of holmium ions. The variation of the probability of the pair interaction with concentration is linear. The effective region of interaction for the ion pair is about 7.5 Å (third nearest neighbour).

Bril and Wanmaker[77] observed energy transfer from gadolinium to terbium in $CaNaBO_3$. On excitation of the phosphor in the region 256–280 nm, both gadolinium and terbium luminesce, the fluorescence of gadolinium being weaker than in the absence of terbium. The excitation of the terbium fluorescence by emission from gadolinium (in the region of 311 nm) can be virtually excluded, since the fluorescence of terbium on excitation with light at λ = 311 nm is very weak. Consequently there is a non-radiative energy transfer from gadolinium to terbium. The quantum yield of the fluorescence of terbium sensitised by gadolinium is 60% according to the authors.

Jonson et al.[78] reported energy transfer from erbium ions to thulium and holmium ions in $CaMoO_4$ crystals. The transition takes place from the ${}^4I_{13/2}$ state of erbium to the ${}^3H_4$ state of thulium and the ${}^5I_7$ state of holmium. As a result of the energy transfer, it is possible to achieve an increase in the infrared emission by thulium and holmium ions. The sensitisation of the emission from thulium and holmium by erbium is used in lasers. The sensitisation of the luminescence of holmium and thulium by erbium in CaF_2 crystals was investigated by Osiko and coworkers[79].

In a study designed to elucidate the role of the effect of lanthanide admixtures in the determination of small amounts of any one lanthanide in yttrium oxide, we found[80] that, in the presence of terbium in an amount of 5×10^{-3}% and above, the luminescence of dysprosium is quenched.

Later Taylor[81] reported the observation in CaF_2 crystals at 300°K not only of the quenching of the luminescence of dysprosium by terbium at their concentrations of about 0.1 at.% but also an increase in the intensity of the fluorescence of terbium (by a factor of about 5). The study of the luminescence kinetics showed that the mechanism of energy transfer from dysprosium to terbium is non-radiative and takes place from the ${}^4F_{9/2}$ level of dysprosium to the ${}^5D_4$ level of terbium.

In connection with the development of methods for the luminescence analysis of lanthanide impurities in pure substances, Poluektov et al.[82] investigated also the effect of extraneous lanthanides on the intensity of the fluorescence of the sought lanthanide ion. The luminescence of samarium, europium, terbium, and dysprosium in different matrices was observed. The greatest luminescence yield was found in compounds of lanthanum, gadolinium, lutetium, and yttrium, which is evidence of their sensitising effect. Elements such as praseodymium, neodymium, holmium, erbium, and thulium quench fluorescence.

III. MECHANISM OF THE INTERACTION OF LANTHANIDE ACTIVATORS

There is a fairly large amount of data on the changes in the luminescence properties of lanthanides in consequence of their interaction. At comparatively low concentrations the interaction is reflected mainly in energy transfer from one lanthanide to another, which leads to the observation of the quenching of the luminescence of one or both interacting ions, in particular concentration-dependent quenching, the quenching of the luminescence of one ion and the sensitisation by it of that of another or only the sensitisation of the fluorescence of the other ion, and as a rule a change in the duration of luminescence.

At high concentrations or in the case of a deviation from the random distribution of lanthanide ions in the crystal lattice, it is possible to observe also other signs of the interaction: a change in the absorption and luminescence spectra—displacement of the lines and redistribution of their intensities, appearance of new lines and disappearance of old lines[74,83,84], and certain other properties.

In this review we are considering mainly processes involving the sensitisation and quenching of the luminescence of lanthanides. The experimental data on the mutual effects of lanthanides are presented in the Table below, where, together with each lanthanide, are indicated others which have a sensitising or quenching effect on its luminescence. The data are presented for liquid solutions, glasses, and organic and inorganic crystals.

Many authors have put forward hypotheses concerning the mechanism of the interaction. Most of them conclude that there is a resonance energy transfer from one ion to another (exchange-resonance or inductive-resonance)[3,5,15,19,30,34,40,48,57,66–71,73,77,87]. Only in isolated cases are other hypotheses put forward: energy transfer via emission[7,14] and energy transfer via energy bands by charge carriers[40,41,50]. Depending on the structure of the system investigated and on the specific conditions of the excitation of the luminescence, any of the mechanisms proposed is possible. When the crystalline phosphor exhibits photoconduction, energy transfer via energy bands by charge carriers is quite possible (Mott–Gurney theory[88]). When the emission spectrum of one lanthanide overlaps the absorption spectrum of another, there is a possibility of energy transfer via emission. However, it appears that most often there is an inductive resonance energy transfer process.

The theory of resonance energy transfer was described in detail by Dexter[89], who concentrated attention on the problem of the sensitised luminescence of solids. At the same time he reviewed critically other theoretical studies on the mechanism of the interaction.

In the presence of sensitised luminescence in inorganic compounds there is usually energy transfer from an allowed level of the sensitiser to a forbidden level of the activator. Some investigators (Botden[90], Kröger[91], and

Effect of lanthanide and other ionic impurities on the luminescent properties of the main lanthanide.

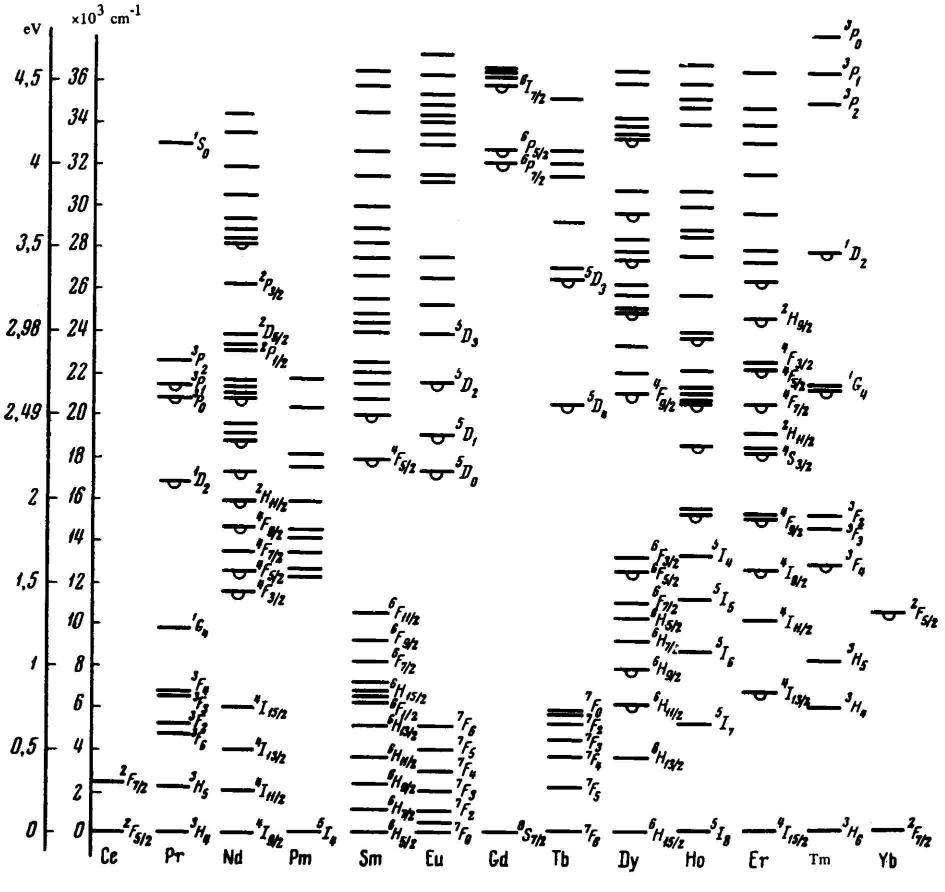
others) believe that the probability of such a transition is determined by the overlapping of the wave functions of the sensitiser and the activator and that the transition is possible only when the activator and sensitiser occupy adjacent sites in the lattice[74]. Tests of this theory showed that this is not always so. Energy transfer can occur also in the case of a random distribution of sensitiser and activator ions in the crystal. When they are located close to one another (about 5 Å), there is a possibility of direct energy transfer from the sensitiser to the activator via quantum-mechanical resonance. If the excited sensitiser ion is remote from the activator ion (at a distance greater than 50 Å), the excitation energy may be transmitted by other sensitiser ions to the activator ion via resonance. Thus the formation of sensitiser–activator pairs is not obligatory. The role of the sensitiser may be fulfilled both by additional admixtures to the main component of the crystal and by the main component itself when the excitation energy is transmitted to the activator directly from the main component as the energy donor[49-54].

The hypothesis of the resonance energy transfer process is not inconsistent with the effect of various factors on energy transfer. According to the literature, these include the following:

1. The distance between lanthanide ions, which is determined mainly by their concentration[5,15,37,38,73]; the probability of dipole–dipole interaction is inversely proportional to the sixth power of the distance between the interacting ions, while the probability of dipole–quadrupole interaction is proportional to the eighth power.

2. The degree of overlapping of the bands[15,61,73] or the energy difference between interacting levels[31,55]; the energy of the excited sensitiser level should be approximately equal to, or should exceed, the energy of the resonance level of the activator, the probability of energy transfer decreasing with increase in the difference ΔE between



Comparison of schematic sets of electronic levels for triply charged lanthanide ions (the semicircles designate "fluoresceing" levels).

these levels. The transfer of excitation energy from one ion to another for large values of ΔE is accompanied by the emission of phonons with energies approximately equal to ΔE.[86]

Since the activator plays the role of a quenching agent in relation to the sensitiser, it is to be expected that the energy of the excited level of the quenching agent should be equal to or lower than that of the resonance level of the activator.

3. The degree of prohibition of the interacting transitions[15].
4. The energy of the principal level of the interacting lanthanide ions, determined by the total orbital moment[29]; the probability of energy transfer increases with increase in the total orbital angular momentum of the $4f$ electrons.
5. Temperature[6,17,40,41] and other factors; with decrease of temperature, in most cases the probability of energy transfer falls, which can be accounted for by a decrease of the overlapping of the energy levels.

Review of published data shows that the luminescence properties of lanthanides vary significantly in consequence of their interaction. The factors enumerated, which influence energy transfer, show that the interaction is intense at high concentrations. The change in luminescent properties under these conditions is greater the more complete is the overlapping of the energy levels of the interacting ions.

Only at very low lanthanide concentrations (about $1 \times 10^{-3}\%$ and below)[39,80,82] is there virtually no interaction and hence no changes in the optical properties. Thus in the determination of small amounts of lanthanide impurities in high-purity substances by the luminescence method the analytical errors owing to their interaction are virtually excluded in many cases. The present authors' recent studies[85,93] showed that the problem of the determination of lanthanide impurities by the luminescence method is not always simple. For example, the determination of small amounts of gadolinium (about $10^{-5}\%$) in europium oxide[85] by the luminescence method is impossible without preliminary enrichment and subsequent introduction of the concentrate into yttrium oxide—a donor of the excitation energy of gadolinium. The reason for this is the nature of the interaction between gadolinium and europium. The relative energy levels in the atoms of these elements (see Figure) is favourable for energy transfer from gadolinium to europium but not conversely. Thus europium behaves in this case as a quenching agent for the luminescence of gadolinium.

In relation to neodymium, holmium, erbium, and thulium, europium can behave as an energy donor and therefore the determination of these impurities in europium oxide by the luminescence method should not present difficulties, if one disregards the partial overlapping of the luminescence spectra.

In the determination of lanthanide impurities in metallic uranium[93] by the luminescence method, the overlapping of the luminescence spectra has been the chief obstacle, since uranium can also function as an effective activator of many compounds[94] and its luminescence spectrum consists of a group of broad bands in the visible region. In this case an important condition for the choice of a base for the crystalline phosphor is the absence from it of uranium luminescence, which is almost impossible, or at least the presence of luminescence with a reduced intensity only. Then it is also necessary to achieve a careful separation of the lanthanide impurity from the base element (uranium). The determination of lanthanides by the luminescence method is not interfered with by the presence of uranium only if the latter is present in an amount less than or equal to $1 \times 10^{-3}\%$.

The Present State of the Problem of Lignin-Carbohydrate Bonds in Plant Tissues

O.P.Grushnikov and N.N.Shorygina

The studies of the last 10-15 years showed that chemical and hydrogen bonds between lignin and carbohydrates and also three-dimensional network structures of lignin immobilising the carbohydrate chains are involved in the formation of a single set of components of the plant cell wall. This review presents data demonstrating the presence of the most likely types of lignin-carbohydrate bonds: ester, ether, acetal, and phenol-glycoside. However, the problems concerning the type, nature, and number of lignin-carbohydrate bonds still remain open. The possible inhomogeneity of the lignin in plant tissues complicates further the solution of these problems.
The bibliography includes 143 references.

CONTENTS

I. INTRODUCTION

During the last 10–15 years considerable advances have been achieved in the chemistry of lignin. The Swedish chemist Björkman developed a method for the isolation of lignin, which consists in the mechanical milling of the lignified material in a ball vibromill and does not involve the use of acid or alkali, thereby yielding a product closest to the "natural" material, i.e. lignin not isolated from plant tissue. The German chemist Freudenberg achieved the laboratory synthesis of a "dehydropolymer" in many respects similar to natural lignin from conifer wood. This preparation was obtained by dehydrogenating *in vitro* a very dilute mixture of coniceryl, *p*-coumaryl, and sinapinic alcohols under the action of laccase (a dehydrogenase). The problems of the biosynthesis of lignin in plants have been elucidated to a considerable degree. There have been undoubted advances in the study of the structure of lignin, its functional groups, and the types of its intramolecular bonds, as well as in the study of processes associated with the modification of lignin in the sulphite and sulphate pulping of wood and in its chlorination for the bleaching of cellulose. Some progress in the industrial utilisation of lignin, which is a large-scale by-product of the cellulose, paper, and hydrolytic industries, may also be noted.

However, despite the appreciable and unquestionable advances in the chemistry of lignin, a number of problems still give rise to a lively controversy among investigators in this field, and these are some of the most important problems in both theory and practice. In the first place this applies to the problem of the lignin–carbohydrate bonds in plant tissues and the related problems of the quantitative content of lignin in lignified material.

Indeed, as regards lignin–carbohydrate bonds, not only the problem of the type, nature, and number of chemical bonds of this kind in plant tissues but the very fact of the presence of such bonds is controversial. Nevertheless, the problem of whether lignin is linked to the carbohydrate components of plant tissues by chemical bonds or whether it is present in a free state, i.e. in a mechanical mixture with polysaccharides, is not only of theoretical interest but is also important for the quantitative separation of plant components in order to analyse them and understand various delignification processes in wood. It is noteworthy that in the chemistry of lignin there is still no single standard method for the quantitative determination of the content of lignin in plant materials, which naturally results in an appreciable discrepancy between results obtained using different methods and between the conclusions based on the results.

The problem of the presence or absence of chemical bonds between lignin and carbohydrate components of plant tissues has been the subject of controversy for more than 100 years. At the beginning two opposed views on this problem were in fact put forward: in 1838 Payen put forward the so called "incrustation theory" on the basis of the fact that cellulose in cell walls does not give rise to characteristic reactions until the non-cellulose material has been removed, namely that wood is a physical mixture of components and that cellulose is subjected to mechanical incrustation by lignin, while in 1866 Erdmann [7,8] postulated the existence in plant tissues of "glycolignose" in which cellulose is linked by an ester or ether bond to a non-carbohydrate component (lignin). In the following period a considerable number of data supporting one or other theory were published. However, in the last decade the majority of investigators clearly tend to recognise the presence of a chemical lignin–carbohydrate bond in plant tissues. A comprehensive review of the literature on this problem was carried out by Merewether [9], who examined in detail data on the morphology of the cell wall and microbiological degradation of wood and also data obtained in various chemical reactions of woody tissues and lignin.

During the ten years which have elapsed since the publication of Merewether's review, a considerable number of interesting data concerning the bonds between the components of plant tissues have been obtained and are discussed below. However, although stress has been laid on studies published in the last decade, in some cases earlier publications have been referred to make the exposition more complete.

2. CHEMICAL BONDS BETWEEN LIGNIN AND CARBOHYDRATE COMPONENTS OF PLANT TISSUES

The existence of lignin–carbohydrate complexes (LCC), consisting of soluble fragments of wood containing both lignin and carbohydrates in a form not separable by physical methods, has now been firmly established.

Lignin–carbohydrate complexes have been isolated by heating wood with water[10,11], on chlorination[10,12], alcoholysis[10,13,14], acetylation[15,16] and ozonolysis[17] of wood, in the sulphite[18-21], sulphate[22], soda[23-25], and chlorite[26] pulping of wood, and also as a result of the enzymatic breakdown of wood[27-31] and its treatment with a neutral aqueous solvent[32]; however, the major advances in the isolation and investigation of these complexes are undoubtedly due to Björkman.

In 1954 Björkman[33] proposed a new method for the isolation of lignin from lignified materials. After preliminary extraction, fir wood sawdust was ground in a ball vibromill in toluene or another solvent which does not cause the swelling of the material. Extraction of the ground wood with moist dioxan permitted the isolation of up to 50% of its lignin content in the form of mechanically ground lignin (MGL).[34] Further extraction of the ground wood with dimethylformamide, dimethyl sulphoxide, and water gave an additional amount of material containing, together with lignin, also a considerable amount of carbohydrates, the components being separated only by acid hydrolysis[35]. Fractionation of the extracts yielded a series of lignin–carbohydrate complexes containing between 16 and 34% of lignin. The composition of the carbohydrate component was always the same and corresponded to the composition of wood hemicelluloses (Table 1).

Table 1. Carbohydrate composition (rel. %) of hemicelluloses and lignin–carbohydrate complexes extracted with dimethylformamide from various species of wood (according to the data of Björkman[35]).

Carbohydrates	Fir (*Picea abies*)		Pine (*Pinus silvestris*)	Birch (*Betula verrucosa*)	
	LCC	Hem.	LCC	LCC	Hem.
Galactan	10	8	15	9	4
Glucan	17	18	25		7
Mannan	50	46	32	3	7
Araban	4	4	13	2	7
Xylan	19	24	15	86	75

LCC = lignin–carbohydrate complex; Hem. = hemicellulose (Ed. of Translation).

Further grinding of the isolated lignin–carbohydrate complexes in the vibromill yielded 40% of their lignin content in the form of MGL, identical in elemental and functional group composition and also in molecular weight to the MGL isolated in the grinding of wood[36]. Moreover, Björkman[35] carried out special experiments to establish whether the complex is formed during the grinding process. After the usual treatment in the vibromill of a mixture of MGL and hemicelluloses from *Picea abies* in proportions of 1 : 3, about 85% of the initial lignin was isolated. On this basis, it was concluded that the lignin–carbohydrate complexes are present in the wood and are not formed during its grinding in the vibromill.

The latter finding was convincingly confirmed by the data of Lindgren[37], who investigated the electrophoretic mobility of MGL and the lignin–carbohydrate complexes isolated from fir wood by Björkman's method. In the electrophoresis of the fraction designated by Björkman as the lignin–carbohydrate complexes, two subfractions were obtained: a slower carbohydrate fraction and a faster fraction containing both lignin and carbohydrates. The latter give a positive response to the test for lignin and yielded on hydrolysis glucose, mannose, and xylose. The relative amounts of lignin and carbohydrates in the fraction were about 1 : 1. Moreover, Lindgren established that MGL obtained in a preliminary grinding of the lignin–carbohydrate complexes had an electrophoretic mobility approximately equal to that of the MGL isolated initially, which constitutes yet another confirmation of the formation of MGL as a result of the dissociation of the lignin–carbohydrate complexes.

Thus, as a result of grinding in the vibromill, it is possible to isolate up to 50% of the lignin content in the wood in the form of MGL. The difficulty of extracting large amounts of lignin by neutral solvents can be accounted for, according to Björkman[34], either by the existence of strong chemical bonds between the lignin and carbohydrates or by the high molecular weight of the lignin and the possibility of the formation of three-dimensional network structures. Björkman also pointed out the possibility of the effect of weaker forces, namely hydrogen bonds, since the solvents employed for the isolation of MGL and the lignin–carbohydrate complexes should exhibit a high capacity for the formation of hydrogen bonds, which is necessary for the dissociation of the lignin–carbohydrate hydrogen bonds.

Hayashi and Tachi[38] showed that dilute alkali can extract from wheat straw powder a lignin–xylose complex, the so called "xylolignin" which breaks down after prolonged treatment with alkali. A similar complex is extracted with butanol, acetone, or ethanol containing water and sodium hydroxide. It has been established that the carbohydrate component of the complex, consisting mainly of xylose, contains small amounts of glucose and arabinose. Acetylated xylolignin has been extracted from acetylated wheat straw powder with acetone and chloroform[39,40]. The carbohydrate part of this complex has a composition analogous to that of the carbohydrates of xylolignin. Hydrolysis of acetylated xylolignin with a methanol solution of sodium hydroxide results not only in deacetylation but also in the dissociation of the lignin–carbohydrate bonds[41]. In subsequent communications Hayashi and Tachi[42-45] showed that dioxan, 50% acetic acid, and dimethylformamide extract lignin–carbohydrate complexes from wheat straw powder without preliminary grinding in the vibromill. The composition of the carbohydrate component (xylose, glucose, arabinose, and galactose) of the lignin–carbohydrate complexes extracted by these solvents differed from that of xylolignin.

Thus glucose predominated in the lignin–carbohydrate complexes extracted with dimethylformamide and the complexes extracted with dioxan and aqueous acetic acid, in which xylose constituted the major part of the carbohydrates, were enriched in galactose and arabinose compared with xylolignin. On the basis of these investigations, the authors[44] suggest the presence in wheat straw of lignin–carbohydrate complexes of different types.

Brownell and West[46] proposed a comparatively mild procedure for the dissolution of both lignin and wood carbohydrates without the application of strong acids, alkalies, or oxidising agents. After preliminary extraction with an alcohol–benzene mixture, air-dry sawdust was ground for 21 days in the usual rotary ball mill. As a result of the grinding, the degree of polymerisation of carbohydrates fell to about 40†. Then the ground wood was dissolved by treatment with epoxyethane in dimethylformamide. The dissolved hydroxyethylated wood was subjected to fractional precipitation, separation by paper and column chromatography, electrophoresis, and partition between two immiscible liquids. The investigation established that the main part of lignin cannot be freed from carbohydrates under such conditions. In subsequent publications Brownell[47–50] reported a method for the separation into components of the wood ground in a ball mill. This method consists in the separation of ground wood into components in the system aqueous solution of sodium thiocyanate–benzyl alcohol–dimethylformamide. Lignin and a lignin–carbohydrate complex analogous to the preparations obtained by Björkman's method were obtained, and the stability of the lignin–carbohydrate complex under conditions of various physical and chemical treatments was investigated[47,48]. Although both Brownell[47,48] and Björkman[35] believed it to be established that the lignin–carbohydrate complex is not formed during the grinding by free-radical grafting, we believe that this conclusion requires additional experimental confirmation, since in the course of intense mechanical degradation (grinding in a vibromill or a rotary ball mill) chemical bonds of different types are broken and the resulting macroradicals are capable of recombination, which may lead to the formation of new chemical compounds differing in bond type and composition from the initial polymers.

The fact that the lignin–carbohydrate complexes can be isolated from wood by a wide variety of methods, which include many different types of chemical treatment, grinding in a vibromill or ball mill, and enzymatic breakdown of lignified materials undoubtedly indicates that at least part of the wood exists in the form of lignin–carbohydrate complexes. At the same time the impossibility of isolating the individual components of the lignin–carbohydrate complexes in a pure form without the use of powerful chemical reagents (acids and alkalies) or without the application of mechanical energy, light energy, irradiation, or ultrasonication constitutes one of the most convincing proofs of the existence of chemical bonds between lignin and carbohydrates in plant tissues.

Interesting data concerning the presence of lignin-carbohydrate bonds were obtained in recent years in studies on lignin by physical methods (ESR spectra, infrared spectroscopy, etc.). Rex[51] showed that lignin does not contain free radicals before isolation from plant tissues. At the same time in isolated lignins free radicals persist for a long time during humification and coal formation. Kleinert and Morton[52] observed that free radicals are present in wood subjected to grinding, ground wood giving an ESR signal approximately ten times more intense compared with ground cellulose. On this basis, the authors concluded that the presence of free radicals is due to the presence of lignin which has a more rigid structure than cellulose. It was suggested that during grinding both carbon–carbon and carbon–oxygen ester bonds are broken. Steelink et al.[53] showed that lignins isolated by treating plant tissues with acids, alkalies, and enzymes or as a result of mechanochemical degradation of plant materials give rise to fairly considerable ESR signals.

According to the view of Chudakov et al.[54], these data indicate that free radicals are formed in lignin as a result of the dissociation of the lignin–carbohydrate bonds. Chemical, enzymatic, or mechanochemical treatments of plant tissues can give rise to the formation in lignin of free radicals such as the aroxy-radicals, owing to the dissociation of β-phenyl glycoside bonds, which the authors believe to be the most probable type of bond between lignin and carbohydrates. Another possible explanation[53] is that, as a result of the above treatments, lignin is demethylated and the preparations obtained contain *ortho*-quinonoid and quinomethane structures, which may serve as sources of free radicals.

Hachihama and Takamuku[55] investigated the effects of γ-radiation on wood and lignin and established that irradiation of the powdered wood of the red pine with γ-rays (4×10^6–10^8 r.e.p.) appreciably reduces its content of holocellulose and α-cellulose but has only an insignificant effect on the lignin content. Sulphite pulping of wood subjected to the action of γ-radiation increases the yield of lignosulphonic acid by a factor of three compared with the control specimen (the digestion was carried out under the conditions adopted by the authors). At the same time lignin from irradiated wood has properties analogous to those of lignin from ordinary wood. Irradiation of wood results also in an increased yield of "Braun's lignin", which can be extracted with 95% ethanol, and also an increase in the yield of lignin–carbohydrate complexes[56]. The latter were extracted with dimethylformamide from irradiated wood after the removal of the Braun's lignin. The extraction was carried out over a period of 12 days at room temperature. The yield of lignin–carbohydrate complexes increased from 0.3% (relative to the initial wood) for the non-irradiated specimen to 1.7% (after irradiation with 8×10^7 r.e.p.) and 6.9% (after irradiation with 1.1×10^8 r.e.p.). It was established that the content of carbohydrates in the lignin–carbohydrate complexes varies appreciably in different fractions, while their composition is almost identical and corresponds to that of the wood hemicellulose. The results were interpreted by the authors on the basis that γ-radiation causes partial dissociation of the lignin–carbohydrate bonds.

Information about lignin–carbohydrate bonds was also obtained in a spectroscopic study of wood and its components. Bolker[57,58], who investigated the infrared spectra of different types of wood, wood celluloses containing different amounts of residual lignin, and also isolated lignin, established that all the isolated lignins give rise to an absorption band at 1710 cm^{-1} (±15 cm^{-1}) with a variable intensity, which depends on the method of their isolation, but the band is absent from all the spectra of various types of wood and celluloses. The value of Bolker's work consists primarily in the fact that, by applying differential spectroscopy (an equivalent amount of holocellulose isolated by a standard method was used as a reference), it proved possible to obtain the infrared spectra of lignin contained in wood without modifying it by a chemical reagent. The above band was assigned by Bolker to a non-conjugated β-keto-group formed in the course of the isolation of lignin as a result of the dissociation of lignin–carbohydrate bonds. Bolker's experimental data were confirmed by subsequent studies of Higgins and coworkers[59,60]. Pilipchuk et al.[61] studied the infrared spectra of fir wood, acetylated MGL, holocellulose, MGL, and a mixture of MGL and holocellulose (in proportions of 3 : 7) in the range 1735–1750 cm^{-1} and from the results obtained concluded that there is a chemical bond between lignin and the carbohydrate components of plant tissue.

---

†The degree of polymerisation of wood cellulose is 2500–3000 (by ultracentrifugation).

3. HYDROGEN BONDS AND THE POSSIBILITY OF THE FORMATION OF THREE-DIMENSIONAL NETWORK STRUCTURES

Apart from the chemical bonds between lignin and carbohydrates (the presence of which is regarded as established, as shown in the preceding section), both Björkman[34] and Brownell[48] pointed out the considerable role of hydrogen bonds in the formation of a single complex of plant tissue components.

Lignin is known to contain a large amount of phenolic and alcoholic hydroxy-groups, ester and carbonyl groups, and also a certain amount of carboxy-groups, which may be involved in the formation of intramolecular hydrogen bonds and also hydrogen bonds between lignin and carbohydrates. In a special study of the intramolecular hydrogen bonds in the lignin macromolecule, Lindberg[62,63] noted their influence on important properties of lignin such as solubility and capacity for precipitation. Lindberg established the presence of lignin of hydrogen bonds with an average energy of 2–3 kcal mole^{-1}. In order to penetrate the lignin macromolecule and dissolve it, the solvent must overcome this barrier, i.e. must be capable of forming hydrogen bonds with the corresponding lignin group and the energy of these bonds must be equal to or greater than 2–3 kcal mole^{-1}. These data were confirmed by the infrared spectra of lignins and model lignin compounds in the region 3600–3000 cm^{-1}, i.e. in the region of absorption by hydroxy-groups, and also by thermodynamic studies on monomeric models.

As regards the hydrogen bonds between lignin and carbohydrates in plant tissues, to which Björkman attributed a great importance, Lindberg concluded that in the complex of bonds between the plant tissue components they play only a secondary role. Indeed, despite the great likelihood of the formation of hydrogen bonds between lignin and carbohydrates in wood, in consequence of the amorphous nature of lignin it is difficult to imagine that these bonds are oriented along the molecules, as happens in cellulose chains, and the effect of irregularly distributed hydrogen bonds is known to be small.

The fact that wood is only very slightly susceptible to the action of enzymes, while the carbohydrate components and lignin are separately readily broken down by microorganisms has been regarded by many investigators[27-31, 64,65] as proof of the presence of a bond between lignin and carbohydrates in plant tissues. The data on the microbiological degradation of wood were interpreted somewhat differently by Pew[66,67]. While noting the undoubted presence of hydrogen and chemical bonds between the plant cell components, Pew emphasised that the immobilisation of the carbohydrate chains by the three-dimensional network structure of lignin, in a manner resembling the "serpent in a cage" system, has a considerable influence on the properties of lignified material and contributes to the formation of a single complex of the components of the plant cell wall. In a study of wood ground in a vibromill and its digestion by cellolytic enzymes, Pew showed that, while ordinary wood is resistant to the action of enzymes, after grinding for 10 min in a vibromill it is possible to remove about two-thirds of the wood carbohydrates and more prolonged preliminary grinding leads to complete digestion of the wood carbohydrate by cellolytic enzymes, leaving lignin as the residue. It is remarkable that the treatment of fir powder with a 1% hydrochloric acid, which should hydrolyse the chemical bonds between lignin and carbohydrates, did not increase its susceptibility to the action of enzymes, while reagents causing the swelling of wood had a very pronounced effect. A similar behaviour in relation to fine grinding and enzymatic digestion was shown by fir holocellulose, which had been impregnated with a water-soluble phenolic resin and then hardened at 110°C. On the basis of the results, Pew concluded that lignification is the factor which prevents the action of cellolytic enzymes on wood carbohydrates. The three-dimensional network structure of lignin, which immobilises the carbohydrate chains, prevents the access of large enzyme molecules to the system. Delignification completely eliminates this barrier, while grinding of wood or its swelling facilitates the contact between enzymes and wood carbohydrates.
