In the summing up remarks at the end of his review, Merewether[9] concluded that the problem of the existence of a chemical bond between lignin and carbohydrates in lignified cellulose materials still remains open. Many facts can be explained on the basis of the incrustation theory, while others may be accounted for only by postulating the presence of chemically bound lignin–carbohydrate complexes. The data obtained during the last decade and discussed above lead to the conclusion that the existence of the chemical bond between at least part of the lignin and the carbohydrate components of plant tissues (mainly hemicelluloses) is established. Hydrogen bonds play a decisive role. Finally, account must be taken of the presence of the three-dimensional network structure of lignin which immobilises the carbohydrate chains.

4. POSSIBLE TYPES OF CHEMICAL LIGNIN–CARBOHYDRATE BONDS

Despite the fact that the majority of studies published in the last ten years hardly cast any doubt on the existence of a chemical bond between carbohydrates and lignin in wood, the problem of the types of the lignin–carbohydrate bond and also the problem whether or not all the lignin macromolecules are chemically bound to carbohydrates remain open.

It is known that after the removal of extractable substances from wood, which are evidently not bound to lignin since they are removed by simple physical methods without the removal of appreciable amounts of lignin, three carbohydrate components remain: cellulose, hemicelluloses, and polyuronides. The reactive groups in the carbohydrate components of plant tissue, which may participate in the formation of lignin–carbohydrate bonds, include primary and secondary hydroxy-groups, carbonyl groups, and finally the carboxy-groups in polyuronic acids. At the same time the reactive groups of lignin include phenolic and alcoholic hydroxyls of various types and also carbonyl groups capable of enolisation. The types of chemical lignin–carbohydrate bonds examined above may in fact arise between these reactive groups of lignin and the carbohydrate components of plant tissue.

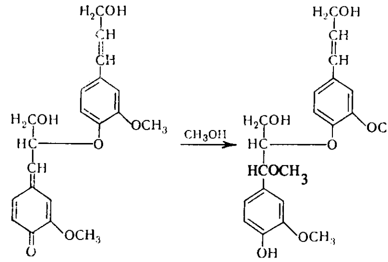
a. Ester and Ether Bonds

The presence of ester and ether bonds between lignin and carbohydrates, postulated at an early stage of Erdmann[7,8], is indicated by the results of a number of investigators. Thus Hoppe–Seyler[68] and Lange[69] concluded on the basis of the results of alkaline digestions of wood that there is an ester bond between the two components. Similar views on the nature of the lignin–carbohydrate bond were maintained by Czapek[70] and Grafe[71].

Klason[72,73] suggested that β-lignin contains a carboxy-group, which is not free in wood and should be bound to cellulose. In a study of the extraction of corn cobs under different conditions, Phillips[74] concluded that lignin is bound to carbohydrates in at least two ways: part of it is weakly bound, probably as ester groups of uronic acids, and the residue is combined via bonds of the ether type. Using the Cross and Beavan method for the determination of cellulose, Hawley and Norman[75] isolated two groups of hemicelluloses, one of which did not contain uronic acid and remained with the cellulose residue, and the other, usually containing uronic acid, was eliminated under the conditions of this determination. The authors believe that lignin is in fact bound to the latter group of hemicelluloses. The concept of an ether or ester bond between lignin and polysaccharides was supported by Lieser and Schwind[76] by experiments on the acetolysis of fir wood. Sarkar and coworkers[77,78] observed that, when jute is treated with 0.25% alkali, the acid number doubles. The authors believe that the additional free acid is formed in the hydrolysis of the ester bonds between lignin and polyuronides. Later Bhattacharjee and Callow[79] also observed an increase in the amount of free carboxyls in jute subjected to both acid (dilute hydrochloric acid) and alkaline (0.25% sodium hydroxide) treatment. Moreover, Sarkar[77] noted for jute and Tachi and Yamamori[80] for beech and elm wood a higher content of carboxy-groups in holocellulose, compared with the initial jute or wood. This observation was also accounted for on the basis of the hypothesis of the presence of an ester lignin–polyuronide bond. Foster et al.[81] believe that the ester bond between the carboxyl of uronic acid and the hydroxyl of lignin constitutes a likely explanation of the different rates of liberation of uronic acid from eucalyptus wood and from the holocellulose of this wood under identical conditions (1 *N* H_2SO_4; 91–92°C; 3 h).

In order to remove hemicelluloses, Harris[82] treated extracted wood powder with cold 17.5% sodium hydroxide and then extracted it four times with boiling methanol. Harris believed that the isolation of the methanol-soluble lignin (24% for fir wood and 70% for maple wood and aspen wood, in relation to Klason's lignin) constitutes proof of the cleavage of ester bonds between lignin and polyuronides. Stewart and coworkers[83,84] carried out a series of methanol extractions of eucalyptus wood at 150°C. The glucuronides found in the methanol extracts of holocellulose or wood pre-treated with alkali were absent from the extracts of the initial wood. The authors suggested that they are formed as a result of the hydrolysis of a lignin–polyuronide complex. Experiments on the pulping of aspen wood with a neutral butanol–water mixture at 158°C led Aaltio[85] to the conclusion that ester bonds are present between the acidic xylan chains and lignin. In a study of the infrared spectra of fir wood, acetylated MGL, holocellulose, MGL, and a mixture of MGL and holocellulose (in proportions of 3 : 7), Pilipchuk et al.[61] established that in the region 1735–1750 cm^{-1} in the infrared spectra of MGL, holocellulose, and their mixture, there are virtually no absorption bands or they are very weak. At the same time the infrared spectra of wood and acetylated MGL show very intense absorption bands in this region. Since it had been shown earlier[86] that the band in the region 1735–1750 cm^{-1} is due to the presence of ester groups, the authors concluded that an ester bond exists between lignin and other components of plant tissue (the amount of acetyl groups in fir wood is very insignificant and therefore their presence alone cannot account for the intense absorption in the above region, which is observed in the spectrum of the wood), without excluding the possibility of the existence also of other types of lignin–carbohydrate bonds.

The possibility of ether bonds of the benzyl ether type between lignin and carbohydrates in plant tissue was postulated by Freudenberg[87,88] on the basis of the preparation and investigation of a synthetic dehydropolymer[89–92]. Enzymatic dehydrogenation of coniferyl alcohol in aqueous methanol solutions results in the formation, together with other dimers and oligomers, of an α-*O*-methyl derivative of guaiacylglyceryl β-coniferyl ether (II, R=CH_3). The formation of this ether takes place via an intermediate quinomethane (I):



(I) (II)

If instead of methanol one uses a fairly concentrated solution of sorbitol or cane sugar, the corresponding α-*O*-derivative of guaiacylglyceryl β-coniferyl ether (II, R=$C_6H_{13}O_5$ or R = $C_{12}H_{21}O_{10}$) is formed. Calculations based on the content of methoxy-groups (10.21%) show that apparently two moles of quinomethane are combined with 1 mole of cane sugar. The sugar ether is readily hydrolysed by inorganic acids to (II, R = H), glucose, and fructose.

In a study of the effect of γ-radiation on wood, Hachihama and Takamuku[55] established that the amount of guaiacylmethanol groups increases in irradiated wood. Since the authors believe that γ-radiation leads to the cleavage of lignin–carbohydrate bonds, one may suppose that these bonds are of the benzyl ether type. In his review, Harkin[93] emphasises the central role of quinomethanes in the formation of the polymeric lignin molecule and of the bond between lignin and carbohydrates.

b. Phenyl Glycosidic Bonds

Hibbert and coworkers[94,95] synthesised a number of compounds simulating glycosides with aliphatic and phenolic aglycones: β-D-xyloside of α-hydroxypropiovanillone, β-o-xyloside of α-hydroxypropiosyringone, β-D-glucoside of α-hydroxypropioveratrone, β-D-xyloside of acetovanillone, β-D-glucoside of acetovanillone, β-D-cellobioside of acetovanillone, phenyl β-D-xyloside, phenyl β-D-glucoside, and guaiacyl β-D-xyloside. The rates of hydrolysis of these compounds and the conditions employed for the isolation of lignin from wood showed that the most likely type of bond between lignin and polysaccharides in plant tissues is the phenyl β-glycosidic bond.

By treating wood with acetic acid containing $MgCl_2$ as a catalyst, Freudenberg and Plankenhorn[96] isolated lignin acetate, which contained 11% of hexosan and after hydrolysis with alkali in an atmosphere of nitrogen yielded a product with a higher content of phenolic hydroxyls. Similar results were obtained by Pauly and coworkers[97,98], who treated wood powder in succession with methanol, 1.5% alkali at room temperature, and 85% acetic acid containing catalytic amounts of sulphuric acid and on the basis of the analysis of the preparations concluded that a phenyl glycoside bond is present between lignin and polysaccharides. Kawamura and Higuchi[99] demonstrated the presence of a lignin–xylose complex in dioxan-lignin isolated from beech wood. The dioxan-lignin obtained was separated by paper chromatography from sugars, exhaustively methylated, and hydrolysed with 5% hydrochloric acid. 2,3,4-Trimethylxylose, and not dimethylxylose, was isolated from the hydrolysis products by paper chromatography, which the authors believe to confirm the presence of glycoside bonds in lignin–carbohydrate complexes.

The work of Odintsov and Shishkova[100] on the cleavage of wood by enzymes, thermophilic cellulose bacteria, soil bacteria, and emulsion showed that the lignin–carbohydrate complex is cleaved, this being accompanied by the formation of new free phenolic hydroxyls. Häggroth and Lindberg[101] made a study whose aim was to explain the differences between sulphite and sulphate celluloses. According to McKinney's hypothesis[102], in sulphate pulping the residual hemicelluloses initially bound to lignin via phenyl glycoside bonds migrate to the cellulose chains of sulphate cellulose. In particular, the enhanced content of pentosans in sulphate cellulose is associated with this fact. Using phenyl β-D-xylopyranoside (III) as a model of the lignin–hemicellulose complex, Häggroth and Lindberg investigated its interaction with various alcohols and polysaccharides (methanol, glycerol, amylose, cotton cellulose). When compound (III) was treated with sodium methoxide in absolute methanol in nitrogen, a good yield of methyl β-D-xylopyranoside was obtained, while the interaction of (III) with sodium monoglyceride in anhydrous glycerol gave a mixture of glyceryl D-xylopyranosides. In the alkaline hydrolysis of compound (III) in the presence of both amylose and cotton cellulose, polysaccharides containing bound xylose were obtained. Thus, after the above treatment, cotton cellulose contained 2.4% of xylose. Hence the treatment of phenyl xylopyranoside in the presence of cellulose involves the cleavage of the phenyl glycosidic bond and xylose migrates to cellulose via transglycosidation, which confirms the McKinney hypothesis.

In the course of studies of lignin–carbohydrate complexes (xylolignin, acetylated xylolignin, complexes extracted with dioxan, 50% acetic acid, and dimethylformamide) isolated from wheat straw, Hayashi and Tachi[103,104] confirmed experimentally the presence of phenyl glycosidic bonds. In the alkaline hydrolysis of the complexes isolated an increase in the content of free phenolic hydroxyls was noted, as determined from the bathochromic shift in the ultraviolet spectrum (in the analogous treatment of lignin the amount of phenolic hydroxyls remains unchanged). Treatment of lignin–carbohydrate complexes with β-glucosidase increased the content of both phenolic hydroxyls of lignin and the reducing groups of sugar. Finally, in the alkaline pulping of lignin–carbohydrate complexes in the presence of cellulose, the migration of the carbohydrates of the complex to cellulose as a result of transglycosidation was observed (in the analogous treatment of a mixture of cellulose and freshly prepared holocellulose, transglycosidation was not observed).

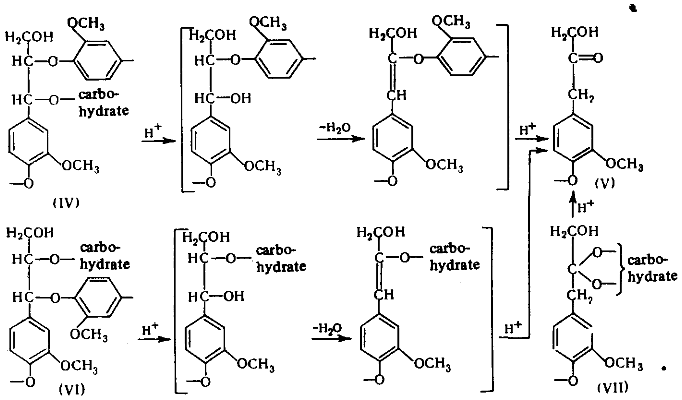
Kiryushina and Tishchenko[23] fractionated the lignins obtained as a result of brief sodium hydroxide digestion of maple wood with respect to their solubility in acetone. Analysis of the acetone-insoluble fraction showed[24] that it consists of lignin and carbohydrates (mainly pentosans) and behaves similarly as the chemically bound complex. Repeated soda pulping, acid hydrolysis, ozonolysis, and infrared spectroscopy confirmed experimentally[25] the hypothesis of the existence of a phenyl glycoside bond between lignin and carbohydrates in the acetone-insoluble fractions of the soda lignin. Moreover, the presence of a glycosidic bond, formed with a phenolic or aliphatic hydroxyl of lignin and the glycoside hydroxyl of the polysaccharides, has been indicated in the reviews of Richtzenhain[105] and Lindgren[106], who believed that this is one of the most probable types of the lignin–carbohydrate bond.

c. Acetal Bonds

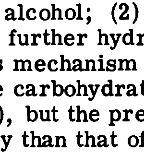
The hypothesis of the presence of an acetal (ketal) or hemiacetal (hemiketal) bond between lignin and hydrocarbons, formed by the carbonyl groups of the side chains of the phenylpropane structural elements of lignins and the hydroxy-groups of the polysaccharide chains, was put forward for the first time by Holmberg and Runius[107] on the basis of a study of the alcoholysis of wood. It is known that, when wood is treated with alcohol in the presence of an acid catalyst, the alcohol reacts with lignin to form an alcohol-soluble alcohol lignin. The authors suggested that the reaction consists in transacetalation: in wood lignin is linked to hydrocarbons, forming an acetal, while during alcoholysis the alcohol employed replaces the carbohydrate. To confirm this hypothesis, Maeda and Kobayashi[108] carried out experiments, which showed that before isolation from wood lignin does not contain free carbonyl or acid hydroxy-groups. To test these results, Nokihara et al.[109] subjected wood, holocellulose, and viscose cellulose to ethanolysis in the presence of hydroxylamine. The differences in the rates of reaction of these preparations suggested that the formation in wood of a lignin oxime is preceded by the hydrolysis of other compounds, tentatively identified as a lignin–carbohydrate complex, which incorporates an acetal bond. Berlin[110] carried out a series of experiments on the oxidation of wood with hydrogen peroxide and on the basis of the results concluded that the low-molecular component of natural lignin, localised in the secondary cell wall, is linked to carbohydrates via an acetal or hemiacetal bond, which is readily cleaved by hot water or dilute acids. The hypothesis of the presence of an acetal bond between the components of plant tissues was also supported by Shorygina[111] on the basis of the results obtained in the decomposition of lignin and wood by metallic sodium and liquid ammonia.

Recently this hypothesis received major support in a number of studies published by Bolker. As stated above, Bolker[57,58] observed that in the infrared spectra of isolated lignins there is an absorption band at 1710 cm^{-1}, which is absent from the spectra of different types of wood and wood celluloses containing residual lignin. This absorption band was assigned to a non-conjugated β-keto-group fromed in the isolation of lignin. Since β-keto-groups appear only in the course of the isolation of lignin, Bolker postulated that in wood and wood celluloses these groups are present as derivatives which do not absorb in the above region, i.e. in the form of acetal or enolic ether groups. Naturally, the spectra obtained do not show whether these groups are involved in intramolecular bonds of lignin (between phenylpropane units) or whether they are incorporated in the link between lignin and carbohydrates. However, the existence of a relation between the isolation of lignin and the accumulation in the latter of keto-groups and the finding that β-keto-groups are never observed in wood and wood celluloses is evidence, according to Bolker, in favour of the second possibility.

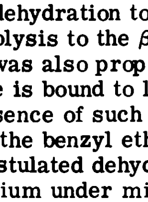
Bolker[112,113] proposed mechanisms for the decomposition of both the acetal (VII) and benzyl ether (IV) bonds between lignin and carbohydrate, resulting in the formation of β-keto-groups (V):



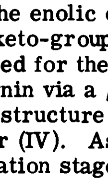
The mechanism of the decomposition of benzyl ether bonds (IV) postulated by Freudenberg[87,88] may, according to Bolker, consist of the following stages: (1) hydrolysis to benzyl alcohol; (2) dehydration to the enolic ether form; (3) further hydrolysis to the β-keto-group (V). An analogous mechanism was also proposed for the case where the carbohydrate is bound to lignin via a β-carbon atom (VI), but the presence of such a structure is much less likely than that of the benzyl ether (IV). As noted by Bolker himself, the postulated dehydration stage, occurring in an aqueous medium under mild conditions, is most vulnerable to criticism. In addition, Bolker put forward also a number of other, albeit indirect proofs, for the presence of an acetal bond between lignin and carbohydrates (the absence of the β-keto-group from lignins isolated by ethanolysis and their appearance after the acid hydrolysis of ethanol lignin[112]; the study of the rate of extraction of lignin from wood by non-aqueous acid mixtures of 2,2-dialkoxypropane and dioxane[113], etc.). In his subsequent communication Bolker[114] presents data on the interaction between two solvent systems: dioxane–2,2-dimethoxypropane–HCl and dioxan–methanol–HCl with the simplest models of the possible lignin–carbohydrate bonds: phenyl β-D-glucoside (VIII; glycoside bond), 1-ethoxy-2-(2″-methoxyphenoxy)-1-(3′,4″-dimethoxyphenyl)ethane (IX; benzyl ether bond), and 2-benzyl-2-methyl-1,3-dioxolane (X; ketal bond):



(VIII)



(IX)



(X) .

As was to be expected, the studies of the kinetics of these reactions did not yield any definite conclusions, although Bolker reports that work with more complex compounds simulating various types of lignin–carbohydrate bonds is being continued.

Bolker's data are of undoubted interest, although their interpretation gives rise to objections. In the first place the assignment of the band at 1710 cm⁻¹ to the β-keto-group is controversial[115–118]. In the second place, according to the data of Adler and coworkers[119–121], β-keto-groups may be formed as a result of the acidolysis of arylglyceryl β-aryl ethers, which may take place in the acid medium most often employed for the isolation of lignin.

---o0o---

Apart from the types of lignin–carbohydrate bonds discussed above, Chudakov[122] postulates the presence of carbon–carbon bonds between lignin and carbohydrates, assuming that the work of Kratzl and coworkers[123], who showed that, on treating lignin with methanol (at 150°C, without the addition of inorganic catalysts), part of the alcohol alkylates the benzyl alcohol groups of lignin and part forms stable C–C bonds, constitutes indirect proof of this possibility.

It should be noted that the hypothesis of each of the lignin–carbohydrate bond types discussed above gives rise to some criticism based on the study of the stability of lignin–carbohydrate complexes under the conditions of different types of physical and chemical treatment[47,48,103,124]. Therefore, despite the relatively large number of studies concerning the problem of the lignin–carbohydrate bond type, the latter still remains open.

5. LIGNIN–CARBOHYDRATE BONDS AND THE PROBLEM OF THE HOMOGENEITY OF LIGNIN

It can now be regarded as firmly established that lignin is non-uniformly distributed in plant tissue. One of the first attempts to investigate the quantitative distribution of lignin in plant tissue was undertaken by Ritter[125,126], who treated 3 mm wood sections and then separated the lignin residue, which was determined by Klason's standard method. It was found that a large proportion of the lignin (about 75% of the total amount) is concentrated in the middle lamella, while the fraction in the secondary cell wall is much smaller and it should be noted that lignins localised in these two sites in plant tissue differ considerably in their content of methoxy-groups.

Bailey[127] separated by means of a micromanipulator 0.5 mg of the substance in the middle lamella from the wood of the Douglas fir and established that the preparation isolated contained 71% of lignin, 14% of pentosans, and 4% of cellulose. On the basis of data obtained in an ultraviolet microscope study, Lange[128] calculated the weight concentrations of lignin in the secondary cell walls and in the material of the middle lamella, which amounted to 16 and 73% respectively.

The problem of the distribution of lignin in the cell wall of plant tissue has been examined critically by Berlyn and Mark[129], who emphasised that the results of Bailey and Lange are diametrically opposed to those of Ritter. Noting that the volume of the material in the middle lamella in the wood of conifers amounts to only 10 to 12% of the volume of the woody tissue, Berlyn and Mark showed that, even if the middle lamella consisted entirely of lignin, it could not contain more than 40% of the total lignin in wood. This hypothesis was confirmed experimentally in a study by Goring and coworkers[130]. The method employed by the authors consisted of a combination of ultraviolet microscopy and densitometric analysis of the negatives of the ultraviolet photomicrographs obtained. Some of the results of these investigators are compiled in Table 2, which shows that the material of the middle lamella is more lignified compared with the secondary cell wall but nevertheless contains only a small proportion of the total lignin of wood.

Table 2. Distribution of lignin in tracheides of the fir (according to the data of Fergus et al.[130]).

Wood	Morphological differentiation	Relative u.v. absorption	Vol. of fraction, %	Lignin, % of total amount	Lignin concn., $g\,g^{-1}$
Early	SW	1	87.4	72.1	0.225
	ML (r) (t)	2.21	8.7	15.8	0.497
	ML (cc)	3.77	3.9	12.1	0.848
Late	SW	1	93.7	81.7	0.222
	ML (r) (t)	2.7	4.1	9.7	0.60
	ML (cc)	4.5	2.2	8.6	1.00

SW = secondary wall; ML = middle lamella; r = radial direction; t = tangential direction; cc = cell corners.

Interesting data on the distribution of hemicelluloses in plant tissue were obtained by Asunmaa and Lange[131]. They used a microspectrographic method and investigated the distribution of carboxy-groups in holocellulose isolated from fir wood and birch wood. It was established that the outer portions of the delignified fibres contained the greatest amount of carboxy-groups, while in the vicinity of the lumen (the cellular cavity of the fibre) their content is a minimum. It is well known that polyuronides containing carboxy-groups enter into the composition of hemicelluloses. On this basis, the authors concluded that in plant tissues the relative content of hemicelluloses diminishes almost linearly from the outer layers towards the lumen. Bearing in mind the analogous variation of the concentration of lignin, the results were interpreted in support of the presence of lignin–hemicellulose bonds. Asunmaa and Lange[132] investigated spectroscopically delignified fir and birch fibres esterified with *p*-phenylazobenzoyl chloride. It was shown that holocellulose is distributed approximately uniformly in the cell wall. However, while cellulose is most closely packed around the lumens, hemicelluloses are concentrated in the outer layers of the fibres (hemicelluloses constitute approximately 50% of the entire carbohydrate material in the outer layers of the fibre and only 10–20% around the lumen).

Thus the studies on the morphology of the cell wall demonstrated unambiguously a non-uniform distribution of lignin in plant tissues, which suggests that the composition and structure of the lignin–carbohydrate complexes localised in the middle lamella and in the secondary cell wall are different. This hypothesis was confirmed by the results of Aaltio[85,133], who carried out a series of nine butanol digestions of aspen wood. After preliminary extraction with acetone, the fine sawdust was pulped with a neutral buffered mixture of butanol and water for 4 h at 158°C and each digestive was carried out on the residue from the preceding one. The solubility of wood was followed by analysing the insoluble residue and the pulping solutions. Some of the results of this study are presented in Table 3.

These investigations showed that aspen wood consists partially of homogeneous lignin–uronide complexes. The first of these dissolves digestions readily, passing into solution in the course of the initial five digestions and is localised in the middle lamella. The ratio of lignin to pentosan uronides in this complex is about 0.75. The second complex dissolving in succeeding digestions is localised in the cell wall and is characterised by a lignin::pentosan uronide ratio of about 0.55. Cellulose is apparently closely associated with this complex. The carbohydrate component of the above complexes includes a homogeneous pentosan uronide in which the weight ratio of pentosans and uronic acids is approximately 7:1. Qualitative analysis of the sugar in the acid hydrolysates of the aqueous phases of various digested solutions showed that they contain D-xylose, 4-*O*-methylglucuronosidoxylose, aldobiuronic acid, D-galactose, D-galacturonic acid, L-arabinose, and traces of D-mannose, and L-rhamnose.

Table 3. Some results of a study on consecutive pulping of aspen wood by buffered aqueous butanol (according to the data of Aaltio[85]).

No. of digestions	Ratio of dissolved lignin to dissolved pentosan uronides	Content of CH_3O groups in dissolved lignin, %	
		found	calculated
1	1.05	21.4	21.7
2	0.75	—	21.3
3	0.77	20.1	20.2
4	0.73	—	21.4
5	0.74	17.9	17.9
6	0.59	—	15.3
7	0.55	15.0	15.0
8	0.54	—	15.0
9	0.55	14.9	12.0

The lignin fractions in both complexes are structurally different. While lignin in the readily soluble complex contains approximately 20–21% of CH_3O groups, the lignin in the more stable complex has a much lower methoxy-group content (about 15%). According to Aaltio's data, this difference is due to the different distribution of vanillin and syringin structures in the molecules of these lignin fractions. Aaltio interpreted his results on the basis that in the course of the first five digestions the pulping solution gradually acts upon the middle lamella, which leads to the isolation of the highly methoxylated lignin and pentosan uronides in proportions of 0.75 : 1. After the dissolution of the entire middle lamella, the material is freed from fibrous tissue and the secondary cell wall is acted upon in subsequent digestions. This leads to the isolation of lignin with a low methoxy-group content and pentosan uronides, again in constant proportions (0.55 : 1), which are however different from those found in the dissolution of the middle lamella.

It is noteworthy that, according to Aaltio, the greater part of lignin in the complex isolated from the middle lamella is in a free state and is not linked chemically to the carbohydrate components. This is consistent with the findings of Bailey[134], who concluded, on the basis of a study of the digestion of wood with a neutral aqueous butanol at 158°C, that in aspen wood the entire lignin is present in a free state, while in pine wood about 20% of the lignin is bound chemically to carbohydrates.

According to Björkman's hypotheses[36], lignin present in plant tissue may be divided into two fractions as regards its bonds with hemicelluloses. One fraction forms a very insignificant number of bonds with hemicelluloses or not at all and is probably localised in the middle lamella, where the concentration of lignin is a maximum. This fraction is isolated under mild conditions and corresponds to MGL obtained by Björkman's method. The second fraction is firmly bound to hemicelluloses, and may be isolated by more severe methods. This fraction corresponds to the lignin–carbohydrate complexes obtained by Björkman's method. The proportions of the fractions are approximately 1 : 1.

Brownell and West[46] also concluded, as a result of the experiments, discussed above, on the fractionation of hydroxyethylated wood dissolved in dimethylformamide and subjected to preliminary grinding in a ball mill, that in wood approximately three-quarters of the total amount of lignin is bound chemically to carbohydrates. About one-quarter of the lignin can be readily separated from carbohydrates. The authors suggest that this part of the lignin is not bound chemically to carbohydrates, although it is quite possible to postulate that the bonds are broken during the treatment of the wood in the ball mill.

As a result of his studies on the oxidation of wood with hydrogen peroxides, Berlin[110] concluded that the lignin in the intercellular material (i.e. localised in the middle lamella) has a higher molecular weight and is not bound to polysaccharides. Tishchenko[17] noted, on the basis of the results of a stepwise ozonolysis of fir wood in ethyl acetate, that the wood contains both free lignin (not less than 43% of the total lignin) and lignin bound chemically to carbohydrates.

All these data confirm partly the hypothesis of Purves[135] who suggested, as early as 1943, that the molecular weight and the relative amounts of "free" and "bound" lignin in plants can vary not only as a function of the plant species but also as a function of its age and conditions, and the even earlier hypothesis of Klason[72] of the presence in wood of two types of lignin: α- and β-lignins.

The data concerning the existence of various lignin–carbohydrate complexes localised in the middle lamella and in the secondary cell wall can explain to some extent why by pulping wood it is impossible to achieve complete delignification of cellulose and additional treatment, in particular bleaching, is necessary.

To some extent, the inhomogeneity of the lignin contained in plant tissue is confirmed by the determination of the molecular weights of preparations obtained by the fractional isolation of lignin using different methods: by sulphite pulping[136-138], by extraction with a dioxane–hydrochloric acid mixture[139], by sulphate pulping[140], and by nitrating with nitric acid in ethanol[141]. These data led to the hypothesis of the presence in plant tissue of two types of lignin: with low and high molecular weights, localised in different sites of the plant cell walls.

Summarising the foregoing, we may note that the "biological and structural role of lignin, the conditions of its formation, and the nature of its interaction with other components of the cell wall in the primary layer and in general in the middle lamella can, of course, differ from the role of lignin and the nature of its bond with other substances in the secondary cell wall. Therefore one must recognise that the attempts to establish a single relation governing the nature of the bond between cellulose and other polysaccharides on the one hand and lignin on the other in all parts of the cell wall without taking into account the characteristics of its structure and the mutual bonds between the components in its various parts are not justified".[142] In addition, one should bear in mind the irregularity of the lignin structure, which follows from its role in the plant and also from the characteristics of its biosynthesis. According to Freudenberg's data[89-92], only dehydrogenases which remove hydrogen from the phenolic hydroxyl of the monomer participate in the *in vitro* biosynthesis of lignin from coniferyl alcohol. The subsequent stages take place, without the participation of the enzyme, in accordance with stochastic laws, which give rise to a wide variety of intramolecular bonds in lignin as well as bonds between lignin and carbohydrates. Thus it is quite reasonable to suppose that the contribution of chemical bonds to the formation of a single complex of components of the plant tissue is different in the middle lamella and in the secondary cell wall. In addition, as stated above, one cannot exclude from consideration the presence of hydrogen bonds between lignin and carbohydrates and also the possibility of the formation of three-dimensional network structures of lignin immobilising the carbohydrate chains.

The problem of the type of chemical bond between lignin and carbohydrates in plant tissues can be solved most probably only as a result of parallel experiments on lignin–carbohydrate complex preparations isolated from wood and compounds simulating the above possible types of chemical lignin–carbohydrate bonds. The behaviour of compounds of these types in different kinds of treatment under otherwise identical conditions will undoubtedly yield information which will permit a first approximation solution of this problem, which is one of the most interesting in the chemistry of wood.

Finally, returning to the problem of the homogeneity of lignin, it is noteworthy that, according to the valid comment by Freudenberg[143], when only part of the lignin in plant tissues is bound to carbohydrates both the incrustation theory and the theory postulating the presence of lignin–carbohydrate bonds are correct and not mutually exclusive as appeared previously.

Stepwise Enzymatic Synthesis of the Specific $C_{(3')}$ - $C_{(5')}$ Internucleotide Bond

S.M.Zhenodarova

The review deals with the methods of synthesis of low-molecular-weight oligoribonucleotides based on the use of various ribonucleases and polynucleotide phosphorylase, whereby oligonucleotides can be obtained rapidly and in fairly high yields by a gradual (stepwise) growth of the oligonucleotide chain. The possibilities of this comparatively new field in the synthesis of oligonucleotides and the prospects for its development are discussed.
The bibliography includes 72 references.

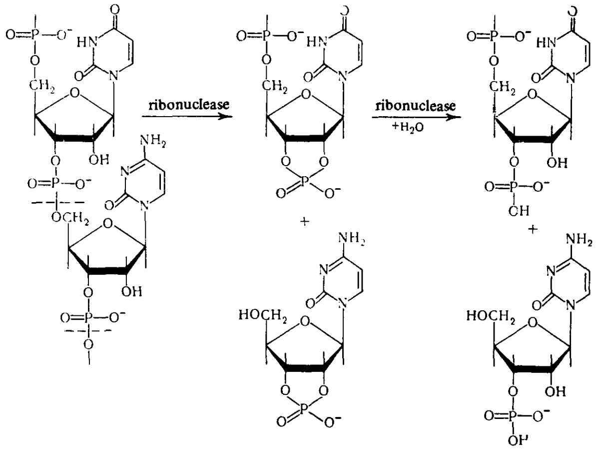
CONTENTS

I. INTRODUCTION

Since the publication of the review of methods for the stepwise synthesis of the specific $C_{(3')}-C_{(5')}$ internucleotide bond[1] several years have elapsed. In this period studies on further elaboration and improvement of these methods have developed widely and effectively (see, for example, Refs. 2–13) and very important results have been obtained. In particular 64 trinucleoside diphosphates containing the usual nucleotides in all possible combinations were synthesised[14], which permitted the final elucidation of the aminoacid code[2]. Studies on the synthesis of the gene coding for an alanine *t*RNA are also being successfully continued. However, it should be noted that the chemical methods for the synthesis of oligonucleotides consist of many stages and are fairly laborious. At the same time the need for oligonucleotides increases continuously in connection with the expansion of research in which they are employed: the study of the mechanism of protein synthesis, the study of substrate specificity and kinetics of enzymatic reactions catalysted by various nucleotidases, etc. Therfore the search for simpler and more effective methods of synthesis of oligonucleotides is continued and at present, together with chemical procedures, enzymatic methods are being increasingly employed. This review deals only with such enzymatic reactions, involving the *stepwise* synthesis of the $C_{(3')}-C_{(5')}$ internucleotide bond—(the synthesis of low-molecular oligonucleotides), while reactions leading to the synthesis of polynucleotides (synthesis with RNA and DNA polymerases[2], polymerisation using polynucleotide phosphorylase[15], etc.) are not considered.

II. SYNTHESIS OF OLIGORIBONUCLEOTIDES USING RIBONUCLEASES

It is well know that the cleavage of the phosphodiester bonds in ribonucleic acids or polynucleotides catalysed by ribonucleases takes place in two stages: (1) cleavage of the bond between the phosphorus atom and the 5'-O atom of ribose with subsequent transphosphorylation and the formation of 2',3'-cyclic phosphates; (2) hydrolysis of 2',3'-cyclic phosphates with formation of 3'-phosphates[16].



Usually ribonucleases catalyse the cleavage of the phosphodiester bond with a specific type of nucleoside whose 3'-oxygen atom is involved in this bond. Thus pyrimidylribonucleases cleave at the highest rate the bond in which a pyrimidinenucleoside donates the 3'-oxygen atom. For example, pancreatic ribonuclease is a pyrimidylnuclease. Similarly guanylribonucleases require that the 3'-oxygen atom be donated by guanosine. For example, the T1 ribonuclease from Takadiastase is of this type. However, non-specific ribonucleases also exist. As early as 1955 Heppel et al.[17] showed that the first stage of this reaction is reversible and under certain conditions pancreatic ribonuclease can catalyse the synthesis of compounds containing the phosphodiester bond. Somewhat later it was established that T1-ribonuclease also exhibits transesterifying activity and is capable of synthesising oligonucleotides[18]. Analogous properties were found also in guanylribonuclease isolated from *Actinomyces aureoverticilatus*[19].

At the present time studies on the application of pancreatic T1 ribonuclease in oligonucleotide synthesis are developing fairly rapidly[20–25]. However, it must be emphasised that the use of specific enzymes permits the synthesis of oligoribonucleotides in which the sequence of monomeric units is determined by the specificity of the enzyme. Recently it was shown that in the synthesis of oligonucleotides and in particular dinucleotides it is desirable to employ ribonucleases without definite specificity, since it is then possible to obtain dinucleotides with any sequence of bases[26,27].

In a discussion of methods for the synthesis of oligonucleotides using ribonucleases it is convenient to examine separately the synthesis of dinucleotides and trinucleotides, although both these reactions are of the same type and have much in common. Longer oligonucleotides have not so far been obtained by this method (see p. 700).

1. Synthesis of Dinucleotides (Dinucleoside Mono- and Di-phosphates)

Since ribonucleases of all the types known at present cleave the phosphodiester bond by the same mechanism, it follows that the synthesis of the phosphodiester bond using ribonucleases also involves substrates of the same type, namely nucleoside 2′,3′-cyclic phosphates. Nucleoside 2′,3′-cyclic phosphates are obtained as a rule from the corresponding nucleoside 2′,3′-phosphates with the aid of dicyclohexylcarbodi-imide or ethyl chloroformate[28]. In certain cases they are isolated from a ribonuclease hydrolysate[29].

The synthesis of dinucleotides in the presence of ribonuclease can be represented by the following mechanism:

$$N{>}p + N' \xrightarrow{\text{ribonuclease}} NpN',$$

where N>p[†] is the substrate(nucleoside 2′,3′-cyclic phosphate) and N′ is an acceptor, which consists of a nucleoside derivative with a free 5′-hydroxy-group (nucleoside, nucleotide, nucleoside 2′,3′-cyclic phosphate). The reaction is usually carried out by incubating with the enzyme a mixture of the substrate and the acceptor dissolved in a buffer solution. At the same time nucleoside 2′,3′-cyclic phosphate is hydrolysed to nucleoside 3′-phosphate.

Substrates. The substrates employed in this reaction were the 2′,3′-cyclic phosphates of uridine[20–23,26,27], cytidine[17,20–23,26,27], adenosine[26,27], guanosine[18,19,24–27], inosine, and xanthosine[25] and also 5′-*O*-substituted nucleoside 2′,3′-cyclic phosphates: 5′-*O*-phosphoryl- and 5′-*O*-methylphosphoryl-uridine 2′,3′-cyclic phosphates[31], 5′-*O*-(α-n-butoxyethyl)-substituted 2′,3′-cyclic phosphates of uridine, cytidine, adenosine, and guanosine[32,33], 5′-*O*-acetyl-, 5′-*O*-methylphosphoryl-, 5′-*O*-sulphonyl-, and 5′-*O*-pyrophosphoryl-guanosine 2′,3′-cyclic phosphates[34], and the methyl ester of 2′,3′-cyclophosphoguanylyl-(5–N)-phenylalanine[35]. Pancreatic ribonuclease is known to be capable of cleaving phosphodiester bonds the 3′-oxygen atom of which belongs to minor (4-thiouridine[36]) or non-natural (6-azauridine, 6-azacytidine[37], 5-halogenouridine[38], etc.) nucleosides and also nucleosides containing an anomalous carbohydrate residue[39]. Therefore it may be supposed that the corresponding nucleoside 2′,3′-cyclic phosphates may function as substrates in the synthesis of oligonucleotides. Indeed it has recently been shown that 5-bromouridine 2′,3′-cyclic phosphate gives rise to 5-bromouridilyl-3′–5′)-uridine after incubation with uridine in the presence of pancreatic ribonuclease[40]. Evidently the number of substrates will increase as the study of the specificity of already known ribonucleases is extended and also as new ribonucleases, differing in the type of their activity from those already known, are discovered.

Acceptors. The second component of this reaction, the phosphate acceptor, may be a nucleoside containing a free 5′-hydroxy-group, a nucletide, and in the case of specific ribonucleases also a nucleoside 2′,3′-cyclic phosphate. Since the specificity of ribonucleases is determined by the donor of the 3′-hydroxy-group, the possibility of the reaction occurring should be independent of the type of heterocyclic base in the acceptor. Thus in syntheses with participation of pancreatic ribonuclease, one may use as phosphate acceptors, together with natural nucleosides, also the aza-analogues of uridine[40], guanosine[41], and 5-chlorouridine[40] and, in the case of T1 ribonuclease, 5-bromouridine, 6-azauridine, $N_{(3)}$-methyluridine, and 5-methyluridine[40]. Heppel et al.[17] noted that in the case of pancreatic ribonuclease nucleotides are poor acceptors and nucleosides and cyclic phosphates are most effective. On the basis of these data and later studies[19], it is asserted that pancreatic ribonuclease uses nucleotides as acceptors to only a slight degree. However, this is erroneous, since Tikhomirova-Sidorova and coworkers[22,23] synthesised under analogous conditions UpUp (10–30%), UpCp (40%), CpCp (9%), and CpUp (29%). Heppel's conclusion that thymidine cannot serve as an acceptor in this reaction also proved to be incorrect: uridilyl-(3′–5′)-thymidine was obtained in about 12% yield from uridine 2′,3′-cyclic phosphate and thymidine[40].

Substrate concentration, ratio of substrate and acceptor concentrations, and effect of solvent. The substrate concentration and also the ratio of the substrate and acceptor concentrations in the reaction mixture are very important for the synthesis of dinucleotides in this reaction. In the studies of various investigators the substrate concentration varied from 0.02–0.08 to 1 M. In a study of the effect of substrate concentration on the synthesis of dinucleoside monophosphates in the presence of pancreatic ribonuclease A, Bernfield[20] established that the yield is proportional to substrate concentration below 0.3 M and is a maximum at a concentration of 0.4 M. It is quite likely that in the presence of other enzymes a different substrate concentration will be optimum, but such data are not at present available.

[†] To abbreviate the naming of the nucleosides, nucleotides, and oligonucleotides, the rules developed by the IUPAC Commission on Biochemical Nomenclature[30] and also the notation proposed by Holý and Smrt[9] have been employed: A = adenosine, C = cytidine, G = guanosine, U = uridine, X = xanthosine, I = inosine, N = nucleoside, and aza N = aza-analogue of nucleoside; p = phosphoric acid residue; when p (or the symbol for any other substituent) is written to the right of the nucleoside symbol, the phosphate group is in the 3′-position or ribose and when it is written to the left of the nucleoside symbol the phosphate group is in the 5′-position; p interposed between two nucleoside symbols denotes a 3′–5′ internucleotide bond; the symbol >p denotes a 2′,3′-cyclic phosphate; HSO_3 = sulphonate group; 5ClU = 5-chlorouridine; 5BrU = 5-bromouridine; T = thymidine; Me = methyl; Be = α-n-butoxyethyl; MeOPhe = methyl ester of phenylalanine.

The dependence of the yield of dinucleoside mono- or di-phosphates on the ratio of the substrate and acceptor concentrations has been investigated somewhat more thoroughly. It has been shown that a ratio close to 1/4 is optimum[25,27,33], but in some cases further increase of the excess of the acceptor increases the yield of dinucleotide. As an example, one may quote the syntheses of ApC and GpC catalysted by the non-specific ribonuclease from *Aspergillus clavatus*[27]. In the synthesis of ApC a large excess of the acceptor (tenfold and more) retards both the cleavage of the substrate and the formation of dinucleoside monophosphate, while in the second case an increase in acceptor concentration leads only to an increase of the yield of dinucleoside monophosphate (27% for a threefold excess and 46% for a tenfold excess). On the other hand, if the reaction mixture contains an excess of the substrate, then monotonic oligonucleotides of various lengths are obtained together with the dinucleotide[20,21].

It is noteworthy that in the case of sparingly soluble nucleosides or nucleotides (adenosine, guanosine, etc.) it is virtually impossible to obtain the required concentrations of the substrate and acceptor, which leads to low yields of dinucleosides. The present author believes that, in order to increase the concentration, it is necessary to employ acceptors in the form of their more soluble derivatives. Such derivatives must meet the following requirements: (1) high solubility in the appropriate buffer; (2) the substituent used to enhance the solubility must be easily introduced into the nucleoside (nucleotide) and easily eliminated; (3) the substituent must not affect the reaction. Preliminary studies showed that one may employ as compounds of this kind the *N*-dimethylaminomethylene derivatives, which are obtained in quantitative yield when the nucleoside (nucleotide) is treated with the dimethyl acetal of dimethylformamide[43,44], are readily soluble in various solvents, and easily lose the dimethylaminomethylene group under mild conditions, for example during chromatography in solvent systems containing ammonia. UpG,[32] ApG, GpG, and GpA [27] have been synthesised using as acceptors the *N*-dimethylaminomethylene derivatives of guanosine and adenosine.

Another method for increasing the acceptor concentration (and if necessary also the substrate concentration) consists in the replacement of aqueous buffers by buffer solutions containing organic solvents. Usually oligonucleotides are synthesised in the presence of ribonucleases in an aqueous buffer at pH 7 – 8. Trishydroxymethylaminomethane (Tris) or phosphate salts are normally employed as buffers, the buffer concentration varying in the range 0.05 – 0.15 M (Tris) and 0.01 – 0.025 M (phosphate). The synthesis of UpazaG and CpazaG in the presence of pancreatic ribonuclease in 50% pyridine was described recently[41]. In the present author's laboratory the effect of various solvents (dimethylformamide, pyridine, acetonitrile) on the synthesis of CpC was investigated. The results presented in Table 1 show that ribonuclease catalyses the synthesis of dinucleoside monophosphate in all cases but in the presence of an organic solvent the reaction is slower and as a rule the yield is lower. The hydrolysis of the substrate is also retarded in the presence of dimethylformamide and acetonitrile, while pyridine accelerates it.

The use of buffer systems containing various organic solvents may prove to be very interesting and useful also in another connection. As already mentioned, when the reaction mixture is incubated with the enzyme, the synthesis of the dinucleotide is accompanied by the hydrolysis of the nucleoside 2,3′ -cyclic phosphate to the 3′-phosphate, the latter reaction often predominating. Therefore it is of interest to find ways of inhibiting the hydrolysis while maintaining the synthesis. All such procedures involve the use of organic solvents. Pancreatic ribonuclease is known to retain its activity at high concentrations of alcohols, which, however, inhibit the enzymatic hydrolysis of cyclophosphate substrates[45]. Alcoholysis of the substrate catalysed by ribonuclease takes place only in the presence of the alcohols satisfying certain structural requirements for the formation of the ester. In particular, it is known that secondary alcohols do not participate in the alcoholysis[45,46]. Therefore a study has been made of the synthesis of oligoribonucleotides in the presence of ribonuclease A in isopropyl alcohol[20], i.e. under conditions where the hydrolysis of cytidine 2,3′-cyclophosphate is inhibited and alcoholysis does not occur. It was found that the yield of oligonucleotide increases with the concentration of the alcohol, but falls sharply at a concentration of 8.7 M. In 7.2 M isopropyl alochol the yield of oligonucleotide is 72% compared with the aqueous buffer and the hydrolysis takes place to the extent of only 42%. It is also extremely interesting that the effect of temperatures on the synthesis of oligonucleotides in isopropyl alcohol and water is not the same: in 7.2 M isopropyl alcohol at 10°C a greater amount of oligonucleotide is formed than at 0°C and more than at 0°C in water. At 24°C the yield of the synthesis in isopropyl alcohol is lower than at 0°C but higher than in water at the same temperature. In the presence of various amounts of methanol, glycerol, ethylene glycol, butane-2,3-diol and also mixtures of isopropyl alcohol with dioxane or formamide the yield in the synthesis did not exceed the level attained in water[20].

Table 1. Effect of organic solvent on the synthesis of CpC in the presence of pancreatic ribonuclease.

Buffer solution	Content of CpC and C>p in reaction mixture, %							
	0.5 h		1 h		2 h		4 h	
	CpC	C>p	CpC	C>p	CpC	C>p	CpC	C>p
0.05 M tris-HCl in water (pH 7.6)	19.5	65.4	17.2	60.6	17.0	57.0	12.4	45.8
0.05 M tris-HCl in 50% dimethylformamide (pH 7.5)	9.6	82.0	11.9	71.4	11.6	66.4	10.2	54.1
0.05 M tris-HCl in 50% acetonitrile (pH 7.6)	15.6	72.6	18.0	61.0	14.9	64.9	18.7	53.2
10% pyridine	14.3	67.0	15.1	59.0	15.2	50.9	10.5	38.3
30% pyridine	12.2	66.7	11.9	60.5	12.0	52.3	10.1	40.0

In the discussion of problems associated with the solubility of the reaction components we must finally draw attention to the fact that the substrate may be used in the form of various salts: ammonium[20,22,25,27], sodium[26,27], potassium[19], dicyclohexylguanidinium, pyridinium, tributylammonium[27], and triethylammonium[27,41]. However, preliminary data obtained in our laboratory showed that the nature of the cation in the substrate influences not only its solubility in the buffer but also the course of the synthesis. In particular, the pyridinium salt of adenosine 2′,3′-cyclic phosphate is cleaved more rapidly under the conditions of synthesis of ApC.

Temperature. The synthesis of oligonucleotides with participation of ribonucleases takes place usually at temperatures close to 0°C. In Heppel's studies[17] it was already noted that the reaction takes place better at a low temperature, while at a higher temperature (37°C) the substrate is rapidly cleaved. These data were confirmed later in other investigations[20,22] for pancreatic ribonuclease and for the non-specific ribonuclease from *Aspergillus clavatus*[27].

Concentration of ribonuclease. The concentration of ribonuclease used in the synthesis is as a rule low and varies in the range from 10 to 40 $\mu g\ ml^{-1}$. In the presence of pancreatic ribonuclease the synthesis varies linearly with enzyme concentration in the range not exceeding 40 $\mu g\ ml^{-1}$ [20] and falls on further increase of concentration. An increase in the concentration of guanylribonuclease from *actinomycetes* accelerates the synthesis and increases the yield of oligonucleotides[19]. In the case of 5-*O*-substituted substrates the synthesis of the oligonucleotide in the presence of pancreatic ribonuclease reaches a plateau at an enzyme concentration of 40 $\mu g\ ml^{-1}$.[31]

Duration of reaction. The dependence of the yield of oligonucleotides on the duration of incubation of the reaction mixture has been investigated. Heppel noted an increase of the yield of dinucleotide with incubation time[17]. Later studies of reactions with participation of pancreatic ribonuclease showed that the synthesis of dinucleotides largely terminates after 3–4 h when the substrate is cytidine 2',3'-cyclic phosphate[20,23] and after 5–6 h when the substrate is uridine 2',3'-cyclic phosphate[22]. However, the hydrolysis of the substrates continues when the acceptor is a nucleoside. When the acceptor is a nucleotide, the synthesis and the hydrolysis terminate simultaneously. Therefore, it has been suggested that the cytidylic or uridylic acid formed in the reaction inhibits the synthetic function of ribonuclease in the first place[22]. It must be emphasised that these results are valid only for this particular enzyme. The synthesis of dinucleotide monophosphate catalysed by the non-specific ribonuclease from *Aspergillus clavatus* is slower and reaches a maximum after 24–48 h, depending on the nature of the substrate[27]. Moreover it has been found that the curves relating the yield of dinucleoside monophosphate to time are influenced by the ratio of the concentrations of the substrate and acceptor in the reaction mixture[27].

Effect of the pH. According to Heppel's data[17], the synthesis in the presence of pancreatic ribonuclease is independent of the acitidity of the medium in the pH range between 5 and 9. In the cases of guanylribonuclease from *Actinomyces*, at pH 5.5 the synthesis takes place at a lower rate than at pH 7.2.[19] In a study of the non-specific ribonuclease from *Aspergillus clavatus* in the synthesis of GpC it was shown that the optimum pH for the synthesis and hydrolysis is the same[27].

Thus it follows from the data examined that it is now possible to synthesise dinucleotides of any composition and with any sequence of nucleic acid bases using a set of ribonucleases or a single non-specific ribonuclease. The synthesis is achieved in one stage and may be carried out on a preparative scale. Table 2 lists all the dinucleoside mono- and di-phosphates synthesised in this way.

The compounds synthesised by this procedure were isolated by preparative paper chromatography in standard solvent systems: 2-propanol–conc. ammonia–water (7 : 1 : 2),[33] 1-propanol–conc. ammonia–water (55 : 10 : 35),[20–23] 1-butanol–acetic acid–water (5 : 2 : 3),[25] and isobutyric acid–0.5 *N* ammonia (10 : 6),[19] with a subsequent check of purity by paper electrophoresis. The converse procedure has also been used: the reaction mixture was separated by paper electrophoresis in 0.05 M triethylammonium bicarbonate and then additionally purified by chromatography in a particular standard system[23,26,32]. The separation of the reaction mixture by chromatography on ion-exchange resins or molecular sieves is promising for syntheses on a preparative scale.

*The Table does not list the dinucleotides for which the yield is not quoted in the original paper.

2. Synthesis of Trinucleotides (Trinucleoside Di- and Tri-phosphates)

The stepwise synthesis of trinucleotides may be achieved in two ways:

$$N > p + N'pN'' \rightarrow NpN'pN'' , \qquad (I)$$

$$NpN' > p + N'' \rightarrow NpN'pN''. \qquad (II)$$

One of the principal characteristics of this synthesis is the presence of the phosphodiester bond in the acceptor [reaction (I)] or in the substrate [reaction (II)], which makes it necessary in such cases to choose the enzyme catalysing the synthesis, or other reaction conditions, in such a way that the cleavage of the bond is reduced to a minimum.

The mechanisms quoted show that the substrates should be 2',3'-cyclic phosphates of nucleosides or of dinucleoside monophosphates. Compounds of the first type are readily available[28,29], but the introduction of the 2',3'-cyclic phosphate group into nucleotides is more difficult. Three methods have now been proposed for the synthesis of compounds of the type NpN'>p: (1) selected phosphorylation of dinucleoside monophosphates with triethyl phosphite and subsequent oxidation with hexachloroacetone[47]; (2) cyclisation of the terminal 3'-phosphate in dinucleotides with the aid of cyclohexyl-β-(*N*-methylmorpholino)ethylcarbodi-imide *p*-toluenesulphonate[48]; (3) cyclisation of the terminal 3'-phosphate with ethyl chloroformate[69].

There exists also a third method for synthesising trinucleotides: incubation of an excess of a nucleoside 2′,3′-cyclic phosphate (N>p) with a nucleoside, which leads to the formation of trinucleoside diphosphates of the type NpNpN′ [reaction (III)]. The first trinucleotides were in fact obtained by this procedure in enzymatic reactions with participation of ribonucleases:

$$2N>p+N' \rightarrow NpNpN'. \qquad (III)$$

Heppel et al.[17] already noted that, at high concentrations of cytidine 2′,3′-cyclic phosphate (> 0.1 M) and cytidine, their incubation with ribonuclease at 2°C leads to the formation (together with CpC, CpCp, CpC>p) of CpCpC and CpCpC>p. When reaction mixtures containing about 0.5 M substrate and acceptor are incubated, oligonucleotides with longer chains are formed. Bernfield and Nirenberg[49] reported the synthesis of UpUpU (12%), UpUpC (8%), and CpCpC (10%), and later[21] of CpCpU (8%) and CpCpA (2%). Each synthesis involved the reaction of two molecules of pyrimidine 2′,3′-cyclic phosphate with a nucleoside.

In 1964 the first communication[24] on the synthesis of the trinucleoside diphosphate GpUpC from a nucleoside 2′,3′-cyclic phosphate (G>p) and a dinucleoside monophosphate (UpC [see reaction (I)] was published. The synthesis was achieved by thermostatting 6.5 micromoles of G>p and 20 micromoles of UpC in 0.1 ml of 0.05 M tris buffer (pH 7) with 1 μg of T1 ribonuclease at 2°C and 24 h.

A series of papers by Grünberger, Holý, and Šorm[25,41,50-54] described the synthesis of 66 different trinucleoside diphosphates with participation of T1 ribonuclease. The synthesis was achieved by reactions (I) and (II) and the substrates were the 2′,3′-cyclic phosphates of guanosine, inosine, 8-azaguanosine, and xanthosine; the reactions of dinucleoside monophosphates with guanosine, inosine, and 8-azaguanosine at the 3′-end were also employed. It was found that in reaction (I) G>p and I>p were more effective substrates than 8-azaG>p or X>p. The acceptors in these reactions were dinucleoside monophosphates without guanosine, inosine, 8-azaguanosine, or xanthosine at the 5′-end and consequently incapable of being cleaved by T1 ribonuclease.

The synthetic activity of T1 ribonuclease depends on the nature of both nucleosides in the dinucleoside monophosphate acceptor, but the effect of the nucleoside at the 5′-end is more pronounced. Other conditions being equal, the yield of the oligonucleotide diminishes in the series C > U > A when the 5′-terminal nucleoside is varied. These results differ from the known sequence of the rates of cleavage of the corresponding internucleotide bonds[55]. GpGpU could not be obtained from G>p and GpU, since in the course of incubation GpU is cleaved more rapidly than the trinucleoside diphosphate synthesised. When the 3′-terminal nucleoside is altered, the yield varies in the series C > U > A > I > G.

Certain other types of oligonucleotides containing anomalous bases (5-methyluracil, $N_{(3)}$-methyluracil, $N_{(1)}$-methylinosine, 5-bromouracil, and 5-iodouracil)[54] or analogues of phosphodiester bonds have been obtained by the same procedure[56].

A reaction of type (II) has been carried out with the substrates CpG>p, UpG>p, CpI>p, and UpI>p in the presence of a tenfold excess of a nucleoside acceptor (C, U, or A‡). Higher yields were obtained in those cases where the 3′-terminal nucleoside was inosine. In a discussion of the synthesis of oligonucleotides with participation of T1 ribonuclease, mention should be made of the report of Podder and Tinoco[57], who observed that under certain conditions (incubation of G>p with T1 ribonuclease at room temperature) T1 ribonuclease catalyses the formation of 2′–5′ phosphodiester bonds. If this result is not an artifact, it is necessary to ensure a particularly rigorous control of the conditions of synthesis and to analyse carefully the oligonucleotides obtained with participation of ribonucleases§.

Comparison of all three versions of the synthesis of trinucleotides shows that pathway (III) is simplest but is also the most restricted, since it yields only trinucleotides containing two identical nucleosides at the 3′-end of the molecule. Moreover, the reaction mixture contains in this case a considerable amount of monotonic oligonucleotides, which makes their separation difficult. Pathways (I) and (II) both require preformed dinucleotides and in the second case there is an additional requirement of the introduction of a 2′,3′-cyclic phosphate group into the dinucleotide. Therefore we believe that pathway (I) is to be preferred, and, for a more complete utilisation of the acceptor dinucleotide, it is desirable to introduce an excess of the substrate into the reaction mixture. In order to avoid the formation in a side process of a series of monotonic oligonucleotides, it is suggested that substrates with a blocked 5′-OH-group be used[31-33]. The synthesis of oligonucleotides in the presence of ribonucleases using substrates of this type has so far been comparatively thoroughly investigated only at the level of dinucleoside monophosphates[31-35]. In these investigations it has been shown convincingly that 5′-*O*-substituted nucleosides 2′,3′-cyclic phosphates may serve as substrates for pancreatic[31-33], guanyl-[34,35] and non-specific ribonuclease from *Aspergillus clavatus*[33] and that the use of an excess of a 5′-*O*-substituted substrate really does not lead to the formation of a mixture of oligomers[34]. The synthesis of pGpApU and pGpUpU from pG>p and the corresponding acceptor in the presence of T1 ribonuclease has also been briefly reported[42].

As already stated, in the synthesis of trinucleoside diphosphates via pathways (I) and (II), under certain conditions the formation of the oligonucleotide and the cleavage of the 2′,3′-cyclic phosphate group in the substrate may be accompanied by the cleavage of the phosphodiester bond in the acceptor [reaction (I)] or the substrate [reaction (II)], which complicates the composition of the reaction mixture and hinders the preparation of the trinucleotide. To avoid this, Bernfield[20] suggested the use of derivatives of pancreatic ribonuclease with synthetic activity but hydrolytically inactive. Thus, it has been established that S-protein[58], 1-carboxymethylhistidine-119-ribonuclease[59], and ε-dinitrophenyl-lysine-41-ribonuclease[60] exhibit synthetic activity (Table 3) but virtually do not hydrolyse C>p and RNA with a high molecular weight.

In the study of the synthesising activity of these derivatives it was established that the substrates for S-protein may be cytidine and uridine 2′,3′-cyclic phosphates. The optimum pH in the syntheses with participation of S-protein and 1-carboxymethylhistidine-119-ribonuclease proved to be 8.0 and the optimum reaction temperature is 23°C.[20] The synthesising activity of the derivatives is

---

‡ In the case of adenosine, a tenfold excess could not be achieved because of the low solubility of adenosine in tris buffer.

§ Later, in a special study Rowe and Smith[71] showed that, under conditions optimum for synthesis, T1 ribonuclease gives rise to the formation of 3′–5′ internucleotide bonds only.

inhibited by lower concentrations of nucleoside 3′-phosphate than in the case of ribonuclease A. The relative initial rates of synthesis for ribonuclease A, S-protein, and 1-carboxymethylhistidine-119-ribonuclease are 100, 21, and 7 respectively. In all cases the dependence of the synthesis on enzyme concentration is linear in the range up to 60 μg ml^{-1}.

Table 3. Depolymerase and synthetic activities of derivatives of ribonuclease A.[20]

Enzyme or derivative	Depolarisation, %	Synthesis, %	Ratio of synthesis to depolymerisation
Ribonuclease A	100	100	1.0
Ribonuclease S	108	103	0.96
S-Protein	5.2	17	3.3
S-Peptide	0	0	0
Carboxymethylhistidine-119-ribonuclease	0.98	5.5	5.6
Ribonuclease inactivated by pepsin	0	0	0
Poly-DL-alanylribonuclease prepared in bicarbonate buffer	10—21	9—22	1
Poly-DL-alanylribonuclease prepared in phosphate buffer	12	14	1.2
ϵ-dinitrophenyl-lysine-41-ribonuclease	4.4	38	8.6

Comparison of the hydrolytic activities of ribonuclease A and S-protein in the reaction mixtures U>p−UpC and C>p−UpC showed that S-protein cleaves UpC 4−5 times more slowly than ribonuclease A and may be used in the synthesis of trinucleotides via pathway (I) using as an acceptor a dinucleotide with a pyrimidine nucleoside at the 5′-end of the molecule[21].

The activities of ribonuclease A and S-protein have also been compared in the reaction with U>p + ApA and C>p + ApA. It has been established that S-protein catalyses the synthesis of UpApA about three times more effectively than ribonuclease A—the reaction is rapid and begins to slow down after 4 h. The yield of UpApA reaches 10% after 48 h.

Thus in the synthesis of trinucleotides via reaction (I) S-protein has certain advantages over ribonuclease A. Bernfield noted[21] that, for a given substrate, the yield of the trinucleotide depends on the nature of the nucleosides at the 3′-end of the acceptor molecule and is low when the cyclic nucleotide and the nucleoside at the 3′-end of the acceptor molecule are complementary (for example, U>p + CpA). The low yields in those cases where the pyrimidine nucleoside is at the 5′-end of the molecule are probably due to the admixtures of ribonuclease in the S-protein.

Evidently the cleavage of the dinucleotide introduced into the reaction may be avoided also by other methods, for example by introducing a blocking group in the 2′-position of the 5′-terminal nucleotide, since it is known that in this case ribonuclease does not cleave the phosphodiester bond. As usual, in the blocking of a particular functional group it is necessary that the blocking group should be readily introduced into the oligonucleotide, should be stable under the conditions of enzymatic synthesis, and should be readily eliminated. However, no studies on these lines have so far been published.

The trinucleotides synthesised with participation of ribonucleases (Table 4) are isolated and identified in the same way as the dinucleotides (see p. 698).

Summarising the discussion of the methods of synthesis of trinucleotides in the presence of ribonucleases, it should be said that in order to obtain trinucleotides of any composition and any sequence of nucleic acid bases, it is necessary to have at one's disposal a set of highly specific ribonucleases (such as guanylribonucleases) or to find conditions under which the preferential synthesising activity of the enzyme will be shown and its hydrolytic activity will be suppressed. Already, using only the known and more or less available ribonucleases or their derivatives, it is possible to synthesise a large number of various trinucleoside diphosphates via pathways (I), (II), or (III), depending on which sequence of nucleic bases it is to be obtained.

Evidently, by combining any of the methods and approaches under discussion, it is possible to synthesise in the presence of ribonucleases also longer oligonucleotides, although the experimental data concerning such syntheses are still unavailable, apart from the reports of the formation of tetranucleotides and longer oligonucleotides by incubating an excess of the substrate with pancreatic ribonuclease[17,20].

After the present review had been sent to the editors, a paper was published by Mohr and Tach[69] in which they report the synthesis of 8 tetranucleotides (ApUpGpU, ApUpGpC, ApUpGpA, ApApGpU, ApUpGpUp, ApUpGpCp, and ApUpGpAp) in yields of 5–37%, 5 pentanucleotides (ApUpGpCpC, ApUpGpUpC, ApUpGpApA, ApUpGpApC, and ApUpGpApU) in yields of 11–25%, 3 hexanucleotides (ApUpGpApApA, ApUpGpApUpG, and ApUpGpUpUpUp) in yields of 8–15%, 2 heptanucleotides (ApUpGpApApApA and ApApApGpApApA) in 5% yields, and 1 octanucleotide ApUpGpApApApApA in 3% yield from oligonucleotide donors and acceptors in the presence of guanyl-specific T1 ribonuclease.

III. SYNTHESIS OF OLIGORIBONUCLEOTIDES USING POLYNUCLEOTIDE PHOSPHORYLASE

The possibility of adding one or more nucleotide residues from a nucleoside 5′-diphosphate to a preformed oligonucleotide in the presence of polynucleotide phosphorylase from *Micrococcus lysodeicticus* was first demonstrated by Singer et al.[62], who obtained and characterised nucleotides such as pApApApU and pApApApGpG.

Table 6. Trinucleoside diphosphates synthesised in the presence of polynucleotide phosphorylase from *Micrococcus lysodeicticus*[63].

Substrates for synthesis			
Dinucleoside monophosphate	Nucleoside diphosphate	Trinucleoside diphosphate	Yield, %
ApA	ppC	ApApC	6.0

UpA	ppU	UpApU	5.0
GpC	ppU	GpCpU	6.0

Leder et al.[63] suggested that trinucleoside diphosphates be synthesised by the addition of a nucleotide residue from a nucleoside 5′-diphosphate to a dinucleoside monophosphate according to the following mechanism

$$\mathrm{N'pN''} + \mathrm{ppN} \xrightarrow{\text{polynucleotide phosphorylase}} \mathrm{N'pN''pN} + \mathrm{P}_i\ ,$$

where ppN is a nucleoside 5′-diphosphate, N′pN″ a dinucleoside monophosphate, and P_i inorganic phosphate. This method may be used for the synthesis of oligonucleotides with any sequence of monomeric units. The reaction was carried out by incubating the substrates with an enzyme at 37°C for 2 h. The trinucleoside diphosphates were isolated from the reaction mixture by paper chromatography and paper electrophoresis. The trinucleoside diphosphates synthesised in this way are listed in Table 6.

The data in Table 6 show that the yields of trinucleoside diphosphates vary from 3 to 30%, depending, according to the authors, on several factors. Thus, at a high concentration of nucleoside 5′-diphosphate, polynucleotides with a long chain (10 or more units) accumulate and shorter oligonucleotides are not formed. Such tendency towards the formation of polynucleotides with a large number of units is particularly typical for adenosine 5′-diphosphate and less so for cytidine 5′-diphosphate. However, even under the most favourable conditions, tetra-, penta-, hexa-, and hepta-nucleotides are formed in addition to the trinucleoside diphosphate. The yield of trinucleotide depends also on the nature of the nucleoside 5′-diphosphate: uridine 5′-diphosphate gives the highest yield. In those cases where the substrates used in the synthesis contain complementary bases, the yield of trinucleotide may be improved by heating the reaction mixture to 70°C before adding the enzyme.

This method was subsequently used for preparative purposes[64]. After incubating for 12 h, the reaction is stopped by adding alkaline phosphatase and the reaction mixture is separated on a column with DEAE cellulose with subsequent purification of the oligonucleotide fractions by paper chromatography. The yields of trinucleoside diphosphates were 5–40% in relation to the initial dinucleoside monophosphate.

An advantage of the method consists in the fact that polynucleotide phosphorylase does not cleave dinucleoside monophosphates[66] and therefore, on the one hand, there can be no rearrangement of the nucleotide sequence in the dinucleoside monophosphate as a result of cleavage and resynthesis and, on the other hand, dinucleoside monophosphates may be regenerated. As already mentioned, a disadvantage of the method is the fact that the reaction mixture contains, together with the trinucleoside diphosphate, also longer oligonucleotides, which reduces the yield of the trinucleoside diphosphate and hinders its isolation.

Comparison of the method of synthesis of oligonucleotides in the presence of polynucleotide phosphorylase with methods based on the application of various ribonucleases shows that both types of method have their advantages and disadvantages; bearing these in mind, the procedures must be regarded as fully of equal value in the stage involving the preparation of oligonucleotides longer than dinucleotides and may be used depending on which substrates and which enzyme are more available in each particular situation. In the synthesis of dinucleotides only the "ribonuclease method" may be employed.

The data discussed above suggest that the methods of synthesis of oligonucleotides based on the use of enzymes, particularly ribonucleases, are more advantageous and therefore more promising than chemical methods. The principal advantages of enzymatic methods are as follows: the relative availability of the initial components (substrates and acceptors), the elimination of the need to block reversibly the "superfluous" functional groups of these components and hence a significant shortening of the time required for the synthesis, the simplicity of separation of the reaction mixture, and in the majority of cases a higher yield of the oligonucleotide.

Further development and propagation of these methods should be accompanied by an increase in the number of enzymes with suitable catalytic properties and also by the development of methods necessary for the rapid and simple separation of large amounts of reaction mixtures. Special mention should be made of the necessity to seek analogous approaches to the synthesis of oligodeoxyribonucleotides, which will significantly extend the scope of enzymatic methods for the stepwise synthesis of the $C_{(3')}-C_{(5')}$ bond between specific nucleotides.

Effect of a Solid Surface on Relaxation and Structure-formation Processes in Polymer Layers Adjoining the Walls

Yu.M.Malinskii

Data on the characteristic properties, in particular crystallisation properties, of low-molecular substances in layers adjoining the walls are briefly discussed. The methods for and the results of the determinations of the thickness of wall layers of solutions and melts of many polymers are quoted. Data on the effect of a solid surface on the rate of relaxation processes and the properties of the polymers due to them are reviewed.

The effect of artificial nucleating agents on the structure (and properties) pf polymers, the suppression of structure formation in thin layers in certain systems, and epitaxy are discussed.

The experimental data presented are treated from the standpoint of the hypothesis of the packet structure of polymers and the effect of the interaction between the solid surface and the polymer on the enthalpy and entropy of the system.

The bibliography includes 232 references.

CONTENTS

1. INTRODUCTION

The specific features of thin layers of polymers (1 – 20 μm thick) in contact with a solid surface have increasingly attracted the attention of investigators in recent years. The physicochemical foundations of recipes for and the technology of the processing and applications of filled polymeric materials, adhesives, and paint and varnish coatings would be impossible without an understanding of the structural characteristics of such layers and their behaviour under conditions of use.

As early as 1935–1936, Rebinder related the effectiveness of the filler to the fraction of the polymer, which, as a result of adsorption interaction with the filler surface, passes into a "special film state" with enhanced mechanical properties[1,2].

In recent years, particularly in the last decade, numerous observations have accumulated, showing that surface layers of the polymer (or layers adjoining the walls), arising when it comes into contact with another (particularly solid) phase, differ in structure and properties from the polymer at a fairly large distance from the phase boundary, and have a thickness, which sometimes reaches many micrometres.

A chemically inert solid surface acts on the surface layers of polymers (and low-molecular substances) via intermolecular attraction and repulsion forces; these forces are responsible for adsorption interaction between the system components and for the purely geometrical restriction on the space available for migration by the kinetic units of the substance in the wall layer.

The unusual properties of the structure of surface layers are a consequence not only of the interaction between the atoms and molecules of the solid and the polymer layer located directly on its surface but also on the transmission of this interaction (more precisely its results) from the layers nearest to the surface to more remote layers. The effect of one phase on another via an interface theoretically extends throughout the entire bulk of the phase and on moving away from the phase boundary, the value of a property of the phase approaches asymptotically the value characteristic of the phase in the absence of such influence[3]. Therefore, the thickness of the wall layers determined in any experiment is only an effective thickness characterising the behaviour of the system under the conditions of the given experiment; the effective thickness varies with the property investigated and the sensitivity of the method employed. The gigantic size of polymer molecules and the presence of supermolecular formations results in a much greater thickness of wall layers in polymers than in low-molecular substances. This fact is of great practical importance in the study of wall layers of polymer systems.

In the vast majority of investigations which have been made, the surface layers of polymers were examined not by direct study of the layers themselves but by studying the properties of complex systems in which the behaviour of certain polymer layers plays a significant role. Quantitative relations governing the effect of an extraneous surface on the structure and properties of a polymer wall layer are not as yet available and qualitative generalisations have been made only concerning certain aspects. The results obtained by different investigators are sometimes contradictory and the reasons for such contradictions are not always clear.

In the present paper an attempt is made to describe the available literature data on the principal properties of polymer wall layers from the standpoints of the energy and geometrical effects of the solid surface on a structured (in packets or crystallites) polymer.

2. PROPERTIES OF WALL LAYERS OF LOW-MOLECULAR SUBSTANCES

In a series of investigations Deryagin and coworkers showed that the wall layers of a number of low-molecular liquids under the influence of the surface forces of the solid acquire properties different from those of the bulk-phase liquid. Thus it was found[4] that the elasticity of water in a layer adjoining a glass surface becomes equal to that of the bulk-phase water only at a distance of about 0.07 μm and the shear elasticities of wall layers of water, acetone, hexanol, and octanol on quartz are about a factor of ten higher than the bulk-phase values[5]. In the thin pores (diameter about 0.01 μm) of amorphous silica water does not exhibit the anomalous thermal expansion (in the range 0−36°C)[6]; similar results were obtained in studies on the behaviour of water in glass capiliaries[7,8] and in carbon pores[9]. The heat capacity of nitrobenzene mixed with a glass powder (activated by treatment in a glow discharge), where the average thickness of nitrobenzene layers was 0.2−0.3 μm, was lower than the bulk-phase value approximately by 10%[†].

Purified mineral oils in a gap between steel surfaces begin to exhibit boundary mechanical properties when the gap thickness is less than 0.3 μm and in gaps 0.1 μm thick, the layer begins to show elastic properties[11].

The unusual properties of liquids in wall layers are caused not only by direct interaction with the surface of another phase but, at least in the majority of cases, by the orientation of molecules in this layer. One may refer, as examples, to the orientation, demonstrated by electron diffraction, in thin films of certain straight-chain hydrocarbons on copper, rock salt, and glass[12] and of lubricating oil (mixtures of saturated and unsaturated hydrocarbons) on a number of metals and alloys[13]; the electron diffraction patterns of the surface layer of the mercury meniscus (at the boundary with air) also show a distinct texture[14].

The effect of the solid surface on the structure and mobility of the wall layer of a liquid cannot fail to influence also its crystallisation. Indeed, in the crystallisation of piperine[15] and betol[16] in a layer with a thickness of several tenths of a millimetre between glass surfaces and also in the case of piperine between mica surfaces, the curves for the temperature variation of the rate of nucleation show two maxima. The authors of these investigations attribute the low-temperature maximum (at a distance of several degrees from the high-temperature maximum) to the effect of the solid surface, in the vicinity of which the molecules of the liquid are in a more ordered state than in deeper layers. The curves relating the rate of nucleus formation in betol to the distance from the surface of glass show a maximum, the effect of the surface extending over a distance of the order of several micrometres[17]. Brief treatment of glass surfaces with hydrogen fluoride, coating of the surface with a thin layer of lactic acid[17], and the application of a magnetic field[18] weaken the effect of the surface on the rate of nucleation while coating of the surface with a layer of collodion (10 μm thick) completely eliminates the surface effect[17][‡].

The results of many investigations demonstrate the dependence of the structure of thin metallic films, obtained by vacuum deposition on a solid support, on their thickness. Under certain experimental conditions, silver telluride (Ag_2Te) films with a thickness less than 300−350 Å are structureless, in films with a thickness of between 350 and 700 Å spherulites 100 μm and above in diameter are formed, while in still thicker layers the spherulite structure is gradually suppressed by microcrystals growing in increasing numbers[19]. Beryllium, vanadium, nickel, chromium, and cobalt films give rise to electron diffraction patterns which coincide with those of the massive specimens only when the thickness is in excess of 70−80 Å; for smaller thicknesses, the diffraction patterns show additional lines and when the thickness is 20−30 Å only diffuse rings are seen[20]. In silver films 40−50 Å thick two phases coexist at room temperature—a face-centred cubic phase and a hexagonal phase, while in thicker films (of the order of 100 Å) the hexagonal modification is unstable[21].

The above data by no means exhaust the abundance of observations on the properties of wall or surface layers of low-molecular substances and are quoted only to assist the reader gain an idea about the general occurrence of the phenomena under discussion for both high-molecular and low-molecular substances. Extensive evidence concerning the unusual properties of the wall layers of low-molecular liquids is presented in a detailed review by Henniker[22].

3. THE THICKNESS OF POLYMER WALL LAYERS AND METHODS FOR ITS DETERMINATION

Recently Kargin and coworkers demonstrated the possibility of forming large supermolecular polymer species in dilute solutions. In solutions of poly-α-butylene ($M = 180\,000$) in rosin at a concentration of 0.1% and above supermolecular species with a length of the order of 1 μm were observed[23], while in solutions of the same polymer in propane species with a length of several tenths of a micrometre were observed at concentrations as low as 0.05%[24]; in solutions of atactic polypropylene ($M = 35\,000$) in propane at concentrations as low as 0.2% particles with dimensions of the order of a micrometer were found[25].

So far it has not proved possible to observe directly supermolecular formations in polymer melts but there is much reliable evidence for their existence. This includes electron diffraction data showing the presence of a high degree of order in the distribution of polymeric molecules in the melt[26,27], results of studies on the sorption properties of polymers above their melting points[28], certain rheological characteristics of melts[29-34], the retention of the steric distribution of the spherulite centres after repeated fusion[35], and the high rate of crystallisation of melts[36].

The existence in melts and solutions of polymers of supermolecular formations must inevitably result in high-molecular substances having much thicker wall layers (with properties differing from those in the bulk-phase) than low-molecular compounds.

We shall examine briefly the methods used to determine the thickness of the wall layers of polymers in systems comprising a polymer solution or melt and a solid surface. Various methods for the determination of the weight of the polymer adsorbed on the surface from its solution are widely employed. Since these methods have been widely discussed in a review by Patat et al.[37], we shall not deal with them.

Viscometry

Viscometric methods are simplest; with their aid, it is possible to determine the effective change in capillary

---

[†] We restrict the review of the work of Deryagin's school to the publications quoted above, which contain the bibliography of other papers by this school on the properties of the wall layers of low-molecular liquids.

[‡] In the publications quoted above[15-18] there is a bibliography of other investigations at Odessa University on the effect of surface on the crystallisation of low-molecular organic liquids.

diameter caused by the appearance of an adsorbed layer[38-42] or in the dimensions of adsorbent particles suspended in a solution or melt of the polymer[43-48].

Öhrn[38] measured the flow times of a polymer solution using a viscometer with two parallel capillaries of different diameters (0.5 and 0.2 mm). The following considerations were employed to calculate the effective thickness of the adsorbed layer. If, for a capillary with a radius r and a thickness of the adsorbed layer δ, the apparent (observed) relative viscosity of the solution is denoted by η^*_{rel}, the true relative viscosity of the solution $\eta_{\text{rel}} = \eta_{\text{soln}}/\eta_{\text{solvent}}$ is given by

$$\eta_{\text{rel}} = \eta^*_{\text{rel}} \left(\frac{r-\delta}{r}\right)^4 = \eta^*_{\text{rel}} \left(1 - \frac{4\delta}{2}\right) + \cdots$$

We shall retain only the first term in the expansion and, on converting to the viscosity number (term recommended by IUPAC), we obtain the expression

$$\eta^*_{\text{sp}}/c = \eta_{\text{sp}}/c + (\eta_{\text{rel}}/c)(4\delta/r) \ .$$

If we assume that for a given concentration the effective thickness of the adsorbed layer δ is independent of the dimensions of the capiliary§, then δ may be calculated from the slope of the linear plot of η^*_{sp}/c against $1/r$.

The thickness of the adsorbed layer may be calculated also directly from the flow times of the solution in two capillaries of different diameters[40], and from the formula[42]

$$\delta = \frac{r\,\Delta t}{4t} \quad ,$$

where r is the capillary radius, t the flow time of the solvent until the viscometer is filled by the test solution, and $t + \Delta t$ the flow time of the solvent after the viscometer had been used for the test solution and then washed with the solvent. The thickness of the adsorbed layer obtained by the last method is probably somewhat too low, since it is very likely that part of the adsorbed polymer is removed from the walls of the capillary when it is washed.

In the determination of the thickness of the adsorbed layer from the change in the dimensions of adsorbent particles suspended in a liquid, measurements were made either of the viscosity of such a system using the Einstein equation[43,45-49] or the rate of sedimentation of the particles[44]. The familiar Einstein equation for the viscosity of suspensions of rigid spherical particles in a Newtonian liquid[50,51] is of the form

$$\eta = \eta_0 (1 + K\varphi) \ ,$$

where η is the viscosity of the suspension, η_0 the viscosity of the pure liquid, φ the volume fraction of the particles, and K a constant. If the particles are spherical and the liquid merely wets them, then $K = 2.5$. When an adsorbed layer is formed on the particles of the suspension, their effective volume increases and the viscosity of the system is described by the Einstein equation in which K (in this case the constant may be denoted by K_{eff}) is greater than 2.5. When the form of the particle deviates from the spherical, K also proves to be greater than 2.5. If this deviation is slight, the value of K characteristic of particles of a given form (it will be denoted by K_0) may be determined by measuring the viscosity of the suspensions in a suitable low-molecular liquid (transformer oil, for example, has been used for this purpose[48]).

Knowing the particle diameter d and the experimental values of K_0 and K_{eff}, it is easy to calculate[47] the thickness of the adsorbed layer δ:

$$\delta = \frac{d}{2}\left(\sqrt[3]{\frac{K_{\text{eff}}}{K_0}} - 1\right) .$$

If a polydisperse absorbent with a specific surface S_{sp} is used, then, having calculated the effective increase of its volume in the suspension per unit weight ($\Delta\varphi_{\text{eff}}$) due to adsorption, it is possible to calculate also the thickness of the layer $\delta = \Delta\varphi_{\text{eff}}/S_{\text{sp}}$. An advantage of this method is the possibility of applying it in studies on concentrated solutions and polymer melts; the measurements must be made for low values of φ and under conditions ensuring Newtonian behaviour of the system.

The following two methods for the determination of the thickness of the wall layer based on its enhanced viscosity may also be included among viscometric methods. The dependence of the viscosity of polymer wall layers on the distance from the solid surface has been investigated by the so called "blowing off" method[52]. The essential features of this method have been described in detail in a number of papers[53-55] and are as follows. A jet of air directed onto a slit between two flat surfaces containing the liquid produces a tangential force causing the profile of the film to assume a definite form reflecting the property investigated. The steepness of the film profile at each point is proportional to the viscosity of the liquid at the corresponding distance from the surface. If the viscosity is independent of the distance from the surface, then the profile of the wedge-shaped film is linear; the increase of viscosity on approaching the surface leads to the "blunting" of the wedge. The steepness of the profile can be comparatively simply determined from the distance between the interference bands obtained on illuminating the film with monochromatic light.

Tsvetkov et al.[56] employed in the investigation of polymers a previously developed method[13,57] for the determination of the thickness of the boundary layer in low-molecular liquids. The essential feature of the method consists in the study of the variation with time of the thickness of a layer of the liquid between the parallel plates of a planar plastometer compressed by a constant force. Extrapolation of the relation to infinite times permits the estimation of the thickness of this rigid "non-fluid" layer, which may be regarded as the wall layer. It has been shown for low-molecular liquids[13,57] that the thickness of this layer depends on the pressure on the plates of the plastometer, the nature of the liquid and of the surface of the plates, and the experimental temperature. There is no doubt that these factors influence also the thickness of the polymer layer. However, one may question the validity of the extrapolation of data obtained over a period of 15 min for the highly viscous polymer melts of the kind investigated by Tsvetkov[56].

Ellipsometry

Ellipsometry is a satisfactory method permitting the measurement of the thickness of the adsorbed layer with an accuracy of several ångstroms. This procedure uses the fact that the formation of a film on the solid surface influences the optical properties of the latter—there is a change in the phase difference and the amplitude ratios of the components of the elliptically polarised light reflected

---

§ The velocity gradient in both capillaries of Öhrn's viscometer was the same and $r \gg \delta$.

from it. The accuracy of this method is considerably reduced if the refractive indices of the film and the solution adjoining it are similar. A method has been described for the calculation (using computers) of the thickness of adsorbed films of low-molecular and polymeric substances from data obtained with the aid of an ellipsometer[58,59]. To improve the precision of the measurements, the incident beam was reflected three times from the test surfaces. Ellipsometry has been used to investigate adsorption from dilute polymer solutions[58–61]; the use of this method to investigate adsorption from polymer melts would be of great interest.

The somewhat arbitrary nature of the ellipsometric values obtained for the thickness of the wall layer is a consequence not only of the fact that these values, as in measurements by any other method, constitute merely effective quantities but also because in the calculation it is necessary to take into account the refractive index (and hence the density) gradient within the layer. In the first studies by Stromberg and coworkers[58–60] the simplest hypothesis was adopted, namely that the adsorbed film is homogeneous and that the refractive index gradient within the layer is zero. Subsequently[61] in the calculation of the thickness it was also postulated that the density gradient is exponential. The refractive index gradient in the film is at present unknown; statistical calculations show that, even for the simplest model (an isolated macromolecule of finite[62] and infinite length[63]), there is a fairly complex relation between the density of the adsorbed layer and the distance from the surface of the support, the relation being influenced by the rigidity of the chain and the adsorption energy.

Table 1. Thicknesses of polymer wall layers in various systems.

a. This range of thicknesses includes results obtained using various solvents.

b. Concentration not indicated in the paper; however, there is no doubt that the behaviour of dilute solutions was investigated.

c. The thicknesses are much too low, since in the calculations the authors assumed that the entire surface of the sorbent (carbon black, titanium dioxide, etc.), determined from the extent of adsorption of nitrogen, is available for the adsorption of the polymer and the density of the adsorbed layer is equal to that of the solid polymer.

d. Thickness of the layer estimated assuming that its density does not differ from that of the solid polymer; this method of estimation yields low results.

e. Isotactic polymer.

f. This range of thicknesses includes results obtained at different temperatures.

g. The layer thickness was estimated by the present author from the weight adsorbed per unit surface area of the adsorbent using[40] 0.17 g ml^{-1} as the density of the layer.

h. It has been stated[74] that the layer thickness fails with increasing concentration of the solution; this range of thicknesses includes the results obtained by extrapolation to zero concentration.

i. The layer thickness decreases with increasing shear stress.

j. From the difference between the viscosities of the wall layer and the bulk-phase polymer.

k. From the zone corresponding to the breakdown of interference bands.

Sorption

An unusual method for estimating the thickness of polymer layer immobilised by the surface of a filler is based on the extent of sorption of the solvent vapour by the filled system at a temperature greater than T_g for the polymer[64]. In the calculation it was assumed that at the experimental temperature the immobilised polymer layer sorbs like the initial polymer in the vitreous state and the remaining polymer in the filled system does not differ in its sorption capacity from the unfilled polymer; it was also assumed that, for low vapour pressures, sorption by the vitreous polymer may be neglected. It is noteworthy that these assumptions lower the thickness of the immobilised layer.

Table 1 presents data for the thicknesses of the wall layers of various polymer – solid surface systems obtained by different methods. A striking feature of the results in Table 1 is their considerable scatter, which is due primarily to the different concentrations of the polymers in the systems to which the particular data refer. Layer thicknesses of the order of tenths and hundredths of a micrometer occur in dilute polymer solutions at concentrations ranging from a fraction of a gramme to several grammes per litre; in all cases where melts were investigated the thickness of the wall layer amounted to several micrometers. It is appropriate to mention here that, in the determination of the extent of adsorption of the polymer from solution over a wide range of concentrations, saturation was not observed with increase in concentration[65,66]. The thickness of the wall layer depends not only on the concentration of the solution, the nature of the solid surface, the molecular weight, and the nature of the polymer and solvent (if it is present in the system) but also on experimental conditions such as temperature, pressure, shear stress and shear velocity, and the method used to determine it (see above, p. 704). It may be supposed that in those cases where the thickness of the wall layer of the polymer is comparable to the dimensions of the solid particles round which the layer is formed (for example in systems with a highly dispersed filler), the thickness of the layer is directly related to the particle diameter.

Table 1 shows also the extreme paucity of information at present available about the thickness of the wall layer in polymer melts.

4. CHARACTERISTICS OF RELAXATION PROCESSES IN POLYMER WALL LAYERS

A solid surface in contact with a polymer can influence the wall layer via two mechanisms¶: as a result of a purely steric effect—by restricting the volume occupied by the units of the macromolecule and the larger kinetic units during their thermal motion, and as a result of an energy effect—by bonding via an intermolecular interaction directly to certain units of the macromolecules adjacent to the surface, via chemical bonding to macromolecules comprising these units, and via intermolecular bonding to supermolecular formations (naturally not only those of which such molecules are constituent parts but also the adjacent formations). As a result, the majority of the relaxation processes in the wall layer are slower than in the bulk of the polymer.

The data on the relaxation times and activation energies for isothermal compression obtained in the study of the unfilled systems poly(methyl methacrylate) – nitron or fibre glass and polystyrene – quartz or nitron lead to the conclusion that in these systems the principal factor responsible for the reduced mobility of the structural units in the polymer wall layers is the decrease of the number of possible conformations of the macromolecules and not their energy interaction with the surface[84]. However, it may be supposed that in certain other systems this energy factor will predominate. The reduced mobility in polymer wall layers is associated with the expansion of the relaxation spectrum towards longer times[85-87].

Effect of the Solid Surface on the Packing Density and Orientation in Wall Layers

The lack of correspondence between the steric disposition of the centres of intermolecular interactions on the solid surface on the one hand and in the polymer on the other, which usually obtains, leads to a lowering of the packing density of the polymer in its wall layers compared with bulk phase. The results of sorption measurements[84,88-90], direct determinations of the deviation of the density of the mixture from addivity[84,88,91,92], and the increase in the coefficient of volume expansion on filling[93] indicate a loosening of the polymer bulk phase in the systems poly(vinyl acetate)[92] and vinyl acetate-vinyl chloride copolymer[88] – titanium dioxide, polystyrene and poly(methyl methacrylate) – fibre glass[89] or quartz powder[84,93], isotactic polypropylene – glass powder[90], and natural rubber – zinc oxide[91] †. The increase of the rate of dissolution of small particles of dye in the melt of isotactic polypropylene on increasing the distance between such a particle and a glass surface, starting with a distance of 30 μm, observed in our experiments[90], also confirms that the density of the polymer in the wall layer is reduced.

A solid surface interacting fairly strongly with the polymer can orient to some extent its molecules and supermolecular formations in the wall layer. In the limiting case this orientation leads to epitaxy‡, which will be considered in the next section. It has been established by electron diffraction that guttapercha is oriented on aluminium[94]; Kozlov et al.[95] concluded, on the basis of studies of the strength, swelling, and contraction of films of cellulose ethers on the surface of glass that the orientation of such films is planar. Calculation, based on data for the sorption of water showed that, when a polyepoxide [from 4,4′-bisglycidylphenyl-2,2′-propane and hexane-1,6-diamine] is filled with titanium dioxide (arutile modification with an average particle size of 0.2 μm), there is a

---

¶ We are not discussing here the chemical interaction between the polymer and the material with which it is in contact nor the effect of the solid surface on polymerisation, polycondensation, and cross-linking processes, which have been described in a number of publications[79-83].

† The observed[92] decrease of the coefficient of volume expansion of poly(vinyl acetate) at 40°C (slightly above the glass point T_g) as a result of the introduction of 12.1% of titanium dioxide is not inconsistent with the hypothesis that the density of the polymer decreases on filling. If at a temperature below T_g the free volume of a filled polymer is significantly greater than that of an unfilled polymer, then, despite the decrease of the coefficient of volume expansion, there is a certain range of temperatures fairly close to T_g where the free volume of the filled polymer will still remain higher than that of the unfilled polymer.

‡ Epitaxy is the formation at the boundaries of the crystals of one substance of oriented crystals of another.

decrease of the free energy and enthalpy (by 2 cal g^{-1}) and of entropy (by 5×10^{-3} cal g^{-1} deg^{-1}) of the polymer, which also indicates some ordering of the latter[78].

The conclusion that the configurational entropy of poly(vinyl acetate) may increase when it is filled with titanium dioxide was also based[92] on a considerable (almost by a factor of 2) decrease of the activation energy for the diffusion of oxygen and argon (at temperatures above T_g) on filling.

The orientation obtained when the polymer is extended may lead to both an increase and a decrease of the packing density of the polymeric molecules[96,97]. By analogy, we must suppose that the orienting effect of the solid surface on the polymer can also lead either to an increase or a decrease of the packing density of the wall layer. Since the molecular attractive forces of the solid act not only on the nearest layer of units of the macromolecules but also on the more remote layers, an enhancement of the interaction between the polymer and the solid surface should favour an increase in packing density; more favourable conditions for relaxation have a similar effect. It can also be supposed that in certain cases filling leads to an increase in the packing density of the polymer at temperatures above T_g, but lowers it below T_g. Indeed, it has been established in a number of studies that above T_g the swelling of the polymer or the sorption of water vapour decrease on filling. This has been observed in the study of the systems natural rubber or polyisobutylene – colloidal nickel or cobalt[98], natural rubber – carbon black[99], poly(vinyl acetate) or polyepoxide – titanium dioxide or copper-phthalocyanine[64], and gelatine – glass[100] (in the last case gelatine sorbed such an amount of water long before the attainment of equilibrium swelling that T_g fell considerably below the experimental temperature).

The packing density of the wall layer can also be influenced by the conditions of its formation. Thus it has been shown[101] that, when a mixture of poly(methyl methacrylate) or polystyrene with a glass powder is obtained from solutions in different solvents (by evaporating the solvent), then, as a rule, with enhanced thermodynamic effectiveness of the solvent (estimated from the second virial coefficient of the osmotic pressure), the packing density of the polymer falls and the capacity for swelling increases correspondingly. This is due to the fact that in thermodynamically more effective solvents the macromolecules are in more extended conformation than in less effective solvents and it has been established by electron microscopy[102] that the initial conformation of the polymeric chains influences their interaction with the solid surface. It has also been observed[99] that the introduction of carbon black into a solution of natural rubber with subsequent evaporation of the solvent yields a mixture which swells much less than the mixture obtained by rolling. It is interesting to note that, after standing at room temperature, the density and degree of ordering of rubber in the mixture increase in the first tens of minutes after the termination of rolling (as shown by the decrease of the capacity for swelling).

Effect of the Solid Surface on Relaxation Processes in Wall Layers

The solid surface, which interacts with polymers and restricts by its steric effect the mobility of the macromolecules and supermolecular structural elements (as already mentioned above), retards the relaxation processes in the wall layer. The decrease in packing density in the polymer wall layer (which occurs at temperatures below T_g) has the opposite effect on relaxation processes, accelerating them[103-105]. The opposing effects of these factors which act simultaneously (the packing density also depends on the polymer – solid surface interaction) greatly complicates the observed situation.

The study of the temperature variation of the tangent of the dielectric loss angle of poly(methyl methacrylate) ($M \simeq 8 \times 10^4$) and polystyrene ($M \simeq 8 \times 10^5$) filled with a quartz powder having a particle diameter of about 4 μm showed[86] that filling (up to 24 vol.%—average distance between particles 4 μm) hardly affects the temperature of the maximum dipole – elastic losses in poly(methyl methacrylate) and greatly increases this temperature in polystyrene; at the same time the temperature of the maximum of the dipole – radical losses for [poly(methyl methacrylate)] falls. These results apparently contradict the dilatometric data showing a considerable increase of T_g for poly(methyl methacrylate) ($M_{visc} \simeq 3 \times 10^4$ and 6×10^6) filled by the same quartz powder[93], according to which the introduction of 30 wt.% of quartz increases T_g by 24°C. These findings found a natural explanation based on the concept of the packet structure of polymers[36,106], taking into account the contribution by the mobility of particular structural units of the polymer to the observed effect.

Not only segments and macromolecules but also various supermolecular formations (packets and in certain cases more complex species) interact with the solid surface, only a small fraction of the functional groups of the polymer being linked directly to the surface§. The side chains of the macromolecules containing the remaining functional groups are not directly influenced by the surface and therefore, on lowering the packing density with the associated increase of free volume[93], may exhibit in the vicinity of the solid surface a greater mobility than further away from it. The increase of the mobility is responsible for the decrease of the corresponding dielectric relaxation time, which is reflected in a lowering of the temperature of the maximum in dipole – radical losses[110].

As already mentioned above, the interaction of the solid surface with the functional groups of the polymers leads to a lowering of the mobility of the packets (and larger structural formations if they are present); Lipatov[86] in fact explained the observed increase of T_g of a polymer interacting with a solid surface by such lowering of the mobility of the packets.

The lack of dependence on the degree of filling of the temperature of the maximum dipole – elastic losses for the systems investigated[86] of shows, that, despite the decrease of the mobility of the packets, the mobility of the segments of the macromolecules in the wall layers does not change or changes only slightly.

The conclusion that there is a sharp decrease in the mobility of the structural elements of the wall layers of polymers also follows from the results of Deryagin and coworkers[111], who investigated the self-adhesion of thin

---

§ Since the thickness of the wall layer exceeds by several powers of ten the diameter of the macromolecules, only a small fraction of the functional polymer groups present in this layer can interact directly with the surface. This conclusion is also a direct result of a number of experimental studies[44,107-109].

layers of natural or butadiene rubbers deposited on quartz filaments. For films with a thickness less than 0.3 μm, the adhesive force was small and, in contrast to thicker films, hardly changed with the duration of contact. Such a weak dependence of the adhesive force on the duration of contact can be accounted for by a considerably reduced mobility of the structural elements in films with this thickness, which leads, on the one hand, to a virtually unchanged area of contact of the films and, on the other hand, to a suppression of the diffusion of macromolecules and their segments, which is known to be responsible[112] for the dependence of the effect of the adhesive bond on the duration of contact of the test specimens.

The results of studies on stress relaxation by the method described previously[114] in the system polyarylate N-1 (obtained from phenolphthalein and the chloride of isophthalic acid[113]) – copper powder showed that the initial activation energy for the relaxation process U_0[¶] diminishes with increasing degree of filling up to a certain limit and then remains virtually unchanged[117]. A similar variation of the activation energy for deformation with the degree of filling was established for the system polystyrene–fibre-glass[118]. The curve relating the constant γ to the filler content in compositions based on polyarylate N-1 passes through a minimum corresponding approximately to 40 wt.% of the copper powder[117]. This form of the curve may be due to the fact that for comparatively low contents of the filler, partial breakdown of the supermolecular structural elements produces a more uniform distribution of stresses despite the appearance of inhomogeneities such as the filler particles. When the filler content is greater than 40 wt.%, the effect of the concentration of stresses in the vicinity of filler particles predominates.

Effect of the Specific Features of the Relaxation Processes in Wall Layers on Certain Properties of Heterogeneous Polymeric Systems

The expansion of the spectrum of relaxation times towards longer times caused by the solid surface of the filler particles or of the support produces significant change in many properties of polymers.

The glass point of the majority of the systems investigated increases with the filler content. This happens in the systems polystyrene–fibre-glass[118], glass powder[122], kaolin[119], colloidal lead[120], and bentonite[121], poly(methyl methacrylate)–glass powder[101,122], bentonite[121,123,124], and kaolin[119], poly(vinyl alcohol), polyvinylbutyraldehyde, and poly(vinyl acetate)–fibre-glass[125], polyisobutylene–glass microspheres[85,126], polyurethane rubber–glass microspheres[126] and sodium chloride[127], polyamide 6,6–fibre-glass[128], phenolformaldehyde resins–highly dispersed iron powder[129] and graphite[130], poly(vinyl chloride)–graphite[130], alkyd-melamine resin–titanium dioxide[131], and epoxy-resin–titanium dioxide[132].

In many cases T_g is found to remain constant or to decrease on introduction of a filler. Thus T_g did not change or changed only slightly on introduction of carbon black into the following elastomers: natural rubber (up to 18 vol.% of carbon black)[133], polyisobutylene (up to 50%) [134], butadiene–styrene (SKS-30) and nitrile (SKN-40) vulcanised rubbers (up to 30 vol.%) [135,136], and fluororubber SKF-6 (up to 15 vol.%) [135]. Similarly chalk, kaolin, and lithopone (20 vol.%) hardly altered T_g for SKS-30 vulcanised rubber; chalk (20 vol.%) T_g had very little effect on T_g for SKN-40 vulcanised rubber[135,136]. Introduction of up to 50 parts by weight of aluminium powder into 100 parts of SKMS-10 butadiene–methylstyrene vulcanised rubber mixture did not increase T_g. [135]

The introduction of 10% of chalk into poly(methyl methacrylate) reduced T_g by 10 deg [137]; when the polymer is plasticised to some extent, the filling of polystyrene and poly(methyl methacrylate) with glass powder also lowers T_g. [122] Carbon black slightly decreased T_g for vulcanised *cis*-polybutadiene[134]. It has been reported that the introduction into polystyrene of 30% of iron powder appreciably lowered T_g for the composition[138], but the lowering is undoubtedly due to the degradation of the polymer on mixing with the filler.

There is no doubt that the absence of an effect or only a slight effect of inert fillers (chalk, kaolin, aluminium powder) on T_g for rubbers is due to the absence of a strong interaction between the rubber molecules and the surface of the fillers. The paucity of the experimental data precludes at present a reliable explanation of the independence of T_g for rubbers of the carbon black content over a fairly wide range of concentrations and there are even fewer grounds for an explanation of the lowering of the temperature as a result of the introduction of carbon black. Possibly the reason for this consists in the high flexibility of rubber macromolecules; another explanation is based on the hypothesis that in filled vulcanised rubber the density of cross-links is somewhat lower than in unfilled rubbers, or they are distributed less regularly[134].

Table 2. Effect of the filler (TiO_2) on the glass points of the vinyl acetate–vinyl chloride copolymer[109].

TiO_2 content, vol.%	0	1,1	3,0	4.8	6,5	12.8	19,1
Glass point, °C	30 and 77	32 and 73	27 and 62	28	48	51	51

* The volume concentration was calculated for 25°C.

An unusual effect of fillers on the glass point of copolymers was observed in dilatometric studies on the system vinyl chloride–vinyl acetate (9 : 1 molar ratio) copolymer–rutile (with a mean particle diameter of 0.220 μm) [109]. Table 2 shows that, for a comparatively low degree of filling (up to 4.8 vol.%), the upper T_g, due to the presence of vinyl chloride units, increases, while the lower T_g, reflecting the mobility of the vinyl acetate units, changes only slightly. Further increase of the filler content leads to some increase in the glass point (now a single point) for the system and finally to its independence of the degree of filling. According to the authors[109], the lowering of the upper T_g can be accounted for by the adsorption of the acetyl group on the filler and the dissociation of the intermolecular bonds formed by these groups, thereby increasing the mobility of the vinyl chloride units. An increase of

---

[¶] One of the constants of the familiar Aleksandrov–Gurevich equation[115,116] $\tau = \tau_0 \exp [(U_0 - \gamma\sigma)/RT]$, where τ is the relaxation time, σ the stress, T the temperature, R the gas constant, and U_0, γ, and τ_0 are constants characterising the relaxation properties of the polymeric material.

the TiO_2 content above 4.8 vol.% leads to the binding of a large number of acetyl groups and an increase of the lower T_g. One may expect that different effects of the filler on the upper and lower glass points will be shown also on filling other copolymers the units of the macromolecules of which differ appreciably in chemical nature and polarity.

The present author's investigations[139-141] established that the temperature variation of the strength of adhesive junctions tested under conditions of a very non-uniform distribution of stresses (tearing away, separation of separate layers, etc.) passes through a maximum in the region of glass formation. The presence of this maximum was explained by the fact that, on approaching the glass formation region from the low-temperature side, the rate of decrease of excess stresses increases in the vicinity of the apex of the growing crack as a result of the acceleration of relaxation processes and the decrease of such stresses leads to an increase of the load necessary to break the specimen. On further increase of temperature, the breaking load diminishes in consequence of the usual temperature-induced decrease of cohesive or adhesive strength. It was found that a decrease in the thickness of the layer of polymeric adhesive in the junction from 30 to 3 μm increased the temperature of the maximum strength of the junction by 10 deg. A similar effect was obtained when, instead of a homogeneous adhesive, a filled adhesive was employed, in which the average distance between the filler particles was close to 2 μm. [140] The observed increase in the temperature of maximum strength can be reasonably attributed to the retardation of relaxation processes in the vicinity of the solid surface.

The yield point (T_y) of filled polymeric systems is even more sensitive to filling than the glass point. This is because fairly large doses of filler in many cases produce a three-dimensional network apart from changing the number of conformations of the macromolecules and the spectrum of relaxation times[125,142-145]. The ability to form a three-dimensional structural network is clearly shown by fibrous and carbon black fillers. Thus the introduction into polystyrene of 20% fibre-glass hardly alters T_g but increases T_y by 40–50 deg [145,146]. The introduction of a filler increases T_y in the systems poly(methyl methacrylate)–fibre-glass[125], kaolin[119], and bentonite[121,124,137], polyisobutylene–Lavsan fibres[147] [a variety of nylon produced in the USSR (Ed. of Translation)], and mixed polyamide G-548–powdered metal oxides in large amounts (CaO, ZnO, MgO, and VO_3). [148] In certain systems the curve relating T_y to the filler content passes through a minimum in the region of low concentrations. This happens in mixtures of poly(methyl methacrylate) with kaolin[119], of polystyrene with bentonite[121], of polyisobutylene with very short (length 25–75 μm) Lavsan fibres[149], and of polystyrene containing 5% of a plasticiser with fibre-glass[146]; the introduction of 10% of chalk lowers T_y for poly(methyl methacrylate) approximately by 25 deg. [137] It may be that at least in some if not all systems the decrease of T_y is caused by the disruptive effect of the filler on the supermolecular structural formations in the polymer[149]. It must be emphasised that the introduction into polyisobutylene of longer Lavsan fibres (3 and 10 mm) as well as filling with fibre-glass of polystyrene not containing a plasticiser or containing more than 10% of a plasticiser inevitably leads to an increase of T_y.

It is known that in the deformation of homogeneous polymers in the state corresponding to rubber elasticity intermolecular bonds are broken as are a certain number of chemical bonds[150]. During the deformation of filled polymeric systems some of the polymer–filler bonds are also broken and in certain cases, in particular in rubbers filled with carbon black, also of filler–filler bonds[151]). After the removal of the load, the relaxation process tending to return the system to the initial state is accompanied by the reformation of the polymer–filler bonds (and also of the bonds between the filler particles in the relevant systems). Then part of the macromolecules and their aggregates are fixed in non-equilibrium positions. As a result, filled polymers exhibit some thixotropy[143,145,152]; the dissociation and reformation of the bonds and the fixation of a certain fraction of deformations of the rubber-elastic type result in a greater similarity of the behaviour of filled systems to that of polymeric materials under conditions of "chemical flow"[36,153-156].

Since the polymer interacts with the surface of solid particles, an increase of the degree of dispersion of the filler enhances its influence on the relaxation properties of the system. This was observed, in particular, in mixtures of poly(methyl methacrylate) or polystyrene with bentonite or kaolin[157] and on introduction of aminated bentonite into methyl methacrylate and subsequent polymerisation of the monomer[158]; for mixtures of polyethylene or butadiene–styrene or natural rubber with a number of mineral fillers, a linear relation has been established between certain properties associated with strength and deformation and the reciprocal of the filler particle dimensions (in the range of dimensions <0.2 μm) [159].

5. CHARACTERISTICS OF STRUCTURE-FORMATION PROCESSES IN POLYMER WALL LAYERS

In the previous section it was shown that wall layers differ from the bulk phase of a polymer in packing density and orientation and by a reduced rate of relaxation. These differences must influence also the structure-formation processes†. The looser packing and lower rate of relaxation should hinder both the formation of crystal nuclei and the growth of crystalline structures; on the other hand, orientation may favour crystallisation. The surface of an extraneous solid may affect the nucleus-formation processes also by influencing the change in surface energy on formation of a nucleus of the crystalline phase. As a result of the different contributions by these factors in various systems, in some cases the solid phase favours crystallisation to some extent while in others it hinders it up to complete suppression; in a comparatively small number of systems polymer crystals oriented in accordance with the crystal structure of the support (epitaxy) are formed at the crystal–support boundaries.

Promotion of Crystallisation in Wall Layers and Its Influence on the Properties of Polymeric Materials

In recent years the possibility of regulating the dimensions (and number) of spherulites in polymeric materials by introducing into the polymers a small amount of a finely dispersed additive[160-204] has been attracting the

---

† We are not considering the differences in the structures and properties of wall layers caused by the differences in the thermal history of these layers and the bulk phase of the polymer (in many cases the rates of change of the temperature of wall and bulk-phase layers differ significantly).

attention of investigators and technologists to a considerable degree. Kargin, Sogolova, and coworkers[174,175,182-184,187,190] showed that the mechanism by which these additives act involves the formation (by adsorption) on the surface of the solid particles of the nucleating agent of ordered regions of the polymer, which act as crystallisation centres. Such ordered regions are retained on the surface of the nucleating agent at high temperatures of the polymer melt when homogeneous crystallisation centres (in the bulk of the melt) are completely decomposed. When the number of added particles is sufficiently large, the number of heterogeneous centres of the surface greatly exceeds the number of homogeneous centres formed in the bulk of the polymer throughout the crystallisation. It has been shown that nucleus-forming agents do not affect the rate of the linear growth of spherulites. An increase in the number of crystallisation centres in combination with a constant rate of linear growth in fact leads to a decrease of the dimensions of the spherulites[‡] and an increase of the rate of crystallisation. It is interesting to note that nucleating agents which alter the dimensions of polyethylene spherulites altogether fail to influence the formation and dimensions of its single crystals.[190]

Several hundreds of compounds, mainly organic[161-163,166,168-175,178,183-186,195,202], have been tested as nucleating agents. These investigations established that the effectiveness of the nucleation depends primarily on the physicochemical nature of the polymer and the nucleator. The particles of a satisfactory nucleating agent should be readily wetted by the polymer melt above its melting point (T_f) and should interact fairly strongly with it below T_f, but they should not dissolve in the polymer at T_f or below it; the melting point of the nucleus-forming agent should be higher than that of the polymer[§]. The similarity between the crystal structures of the polymer and the nucleating agent is not essential.

It has been noted[206-208] that carbon black present in considerable amounts (tens per cent) promotes the crystallisation of vulcanised rubbers and in some cases[206] larger crystals with more regular shapes are formed in carbon-filled rubbers on extension than in unfilled vulcanised rubbers. Possibly the higher rate of crystallisation in vulcanised rubbers is due to the lowering of the density of cross-links in them as a result of the adsorption of vulcanising agents on the carbon black[208].

The considerable reduction of the dimensions of supermolecular formations achieved by the use of nucleating agents leads to a significant improvement of a number of properties of finished articles. There is an increase in transparency[160,164,169-172,176,178,185,186,197], strength and capacity for deformation and extension[169,173,176,181,183-187,198,200], stress resulting in the formation of a "neck"[176,200], resistance to long-acting[199] and impact loads[164,166,168-172,176,188], hardness[161,169,176,186], and resistance to wear[188] and there is a decrease in the coefficient of friction[164] and in the evolution of heat on cyclic application of loads[200]. The presence in the polymer system of nucleating particles stabilises the supermolecular structure and properties of the material at elevated temperatures[184]; it has been shown that thermal-oxidative degradation of polyethylene takes place more slowly when an antioxidant with a nucleating action is introduced into the polymer[201]. This is evidence that the use of nucleating agents improves certain technological properties of polymeric materials[169,176,186], but an increase in the viscosity of the polymer melt has also been observed following the introduction of nucleating agents[191-195].

Inhibiting Effect of the Solid Surface on the Crystallisation of Polymers in Wall Layers

Apart from the present author's investigations[90,209,210], it was possible to find only a few unsystematic data concerning the retarding effect of the solid surface on crystallisation in the adjacent layer of polymer. To account for the protecting effect of carbon black in the thermal oxidation of polyethylene, it was suggested[211] that near the surface of the carbon black particles the concentration of the amorphous polymer phase is above average. On the basis of a study of the mechanical properties of mixtures of polyarylate F-1 with powders of various metals and mineral fillers, Korshak and Slonimskii concluded that the filler particles to some extent prevent the natural development of structure-formation processes in the polymers[117,212]. In contrast to the effect of carbon black on vulcanised rubbers mentioned above, the introduction of 50 wt.% of particles of carbon black into non-vulcanised natural rubber reduced the rate of its crystallisation (the introduction of 2% of carbon black did not alter appreciably this rate)[213]. This observation is related to the conclusion, based[214] on the results of an electron-microscope study of mixtures of natural rubber with carbon black and activated silica gel, that in the vicinity of the particles of these fillers there is a layer 0.03 – 0.05 μm thick in which rubber does not crystallise[¶]. Schoon and Adler[214] suggested that crystallisation is hindered by mixtures adsorbed on the surface of the filler but did not put forward any facts in support[†].

The effect of the thickness δ of the polymer layer between two glass surfaces on the kinetics of the crystallisation of certain polymers has been investigated[90] by microcinematographic techniques. The Figure presents curves characterising this effect for isotactic polypropylene; similar curves were obtained for guttapercha and cellulose tribenzoate. Curve *2* shows that a linear rate of growth of spherulites, which is low at low values of δ, increases with δ, and, for a certain thickness of the film when the effect of the surface no longer operates, ceases to depend on δ.

The minimum in curve *3* describing the effect of δ on the rate C_3 of nucleus formation calculated per unit volume of the polymer can be explained as follows. C_3 is the sum of the rates of nucleation on the polymer – glass interface and in the bulk of the film. Nucleus formation on the surface is slower than in the bulk phase. In the region of low values of δ surface nucleation predominates; in this range of thicknesses, an increase of δ favours a more

---

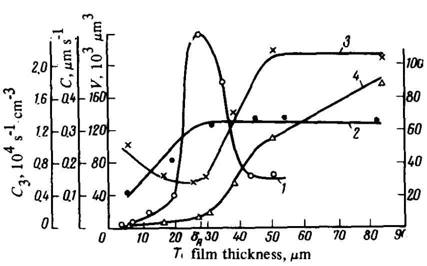
[‡] The method of modifying the structure and properties of polymeric materials by introducing into the polymer surface-active substances[205] yields a result similar in many respects, but it is based on a different mechanism of action on crystallisation.

[§] Amorphous polymers, liquids, and even air exhibit some nucleus-forming properties[184,187,192,193,195].

[¶] The photographs quoted by Schoon and Adler[214] are insufficient to determine the validity of this conclusion.

[†] There exist data of the opposite kind[199] — crystals of natural rubber which do not melt up to 125°C (the usual crystals of natural rubber melt[215] at 28°C) grow on the surface of amorphous carbon.

rapid increase in the volume of the film than in the number of nuclei and the C_3 curve moves downwards. The minimum in curve *3* corresponds to a thickness δ_A for which the contribution of the bulk-phase nucleus formation to C_3 begins to increase sharply. For sufficiently thick films, bulk phase nucleation plays a significantly more important role than surface nucleation and the number of nuclei in the film increases in proportion to its thickness, like its volume. This results in C_3 being independent of δ. This explanation is confirmed by the form of curve *4*, which shows the variation of the rate of nucleation C_S, calculated per unit surface, with δ. C_S is almost independent of film thickness up to δ_A and, when δ_A is reached, the slope of curve *4* rises sharply.



Effect of the thickness of the polypropylene layer, on the volume of spherulites (V, curve *1*), linear rate of growth of spherulites (C, curve *2*), and rate of nucleus formation (C_3, curve *3*—rate calculated per unit volume of the polymer; C_S, curve *4*—rate calculated per unit surface of the specimen).

The variation with thickness of the rate of linear growth of spherulites (curve *2*) and nucleus formation (C_3; curve *3*) is responsible for the maximum (observed in this investigation and previously[209]) in the curve relating the volume of the spherulites to δ (curve *1*) in the region of thicknesses for which the crystallisation behaviour of the polymer layer is determined by the crystallisation in surface layers.

In the case of isotactic polystyrene the linear rate of growth of spherulites depends on δ similarly, but, probably owing to the low rate of homogeneous nucleus formation in this polymer[183], C_S is independent of δ.

The decrease in the thickness of the polypropylene layers achieved by increasing the extent of its filling with glass powder influences the crystallisation kinetics in the same way as the decrease (described above) of the distance between the comparatively large glass surfaces confining the film.

The same surface may influence in opposite ways the crystallisation of different polymers. Thus the inhibiting effect of the glass surface on the crystallisation of certain polymers has been described. However, in the study of a film of polyamide 66 compressed between glass surfaces it was established that a decrease of its thickness from 30 to 10 μm results in an increase of the rate of linear growth of spherulites[216].

A solid surface can influence not only the rate of crystallisation processes but also the morphology of thin films. Thus in guttapercha[90,209,217], cellulose tribenzoate, and isotactic polypropylene and polystyrene[90,217] films with a thickness less than several micrometres imperfect crystalline formations were observed, while spherulites were formed in thick layers. For $\delta < 1-1.5$ μm, no structures could be observed at all with the aid of a light microscope. Similarly, films of many polymers with a thickness less than 0.1 μm on metallic surfaces did not exhibit a spherulite structure, in contrast to thicker films[218]. In films of mixtures of poly(ethylene adipate) or poly(ethylene sebacate) with poly(methyl methacrylate) or certain other amorphous polymers with a thickness amounting to several hundreds of ångstroms, no structure was observed either, while films with a thickness in excess of 20–30 μm were crystalline[219]‡.

The crystallinity of polypropylene films with a thickness of 1–1.5 μm was also not observed in the studies of polypropylene by differential thermal analysis and by X-ray diffraction[90,217]. Crystallisation does not occur in such thin films, possibly as a result of the strong interaction of the macromolecules, packets, and other structural elements of the melt with the solid surface, which is so pronounced that the activation energies for nucleus-formation processes become very high and the rates of these processes are correspondingly negligible. It is also possible that the change in surface energy in certain solid–polymer systems during the crystallisation of the polymer in thin layers is so great that this phase transition becomes thermodynamically unfavourable.

It may be supposed that in the presence of a very weak interaction between the polymer and the surface of an extraneous body the surface does not affect the crystallisation processes, when the interaction is very pronounced the processes are retarded, and for moderate interactions the surface exhibits a nucleus-forming effect§.

Epitaxy of Polymers

As already mentioned above, in certain systems thin polymer films have an epitactic structure. Thus on freshly cleaved (001) surfaces of the crystals of certain alkali metal halides, usually sodium chloride, oriented crystallisation of polyethylene[222-226], isotactic polypropylene[226,227], poly-3,3-bischloromethylcyclobutane (pentone), poly(ethylene terephthalate), isotactic polystyrene[226], polyoxymethylene and polyoxypropylene[227], polyamides 6.66 and 610,[228] polyamides 7 and 8,[229] polyacrylonitrile[230], and polyurethane[229] was observed. Epitactic crystallisation of polyacrylonitrile on a freshly etched surface of crystalline quartz has also been observed[231]. A case of the epitaxy of polyethylene on stretched films

---

‡ These relations are closely related to the findings described above (p. 704) namely a sharp transition from a structured film of silver telluride on glass to a structureless form when the thickness is 300–350 Å and the variation of the structure of vacuum-deposited films of a number of metals with their thickness in the range up to 70–80 Å; a similar variation is observed also for tantalum up to a thickness of 250 Å.[220]

§ This hypothesis is fully consistent with the results of the calculations of Moazed[221], who showed that a stable epitactic nucleus of a low-molecular substance can be formed from its vapour only when the angle between the surfaces of the nucleus and the substrate is in the range 10–40°.

of polyoxymethylene has been described, the needlelike crystals of polyethylene being oriented perpendicular to the direction of the stretching of the support[232].

The crystallisation of polyethylene, pentone, and polystyrene (on alkali metal halides) begins with the formation of needlelike crystals arranged along the [110] direction on the support; subsequently these crystals grow, giving rise to an oriented network structure. Polypropylene forms squares with dimensions of up to 20 × 20 μm with the sides parallel to the [100] and [010] directions of the salt crystals and poly(ethylene terephthalate) and polyoxymethylene form long (up to 100 μm for PETP and up to 6 μm for POM) needles along the [110] direction on the alkali metal halide crystals. It has been established by electron diffraction that molecular chains in polyethylene, polystyrene, and pentone crystallites are oriented preferentially parallel to the surface along the [110] direction of the support, while in polyoxymethylene, polypropylene, and polyoxypropylene crystallites the chains are arranged perpendicular to the surface of the support.

Two explanations are possible for the orienting effect of the surface of alkali metal halide crystals[227]. One possibility involves the attribution of the orienting effect to sequences of similarly charged ions arranged along the [110] direction of the (001) plane. Another explanation is based on the nucleus-forming effect of dislocations, formed in large amounts when small crystals are cleaved, extended along the [110] direction; each of these dislocations contains a multiplicity of sections with an enhanced surface energy.

For epitaxy (as for the nucleus-forming agent–polymer systems), there is apparently no obligatory requirement of a correspondence between the dimensions of the crystal lattices of the support and the polymer. Thus polyethylene exhibits epitaxy on lithium fluoride, sodium chloride, sodium bromide, sodium iodide, potassium chloride, and potassium iodide despite the considerable differences in the lattice dimensions of these crystals (the lattice constant a_0 for the crystals varies from 4.01 to 7.05 Å).[226]

As a result of the presence in polymers of supermolecular formations, each of which behaves in many processes as a single kinetic entity, the wall layers of the polymer at its boundary with the solid surface differ in some of their properties from the bulk-phase layers and their thickness may exceed that of wall layers in low-molecular substances.

The relaxation processes in the wall layers of the polymer are retarded. This is because the solid surface in contact with the polymer not only restricts the volume accessible to the kinetic units of the polymer in their thermal motion, but also combines with them via intermolecular interaction forces. Interaction of the solid surface with the polymer can result in a partial orientation of the polymer in the wall layer and also in a lowering of the packing density.

The different contributions of these factors (rate of relaxation and orientation and packing density) in various polymer–solid surface systems give rise to a wide range of effects of solid surfaces on relaxation and structure-formation processes in wall layers of polymers. In some systems the solid surface promotes to some extent the crystallisation of the polymer while in others it either retards or even completely suppresses the crystallisation.

Further theoretical and experimental studies of wall layers of polymers are essential, in particular with the aid of methods such as nuclear magnetic resonance, infrared spectroscopy, radiothermoluminescence, and a combination of these methods, and also electron and light microscopy together with the investigation of the mechanical, electrical, and physicochemical properties of heterogeneous polymeric systems. Such study will not only throw light on certain fundamental characteristics of polymers but will help develop technological processes for the preparation of new materials of importance in engineering.

Aminoacids and Peptides Containing the Di-(2-chloroethyl)amino-group

L.Rasteikiene, M.Dagiene, and I.L.Knunyants

The review deals with studies on the relation between the antitumour activity of di-(2-chloroethyl)amino-derivatives of aminoacids and peptides and their chemical structure.
The bibliography includes 236 references.

CONTENTS

I. INTRODUCTION

The incorporation of the di-(2-chloroethyl)amino-group in biologically important compounds such as aminoacids, peptides, sugars, and various metabolites or physiologically active substances frequently yields antitumour preparations. Research on the synthesis and properties of cytotoxic derivatives of aminoacids and peptides is being pursued on a particularly wide front.

The properties of the di-(2-chloroethyl)amino group and the mechanisms of biological alkylation have been fairly widely described in Ross's monograph[1]. Among later publications, mention should be made of Wheeler's paper[2].

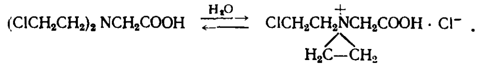
II. DI-(2-CHLOROETHYL)AMINOACIDS AND THEIR DERIVATIVES

The most thoroughly investigated representatives of this series of compounds are di-(2-chloroethyl)glycine (R = H) and di-(2-chloroethyl)alanine (R = CH_3):

$$(ClCH_2CH_2)_2NCHRCOOH\,.$$

Analogous derivatives of other aminoacids are also known (Table 1)†.

In water these acids are readily cyclised into aziridinium salts, which are less stable than the ions derived from di-(2-chloroethyl)methylamine (Embichin)[19]:



$$(ClCH_2CH_2)_2NCH_2COOH \xrightleftharpoons{H_2O} ClCH_2CH_2\overset{+}{N}(CH_2CH_2)CH_2COOH \cdot Cl^-\,.$$

It is believed that the alkylating properties of such acids depend on the pH in the tissues[20]. When the distance between the carboxyl and the di-(2-chloroethyl)amino-group is increased, the reactivity of the chlorine atoms in these acids rises. This accounts for the enhanced toxicity of di-(2-chloroethyl)-β-alanine[12].

Di-(2-chloroethyl)aminoacids with free carboxyls are less toxic than their amides or esters, the toxicity of which

---

† We believe that this group of compounds should be regarded as Embichin derivatives rather than those of aminoacids; nevertheless the terminology of the authors quoted is retained in the review.

approaches that of di-(2-chloroethyl)methylamine (Embichin), probably owing to the presence of the free electron pair at the nitrogen atom of the di-(2-chloroethyl)amino-group. In compounds with a carboxy-group, this electron pair is protonated to give a zwitter ion[21,22]. For this reason, the chlorine atoms in di-(2-chloroethyl)-aminoacids are less mobile than in other di-(2-chloroethyl)amino-derivatives[22].

It has been suggested that the formation of a metal complex via the unshared electron pair of the nitrogen atom would reduce the toxicity of di-(2-chloroethyl)aminoacids. Therefore tests were made on the biological activity of complex copper(II) salts of di-(2-chloroethyl)glycine and di-(2-chloroethyl)alanine. The toxicity of these compounds was in fact reduced, but their antitumour activity was not improved[23].

After a single administration to mice with Yoshida sarcoma, di-(2-chloroethyl)alanine temporarily reduced the amount of nucleic acids in the cancer tissues as well as the number of the cancer cells themselves[24]. Di-(2-chloroethyl)glycine and di-(2-chloroethyl)alanine prolonged the life of mice with leukaemia *L* 1210 by 20 and 19% (if the activity of amethopterin is taken as 100%).[25] The amides of these acids are more effective although their chemotherapeutic index is lower. *In vitro* they showed a lower cytotoxic activity compared with the free acids, which the authors[11] believe to be due to the stability of the amides in water.

The antitumour activities of the diastereoisomers of di-(2-chloroethyl)alanine amide were compared but no differences were found in the biological properties of the L- and D-forms[26].

Di-(2-chloroethyl)alanine arrests the incorporation of labelled aminoacids into the proteins of the tumours in rats affected by Walker carcinosarcoma 256; this constitutes their advantage over Embichin, which arrests the incorporation of aminoacids also into the normal tissues of the organism. Di-(2-chloroethyl)alanine arrests the incorporation not only of alanine but also of other aminoacids: lysine and methionine. This shows that it does not behave as an antimetabolite but as an alkylating agent. The incorporation of labelled aminoacids into the acid-insoluble fraction of nuclear proteins is arrested particularly markedly, which is evidence of the importance of this fraction in the growth of tumours[27].

It has been shown that the phenyl ester of di-(2-chloroethyl)-β-alanine has a powerful mutagenic activity[13].

Di-(2-chloroethyl)glycine, di-(2-chloroethyl)-α-alanine and its amide, and di-(2-chloroethyl)-β-alanine all exhibited cholinergic and leukopenic activity[28].

Comparison of the antitumour properties of di-(2-chloroethyl)aminoacids revealed that di-(2-chloroethyl)-alanine has the best chemotherapeutic index[12,29]. It was tested in several clinics in Japan on leukaemic patients[30-33]. Clinical tests on 69 patients with different forms of cancer showed that objective improvement was observed only in the case of lymphoma. The authors concluded that under clinical conditions di-(2-chloroethyl)alanine is not superior to Embichin[34].

Other di-(2-chloroethyl)aminoacids have been less widely investigated. They too are probably not promising anticancer agents.

N-Di-(2-chloroethyl)phenylalanine and its amide showed no antitumour activity at all[14]. 4-Di-(2-chloroethyl)-amino-L-proline was less effective than Sarkolysin in tests on a wide spectrum of tumours[35]. Analogous lysine derivatives—a mixture of N_α- and N_ϵ-di-(2-chloroethyl)-lysine called "Lysepsin"—were also investigated. It was shown that the L-form is less active than Sarkolysin[36,37]. This preparation arrested the incorporation of [^{14}C]lysine and phenylalanine into the tumour proteins of sarcoma 45 in rats[38].

Di-(2-chloroethyl)glycyl-6-aminopenicillanic acid was less toxic but showed also a less pronounced antitumour activity than di-(2-chloroethyl)glycine.[9]

Several unsaturated di-(2-chloroethyl)amines and di-(2-chloroethyl)-derivatives of unsaturated aminoacids and peptides with the general formula[39]

$$(ClCH_2CH_2)_2N{-}\overset{R}{C}{=}CHR'$$

where R = H, $COOCH_3$, $COOC_2H_5$, $CONH_2$, CO–Gly–OC_2H_5, CO–Val–OC_2H_5, CO–L-Phe–OCH_3, CO–L-Tyr–OC_2H_5, $COOC_2H_5$, or *p*-$NO_2C_6H_4$ and R′ = $COOCH_3$, $COOC_2H_5$, $COO(CH_2)_nCH_3$ (*n* = 2, 4, or 6), $CONH_2$, H, or C_6H_5, were synthesised. Most of these compounds did not show antitumour activity.

On oxidation, di-(2-chloroethyl)aminoacids are converted into the corresponding *N*-oxides[40]:

$$(ClCH_2CH_2)_2N(O)CHRCOR'$$

where R = H or CH_3 and R′ = OH, OC_2H_5, or NH_2. The antitumour activity of these derivatives was lower than that of the corresponding di-(2-chloroethyl)aminoacids. In water they are converted into 1,2-dimethyleneoximmonium ions[19]. *N*-Di-(2-chloroethyl)hydrazinocarboxylic acids,

$$(ClCH_2CH_2)_2NNHCH(R)COOH,$$

where R = CH_3, C_2H_5, or n-C_3H_7, have been synthesised, but their biological properties have not been described[41].

III. AMINOACID DI-(2-CHLOROETHYL)AMIDES

A series of known di-(2-chloroethyl)amides of aminoacids and their *N*-acylated derivatives are listed in Table 2.

Aminoacid di-(2-chloroethyl)amides are unstable, rearranging to esters in the presence of traces of moisture[44-49]:

$$NH_2CH(R)CON(CH_2CH_2Cl)_2 \rightarrow NH_2CH(R)COOCH_2CH_2NHCH_2CH_2Cl \cdot HCl\ .$$

Aminoacid amides containing the di-(2-chloroethyl)amino-group in the benzene ring have been synthesised[49-52]:

$$RNH(R')_2CONHC_6H_4N(CH_2CH_2Cl)_2\text{-}p\ ,$$

where R = H or $C_6H_4(CO)_2$ and R' = CH_2, CH_2CH_2, CH_3CH, $CH_2CONHCH_2$, or C_6H_5CH.

Glycine and phenylalanine derivatives did not exhibit antitumour activity[50]. Among glutamic acid derivatives[53], the compound with a free γ-carboxy-group was less active than the derivative in the L-form with a free α-carboxy-group. However, the activities of these compounds were lower than that of Melphalan[54].

A number of aminoacid di-(2-chloroethyl)hydrazides are known:

$$RNHCH(R')CONH{-}N(CH_2CH_2Cl)_2 ,$$

where R = C_2H_5OCO and R' = H, $(CH_3)_2$, $CH(CH_3)_2$, $CH_2CH(CH_3)_2$, $CH(C_2H_5)CH_3$, $(CH_2)_2COOH$, or $CH_2C_6H_4OH$-*p*, but the biological properties of these compounds have not been described[55].

Several hydrazones of *p*-di-(2-chloroethyl)aminobenzaldehyde have been synthesised from the hydrazides of acetamidoacids:

$$(ClCH_2CH_2)_2NC_6H_4CH{=}N{-}NHCOCH(R)NHCOCH_3 ,$$

where R = $CH_2C_6H_5$, $CH_2C_6H_4OH$-*p*, $CH_2CH_2SCH_3$, or CH_2-β-indole. They did not exhibit antiviral activity[56].

Among compounds of this group, *N*-di-(2-chloroethyl)-carbamoylaminoacids, which exhibit antitumour activity, were examined:

$$(ClCH_2CH_2)_2NCONHCH(R)COOC_2H_5 ,$$

where R = H, $CH_2CH(CH_3)_2$, CH_2COOH, $CH_2C_6H_5$, or $(CH_2)_2SCH_3$.[57] Under the action of water, they are rearranged to urethanes:

$$ClCH_2CH_2NCH_2CH_2OCONHCH(R)COOR' \cdot HCl .$$

NN-Di-(2-chloroethyl)carbamoyl derivatives of serine and threonine are also known[58]:

$$(ClCH_2CH_2)_2NCOOCH(R)CH(NH_2)COOC_2H_5 ,$$

where R = H or CH_3.

Tests of the antitumour activity of *O*-derivatives of serine in relation to Walker carcinosarcoma 256 showed that the L-form is more active than the racemate. *O*-Derivatives of threonine are inactive[58]. The study of the diffusion of these compounds through the membrane of intestinal cells showed that, despite their different antitumour activities, the permeability of the membrane in relation to them is the same[59]. This finding casts doubt, according to Evered and Randall[59], on the theory of the cytotoxic group carrier according to which the aminoacid component of the molecule behaves as a kind of transferring agent for the di-(2-chloroethyl)amino-group across the cell membrane and the antitumour activity is regarded as a direct function of the permeability.

O-Di-(2-chloroethyl)carbamoylserine arrested the incorporation of labelled methionine and serine into the nucleoproteins of Walker's tumour 256.[60]

IV. AROMATIC AMINOACIDS AND THEIR PEPTIDES CONTAINING DI-(2-CHLOROETHYL)AMINO-GROUPS IN THE BENZENE RING

The first aminoacid in which the di-(2-chloroethyl)-amino-group was introduced into the benzene ring was phenylalanine. This resulted in antitumour preparations (Sarkolysin and Melphalan) which have since been used in many oncological clinics in the treatment of certain forms of neoplasm. The high antitumour activity of these preparations stimulated a whole series of investigations on the specific synthesis of antitumour compounds containing the phenylalanine residue.

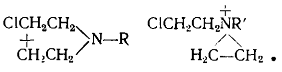
1. *p*-Di-(2-chloroethyl)aminophenylalanine

p-$(ClCH_2CH_2)_2NC_6H_4CH_2CH(NH_2)COOH$

This compound was synthesised and studied almost simultaneously by two groups of investigators: in England by Bergel and Stock as the L-enantiomer (Melphalan, abbr. Mel.), the D-enantiomer (Medphalan, abbr. Med.), and the DL-racemate (Merphalan, abbr. Mer.)[61,62] and in the Soviet Union by Khokhlov and coworkers under Larionov's supervision as the racemate under the name "Sarkolysin"[63] (abbr. Sark.).[61-71]

Together with high antitumour activity in relation to a number of transplantable tumours, Sarkolysin exhibited also high toxicity[72]. Sarkolysin is employed in clinical practice in the treatment of certain forms of neoplasm. However, it does not affect the majority of neoplasms. Sarkolysin has also shown a carcinogenic effect more pronounced than that of Embichin[73]. For a description of the biological and clinical tests of this widely known preparation, see Larionov[72]. This review deals only with the comparison of Sarkolysin with other similar compounds.

Sarkolysin contains the di-(2-chloroethyl)amino-group in the aromatic ring. It has been reported that, in contrast to aliphatic di-(2-chloroethyl)amines, such compounds undergo the alkylation reaction vis an S_N1 mechanism. An attempt was made to explain thereby the reduced toxicity of aromatic di-(2-chloroethyl)amines, including Sarkolysin[1]. However, a paper was published recently[74], where it was shown experimentally that *p*-di-(2-chloroethyl)-aminophenylalanine does not alkylate via a carbonium ion but via the formation of an unstable immonium ion, as in the case of aliphatic derivatives:



The rate of hydrolysis of the chlorine atoms in Sarkolysin and its derivatives has been investigated in aqueous alcohol[75-78]. It has been shown that the chlorine atoms in Sarkolysin are hydrolysed at unequal rates[78] and that chloride ions retard this process[73,77]. A spectrophotometric determination of Sarkolysin has been described[79].

In an acid medium Sarkolysin is readily oxidised with formation of a comparatively unstable free radical:

$$(ClCH_2CH_2)_2\,NC_6H_4CH_2CH\,(NH_2)\,COOH\ .$$

It is suggested that the same radical is formed in tumour cells[80].

The mechanism of the biological action of Sarkolysin and the selectivity of its action on certain tumours have not so far been elucidated.

It has been noted that D-Sarkolysin is deaminated and inactivated by D-amino-oxidase, the activity of which is appreciably greater in rat kidney tissue than in sarcoma 45. This is thought to account for the reduced antitumour activity of D-Sarkolysin on this tumour strain compared with the L-form[81].

Three modifications of radioactive Sarkolysin have been synthesised: (1) the derivative labelled in the aminoacid part of the molecule—*p*-di-(2-chloroethyl)amino-DL-[β-^{14}C]phenylalanine[82]; (2) the derivative labelled in the cytotoxic part of the molecule—*p*-di-(2-chloro-[β-^{14}C]-ethyl)amino-DL-phenylalanine[82]; (3) Melphalan labelled with tritium[83].

In a study of the distribution in the organism of normal rats and rats with a grafted tumour of Sarkolysin labelled in the aminoacid[84] and cytotoxic[85] groups and also of Melphalan labelled with tritium[83] it was shown that all the preparations administered in toxic doses are equally distributed in the rat organism. Selective accumulation of radioactivity in the tumour proteins was not observed.

It has been noted that labelled Sarkolysin is not converted in the organisms into tyrosine or phenylalanine[84]. In contrast to Sarkolysin, the labelled product of the hydrolysis of Melphalan [*p*-di-(2-hydroxy[β-^{14}C]ethyl)amino-L-phenylalanine] is not incorporated into the proteins of the blood or liver of rats; this suggests that Sarkolysin acts on proteins as an alkylating agent[86]. Other investigators arrived at a similar conclusion[34,87].

Melphalan and Sarkolysin arrest the incorporation of labelled aminoacids (phenylalanine, lysine, or methionine) into tumour proteins, particularly into the acid-insoluble fraction of proteins in the cell nucleus[34,39].

In a study of the effect of Melphalan on the incorporation of labelled methionine into tumour proteins of rats *in vivo* and *in vitro* in a tissue culture, it was concluded that different processes take place under the action of Melphalan in the organism and in an isolated tumour cell. Moreover, Melphalan causes a more pronounced arrest than its D-enantiomer of the incorporation of labelled methionine into tumour proteins[88]. It also arrests the incorporation of labelled aminoacids into microsomal proteins[89].

Sarkolysin alters the activity of enzymatic systems in the organism[2]. It reacts with cytochrome c *in vitro*[90] and acts in the organism on the enzymes and proteins containing sulphydryl groups[91]. Melphalan reacted with blood albumen *in vitro*[92]. Like other bifunctional alkylating agents, it affects the metabolism of nucleic acids or nucleoproteins[34,93-96]. In a study of the kinetics of the reaction of Sarkolysin with DNA *in vitro*, it was shown that Sarkolysin reacts with the phosphate groups of nucleic acids[97].

Sarkolysin exhibits mutagenic activity. It damages the gene locations in Drosophila which are resistant to the action of X-rays[98].

The antitumour activities of the L- and D-forms of *p*-di-(2-chloroethyl)aminophenylalanine were investigated, but the difference between the biological effects of the two forms has not as yet been completely elucidated. Possibly the difference depends on the nature of the tumour itself[99,100]. The L-enantiomer gave rise to marked leukopenia in rats, although its dose was smaller by a factor of 4 than that of its D-enantiomer[101]. In contrast to Sarkolysin, Melphalan lowered the amount of DNA in the intestine of experimental animals and was more toxic[102].

A number of derivatives of *p*-di-(2-chloroethyl)amino-phenylalanine substituted in the carboxy- and amino-groups have been synthesised (Table 3):

$$p\text{-}(ClCH_2CH_2)_2\,NC_6H_4CH_2CH\,(NHR)\,COR'.$$

The antitumour activity and toxicity of the lower esters differ little from those of Sarkolysin itself[101,124]. On the other hand, the *N*-acyl derivatives proved to be less toxic and the spectrum of their antitumour activity (their effect on various curable tumour strains in rodents) differed from that of Sarkolysin[101,124-128].

In a study of the reaction of *N*-formyl- or *N*-acetylsarkolysin with blood plasma it was found that these preparations are bound to the plasma to the extent of 60%, while Sarkolysin is bound only to the extent of 24%.[129]

Labelled *N*-[^{14}C]formylsarkolysin was synthesised and its metabolism in the rat organism was investigated[111]. When administered in a dose eight times as large as that of Sarkolysin, *N*-formylsarkolysin arrested the incorporation of labelled phosphorus into nucleic acids in rat spleen, into Erlich ascites carcinoma of mice, and into the DNA of Yoshida sarcoma[130].

N-Formylsarkolysin and *N*-acetylsarkolysin proved to be active mutagenic agents for Actinomyces. Their activity greatly exceeds that of Sarkolysin[131].

Preliminary data on the application of *N*-formylsarkolysin in clinical practice have been established. It has proved active in the treatment of the seminoma of testicles[132]. *N*-Methylsarkolysin was also tested under clinical conditions. Its antitumour activity proved to be similar to that of Sarkolysin[133].

2. Peptides of *p*-di-(2-chloroethyl)aminophenylalanine

The comparatively low selectivity of the antitumour action of Sarkolysin and its simplest derivatives made it desirable to search for more effective preparations. The research begun by Knunyants and Kil'disheva and coworkers in 1956 on the synthesis of Sarkolysin peptides proved to be particularly fruitful[110]. Somewhat later Bergel and Stock published a paper describing the synthesis of peptides of *N*-benzoyl-melphalan[119]. Knunyants and Kil'disheva and coworkers investigated mainly the peptides of Sarkolysin formed via its carboxy-group, while Bergel and coworkers studied Melphalan peptides formed via its amino-group.

So far many peptides of *p*-di-(2-chloroethyl)aminophenylalanine, where it is the *N*- or *C*-terminal aminoacid or is located in the centre of the chain, have been synthesised and investigated. Peptides with a free amino-group of Sarkolysin or another aminoacid as well as those where the amino-group is protected by an *N*-acyl group are known (Table 4).

It was shown that the antitumour activity of these peptides is almost independent of whether the terminal aminoacid has a free carboxy-group or whether the latter is protected by the formation of an ester or an amide[101,105].

The role of the free amino-group in Sarkolysin peptides proved to be very important. The investigators arrived at the interesting conclusion that the toxicity and antitumour activity of Sarkolysin peptides containing a free amino-group are indistinguishable from those of Sarkolysin itself. This phenomenon was noted in a series of peptides where Sarkolysin is the *N*-terminal aminoacid[147] and the peptides where the free amino-group is in the residue of another aminoacid[53,101,105,145]. The only exception was the ethyl ester of Sarkolysylphenylalanyl-leucine, which, in the form of a salt of methylenedi-(*β*-hydroxynaphthoic) acid, showed a superior effect to that of Sarkolysin in relation to sarcoma 45 and Jensen sarcoma[148].

When the amino-group in peptides with *N*- or *C*-terminal Sarkolysin is protected by an *N*-formyl or *N*-acetyl residue, the biological activity is altered sharply. Such peptides are much less toxic than Sarkolysin and their chemotherapeutic indices are better[105,149,150]. One preparation of this series—the ethyl ester of *N*-acetylsarkolysylvaline (Asaline) was tested under clinical conditions on 49 patients with different forms of cancer. It proved to be less toxic than Sarkolysin, had a less pronounced effect on the blood generating system, and showed an objective effect on reticulocytic sarcoma and myeloma[151].

It is interesting to note that, although the biological activity of Sarkolysin differs from that of its *N*-acyldipeptides, the mobility of the chlorine atoms remains the same[101,105].

Comparison of the biological activities of *N*-formyl- and *N*-acetyldipeptides of Sarkolysin on 35 strains of experimental tumours did not show an appreciable difference between their effects[152].

The dipeptide of *N*-formylsarkolysin, where the *C*-terminal aminoacid was tryptophan, proved to be completely inactive[149] even in large doses[152].

A difference was noted between the antitumour activities of the ethyl ester of α- and β-aspartyl-melphalan on the one hand and the analogous $\alpha\gamma$-glutamyldipeptides[53].

The optical configuration of the molecule has a marked effect on the antitumour activity of Sarkolysin in peptides. Five pairs of optically pure ethyl esters of Melphalan dipeptides were synthesised. Tests on Walker carcinosarcoma 256 showed that the dipeptides with the LL-configuration are a hundred times more active than those with the DL-configuration[146]. Analogous results were obtained for the enantiomers in the aspartyl- and glutamyl-melphalan dipeptide series[53].

All possible optical isomers of the dipeptides of *N*-acetylsarkolysin with phenylalanine, methionine, and valine have been tested. Among the dipeptides with phenylalanine and methionine, the isomers with the LL-configuration proved to be the most active and those with the DD-configuration the least active. The dipeptide with valine exhibited similar activity in relation to mouse sarcoma 37, but the same peptide proved to the most active in the LD- and DD-configurations in relation to rat sarcoma[153].

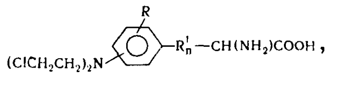
The following polypeptides of *p*-di-(2-chloroethyl)-phenylalanine have also been synthesised: $(\text{Sark.})_n$ (n = 10, 50–100),[154,155] $(\text{Mel.})_n$,[155] and $(\text{Am})_n-\text{Mel}-\text{OEt}$, where Am = Gly, Ser, Phe, Leu, SerGlu, or TyrGlu; acids with the L- and D-configurations were employed. Comparison of the antitumour properties of these polymers showed that preparations containing aminoacids with the D-configuration are less active[155]. The Sarkolysin polymer also proved to be less active[154].

3. *o*- and *m*-Di-(2-chloroethyl)aminophenylalanines

To investigate the effect of isomerism on biological activity, *o*-di-(2-chloroethyl)amino-DL-phenylalanine[104,156,157], the *meta*-derivative[65,158–161], the L- and D-enantiomers of the *meta*-isomer, and the *N*-formyl derivative[161] were synthesised. The *ortho*-isomer was more toxic than Sarkolysin and showed a similar spectrum of antitumour activity[163]. The chlorine atoms in the *ortho*- and *meta*-isomers are more easily hydrolysed than in the *para*-isomer[77]. The *meta*-isomer was more effective than Melphalan in relation to experimental tumours[158,164–166]. In a study of the antitumour activity of enantiomers of the *meta*-isomer, no difference was found between the L- and D-forms[162].

Preliminary clinical tests with the *meta*-isomer of Sarkolysin on 40 patients with cancer in different locations showed that this preparation differs little from Sarkolysin itself[167].

Other derivatives of di-(2-chloroethyl)aminophenylalanines and aminoacids with the general formula (Table 5)



were also synthesised.

Derivatives of *p*-di-(2-chloroethyl)aminophenylalanine containing halogens in the benzene ring did not show antitumour activity[185] and only 3-di-(2-chloroethyl)amino-2-fluorophenylalanine had an antitumour activity superior to that of Sarkolysin[186].

Tests on the antitumour activities of β-alanine derivatives [*p*- and *m*-di-(2-chloroethyl)aminophenyl-β-alanines] showed that they are more toxic and less effective than the analogous derivatives of α-alanine[65,174,175,187].

[a] In the general formula $NH_2 = H$; [b] ethyl ester; [c] L-enantiomer; [d] D-enantiomer; [e] *N*-acetyl; [f] CH_3 instead of H in the general formula; [g] $(ClCH_2CH_2)_2NCOO$ group instead of $(ClCH_2CH_2)_2N$.

In an attempt to find aromatic di-(2-chloroethyl) amines with a more selective activity, *p*-di-(2-chloroethyl)aminophenylalkanoic acids were synthesised[176]:

$$p\text{-}(ClCH_2CH_2)_2NC_6H_4(CH_2)_nCH(NH_2)COOH \quad (n = 0;\ 2;\ 3).$$

L- and D-forms of *p*-di-(2-chloroethyl)aminophenyl-α-aminobutyric acid were isolated. The L-isomer showed an antitumour activity in relation to mouse melanoma five times greater than the D-isomer, but its activity did not exceed that of Melphalan[71]. The analogous derivative of α-amino-Δ-phenylvaleric acid proved to be very toxic (n = 3). Comparative tests on *p*-di-(2-chloroethyl)aminophenyl-α-aminobutyric acid (under the name "aminochlorambucil") and Melphalan were carried out under clinical conditions on 47 patients with different forms of cancer. Both preparations proved to be equally active in relation to reticulosarcoma but did not exhibit any activity in other types of cancer[100].

A number of homologues of *S*-*p*-di-(2-chloroethyl)aminophenylcysteine showed a weak antitumour activity[180,188]:

$p\text{-}(ClCH_2CH_2)_2N(CH_2)_nC_6H_4S(CH_2)_mCH(NH_2)COOH \quad (n = 0;\ 1;\ \ m = 1;\ 2).$

A low antitumour activity of the corresponding *N*-benzylleucine derivative was noted[189]:

$p\text{-}(ClCH_2CH_2)_2NC_6H_4CH_2NHCH(COOEt)CH_2CH(CH_3)_2.$

4. Di-(2-chloroethyl)aminomethylenephenylalanines

All three isomers (*o*-, *m*-, and *p*-) of di-(2-chloroethyl)aminomethylenephenylalanine

$(ClCH_2CH_2)_2NCH_2C_6H_4CH_2CH(NH_2)COOH$[185,190]

and 2′-di-(2-chloroethyl)aminomethylene-5′-nitrophenylalanine[191] were synthesised and their biological activity was tested. The antitumour activities of these compounds proved to be equal to that of Sarkolysin[190].

5. Di-(2-chloroethyl)aminotyrosines

In view of the important role of tyrosine in the living organism and its enhanced content in melanoma, di-(2-chloroethyl)amino-derivatives of tyrosine were synthesised and investigated (Table 6):

Table 6.

Position of $(ClCH_2CH_2)_2N$ group	R	References to syntheses	Position of $(ClCH_2CH_2)_2N$ group	R	References to syntheses
2-	4-OH	192	4-	2-OCH_3	168
3-	4-OH	193	4-	2-OCH_3[e]	168
3-	4-OH[a]	193	4-	2-OCH_3[e, f]	168

3-	4-OCH_3[c, d]	195	5-	2-OCH_3	196
4-	2-OH	168	4-	H[h]	197

[a] L-enantiomer; [b] di-(2-chloroethyl)aminomethylene group in benzene ring; [c] *N*-phthaloyl; [d] methyl ester; [e] *N*-formyl; [f] peptide with ethyl ester of DL-valine; [g] peptide with ethyl ester of DL-phenylalanine; [h] *p*-di-(2-chloroethyl)aminophenoxy-group in benzene ring.

The chlorine atoms in 2-di-(2-chloroethyl)aminotyrosine are hydrolysed more rapidly than in Sarkolysin[193].

Di-(2-chloroethyl)aminomethylenetyrosines proved to be active in relation to Erlich ascites carcinoma in mice[194].

The antitumour activity of 2-hydroxy-4-di-(2-chloroethyl)aminophenylalanine and its alkoxy-derivatives fell with increasing size of the alkoxy-group. The 9-methoxy-derivative, which was most active, was tested under clinical conditions on 30 cancer patients[168].

N-Formyl dipeptides of this compound with ethyl esters of valine and phenylalanine were synthesised[168].

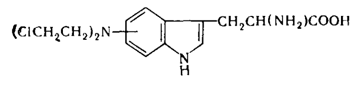
O-[*p*-Di-(2-chloroethyl)aminophenyl]-DL-tyrosine

$p\text{-}(ClCH_2CH_2)_2NC_6H_4OC_6H_4CH_2CH(NH_2)COOH$

initially did not exhibit any activity on the growth of Walker carcinosarcoma 256.[197] However, when tested in large doses on six strains of transplantable tumours, its antitumour activity proved to be considerable[144].

6. Di-(2-chloroethyl)aminotryptophans

In view of the important biological properties of tryptophan, di-(2-chloroethyl)amino-derivatives of this aminoacid were synthesised. At the present time three DL-isomers of this type are known: 5-di-(2-chloroethyl)-aminotryptophan[198,199] and 6- and 7-di-(2-chloroethyl)-aminotryptophans[200]:



Comparison of the antitumour activities of these compounds showed that the 7-isomer is more active in relation to sarcoma 180 than the 5-isomer[200]. However, the 5-isomer is more readily available and therefore its biological properties have been more thoroughly investigated. The DL-form of this compound was tested on 32 strains of transplantable tumours and its activity proved to be higher than that of Embichin and close to that of Melphalan[199]. It arrested the incorporation of labelled aminoacids into the proteins of Walker carcinosarcoma 256, particularly into the proteins of the cell nucleus[201].

The distribution of tritium-labelled 5-di-(2-chloroethyl)amino-DL-tryptophan in the organism of rats with a grafted Jensen sarcoma was investigated. The highest radioactivity was found in the kidneys and the lowest in the tumour[202].

5-Di-(2-chloroethyl)aminotryptophan was tested in clinical trails. It proved to be toxic but the authors concluded that it may be employed as a chemotherapeutic preparation for the treatment of melanoma[203].

7. Di-(2-chloroethyl)amino-derivatives of Non-natural Aminoacids

Derivatives of aromatic unsaturated aminoacids were synthesised:

$p\text{-}(ClCH_2CH_2)_2NC_6H_4CH{=}C(NHCOC_6H_5)COR,$

where R = OCH_3,[204] NH_2, NHC_2H_5, NHC_6H_{11}, Gly-OH, Gly-OEt, DL- and L-Ala-OH, L-Val-OH, L-Leu-OEt, and DL-Phe-OEt. However, no information about the antitumour activities of these compounds has been reported[119].

1-Amino-6(and 7)-di-(2-chloroethyl)aminoindan-1-carboxylic acids, 2-(and 1-)amino-7-di-(2-chloroethyl)-amino-1,2,3,4-tetrahydro-2-(and 1-)naphthoic acids, and the hydantoins derived from them were synthesised and tested. They all showed a slight antitumour activity[104,205].

Heterocyclic derivatives of alanine have been synthesised: β-[7-(4-)-di-(2-chloroethyl)aminobenzo-1,2,3-thiadiazol-4-yl-(and -5-yl)]alanine[206] and β-[5-di-(2-chloroethyl)aminobenzimidazol-2-yl]alanine and their esters[207], but data on their antitumour activities have not so far been reported.

V. AMINOACIDS AND PEPTIDES ACYLATED BY *p*-DI-(2-CHLOROETHYL)AMINOPHENYLALKANOIC ACIDS

A large number of *N*-di-(2-chloroethyl)aminoacids and their derivatives of the type $(ClCH_2CH_2)_2NC_6H_4(CH_2)_nCO$-aminoacid (its ester or peptide), with $n = 0-3$, have been synthesised and investigated. The initial di-(2-chloroethyl)aminophenylalkanoic acids exhibit antitumour activity but are toxic. A clinical application has been found for *p*-di-(2-chloroethyl)aminophenylbutyric acid, which is used under the name "Chlorobutin", "Chlorambucil" or "Leukeran" in the treatment of certain forms of leukaemia[72].

1. Aminoacids Acylated by Di-(2-chloroethyl)aminobenzoic Acids

Glycine[208,209], γ-aminobutyric acid[208], DL-[210] and L- and D-glutamic acids[211,212], the ethyl esters of these acids, and the mono-ethyl ester of the α-(*p*-ethoxycarbonylanilide) of glutamic acid[213] were acylated by *o*-, *m*-, and *p*-di-(2-chloroethyl)aminobenzoic acids.

The *ortho*-isomer of di-(2-chloroethyl)aminobenzoyl-L-glutamic acid proved to be most active in relation to Erlich ascites tumour in mice and in a tissue culture. It also showed a high activity in relation to microbiological systems. The activity of the free acids did not differ from that of the ethyl esters. Among the compounds tested, the *para*-D-isomer proved to be the least active.

The *ortho*-isomers are the most active in the case of di-(2-chloroethyl)aminobenzoylglycine and γ-aminobutyric acid[208].

The toxicity of *p*-di-(2-chloroethyl)aminobenzoyl-6-aminopenicillanic acid, which shows antibacterial activity, is lower than that of the initial *p*-di-(2-chloroethyl)aminobenzoic acid[9].

2. Aminoacids and Peptides Acylated by *p*-Di-(2-chloroethyl)aminophenyl-acetic, -propionic, and -butyric Acids

A number of such compounds have been synthesised (Table 7). One derivative of 6-aminopenicillanic acid acylated by *p*-di-(2-chloroethyl)aminophenylacetic acid is known[9].

Only the derivatives of natural aminoacids showed antitumour activity. *p*-Di-(2-chloroethyl)aminophenylacetylhexafluorovaline and -phenyl-β-alanine proved to be inactive[221]. Natural aminoacids and their esters or peptides acylated by *p*-di-(2-chloroethyl)aminophenylacetic acid are as a rule less toxic than the initial acid (by a factor of 6–19). The activity of these compounds as well as its spectrum depends on the *C*-terminal aminoacid[221–223] as in the case of *N*-acylsarkolysin peptides.

p-Di-(2-chloroethyl)aminophenylacetyl-DL-phenylalanine (Lophenal) proved to be an effective chemotherapeutic preparation for the treatment of patients with cancer of the uterus and certain forms of leukosis[224].

NN'-$\alpha\alpha'$-di-[*p*-di-(2-chloroethyl)aminophenylacetamido]propionic acid[219]

$$[(ClCH_2CH_2)_2NC_6H_4CH_2CONH]_2C(CH_3)COOH$$

showed antitumour activity. This preparation was tested under the name "Lonin 4" in clinical trials and proved to be effective in the treatment of malignant diseases of the lymphoreticular system but it also had a supressive effect of haemopoeisis[225].

Only one derivative of *p*-di-(2-chloroethyl)aminophenylpropionic acid—*NN'*-$\alpha\alpha'$-di-[*p*-di-(2-chloroethyl)aminophenylpropionamido]propionic acid—is known, but its biological properties have not been investigated[217].

Among the aminoacids acylated by *p*-di-(2-chloroethyl)aminophenylbutyric acid, antitumour activity was investigated only for the ethyl ester of valine. It proved to be less toxic than Chlorobutin itself but less active than the analogous derivative of phenylacetic acid[226].

A limited number of studies have been made in which the biological activities of Sarkolysin peptides were compared with those of peptides acylated by di-(2-chloroethyl)aminophenylalkanoic acids.

[a] L-enantiomer; [b] n = 2.

Thus *p*-di-(2-chloroethyl)aminophenylacetylphenylalanine showed a different spectrum of antitumour activity than the ethyl ester of *N*-formylsarkolysylphenylalanine[147]. A Sarkolysin peptide with a free amino-group (the ethyl ester of sarkolysylphenylalanyl-leucine) showed a more potent antitumour activity than the ethyl ester of *p*-di-(2-chloroethyl)aminophenylacetylphenylalanyl-leucine[148].

The ethyl ester of *p*-di-(2-chloroethyl)aminophenylacetylmethionine suppressed the regeneration of the liver like the initial *p*-di-(2-chloroethyl)aminophenylacetic acid or Chlorobutin, while Sarkolysin itself and certain dipeptides of *N*-acetylsarkolysin did not show such activity[227].

VI. AMINOACIDS ACYLATED BY *p*-DI-(2-CHLOROETHYL)PHOSPHORAMIDIC ACID

The higher antitumour activity and chemotherapeutic index of Endoxan (Cyclophosphamide, Cyclophosphan)—a cyclic ester of *NN*-di-(2-chloroethyl)-*N'*-γ-hydroxypropyldiamide of phosphoric acid[72]—stimulated research on other derivatives of this type including derivatives formed with aminoacids. A number of compounds with the general formula $(ClCH_2CH_2)_2NP(O)RR'$ were synthesised (Table 8).

The biological properties of only two compounds of this series have been described[234]. The compound with R = R' = Gly-OEt showed antitumour activity. The analogous thio-derivative was inactive.

Cyclic derivatives of di-(2-chloroethyl)aminophosphorylaminoacids and peptides have also been synthesised (Table 9):

$(ClCH_2CH_2)_2NP(O)OCH(R)CH(COR')NH$.

Other compounds synthesised are the cyclic derivative of phenylserine with the DL-, LL-, and DD-configurations[236] and polyserine containing di-(2-chloroethyl)aminophosphoryl groups[236].

Tests on the antitumour activity of such cyclic derivatives of serine, serylserine, and polyserine with various optical configurations showed that they exhibit an appreciable antitumour effect and that the optical configuration is very important for biological activity[71,220]. The antitumour activity is also related to the length of the peptide component of the molecule. The polyserine derivative was less toxic and its chemotherapeutic index was higher than that of the analogous serylserine derivative[54].

Cyclic *ON*- and *SN*-derivatives of serine[54,218] and cysteine[185] respectively proved to be less active.

---o0o---

The above review reveals certain regularities in the behaviour of Sarkolysin peptides and aminoacids and peptides acylated by di-(2-chloroethyl)aminophenylalkanoic acids. Sarkolysin peptides with a free amino-group exhibit a low selectivity in their effect, destroying to an equal extent not only tumour but also normal cells of the organism. Protection with *N*-formyl and *N*-acetyl groups sharply increases the selectivity of action of the compounds. The carboxy-group is not so important. Compounds with non-natural aminoacids have almost no antitumour activity.

The steric configuration of the aminoacids is extremely important. In the majority of the cases investigated peptides of the L-series showed much more pronounced antitumour activity. However, the mechanism of the biological action of these compounds has still been little investigated.

Research on the specific synthesis of antitumour preparations is only beginning and it is to be hoped that the combined efforts of chemists, biologists, and physicians in this interesting and important field will lead to useful discoveries.

The Favorskii Rearrangement

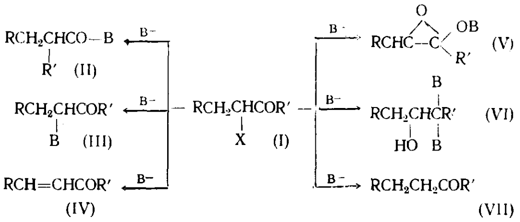
A.A.Akhrem, T.K.Ustynyuk, and Yu.A.Titov

The skeletal rearrangement of α-halogeno-ketones, which is known as the Favorskii rearrangement, is met most frequently in aliphatic monocyclic, and polycyclic halogenated ketones. This molecular rearrangement is used in the synthesis of branched carboxylic acids and *cis*-αβ-unsaturated acids and for obtaining smaller rings in alicyclic and to a less extent heterocyclic compounds. The sterochemistry and the mechanism of the Favorskii rearrangement are also considered, these being of great interest for theoretical organic chemistry. A list of 261 references is included.

CONTENTS

I. INTRODUCTION

The rearrangement of the carbon skeleton of α-halogeno-ketones (I) (here and subsequently X denotes a halogen and B^- the anion of a base), which occurs under the influence of bases, is termed the Favorskii rearrangement. Various derivatives of carboxylic acids (II) containing the same number of carbon atoms as in the initial ketone can be formed depending on the base used and the number of halogen atoms in the ketone. The α-halogeno-ketones are extremely reactive compounds, and in the presence of bases they yield also products in which the halogen has been replaced (III) or eliminated (IV), oxides (V), α-hydroxy-acetals (VI), saturated ketones (VII), etc. Which reaction occurs depends on the structure of the initial ketone and the conditions.



The rearrangement of the carbon skeleton of α-halogeno-ketones was described for the first time as a general reaction by Favorskii[1-3] in 1892, although isolated examples of such rearrangements had been known earlier[4-6]. There have been several reviews[7-12] of the Favorskii rearrangement, covering the literature up to 1959.

II. THE FAVORSKII REARRANGEMENT AS A SYNTHETIC METHOD

The chief synthetic uses of the Favorskii rearrangement are the preparation of branched carboxylic acids, the stereospecific synthesis of *cis*-αβ-unsaturated acids, ring contraction in alicyclic and heterocyclic compounds, and the modification of steroids.

The Favorskii rearrangement is usually effected by adding the halogeno-ketone to a solution or a suspension of the base. Hydroxides of alkali or alkaline-earth metals, alkoxides, alkali-metal carbonates and hydrogen carbonates, ammonia, and amines are used as the bases. The first two groups are strong bases, and the latter two weak bases. The solvents used can be divided into protic (water, alcohols) and aprotic (ether, dioxan, dimethoxyethane). The course of the reaction depends primarily on the structure of the initial halogeno-ketone; hence no general recommendations can be given on the choice of optimum conditions for the reaction: they must be chosen separately for each type of ketone.

1. Aliphatic Halogeno-ketones

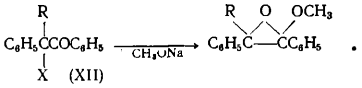
This is the most numerous group of halogeno-ketones. Favorskii's first work on α-monochloro-ketones was done as early as 1901[13]. The principal synthetic application of these compounds is to the preparation of branched aliphatic acids, which can be illustrated by the preparation of derivatives of αα-dimethylpropionic acid from the ketone (VIII: X = Br, Cl). Sodium methoxide in ether, the prop-2-oxide, and the phenoxide give yields of 61%, 64%, and 47% of the corresponding esters[14,15]. The free acid can be obtained in 30–40% yield by reaction of the ketone (VIII) with alkalis[16,17]:

$$(CH_3)_2\underset{X}{C}COCH_3 \rightarrow (CH_3)_3CCO_2R \quad \text{(VIII)}$$

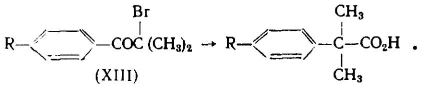
Increasing the degree of substitution at the α-carbon atom (to which the halogen is attached) usually favours the Favorskii rearrangement by lowering the rate of side-reactions, whereas substitution on the α′-atom hinders rearrangement[14,18-20]. Nevertheless, these principles are structurally equivalent: i.e. independently of the position of the halogen relative to the keto-group in compounds (IX) and (XI), the action of bases on them leads to derivatives of the same acid (X). Thus when $R^1 = R^2 = C_6H_5$, the action of sodium ethoxide on the ketone (IX) yields the acid (X: $R = C_2H_5$) in 85% yield, and on ketone (XI) in 69% yield[21]. Similar results are obtained with ketones of the types (IX) and (XI) when $R^1 = C_6H_5$, $C_6H_5CH_2$, Alk and $R^2 = H$[19,22-25]. In this case substitution of the halogen (Cl by Br) has no significant effect on the yield of the acid (X).[26,27] The equivalence of the α- and α′-positions is important in the synthetic application of the Favorskii rearrangement: it enables ketones to be brominated directly and the resulting mixture of α-bromo- and α′-bromo-isomers to be subjected to rearrangement without separation, with the formation of a single reaction product[20].

(IX) (X) (XI)

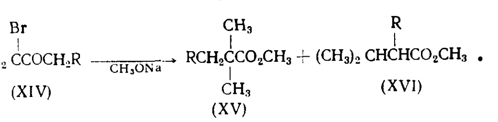
In the case of the ketones (VIII), (IX), and (XI) it has been shown that the Favorskii rearrangement takes place with both alkylated and arylated ketones. However, when aryl substituents are present on both α- and α′-carbon atoms (XII: X = Cl, Br; R = H, Alk, Ar), rearrangement is replaced by formation of the corresponding alkoxy-oxides[26,28–32]:



In the above examples the α-halogeno-ketones contained an α′-hydrogen atom. However, cases are known in which rearrangement takes place in ketones containing no α′-hydrogen, e.g. in compounds of the type (XIII: R = H, C_6H_5):[33–35]

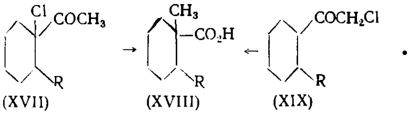


Sometimes the Favorskii rearrangement of monohalogeno-ketones yields a mixture of structural isomers. Thus ketones of the type (XIV) gave a mixture of the esters (XV) and (XVI), the proportion of the latter ester increasing from 16% to 80% with increase in the bulk of the alkyl radical R from methyl to isopropyl[36]:



Possible reasons for this are discussed in Section III.

Many halogenated ketones undergoing the Favorskii rearrangement contained the keto-group in a side-chain attached to a cyclic residue. An example is the rearrangement of compounds of the type (XVII: R = H, CH_3) to the corresponding acids (XVIII)[15,37,38]. In conformity with the above equivalence of the α- and α′-positions the same acids are formed from isomeric ketones of the type (XIX: R = H, CH_3)[39,40] (see, however, Ref. 41):

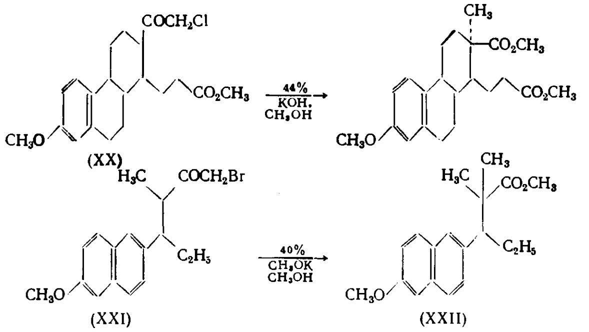


(XVII) (XVIII) (XIX)

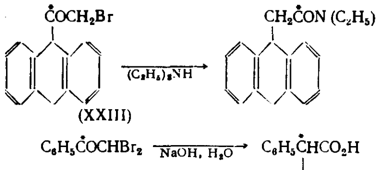
Replacement of the chlorine atom in (XIX) by bromine favours the Favorskii rearrangement but not side-reactions[39]. Other results indicate[37] that brominated ketones of the type (XIX) form only hydrolysis products with bases.

When R = CH_3, two isomeric acids (XVIII) can be formed from (XVII). It was shown initially that with sodium benzyloxide in ether the rearrangement proceeds strictly stereospecifically, with inversion of configuration at the carbon atom to which the halogen is attached[42]. Later, however, it appeared that this stereospecificity (which was not altogether exact) is observed only in aprotic solvents such as dimethyoxyethane and dimethyl sulphoxide, whereas in methanol or water a mixture of approximately equal quantities of the two possible isomers (XVIII) is formed; the proportions of the latter depend also on the concentration of the base[43–45]. Rearrangement of the isomeric chloro-ketone (XIX: R = CH_3) yields approximately equal quantities of the isomeric acids (XVIII: R = CH_3) in both protic and aprotic solvents[40].

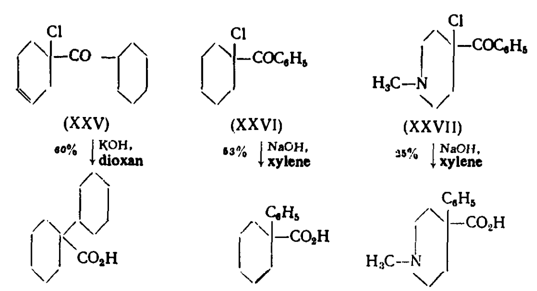
Rearrangement of the ketones (XVII) and XIX) is of interest primarily as a method for synthesising angularly methylated tertiary acids. Such structures are present in abietic, marrianolic, and allenolic acids, and therefore the Favorskii rearrangement may prove useful for their synthesis. An example of its application to marrianolic acids is the rearrangement of the chloro-ketone (XX).[46] The resulting diester on Dieckmann cyclisation gave an isomer of oestrone ("oestrone-c"). Application of the Favorskii rearrangement to the synthesis of allenolic acids is illustrated by the conversion of the bromo-ketone (XXI) into the methyl ester (XXII).[47]



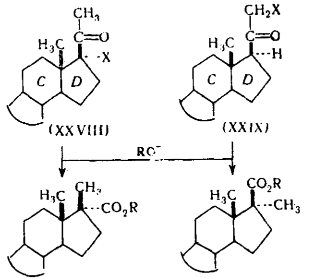
On rearrangement of the bromo-ketone (XXIII) in which the carbonyl group is labelled, in the presence of diethylamine as base, the tracer passes into the carbamoyl group, which demonstrates unambiguously that the carbon skeleton has undergone rearrangement[48]. These results are especially valuable, since only skeletal changes should be included in the range of Favorskii rearrangements. Therefore numerous examples of the reactions of α-halogeno-aldehydes with bases, for example should not be termed Favorskii rearrangements, since the carbon skeleton is not reorganised in this case, the analogy being purely formal. A tracer technique has shown that the carbon skeleton undergoes no rearrangement when the dibromo-ketone (XXIV) is converted into the corresponding hydroxy-acid[49]. Hence caution must be exercised in including reactions of dibromo-ketones of the types (XXXVII) and (XLV) in the range of the Favorskii rearrangement.



Ketones containing cyclohexyl groups (XXV)[50–52] and aryl groups (XXVI and XXVII)[53–57] undergo Favorskii rearrangement when boiled with alkalis in aprotic solvents, to form cyclic acids which are difficult to obtain by other methods. The reaction of piperidine chloro-ketones of the type (XXVII) has found application for the synthesis of the analgesics demerol and β-pethidine[54,56,58]. In optically active compounds of the types (XXVI) and (XXVII) the Favorskii rearrangement is accompanied by racemisation[54-57]. Replacement of chlorine by bromine in the ketone (XXVI) lowers the yield of the corresponding acid[59].

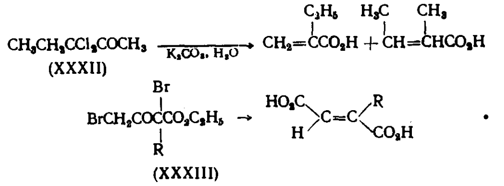


The keto-group is present in the side-chain also in 20-oxosteroids containing a halogen atom at $C_{(17)}$ (XXVIII) and $C_{(21)}$ (XXIX). In conformity with the principle of the equivalence of α- and α'-positions, rearrangement of both ketones gave good yields of a mixture of the epimeric 17ξ-methyletianic acids (XXX) and (XXXI).[60-63] The composition of the mixture depends on the structure of the initial steroid, the nature of the halogen, and the conditions of reaction. In most cases the isomer (XXXI) is formed predominantly, with maintenance of the configuration at $C_{(17)}$, both from (XXVIII: X = Br)[64-66] and from (XXIX: X = F, Cl, Br)[64,67-70]. The nature of the solvent is probably the decisive factor in the stereochemistry of the rearrangement. For example, 17α-bromopregnenolone acetate forms almost pure isomer (XXX) with sodium methoxide in dimethoxyethane, but almost pure isomer (XXXI) in aqueous potash[71].



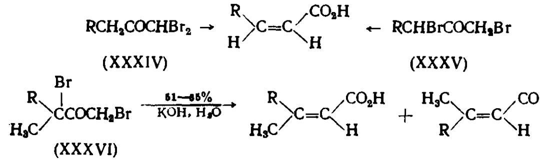
By using the product (XXXI) of the Favorskii rearrangement as starting material it was possible to accomplish a transition to highly active analogues of gestagens[63,72] and corticosteroids[70,73,74] containing a 17α-methyl group.

Di- and poly-halogeno-ketones, as well as monohalogeno-ketones, can undergo the Favorskii rearrangement. Derivatives of acrylic acids are formed from dihalogenoketones, an example being provided by the reactions of compounds (XXXII)[2,75,76] and (XXXIII: R = H, $CH_2COOC_2H_5$)[4,6,77]:



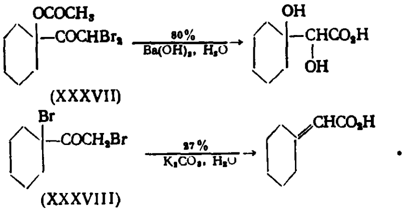
The same acids are formed in 50–90% yields by the action of bases on $\alpha\alpha$- and $\alpha\alpha'$-dihalogeno-ketones (XXXIV and XXXV: R = Alk, cycloalkyl): i.e. the equivalence of α- and α'-positions is observed here[78-82].

Therefore dibromination of ketones followed by Favorskii rearrangement (without separation of the isomers) provides a method for synthesising $\alpha\beta$-unsaturated acids[83]. The rearrangement of ketones of the type (XXXIV) and (XXXV) usually proceeds stereospecifically to yield *cis*-isomers of substituted acrylic acids. In the presence of bases, however, they readily isomerise to the more stable *trans*-isomers, which may distort the stereochemical picture of the reaction[78,80].

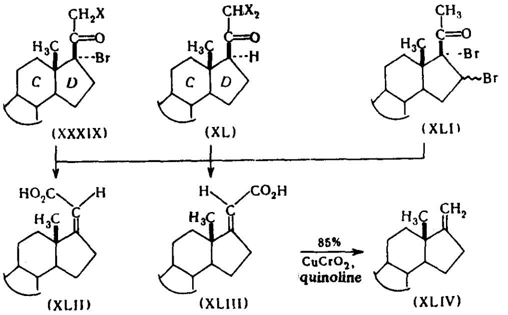


With branched dibromo-ketones of the type (XXXVI: R = Alk) the stereospecificity of the rearrangement disappears, and approximately equal quantities of the two possible isomers are formed[84,85].

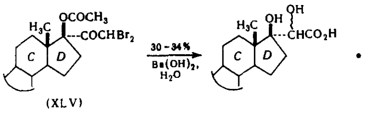
Dibromo-ketones involving a side-chain attached to a six-membered ring have also been subjected to the Favorskii rearrangement. Examples are given below for $\alpha\alpha$-dibromo-ketones of type (XXXVII)[86,87] and $\alpha\alpha'$-dibromo-ketones of type (XXXVIII)[85,88,89]:



Examples of dihalogeno-ketones in which the side-chain is attached to a five-membered ring are the steroid $\alpha\alpha'$-, $\alpha\alpha$-, and $\alpha\beta$-disubstituted ketones—(XXXIX: X = Br, I)[62,68,88,90-93], (XL: X = F, Br)[67,94], and (XLI)[95] respectively—all three types giving high yields (up to theoretical) of mixtures of the isomeric acids (XLII) and (XLIII), in which the latter isomer probably predominates[96]. These acids are used to build up a corticoid side-chain[97,98], and their decarboxylation yields a 17-methylene-steroid (XLIV)[93]. Compounds similar to (XLIV) can be obtained also by the Favorskii rearrangement of 17α-bromo-20-oxo-steroids (XXVIII) under oxidising conditions capable of detaching the carbonyl group from the intermediate cyclopropanone derivative[99].



Dibromo-ketones like (XLV) containing a 17α-side-chain yield on rearrangement mixtures of diastereoisomeric 17β,20ξ-dihydroxy-acids[100,101], which are readily interconvertible under mild conditions:

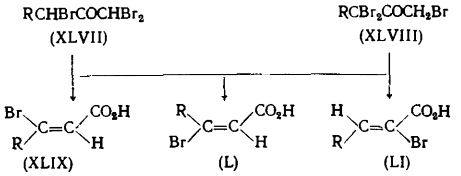


(XLV)

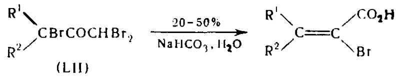
The Favorskii rearrangement of trihalogeno-ketones produces halogenated acrylic acids. With the simplest example, a 1,1,3-trihalogenoacetone (XLVI: X = Cl, Br), the only product is the *cis*-β-halogenoacrylic acid[102]:

(XLVI)

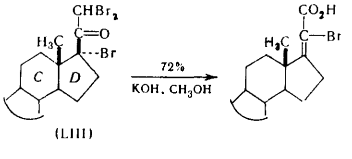
With the higher homologues—e.g. the ketones (XLVII) and (XLVIII)—structural and steric specificity is usually lost, a mixture of β- and α-halogenoacrylic acids (XLIX)–(LI) being formed, the proportions of which depend both on the bulk of the alkyl radical R and on the reaction conditions[103,104]. Replacement of one or two bromine atoms in (XLVII) or (XLVIII) by chlorine yields predominantly β-chloro-analogues of the acids (XLIX) and (L), which indicates that bromine is more readily eliminated than chlorine under the conditions of the Favorskii rearrangement[104,105].



Only α-halogenoacrylic acids are formed by rearrangement of tribromo-ketones of type (LII) containing a branched carbon chain. When $R^1 \neq R^2$, a mixture of roughly equal quantities of geometric isomers is formed[103,106]. The analogous steroid tribromo-ketones of type (LIII) yield α-bromo-acids on treatment with alkalis[96,106-108].

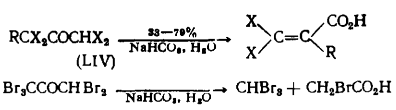


(LII)



(LIII)

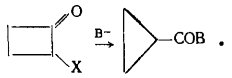
Tetrahalogeno-ketones (LIV: R = H, Alk; X = Cl, Br) undergo a Favorskii rearrangement with the formation of ββ-dihalogenated acrylic acids[109,110]. Under the conditions of the rearrangement penta- and hexa-halogenoketones are cleaved by a halogenoform reaction, as indicated below for pentabromoacetone[111,112].



2. Monocyclic Halogeno-ketones

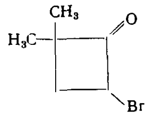
The Favorskii rearrangement has been widely applied to monocyclic halogeno-ketones to prepare compounds containing one less atom in the ring. The reaction is applicable to alicyclic and heterocyclic compounds containing 4–13 atoms in the ring.

Rearrangement of cyclobutane derivatives yields cyclopropanecarboxylic acids. An example is the reaction of the 2-halogenocyclobutanones (LV), which occurs extremely readily when X = Br and rather less readily when X = Cl[113-116]:

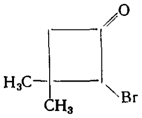


(LV)

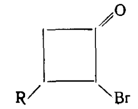
The substituted cyclobutanones (LVI), (LVII), (LVIII: R = CH_3, OC_6H_5), and (LIX) react similarly to (LV)[115,117-119]. The reactions of the disubstituted ketones (LVIII) and (LIX) occur stereospecifically with formation of the *cis*-isomers of the monosubstituted cyclopropanecarboxylic acids. The αα'-disubstituted ketone (LIX) undergoes a Favorskii rearrangement, whereas αα-substituted ketones (LX) and (LXI) undergo ring cleavage in the presence of bases with the formation of γγ-di- and ααγγ-tetra-bromobutyric acids[115]. It has not proved possible to obtain benzocyclopropene derivatives by a Favorskii type of rearrangement[120].



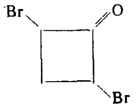
(LVI)



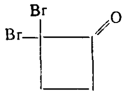
(LVII)



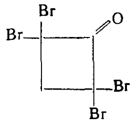
(LVIII)



(LIX)

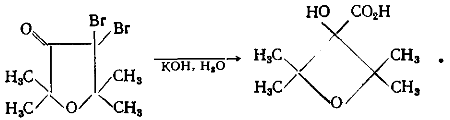


(LX)



(LXI)

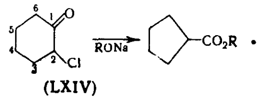
α-Halogenated cyclopentanones do not undergo the Favorskii rearrangement, but form products of polycondensation, substitution, or dehalogenation depending on the conditions[121-126]. However, condensed bromo-ketones of the type (CIX) (see below) yield the cubane system: i.e. five-membered rings are converted into four-membered rings. A similar transformation may occur when the dibromo-oxofuran (LXII) is treated with alkalis[126]:



(LXII) (LXIII)

However, the structure of the product (LXIII) cannot be regarded as completely proved.

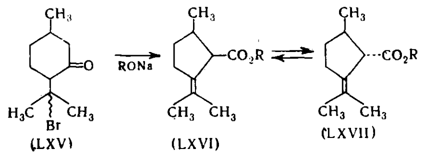
The Favorskii rearrangement of α-halogeno-ketones containing a six-membered ring has been the most thoroughly studied. A typical representative, 2-chlorocyclohexanone (LXIV), forms derivatives of cyclopentanecarboxylic acid:



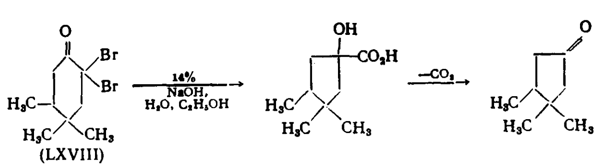
(LXIV)

A comparative study of the activity of various bases (alkalis[121,124], alkoxides[127–133], and alkyl sulphides[131,132,134–136]) has shown aliphatic branched-chain alkoxides to be the most efficient. The 2-bromo- and 2-fluoro-analogues of (LXIV) give smaller yields of the reaction products[67,137]. Alkyl homologues of (LXIV) containing substituents in positions 3–6 also undergo the Favorskii rearrangement[34,124,138–144], whereas 2-chloro-2-methylcyclohexanone does not undergo rearrangement[42,145].

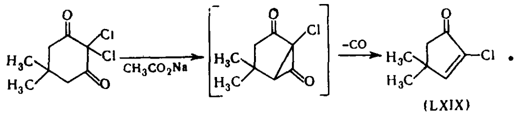
Dibromo-ketones containing a six-membered ring have been studied in especial detail in the case of pulegone dibromide (LXV)[146–153]. The pulegenic acid formed by its rearrangement can be used as a valuable intermediate for the synthesis of cyclopentanoid terpenes, which occur widely in plants and in insects. Both *cis*- and *trans*-isomers of pulegenic acid (LXVI) and (LXVII) can be obtained[154]. An attempt was made to use the stereospecificity of the reaction to establish the mechanism of the Favorskii rearrangement[155]. However, it was shown that the ratio of the isomeric pulegenic acids (LXVI and LXVII: R = H) is not a result of the rearrangement itself but depends on their ease of mutual isomerisation under the influence of bases (the equilibrium mixture contains 26% of the *cis*- and 74% of the *trans*-isomer) and on the slower rate of hydrolysis of the sterically hindered *cis*-ester (LXVI: R = CH_3, C_2H_5) in comparison with the *trans*-ester (LXVII: R = CH_3, C_2H_5). In several cases, therefore, the *trans*-acid, corresponding to the more readily hydrolysed ester (LXVII), is formed exclusively[156,157].



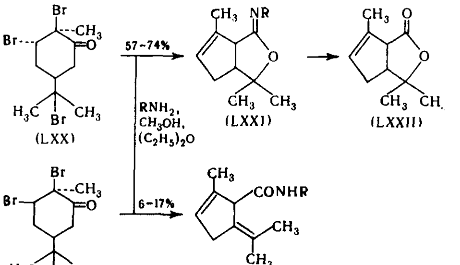
2,2-Dibromocyclohexanones of type (LXVIII) react with alkalis to form 2-hydroxy-acids, decarboxylation of which provides an easy route to the corresponding cyclopentanones[158,159]. Here, as with the ketones (LXII), (LXXVIII), and (LXXXI), it is entirely possible that the reaction may not be a Favorskii rearrangement but involve hydrolysis of (LXVIII) with formation of the 1,2-dione, which then undergoes a benzilic acid rearrangement.



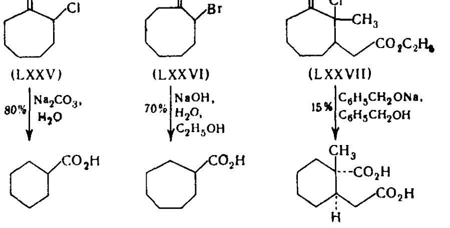
Ring contraction occurs also in the reaction of 2,2-dichlorodimedone with sodium acetate. Formation of the unsaturated chloro-ketone (LXIX) was explained by decarbonylation of the intermediate cyclopropanone derivative[160]:



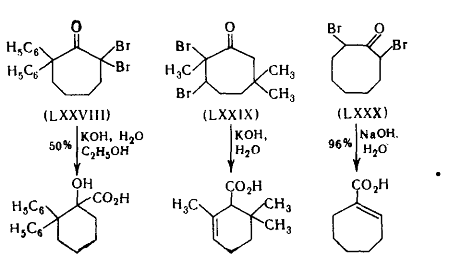
The individual tribromo-ketone isomers (LXX) and (LXXIII) or their mixtures undergo the Favorskii rearrangement under the influence of ammonia or an amine to form an iminolactone (LXXI) contaminated with an unsaturated amide (LXXIV). Hydrolysis of (LXXI) yields carvenolide (LXXII), which is the starting material for the synthesis of various iridolactones[161,162].



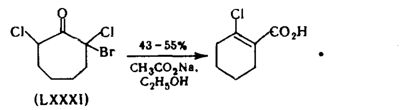
α-Halogeno-ketones containing a seven- or an eight-membered ring react with bases similarly to their six-membered analogues, forming in the Favorskii rearrangement acids containing respectively a six-membered or a seven-membered ring. Examples are the reactions of 2-chlorocycloheptanone (LXXV)[121,163,164] and of 2-bromocyclo-octanone (LXXVI)[165,166]. The α-chloro-ketones (LXXVII) gave a low yield of a compound which was a fragment of the structure of marrianolic acids[42].



Dibromo-ketones containing the halogen atoms in the αα-, αδ-, and αα′-positions—(LXXVIII)[167,168], (LXXIX)[169,170], and (LXXX)[166]—react with bases to form the corresponding unsaturated acids or hydroxy-acids containing contracted rings:



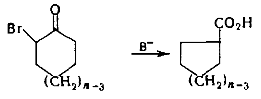
Rearrangement of the trihalogeno-ketone (LXXXI) gives a chlorinated unsaturated acid:



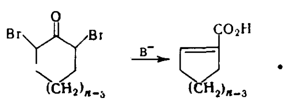
which indicates that bromine is more easily detached than is chlorine[171]. Tribromocyclo-octanone reacts similarly[166].

The Favorskii rearrangement has found application also for contracting rings of moderate size, examples being the reactions with bases of monobromo-ketones of the type

(LXXXII: $n = 10, 12$)[172,173] and dibromo-ketones of the type (LXXXIII: $n = 10$–12)[172–174]:



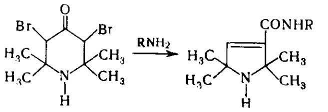
(LXXXII)



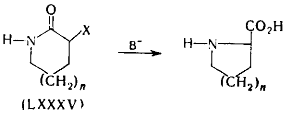
(LXXXIII)

the yields of the acids reaching 65–75%.

The Favorskii rearrangement has been accomplished also with heterocyclic α-halogeno-ketones. Thus the reaction of dibromopiperidone (LXXXIV) with ammonia or an amine yields the corresponding amide[175,176]. Analogues of proline are formed by the reaction of α-halogeno-lactams of the type (LXXXV: X = Cl, Br; n = 3, 7–11) with barium hydroxide[177–179] or with potassium t-butoxide[180]. In this case the resulting α-imino-acids may be formed by hydrolysis of (LXXXV) followed by recyclisation.



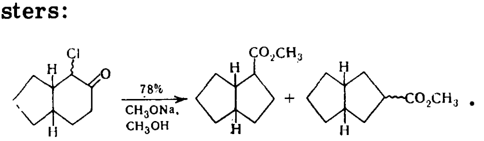
(LXXXIV)



(LXXXV)

3. Dicyclic and Polycyclic Halogeno-ketones

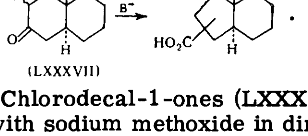
α-Halogeno-ketones containing the oxo-group in a fused carbocyclic system also undergo the Favorskii rearrangement, which provides a method for obtaining fused systems containing a smaller number of carbon atoms in the ring. The simplest example is the chloro-derivative of *cis*-perhydroindanone (LXXXVI), which under the influence of bases forms a mixture of *cis*-bicyclo[3,3,0]octanecarboxylic esters:



(LXXXVI)

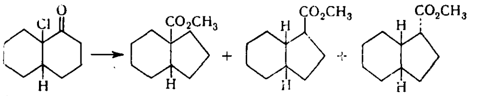
The corresponding *trans*-derivative does not undergo Favorskii rearrangement, perhaps owing to the steric strain in the *trans*-bicyclo[3,3,0]octane system[181–184].

The most widely investigated dicyclic halogeno-ketones are *trans*-decal-2-one derivatives of the type (LXXXVII: X = Cl, Br; R = H, CH_3), rearrangement of which yields a mixture of isomeric perhydroindanecarboxylic acids[142,185–189]:

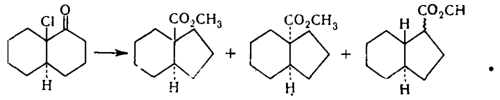


(LXXXVII)

cis- and *trans*-9-Chlorodecal-1-ones (LXXXVIII) and (LXXXIX) react with sodium methoxide in dimethoxyethane to form products which almost completely retain the initial configuration at $C_{(9)}$:



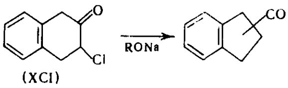
(LXXXVIII) 32% 57% 11%



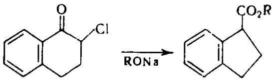
(LXXXIX) (XC) 88% 2% 10%

The yields of the products are indicated below the formulae. Especially interesting is the stereospecific synthesis of the *trans*-perhydroindane derivative (XC) with a methoxycarbonyl group between the rings[190].

The chlorotetralone (XCI) reacts with alkoxides to form the corresponding esters[140,191]. Its isomer (XCII) also forms products of the Favorskii rearrangement according to some results[140,191], but only alkoxy-oxides of type (V) according to other results[192].

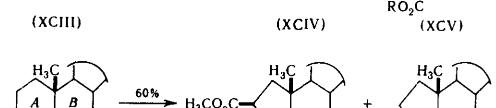


(XCI)

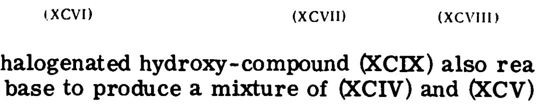


(XCII)

Application of the Favorskii reaction to halogenated steroid ketones, which are structurally related to decalone derivatives, enables modified steroids to be obtained in which A or B is a five-membered ring. The reactions of bases with halogenated cholestan-3-ones have been studied in greatest detail. Compounds in which the relative orientation of rings A and B is *trans* (XCIII) form a mixture of 2- and 3-alkoxycarbonyl isomers (XCIV) and (XCV). Some results[193,194] indicate that the former isomer (XCIV) predominates strongly, whereas others[195–198] show approximately equal quantities of the two isomers. The rate of the reaction depends on the nature of the halogen, decreasing in the sequence I > Br > Cl[143,144,199]. Compounds in which the orientation of rings A and B is *cis* (XCVI) also form a mixture of isomeric esters (XCVII) and (XCVIII)[194,200].



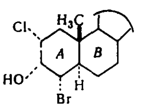
(XCIII) (XCIV) (XCV)



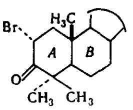
(XCVI) (XCVII) (XCVIII)

The dihalogenated hydroxy-compound (XCIX) also reacts with a base to produce a mixture of (XCIV) and (XCV)[201]. This probably involves initial dehydrohalogenation with formation of the ketone (XCIII). Yet the bromo-ketones

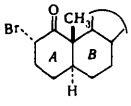
(C) and CI) do not undergo Favorskii rearrangement, but form only hydrolysis or substitution products with bases[202].



(XCIX)

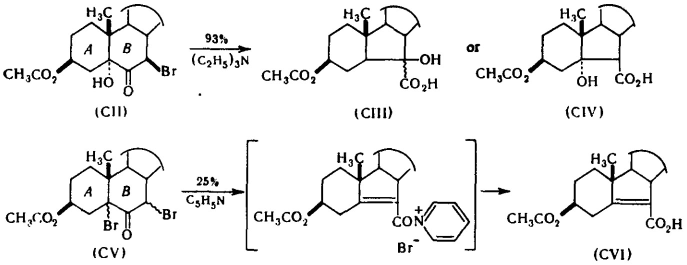


(C)

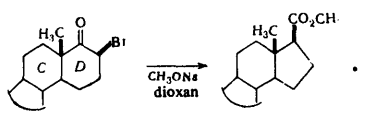


(CI)

Examples of the contraction of ring B are provided by Favorskii rearrangement involving cholestane derivatives (CII) and (CV). The structure (CIII) was ascribed to the product in the former case[203]. It has been pointed out[204] that the structure (CIV), in which the hydroxyl remains at its previous position, must be regarded as more probable. When the dibromocholestanone (CV) was boiled with pyridine, dehydrobromination products were accompanied by the B-nor-acid (CVI), probably formed via the corresponding acylpyridinium bromide[205,206].

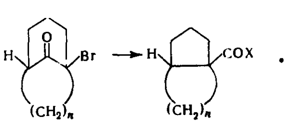


Contraction of the six-membered ring D by rearrangement of the D-homoandrostane derivative (CVII) could be accomplished only in very low yield[194,200,207]:



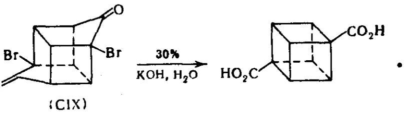
(CVII)

An interesting example of the Favorskii rearrangement involving bridged bicyclic systems is provided by the reactions of bromo-ketones of the type (CVIII: n = 5–8) with alkoxides, sodamide, silver nitrate, and mercury(II) acetate, when *cis*-isomers of derivatives of the corresponding acids (X = OH, OR, NH_2) are formed in 70–94% yield[35,208,209]:



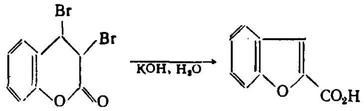
(CVIII)

The Favorskii rearrangement is applied also in the synthesis of cubane derivatives[210-212]. An example is the reaction of the dibromo-dione (CIX) with boiling aqueous alkali[213]:



(CIX)

The only example known of the Favorskii rearrangement of a bicyclic heterocycle is the reaction of mono- and di-bromocoumarins with alkalis to give acids of the type (CX)[214-218]:



(CX)

The formation of these acids can equally well be explained by opening of the pyran ring followed by recyclisation.

The results surveyed in this Section enable us to discuss the part played by the conformation of the halogen in the Favorskii rearrangement. Conformationally rigid structures (LXXXVII), (XCIII), and (XCVI), containing equatorial halogen, readily undergo rearrangement in good yield. Nevertheless, derivatives of the ketone (LXXXVII) and the chloro-ketone (LXXXIX)[219] (in protic solvents), containing axial halogen, did not undergo Favorskii rearrangement. It was therefore concluded[188] that an equatorial conformation of the halogen is necessary for this reaction to occur. However, this conclusion is disproved by other results[220], according to which the ketone (LXXXIX) containing an axial chlorine atom rearranges in aprotic solvents in high yield. Monocyclic tribromo-ketones (LXX) and (LXXIII)[162], as well as *cis*-2-chloro-4-t-butylcyclohexanone[143], also undergo Favorskii rearrangement. The presence in these compounds of a bulky 1-bromo-1-methylethyl or t-butyl substituent confers great rigidity on the axial conformation of their α-halogeno-substituents. All this indicates that the conformation of the halogen can have no significant effect on the possibility or the course of the Favorskii rearrangement.

III. MECHANISM OF THE FAVORSKII REARRANGEMENT

A considerable number of papers on the mechanism of the Favorskii rearrangement have been summarised in several reviews[11,204,221-223]. Nevertheless, no mechanism has yet been suggested which would be suitable for all structural types of α-halogeno-ketones and would explain unambiguously the features of the reaction. Most workers therefore assume that the rearrangement may occur by different mechanisms depending on the structure of the initial ketone and even on the conditions.

The α-halogeno-ketones undergoing the Favorskii rearrangement, which have been discussed in the preceding sections, can be divided into four structural types (A–D) distinguished by the presence or absence of hydrogen atoms in the α- and α'-positions:

Hydrogen atoms attached to α- and α'-carbon atoms—(XI), (XIX)–(XXI), (XXIII), (XXIX), (XXXIV), (XXXV), (XL), (XLVI), (XLVII), (LV), (LVII)–(LIX), (LXIV), (LXXV), (LXXVI), (LXXX), (LXXXII)–(LXXXIV), (LXXXVI), (LXXXVII), (XCI), (XCIII), (XCVI)

A

$-\overset{H}{\underset{X}{C_\alpha}}-\overset{O}{\overset{\|}{C}}-\overset{H}{C_{\alpha'}}-$.

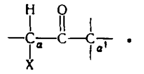
Hydrogen attached only to α'-carbon atom–(VIII), (IX), (XIV), (XVII), (XXV), (XXVIII), (XXXII), (XXXIII), (XXXVI), (XXXVIII), (XXXIX), (XLI), (XLVIII), (LII)–(LIV), (LXV), (LXX), (LXXIII), (LXXVII), (LXXIX), (LXXXI), (LXXXVIII), (LXXXIX), (CVIII), (CIX)

B

$-\underset{X}{C_\alpha}-\overset{O}{\overset{\|}{C}}-\overset{H}{C_{\alpha'}}-$.

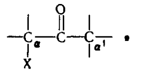
Hydrogen attached only to α-carbon atom—(XXXVII), (XLV), (LVI), (LXVIII), (XCII), (CII), (CV), (CVII)

C



No hydrogen attached to α- and α'-carbon atoms—(XIII), (XXVI), (XXVII), (LXIII), (LXXXVIII),

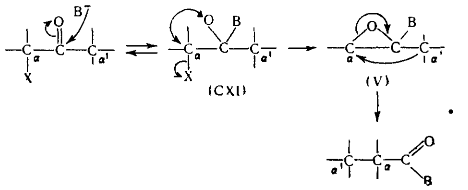
D



The equivalence of the α- and α'-positions in the Favorskii rearrangement, many examples of which have been quoted for the different structural types of ketones in subsections 1–3 of Section II, is extremely significant for the mechanism. It is convenient to divide the mechanisms which have been suggested into two groups according to whether they are able to explain this equivalence ("symmetrical" mechanisms) or require additional postulates for such explanation ("unsymmetrical" mechanisms).

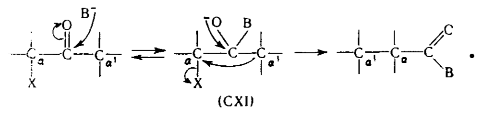
1. "Unsymmetrical" Mechanisms

The first unsymmetrical mechanism to be considered is the oxide–ester mechanism suggested by Favorskii in 1894[2,13,224], according to which the base attacks the carbonyl group to form as the first step the anion (CXI), which is converted with loss of halogen into the intermediate oxide (V), further rearrangement of which yields the final product:



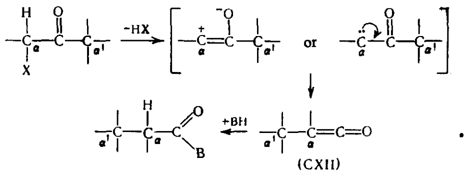
The Favorskii mechanism is applicable to all structural types of halogeno-ketones. It was considered to be supported by the isolation of oxide–ethers of the type (V: B = OR) in certain rearrangements[225,226]. However, these oxide–ethers could not be converted into the final products[227,228], and their formation is therefore a secondary process, unrelated to the main reaction.

The semibenzilic mechanism[53], so called from its resemblance to the mechanism of the benzilic rearrangement, is more soundly based. It also involves initial formation of the anion (CXI), but this then undergoes direct rearrangement with migration of the α'-atom, the oxide stage being bypassed:



The semibenzilic mechanism is also applicable to ketones of types A–D. A modified (push–pull) form of this mechanism was suggested[35] for rearrangements occurring under the influence of silver(I) and mercury(II) salts. It is noteworthy that these cations are electrophilic—not nucleophilic—reagents, and therefore cannot be regarded as usual catalysts for the Favorskii rearrangement. The semibenzilic mechanism and its push–pull modification are normally applied to ketones with which the formation of symmetrical intermediates is impossible or difficult for structural reasons. The limits of the possible applicability of the semibenzilic mechanism will be examined later in discussing symmetrical mechanisms.

According to the keten mechanism, suggested by Richard in 1938[229], the first stage in the rearrangement is the elimination of hydrogen halide from the α-atom of the initial ketone[48] (or detachment of a proton from the enolic form followed by removal of halogen[229]). The resulting dipolar or diradical (carbene) intermediates undergo direct rearrangement into a keten (CXII), which reacts with the base to form the final product:

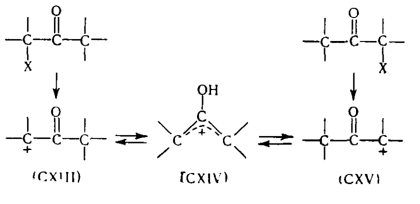


The keten mechanism is obviously applicable only to ketones of types A and C, containing hydrogen attached to the α-carbon atom. This mechanism is considered[118,119] to be inconsistent with data on the stereochemistry of the Favorskii rearrangement.

In all unsymmetrical mechanisms the carboxyl in the product should be attached to the α-carbon atom (with which the halogen was combined in the initial ketone). This leads to the conclusion that the α- and α'-positions are not equivalent with respect to the structure of the products, which is inconsistent with numerous experimental results. In order to avoid this difficulty, it was suggested that halogen migrated from α- to α'-positions, which would have explained the observed equivalence of these positions[64,65,230]. When this hypothesis was tested on acyclic[25,231] and cyclic[48] ketones, it was found that such migration of the halogen does not take place under the conditions of the Favorskii rearrangement. Therefore some "symmetrising" stage in the reaction must be postulated to explain the equivalence of α- and α'-positions.

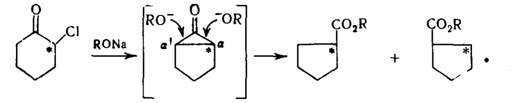
2. "Symmetrical" Mechanisms

The first "symmetrical" mechanism was put forward by McPhee and Klingsberg in 1944[22]. The symmetrising stage in this mechanism is tautomeric equilibrium between the carbonium ions (CXIII) and (CXV) formed in the first stage, through a common enolic form (CXIV), which undergoes rearrangement into the final products:



The principal defect of the above mechanism is that it does not explain the part played by the base in the reaction. According to this mechanism the rate of elimination of halogen should be independent of the concentration of the base, whereas experiment indicates kinetics of the first order with respect to B^-.[23,144] A somewhat modified form of this mechanism suggested recently is also inconsistent with experimental results[25].

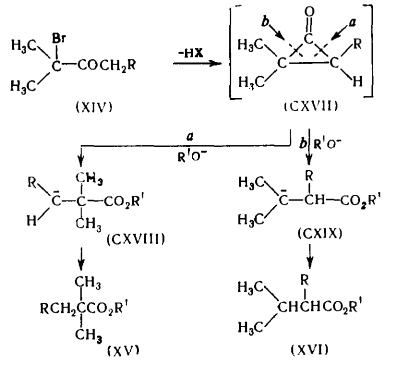
The cyclopropanone mechanism put forward by Loftfield in 1950[48,232] is free from these defects†. The rearrangement of 2-chlorocyclohexanone labelled with carbon-14 at the point of chlorination yielded a mixture of cyclopentanecarboxylic esters in which the tracer was equally distributed between the α- and β-carbon atoms (relative to the carboxyl). This was explained by the intermediate formation of a substituted cyclopropanone (CXVI), in which the α- and α′-carbon atoms were formally equivalent as a consequence of symmetry, and cleavage of the three-membered ring could occur with equal probability at the two bonds:



(CXVI)

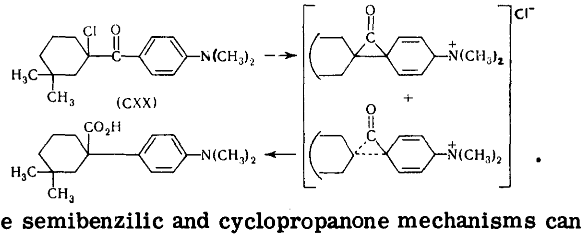
At the present time the cyclopropanone mechanism is generally accepted for the Favorskii rearrangement. It is supported by the isolation of cyclopropanone intermediate products in the reactions of monohalogeno-ketones with bases[238] and of cyclopropenone derivatives in those of αα′-dihalogeno-ketones[239,240]. Direct evidence has also been obtained that already formed cyclopropanones[241,242] and cyclopropenones[243,244] react with strong bases in conformity with the Favorskii rearrangement to form acid derivatives. Compounds in which the cyclopropane ring is separated from the keto-group by a double bond also react in similar fashion[245]. Cyclopropanone intermediates have also been isolated and identified in reactions with dienes and with methanol[246-250].

The cyclopropanone mechanism explains quite well the structural selectivity of the reaction. It is supposed that cleavage of the intermediate cyclopropanone yields the more stable of the two possible carbanions. The stability of non-conjugated carbanions increases in the sequence: tertiary < secondary < primary < benzyl[11]. In conformity with this the intermediate dimethylcyclopropanone (CXVII: R = H) formed from halogeno-ketones of the type (XIV: R = H), for example, is cleaved with the formation of derivatives of αα-dimethylpropionic acid (XV: R = H)—not of β-methylbutyric acid (XVI: R = H)—since the former are produced via the primary anion (CXVIII: R = H), and the latter via the less stable tertiary anion (CXIX: R = H). It is interesting that fission of the specially prepared dimethylcyclopropanone (CXVII: R = H) occurs in the same way under the influence of bases[242].

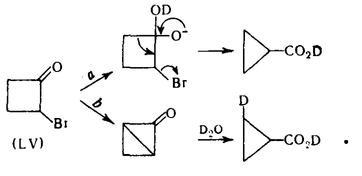


The above considerations are sufficient to explain the structural selectivity in the large majority of examples of the Favorskii rearrangement which have been studied. Recently however, results have been obtained which require more detailed account to be taken of possible operative factors[36]. Rearrangement of ketones of the type (XIV: R = Alk) is found to yield a mixture of the two possible products in which the proportion of (XVI), which is formed via the less stable tertiary carbanion (CXIX), increases with increase in the bulk of the alkyl radical R. This indicates that the course of the reaction is controlled not only by the stability of the intermediate carbanions but also by steric factors. With the ketone (XIV: R = H) these two factors act in the same direction: the intermediate product (CXVII: R = H) is attacked on the sterically less hindered side to form the more stable primary carbanion (CXVIII). In the case of ketones (XIV: R = Alk), however, these factors oppose one another, which results in the formation of a mixture of isomers. It should also be noted that the proportion of (XV: R = CH_3) in the reaction products is smaller when rearrangement is effected by sodium methoxide than with sodium ethoxide, and especially with potassium t-butoxide. This indicates that the part played by steric factors involving the base must be taken into account in addition to the influence of the bulk of the alkyl group of the alkoxide[36].

In its classic form the cyclopropanone mechanism is applicable only to ketones of types A and B, which contain the α′-hydrogen atom necessary for closure of the three-membered ring. With ketones of type C and D the semibenzilic mechanism is usually assumed without proof, their reactions being combined under the name Favorskii quasi-rearrangement, which emphasises this difference in mechanism. For several examples of the rearrangement of ketones of type D containing aryl substituents, however, the cyclopropanone mechanism can be applied in a somewhat modified form. Thus rearrangement of the ketone (CXX) and its heterocyclic analogues, which is accompanied by racemisation at the reactive centre, cannot be explained by a semibenzilic mechanism, but requires the acceptance of a "racemising" stage—assumed to be the formation of cyclopropanone intermediates[54-57]:



The semibenzilic and cyclopropanone mechanisms can be more reliably distinguished by investigating the incorporation of deuterium into the final product when the reaction is conducted in a deuteriated solvent. The difference between these mechanisms can be conveniently explained with the rearrangement of 2-bromocyclobutanone (LV) in heavy water as example:



According to the semibenzilic mechanism (*a*) the resulting cyclopropanecarboxylic acid should not contain deuterium

---

† A mechanism involving cyclopropanone intermediates was suggested as early as the 1890s[2,77,233,234]. It unites the Favorskii rearrangement with similar rearrangements of α-halogeno-sulphones[235], α-halogeno-amides[236], halogenated diazoethers[237], etc.

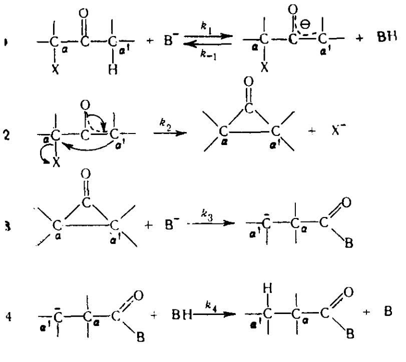
in the ring, whereas the cyclopropanone mechanism (*b*) leads to a deuteriated product. The undeuteriated acid obtained experimentally indicated that this reaction had a semibenzilic mechanism[119,251]. A more exact interpretation of the process requires that the exchange of deuterium between ketone and heavy water, unconnected with the Favorskii rearrangement, should be taken into account. According to the unsymmetrical scheme (*a*) the *α*- and *β*-carbon atoms (with respect to the carboxyl) should have different degrees of deuteriation, but according to the symmetrical scheme (*b*) they should be the same. Investigations on this basis confirmed the semibenzilic mechanism of the Favorskii rearrangement for the ketone (LV)[252].

Nevertheless, the rearrangement of 17*α*-bromo-20-oxo-steroids of the type (XXVIII) in deuteriated solvents (D_2O, CH_3OD) yielded predominantly the products (XXX) and (XXXI) containing one deuterium atom in the 17-methyl group. This is evidence of the cyclopropanone mechanism of this reaction (exchange of deuterium between the ketone and the medium is negligible here)[66].

As a third example we can consider the mechanism of the Favorskii rearrangement of ketones of the type (CVIII: $n = 6-8$), determined from the entry of deuterium into the reaction products[209]. When $n = 6$, the ketone (CVIII) reacts by the semibenzilic mechanism both with NaOD–C_2H_5OD and with t-C_4H_9OK–t-C_4H_9OD. When $n = 7$, the semibenzilic mechanism operates with NaOD, but the cyclopropanone mechanism with t-C_4H_9OK. Finally, when $n = 8$, the Favorskii rearrangement takes place by the cyclopropanone mechanism in both cases, as is confirmed by the racemisation of the optically active ketone (CVIII: $n = 8$) during the reaction. Thus with compounds of type (CVIII) the mechanism of the rearrangement may depend not only on the structure of the initial ketone but also on the reaction conditions.

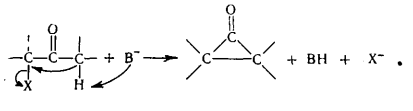
The kinetics and stereochemistry of the Favorskii rearrangement are usually explained in terms of the cyclopropanone mechanism. The elementary form of this mechanism outlined above becomes inadequate to explain all the kinetic and stereochemical results. We must therefore examine in detail existing views on the sequence of stages in the rearrangement, the significance of each of them, and also the nature of the transition state. The most probable variant of the cyclopropanone mechanism can be represented in its complete form by the four-stage scheme 1.

Scheme 1



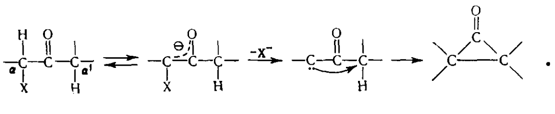
The first stage in the Favorskii rearrangement according to this scheme consists in enolisation of the ketone with loss of the *α*'-proton. In the second stage the resulting enolate splits off halogen as the anion and gives a cyclopropanone intermediate. This is followed by opening of the cyclopropanone by the anion of the base (third stage) and reaction of the resulting carbanion with the base to yield the final product (fourth stage). Stages 3 and 4 are supposed to occur so rapidly that they have no effect on the overall rate of the process.

The above scheme of the Favorskii rearrangement has been partly modified by many authors. Thus it has been suggested that stages 1 and 2 occur synchronously and that 1,3-elimination of the hydrogen halide to form the cyclopropanone[39] takes place in a single step:



This hypothesis, however, sharply contradicts the stereochemistry of many cases of the Favorskii rearrangement which have been studied, especially among the steroids[223].

As an alternative to the above four-stage mechanism it has been suggested also that formation of the anion may involve the *α*-hydrogen atom—not the *α*'-atom—after which chlorine is detached from the same atom and the resulting carbene is converted into a cyclopropanone[221]. An argument in favour of this possibility was the ease of enolisation of the initial halogeno-ketone at the *α*-atom. This peculiar combination of carbene and cyclopropanone mechanisms imposes additional structural limitations on the initial ketone, and is applicable only to halogeno-ketones of type A, containing hydrogen on both *α*- and *α*'-carbon atoms:



Neither of the above modifications of the main scheme is consistent with the kinetic and stereochemical data[23,25], and is therefore rejected by most authors at the present time. The kinetics and the stereochemistry of the Favorskii rearrangement are usually interpreted in terms of a four-stage scheme. The rate-determining stage in the reaction is established by study of deuterium exchange between the ketone and the medium and of the effect of the nature of the halogen.

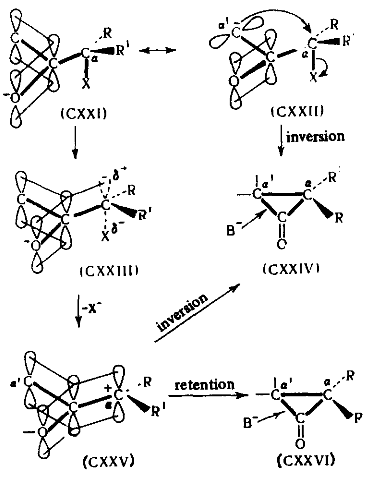
Enolisation at the *α*'-atom as the first stage in the Favorskii rearrangement is proved by the occurrence of deuterium exchange between this position in the halogeno-ketone and the medium or by conducting the reaction in a deuteriated solvent or with a deuteriated halogeno-ketone. Such exchange is observed to some extent with most halogeno-ketones—both acyclic ketones of types (IX), (XI), and (XVII)[23,25,40,253-255] and 2-halogenocyclohexanones and their derivatives[144,256]—and also with 2*α*-halogeno-3-oxo-steroids[143,144,199]. Yet it is negligible with 17*α*-bromo-20-oxo-steroids (XXVIII)[66] and 9-chloro-*trans*-decal-1-one (LXXXIX)[219]. The occurrence of stage 1 explains also the catalytic effect of certain salts (lithium chloride, lithium iodide, sodium iodide) on the Favorskii rearrangement[25,38,44]. It was assumed that these salts associate with the base formed in stage 1 (BH—methanol in the present example), thereby shifting the equilibrium in this stage to the right and increasing the concentration of the enolate.

The degree of deuterium exchange, which depends primarily on the structure of the halogeno-ketone, is of fundamental importance for comparing stages 1 and 2. We can cite as example ketones of the types $ArCH_2COCH_2X$ and $ArCH_2COCHXCH_3$, which differ only in the presence of a methyl group in the latter[25,38]. Whereas ketones of the first type exchange ~ 80% of the α′-hydrogen for deuterium before the reaction, the degree of deuterium exchange in ketones of the second type does not exceed 5%. Hence stage 1 is rapid ($k_{-1} > k_2$) in the first case: i.e. the rate of rearrangement is determined by the stage in which halogen is eliminated. In the second case, however, the presence of the methyl group increases the rate of solvolysis of the enolate and makes $k_2 > k_{-1}$. Deuterium exchange is therefore poor, and the reaction velocity is determined by the first stage—enolisation of the initial ketone.

With 4,4-disubstituted 2-halogenocyclohexanones and steroid ketones of the type (XCIII) deuterium exchange depends on the nature of the halogen[143,144,199]. In the α′-position deuterium exchange is considerably more facile with chloro-ketones than with bromo-ketones. In the first case, therefore, the rate of the reaction is determined by stage 2 ($k_2 < k_1$) and in the second case by stage 1 ($k_1 < k_2$). The group which is eliminated also has quite considerable effects in these examples: $k_{Br}/k_{Cl} = 6-116$ (according to various results). Thus, depending on the structure of the initial halogeno-ketone, the rate of the Favorskii rearrangement may be determined by either stage 1, stage 2, or both.

The electronic interpretation of the second stage in the Favorskii rearrangement, which is associated with the explanation of its stereochemistry, has also been the subject of prolonged controversy. Scheme 2 shows the chief possibilities for the occurrence of this stage.

Scheme 2



The anion produced in stage 1 in the form (CXXI) or (CXXII) can be further converted into cyclopropanone in two ways. Intramolecular substitution of S_N2 type—(CXXII) → (CXXIV)—involves inversion of configuration at the reaction centre (the α-carbon atom). This results in stereospecific formation of the cyclopropanone (CXXIV), which is opened by the base at stages 3 and 4 to give a final product having a configuration at the α-atom‡ which is the inverse of the initial configuration.

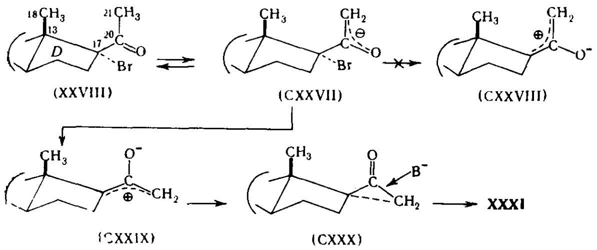
Attainment of the configuration necessary for S_N2 substitution requires considerable distortion of the normal geometry of the enolate anion (CXXI) on passing to the carbanion (CXXII), which should result in a considerable energy barrier. It was therefore suggested[257-259] that a halogeno-enolate (CXXI) first loses the anion X^- to form the delocalised intermediate (CXXIII), which gives rise to the zwitterion (CXXV). Calculations by the LCAO-MO method indicate that the change (CXXI) → (CXXV) is accompanied by an increase in the delocalisation energy, this increase being regarded as the driving force of the process. The zwitterion (CXXV) can undergo direct cyclisation of the disrotatory type into the cyclopropanone[260]. In the transition state (CXXIII) during detachment of the X^- anion the C–X bond is highly ionic in character. A considerable positive charge appears on the α-carbon atom, which can be balanced by the supply of electrons from substituents attached to the α′-atom and especially from those on the α-atom. Therefore the stage of detachment of X^- is accelerated on α′-substitution by electron-donor groups (this is reflected in the high negative value of the Hammett ρ-coefficient, from −2.4 to −5.0, in halogeno-ketones of the type $ArCHClCOCH_3$ and $ArCH_2COCH_2Cl$[23,25]) and especially by the introduction of a donor methyl group in the α-position[255]. All these results support the possibility that the reaction may occur via the zwitterion (CXXV). The planar intermediate state (CXXV), in which the centre of asymmetry has disappeared, can obviously yield on cyclisation both the cyclopropanone (CXXIV) and the cyclopropanone (CXXVI), ring-opening of which will give final products with inversion and retention of the initial configuration at the α-centre (Scheme 2).

It is now accepted that the Favorskii rearrangement may occur by both the routes considered—through (CXXII) and through (CXXV)—and the stereochemistry of the reaction is interpreted on this basis. As shown in Section II, the Favorskii rearrangement is not characterised by any definite stereochemical requirements: depending on the structure of the halogeno-ketone, the type of base, and even the concentration of the latter, it occurs with either complete retention or complete inversion of configuration, or even with formation of a mixture of isomers. However, the most thoroughly studied examples of the rearrangement of ketones of type (XVII) and (XVIII) indicate that in aprotic solvents (ether, dimethoxyethane) the reaction involves inversion of configuration, whereas in protic solvents (methanol, water) either a mixture of isomers or one isomer with retention of the initial configuration is formed. The influence of the solvent on the fate of the anion formed in stage 1 has been discussed[43,45,241]. In aprotic solvents this anion is slightly if at all solvated, and therefore its "free" negative charge may enter the reaction as the carbanion (CXXII), forming products with inversion of configuration (CXXIV). Solvation of the anion in protic solvents confers on it an enolic structure and directs the reaction through the zwitterion (CXXV) to the product (CXXIV) or (CXXVI). The relative proportions of these isomers are determined primarily by steric factors. With 17α-bromo-20-oxo-steroids (XXVIII), for example, it has been shown that, in the detachment of Br^- from the intermediate enolate (CXXVII), steric hindrance

---

‡ The same stereochemical course of the reaction should be characteristic also of the concerted 1,3-elimination mentioned above.

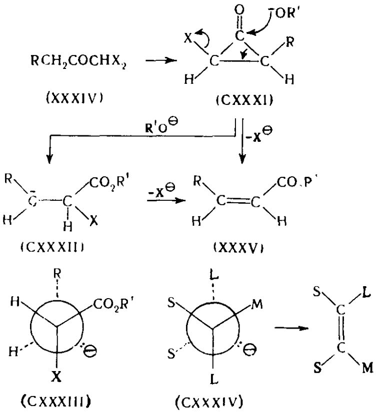
by the angular methyl group $C_{(18)}$, tending to prevent rotation about the $C_{(17)}$–$C_{(20)}$ bond, will ensure formation predominantly of the zwitterion (CXXIX), not of (CXXVIII). Cyclisation of (CXXIX) will lead to the corresponding cyclopropanone (CXXX), ring-opening of which by bases should yield a reaction product in which the initial configuration at the α-atom is retained (XXXI). Such stereochemistry is observed in protic solvents[66,71,223].



Various explanations of the stereochemistry of the Favorskii rearrangement have also been based on the intermediate formation of the cyclopropanones (stages 3 and 4)[42,43], but they are not so generally applicable, and are to some extent inconsistent with kinetic data.

The stereospecific formation of *cis*-acids of acrylic type in the Favorskii rearrangement of di- and tri-halogeno-ketones, e.g. (XXXIV), is explained on a different basis. The formation of *cis*-acids (XXXV) can be regarded[80,81] as resulting from concerted *trans*-antiparallel 1,3-elimination with formation of a *cis*-2-alkyl-3-halogenocyclopropanone (CXXXI). This product is then opened by the base into the acid (XXXV), also by a concerted process of elimination of the halide anion with preservation of the configuration.

Scheme 3



A more probable form of explanation is that the stereochemistry of the reaction is determined at the stage of elimination of halogen from the anion (CXXXII) formed when the cyclopropanone (CXXXI) is opened by the base[261]. Analysis of possible conformations of this anion indicates that the most probable type of conformation will be (CXXXIII), detachment of X^- from which will give the *cis*-acid (XXXV) stereospecifically. This conformation can be written more generally as (CXXXIV), where L denotes a large substituent, M a medium substituent, and S a small substituent (the sizes of the substituents are arbitrarily assumed to form the sequence $X > R \gg COOR > H$). This hypothesis explains most of the known facts on the stereochemistry of the rearrangement of acyclic polyhalogeno-ketones[261] (Scheme 3).

Polyphosphoric Acid in Cyclisation and Polycyclisation Reactions

E.S.Krongauz, A.L.Rusanov, and T.L.Renard

The literature data on the structure of polyphosphoric acid (PPA) and cyclisation and polycyclisation reactions in polyphosphoric acid whereby thermally stable polyheteroarylenes of various structures may be obtained are reviewed and the possible mechanisms of these reactions are discussed.
The bibliography includes 235 references.

CONTENTS

I. INTRODUCTION

Syntheses in polyphosphoric acid (PPA) are nowadays so widely employed that it is difficult to point to a branch of organic chemistry where it has not found an application.

Polyphosphoric acid was first recognised as a cyclising agent and was then extensively employed in a wide variety of reactions catalysed by acids such as condensation, esterification, hydrolysis, and acylation; polyphosphoric acid is an excellent reagent for many rearrangements, etc. The great importance which this acid has acquired in synthetic organic chemistry is shown also by numerous original papers on the subject. A number of reviews published during the period 1954–1963 give a complete bibliography on this question[1-8].

In subsequent years polyphosphoric acid found application in macromolecular synthetic chemistry. This was facilitated by a unique combination of properties in polyphosphoric acid: it is at the same time a good solvent for organic compounds, including macromolecular compounds, a proton donor which favours condensation reactions, and a cyclodehydrating agent which ensures slow intramolecular cyclisation over a wide range of temperatures. In many cases this makes it possible to carry out simultaneously two or three stages without isolating the intermediates, which is particularly important in the synthesis of polymers.

The use of polyphosphoric acid instead of other acid reagents (aluminium chloride, phosphorus pentoxide, hydrofluoric acid, and concentrated sulphuric acid) is frequently preferable, since it does not usually give rise to side reactions, in particular oxidation processes; reactions in polyphosphoric acid can be readily carried out without the need for special precautions; as a rule higher yields of the final products are obtained. Certain reactions cannot be achieved at all with other acid reagents.

This review deals with one aspect of the application of polyphosphoric acid where it has particular advantages: the cyclisation and polycyclisation reactions, which lead to the formation of low-molecular and polymeric heterocyclic compounds and which evidently take place via the same mechanism.

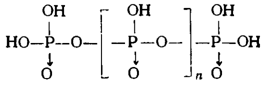
Since cyclisation processes have already been dealt with to some extent in earlier publications, this review does not quote an exhaustive bibliography on this problem. Attention was concentrated on the syntheses of heterocycles in polyphosphoric acid which have already found or may find applications in macromolecular chemistry for the synthesis of polyheteroarylenes.

II. PREPARATION AND PROPERTIES OF POLYPHOSPHORIC ACID

In the early studies phosphorus pentoxide was added to a solution of an organic compound in phosphoric acid[9,10]. Subsequently this method was improved and nowadays polyphosphoric acid is usually obtained by dissolving phosphorus pentoxide in orthophosphoric acid with heating until a homogeneous mixture is produced[10-14]. Polyphosphoric acid can also be prepared by the thermal dehydration of phosphoric acid or by treating the latter with phosphorus trioxide, but regardless of the method of preparation, polyphosphoric acid has a composition and properties which are determined by its P_2O_5 and water content[15].

Polyphosphoric acid is a complex mixture of polymeric phosphoric acid species with different degrees of condensation. A large number of studies have been made on the structure of polyphosphoric acid, among which mention should be made in the first place of the work of Thilo and Sauer[15], Bell[16], and Huhti and Gartaganis[17]. The use of β-naphthylamine and benzidine, which are capable of precipitating chains of particular length, and also paper chromatography, ion-exchange chromatography, and nuclear magnetic resonance (NMR) led to the determination of the approximate composition and structure of the complex mixture referred to as polyphosphoric acid[18-22].

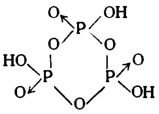
It has been shown that mixtures with 82–86% P_2O_5 contain, apart from orthophosphoric and pyrophosphoric acid, linear polyphosphoric acid with the following general structure:

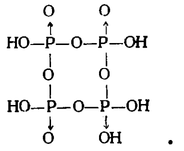


$$HO-\overset{OH}{\underset{\downarrow\atop O}{P}}-O-\left[-\overset{OH}{\underset{\downarrow\atop O}{P}}-O-\right]_n-\overset{OH}{\underset{\downarrow\atop O}{P}}-OH .$$

The Table presents the compositions of these mixtures referred to as polyphosphoric acid, since it cannot be obtained with a uniform degree of polymerisation and is always polydisperse.

When the content of phosphorus pentoxide in the mixture is higher, cyclic compounds and compounds with a three-dimensional structure are present; as a result of reaction with water, these again give rise to linear acids:





Composition of polyphosphoric acids with different contents of phosphorus pentoxide.

Mixture component	Mixture compositions with different P_2O_5 contents, wt.%		
	80.5[33]	81.6[17]	84.2[17]
Orthophosphoric acid	14	8	4
Pyrophosphoric acid ($n = 0$)	38	27	11
Triphosphoric acid ($n = 1$)	23	22	11
Tetraphosphoric acid ($n = 2$)	13	17	13
Pentaphosphoric acid ($n = 3$)	7	11	12
Hexaphosphoric acid ($n = 4$)	2	6	10
Heptaphosphoric acid ($n = 5$)	1	4	8
Octaphosphoric acid ($n = 6$)	0.2	2	6
Nonaphosphoric acid ($n = 7$)	—	2	5
Acids with higher values of n	—	1	20

The structure of these acids has been the subject of recent studies, which led to more accurate values of the angles between different bonds and also of the bond length[24,25].

Using a flexible linear acid model, Parks and van Wazer[26,27] found the theoretical distribution of acid species in PPA; their results agree with the experimental data[24]. Pearson and coworkers[28,29] investigated the specific gravity, viscosity, refractive index, and the rate of rearrangement as a function of the concentration of phosphorus pentoxide in various PPA mixtures. The measurements of the refractive index are less accurate than those of viscosity but they are simpler and may be used to determine the concentration of phosphorus pentoxide in PPA.[28]

The dissociation constants of various phosphoric acids are quoted by Quimby[30]. The ionisation constants of ortho- and pyrophosphoric acids have not been determined with adequate accuracy and the published data do not agree[31-33].

Polyphosphoric acid exhibits simultaneously the properties of an acid and an anhydride, since it contains both the acid and the anhydride groups of the initial compound used in its preparation. The anhydride groups bind the water evolved in the process, preserving thereby the effectiveness of the reagent for some time. They are then converted into acid groups, with splitting off of orthophosphoric acid molecules.

The mechanism of the hydrolysis of polyphosphoric acid was represented by van Wazer[34] in the following way: the simultaneous rupture of several P–O–P bonds in one molecular ion is impossible; the rupture takes place exclusively at the end of the chain. Thus triphosphoric, pyrophosphoric, and orthophosphoric acids are formed in succession from tetraphosphoric acid. At room temperature and at neutral pH the time required for the hydrolysis of the P–O–P linkage is several years. A decrease of the pH and an increase of temperature appreciably accelerate the hydrolysis; for example, for each 5 deg of temperature rise, the rate of hydrolysis increases by a factor of 2.

The removal of water, which is a stronger base than many organic compounds reacting under the influence of PPA, from the reaction sphere is important for the preservation of the effective acidity of the reaction medium.

The dehydrating action of polyphosphoric acid is much milder than that of phosphorus pentoxide, which makes it possible to carry out reactions at a higher temperature. Reactions in polyphosphoric acid are much more rarely accompanied by a rearrangement with a change in the carbon skeleton than in other acid agents, although they are sometimes possible[35].

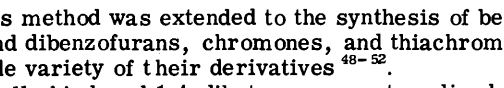
Usually polyphosphoric acid is employed in amounts such that it serves at the same time as a solvent and a reactant. However, the application of solvents in reactions with polyphosphoric acids, for example glacial acetic acid in chloroform[36], have been described. The reaction products are usually isolated by decomposing the reaction mixture with water or ice. In experiments with basic substances, it may be necessary to neutralise the dilute phosphoric acid before isolating the reaction products. Koo[37,38], Uhlig[5], and others[39,40] investigated cyclisation in polyphosphoric acid as a function of the nature of the products formed and the reactivity of the starting materials and established that the higher the melting points of the latter the more severe are the reaction conditions.

III. SYNTHESIS OF HETEROCYCLIC COMPOUNDS IN POLYPHOSPHORIC ACID

Polyphosphoric acid proved to be an effective cyclising (condensing) agent in the synthesis of a wide variety of heterocyclic systems. Numerous derivatives of indole, quinoline, isoquinoline, and others have been obtained using polyphosphoric acid; polyphosphoric acid is important in the synthesis of intermediates for many alkaloids[41], medicinal preparations[42], steroids, and other heterocyclic compounds containing nitrogen, oxygen, and sulphur[43-45].

I. Oxygen-Containing Heterocycles

Polyphosphoric acid was used for the first time in the syntheses of oxygen-containing heterocycles by Nowlin[46], who obtained diarylfurans from the corresponding 1,4-diketones in almost quantitative yields:



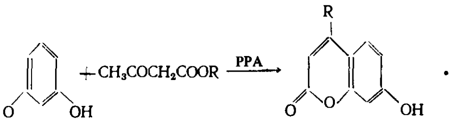
Later this method was extended to the synthesis of benzofurans and dibenzofurans, chromones, and thiachromones, and a wide variety of their derivatives[48-52].

Sterically hindered 1,4-diketones are not cyclised with formation of the furan ring; an aromatic hydrocarbon and an acid are formed under these conditions. A similar phenomenon has been observed earlier by Lutz et al.[47] in other systems.

Chromanone and 6-phenylchromanone[53] and 7-methoxychromanone and 6-nitrochromanone[52] were obtained by the cyclisation of β-phenoxypropionic acid and its derivatives in polyphosphoric acid.

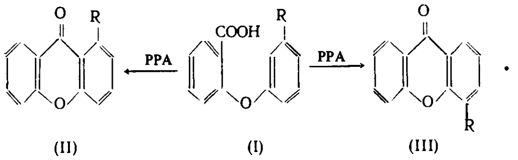
A number of substituted 1,2,3,4-tetrahydrodibenzofurans were synthesised by treating the corresponding 2-phenoxycyclohexanones with polyphosphoric acid[50].

The use of polyphosphoric acid as a condensing agent in the synthesis of coumarins by Pechmann's method[51] has been described. Thus, 4,7-dimethylcoumarin was obtained in 76% yield from m-cresol and acetoacetic ester[54] and the condensation of resorcinol with acetoacetic, α-methylacetoacetic, and benzoylacetic esters led to the synthesis of the corresponding hydroxycoumarins in very high yields[38]:



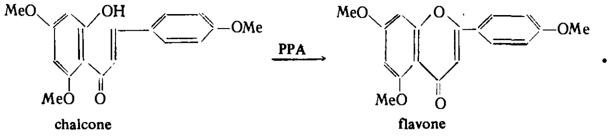
The mechanism of the formation of chromones and coumarins by Pechmann's method involving the interaction of β-arylcrotonic acids and β-ketoesters with phenols in the presence of polyphosphoric acid, has been investigated[55]. However, it is noteworthy that cyclisation does not always take place[56].

Xanthones have been synthesised with the aid of polyphosphoric acid[57]:



It has been shown that in the cyclisation of 3-substituted 2-carboxydiphenyl ethers (I) the mode of ring closure [(II) or (III)] depends on the nature of the substituent in the 3-position. For substituents with powerful-I and $-M$ effects (NO_2, COOH, CN), the ratio of products of cyclisation in the 2-position (II) and 6-position (III) is about 4 : 1, for substituents with powerful-I and $+M$ effects (NHAc, MeO), the ratio is approximately 1 : 3, and for Me or Cl as substituents the ratio is 1 : 1. The authors note that these ratios are independent of the choice of cyclising agent.

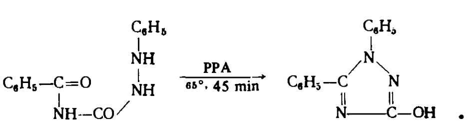
Mention should also be made of the synthesis of flavone from the corresponding chalcone in polyphosphoric acid[58]:



2. Nitrogen-containing Heterocycles

Among heterocyclic systems, the most widespread are nitrogen-containing heterocycles and, apart from other methods, their syntheses with the aid of polyphosphoric acid play an important role.

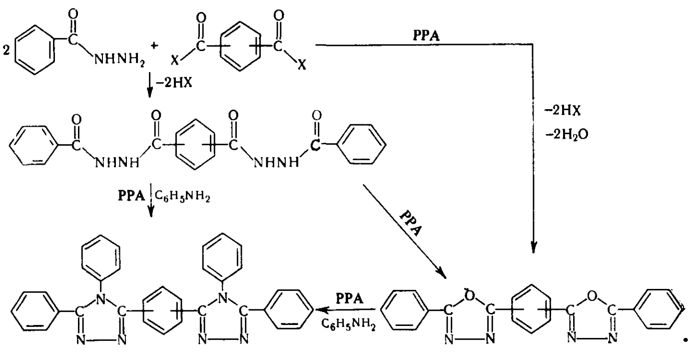
The simplest heterocycle obtained by the action of polyphosphoric acid on semicarbazide derivatives is substituted triazole:



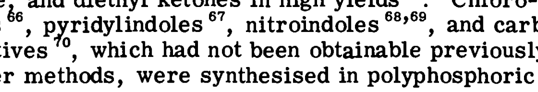
3-Hydroxy-1,5-diphenyl-1,2,4-triazole was obtained in 76% yield[59]. When the benzoyl group in the initial semicarbazide is replaced by the p-nitrobenzoyl group, 3-hydroxy-5-p-nitrophenyl-1-phenyl-1,2,4-triazole, which is unobtainable by other methods, is produced, but in the case of the 2,4-dinitrobenzoyl derivative the reaction could not be achieved[59].

3,4,5-Triphenyl-1,2,4-triazole was obtained in two ways: by treating 2,5-diphenyl-1,3,4-oxadiazole with aniline in polyphosphoric acid and by the cyclocondensation of dibenzoylhydrazine with aniline in polyphosphoric acid[60].

Holsten and Lilyquist[61] synthesised phenyl-substituted bis-1,2,4-triazoles via the following mechanism:



The Fischer synthesis of indoles, improved by the use of polyphosphoric acid, is carried out both by the cyclisation of arylhydrazones and in one stage—by the interaction of phenylhydrazine with α-ketoesters, ketones, and aldehydes[62–65]:

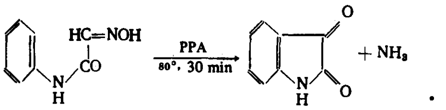


The single-stage synthesis is a general method whereby it is possible to prepare and investigate the entire series of alkyl- and aryl-substituted indoles. Thus 2-phenylindole, 3-methyl-2-phenylindole, 2-methylindole, and 3-ethyl-2-methylindole were obtained respectively from derivatives of hydrazine and acetophenone, propiophenone, acetone, and diethyl ketones in high yields[62]. Chloroindoles[66], pyridylindoles[67], nitroindoles[68,69], and carboline derivatives[70], which had not been obtainable previously by other methods, were synthesised in polyphosphoric acid.

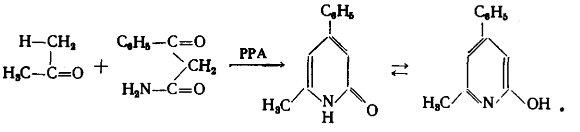
It has also been noted that polyphosphate esters are effective in the synthesis of indoles by the Fischer method, which makes it possible to carry out the reaction in boiling chloroform[71]. There exists a patent[74] for the synthesis of 2,3-dimethylindole from N-butenylaniline.

However, in many cases cyclisation to indoles does not occur[73]. Frasca and coworkers[74,75] showed that, when t-nitrophenyl hydrazones of certain acetophenones, benzaldehydes, and benzophenones are heated in polyphosphoric acid, indazoles are formed and not the expected indole derivatives; in addition, rearrangement products are isolated. Attention has been drawn to the fact that[76] polyphosphoric acid is relatively ineffective in the synthesis of indoles unsubstituted in the 2-position.

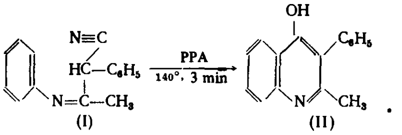
The action of polyphosphoric acid on isonitrosoacetanilide and its derivatives leads to the formation of isatin and substituted isatins in 50–60% yields via the mechanism[77]



Hauser and Eby[78] used polyphosphoric acid in the synthesis of substituted pyridones formed when β-ketoamides or β-ketonitriles reaction with ketones:



The syntheses of many derivatives of six-membered heterocyclic systems have been achieved in polyphosphoric acid. The formation of 4-hydroxyquinolines by the reaction of arylamines on β-ketoesters or β-ketonitriles (the Conrad–Limpach method) takes place smoothly in polyphosphoric acid in a single stage[79]. The anils of β-ketonitriles and β-ketoamides are also smoothly converted under the action of polyphosphoric acid into 4-hydroxyquinolines in high yields. Thus 4-hydroxy-2-methyl-3-phenylquinoline (II) was obtained from the anil (I) or directly from aniline and α-aceto-α-tolunitrile in 56% yield (instead of 4% when the usual catalysts are employed in the Conrad–Limpach method)[79]:

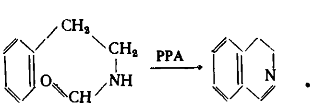


Similarly 4-hydroxy-2,3-diphenylquinoline was obtained in 34% yield.

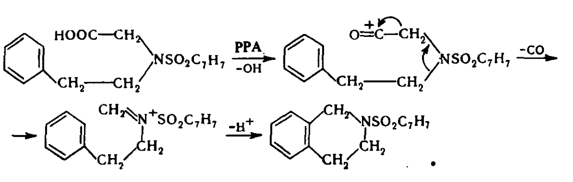
The use of polyphosphoric acid as a catalyst in the Skraup reaction was not successful[80].

6,7-Dimethoxyisoquinoline[81] and 7,8-dimethoxyisoquinoline[82,83] were synthesised in polyphosphoric acid by a modified Pomeranz–Fritsch reaction; the aminoacetyl derivatives of furfural were not cyclised under the action of polyphosphoric acid[82].

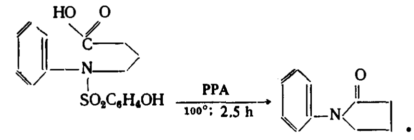
A complete study of polyphosphoric acid as a cyclodehydrating agent in syntheses of dihydroisoquinolines by the Bischler–Napieralski reaction demonstrated its high effectiveness[84]; in all cases the yields of dihydroisoquinolines in polyphosphoric acid were much higher than with other acid reagents[86–89]:



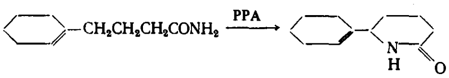
Proctor and Thompson[89] described a new method for the synthesis of tetrahydroisoquinoline derivatives. When toluenesulphonamide of N-β-phenylethylalanine is heated with polyphosphoric acid, the toluenesulphonamide of tetrahydroisoquinoline is formed instead of the expected product, probably by the following mechanism[89]:



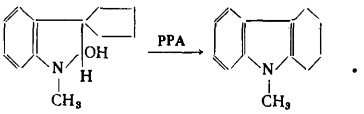
However, 1-phenyl-2-pyrrolidinone was obtained in 94% yield from the toluenesulphonamide of N-phenyl-γ-aminobutyric[90]:



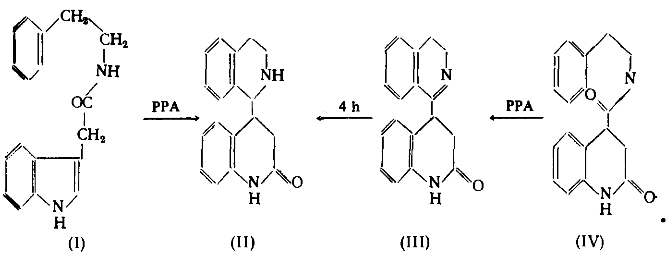
In the presence of polyphosphoric acid it proved possible to synthesise perhydro-1,4,6,9-tetraoxopyridazo-[1,2-*a*]pyridazine from succinic acid and hydrazine hydrate[91] and spiropiperidinone from γ-cyclohexen-1-ylbutyric acid amide[92,93]:



A new method has been developed for the synthesis of benz[*a*]-acridines[94]. An interesting ring expansion reaction under the action of polyphosphoric acid, consisting in the conversion of spirooxindole into 9-methyltetrahydrocarbazole and accompanied by a rearrangement of the Wagner–Meerwein type, was achieved by Witkop and Patrick[95]:

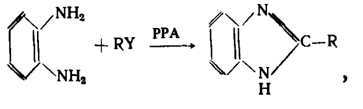


Other polynuclear heterocyclic systems synthesised in polyphosphoric acid include phenanthridine[96], 3,4-benzophenanthridine[97], 3,4-dihydro-4-phenylcarbostyril and 3,4-dihydro-4-phenylisocarbostyril[98], 2,4-dimethylindeno-[3′,2′:6,7]quinoline obtained from the anil of acetophenone and 2-aminofluorene[99], and 4-(1,2,3,4-tetrahydro-1-isoquinolyl)hydrocarbostyril, which is obtained by the rearrangement of the β-phenylethylamide of heteroauxin with subsequent cyclisation[100] according to the mechanism:



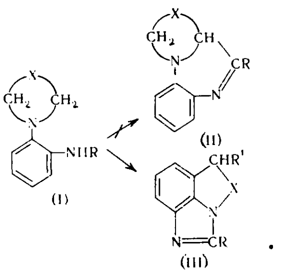
The conversion of the β-phenylethylamide (I) into the carbostyril derivative (II) can be explained only by the migration of the indoline component, which permits the formation of a six-membered ring. Structure (II) was confirmed by synthesising compounds (III) and (IV).[100] It was shown that in certain cases a mixture of polyphosphoric acid and $POCl_3$ is more effective than each component separately. In some cases the heterocycles formed were alkylated in the cyclisation process[101,102].

Polyphosphoric acid was successfully employed in the synthesis of heterocycles containing more than one nitrogen atom. 2-Substituted benzimidazoles were obtained by the following general reaction of o-diamines with carboxylic acids and their derivatives[103,104]:



where Y = COOH, COOR, $CONH_2$, or CN and R = alkyl, aryl, or substituted aryl. Similarly, using tetramines in reactions with carboxylic acids or *o*-diamines in reactions with dicarboxylic acids, bisbenzimidazoles of different structures were obtained[105,106].

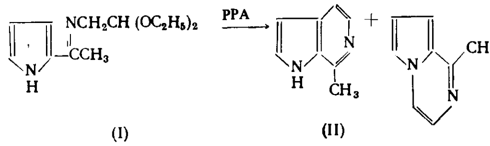
Suschitzky[83] observed an interesting and unexpected reaction involving the formation of the benzimidazole ring when *N*-2-acylaminophenyl heterocycles were treated with hot polyphosphoric acid:



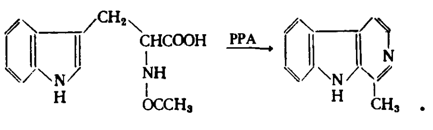
Instead of the expected 1,2-dihydroquinoxalines [(II), X = $(CH_2)_3$, $(CH_2)_4$, or $CH_2)_5$],[107] benzimidazoles (III) were obtained from the acylated amines. The authors believe that, under the action of polyphosphoric acid, the heterocyclic ring in the initial compound (I) is opened and the next stage is cyclic dehydration involving the tautomeric form of the amide N: C(OH)R, which leads to imidazole. Further alkylation of the benzene ring gives a product of type (III).

Polyphosphoric acid has found application in the synthesis of six-membered heterocycles[108-110], which could not be obtained by the Pomeranz–Fritsch and Bischler–Napieralski reactions using sulphuric acid.

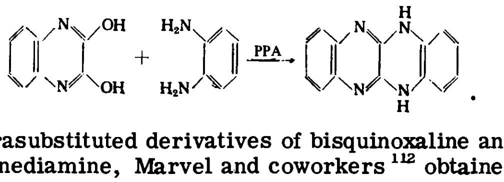
The cyclisation of Schiff bases derived from pyrrole frequently leads to a mixture of pyrazine and pyridine derivatives; for example, the aminoacetyl derivative of 2-acetylpyrrole gives a mixture of apogarmine (II) and 1-methylpyrrolo[1,2-*a*]pyrazine[108]:



Under the action of polyphosphoric acid, *N*-formyltryptophan and *N*-acetyltryptophan gave the corresponding harmans[87]:

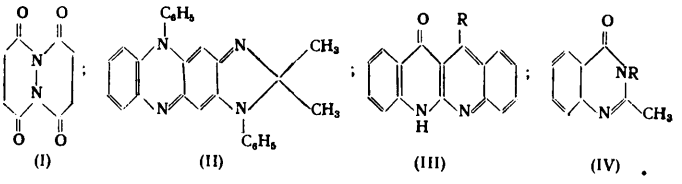


Badger and Nelson[111] obtained a new heterocycle containing four nitrogen atoms (fluoflavine) by the reaction of 2,3-dihydroxyquinoxaline with *o*-phenylenediamine in polyphosphoric acid:



From tetrasubstituted derivatives of bisquinoxaline and *o*-phenylenediamine, Marvel and coworkers[112] obtained 2,2-bisfluoflavine.

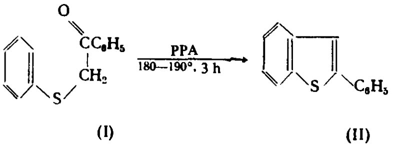
New syntheses in polyphosphoric acid of bicyclic and polycyclic nitrogen-containing systems of the following type have been developed: perhydro-1,4,6,9-tetraoxopyridazo[1,2-*a*]pyridazine (I),[113] 5,2'-dihydro-2',2'-dimethyl-5,1'-diphenylquinoxalino[5',4' : 2,3]phenazine (II),[114] 4-hydroxy-1,4-quinolono[2,3 : 2',3']quinoline (III),[115] quinazolones (IV),[116] and others[117-119]:



3. Heterocycles Containing Sulphur and Arsenic

Only a limited number of such compounds are known and the application of polyphosphoric acid in their synthesis has been investigated in much less detail than in the reactions discussed in the preceding section.

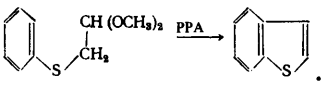
The cyclisation of α-arylthioketones of the type $AR-S-CH_2COR$, where R = aryl, is accompanied by a rearrangement and leads to the formation of 2-arylthionaphthene instead of the expected 3-arylthionaphthene[120]:



When, instead of the benzoyl derivative the acetyl derivative is employed, 3-alkylthionaphthenes are formed without rearrangement[121]. In the presence of hydrofluoric acid, compound (I) also rearranges to compound (II).[55]

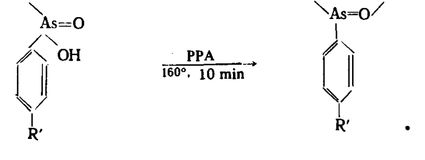
According to the data of Davies and Middleton[121], phenyl phenacyl ether undergoes an analogous rearrangement to 2-phenylbenzofuran in the presence of polyphosphoric acid. When sulphur or oxygen in the above compounds are placed by the methylene group, ring closure takes place without rearrangement[37,121].

A number of thionaphthenes were obtained in polyphosphoric acid in high yields from arylthioaldehyde acetals[122,123]:



Under the action of polyphosphoric acid, arylthiophenoxyacids also form cyclic products[124,125].

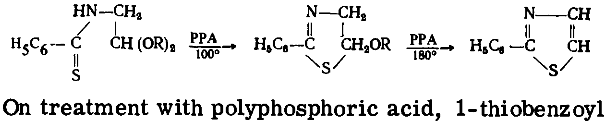
Using polyphosphoric acid, Campbell and Poller[126] synthesised arsafluorene oxide in 70% yield in one stage, while in the usual three-stage method the yield did not exceed 55%:



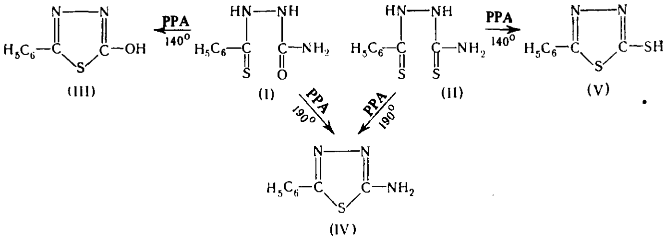
4. Mixed Heterocycles

The use of polyphosphoric acid as a condensing agent greatly extended the scope of the syntheses of a wide variety of heterocycles, including some of practical importance[127].

2-Phenylthiazoline was obtained by the cyclisation of a 2-thiobenzamidoacetal under the action of polyphosphoric acid. 5-Ethoxy-2-phenylthiazoline is formed similarly at 100°C; at a higher temperature (180°) 2-phenylthiazole is formed[128]:

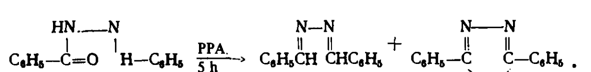


On treatment with polyphosphoric acid, 1-thiobenzoylsemicarbazide gives thiadiazole derivatives in high yields. The reaction conditions are very important for cyclisation in polyphosphoric acid; the temperature and duration of the reaction frequently determine the nature of the compound obtained. Thus in the cyclisation of thiobenzoylsemicarbazide (I) and thiobenzoylthiosemicarbazide (II) at different temperatures, various substituted 1,3,4-thiadiazoles are formed[228]:

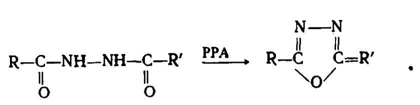


After isolation and purification, the yields were 88% of 2-hydroxy-5-phenyl-1,3,4-thiadiazole (III), 65% of 2-amino-5-phenyl-1,3,4-thiadiazole (IV), and 83% of 2-mercapto-5-phenyl-1,3,4-thiadiazole (V).

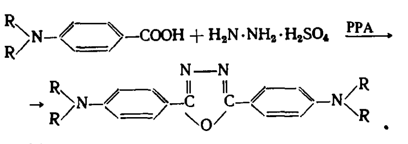
When 1-benzoyl-2-benzylidenehydrazine was treated with polyphosphoric acid under mild conditions (reaction temperature below 100°C), a mixture of benzaldazine and 2,5-diphenyl-1,3,4-oxadiazole was obtained[129]:



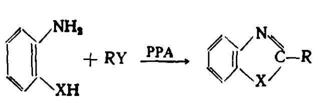
Cyclisation of hydrazine derivatives under more severe conditions (180–205°C) gives rise to derivatives of 1,3,4-oxadiazoles in quantitative yields[130,131]:



2,5-Di-(*p*-aminophenyl)-1,3,4-oxadiazole was obtained by treating *p*-aminobenzoic acid with hydrazine sulphate in polyphosphoric acid[132,133]:



Hein et al.[104] achieved the synthesis of benzimidazoles, benzoxazoles, and benzothiazoles substituted in the 2-position by the condensation of carboxylic acids, their esters, amides, and nitriles with *o*-amino-, *o*-hydroxy-, and *o*-mercapto-anilines in polyphosphoric acid:



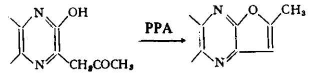
where X = NH, O, or S, Y = COOH, COOR, $CONH_2$, or CN, and R = alkyl or aryl.

Advances have been achieved in the synthesis of bisazoles and bisbenzazoles in polyphosphoric acid[134,135].

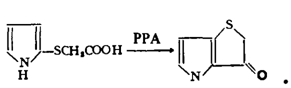
Thieno[2,3-*c*]pyridine (I) and thieno[3,2-*c*]pyridine (II) were synthesised by the cyclisation of the Schiff bases (Pomeranz–Fritsch reaction) obtained by the reaction of formylthiophencarboxylic acids and aminoacetals in polyphosphoric acid. Thianaphtheno[2,3-*c*]pyridine (III) and thianaphtheno[3,2-*c*]pyridine (IV) were obtained in low yields. A mixture of polyphosphoric acid and phosphorus oxychloride is recommended for these syntheses[108]:

(I) (II) (III) (IV)

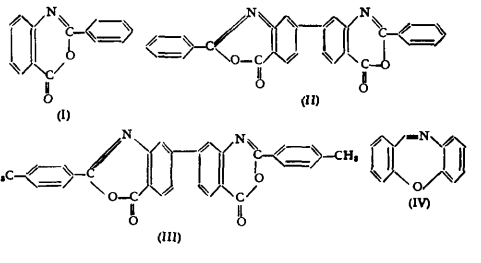
On treatment with polyphosphoric acid, xanthopterin derivatives are cyclised with formation of natural dyes—pteridines[136,137]:



A convenient method has been described for the synthesis of thieno[3,2-*b*]pyrrole, the first stage of which is the formation of 2*H*,3*H*-thieno[3,2-*b*]pyrrol-3-one as a result of the rearrangement and cyclisation of 2-pyrrolylthioacetic acid under the action of polyphosphoric acid[138–140]:

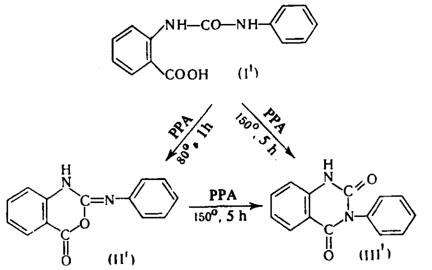


New syntheses in polyphosphoric acid of 2-phenyl-4*H*-3,1-benzoxazin-4-one (I) 2,2′-diphenyl-(6,6′-bi-4*H*-3,1-benzoxazyl)-4,4′-dione (II), 2,2′-di-*p*-tolyl-(6,6′-bi-4*H*-benzoxazyl)-4,4′-dione (III),[141,142] and a seven-membered cyclic compound (IV) containing nitrogen and oxygen as heteroatoms[143] have been developed:



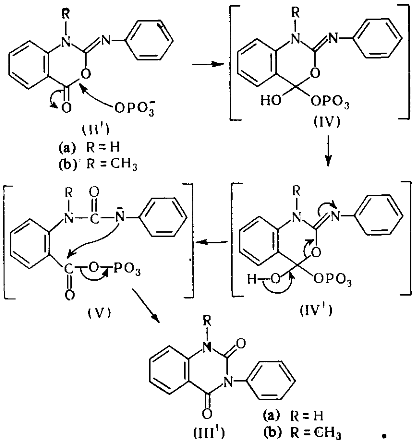
Compound (I) was obtained from benzoylanthranilic acid and compounds (II) and (III) from benzidinedicarboxylic acid and benzoyl chloride or *p*-toluoyl chloride.

The formation of the heterocycles (III′) is accompanied by an intramolecular rearrangement[141]. Thus, when *N*-phenylcarbamoylanthranilic acid (I′) is heated for 1 h at 80–100°C, 1,2-dihydro-2-phenylimino-4*H*-3,1-benzoxazin-4-one (II′) is formed (yield 95%, m.p. 193°C). Heat treatment of this acid at 150°C for 5 h leads to 3-phenyl-2,4-(1*H*)-quinazolinedione (III') (quantitative yield, m.p. 280°C):



When compound (II') is treated with polyphosphoric acid at 150°C, compound (III') is formed in 70% yield, which can only be accounted for by the migration of the ureide group.

Kurihara and Yoda[144] suggest the following mechanism for this rearrangement: on further heating of compound (II') in polyphosphoric acid, the carbonyl group of benzoxazinone is phosphorylated with formation of an intermediate (IV and IV'); subsequent ring opening leads to a mixed anhydride of a carboxylic and phosphoric acid (V). The negatively charged ureide nitrogen attacks the carbonyl group of the mixed anhydride displacing phosphoric acid. Recyclisation gives the quinazolinedione ring (II):



IV. SYNTHESIS OF POLYHETEROARYLENES IN POLYPHOSPHORIC ACID

The synthesis of thermostable polymers which can be worked constitutes one of the most urgent problems in the modern chemistry of macromolecular compounds. Considerable advances in this field have been achieved using the polyheterocyclisation reaction, whereby it is possible to obtain aromatic polymers with alternating carbocycles and heterocycles—the so called polyheteroarylenes[145]. In recent years considerable attention has been devoted to the development of new methods for polyheterocyclisation processes, among which high temperature polycyclisation in solution occupies a special place. This method has been successfully used in the first place for the synthesis of polyheteroarylenes (for example, polyimides[146]) soluble in the reaction mixture.

Naturally in reactions of this kind the correct choice of solvent is of exceptional importance. It is most useful to employ compounds with a high solvent power and a high boiling point or decomposition temperature which catalyse the reaction and bind the side products liberated (the usual side product in polyheterocyclisation reactions is water). Polyphosphoric acid meets all these requirements to a considerable degree.

Since 1960 polyphosphoric acid has been fairly extensively employed to prepare various polyheteroarylenes[147,148]. As shown above, polyphosphoric acid is an exceptionally effective condensing and cyclising agent; among the specific features of the syntheses of polyheteroarylenes in polyphosphoric acid, we shall mention the following.

1. As a rule, polycyclisation in polyphosphoric acid yields polymers with higher molecular weights than those obtained by other methods.

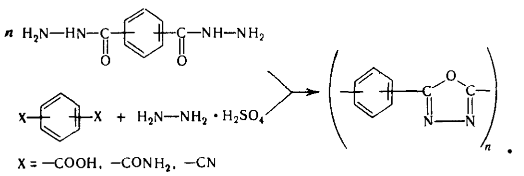
2. One of the most important problems in the synthesis of polyheteroarylenes is the attainment of the highest possible degree of cyclisation, since this parameter determines to a considerable extent the thermal and other characteristics of polymers. In solid-phase polycyclisation, macromolecular chains become increasingly rigid as the reaction proceeds, which hinders to a considerable degree the completion of the polycyclisation reaction, since the activation energy for the cyclisation process rises continuously[149] and free rotation about the bonds in the ring-forming fragments becomes more difficult.

Polyphosphoric acid behaves as a plasticiser, which is responsible to a considerable degree for the possibility of attaining a higher extent of cyclisation compared with other methods.

3. In many cases the polymers obtained in polyphosphoric acid differ significantly in their properties from polymers with similar structures prepared by other procedures. Thus poly-(1,3,4-oxadiazole-2,5-diyl-1,4-phenyleneoxy-1,4-phenylene) obtained in polyphosphoric acid[150] is more soluble than the similar polymer synthesised by a multistage process[151], which may be attributed both to only a weak development in polyphosphoric acid of intermolecular "cross-linking" reactions and to the difference in the phase states of these polymers. This finding has attracted particular interest, since the synthesis of soluble and hence workable polyheteroarylenes in one stage is technologically and economically more convenient compared with a two-stage process.

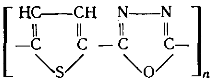
4. The use of polyphosphoric acid solves to a considerable degree the problems associated with the raw material base for the synthesis of polyheteroarylenes. For example, in the synthesis of various polybenzazoles polyfunctional nucleophilic agents are employed—bis-(*o*-phenylenediamines), bis-(*o*-aminophenols), bis-(*o*-aminothiophenols), etc., which are extremely unstable in the form of free bases and are readily oxidised. When the reaction is carried out in polyphosphoric acid, these compounds may be introduced in the form of much more stable salts—hydrochlorides, sulphates, phosphates, etc. Moreover, instead of employing the halides or anhydrides of the acids as the acid component of the reaction, it is possible to employ the more readily available free polycarboxylic acids.

The above advantages of the synthesis of polyheteroarylenes in polyphosphoric acid led to the wide employment of the polyheterocyclisation reaction for the synthesis of a wide variety of different classes of polymers. The principal classes of polyheteroarylenes containing five-membered heterocycles are polyazoles and polybenzazoles. The characteristics of the synthesis of polyazoles in polyphosphoric acid have been investigated in greatest detail for poly-1,3,4-oxadiazoles. Aromatic poly-1,3,4-oxadiazoles were obtained for the first time by Iwakura et al.[152] in a reaction of hydrazine sulphate with aromatic dicarboxylic acids, their amides, and nitriles, and also in the homocondensation of the dihydrazides of aromatic dicarboxylic acids:



Together with poly-1,3,4-oxadiazoles, the same investigators synthesised on the basis of isophthalic and terephthalic acids polymers containing alternating 1,3,4-oxadiazole and pyridine rings by the homocondensation of the dihydrazides of isomeric pyridinedicarboxylic acids—isocinchomeronic, dinicotinic, 2,6-dimethyldinicotinic, and dipicolinic[153].

Yet another type of polymer, containing only heterocycles—poly[2,3-thienylene-1,3,4-oxadiazole]—corresponding to the structural formula



was obtained by Manecke and coworkers[154] on heating the polyhydrazide of thiophendicarboxylic acid in polyphosphoric acid at 150°C for 5 h.

All the polymers synthesised exhibited high thermal stability and poly-1,3,4-oxadiazoles based on isophthalic and terephthalic acids also had high molecular weights: however, these polymers are soluble only in concentrated sulphuric acid and it is difficult to work them.

In order to obtain soluble polymers, Iwakura and coworkers[155] attempted to synthesise poly-1,3,4-oxadiazoles from the dihydrazides of aliphatic acids with the general formula

$$H_2NHNCO(CH_2)_mCONHNH_2\,,$$

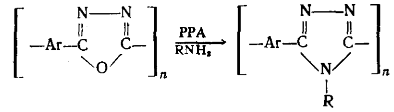
where m = 0, 1–10, 12, 15, and 20,[155] and alicyclic dicarboxylic acids[156]; poly-1,3,4-oxadiazole containing cyclohexane, cyclopropane, and spiro[3,4]heptane rings were obtained in the latter case[208].

In a number of cases the polymers were soluble in organic solvents but their thermal stability and resistance to heat were considerably inferior to those of aromatic poly-1,3,4-oxadiazoles.

A successful combination of useful thermal properties with solubility was achieved for poly-1,3,4-oxadiazoles by Korshak and coworkers, who synthesised these polymers on the basis of derivatives of di-(4-carboxyphenyl) ether[150] and diphenylphthalide-4′,4″-dicarboxylic acid[157,158].

The study of certain characteristics of the polyheterocyclisation reaction in polyphosphoric acid by Korshak, Krongauz, and coworkers[159] showed that the following factors favour the formation of high molecular-weight poly-1,3,4-oxadiazoles: (1) the absence of sulphuric acid from the reaction medium, which can be conveniently achieved by using hydrazinium phosphate instead of hydrazinium sulphate; (2) the binding of the water evolved in the condensation process by adding to the reaction mixture an additional amount of P_2O_5; (3) a high reaction temperature and short duration of the process.

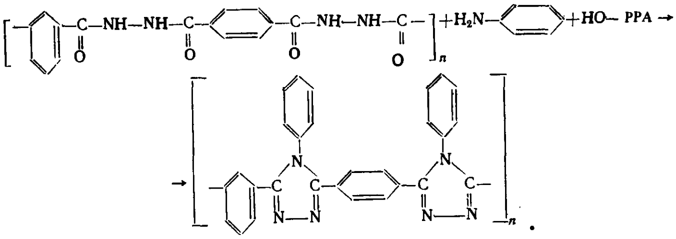
The relative ease of the opening of the 1,3,4-oxadiazole ring in polyphosphoric acid under the influence of different reagents permitted a series of polymer-analogue conversions of poly-1,3,4-oxadiazoles into other polyazole systems. Thus in a reaction of poly-1,3,4-oxadiazoles with various amines in polyphosphoric acid, Korshak and coworkers obtained a series of poly-(4-substituted)-1,2,4-triazoles[102,160–163]:



The amines employed were aniline, α-naphthylamine, cyclohexylamine, etc. Amines form stable complexes with polyphosphoric acid[164]. The reaction involving substitution of the oxygen in the oxadiazole ring by the N–R residue occurs only when the reaction medium contains a free amine, formed as a result of the dissociation of the amine–PPA complex at the reaction temperature. Therefore the successful occurrence of the substitution reaction depends on the basicity of the amines, which determines, on the one hand, the ease of dissociation of the amine–PPA complex and, on the other, the ease of substitution[162].

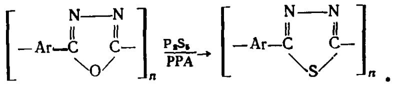
Poly(4-aryl)-1,2,4-triazoles contain bulky aryl substituents which weaken the interaction between the macromolecules; consequently these polymers are readily soluble in strong organic and inorganic acids. For this reason, the conversion of the insoluble aromatic poly-1,3,4-oxadiazoles into soluble poly(4-aryl)-1,2,4-triazoles, which can be carried out in a single reaction system without isolating the intermediate poly-1,3,4-oxadiazole[165], is of definite practical interest.

Holsten and Lilyquist showed[166,167] that analogous polymers may be obtained by heating polyhydrazides with aromatic amines in polyphosphoric acid:

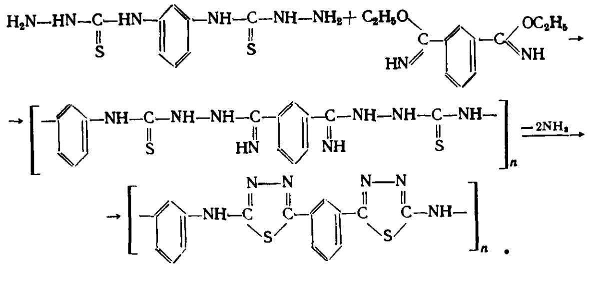


This method is more complex than direct substitution of oxygen in the 1,3,4-oxadiazole ring, but it yields products with higher molecular weights.

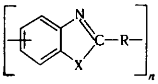
When P_2S_5 in polyphosphoric acid acts on poly-1,3,4-oxadiazoles, the latter undergo a polymer-analogue conversion into poly-1,3,4-thiadiazoles[168,169]:



Poly-1,3,4-thiadiazole with a somewhat different structure were obtained by the reaction of m-phenylenedithiosemicarbazide with diethyl isophthalimidate in polyphosphoric acid at 100–180°C:[170]

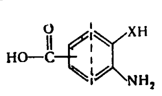


Another class of polyheteroarylenes in the synthesis of which polyphosphoric acid is widely employed are polybenzazoles. The principal representatives of this class of polyheteroarylenes are polybenzimidazoles, polybenzoxazoles, and polybenzothiazoles, corresponding to the general formula

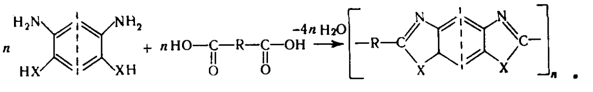


where X = NH, O, or S.

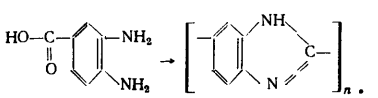
These polymers were obtained by the homocondensation of compounds with the general formula



or by the polycondensation of tetrafunctional nucleophilic agents with dicarboxylic acids or their derivatives:



Polybenzimidazoles have been investigated in greatest detail among polybenzazoles; this is probably because the majority of them dissolve in strong acid and certain amide solvents, even when the degree of cyclisation is high, and therefore by carrying out the process in one stage in polyphosphoric acid one does not preclude the formation of a workable polymer. Iwakura and coworkers[171,172] synthesised in polyphosphoric acid aromatic polybenzimidazoles by the homocondensation of 3,4-diaminobenzoic acid, its hydrochloride, sulphate, phosphate, and the potassium salt at 160°C, for 1–5 h:

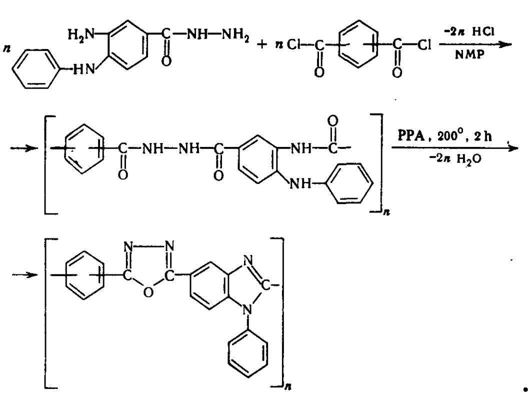


Apart from 3,4-diaminobenzoic acid, 3,4-diamino-3′-carboxybiphenyl, 3,4-diamino-4′-carboxybiphenyl, and 2,3-diamino-6-carboxynaphthalene have been employed as starting materials[171].

The same workers[173-177] synthesised polybenzimidazoles from the tetrachloride of 3,3′-diaminobenzidine and isophthalic, terephthalic, fumaric, and certain saturated aliphatic and alicyclic dicarboxylic acids. Both the acids themselves and their chlorides, nitriles, hydrazides, and esters were introduced into the reaction.

Koton and coworkers[178] employed di-(4-carboxyphenyl) ether and di(4-carboxyphenyl) sulphone as the acid components. In almost all cases high-molecular-weight polymers were obtained ($\eta_{\log}$† = 0.8–2.6), the syntheses of aromatic polybenzimidazoles being carried out under fairly severe conditions.

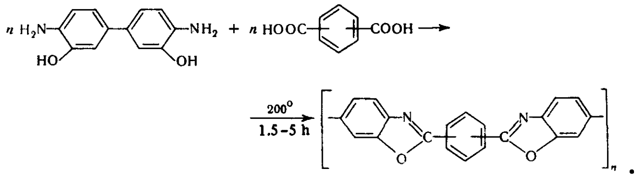
At the present time there are very few literature data on the application of polyphosphoric acid in the syntheses of poly-(*N*-aryl)benzimidazoles—polymers distinguished by enhanced solubility and resistance to thermo-oxidative degradation, compared with unsubstituted polybenzimidazoles[179]. We may note the work of Culbertson and Dietz[180], where polyaminohydrazides—the products of the low-temperature polycondensation of the hydrazide of 3-amino-4-anilinobenzoic acid with the dichlorides of isophthalic and terephthalic acid in *N*-methylpyrrolidinone—were subjected to cyclodehydration in polyphosphoric acid:



The poly-[2-(*mp*-phenylene)-5-(1,3,4-oxadiazolyl)-1-phenylbenzimidazoles] obtained in this way began to decompose only above 440°C both in nitrogen and air.

Considerable attention has been devoted to the synthesis in polyphosphoric acid of polybenzoxazoles and polybenzothiazoles. Aromatic polybenzoxazoles were obtained by the homocondensation at 160–200°C of isomeric aminohydroxybenzoic acids: 4-amino-3-hydroxybenzoic and 3-amino-4-hydroxybenzoic acids or their hydrochlorides[172]; the polymers had $\eta_{\log}$ = 0.7–2.2.

Aromatic polybenzoxazones with a somewhat different structure were synthesised by the reaction of bis-(*o*-aminophenols) or their hydrochlorides with aromatic dicarboxylic acids[181]; 3,3′-dihydroxybenzidine has been most often employed as the bis-(*o*-aminophenol):



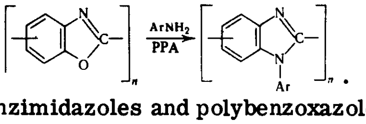
Aromatic polybenzoxazoles are obtained under very severe conditions; when the reaction is carried out at 200°C and lasts 1.5–5 h, their molecular weights reach high values ($\eta_{\log}$ = 1.36–2.1).

The reaction of bis-(*o*-aminophenols) with aliphatic dicarboxylic acids takes place, as in the synthesis of polybenzimidazoles[176], under milder conditions—at 100 to 120°C.[181]

The study of the thermal stability of polybenzoxazoles showed that the aromatic polymers decompose in air at about 450°C and those containing aliphatic units at about 300°C.

Polybenzoxazoles based on alicyclic dicarboxylic acids have also been synthesised[177].

Although the benzoxazole ring exhibits higher thermal and chemical stability compared with the 1,3,4-oxadiazole ring, under the action of primary aromatic amines in polyphosphoric acid, polybenzoxazoles are converted into the corresponding poly-(*N*-aryl)benzimidazoles[182]:



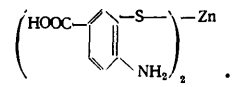
Like polybenzimidazoles and polybenzoxazoles, polybenzothiazoles may be synthesised in polyphosphoric acid both by the homocondensation of compounds containing

---

†Inherent viscosity or logarithmic viscosity number (Ed. of Translation).

nucleophilic and carboxy-groups and by the reaction of polyfunctional nucleophilic agents with dicarboxylic acids or their derivatives.

Iwakura and coworkers [172] synthesised aromatic polybenzothiazoles by the homocondensation of 4-amino-3-mercaptobenzoic acid as the hydrochloride and as the zinc thiophenoxide derivative:

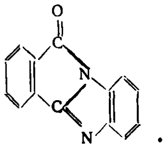


At a reaction temperature of 160–200°C for a process duration of 4 h, polymers with high molecular weights were obtained ($\eta_{\log} = 0.43-2.03$). Later investigations [183] showed that 4-amino-3-mercaptobenzoic and 3-amino-4-mercaptobenzoic acids, 3-amino-4-mercaptobenzamide, and 2,2-dimethylbenzothiazole-5-carboxamide may be employed as the initial compounds. The polycondensation was carried out at 250°C for 3 h; the molecular weights of the polymers thus obtained ($\eta_{\log} = 0.91-1.33$) greatly exceeded those of analogous polymers obtained in the melt and in solution in *m*-cresol and dimethylacetamide.

The syntheses of polybenzothiazoles in polyphosphoric acid on the basis of the dihydrochloride of 3,3′-dimercaptobenzidine were carried out at 200°C for 5–10 h in the case of isophthalic and terephthalic acids and at 120°C for 2 h in the case of sebacic acid [181]. The polymers had fairly high molecular weights ($\eta_{\log} = 0.31-1.02$).

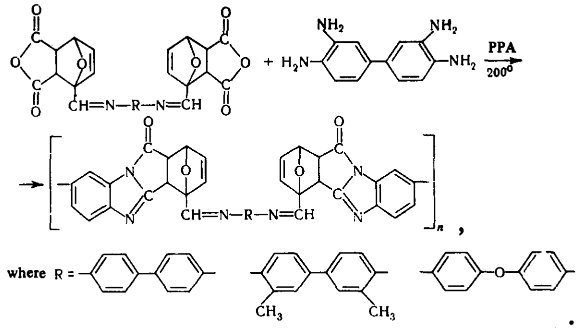
Hergenrother and coworkers [184] synthesised polybenzothiazoles from the dihydrochloride of 3,3′-dimercaptobenzidine and the following acid components: isophthalic acid, the diamide of isophthalic acid, di-(4-carboxyphenyl) ether, and the dimethyl ester of 4,4′-dicarboxybenzophenone. They succeeded in obtaining products with even higher molecular weights ($\eta_{\log} = 0.36-1.51$).

Yet another class of polybenzazoles which were synthesised in polyphosphoric acid is polybenzoylenebenzimidazoles containing 1,2-benzoylenebenzimidazole as the characteristic structural fragment of the condensed system:



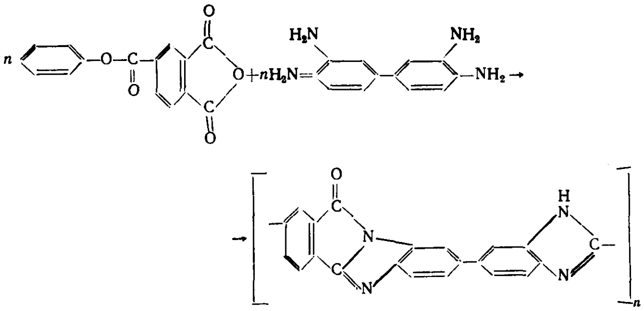
Polybenzoylenebenzimidazoles have been recently attracting particularly close attention of investigators in connection with the search for new types of so called "ladder" and "block-ladder" polymers, which, according to Tessler's theoretical postulates [185], should exhibit higher thermal stability and heat resistance than the usual polyheteroarylenes.

Dawans and Marvel [186] synthesised polybenzoylenebenzimidazoles in polyphosphoric acid from pyromellitic dianhydride and the tetrahydrochlorides of 1,2,4,5-tetraaminobenzene, 3,3′-diaminobenzidine, and di-(3,4-diaminophenyl) ether. The polycyclisation reactions were carried out at 200–220°C and yielded polybenzoylenebenzimidazoles with $\eta_{\log} = 1.91-1.81$‡. Berlin and coworkers [187] obtained polybenzoylenebenzimidazoles by the reaction in polyphosphoric acid of the dianhydrides of tetracarboxylic acids obtained as the bisadducts of the Diels–Alders reaction of furans and maleic anhydride derivatives with 3,3′-diaminobenzidine at 200°C for 8 h:

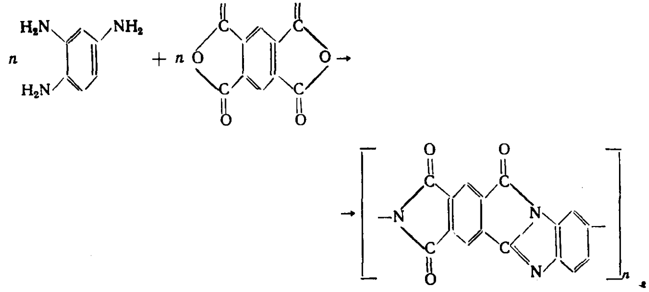


The polymers proved to be stable in air up to 350 to 450°C and dissolved in polyphosphoric acid and sulphuric acid; the reduced viscosity of their 1% solutions in concentrated sulphuric acid did not exceed 0.25.

Culbertson and Murphy [188], who carried out the reaction of the anhydride of 4-phenyltrimellitate with the tetrahydrochloride of 3,3′-diaminobenzidine in polyphosphoric acid at 200–210°C for 2 h, obtained an aromatic polymer containing alternating benzimidazole and benzolyenebenzimidazole rings and soluble in concentrated sulphuric acid only ($\eta_{\log} = 0.22$):



The polymer exhibited high thermal stability—intense decomposition in nitrogen and in air began at 550°C; in nitrogen the polymer retained 70 wt.% of its weight at 1000°C. A polymer with an analogous structure but a higher molecular weight ($\eta_{\log} = 0.513$) was obtained by the reaction of trimellitic anhydride with 3,3′-diaminobenzidine [189]. In addition the reaction of 1,2,4-triaminobenzene with pyromellitic dianhydride gave poly(imidobenzoylenebenzimidazole) with $\eta_{\log} = 0.63$: [189]

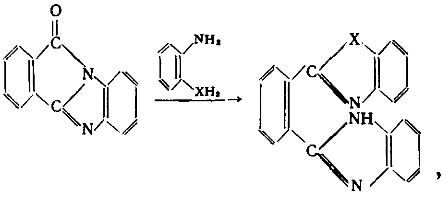


All the polymers containing benzoylenebenzimidazole rings and obtained in polyphosphoric acid are very insoluble. This may be a consequence both of the nature of the macromolecules themselves, and the presence of

---

‡Intrinsic viscosity = 1.1–1.8 according to the original paper (Ed. of Translation).

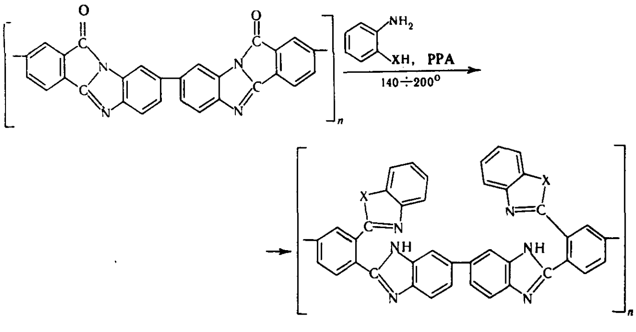
"cross-links" between them. "Cross-linked" structures may be formed as a result of the reaction of 1,2-benzoylenebenzimidazole with aromatic nucleophilic agents in polyphosphoric acid, analogous to the reaction of these compounds in nitrobenzene[190]:



where X = NH, O, or S.

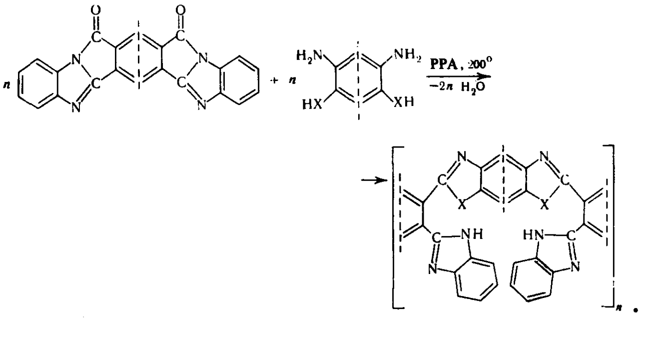
According to this reaction, one may expect that the terminal *o*-phenylenediamine groups of these macromolecules may react with the benzoylenebenzimidazole rings in their centre giving rise to "branching" of the bibenzimidazole type, which subsequently leads to "cross-linking". This reaction of the benzoylenebenzimidazole ring has been used to prepare various polybenzazoles containing attached benzazole groups.

Thus, by treating polybenzoylenebenzimidazoles with *o*-phenylenediamine, *o*-aminophenol, and *o*-aminothiophenol in polyphosphoric acid at 140–200°C, polybenzimidazoles were obtained with attached benzimidazole, benzoxazole, and benzothiazole groups in the *o*-position relative to the benzimidazole rings of the main macromolecular chains[191,192]:



where X = O, S, or NH.

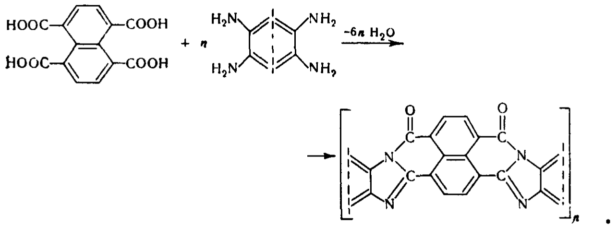
When this reaction was extended to bisbenzoylenebenzimidazoles, which are the products of the reaction of aromatic tetracarboxylic acids or their anhydrides with *o*-phenylenediamine, various polybenzazoles containing attached benzimidazole groups were obtained[193,194]:



Polymers of this kind show a combination of high thermal stability with high solubility in polar solvents.

Polyphosphoric acid has been used successfully in syntheses of polymers containing five- and six-membered condensed heterocycles, typical representatives of these polymers being polynaphthoylenebenzimidazoles—the products of the reaction of naphthalene-1,4,5,8-tetracarboxylic acid or its derivatives with bis-(*o*-phenylenediamines).

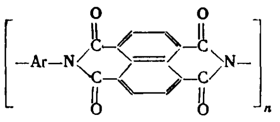
Van Deusen and coworkers[195,196] carried out the reaction of naphthalene-1,4,5,8-tetracarboxylic acid with 1,2,4,5-tetra-aminobenzene tetrahydrochloride and 3,3′-diaminobenzidine in polyphosphoric acid at 180–190°C for 20–24 h:



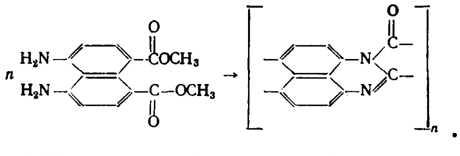
In the first case the product was a polymer entirely of the "ladder" type and in the second a polymer containing "ladder" blocks comprising eight condensed rings. The polymers dissolved in polyphosphoric and sulphuric acids had a high viscosity ($\eta_{\log} = 0.9–1.5$).

Berlin and coworkers[197,198] synthesised polymers of a similar structure from the dianhydride of naphthalene-1,4,5,8-tetracarboxylic acid and 3,3′-diaminobenzidine. The same investigators obtained polynaphthoylenebenzimidazoles based on di-(3,4-diaminophenyl)methane and di-(3,4-diaminophenyl) ether[199,200]. When the dianhydride of naphthalene-1,4,5,8-tetracarboxylic acid was replaced by the dianhydride of perylene-3,4,9,10-tetracarboxylic acid, the polymers had a relatively low molecular weight but exhibited high thermal stability[200,201].

When aromatic diamines (benzidine and others) were introduced into these reactions instead of bis-(*o*-phenylene diamines), polymers containing six-membered imide rings were obtained[198,200]:



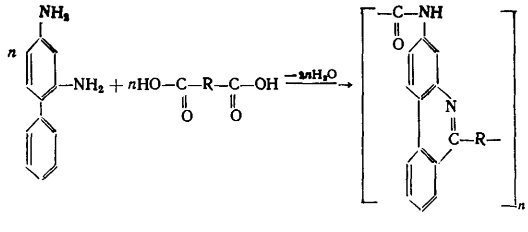
Van Deusen and coworkers[202] showed that the homypolycondensation of dimethyl 4,5-diaminonaphthalene-1,8-dicarboxylate and the anhydride of 4,5-diaminonaphthalene-1,8-dicarboxylic acid in polyphosphoric acid at 100 to 250°C results in the formation of a polymer with a "ladder" structure-poly(perimidine-6,7 : 1,2-tetrayl-1-carbonyl):



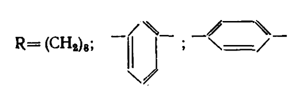
Polymers of this type are distinguished by high thermal stability: they are stable in air up to 450°C and in argon up to 600°C.

A number of studies have been made on the synthesis in polyphosphoric acid of other polyheteroarylenes incorporating six-membered nitrogen-containing heterocycles.

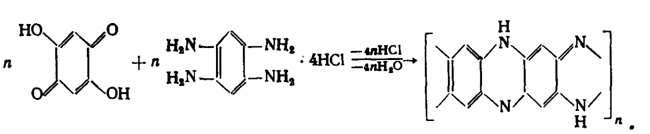
Thus Kolesnikov and coworkers[203] synthesised polyphenanthridinylamides from 2,4-diaminobiphenyl and aliphatic and aromatic dicarboxylic acids:



where

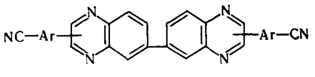


Stille and coworkers[204-207] employed polyphosphoric acid as a reaction medium in the synthesis of "ladder-type" polyquinoxalines. Thus, in the polycondensation of 2,5-dihydroxy-*p*-benzoquinone with 1,2,4,5-tetra-aminobenzene tetrahydrochloride in polyphosphoric acid at 150°C for 6–12 h, a hydrogenated aromatic "ladder-type" polyquinoxaline soluble in hexamethylphosphoramide and having $\eta_{\log} = 1.4$ was obtained[204,206,207]:



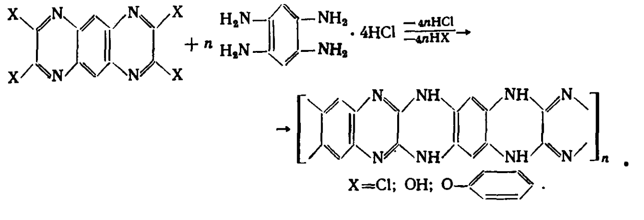
At an elevated temperature the polymer was dehydrogenated and acquired a stable fully aromatic structure. Other starting materials employed were 1,2,6,7-tetraoxopyrene and 1,2,5,6-tetraoxoanthracene[205,207] and also 2,3,6,7-tetra-aminodibenzo-*p*-dioxin and 3,3′-diaminobenzidine[207].

Copolymers containing in the main chain quinoxaline and benzimidazole rings were obtained by the reaction of phenoxycarbonylphenylglyoxals with bis-(*o*-phenylene diamines)[208]. The same polymers were also formed by the reaction of biscyanoarylquinoxalines having the general formula

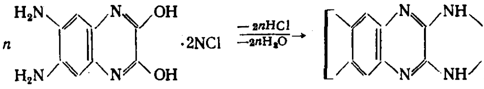


with 3,3′-diaminobenzidine tetrahydrochloride in polyphosphoric acid.

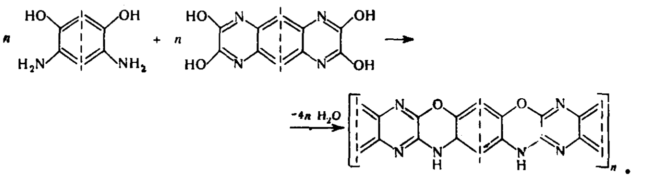
Marvel and coworkers[112,209-211] condensed substituted derivatives of quinoxaline with bis-(*o*-phenylenediamines), bis-(*o*-aminophenols), and bis-(*o*-aminothiophenols) to synthesise quinoxaline-containing polymers. Thus the reaction of tetra-aza-anthracene derivatives with 1,2,4,5-tetra-aminobenzene tetrahydrochloride in polyphosphoric acid at 250°C for 24 h gave "ladder-type" polymers containing quinoxaline and diazine rings[209]:



A polymer with a similar structure was obtained in the homopolycondensation of a diaminodihydroxy-compound containing a quinoxaline ring[209]:

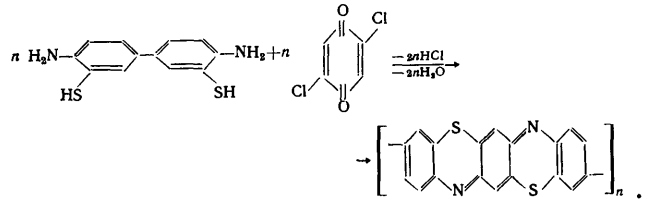


The reaction of diaminodihydroxy-compounds (2,5-diamino-1,4-dihydroxybenzene and 3,3′-dihydroxybenzidine) with tetrasubstituted quinoxalines [2,3,7,8-tetrahydroxy-1,4,6,9-tetra-aza-anthracene, 2,2′,3,3′-tetrahydroxy-6,6′-bisquinoxaline, and bis-(2,3-dihydroxy-6-quinoxalyl) ether] in polyphosphoric acid at 230–250°C for 24 h resulted in the formation of polymers containing quinoxaline and oxazine rings, which were partially soluble in concentrated sulphuric and methanesulphonic acids[210,211]:

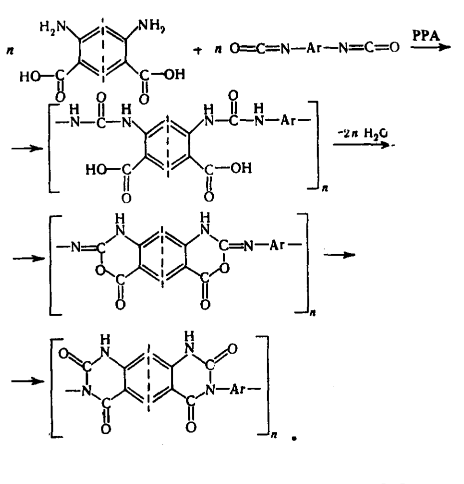


Tetrachloro-substituted quinoxalines have also been employed as the quinoxaline component[211].

Polytriphenodithiazine was obtained similarly by the reaction of 3,3′-dimercaptobenzidine with 2,5-dichloro-*p*-benzoquinone in polyphosphoric acid[212]:

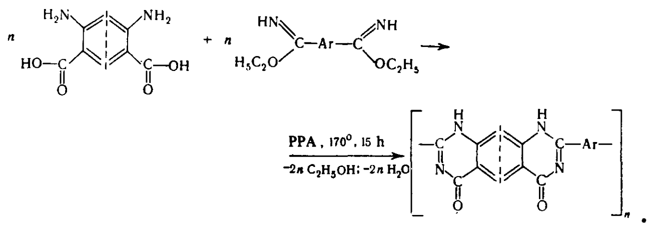


A number of cyclochain polymers with a set of valuable properties were synthesised on the basis of certain diaminodicarboxylic acids. In particular, a detailed study was made of the products of the bisanthranilic interaction in polyphosphoric acid of bisanthranilic acids [4,4′-diamino-3,3′-biphenylenedicarboxylic acids (Ed. of Translation)] with di-isocyanates—the so called polyquinazolinediones[141,142,213,214]:



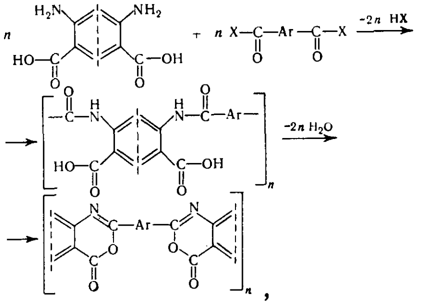
3,3′-Dicarboxybenzidine is the most widely employed bisanthranilic acid. [Inorganic] isocyanate, 3,3′-dimethyl-4,4′-diphenylene di-isocyanate, 3,3′-dimethoxy-4,4′-phenylmethane, etc. have been employed together with this compound. *p*-Phenylene di-isocyanate, *p,p'*-diphenylmethylene di-isocyanate, 1,5-naphthylene di-isocyanate, 3,3'-dimethyl-4,4'-diphenylene di-isocyanate, 3,3'-dimethoxy-4,4'-diphenylene di-isocyanate, 2,4-toluylene di-isocyanate, etc. have been used as the di-isocyanate component.

Eda and coworkers synthesised polyquinazolones by the reaction of bisanthranilic acids with bisimino ethers[215]:



The polyquinazalones had a comparatively low molecular weight—the characteristic§ viscosities of 0.5% solutions of these polymers in sulphuric acid did not exceed 0.15.

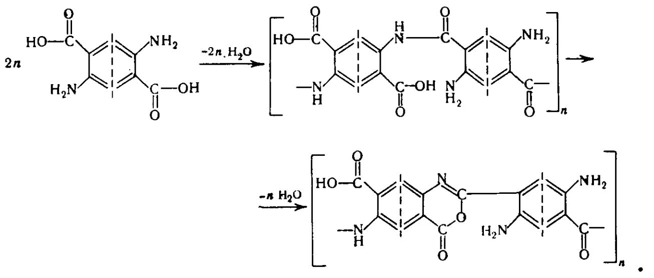
Products with much higher molecular weights were obtained by the reaction of bisanthranilic acids with aromatic dicarboxylic acids and their derivatives[216-220]. Here the first stage involves the formation of poly-*o*-carboxyamides, which on further increase of temperature are cyclised to the corresponding polybenzoxazinones:



where X = COOH, COCl, COBr, $CONH_2$, CN, or $COOCH_3$.

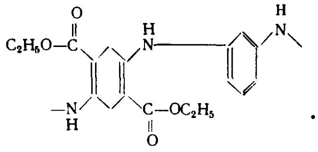
Polybenzoxazinones as well as polyquinazolinediones are very insoluble—they dissolve only in sulphuric and nitric acids; therefore it is desirable to convert them into finished products at the stage of poly-*o*-carboxyamides, which are soluble in organic solvents. The temperature of the onset of the decomposition of the fully aromatic polymers reaches 550°C.

Polymers containing benzoxazine fragments were obtained by the homopolycondensation of bisanthranilic acids (2,5-diaminoterephthalic, benzidine-3,3'-dicarboxylic, and others) in polyphosphoric acid[221,222]:

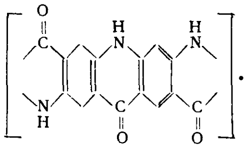


These polymers showed somewhat lower thermal stability compared with polyquinazolinediones and polybenzoxazinones: they proved to be stable in an inert atmosphere up to 450°C and began to decompose under the conditions of thermo-oxidative degradation at 350°C.

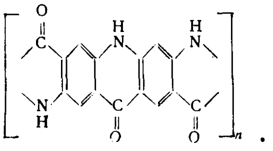
Kimura[223] developed a synthesis of polyquinolones—a new class of polyheteroarylenes. The reaction in polyphosphoric acid of diethyl succinosuccinate with aromatic diamines [m-phenylenediamine and di-(4-aminophenyl) ether] gave polyamines of the following type:



Their cyclisation in polyphosphoric acid (in an inert atmosphere) yielded insoluble polydihydroquinolones infusible up to 400°C and having a "ladder" structure:



The same polyamines may be oxidised by chloranil in dimethylformamide to aromatic polyamines, whose cyclisation in polyphosphoric acid gives infusible and insoluble polyquinolones:



V. THE MECHANISM OF CYCLISATION REACTIONS IN POLYPHOSPHORIC ACID

The complex composition of polyphosphoric acid makes it extremely difficult to investigate the mechanism of reactions occurring in it and for this reason very little has been done in this field. The high viscosity of polyphosphoric acid, which prevents the isolation of intermediates by crystallisation, and the impossibility of employing cyroscopic methods made it very difficult to carry out the necessary kinetic measurements and therefore in the interpretation of the mechanisms there remains a considerable element of guesswork.

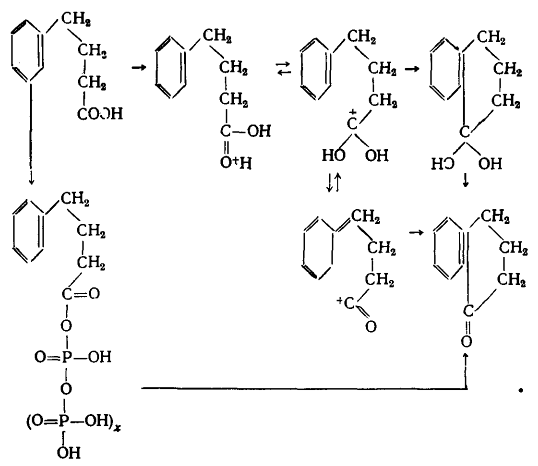
Among the reactions in polyphosphoric acid, the cyclisation of substituted aromatic acids, the conversion of γ-lactones into cyclopentanones, and the Beckmann and Lossen rearrangements have been investigated in greatest detail.

According to the literature, polyphosphoric acid functions simultaneously as a protic acid, a Lewis acid, and a phosphorylating agent[224]. Thus in the cyclisation of γ-phenylbutyric acid protonation or the formation of a

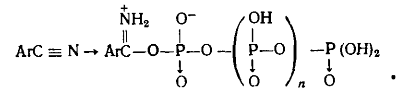
---

§Probably inherent (Ed. of Translation).

mixed anhydride is postulated as the initial stage, as shown below:



In the conversion of γ-lactones into cyclopentanones the intermediate formation of a ketocarbonium ion is suggested[225]. In the cyclisation of nitriles and also in the conversion of γ-lactones into cyclopentanones, phosphate esters may be formed and in the first case this is probably preceded by the addition of elements of polyphosphoric acid to the triple bond[5]:



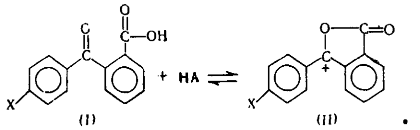
$$\mathrm{ArC\equiv N\rightarrow Ar\overset{\overset{+}{N}H_2}{C}{-}O{-}\underset{\downarrow\atop O}{\overset{O^-}{P}}{-}O{-}\left(\underset{\downarrow\atop O}{\overset{OH}{P}}{-}O\right)_n{-}\underset{\downarrow\atop O}{P}(OH)_2}\ .$$

The presence of the intermediate carbonium ion has been confirmed only indirectly[226].

Since the majority of the latest communications on the applications of polyphosphoric acid are related to cyclodehydration or more specific intermolecular acylation, kinetic study of this type of reaction is of the greatest practical and theoretical interest. The elucidation of the mechanism of these reactions was preceded by a detailed study of the acid properties of polyphosphoric acid itself treated as the $P_2O_5-H_2O$ system.

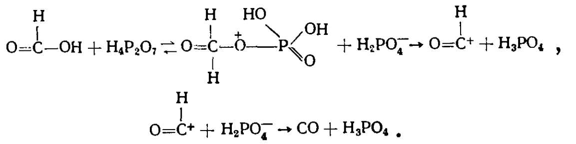
In an early investigation by Downing and Pearson[29] it was shown that the acidity of the $P_2O_5-H_2O$ system (from 65 to 85.7 wt.% P_2O_5 at 25–27°C) increases monotonically with increasing P_2O_5 content. The data obtained by Gel'bshtein et al.[227] in a study of the acid properties of the $P_2O_5-H_2O$ system between 2.7 and 83.5 wt.% P_2O_5 at 25°C with 2,4-dichloro-6-nitroaniline and 2-bromo-4,6-dinitroaniline as indicators also confirm the absence of an acidity maximum in the $P_2O_5-H_2O$ system in the region corresponding to polyphosphoric acid.

In this connection it is noteworthy that, when polyphosphoric acid is employed as a catalyst in a number of reactions, its catalytic activity passes through a maximum. For example, the rate of heterolytic decomposition of formic acid is a maximum at 80 wt.% P_2O_5.[228] This was also reported by Downing and Pearson[229], who established that the rate of intermolecular acylation of *o*-benzoylbenzoic acids [*o*-benzoyl-, *o*-(*p*-chlorobenzoyl)- and *o*-(*p*-tolyl)-benzoic acids] passes through a maximum in the range of compositions corresponding to 78–83 wt.% P_2O_5. The authors found it difficult to explain this observation, since they postulated that the mechanism of the cyclisation of *o*-benzoylbenzoic acids in polyphosphoric acid is in general analogous to the mechanism proposed by Newman[230] for sulphuric acid, i.e. that the reaction takes place via an intermediate cyclic carbonium ion (II):



Thus in the above reactions there is no correspondence between the acidity of the medium and their rate. This is also reflected in the fact that for certain heterolytic reactions, a given rate is observed in polyphosphoric acid with a much lower acidity than in sulphuric acid, for example. Thus the rate constants for the reaction $HCOOH = CO + H_2O$ at 50°C in polyphosphoric acid containing 80.5 wt.% P_2O_5 and in 90% sulphuric acid are virtually identical ($2.4 \times 10^{-3}\ s^{-1}$ and $2.7 \times 10^{-3}\ s^{-1}$ respectively). Nevertheless the acidity function of polyphosphoric acid of the above composition is $H_0 = -5.80$ at 25°C and that of 90% sulphuric acid is $H_0 = -8.44$ at 20°C.[228] Analogous relations have been observed for the Beckmann rearrangement of acetophenone oximes[231] and also for intramolecular cyclisation[229]. According to many investigators, the above findings may be explained by rejecting the hypothesis of purely proton-dependent mechanisms of the above reactions in polyphosphoric acid, adopting instead a mechanism including acid-catalysed phosphorylation. Probably polyphosphoric acid transfers to the substrate the $(H_2PO_3)^+$ ion, and not H^+, with formation of the corresponding anion, for example: $H_4P_2O_7 = [H_2PO_3]^+ + H_2PO_4^-$.

In the decomposition of formic acid in polyphosphoric acid this will correspond to the following mechanism:



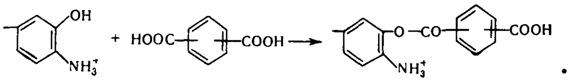
$$\mathrm{O{=}\overset{H}{C}{-}OH+H_4P_2O_7\rightleftarrows O{=}\underset{H}{\overset{H}{C}}{-}\overset{+}{O}{-}\overset{HO}{P}\begin{smallmatrix}OH\\O\end{smallmatrix}+H_2PO_4^-\rightarrow O{=}\overset{H}{C}{}^+ + H_3PO_4}\ ,$$

$$\mathrm{O{=}\overset{H}{C}{}^+ + H_2PO_4^-\rightarrow CO+H_3PO_4}\ .$$

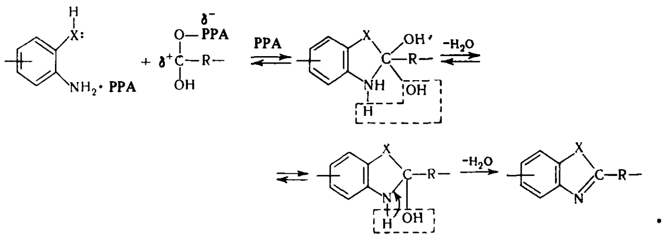
It is known that H_3PO_4 and polymeric metaphosphoric acid $(HPO_3)_n$ are incapable of phosphorylation, while acids such as $H_4P_2O_7$ and $H_5P_3O_{10}$ behave as phosphorylating agents. The content of these acids in the $P_2O_5-H_2O$ system is a maximum in the range of P_2O_5 concentrations where there are maxima in the rates of the reactions considered. Thus the existence of reaction rate maxima in polyphosphoric acid has been explained. In media incapable of phosphorylation, the reactions take place via a proton mechanism which corresponds to a lower rate at the same acidity[227].

The results of kinetic studies on the ring closure of 2-carboxy-2′-deuterobiphenyl to fluorenone by Donney and Klemchuk[232] and the data of Goldberg and Wragg[233], who determined the rate constants for the cyclisation of *o*-phenoxybenzoic acid to xanthone in polyphosphoric acid containing 81.6% P_2O_5, can also be explained from this standpoint.

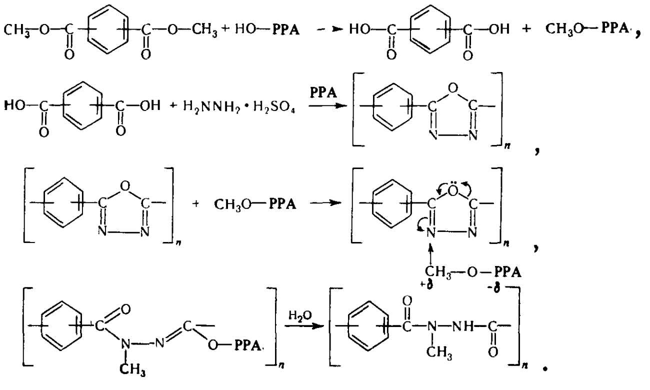
Problems associated with the changes in the reactivity of various compounds in polyphosphoric acid are of considerable interest[181]. It has been shown that polyphosphoric acid, which is a strong Lewis acid, increases the positive charge at the carbon atom of the carbonyl group and thereby leads to an increase of its electrophilic reactivity. It is also interesting to note that in reactions in polyphosphoric acid the basicity of the hydroxy-group is higher than that of the amino-group; therefore in the reaction of bis-(*o*-aminophenols) with dicarboxylic acids in polyphosphoric acid, there is initially selective formation of a polyester[181]:



Taking into account these facts, Iwakura and coworkers[181] proposed the following general mechanism for the formation of polybenzazoles:

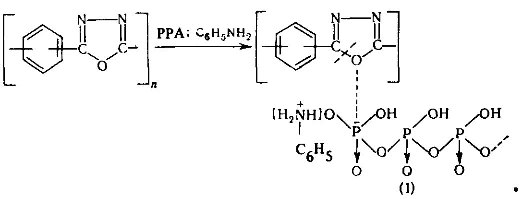


Probably the mechanism of the formation of poly-1,3,4-oxadiazoles from dicarboxylic acids and hydrazine derivatives is similar. However, in the presence of alkylating agents the 1,3,4-oxadiazole ring is opened. Thus, when dimethyl and diethyl esters of isophthalic and terephthalic acids were employed as starting materials, poly-(*N*-alkyl)-hydrazides were obtained[147]. The reaction probably takes place via the following mechanism:



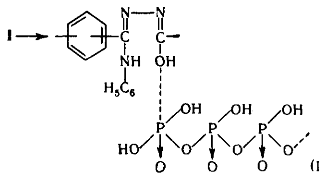
This mechanism is supported by the finding that in the interaction of poly-1,3,4-oxadiazole (obtained separately) with alkylating agents in polyphosphoric acid, the oxadiazole ring is opened with subsequent *N*-alkylation and formation of a poly-(*N*-alkyl)hydrazide.

Substitution of one of the heteroatoms in the heterocycle by another also takes place with opening of the oxadiazole ring. The mechanism of the substitution reaction was examined in the synthesis of poly-(4-phenyl-1,2,4-triazoles)[161]. According to the mechanism proposed, a molecule of the polyphosphoric acid salt and a molecule of aniline add to the oxygen atom of the oxadiazole ring, forming an unstable intermediate complex (I), in which the C–O bond in the ring is weakened:



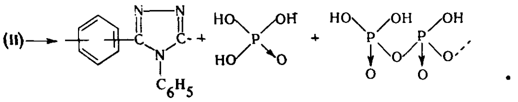
(I)

Under the influence of high temperature, the complex (I) dissociates with liberation of free aniline, which attacks the weakened C–O bond. The ring is then opened and the aniline residue adds to the carbon atom in the 5-position and the proton adds to the oxygen atom [compound (II)]:

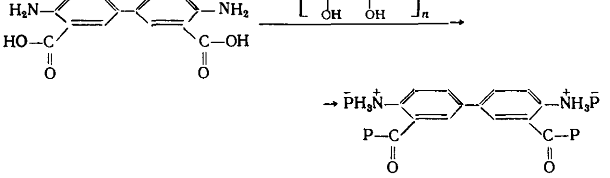


(II)

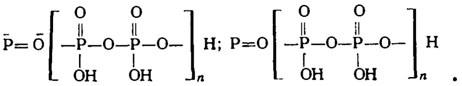
Then the polyphosphoric acid molecule is split off together with the hydroxy-group and the mobile hydrogen atom at the nitrogen acts on the O–P bond and facilitates the dissociation of an orthophosphoric acid molecule from polyphosphoric acid; at the same time the ring is closed and a polytriazole is formed:



The mechanism of the homocondensation and co-condensation reactions of bisanthranilic acid in polyphosphoric acid[234,235], which takes place via the formation of a phosphorylated intermediate, was examined in somewhat greater detail:

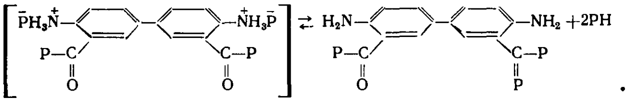


where



$$\bar{P}=\bar{O}\left[\begin{matrix} & \overset{O}{\overset{\|}{}} & & \overset{O}{\overset{\|}{}} & \\ - & P & -O- & P & -O- \\ & \underset{OH}{|} & & \underset{OH}{|} & \end{matrix}\right]_n H;\quad P{=}O\left[\begin{matrix} & \overset{O}{\overset{\|}{}} & & \overset{O}{\overset{\|}{}} & \\ - & P & -O- & P & -O- \\ & \underset{OH}{|} & & \underset{OH}{|} & \end{matrix}\right]_n H .$$

When the temperature is raised, the phosphorylated product dissociates:



The products thus formed contain free amino-groups and mixed anhydride groups, which facilitates the amidation reaction and is responsible for the possibility of both the homocondensation of bisanthranilic acids and their copolycondensation with dicarboxylic acids.

---o0o---

The cyclisation and polycyclisation reactions in polyphosphoric acid constitute a comparatively new and rapidly developing field, which will undoubtedly enrich organic chemistry in new valuable experimental and theoretical data in the immediate future.

Differentiating Effect of Amphiprotic Solvents in Relation to Phenol and Benzoic Acid Derivatives

L.N.Bykova and S.I.Petrov

The review deals with the methods of estimating the differentiating effect of amphiprotic solvents on the acid strengths of phenol and benzoic acid derivatives. New literature data are presented for the dissociation constants and half-neutralisation potentials of electrolytes of the above classes. The possibility of using the Hammett equation to characterise the differentiating effect of solvents is discussed. The available literature values of the autoprotolysis constants of amphiprotic solvents are analysed critically. The problem of the relation between the parameters characterising the differentiating effect of amphiprotic solvents is considered particularly as regards individual groups of electrolytes and the autoprotolysis constant. The causes of the different differentiating capacities of amphiprotic solvents in relation to phenols and benzoic acids are discussed.
The bibliography includes 119 references.

CONTENTS

I. INTRODUCTION

The problem of the differentiating effect of solvents on the strengths of electrolytes has been attracting the attention of specialists in various branches of chemistry in connection with wide employment of non-aqueous solvents in physical, organic, and analytical chemistry[1-4]. According to Brönsted's proton theory of acids and bases[5], the differentiating effect of solvents, i.e. their capacity to alter the relative strengths of electrolytes, is shown only in relation to electrolytes of different charge types: cationic, neutral, and anionic acids. When the p*K* values for the dissociation of electrolytes in two solvents are compared, they are found to fit on three parallel lines with a slope of unity according to the particular charge type to which the acids belong.

The reviews of data for the dissociation constants of acids and bases in various solvents, in the monographs of Shatenshtein[6] and Izmailov[1] showed that there are linear relations between the p*K* values for the dissociation of acids or bases in water and a non-aqueous solvent or between the values in two non-aqueous solvents. However, as a refinement of Brönsted's theory, it was established that in many solvents uncharged acids exhibit relations associated with various natural groups to which they belong. A detailed study of the charges of the relative strengths of acids and bases under the influence of solvents enabled Izmailov[1] to find the limits of applicability of Brönsted's theory and to establish the differentiating effect of solvents on the strengths of acids and bases.

Izmailov[1] showed that the differentiating effect of solvents is related to their solvating capacity. The relative dissociation constants of different acids in the same solvent depend on their relative intrinsic acidities and the differences between the solvation energies of the acid anions and molecules. The change in the strength of the electrolyte on passing from one solvent to another is due to the change in the relative solvation energies of the ions and molecules of the acid in the two solvents.

Numerous studies have been made on the nature of the solvating effect of solvents[7-14], which showed that the solvation of ions and molecules of electrolytes in solution depends on a number of factors. Apart from the proton affinity of the molecules and lyate ions of solvents (the basicity and acidity of solvents), solvation is determined by the donor–acceptor interaction between the solvent molecules and the molecules and anions of the acid, the formation of hydrogen bonds, electrostatic forces, dipole–dipole and ion–dipole interactions, dispersion interaction, and changes in the structure of the solvent.

Various methods are available for estimating the differentiating effect of solvents. The principal method consists in the measurement and comparison of the dissociation constants of electrolytes (K_{diss}).[1] Recently the half-neutralisation potentials of electrolytes ($E_{1/2}$) have also been measured and compared[4,15-20]. This simple method is widely used in analytical chemistry, since it makes it possible to predict the optimum conditions for the separate titration of acids or bases in mixtures. The differentiating effect of solvents can also be estimated on the basis of the Hammett and Taft equations by comparing the reaction constants ρ and ρ^*, since they depend not only on the type of reaction but also on its conditions, i.e. primarily on the nature of the solvent[21-25].

The present review deals with the differentiating effect of amphiprotic solvents in relation to compounds which exhibit acid properties in solutions, mainly in relation to phenol and benzoic acid derivatives—the most thoroughly investigated classes of electrolytes. Amphiprotic solvents include those whose acidic and basic properties are not more pronounced than the corresponding properties of water: alcohol, ketones; acetonitrile, and dimethylformamide; an exception is dimethyl sulphoxide, whose basic properties are somewhat more marked than those of water.

The differentiating effect of solvents may be characterised in terms of the following parameters: (1) the slope of the relation $pK_A(ns)^† = \alpha pK_A(H_2O) + \beta$, i.e. the parameter α, which is equal to the difference between the pK_A values of two electrolytes in a non-aqueous solution when their $pK_A(H_2O)$ differ by unity; (2) the slope of the relation $\Delta E_{1/2} = A pK_A(H_2O) + B$, i.e. the parameter A, which is equal to the difference between the half-neutralisation potentials of two electrolytes in a non-aqueous solution when their $pK_A(H_2O)$ values differ by unity; (3) the slope of the relation $\Delta E_{1/2} + A'\Sigma\sigma + B'$, i.e. the parameter A', which is equal to the difference between the half-neutralisation potentials of two electrolytes in a non-aqueous solution when their $\Sigma\sigma$ values differ by unity (the σ are the constants of the substituents); (4) the reaction constant ρ in the Hammett equation $pK_{rel} = \rho\Sigma\sigma$.

2. STUDY OF THE DIFFERENTIATING EFFECT OF SOLVENTS BY MEASURING THE DISSOCIATION CONSTANTS OF ELECTROLYTES

The dissociation of acids in non-aqueous solutions takes place in a much more complex manner than in an aqueous medium. Izmailov[1] showed that the interaction of an acid with a solvent includes a number of interrelated processes involving the formation of addition products of solvent molecules with the electrolyte molecules and the formation of solvated ions and ion pairs. The study of acid–base interaction in solvents with weak acidic properties, which are therefore incapable of forming hydrogen bonds via the hydrogen atoms in solvent molecules, showed that the mechanisms of the dissociation of acids and bases must be supplemented by the following equilibria[26-31]:

$$A^- + HA \rightleftarrows HA_2^-,$$
$$BH^+ + B \rightleftarrows B_2H^+.$$

These processes, called homoconjugation, take place to a particularly high degree in solvents which Parker[8,9,32] called "aprotic dipolar", since they are incapable of forming hydrogen bonds with the anions of acids and the molecules of bases. Such solvents include in the first place acetonitrile whose basic and acidic properties are both weak. In dimethylformamide and dimethyl sulphoxide homoconjugation processes are weaker because of the higher basicity of these solvents (SH), whose molecules enter into the following competitive reaction with the anion A^-:[33]

$$A^- + HS \ldots HA \rightleftarrows A^- \ldots HA + SH.$$

The studies of Yasinskii's and coworkers[34] showed that in acetone as well as in acetonitrile homoconjugation processes occur to a considerable extent.

As a result of the complexity of the dissociation of acids in non-aqueous solutions, the use of different methods for the determination of K_{diss} in such media produces greater discrepancies than in water. Thus in acetonitrile the range of pK_A values for 2,4,6-trinitrophenol is between 4.34 and 11.0.[30,31,35-38] In solvents with high dielectric constants ($\epsilon < 20$) a considerable proportion of ions are bound in ion pairs which behave as free ions in spectrophotometric and indicator methods for the measurement of pK_A. Therefore in such solvents the K_A values determined by optical methods prove to be higher than those found by electrometric methods. In "aprotic dipolar" solvents homoconjugation processes complicate the calculation of the pK_A values from conductimetric and potentiometric measurements. Reliable pK_A values for acids in such solvents may be obtained by employing a group of methods for measurement (potentiometric, conductimetric, and spectrophotometric).[30,31] For a quantitative interpretation of the acid–base interaction in acetonitrile, it is necessary to take into account more than 10 equilibria[39].

In order to characterise the differentiating effect of solvents, we interpreted the literature pK_A data for phenols and benzoic acids in alcohols, ketones, acetonitrile, dimethylformamide, and dimethyl sulphoxide. The pK_A values for phenols and benzoic acids in non-aqueous solvents are listed in Tables 1 and 2 respectively. For alcohols, their mixtures with water, and acetone, the pK_A values were measured largely by electrometric methods, while for acetonitrile, dimethyl sulphoxide and dimethylformamide the chosen values were obtained by both electrometric and spectrophotometric methods.

The greatest scatter of experimental pK_A data occurs in the case of 2,4,6-trinitrophenol in all the solvents examined. Even in water the pK_A values for 2,4,6-trinitrophenol range from 0.4 to 2.3.[48,60] For 2,4,6-trinitrophenol, we employed $pK_A(H_2O) = 0.71$ obtained conductimetrically[40]. In methanol we adopted $pK_A = 3.67$ taken from Juillard[44] instead of 4.80 which Izmailov[1] quoted without indicating the method of measurement. Examination of the pK_A data for 2,4,6-trinitrophenol in acetone and dimethylformamide showed that it is difficult to give preference to any one value and therefore we employed the average of the data quoted in Table 1.

It follows from Brönsted's theory[5] that the pK_A values for acids in a non-aqueous solvent and in water are related as follows:

$$pK_A(\text{ns}) = pK_A(H_2O) + \text{const.} \qquad (1)$$

On the basis of the literature and his own data, Izmailov[1,46] showed that, for acids of the same natural group in two solvents, Eqn. (1) is of the following form:

$$pK_A(\text{ns}) = \alpha pK_A(H_2O) + \beta, \qquad (2)$$

where α and β are quantities which depend on the natural group of acids and the chemical nature of the solvent.

Fig. 1 presents examples of the relations for the pK_A of phenols in non-aqueous solvents as a function of $pK_A(H_2O)$. The numbers of the points in Fig. 1 correspond to those in Table 1. In plotting the above relations, use was made of the average values of the concordant data quoted in Table 1. The straight lines referring to acetone, dimethylformamide, and acetonitrile are almost parallel and have a much higher slope than the lines for methanol.

Fig. 2 presents examples of the relations between the pK_A for benzoic acids in non-aqueous solvents and the $pK_A(H_2O)$; in plotting these functions, use was made largely of the $pK_A(ns)$ values for benzoic acids determined potentiometrically. The numbers of the points in Fig. 2 corresponds to those in Table 2. The variation of pK_A in ethanol with $pK_A(H_2O)$ shows different changes in the $pK_A(ns)$ values for the *m*- and *p*-derivatives of benzoic acid on passing from an aqueous to a non-aqueous solution compared with the *o*-derivatives, which are weaker in non-aqueous solutions than would be expected from their

---

p$K_A(H_2O)$. Owing to the small number of points, individual relations for the *m*- and *p*-derivatives on the one hand and the *o*-derivatives on the other could not be obtained in other solvents. In the derivation of Eqns. (2), the pK_A values for the *m*- and *p*-derivatives only were employed.

Eqns. (2) were derived by least squares on a "Promin" computer. The equations obtained, the number of experimental points used in their derivation (*n*), the correlation coefficients (*r*), and the standard deviations (*s*) are listed in Table 3.

The empirical Eqns. (2) were compared with the thermodynamic equation derived by Izmailov[1] and Grunwald and Berkowitz[7]:

$$pK_{A(ns)} = \overbrace{pK_A(H_2O) + \lg\frac{\gamma_{0A^-}}{\gamma_{0HA}}}^{a pK_A(H_2O)} + \overbrace{\lg\gamma_{0H^+}}^{\beta}. \qquad (3)$$

If on passing from water to a non-aqueous solvent the quantity $\lg(\gamma_{0A^-}/\gamma_{0HA})$ for a given reaction series varies in proportion to p$K_A(H_2O)$:

$$\lg\frac{\gamma_{0A^-}}{\gamma_{0HA}} = b pK_A(H_2O), \qquad (4)$$

then the coefficient α in Eqn. (2) will differ from unity owing to the effect of the term $\lg(\gamma_{0A^-}/\gamma_{0HA})$ and is equal to $1 + b$. In this case the constant term should be equal to $\lg\gamma_{0H^+}$ for the given solvent. If on passing from water to a non-aqueous solvent the relation

$$\lg\frac{\gamma_{0A^-}}{\gamma_{0HA}} = b pK_A(H_2O) + c, \qquad (5)$$

holds, the constant term β will differ from $\lg\gamma_{0H^+}$ by an amount c.

It follows from Table 3 that β is indeed close to $\lg\gamma_{0H^+}$ for phenol and *m*- and *p*-derivatives of benzoic acid in alcohols and acetone[61]. The value of $\lg\gamma_{0H^+}$ for dimethylformamide is unknown, but comparison of the relative positions of the relative acidity scales for dimethylformamide and water shows that the value of $\lg\gamma_{0H^+}$ should be close to zero[62]. The $\lg\gamma_{0H^+}$ literature data for acetonitrile differ somewhat among themselves[33,61]. Possibly Eqn. (5) holds for acetonitrile. Fig. 2 shows that for

Table 2. The negative exponents of the dissociation constants of benzoic acids at 25°C in various solvents measured potentiometrically (P), conductimetrically (C), spectrophotometrically (SP) and by an indicator method (I).

o-derivatives of benzoic acid the constant term β in Eqn. (2) is not equal to $\lg \gamma_{0\mathrm{H}^+}$ for the given solvent. This can be accounted for by the specific effect of substituents in the *o*-position on the changes in the relative solvation energies of the anions and molecules of the acids on passing from water to a non-aqueous solvent.

The data presented in Table 3 show that, in terms of the coefficient α in Eqns. (2), which reflect the differentiating effect of the solvent in relation to a single reaction series of electrolytes, the solvents examined can be arranged in the following series, which is common to both phenol derivatives and *m*- and *p*-derivatives of benzoic acid:

$$(CH_3)_2SO > CH_3CN > (CH_3)_2NCHO > CH_3COCH_3 > C_2H_5OH > CH_3OH > H_2O.$$

When water is added to a non-aqueous solvent, the differentiating effect of the latter falls, as can be seen for aqueous ethanol mixtures with respect to benzoic acids

and water–isopropyl alcohol mixtures with respect to phenols.

The differentiating effect of solvents in relation to electrolytes of different classes is various: the acid strength of benzoic acids is different in amphiprotic solvents compared with water and to a greater extent than for phenols. As a result, the difference $\Delta pK_A(ns)$ between benzoic acid and phenol derivatives depends on the $pK_A(H_2O)$ values for the electrolytes compared and is greater the higher is $pK_A(H_2O)$ (Fig. 3). For this reason ΔpK_A is not always constant for two different groups of electrolytes and in such cases does not characterise the differentiating effect of the non-aqueous solvent relative to water, as was assumed in a number of investigations[47,48,63,64]. The similarity of the slopes of the plots of $pK_A(ns)$ against $pK_A(H_2O)$ for phenols and carboxylic acids is a consequence of the fact that the group of carboxylic acids includes electrolytes of different reaction series (aromatic and aliphatic carboxylic acids). To establish the laws governing the variation of the relative strengths of acid on passing from solvent to solvent, i.e. the differentiating effect of solvents, it is necessary to examine narrow series of electrolytes[22,60,65].

3. STUDY OF THE DIFFERENTIATING EFFECT OF SOLVENTS BY MEASURING THE HALF-NEUTRALISATION POTENTIALS OF ELECTROLYTES

This method of measuring the relative strengths of electrolytes has proved fruitful not only in the determination of acid strengths in aprotic solvents, where it is possible to determine only relative constants, but also in protolytic solvents, where it is possible to avoid many difficulties associated with the determination of the usual dissociation constants.

The relative strengths of acids and bases in non-aqueous solvents are characterised in three ways, which differ only in the scale of the measurements employed: by the value of pK_{rel} and the pH or potential at the half-neutralisation point—$pH_{1/2}$ and $E_{1/2}$.[4,66-71] In the potentiometric measurement of the relative dissociation constants of acids the pK_{rel} are related to $pH_{1/2}$ and $E_{1/2}$ by the following equations: $pK_{rel} = pH^{x}_{1/2} - pH^{st}_{1/2}$ or $pK_{rel} = (E^{x}_{1/2} - E^{st}_{1/2})/59$, where $pK^{x}_{1/2}$ and $E^{x}_{1/2}$ are the half-neutralisation pH or potentials (mV) for the test compound and $pH^{st}_{1/2}$ and $E^{st}_{1/2}$ are the corresponding values for a standard compound.

To characterise the relative acidities of electrolytes, one employs absolute values of $pH_{1/2}$ and $E_{1/2}$ as well as values referred to a standard ($\Delta pH_{1/2}$ and $\Delta E_{1/2}$), which reduces the effect of variations in the diffusion-potential. In non-aqueous solvents $pH_{1/2}$ and $E_{1/2}$ or $\Delta pH_{1/2}$ and $\Delta E_{1/2}$ are not always functions of the dissociation constants of the electrolytes only but also reflect the effect of factors on which the form of the titration curves depends (the degree of dissociation of the salt formed, its solubility, homoconjugation phenomena, etc.). An increase in the slope of the titration curve in the buffer region results in a displacement of the half-neutralisation potential of the acid to a more basic region; this is facilitated by homoconjugation phenomena[34,39]. A decrease of the slope of the titration curve in the buffer region results in a displacement of the half-neutralisation potential of the acid to a more acidic region; this is favoured by the formation of ion pairs of the salt and its precipitation. However, for acids of a single natural group, the change in $E_{1/2}$ basically correctly reflects the variation of the dissociation constants of the electrolytes in the same solvent.

The half-neutralisation potentials of phenol derivatives were measured in alcohol (methyl, ethyl, propyl, isopropyl, butyl, isobutyl, and t-butyl), ketones (acetone, ethyl methyl ketone, and isobutyl methyl ketone), acetonitrile, dimethylformamide, dimethyl sulphoxide, and other solvents[4,17-19,59,71-76]. Comparison of the half-neutralisation potentials with the $pK_A(H_2O)$ values yields relations described by the equation

$$\Delta E_{1/2}(\text{HP}) = ApK_A(H_2O) + B, \tag{6}$$

where $\Delta E_{1/2}$ is the half-neutralisation potential of phenol measured relative to the half-neutralisation potential of benzoic acid. Measurements for halogeno- and nitro-derivatives of phenol with substituents in the *m*- and *p*-positions showed that the sequence of acidities characteristic of the aqueous solutions is retained[18,72,73]. In a study of halogeno- and nitro-derivatives of phenol containing only *o*-substituents or *o*-substituents together with *m*- and *p*-substituents, it was established that in alcohols phenols with *o*-substituents behave as weaker electrolytes than the *m*- and *p*-derivatives which have the same values of $pK_A(H_2O)$ (Fig. 4). The weaker acid strength of *o*-derivatives of phenol compared with the *m*- and *p*-derivatives may be accounted for by the effect of the intramolecular hydrogen bond between the hydrogen of the phenolic hydroxyl and the substituent in the *o*-position. In ketones, acetonitrile, and dimethylformamide, the effect of the formation of an intramolecular hydrogen bond in *o*-derivatives of phenol cannot be detected, since the titration curves have high slopes in the buffer region owing to homoconjugation, which leads to a displacement of $E_{1/2}$ to a more basic region (Fig. 5). This has a particularly

marked effect on *m*- and *p*-derivatives and therefore *o*-, *m*-, and *p*-derivatives of phenol have a common relation between $\Delta E_{1/2}$ and $pK_A(H_2O)$ in ketones, acetonitrile, and dimethylformamide.

Pearce and Simkins[60] investigated the differentiating effect of ethyl alcohol and acetone with respect to various phenol derivatives: nitrophenols, derivatives of picric acid, and derivatives of styphnic acid. Comparison of $\Delta E_{1/2}$ with $pK_A(H_2O)$ showed that there is no single relation between these quantities for all the electrolytes investigated; instead, there is a family of straight lines: one relation refers to derivatives of picric acid, dinitrophenols give rise to another straight line with a smaller slope relative to the $pK_A(H_2O)$ axis, and it is possible that styphnic acids also have a specific relation with a steeper slope. The authors showed that, when a small number of species are investigated, apparent relations may be obtained between $E_{1/2}$ and $pK_A(H_2O)$, which hold only for a strictly limited group of compounds. Thus an apparent relation for picric acid derivatives, including also styphnic acid, was obtained by Elder and Mariella[74].

The half-neutralisation potentials of benzoic acids have been measured in methyl, ethyl, and isopropyl alcohols, acetone, ethyl methyl ketone, isobutyl methyl ketone, acetonitrile, dimethylformamide, and other solvents[4,16,18,59,60,77,78]. Separate relations corresponding to Eqn. (6) for

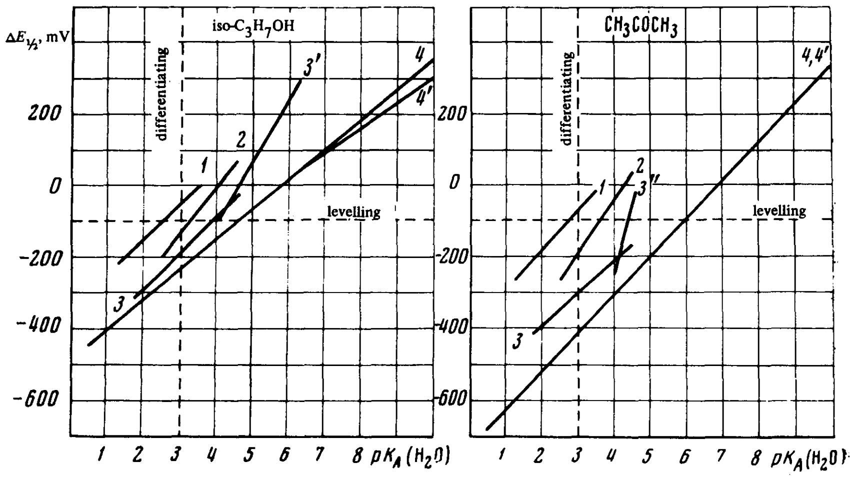

Figure 7. Variation of the half-neutralisation potentials of electrolytes in non-aqueous solvents with $pK_A(H_2O)$: 1) *o*-derivatives of benzoic acid; 2) *m*- and *p*-derivatives of benzoic acid; 3) and 3″) dicarboxylic acids (first dissociation); 3′) dicarboxylic acids (second dissociation); 4) *o*-derivatives of phenol; 4′) *m*- and *p*-derivatives of phenol.

m- and *p*-derivatives and for *o*-derivatives were obtained for all the solvents (Fig. 6). In the case of benzoic acids, on passing from water to non-aqueous solvents, a more pronounced weakening is observed for the *o*-derivatives compared with the *m*- and *p*-derivatives than in the case of phenol. This can probably be accounted for by the steric factors operating in the formation of the intramolecular hydrogen bond (in particular the formation of six-membered rings by *o*-derivatives of benzoic acid). The weakening of the acid strengths of the *o*-derivatives of benzoic acid is so pronounced that homoconjugation even in acetonitrile does not eliminate the difference between the behaviour of *m*- and *p*-derivatives on the one hand and *o*-derivatives on the other, although in acetonitrile $E_{1/2}$ for the *m*- and *p*-derivatives of benzoic acid approaches the value of $E_{1/2}$ for the *o*-derivatives with the same acid strength in water.

Benzoic acid derivatives containing in the same molecule *m*- or *p*-substituents together with *o*-substituents lie on the plot for *o*-derivatives. An appreciable deviation from linearity in all the solvents is shown by *o*-hydroxy derivatives which, owing to the stabilisation of the anion by the intramolecular hydrogen bond, become stronger acids in non-aqueous solvents compared with other acids with the same values of $pK_A(H_2O)$. A deviation from linearity is also shown by acids which on titration give rise to the formation of salt precipitates.

The measurements of the half-neutralisation potentials of phenol and benzoic acid derivatives permit a comparison of the differentiating effects of solvents relative to these groups of electrolytes. On passing from water to amphiprotic solvents, the points for phenols and benzoic acids lie on different straight lines, i.e. there is a differentiating effect of the solvent. Fig. 7 shows as an example the relations between $\Delta E_{1/2}$ in non-aqueous solutions and $pK_A(H_2O)$ for isopropyl alcohol and ethyl methyl ketone. It is evident that the strengths of electrolytes of different groups with the same $pK_A(H_2O)$ values are differentiated to varying extents depending on the value of $pK_A(H_2O)$. For example, in isopropyl alcohol for $pK_A(H_2O) = 2.5$, the half-neutralisation potentials of phenol and any *m*- or *p*-benzoic acid differ by 80 mV and for $pK_A(H_2O) = 4$ by 150 mV. As a result, in relation to some electrolytes the non-aqueous solvents exhibit a differentiating effect while in relation to others they have a levelling effect. Thus on passing from water to isopropyl alcohol or ethyl methyl ketone, the non-aqueous solvents have a differentiating effect with respect to the electrolytes located on the vertical line in Fig. 7 and a levelling effect in relation to the electrolytes located on the horizontal line.

The coefficient *A* in Eqns. (6) represents the slope of the straight lines, i.e. the differentiating effects of the solvents with respect to electrolytes of the same group. The constant term in the equation makes it possible to arrange the groups of electrolytes in a sequence relative to one another. The physical significance of the coefficient *A* is that it represents the difference between the half-neutralisation potentials in a non-aqueous solution between two electrolytes whose $pK_A(H_2O)$ values differ by unity. The differentiating effects of non-aqueous solvents in terms of the coefficient *A*, i.e. in terms of the number of millivolts per unit $pK_A(H_2O)$ value, are compared in Table 4, which shows that alcohols can be arranged in the following sequence in terms of their differentiating effects in relation to phenols and benzoic acids:

$$\text{iso-}C_3H_7OH > \text{iso-}C_4H_9OH > \text{n-}C_4H_9OH > \text{n-}C_3H_7OH,\ C_2H_5OH > CH_3OH\ .$$

Comparison of the differentiating effects of alcohols in relation to phenol and benzoic acid derivatives containing only *m*- and *p*-substituents and derivatives with *o*-substituents shows that alcohols behave differently in relation to phenols and benzoic acids. Thus the differentiating effect of alcohols is greater in relation to phenols containing *o*-substituents than in relation to phenols with only *m*- and *p*-substituents. On the other hand, in relation to benzoic acids, alcohols show a greater differentiating effect for *m*- and *p*-derivatives than for *o*-derivatives. The greater differentiating effect of alcohols with respect to *o*-derivatives compared with *m*- and *p*-derivatives is evidence of a greater difference between the solvation energies of the molecules and ions of *o*-derivatives of phenols compared with the *m*- and *p*-derivatives. In the case of benzoic acids the lower differentiating effect with respect to *o*-derivatives shows that the differences between the solvation energies of the molecules and ions of *m*- and *p*-derivatives of benzoic acid are greater than for the *o*-derivatives. The explanation is probably that the effect of the *o*-substituents diminishes as the polarity of the solvent is reduced owing to a greater non-coplanarity of the carboxy group with respect to the benzene ring, as shown by Charton and Charton[79].

Table 4. Differentiating effects of non-aqueous solvents in relation to phenol and benzoic acid derivatives[72,73,78,81].

Acetonitrile	219	219	113	127
Dimethylformamide	267	267	149	125

The differentiating effects of acetone and ethyl methyl ketone with respect to acids are almost the same. The differentiating effect of acetonitrile is less marked than that of ketones, probably due to homoconjugation in the electrolyte solutions, which is particularly pronounced in the titration process. The differentiating effect of dimethylformamide with respect to phenols and benzoic acids is similar to that of ethyl methyl ketone. Thus, ketones, acetonitrile, and dimethylformamide can be arranged in the following series in order of their differentiating effects:

$$(CH_3)_2NCHO > CH_3COC_2H_5,\ CH_3COCH_3 > CH_3CN\ .$$

Gur'ev[76] gave a systematic account of data for the coefficients of pK_A(H$_2$O) in the relation between $\Delta E_{1/2}$ in non-aqueous solutions and pK_A(H$_2$O); he took these coefficients from studies dealing with relations of this kind, calculated them from the pK_{rel} for electrolytes determined by non-electrometric methods, or determined them from potentiometric titration curves. In relation to all groups of acids, pyridine showed the greatest differentiating effect, and was followed in this respect by dimethylformamide, ketones, acetonitriles, and aprotic solvents and their mixtures with protolytic solvents. Compared with water, all the solvents differentiate the acid strengths of benzoic acids to a greater extent than those of phenols.

Hitherto, we have considered changes in the differentiating effect on passing from water to a non-aqueous solvent. In turn, water as a solvent has varied differentiating effects on different groups of electrolytes depending on their molecular structure. Thus the differentiating effect of water with respect to phenol derivatives is shown to a much greater extent than with respect to benzoic acids, owing to the closer location of the substituent in the phenol molecule to the reaction centre than in the benzoic acid molecule. Thus in the Hammett equation the reaction constant ρ for the dissociation of benzoic acids in aqueous solution is unity and for the dissociation of phenols 2.23.[80] Therefore, apart from a comparison of $\Delta E_{1/2}$ with pK_A(H$_2$O), it is of considerable interest to compare $\Delta E_{1/2}$ with the σ constants for the substituents[18,78,81].

Comparison of the differentiating effects of solvents in terms of the slope of the plots of $\Delta E_{1/2}$ against σ or $\Sigma\sigma$ in the presence of several substituents in the same molecule (Table 4) makes it possible to follow the changes in the differentiating effect of solvents with respect to electrolytes belonging to different reaction series as a function of the structural differences between the molecules. Figs. 4–6 present examples of the relations between $\Delta E_{1/2}$ in non-aqueous solutions and $\Sigma\sigma$ for phenol and benzoic acid derivatives. These relations are characterised by an equation of the form

$$\Delta E_{1/2} = A'\Sigma\sigma + B'. \tag{7}$$

The coefficient A' is equal to the difference between the half-neutralisation potentials of two electrolytes whose $\Sigma\sigma$ values differ by unity.

In the first place mention should be made of the fact that the number of millivolts per pK_A(H$_2$O) unit and the number of millivolts per σ unit are very similar for benzoic acids, since the reaction constant ρ for the dissociation of benzoic acids in aqueous solution is unity. The slight discrepancies between these values are a consequence of the deviation from unity of the correlation coefficient for the relation between pK_A(H$_2$O) and $\Sigma\sigma$ and also of the fact that, as a result of the different degrees of dissociation of the salts formed, the formation of ion pairs, and homoconjugation, the half-neutralisation potentials are not always functions of the acid dissociation constants alone. Comparison of the differentiating effects of the solvents on the basis of the number of millivolts per $\Sigma\sigma$ unit shows that the differentiating effect on non-aqueous solvents, like that of water, is much greater for phenol derivatives than for benzoic acid derivatives.

The relative E_S acidity scale, the extent of which determines the possibility of the differential titration of mixtures of electrolytes, is an analytical chemical characteristic of solvents in acid–base potentiometric titrations[4,62,82]. The E_S scale for solvents is measured under the same conditions as the half-neutralisation potentials of electrolytes. It is therefore of interest to compare quantities characterising the differentiating effects of solvents with respect to individual groups of electrolytes with the extents of the relative acidity scales of the solvents. It is to be expected that the correlation between these quantities will be most clear cut within the limits of a single chemical group of solvents. Fig. 8 shows a comparison of the extents of the E_S scales for solvents with the coefficients A and A' in Eqns. (6) and (7). It is seen from the Figure that there is a linear relation between the extents of the relative acidity scales for alcohols and the coefficients A and A' characterising the differential effects of the alcohols not only in relation to phenols and benzoic acids but also in relation to dicarboxylic acids[83]. The differentiating effects of non-aqueous solvents in relation to phenols and benzoic acid can also be compared in terms of the relative dissociation constants of these electrolytes in different solvents, which are calculated from the half-neutralisation potentials of phenols and benzoic acids[78,81] by the formula (at 20°C)

$$pK^{x}_{\mathrm{rel}} = pK^{x}_{\mathrm{A}} - pK_{\mathrm{A}}^{C_6H_5COOH} = \frac{\Delta E_{1/2}}{58} \quad . \qquad (8)$$

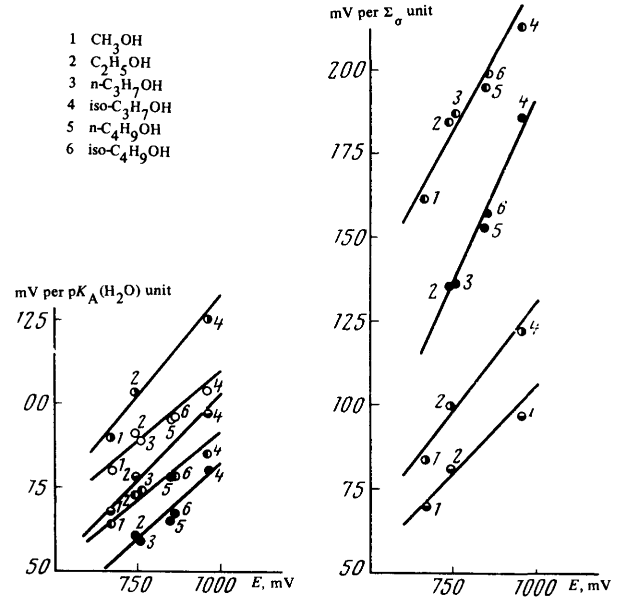

Figure 8. Relation between the slopes of plots of $\Delta E_{1/2}$(ns) against $pK_A(H_2O)$ and $\Delta E_{1/2}$(ns) against $\Sigma\sigma$ and the range of the relative acidity scale of the solvent: ●—*m*- and *p*-derivatives of phenol; ◐—*o*-derivatives of phenol; ◑—*m*- and *p*-derivatives of benzoic acid; ⊖—*o*-derivatives of benzoic acid; ○—dicarboxylic acids (first dissociation).

The pK_{rel} values for phenols and benzoic acids in various solvents are compared in Figs. 9–12. On passing from water to alcohols, the acid strength of phenols increases relative to that of benzoic acids (Fig. 9). The same also happens on passing from water to other non-aqueous solvents. Consequently, on passing from water to alcohols, the solvation of phenoxide ions compared with that of phenol molecules increases more than the solvation of benzoate ions compared with that of benzoic acid molecules. In solvents belonging to the same natural group (ethyl and isopropyl alcohols) differentiation of the acid strengths of phenols and benzoic acids is not observed. According to Brönsted's theory, the points for all electrolytes lie on a single straight line with a slope of unity (Fig. 10). The same happens on passing from acetone to ethyl methyl ketone.

On passing from ketones to alcohols, i.e. solvents of another natural group, the acid strengths of phenols and benzoic acids are differentiated. However, whereas on

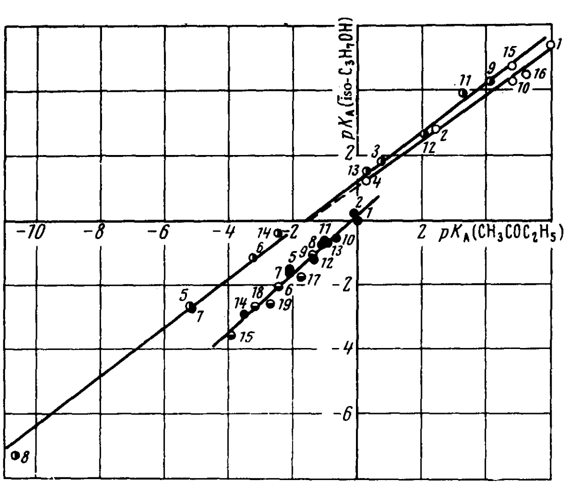

Figure 11. Relation between the pK_{rel} of phenol and benzoic acid derivatives in ethyl methyl ketone and isopropyl alcohol (the numbers and designations of the points correspond to those in Fig. 9).

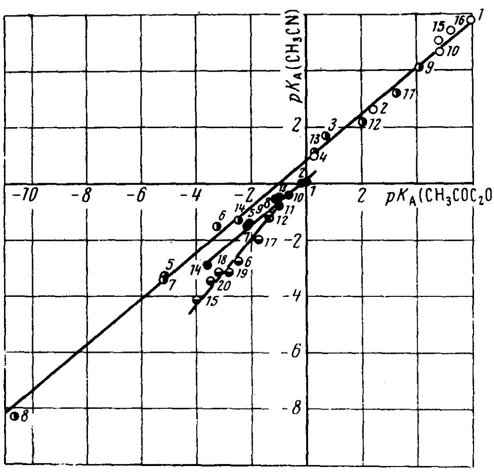

Figure 12. Relation between the pK_{rel} of phenol and benzoic acid derivatives in ethyl methyl ketone and acetonitrile (the numbers and designations of the points correspond to those in Fig. 9).

passing from water to alcohols there is an increase in the acid strength of phenols compared with benzoic acids, on passing from ketones to alcohols the opposite phenomenon is observed: phenols become weaker than benzoic acids (Fig. 11). Within a single class of electrolytes, the differentiating effect changes on passing from ketones to alcohols only among phenols. The points for all the benzoic acids lie on a single straight line with a slope close to unity, which is evidence that the solvation energies of the ions and molecules of benzoic acids change to the same extent on passing from ketones to alcohols. On going from ketones to acetonitrile, the acid strengths of phenols and benzoic acids are also differentiated (Fig. 12). In contrast to the effect on passing from ketones to alcohols, the acid strengths are differentiated within the class of benzoic acids but not within the class of phenols. As stated above, *m*- and *p*-derivatives of benzoic acid become weaker in acetonitrile compared with *o*-derivatives than in ethyl methyl ketone, in consequence of homoconjugation, which is particularly pronounced in acetonitrile.

The results of the above comparison of the relative acid strengths of phenols and benzoic acids in various solvents are consistent with the data presented in the monographs of Izmailov[1] and Shatenshtein[6] for solvents of the same and different natures. Shatenshtein's latest data on the differentiating effects of solvents in relation to C–H acids obtained by an isotope exchange method also confirmed the conclusion that the differentiating effect is due to a change in the solvation of ions and molecules of acids in the solvents compared[10].

4. STUDY OF THE DIFFERENTIATING EFFECT OF SOLVENTS BASED ON THE HAMMETT EQUATION

Acid strengths, particularly of benzoic acid and phenol derivatives, in aqueous solutions can be successfully predicted on the basis of the Hammett equation[80,84]. If the σ constants did not change on passing from water to non-aqueous solvents, the effect of the latter on the dissociation of substituted acids might be taken into account using the constant ρ:

$$\lg \frac{K}{K^0} = \rho\sigma \quad , \tag{9}$$

where K and K^0 are the dissociation constants of the substituted and unsubstituted acids.

It has been stated[21,22,85-94] that the σ constants vary on passing from water to non-aqueous solvents owing to changes in the solvation of the polar groups of the substituents, in particular the type of hydrogen bond between the substituent and the solvent molecules; under the influence of the solvent, the capacity of the substituent for polar conjugation with the reaction centre may alter, etc. As a rule, the effect of the solvent on the σ constant is small[21]. Only certain substituents (for example OH groups) show an appreciable variation of the σ constants on changing the solvent[21,23,90].

The effect of the solvent on the σ constant cannot be taken into account with the aid of the dielectric constant ϵ of the medium, as suggested by Hammett[22,84]. For example, it is known that the relation

$$\rho = \left(1.87 + \frac{67}{\varepsilon}\right) \cdot \frac{1.09}{2.8^n},$$

(where n is the number of atoms separating the reaction centre from the phenyl carbon atom) holds satisfactorily for benzoic acids in water, ethylene glycol, and methyl and ethyl alcohols, but not in n-propyl and n-butyl alcohols and aqueous dioxan mixtures[93].

The use in Eqn. (9) of known Hammett's σ constants for aqueous solutions does not yield a constant ρ which would reflect the influence of the solvent on the transmission of only the inductive effect of the substituents. In this connection, the method of estimation of the constant ρ proposed by Palm[22] and based on the use of Taft's universal σ^* induction constants for aliphatic substituents and the ρ^* universal interaction constant is of interest. However, the lack of adequate literature data for the K_A of aliphatic carboxylic acids in non-aqueous solvents precludes the use of this method for the estimation of the effect of the solvent on the ρ^* constant. Therefore one may assume, as emphasised in a number of monographs[21,22] and papers[23,24,94], that at the present time the weakest point of all quantitative theories of the effect of substituents is the little investigated effect of solvents.

In earlier reviews[23,24] the ρ constants for the dissociation of benzoic acid in certain alcohols, aqueous alcoholic, and aqueous dioxan mixtures were given. In contrast to Jaffe[23], Wells[24] quotes in his review also the values of ρ obtained by the method described in the paper of van Bekkum et al.[95], who used a reaction series involving only *m*-derivatives of benzoic acid to exclude the effect of polar conjugation between the substituent and the reaction centre; this leads to an increase of ρ. The values of ρ quoted in the reviews[23,24] were obtained on the basis of the K_A constants for benzoic acid measured largely by indicator methods.

The data for the dissociation constants of *m*- and *p*-derivatives of benzoic acid obtained by electrometric methods permitted the calculation of new values of the constant ρ.[44,56,58,89,96,97] These values of ρ, calculated by ourselves and taken from papers by other investigators are listed in Table 5. The reaction constants ρ, the correlation coefficients r, and the standard deviations s were calculated by least squares on a "Promin'" computer. Table 5 also lists the numbers of correlated quantities n.

Table 5. Reaction constants ρ in the Hammett equation for the dissociation of *m*- and *p*-derivatives of benzoic acid in non-aqueous solutions.

Solvent	Calc. from pK_A (25°)					Calc. from $\Delta E_{1/2}$ (20° ± 2°)				
	ρ	n	r	s	from Refs. 44, 56, 58, and 96	ρ	n	r	s	from Refs. 59 and 60
Methyl alcohol	1.38	9	0.995	0.05	1.38; 1.54; 1.55	1.42	16	0.969	0.18	—
Ethyl alcohol	1.67	13	0.984	0.09	1.65; 1.67	1.68	15	0.955	0.25	1.3
33.2% ethyl alcohol	—	13	—	—	1.28	—	—	—	—	—
52% ethyl alcohol	—	13	—	—	1.40	—	—	—	—	—
73.4% ethyl alcohol	—	13	—	—	1.52	—	—	—	—	—
85.4% ethyl alcohol	—	13	—	—	1.53	—	—	—	—	—
Isopropyl alcohol	—	—	—	—	—	2.01	15	0.988	0.15	—
Acetone	1.96	5	0.997	0.09	—	2.30	14	0.970	0.27	—
Ethyl methyl ketone	—	—	—	—	—	2.41	13	0.987	0.18	—
Acetonitrile	2.65	4	0.998	0.09	2.8	1.91	14	0.990	0.13	—
Dimethylformamide	2.65	3	0.991	0.35	—	2.42	14	0.986	0.19	—
Dimethylsulphoxide	3.13	11	0.982	0.27	2.6	—	6	—	—	2.5

In examining the data in Table 5, it is necessary to bear in mind that the values of ρ quoted were obtained on the basis of K_A data for *m*- and *p*-derivatives of benzoic acid and therefore they reflect the influence of the solvent on the inductive and resonance effects and the effect of polar conjugation of substituents with the reaction centre.

As in the calculation of α in Eqn. (2), the most reliable values of ρ refer to methyl and ethyl alcohol, water–ethyl alcohol mixtures, and dimethyl sulphoxide, since a large number of experimental points ($n = 9 - 13$) were employed in these calculations. For acetonitrile, ρ was obtained without taking into account *p*-hydroxybenzoic acid, since the latter shows a marked deviation from linearity, which is probably due to the change in the ρ constant of the OH group on passing from water to acetonitrile.

The lack of data or their inadequacy for solvents such as isopropyl alcohol, acetone, ethyl methyl ketone, dimethylformamide, and acetonitrile led to the necessity for the determination of the constant ρ also on the basis of the relative concentration dissociation constants of *m*- and *p*-derivatives of benzoic acids obtained from half-neutralisation potentials (see Section 3).

Table 5 shows that the values of ρ for methyl and ethyl alcohols obtained by the two methods agree well. The constants ρ for ketones, acetonitrile, and dimethylformamide obtained from the pK_{rel} data should of course be lower than the true values owing to the distortion of the potentiometric titration curves. The value of ρ for acetone obtained from pK_{rel} is higher than ρ calculated from pK_A. In all probability this suggests that the available literature values of pK_A of benzoic acid in acetone are not sufficiently valid characteristics of the differentiating effect of this solvent. The values of ρ for isopropyl alcohol, acetone, and ethyl methyl ketone indicate a higher differentiating effect of these solvents for benzoic acid compared with ethyl and methyl alcohols.

There is a limited amount of ρ data[23,24] for the dissociation of phenol derivatives in water–ethyl alcohol mixtures. The constant ρ has also been determined for 45 vol. % isopropyl alcohol in water ($\rho = 2.80$).[98]

It follows from the data in Table 1 that the experimental dissociation constants of phenol derivatives refer predominantly to nitro-derivatives containing *o*-substituents together with *m*- and *p*-substituents. Even in aqueous solutions *o*-substituents do not have invariant values of the σ constants[80]. Therefore there is all the more reason to expect a change in σ_{ortho} on passing from water to non-aqueous solvents. Consequently the data in Table 1 were not used to calculate the constants ρ for the dissociation of phenol derivatives in non-aqueous solvents.

Table 6. Reaction constants ρ in the Hammett equation for the dissociation of phenol derivatives in non-aqueous solutions calculated from half-neutralisation potentials (20° ± 2°).

Solvent	ρ	n	r	s
Propyl alcohol	2.25	6	0.997	0.08
Butyl alcohol	2.59	6	0.993	0.16
Isobutyl alcohol	2.67	6	0.986	0.24
Isopropyl alcohol	3.17	6	0.993	0.20
Acetonitrile	3.72	16	0.998	0.29
Acetone	4.11	16	0.999	0.22
Ethyl methyl ketone	4.48	16	0.999	0.21
Dimethylformamide	4.57	16	0.995	0.39

Mention should be made of an investigation[25] where the relative acidities of 4-substituted derivatives of 2,6-dichloro and 2,6-dimethylphenols in water, methyl and isopropyl alcohols, acetone, and water–dioxan mixtures were determined from measurements of half-neutralisation potentials. The differentiating effect of non-aqueous solvents increases with decrease in the polarity of the solvent. Thus ρ for 4-substituted 2,6-dichlorophenols is 2.55 in water, 2.99 in methyl alcohol, 4.13 in isopropyl alcohol, and 5.39 in acetone. On addition of water to dioxan there is a sharp decrease of ρ, which is 5.15 in 99.8% dioxan containing 0.2 vol. % of isopropyl alcohol, 4.00 in 98% dioxan, 3.66 in 95% dioxan, 3.43 in 91% dioxan, and 2.72 in 71% dioxan.

An attempt has been made to investigate the ρ constant for the dissociation of phenols in non-aqueous solutions by measuring the half-neutralisation potentials, from which the pK_{rel} for phenols in alcohols, acetone, ethyl methyl ketone, dimethylformamide, and acetonitrile were calculated[81]; the constants ρ for these solvents are listed in Table 6. It is noteworthy that in alcohols the reaction series contains only *m*- and *p*-derivatives of phenol and in ketones, dimethylformamide, and acetonitrile also derivatives with *o*-substituents, since (as already mentioned in section 3) in these solvents there is a common relation between $E_{1/2}$ and the σ constants adopted for the substituents in aqueous solutions.

Table 6 shows that, on passing from solvent to solvent, the differentiating effect of solvents determined from measurements of the pK_{rel} values for phenols varies in the same sequence as in relation to *m*- and *p*-derivatives of benzoic acid. The values of ρ for isopropyl alcohol and acetone listed in Table 6 are lower than those obtained by Fischer et al.[25] (3.46 and 4.93 respectively), which can be accounted for by the effect of the titrant solvent employed in the determination of pK_{rel}; the data in Table 6 were obtained with about 1% methyl alcohol in the solvent and those of Fischer et al.[25] with about 0.2% of isopropyl alcohol.

The data on the differentiating effect of amphiprotic solvents obtained from the ρ constants in Hammett's equation and those found by comparing $pK_A(ns)$ or $\Delta E_{1/2}$ with $pK_A(H_2O)$, quoted in Sections 2 and 3, agree well with one another if account is taken of the difference between the values of ρ in water for the corresponding reaction series. The change in the differentiating effect of solvents for a given reaction series may be expressed by the ratio ρ_{ns}/ρ_{H_2O}, the physical significance of which is equivalent to that of the quantity α in Eqn. (2).

5. THE AUTOPROTOLYSIS CONSTANT AS A CHARACTERISTIC OF THE DIFFERENTIATING EFFECT OF A SOLVENT

The autoprotolysis of a solvent is accompanied by the formation of lyonium and lyate ions which in a given solvent are the strongest acid and the strongest base respectively. Therefore the autoprotolysis constant of the solvent,

$$K_s = a_{SH_2^+} a_{S^-} ,$$

is a measure of its differentiating effect on the strengths of acids and bases. The negative exponent of the autoprotolysis constant defines the extent of the acidity scale of the solvent. The more pronounced are the acidic and basic properties of the solvent, the higher is the autoprotolysis constant, and the smaller the extent of its acidity scale. With decrease of the acidic and basic properties of the solvent, the extent of the acidity scale increases together with the differentiating effect of the solvent in relation to acids and bases.

If the acidic and basic properties of the solvent are less pronounced than those of water, its differentiating effect relative to water is greater for all classes of electrolytes. On the other hand, if the acidic or basic properties of the solvent exceed those of water, then in comparing their differentiating effects it is necessary to take into account also the relative positions of the acidity scales of the solvents in terms of a single acidity scale. The displacement of the acid limit of the acidity scale of the solvent relative to that of the water scale is unambiguously characterised by the transolvation energy of the proton on passing from an infinitely dilute aqueous solution to the given solvent[61]. With decrease in the acidity of the solvent, which leads to a displacement of the basic limit of its acidity scale towards lower proton activities, the differentiating effect of the solvent in relation to weak acids and strong bases increases; with decrease of the basicity of the solvent (shift of the acid limit of the scale towards higher proton activities), its differentiating effect in relation to weak bases and strong acids increases. Thus, the differentiating effect of the solvent is different for electrolytes of different strengths and is characterised by its autoprotolysis constant and the position of its acidity scale in terms of a single acidity scale. Moreover, according to Izmailov's theory of solvation[1], the differentiating effect of solvents is different for electrolytes belonging to different reaction series.

Table 7. Negative exponents of the autoprotolysis constants of certain solvents.

Solvent	pK_s		
	calc. from Eqn.(10)	measured values (25°)	obtained by methods of comparative calculations
Methyl alcohol	15.9	16.7[99–101]	16.3[115] 16.7[117]
Ethyl alcohol	—	16.8[102]; 17.9[100]; 18.9[103]; 19.1[99,104]; 19.5[105,106]	17.1[115] 18.8[117]
Propyl alcohol	—	19.4[103]	20.8[115] 19.4[117]
Isopropyl alcohol	22.0	20.8[100,103]	21.3[115]
Butyl alcohol	—	—	21.1[115] 19.6[116]; 21.6[117]
t-Butyl alcohol	26.8	22.2[100]	21.1[115]
Acetone	32.5	—	22.3[115] 22.8[118]
Ethyl methyl ketone	—	25.7[107]	21.5[115] 21.0[118]
Acetonitrile	33.2	19.5[108]; 26.5[109] 28.5[30]; 33.3[110]	25.5[117]
Dimethylformamide	29.4	18.0[111]	17.0[117]
Dimethylsulphoxide	31.8	17.3[112]; 33.3[51]	—

The autoprotolysis constants of by no means all amphiprotic solvents have now been measured and their reliability in many cases is not great, since the range of pH values which may be used in acid–base titration frequently correspond to a higher value of pK_S than indicated by the available literature data[82]. Table 7 lists the pK_S values for certain amphiprotic solvents measured by different methods[30,51,99–112]. The Table shows that the values quoted by various authors for a series of solvents differ appreciably among one another. Thus the discrepancy for ethyl alcohol is about 3 pH units, for acetonitrile 6.8 pH units, and for dimethyl sulphoxide up to 16 pH units. In the first place this discrepancy is evidence of the experimental difficulties in the determination of autoprotolysis constants, particularly for solvents with low values of K_S and is a consequence for the errors associated with the different methods for the determination of the dissociation constants of a base and its conjugate acid, the indeterminancy of the diffusion junction potential in cells with transport, incomplete dissociation of electrolytes, etc.[82,110] One of the most important causes of unduly high values of K_S is also the presence of water in solvents, the ionisation of which is responsible for protolysis in the given solvent[113].

The values of pK_S for solvents may be estimated by measuring the relative acidity scale values for solvents from the approximate equation[82]

$$pK_s = \frac{E_s}{59} + \lg c_{HClO_4}c_{R_4NOH}, \tag{10}$$

where E_S is the relative acidity scale value (mV) for the solvent, equal to the difference between the half-neutralisation potentials of $HClO_4$ and R_4NOH in the given solvent, and c_{HClO_4} and c_{R_4NOH} are the concentrations of the acid and base at the instant of half neutralisation.

The measurements of the E_S scale values for solvents are usually made under conditions where the solvent contains 1–1.5% of water and methanol; the E_S for pure solvents may be found by extrapolation using equations describing the variation of the limits of the scale with the composition of the mixed solvents[114]. It must be emphasised that the values of pK_S for solvents calculated in this way are low because the activities of H^+ and OH^- ions are not equal to the concentrations of $HClO_4$ and R_4NOH and in consequence of the use of a base not containing the lyate ions of the solvent, the inadequate sensitivity of the glass electrode in strongly acidic and strongly basic media, and other causes. However, the values of pK_S calculated from the E_S for pure acetonitrile and dimethyl sulphoxide are close to the latest literature data, which is evidence of the adequate reliability of the pK_S obtained from measurements of the relative acidity scale values. They may be regarded as the lower limits of the true values.

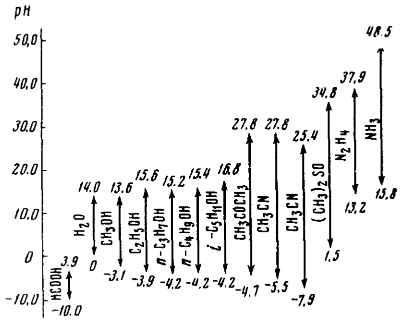

Figure 13. Izmailov's unique acidity scale for solvents.

Comparison of the pK_S calculated by Eqn. (10) for amphiprotic solvents with the literature data (Table 7) shows that the literature values of the pK_S for isopropyl and t-butyl alcohols, ethyl methyl ketone, and dimethylformamide are too low. It also follows from Table 7 that the methods of comparative calculation are suitable only for the estimation of the pK_S of lower alcohols[115,117,118]. Fig. 13 shows a single pA solvent acidity scale[1,61] obtained using the most reliable values of pK_S for amphiprotic solvents (printed bold in Table 7) as well as certain others on the basis of the primary effects of the medium ($\lg\gamma_{0H^+}$) determined by Izmailov[61] and other workers[33]. It follows from Fig. 13 and Table 7 that amphiprotic solvents are characterised by a wide range of acidity scales.

On the basis of data for the relative basicities and acidities of solvents, one may assume the decrease of the K_S values for alcohols with increase of the size of the alkyl group and the degree of its branching is largely due to the decrease of the contributions to acidity which depend on the electron-donating properties of the alkyl group in the alcohol molecule. The low autoprotolysis constants of ketones, dimethylformamide, acetonitrile, and dimethyl sulphoxide are related to their extremely weak acid properties as C–H acids; ketones and acetonitrile are also extremely weak bases[119].

The differentiating effects of amphiprotic solvents can be arranged in the following sequence on the basis of the autoprotolysis constants:

$$(CH_3)_2SO,\ CH_3CN > CH_3COC_2H_5,\ CH_3COCH_3 > (CH_3)_2NCHO >$$
$$> t\text{-}C_4H_9OH > iso\text{-}C_3H_7OH > n\text{-}C_4H_9OH,\ n\text{-}C_3H_7OH,$$
$$n\text{-}C_2H_5OH > CH_3OH > H_2O,$$

which, within the limits of the reliability of the K_S values, is the same as the sequence of the differentiating capacities of the solvents established on the basis of the dissociation constants and the half-neutralisation potentials of the electrolytes.

It was of interest to follow the relation between the pK_S for amphiprotic solvents and α in Eqn. (2), since these are parameters characterising the differentiating effects of solvents. According to Eqn. (2), for a reaction series of n electrolytes arranged in order of increasing pK_A values, the difference between the pK_A values of two consecutive electrolytes is

$$\Delta pK_A^i\,(\mathrm{ns}) = \alpha\Delta pK_A\,(H_2O), \text{where } i = 1, 2, 3, \ldots, n-1$$

and

$$\sum_{i=1}^{n-1} \Delta pK_A^i\,(\mathrm{ns}) = \alpha \sum_{i=1}^{n-1} \Delta pK_A^i\,(H_2O) \quad . \tag{11}$$

The positions of the reaction series on the acidity scales of water and the non-aqueous solvent may be represented as follows:

$$pK_s\,(H_2O) = \sum_{i=1}^{n-1} \Delta pK_A^i\,(H_2O) + a + b \tag{12}$$

and

$$pK_s\,(\mathrm{ns}) = \sum_{i=1}^{n-1} \Delta pK_A^i\,(\mathrm{ns}) + c + d \quad , \tag{13}$$

where a, b, c, and d are the sections of the acidity scales of the solvents in the acid and alkaline regions unoccupied by the given reaction series.

Eqn. (11) suggests that Eqn. (13) is a first-degree polynomial in α. Then it is possible to obtain from Eqns. (12) and (13) a relation between pK_S and α:

$$pK_s\,(\mathrm{ns}) = \mathrm{const}_1\,\alpha + \mathrm{const}_2\ , \tag{14}$$

where const_1 and const_2 are constants for each reaction series.

Tests of Eqn. (14) for phenol and benzoic acid derivatives showed that there is indeed a linear relation between the negative exponents of the autoprotolysis constants of amphiprotic solvents and the values of α in Eqn. (2) for the corresponding reaction series (Fig. 14). It follows from Fig. 14 that benzoic acid and phenol derivatives give rise to separate relations characterised by different slopes. It is also seen that, compared with water, the differentiating effect of amphiprotic solvents is greater with respect to benzoic acids. The ratio of the slopes of lines I and II is close to the ratio of the ρ_{H_2O} constants for the reaction series considered (about 2.5). This suggests that the effect of substituents on passing from solvent to solvent is constant and the effect of the solvent may be taken into account by the change of the constant ρ. Since $\alpha = \rho_{ns}/\rho_{H_2O}$, there should be a linear relation between the pK_S and ρ for amphiprotic solvents. Fig. 14 shows the presence of such a linear relation for *m*- and *p*-derivatives of benzoic acid (line III). In plotting the relation between pK_S and ρ, use was made also of the values of ρ obtained from measurements of the half-neutralisation potentials.

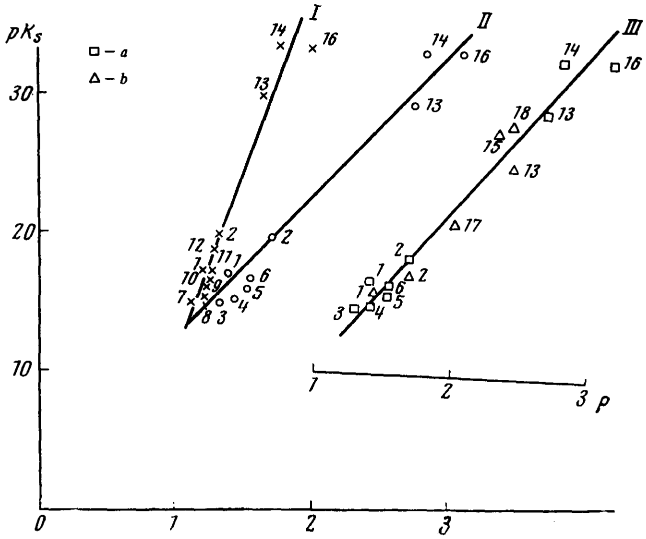

Figure 14. Correlation between the pK_S of solvents and the coefficients α in Eqn. (2) or the constants ρ in Hammett's equation: I) phenol derivatives; II) and III) benzoic acid derivatives [*a*) on the basis of pK_A; *b*) on the basis of $E_{1/2}$; the numbers of points *1* to *16* correspond to those in Table 3; *17*) isopropyl alcohol; *18*) ethyl methyl ketone].

Bearing in mind that at the instant of the measurement of $E_{1/2}$ for benzoic acids the solvents contained about 1–1.5% of water and methyl alcohol, the ρ values were compared with the pK_S of solvents containing the same amounts of water and methanol. These pK_S were calculated from Eqn. (10) on the basis of the values scale $\dot{E}_S$ measured under the same conditions as $E_{1/2}$.

---oOo---

The above examination of the differentiating effects of amphiprotic solvents with respect to *m*- and *p*-benzoic acids and phenol derivatives on the basis of the pK_A and $E_{1/2}$ values for electrolytes and the ρ constants in the Hammett equation showed that the autoprotolysis constant of an amphiprotic solvent is a quantitative characteristic of its differentiating effect. The lower is the value of K_S, the greater the differentiating effect of the amphiprotic solvent.

According to Izmailov's solvation theory[1], the differentiating effects of solvents are related to changes in the ratio of the solvation energies of the anions and molecules of the acids, the transolvation of anions making the greatest contribution to this change. In hydroxylated solvents hydrogen bonds play a considerable role in the solvation of anions, which reduces the difference between the anion solvation energies on passing from one solvent to another. In aprotic dipolar solvents, incapable of forming hydrogen bonds with anions, the difference between the anion solvation energies are much greater. This is because electrostatic and dispersion interaction forces, which are related, on the one hand, to properties of the solvents such as their dielectric constant, dipole moment, and polarisability of their molecules and on the other hand to the charge, radius, and polarisability of the anions, play the greatest role in the solvation of anions. As a result of all these factors, in aprotic dipolar solvents, the solvation of ions and electrolyte molecules is largely determined by the specific characteristics of the electrolyte.

Epitaxial Synthesis of Diamond in the Metastable Region

B.V.Deryagin and D.V.Fedoseev

Recent trends in the preparation of synthetic diamonds, relying on the influence of surface forces exerted by the diamond seed crystal on the carbon deposition processes, are discussed. Epitaxial synthesis can occur from carbon-containing gases or from molten metals. Foreign publications and patents are discussed as well as the work of Soviet scientists.
The preparation and properties of filamentary and of isometric diamond crystals, prepared at low pressures for the first time, are also discussed. 22 references.

CONTENTS

I. INTRODUCTION

Leipusnkii's theoretical work[1], published in 1939, showed that diamond can be prepared from graphite, in principle, at high temperatures and pressures. A more accurate phase diagram for carbon has since become available[2].

A team led by L. F. Vereshchagin at the USSR Academy of Sciences successfully solved the problem of the synthesis of diamonds at high temperatures and pressures in 1960. The Institute of Super-hard Materials played an important role in the development of industrial methods of production of diamonds.

The high-pressure method for the synthesis of diamond adopted in many countries, characterised by a high reaction rate, has some well-defined regions of application whose boundaries are determined by the specific crystallisation conditions. Under certain conditions the main advantage of the method—its high speed—may become a drawback by making the synthesis uncontrollable and by preventing the formation of crystals of appreciable size.

The principle of an alternative method of synthesis of diamond, briefly mentioned in Leipunskii's paper, is closely bound up with the physicochemical study of surface phenomena. In principle, if a diamond crystal is already present in the system, it can be made to grow even in the region of metastable existence of this allotropic modification (for example, under atmospheric or reduced pressure) if the flux of carbon atoms to the diamond surface is not too large.

Research on the epitaxial synthesis of diamonds began in the Surface Phenomena section of the USSR Academy of Sciences (Institute of Physical Chemistry) in 1956.

2. GENERAL THEORY OF THE NUCLEATION OF DIAMOND IN THE METASTABLE REGION

The epitaxial method for the synthesis of diamond from carbon-containing gases is based on the heterogeneous decomposition reactions

$$CH_4 \rightleftarrows \underset{\text{diamond}}{C} + 2H_2$$

$$C_2H_2 \rightleftarrows \underset{\text{diamond}}{2C} + H_2$$

The epitaxial synthesis can be explained either from the standpoint of the molecular mechanism of crystal growth or in terms of the general theory of the formation of a new phase (nucleation). If the concentration of carbon atoms (either in the form of vapour or chemically bound as methane or ethylene molecules) in the neighbourhood of a diamond crystal face is higher than the corresponding equilibrium value, the excess of carbon atoms will be deposited on the surface. These atoms will experience the force field of the crystal lattice, tending to extend the array of "building blocks" which had initially given rise to the substrate. In other words, the substrate compels new carbon atoms to take up the predetermined positions. The process by which a substrate influences the growth of a crystal modification isomorphous with or similar in structure to itself is known as epitaxy. The present example can be termed autoepitaxy (homoepitaxy). However, if the supersaturation with respect to diamond is too large, and the deposition process is too fast, the influence of surface forces may cease to control the process, and nuclei of the thermodynamically preferred modification (graphite) may be formed and grow. Initially, graphite and diamond can grow simultaneously on different parts of the surface, but if the supersaturation of carbon remains high the graphite modification will cover the entire surface and the autoepitaxial growth of diamond will stop.

The conditions under which this situation can be avoided are implied in the general theory of crystal nucleation and growth developed by Gibbs, Volmer, Kaishev, and others. It is shown that the probability of formation of a stable (critical) nucleus of a new phase decreases as the work of formation of the new phase increases. The work of formation is proportional to the surface energy of the nucleus of "critical" size: this size increases as the supersaturation decreases. Hence the probability of formation of graphite can be minimised by controlling the supersaturation at a level just sufficient to allow growth of the diamond crystal to proceed. However, if we approach too closely the boundary below which the diamond seed cannot grow, the linear velocity of crystallisation will be unacceptably low. Under these conditions, and in spite of the presence of the seed crystal, some of the stages involved in the deposition of a new layer of atoms may be rate-limited by the work of formation of a two-dimensional critical nucleus. At very low supersaturations the probability of formation of such a nucleus is low, and the growth of the diamond crystal becomes "hesitant". However, growth may be continuous on some areas of the crystal surface, either because the work of formation of the two-dimensional nucleus is locally zero (e.g. on a (100) diamond face), or (e.g. at the outcrop of a screw dislocation) because two-dimensional nucleation is unnecessary and growth can proceed uniformly and continuously as when ascending a spiral ramp.

Thermodynamic calculations show that the equilibrium pressure of carbon-containing gas, of vapour, or of solution over diamond is approximately twice as large as over graphite. This is the basic reason for the difficulty of growing diamond epitaxially from carbon-containing gases.

The theory of the epitaxial synthesis of diamond by chemical decomposition of carbon-containing gases has not yet been developed. On the one hand, a sufficiently general theory of nucleation is not available, and on the other hand the chemical crystallisation of two competing phases (diamond and graphite) is too complex a situation. A few theoretical propositions relating to the low-pressure epitaxial synthesis of diamond have been put forward[3], and also discussed at the 22nd International Congress on Theoretical and Applied Chemistry[4].

We shall compare the rates of formation of critical nuclei of diamond and graphite on the surface of a seed crystal of diamond†. Since the (111) is both the equilibrium and the most commonly encountered face of diamond, we shall confine the discussion to this face. It consists of two layers of atoms in a puckered hexagonal configuration. The projection of the elementary edge of the hexagonal network on a (111) plane is 1.44 Å long, i.e. is not very different from the lattice constant of the graphite basal plane (1.42 Å). Hence, we shall assume that a graphite nucleus on a (111) diamond face is oriented as though the substrate were a basal plane of graphite.

The work of formation ΔG of a two-dimensional nucleus of perimeter l and thickness h can be expressed in the general form

$$\Delta G = l\varepsilon + \gamma l^2 h \Delta G_V + \gamma l^2 (\sigma_{C-X} - \sigma_{X-V} + \sigma_{C-V}) \qquad (1)$$

where γl^2 is the area of the nucleus; σ_{C-X}, σ_{X-V}, and σ_{C-V} are the specific interfacial free energies at the boundaries between the nucleus (C), the crystal (X), and the medium (V); ϵ is the specific free energy of the edge. We can write

$$\Delta G_V = -\frac{kT}{\Omega} \ln \frac{p}{p_e} \quad ,$$

where p is the partial pressure of carbon-containing gas, p_e is the equilibrium pressure of this gas, Ω is the volume occupied by one atom in the crystalline state, and T is the absolute temperature.

Since the distance between the graphite layers (3.35 Å) is much greater than the bond length in the diamond crystal (1.55 Å), we can equate the energy of the bond between the crystal and the graphite nucleus to the binding energy between graphite layers:

$$\sigma_{C-X} = \sigma_{X-V} - \sigma_{C-V} \qquad (2)$$

In this case the last term in the right-hand side of Eqn. (1) vanishes. By maximising ΔG_V with respect to l we obtain the work of formation of the critical nucleus (ΔG^*) and the perimeter of the critical nucleus (l^*):

$$\Delta G^* = -\frac{\varepsilon^2}{4\gamma h \Delta G_V} \qquad (3)$$

$$l^* = -\frac{\varepsilon}{2\gamma h \Delta G_V} = \frac{2\Delta G^*}{\varepsilon}$$

According to the Volmer–Weber–Becker–Dering theory[5], the rate of formation of nuclei of critical size is given by

$$I = l^* a \exp\left(-\frac{\Delta G^*}{kT}\right). \qquad (5)$$

The factor a depends on the molecular collision frequency and on the pressure, and is the same for diamond and graphite.

Using the subscripts α and β to denote quantities relating to diamond and graphite respectively, and introducing Eqn. (4), we obtain

$$\frac{I_\alpha}{I_\beta} = \frac{\varepsilon_\beta \Delta G_\alpha^*}{\varepsilon_\alpha \Delta G_\beta^*} \exp\left[-\frac{\Delta G_\alpha^*}{kT}\left(1 - \frac{\Delta G_\beta^*}{\Delta G_\alpha^*}\right)\right] \qquad (6)$$

The equilibrium form of the two-dimensional nuclei, calculated by means of Wulff's theorem, is a regular hexagon for graphite ($\gamma_\beta = \frac{1}{\gamma\sqrt{3}}$) and a triangle with [110], [011], and [101] sides for diamond ($\gamma_\alpha = \frac{1}{\gamma\sqrt{3}}$) as shown in Fig. 1. The specific free energies of the edges are

$$\varepsilon_\alpha = \frac{\varphi_\alpha}{3d\sqrt{3}}, \quad \varepsilon_\beta = \frac{\varphi_\beta}{2d\sqrt{3}},$$

where φ_α and φ_β are the bond energies between nearest neighbours in the diamond and the graphite lattice, and d is the lattice constant of the basal graphite plane.

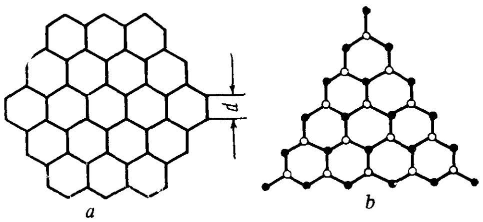

Figure 1. Nuclei of (*a*) graphite and (*b*) diamond on the (111) face of a diamond seed crystal.

The ratio of the energies of formation of the critical nuclei is

$$\frac{\Delta G_\beta^*}{\Delta G_\alpha^*} = 2.5 \frac{\ln p/p_{e\alpha}}{\ln p/p_{e\beta}}. \qquad (7)$$

As stated above, thermodynamic calculations indicate that between 1000 and 2000°K (i.e. in the region of spontaneous graphitisation of diamond)

$$p_{e\alpha} = 2p_{e\beta} \qquad (8)$$

Introducing the symbol

$$\frac{\ln \frac{p}{p_{e\beta}}}{\ln 2} = x,$$

we can readily show that

$$\frac{I_\alpha}{I_\beta} = 0.8 \frac{x}{x-1} \exp\left[-0.9 \left(\frac{\varphi}{kT}\right)^2 \frac{1-0.6x}{x(x-1)}\right]. \qquad (9)$$

---

† We acknowledge V. P. Varnin's assistance in the calculation which follows.

The maximum of this expression corresponds to $x = 2.7$. For $x \to 0$, $I_\alpha/I_\beta \to 0$; for $x \to \infty$, $I_\alpha/I_\beta \to 0.8$. For $x = 1.67$, the exponent vanishes and $I_\alpha/I_\beta = 2.00$.

Fig. 2 shows a plot of the function (9).

In this way, classical nucleation theory can identify the most favourable region $(p/p_{e\beta})$ for the epitaxial growth of diamond. However, the present calculation, given as an example, assumes that the rates of nucleation of diamond and graphite are mutually independent, whereas under real conditions the two processes are competitive.

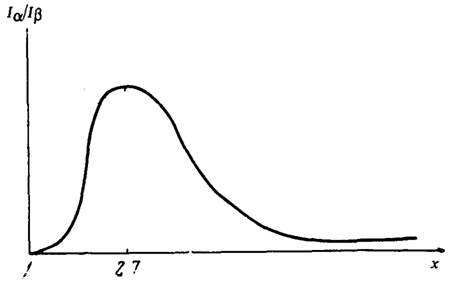

Figure 2. Variation with supersaturation of the ratio of the nucleation rates of diamond and graphite.

It should also be noted that the equilibrium pressure of methane decreases on raising the temperature, whereas that of the other carbon-containing gases (e.g. acetylene) over diamond and graphite changes in the opposite sense. Hence, the methane supersaturation (at constant total pressure) increases rapidly, whereas in an acetylene atmosphere the supersaturation changes much less rapidly with temperature.

3. MAIN METHODS OF PRODUCTION OF DIAMOND IN THE METASTABLE REGION

We shall review the most important patents and papers dealing with the epitaxial synthesis of diamond in the metastable region (between 10^{-3} mmHg and 1000 atm). In 1962 Eversole filed two patents[6]. In the first, the carbon-containing gas is passed over the diamond seed crystal held at a controlled temperature. The temperature range quoted in the patent is 600–1600°, but the best results are obtained at 900–1100°. The partial pressure of carbon-containing gases (with methyl groups) must not exceed 75 mmHg, and should preferably be in the range 0.1–1 mmHg When carbon monoxide (or a mixture of the monoxide and dioxide) is used, the pressure can be as high as 2500 atm. The preferred pressure range is 70–140 atm. Diamond grows on the seed crystal until the formation of other modifications of carbon arrests the growth. The seed can be freed from graphite, and exposed to further diamond growth. The time for the whole cycle of operations (growth and reactivation) varies from a few minutes to 100–200 h, depending on conditions. The reactant can be methane, ethane, propane, chloromethane, methanethiol, or acetone. No growth was observed with benzene, carbon disulphide, dichloromethane, and other hydrocarbons not containing methyl groups. Argon and nitrogen do not inhibit the reaction.

Most of the experiments described[6] were made with diamond powders of 0.1 μm average size, and crystals up to 0.1 carat in weight were obtained. The use of powders offers the advantage of a large specific surface area (up to 20 m^2 g^{-1}).

Non-diamond carbon was removed either by boiling in a mixture of sulphuric and chromic acids, or in hydrogen at pressures up to 50 atm and temperatures between 1000 and 1100°. The latter method relies on the different kinetic activities of diamond and graphite.

The growths of diamond were identified by density measurements and by lattice parameter determinations using electron diffraction.

The maximum increase in weight of the starting powder was 59.5%. This required 85 successive cycles of growth (1.79 h) and graphite removal (4.5 h).

Eversole's second patent is an extension of the first, and essentially consists in the use of gases which can dissociate with formation of free methyl radicals. Angus and coworkers[7] repeated and checked Eversole's work in 1968. They subjected the processed diamond powders to density measurements, to spectroscopic, X-ray diffraction, and electron diffraction analysis, and they studied their microwave absorption and ESR behaviour. The starting and the grown material were identical in every respect. These workers also compared the reaction rates of diamond and of graphite with hydrogen. The activation energy of the diamond–hydrogen reaction was found to be 125 kcal $mole^{-1}$, with an approximately fifth-power pressure dependence, as compared with 85.5 kcal $mole^{-1}$ and a linear pressure dependence for graphite. However, these results were obtained over a narrow pressure range (50–70 atm).

The West German firm of Siemens und Halske filed a French patent in 1962 entitled[8] "Method of Production of Carbon in the Diamond Form at Low Pressures". The invention consists in admitting to the hot reaction zone a carbon compound whose structure is a complete or partial replica of that of the diamond lattice. One of the recommended starting materials is cyclopentane, whose five-membered ring of carbon atoms is practically unstrained (angular deformation less than 1°). In addition to cyclopentane and cyclohexane, other carbon compounds can be used if their thermal decomposition gives rise to products in which the carbon chains are a replica of the diamond lattice structure. Inert gases, hydrogen, or gaseous hydrocarbons at room temperature can be used as carrier gases for the starting material.

To assist the formation of seeds of the diamond form in the reaction zone, catalysts are used. These include substances capable of forming carbides with a cubic structure, e.g. silicon, titanium, Group V elements such as niobium and tantalum, and also a tungsten–cobalt alloy. The catalyst is introduced into the reaction zone either in the form of a solid substrate (for the preparation of crystalline layers) or as metal-containing vapours (for the preparation of carbon powders with the diamond structure). The preferred reaction temperature is between 800 and 1200°. The reaction mixture is activated by some form of electrical gas discharge.

Another patent[9] by the same firm claims every method of preparation of diamonds by means of chemical transport reactions. The pressure of carbon-containing gas must not be allowed to depart too significantly from the equilibrium value for diamond, otherwise carbon may be deposited in a non-diamond form. The theory of the transport process has been discussed by the present writers[10] from the standpoint of non-equilibrium thermodynamics.

The patent[11] "Method and Apparatus for the Replication of Crystal Structures" has interesting possibilities in microelectronics technology. The diamond seed crystal is heated by a controlled electron beam, and a carbon-containing gas is led through the reaction zone without interrupting the electron beam. According to the patent, diamond is deposited on the area where the electron beam is focussed. Gases mentioned in the patent include carbon tetrachloride, carbon tetrabromide, carbon disulphide, and some others. The diamond substrate is heated between 1000 and 3000°: the preferred temperature range is 1800–2500°. Silicon layers can be grown by the same method over the diamond layers from silicon tetrachloride, and these can in turn be overgrown with diamond layers.

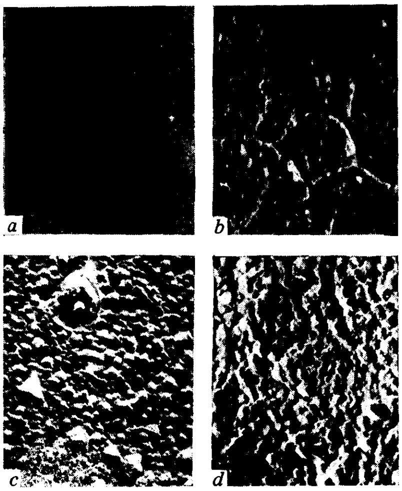

Figure 3. Successive stages in the growth of a (111) diamond face, × 10 000: *a*) initial surface, *b*) and *c*) successive growth stages, *d*) stage corresponding to the formation of a continuous crystallisation front.

In 1964, Brinkman and coworkers[12] extended their earlier work (1957) by disclosing a method for the epitaxial growth of diamond from solutions of carbon in metals. The source of carbon is a sample of graphite held at a higher temperature than the diamond seed crystal. The method can be reduced in practice to two forms: the flow method and the static method. In the flow method, liquid metal is continuously pumped through the system, and carbon atoms are transported from the graphite to the diamond. In the static method the liquid metal is saturated with carbon from the walls of a graphite crucible, the temperature is decreased by an amount corresponding to the desired supersaturation with respect to diamond, and the seed crystal is immersed in the solution. Another patent by the same workers[13] discloses a method for the production of diamond from carbon atoms emitted by a carbon source at high temperature (up to 4000°).

Litvin and Butuzov[14] published a very interesting paper on the growth kinetics of diamond from a solution of carbon in molten metal at 1150° and pressures of the order of 40 000 atm. The planar metal–graphite interface was oriented parallel to the (100) face of the diamond seed crystal. The distance between the two surfaces was of the order of 0.5 mm, and the temperature difference was not allowed to exceed 15°. The kinetic data obtained in this work are of fundamental importance for the development of a theory of crystallisation in the metastable region.

We have recently described[15] the autoepitaxial growth of diamond layers from the gas phase (methane) on natural diamond powder and also on the (111) face of a natural diamond seed crystal. Electron micrographs of successive stages of growth of the same layer are shown in Fig. 3. Fig. 3*a* shows the initial surface, Fig. 3*b* and 3*c* show intermediate stages, and Fig. 3*d* corresponds to the formation of a continuous layer.

4. FILAMENTARY DIAMOND CRYSTALS

The growth of filamentary diamond crystals is of the utmost importance. Such crystals have been obtained by the present writers in collaboration with Luk'yanovich, Ryabov, Spitsyn, Lavrent'ev, and Builov[16-19]. Filamentary crystals (or "whiskers") have a number of unique properties and have attracted a great deal of interest: they have a perfect crystal structure, they retain their elasticity and strength at high temperatures, they show complete strain recovery on subsequent heating, and they have an exceptionally high strength, close to the theoretical value. For example, whereas the tensile strength of ordinary iron is 18–23 kg mm^{-2}, iron whiskers 2 μm in diameter and ~ 2 mm long have a tensile strength of 1200–1300 kg mm^{-2}. The use of sapphire whiskers in niobium composites (50 wt. %) increases the strength of mechanical components by a factor of 4 as compared with pure niobium whilst at the same time reducing their weight: the importance of these properties in aerospace technology is evident.

Filamentary crystals had previously been grown only in the region of thermodynamic stability. Our discovery of filamentary diamond crystals has a twofold significance: on the one hand, it has demonstrated the possibility of growing whiskers under metastable conditions, and on the other hand it has shown that diamond crystals can be grown at low pressures from carbon-containing gases at appreciable linear velocities of crystallisation (at least, in principle). These velocities are many orders of magnitude higher than the linear growth rate of diamond powders (from a few to a few tens of Ångstroms per hour).

The experiments were carried out in a radiation furnace based on a super-high-pressure xenon lamp (type DKSR-6000). The apparatus has already been described in detail[20,21]. The diamond seed crystal was secured by pointed rhenium supports, and located at the focal spot of the apparatus, whose diameter was greater than the largest dimension of the seed crystal. The temperature of the crystal was measured with an optical pyrometer.

The surface of the seed crystal could be observed in a microscope during the experiment. The formation and subsequent growth of filamentary diamond crystals was established in this way. The growth rate is a function of temperature, pressure, and some other parameters. Since the parameters of the radiant flux at the focal spot are not uniform, conditions at the apex of the growing whisker are not the same as at the substrate surface. Thus, the illumination could vary by a factor of two as between the apex and the base of a whisker 400 μm long. The mean growth rate of the whiskers was 50–250 μm h^{-1}: this was genuinely a mean linear velocity, and it is reasonable to assume that much higher linear growth velocities are possible and did indeed obtain at some stage in the growth of these whiskers.

Fig. 4 shows a filamentary diamond crystal approximately 1.00 mm long, grown on the (111) face of a diamond seed crystal. The pointed rhenium seed holder is visible in the photograph.

Diamond whiskers grown on a (111) face are inclined at an angle of 50–60° to this face: their growth is probably normal to a (110) face, as in the case of silicon and germanium whiskers, which crystallise in the diamond lattice.

Figure 4. Filamentary diamond crystal, 1.0 mm long.

The cathodoluminescence of the diamond whiskers has been found to be similar to that of the substrate. After one experiment, the formations were identified unequivocally as diamond by examining the powdered whisker in an electron microscope in the electron diffraction mode. Using platinum as a standard, the interplanar spacings were calculated from the diffraction pattern and compared with tabulated values.

d_{tab}, Å	2,05	1,26	1.072	0,885	0.813	0.721
d_{calc}, Å	2,07	1,24	1.068	0,920	0.825	0.740

The electron diffraction patterns show that the whiskers are single crystals. Kikuchi lines are clearly visible in some of the patterns.

The apex of the diamond whiskers was occasionally found to be covered by a dark, spherical formation. One possible explanation is metallic contamination of the substrate surface before growth. A special series of experiments was therefore devised to study the growth of filamentary diamond crystals under droplets of molten metal by the VLS (vapour–liquid–solid) method[19]. Transparent filamentary crystals supporting a droplet of solidified metal were produced. The best results were obtained with metals in which the solubility of carbon is high and which can wet diamond (nickel, iron, manganese). No formations were observed under molten gold droplets. Evidently, the VLS method must be considered among the possible methods of growing diamond crystals. The role of the intermediate liquid metal phase in the growth of diamond has been discussed by one of us[3]. The energy of formation of a two-dimensional diamond nucleus under the layer of metal can be very much lower than the energy of formation of a three-dimensional critical nucleus of graphite. This is because surface energies at the graphite–metal interface are usually much higher than the surface energy at the graphite–air interface, and therefore the work of formation of graphite nuclei is increased and the generation of such nuclei is suppressed.

The recently observed conversion of filamentary crystals into isometric crystals is also worth noting. We were able to follow, using a microscope, the growth of a diamond whisker. When growth stopped, the crystal began to thicken until an isometric crystal of diamond with 0.1 mm average cross-section and very weakly developed facets was obtained. This crystal was examined by X-ray micro-diffraction (beam diameter 12 μm) at the top, the side, and the bottom of the crystal as grown, and it was found to be a single crystal.

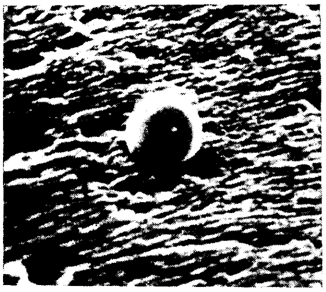

Figure 5. Isometric diamond crystal grown on a (111) face, photographed in a scanning electron microscope. Crystal diameter 20 μm.

Scanning electron microscopy is a particularly revealing technique for examining isometric crystals. A scanning electron micrograph of an isometric crystal 20 μm in diameter, taken in V. G. Spivak's laboratory at the Moscow State University, is shown in Fig. 5.

Metal-Metal Bonds and Covalent Atomic Radii of Transition Metals in Their π-Complexes and Polynuclear Carbonyls

B.P.Biryukov and Yu.T.Struchkov

The review presents a compilation of recent results in one of the most important fields of structural chemistry at the present time—compounds with metal-metal bonds.
The bibliography includes 56 references.

CONTENTS

I. INTRODUCTION

The rapid development of the chemistry of the π-complexes of transition metals has already led to the synthesis of numerous groups of compounds the molecules of which contain two or several metal atoms linked either directly or via additional bridging ligands. The considerable interest in this unusual class of compounds is due to the fact that metal–metal bonds in many respects determine the chemistry of transition metal compounds.

The problem of the interaction between metal atoms in complexes has attracted attention for a long time. The accumulation of extensive experimental data led to many attempts at reviews, primarily those listed in Refs. 1–12.

The present review deals with the metal–metal interaction in the π-complexes of transition metals and is based on the experimental interatomic distances and valence angles in their molecules.

The most successful classification of compounds on the basis of metal–metal bond types has been proposed by Nyholm[2,5] and is partially applicable also to π-complexes and polynuclear carbonyls. In the first place, it is necessary to distinguish a group of compounds with covalent bonds between metal atoms, including both molecules with covalent bonds between transition metal atoms—for example, $Mn_2(CO)_{10}[(\pi\text{-}C_5H_5)Mo(CO)_3]_2$, $(\pi\text{-}C_5H_5)Mo(CO)_3\text{-}Mn(CO)_5$—and molecules with covalent bonds between elements in Groups IB–IVB and transition metals—for example, $(C_6H_5)_3PAuMn(CO)_5$, $Hg[Co(CO)_4]_2$, and $[(C_6H_5)_3SnMn(CO)_5]$. The first group may be subdivided into homopolymetallic complexes with identical electronic configurations of the transition metal atoms—for example, $Mn_2(CO)_{10}$ and $[(\pi\text{-}C_5H_5)Mo(CO)_3]_2$—and heteropolymetallic complexes, i.e. with different electronic configurations of the transition metal atoms—for example, $(\pi\text{-}C_5H_5)Mo(CO)_3\text{-}Mn(CO)_5$.

It is possible to distinguish further a group of π-complexes with metal–donor bonds, the molecules of which are combined in the crystal into polymeric chains owing to metal–metal interaction.

II. π-COMPLEXES WITH COVALENT METAL–METAL BONDS

In their reviews Lewis and Nyholm[2-6] attempted to estimate the factors which determine the nature of the interaction between covalently linked metal atoms. Most important among these factors are the effective charge of the metal atom, its electronic configuration, and also the electronic properties of ligands and their steric characteristics. However, these factors probably do not exhaust the entire set of influences on the type of metal–metal bonds, since, as will be shown in the discussion of interatomic distances, these bonds are fairly variable in their strength, length, and number of electrons involved in them. The effect of bridging groups, which in many complexes to a considerable degree determine the nature of the metal–metal interaction, is also undoubtedly important.

A. COMPOUNDS WITH COVALENT BONDS BETWEEN TRANSITION METALS

1. Homopolymetallic Complexes

The lengths of the metal–metal bonds in homopolymetallic complexes (Table 1) vary within fairly wide limits (up to about 0.5 Å for Fe–Fe bonds). As pointed out by Poray-Koshits and Gilinskaya[11], this means that the curve relating the metal–metal interaction energy to the interatomic distance has a fairly gently sloping profile with a diffuse minimum or a series of several closely spaced minima.

Therefore the problem arises of the validity of the application of a widely used criterion—the sum of single bond covalent radii—to characterise the metal—metal interaction forces. The problem of the values of the single bond covalent radii of transition metal atoms in their π-complexes has been frequently discussed (see, for

*According to Andrianov et al.[13]

**Single bond covalent radii according to Pauling[14]: the first for a coordination number of 6 and the second for a coordination number of 12.

example, Andrianov et al.[13]), since theoretical and experimental results have shown that the single bond transition metal radii proposed by Pauling[14] cannot be used to analyse the interatomic distances in their π-complexes. Incidentally, we may note that the revision of the atomic radii of transition metals was in fact stimulated by the study of compounds with metal–metal bonds. Indeed the Mn–Mn bond length (2.926 Å) in the dimanganesetetracarbonyl molecule[15] $Mn_2(CO)_{10}$ is greater by about 0.4 Å than twice the value of Pauling's atomic radius of manganese (2.54 Å). However, Cotton[16] found a contradiction between the fairly high energy of this bond (34 kcal $mole^{-1}$)† and its very marked extension, which clearly indicated that the value of 1.27 Å for the atomic radius of manganese is too low.

The single bond covalent radii of transition metals in their π-complexes[13], which will be employed‡ in the analysis of the metal–metal interatomic distances, are compared in Table 2 with the values proposed by Pauling[14]. In the analysis of the interatomic metal–metal distances in homopolymetallic π-complexes (Table 1) the fact that the shortest of them are observed in molecules with bridging ligands attracts attention. This suggests that such ligands draw the metal atoms together by virtue of the rigidity of their geometry.

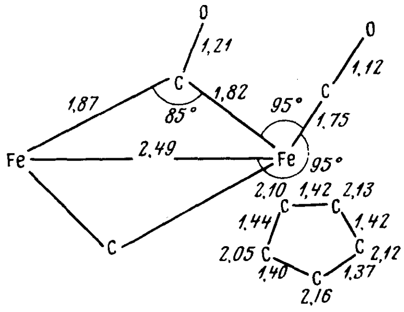

Figure 1. Geometry of the $[(\pi\text{-}C_5H_5)Fe(CO)_2]_2$ molecule.

The most widespread and the most readily available molecules for a simple geometrical examination are those in which the bridging ligands are linked to only two metal atoms (the so called "edge" bridges) and form MXM groups (X = C, N, S, etc.) via only one of their atoms, for example in bis(dicarbonyl-π-cyclopentadienyl-iron) $[(\pi\text{-}C_2H_5)Fe(CO)_2]_2$ (Fig. 1).[20] In the formation of the FeCFe group in this molecule the bridging carbon atom is in the sp^2-hybridised state and therefore the most favourable angle is probably 120°. However, examination of the geometry of the planar fragment Fe_2C_2 (Fig. 1) shows that in this case the distance between the bridging carbon atoms not linked by valence bonds is 1.9–2.0 Å (while twice the van der Waals radius is 3.6 Å), i.e. is unexpectedly small. This factor probably in fact forces the bridging carbon (nitrogen, sulphur) atoms to move apart to acceptable distances with a decrease of the real

---

† See the footnote on p. 791.

‡ It must be specially emphasised that, according to one view[17], the very concept of atomic radius is inapplicable to complex (three-dimensional) cluster systems (see p. 791) and this undoubtedly true owing to the many-centre nature of all the bonding orbitals responsible for the metal–metal interaction[8,18,19]. Therefore the system of radii proposed by Andrianov et al.[13] is applicable to complexes in which the bonds are largely localised and collective groups of atoms are absent.

$MX_{bridge}M$ angles to 67–86°C (instead of the "ideal" value 120°C). Thus if the FeCFe angle in the molecule under discussion is assumed to be 90°C and the length of the Fe–C bond is taken to be 1.9 Å, the C... C distance between bridging carbon atoms not linked by valence bonds increases to the now admissible value of 2.7 Å. Then the Fe–Fe distance also becomes close to 2.7 Å, i.e. it is virtually equal to twice the single bond radius of the iron atom (2.68 Å). Thus it appears that the FeCFe angle close to 90°C corresponds to the optimum configuration of the Fe_2C_2 fragment.

However the problem then arises of the cause of the decrease of the Fe–Fe distance to 2.49 Å and the decrease of the FeCFe angle to 85°C in the $[(\pi\text{-}C_5H_5)Fe(CO)_2]_2$ molecule compared with the optimum values 2.7 Å and 90°C, and in the more general case of the cause of the considerable variability of the metal–metal distance and of the bridging angle in the range 67–86°C§. An attempt may be made to answer these questions in the following way. By virtue of the rigidity of their geometry, the bridging ligands exert a purely geometrical influence on the metal–metal distance; then the difference between the geometrical requirements of the bridging groups (and in particular the dimensions of the bridging atom) are responsible for certain differences in the metal–metal distances. This is combined also with effects which determine the nature of the direct interaction between the metal atoms, namely their electronic configuration, effective charge, the repulsion of the non-bonding electrons, and the steric effects of the ligands. All these factors give rise to variations in the metal–metal distances, which in turn lead to a change in the bridging angles. Thus it becomes quite evident that the variability of the metal–metal distances over a wide range in π-complexes in the presence of bridging ligands is reasonable.

All that has been said refers also to molecules containing bridging ligands linking three metal atoms (the so called "face" bridges); in this case the geometrical requirements of the ligands also give rise to an appreciable variation in the metal–metal distances but now in trigonal systems comprising metal atoms.

It is clear from these facts that, in the presence of bridging or pseudo-bridging groups, a widely used criterion of bond types, such as the sum of single bond covalent radii, cannot be applied because the metal–metal distance does not reflect the true nature of the interaction. Moreover, magnetic measurements have shown[10] in many cases that in some molecules the bridging groups may bring appreciably more closely together the non-bonded metal atoms, while in others the marked overlapping of the orbitals of the metal atoms can occur over a large distance. The problem arises of the characterisation of the force of the metal–metal interaction in molecules with bridging groups. In many cases the magnetic properties of the compound may serve as a criterion of this kind but, as pointed out by Lewis[4], it is often difficult to distinguish direct interaction between two metal atoms from interaction via a bridging group and there is no doubt that sometimes interactions of both types occur.

In a comparison of metal–metal bond lengths in molecules (not containing bridging ligands) with twice the values of single bond radii (Table 1) it is important to note that, for elements of the first series, the bond lengths are appreciably increased. This indicates some weakening of the bonds between the metal atoms of the first transition series compared with ordinary covalent bonds. However, with increasing atomic number of the metal within the limits of a given transition series, a tendency is observed for the experimental interatomic metal–metal distances to approach twice the values of the single bond covalent radii, i.e. in the first transition series the force of the metal–metal interaction increases from vanadium to nickel. This tendency is maintained also in the second and third series and the metal–metal bonds actually become shorter than twice the single bond radii (Table 1), which according to Lewis and Nyholm[2–6] is due to a change in the dimensions of the atomic orbitals participating in the formation of the metal–metal bond.

Thus metals in the second and third transition series form stronger bonds than their analogues in the first transition series, which is clearly illustrated by an examination of similar $M_2(CO)_{10}$ (M = Mn, Tc, or Re) molecules with the same structures (Fig. 2). Comparison of the Mn–Mn bond length (2.923 Å) in the dimanganesedecacarbonyl $Mn_2(CO)_{10}$ molecule[15], the Tc–Tc bond length (3.036 Å) in the ditechnetiumdecacarbonyl $Tc_2(CO)_{10}$ molecule[22], and the Re–Re bond length (3.02 Å) in the dirheniumdecacarbonyl $Re_2(CO)_{10}$ molecule[23] with twice the single bond covalent radii (2.76, 3.0_6, and 3.02 Å respectively) indicates a significant difference between the metal–metal bonds in these molecules with identical structures: the Mn–Mn length is increased by about 0.16 Å (i.e. is weakened compared with the ordinary covalent bond), while the Tc–Tc and Re–Re bond lengths are virtually equal to twice the radii (i.e. these bonds are essentially of the ordinary covalent type).

This conclusion is fully consistent with the relative anionic nucleophilicities $[Mn(CO)_5^- \ll Re(CO)_5^-]$,[24] the dissociation energies[25] of the Mn–Mn (0.96 eV or 22 kcal)¶ and Re–Re (2.22 eV or 51.1 kcal) bonds and force constants (Mn–Mn < Re–Re).[25] The strengthening (or more precisely the lack of weakening) of the Tc–Tc and Re–Re bonds compared with the Mn–Mn bond cannot be due to steric effects: the molecules have the same structures and the distances in them between valence non-bonded atoms are similar. Probably the causes of the difference in the behaviour of transition metals of the same Group should be sought also in the variation of the dimensions of their atomic orbitals.

In the case of homopolymetallic complexes where metals of the same Group but different series are combined, their "additive" interaction is observed. Thus in the $(CO)_5Mn–Re(CO)_5$ molecule the Mn–Re bond (length 2.96 Å)[26] is intermediate in strength between the Mn–Mn and Re–Re bonds in the decacarbonyls of the two metals: the Mn–Mn bond length increases by about 0.16 Å, Mn–Re by about 0.07 Å, and the Re–Re bond length is the same as the length of the ordinary covalent bond.

The work of Dahl and coworkers on structural studies of homopolymetallic complexes is outstanding; they investigated the dinuclear carbonyls of iron in which the sulphur

---

§ As pointed out by Wei and Dahl[21], who analysed structures with bonds between metal atoms of the first transition series and with symmetrical CO bridging groups, in these molecules, with the exception of $C_8H_8Fe_2(CO)_5$ and $[C_8H_4(CH_3)_4]Fe_2(CO)_5$, the metal–metal distances do not exceed 2.58 Å, the $M–C_{bridge}$ bond lengths are in the range 1.82–1.96 Å, and the MCM angles are in the range 78–86°C. A direct correlation between these quantities has not been observed.

¶ We may note that clearly contradictory data are quoted in the literature for the energy of the Mn–Mn bond: 34 ± 13 kcal $mole^{-1}$ (kinetic data[16]) and 18.9 ± 1.4 and 22.1 kcal $mole^{-1}$ (mass-spectrometric data[24]).

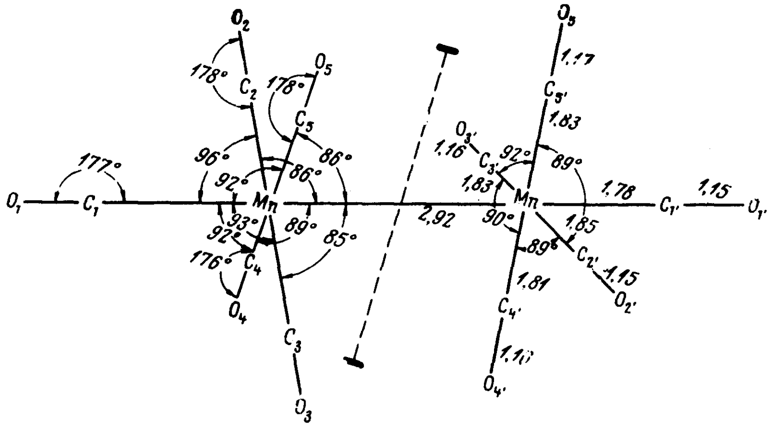

Figure 2. Molecules of the series $M_2(CO)_{10}$(M = Mn, Tc, or Re).

or selenium atom plays the role of the bridge. This group of molecules with the general formula $[XFe(CO)_3]_2$ (where X = S, RS, or RSe and R is an organic group), a typical example of which is $[C_2H_5SFe(CO)_3]_2$ (Fig. 3)[27], has attracted attention because here the concept of so called bent bonds was introduced to describe the metal–metal interactions. Indeed, in molecules of this group the formation of covalent bonds between metal atoms via a colinear overlapping of their atomic orbitals is impossible without a significant distortion from octahedral symmetry. Consequently Dahl[28] postulated an almost undistorted octahedral configuration of the metal atom, which forms a bond with another metal atom via a non-colinear overlapping of a pair of their axial orbitals, i.e. the bond is bent (Fig. 3).

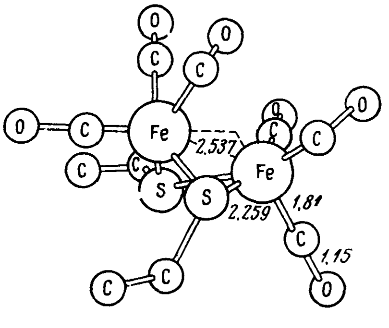

Figure 3. Geometry of the $[C_2H_5SFe(CO)_3]_2$ molecule.

The most interesting of the fields, developed by Dahl and coworkers, comprises work on the elucidation of the effect of the unpaired electrons on the molecular geometry of the complex. This is illustrated by the isomorphous complexes $Co_3(CO)_9S$ and $FeCo_2(CO)_9S$. The paramagnetic molecule of tricobaltenneacarbonyl sulphide[29] $Co_3(CO)_9S$ contains a triangle of Co atoms (Fig. 4) whose side has an average length of 2.64 Å; the S atom is a triple bridge and is located at equal distances (2.14 Å) from all the CO atoms. In the isomorphous complex $FeCo_2(CO)_9S$, which differs from $Co_3(CO)_9S$ by the replacement of a Co atom by an Fe atom, the average metal–metal bond length is 2.554 ± 0.007 Å,[30] i.e. it is shorter by 0.08 Å, although the covalent radius of iron is greater by 0.05 Å than the radius of cobalt. According to Dahl[30], this shortening is evidence of the effect of the unpaired electron on the molecular geometry of the complex. Indeed the replacement of one of the cobalt atoms in the paramagnetic $Co_3(CO)_9S$ molecule by an iron atom leads to a diamagnetic complex $FeCo_2(CO)_9S$ and strengthening of the metal–metal bonds; this shows that the unpaired electron in $Co_3(CO)_9S$ must be located in an antibonding molecular orbital.

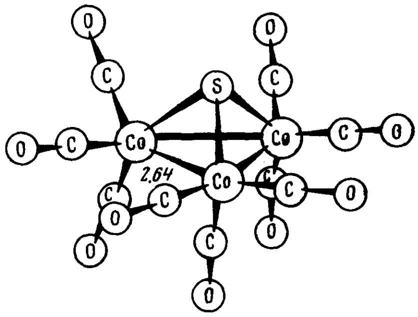

Figure 4. Geometry of the $Co_3(CO)_9$ molecule.

Finally, mention must be made of the structural work of Dahl and coworkers on organocobalt sulphur-containing complexes in which an attempt was made to determine the Co–Co bond order on the basis of quantum-chemical concepts used to analyse the structure of the anion $[Re_3Cl_{12}]^{-3}$ (see, for example, Wei and Dahl[31]).

Nowadays many workers are vigorously investigating the so called cluster compounds, which contain groups of a finite number of metal atoms. According to Cotton[8], the term "cluster" is usually understood as comprising compounds with finite closed groups of metal atoms, forming triangles, for example $(\pi\text{-}C_5H_5Ni)_3(CO)_2$ (Fig. 5)[32], tetrahedra, for example $Rh_4(CO)_{12}$(Fig. 6)[33], pentameric groups, for example $Fe_5(CO)_{15}C$ (Fig. 7)[34], and even octahedra, for example $Rh_6(CO)_{16}$ (Fig. 8)[35]. The wide interest in cluster compounds can be explained in the first place by their very unusual properties; one deals not with an individual transition metal atom but with a group, for which such firmly established concepts as, for example, the coordination number and atomic radius† are sometimes inapplicable, since instead of individual atoms one has to consider a fairly complicated collective electron system of a group of metal atoms. This factor permits the inclusion among complexes with covalent bonds only some of the cluster compounds; some of these, for reasons indicated above, can be treated only within the framework of the molecular orbital method, the application of which to such systems is valid and fruitful.

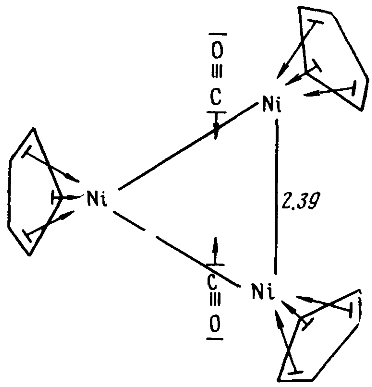

Figure 5. Trigonal group of metal atoms in the $(\pi\text{-}C_5H_5Ni)_3(CO)_2$ molecule.

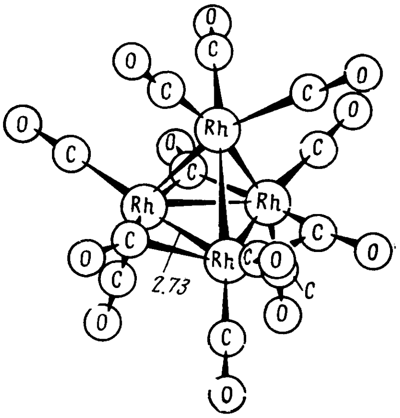

Figure 6. Tetrahedral grouping of metal atoms in the $Rh_4(CO)_{12}$ molecule.

2. Heteropolymetallic Complexes

The number of π-complexes with bonds between transition metals belonging to different Groups‡, whose structures have been investigated, is small (Table 3) and studies of this kind have not been systematic.

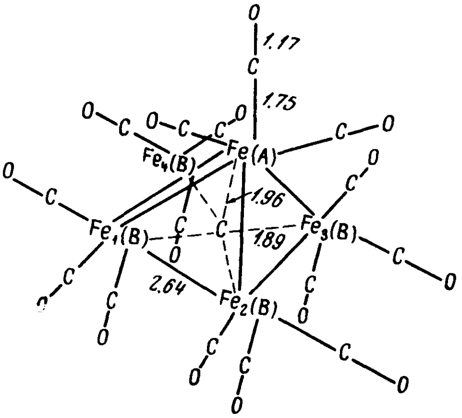

Figure 7. Pentameric grouping of metal atoms in the $Fe_5(CO)_{15}C$ molecule.

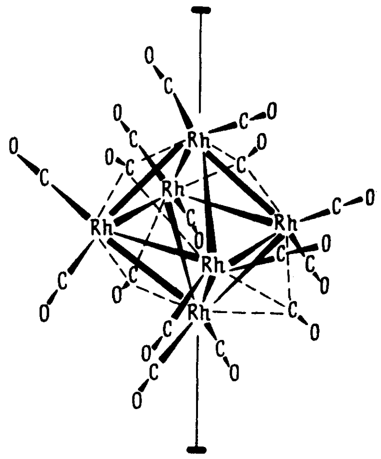

Figure 8. Octahedral grouping of metal atoms in the $Rh_6(CO)_{16}$ molecule.

The results of the investigations of heterodimetallic molecules such as $(\pi\text{-}C_5H_5)Mo(CO)_3\text{-}Mn(CO)_5$ (Fig. 9)[36], which are a combination of the monomeric fragments of dimeric homodimetallic molecules {in this case $[(\pi\text{-}C_5H_5)Mo(CO)_3]_2$ [37] and $Mn_2(CO)_{10}$ [15]} via a metal–metal

---

† See the footnote on p. 791.

‡ Heteropolymetallic π-complexes of course include also compounds containing the same metal atoms with different electron configurations, but the metal–metal bond lengths in them are close to those found in homopolymetallic complexes.

bond. The equality of the Mo–Mn bond length (3.08 Å) in this molecule to half the sums of the Mo–Mo and Mn–Mn distances in dimeric molecules [(3.222 + 2.923)/2 = 3.072] indicates that in the formation of heterodimetallic complexes the interaction of monomeric fragments is "additive", i.e. takes place without appreciable changes in the nature of the orbitals of the metal atoms participating in the formation of the metal–metal bonds.

Table 3. Metal–metal bond lengths in heteropolymetallic π-complexes.

Bond	Bond length, Å	Sum of single bond covalent radii	Absolute change in bond length	Relative change in bond length, %
Fe—Mn	2.82	2.7_2	+0.10	+3.7
Fe—Pd*	2.59	2.8_3	−0.24	−8.5
Mo—Mn	3.08	2.9_6	+0.12	+4.1
Mo—Re	3.12	3.0_9	+0.03	+1.0
W—Mn	3.16	2.9_7	+0.19	+6.4
Pt—Co	2.61	2.7_2	−0.11	−4.0
Pt—Mn	2.74	2.8_1	−0.07	−2.5

*Bond "strengthened" by a bridging group.

Thus the type of interaction between covalently linked metal atoms in heteropolymetallic complexes is determined by the same factors as in the previously discussed homopolymetallic complexes.

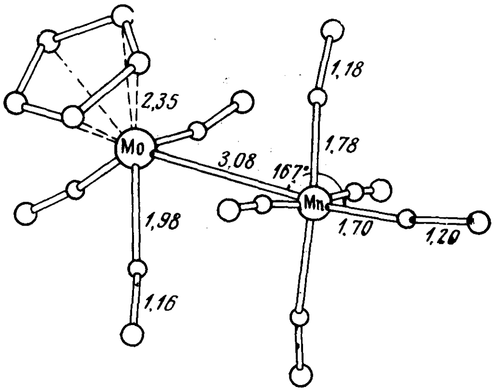

Figure 9. Geometry of the $(\pi\text{-}C_5H_5)Mo(CO)_3Mn(CO)_5$ molecule.

To illustrate this conclusion, we shall consider the pairs of compounds $(\pi\text{-}C_5H_5)Mo(CO)_3\text{–}M(CO)_5$ (M = Mn or Re) and $(\pi\text{-}C_5H_5)M(CO)_3Mn(CO)_5$ (M = Mo or W). Comparison of the metal–metal bond lengths (3.08 Å[36] and 3.12 Å[26]) with the sums of the single bond covalent radii (2.96 and 3.09 Å) for the first pair of compounds shows that the Mo–Mn bond (relative bond elongation Δ_{rel} = +4.1%, see Table 3) is somehwat weaker than the Mo–Re bond (Δ_{rel} = +1.0%). Comparison of the second pair of compounds shows that the W–Mn bond is somewhat weaker than Mo–Mn (Δ_{rel} = 6.4 and 4.1% respectively). Thus in the case of heteropolymetallic complexes too the metals of the second and third transition series from stronger bonds and the maximum tendency of this kind is shown by metals of the second transition series.

It is noteworthy that, although the molecules with metal–metal bonds discussed are not overcrowded in the usual sense of this term, certain details of their real conformations are in fact due to the interaction of the valence non-bonded atoms. Thus in the $(\pi\text{-}C_5H_5)Mo(CO)_3\text{–}Mn(CO)_5$ molecule[36] already discussed (Fig. 9) there is a considerable number of brief contacts between the carbonyl groups at the Mo and Mn atoms, i.e. the $(\pi\text{-}C_5H_5)Mo(CO)_3$ and $Mn(CO)_5$ fragments undergo mutual steric repulsion, which leads to a weakening of the metal–metal interaction.

B. COMPOUNDS WITH COVALENT BONDS BETWEEN TRANSITION METALS AND ELEMENTS OF GROUPS IB–IVB

The number of structural studies on compounds of this type has been small and they have been systematic only for compounds with direct bonds between transition metals and non-transition elements of Group IVB.

A characteristic feature of compounds with direct bonds between Group IB elements (copper, silver, and gold) and transition metals, for example $(C_6H_5)_3PAu\text{–}Mn(CO)_5$,[38] is the presence of phosphine or arsine ligands attached to the

Table 4. Covalent bonds between transition metal atoms and those of elements in Groups IB–IVB.

*Pauling's radii[14] corresponding to a coordination number of 12 were employed for elements in Group IB–IIIB; the values for Group IVB elements were taken from Bokii and Struchkov[55] and those for transition metals from Andrianov et al.[13] see Table 2.

non-transition element. Groups such as $(C_6H_5)_3PAu$ and $(C_6H_5)_3SbCu$ have electronegativities similar to those of halogens[2]. This suggests[39] the possibility of an electronic d_π–d_π interaction between these groups and transition metals. As a result there is a transfer of non-bonding *d* electrons of the transition metal atom to the vacant *d* orbitals of the IB Group element and the stability of derivatives of the type $R_3P \rightarrow Au{-}Mn(CO)_5$ increases[40] as the electron-acceptor properties of the R substituents become more pronounced.

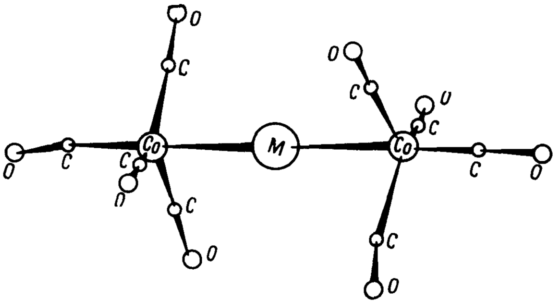

Figure 10. Molecules of the series $M[Co(CO)_4]_2$ (M = Hg or Zn).

The occurrence of d_π–d_π interaction is supported also by the fact that substitution reactions in derivatives of this kind involve carbonyl groups. Finally, comparison of the bond lengths between Group IB elements and transition metals with the sums of the single bond covalent radii (Table 4) shows that the bond lengths are appreciably shorter (by about 0.1–0.3 Å), which is evidence of an increase in the multiplicity of these bonds compared with ordinary covalent bonds.

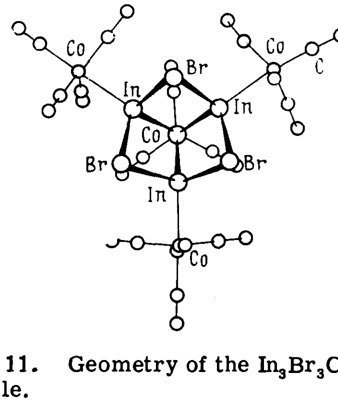

Figure 11. Geometry of the $In_3Br_3Co_4(CO)_{15}$ molecule.

An analogous situation is observed also for compounds with direct bonds between elements of Group IIB and transition metals, for example $M[Co(CO)_4]_2$ (M = Hg [41] or Zn,[42] Fig. 10). The significant shortening (by about 0.3–0.4 Å, Table 4) of these bonds also suggests their partial double bond character, caused[43] by the transfer of *d* electrons from the occupied orbitals of the transition metal to vacant orbitals of the IIB Group elements.

Amongst compounds with bonds between Group IIIB elements and transition metals, structural studies have been made[44] only on the product of the reaction of InBr and $Co_2(CO)_8$ having the composition $In_3Br_3Co_4(CO)_{15}$.

The molecule contains a buckled six-membered ring (Fig. 11) consisting of alternating In and Br atoms. Each indium atom is linked to a $Co(CO)_4$ group via a metal–metal bond with a length of 2.53–2.58 Å and the fourth cobalt atom (in a $Co(CO)_3$ group), which is different from the other cobalt atoms, forms bonds with all three indium atoms with a length of 2.57–2.63 Å. All these bonds are shorter than the sum of the single bond radii (2.73 Å).

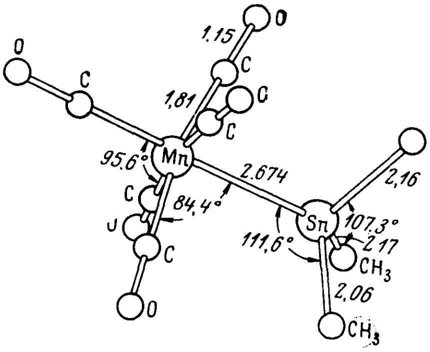

Figure 12. Bond lengths and valence angles in the $(CH_3)_3SnMn(CO)_5$ molecule.

We now come to the discussion of π-complexes with bonds between transition metals and non-transition Group IVB elements, a typical example of which is $(CH_3)_3Sn{-}Mn(CO)_5$ (Fig. 12);[45] this group of compounds has been most completely investigated. Examination of the metal–metal distances of these molecules reveals two striking facts: appreciable variability of the metal–metal bond lengths and a significant shortening of the bonds compared with the sums of the single bond covalent radii (Table 4). For example the Sn–Mn and Sn–Fe bond lengths vary in the ranges 2.63–2.74 and 2.47–2.75 respectively, while the sums of the radii are 2.78 and 2.74 Å.

Numerous studies of the infrared spectra of such series of compounds show that the stretching vibration frequencies of the carbonyl groups attached to the transition metal atoms are exceptionally sensitive to the nature of the substituent X at the atom of the non-transition Group IVB element. This effect has been treated in two different ways in the literature (see, for example, Refs. 46–48). According to the first treatment, the change in the nature of the σ bond between metal atoms on replacement of X (for example as a result of a change in the σ-donor properties of the ligands $X_3Sn{-}$, $X_2Sn\!<$, and $XSn\!\lessdot$) leads to a change in the effective charge at the transition metal atom, which is reflected in a variation of the stretching vibration frequencies of the CO groups. For example, an increase in these frequencies on replacement of $X = CH_3$ by the more electronegative X = Cl in the series $X_3Sn{-}Mn(CO)_5$ ($X = CH_3$, Fig. 12) can be due to the more positive nature of the Mn atom in the latter case (in other words a lower negative charge of the atom), which leads to a weakening of the dative $d_\pi - p_\pi$ Mn–C bond and an increase in the multiplicity of the C–O bond.

In the treatment of the second type of effect of the substituent X consists in a change of the affinity of the vacant *d* orbitals of the non-transition Group IVB element for the non-bonding *d* electrons of the transition metal atom if one postulates the occurrence of $d_\pi - d_\pi$ interaction in the metal–metal bond under consideration. Thus the two types of treatment are not mutually exclusive and require both σ-donor and π-acceptor properties of the ligands to be taken into account.

We are bound to admit that the problem of the occurrence of $d_\pi - d_\pi$ interaction in metal–metal bonds is at present controversial, particularly owing to the lack of quantum-chemical calculations for this group of compounds, but there is much indirect spectroscopic[48] and chemical evidence in favour of such interaction.

The experimental data for interatomic metal–metal distances also indicate some increase in the bond multiplicity. For example, the length of the Mn–Mn bond varies in the range 2.63–2.74 Å and is much shorter than the sum of the single bond covalent radii (2.78 Å).

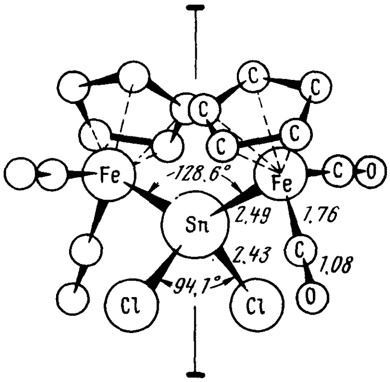

Figure 13. Bond lengths and valence angles in the $[(\pi\text{-}C_5H_5)Fe(CO)_2]_2SnCl_2$ molecule.

In another very fully investigated group of compounds with Sn–Fe bonds, it is possible to distinguish molecules of the series $[(\pi\text{-}C_5H_5Fe(CO)_2]_2SnX_2$, for example with X = Cl (Fig. 13).[49] Spectroscopic studies also show[50,51] a change in the stretching vibration frequencies of the CO group as a function of the properties of the substituent X. The Sn–Fe bonds gradually become shorter with increasing electronegativity of X, the length decreasing from 2.60 Å for X = CH_3 [52] to 2.49 Å for X = Cl,[49] while the sum of the single bond covalent radii is 2.75 Å. At the same time a gradual increase of the FeSnFe angle is observed: from 123.4° to 128.6°C on replacement of CH_3 by Cl. All these findings suggest that, with increase of the electronegativity of X, the multiplicity of the metal–metal bond also increases owing both to an enhancement of the $d_\pi - d_\pi$ interaction and the hybridisation ($sp^3 \rightarrow sp^2$) of the tetrahedral atomic orbitals of the non-transition element participating in the metal–metal bond, in accordance with Bent's rule[53].

The experimental interatomic distances permit a comparison of the molecules of the series under consideration, differing both in the transition metal atoms, for example $(C_6H_5)_3Ge-M(CO)_5$ (where M = Mn or Re), and the atom of the non-transition Group IVB element, for example $(C_6H_5)_3A-Re(CO)_5$ (where A = Ge, Sn, or Pb).

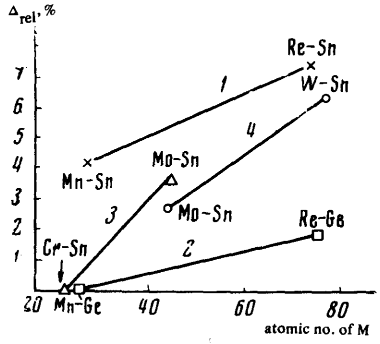

Figure 14. Variation of the relative shortening of metal–metal bonds with the atomic number of the transition metal in molecules with covalent bonds between transition metal atoms and those of a non-transition Group IVB element:
1) $(OC)_5MSn(C_6H_5)_3$; *2*) $(OC)_5M-Ge(C_6H_5)_3$;
3) $C_5H_5(CO)_3M-Sn(C_6H_5)_3$; *4*) $[C_5H_5M(CO)_3]_2Sn(C_6H_5)_2$.

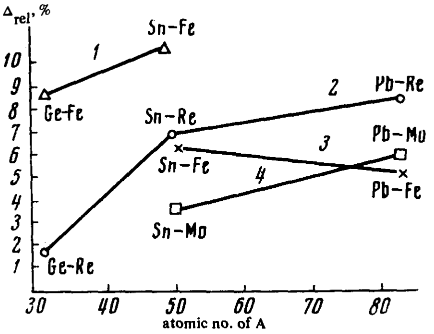

Figure 15. Variation of the relative shortening of metal–metal bonds with the atomic number of the transition metal in molecules with covalent bonds between transition metal atoms and those of a non-transition Group IVB element:
1) $[C_5H_5Fe(CO)_2]_2.ACl_2$; *2*) $(OC)_5Re-A(C_6H_5)_3$;
3) $[C_5H_5Fe(CO)_2]_2A(CH_3)_2$; *4*) $C_5H_5(CO)_3Mo-A(C_6H_5)_3$.

Fig. 14 presents plots of the relative shortening of the metal–metal bonds $\Delta_{rel} = \Delta_{abs}/\Sigma r$ with the atomic number of the transition metal showing that the overall tendency of the transition metal atoms of the second and third series to form more stable metal–metal bonds compared with their analogues in the first series is maintained also when they combine with a non-transition Group IVB element.

As regards molecules with different non-transition Group IVB elements, it is found that, within the limits of the available experimental data (Fig. 15), tin forms stronger bonds than germanium, while for lead no systematic trend has been observed.

III. COMPLEXES WITH METAL–DONOR BONDS

This group includes molecules with square planar coordination about the central metal atom, which has a d^8 valence configuration, for example $Rh(CO)_2[(CH_3CO)_2CH]$ [54] (Fig. 16). In crystals molecules of such compounds are distributed one on top of the other in parallel planes with metal–metal distances of 3.2–3.33 Å (while the distance equal to twice the covalent radius is 2.7–3.0 Å).

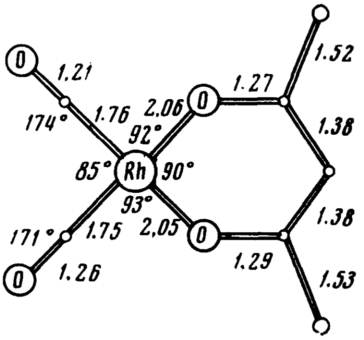

Figure 16. Geometry of the $Rh(CO)_2[(CH_3CO)_2CH]$ molecule.

Thus the coordination about the metal atom is increased to give a distorted octahedron as a result of the formation of the so called metal–donor or polymeric metal–metal bonds. It has been shown[3] that such metal–metal interaction, leading to the formation of an infinite one-dimensional polymetallic system, takes place as a result of the overlapping of the filled d_{z_2} orbital of one metal atom and the vacant p_z orbital of an adjacent atom. These bonds impart to the crystal certain properties of the metal, giving rise, in particular, to a sharp anisotropy of its electrical conduction and photoconduction. The metal–metal interaction of this type is probably not entirely covalent, so that crystals of compounds of this kind exhibit semiconductor properties to a greater extent than metallic properties.

The Mechanism of the Action of Antioxidants and the Synergism of Mixed Antioxidants

P.I.Levin and V.V.Mikhailov

The review considers the mechanism by which various types of inhibitors act in the oxidation processes of carbochain polymers and also mixtures of inhibitors exhibiting a synergistic effect. In conclusion a new and promising class of stabilisers (polyfunctional inhibitors) is considered.
The bibliography includes 85 references.

CONTENTS

I. INTRODUCTION

The effective protection of polymers against thermo-oxidative degradation is an important theoretical and technical problem. The oxidation of organic compounds, including polymers, may be sharply inhibited by the introduction of small amounts of inhibitors or antioxidants. Antioxidants protect polymers from oxidative degradation during their processing at high temperatures and increase the useful life of articles made of polymers.

Mixtures of antioxidants have found application in recent years in the stabilisation of polymers and lubricating oils, since the effect of many mixtures proved to be much greater than would be expected from the additive effects of their components. Numerous studies have been devoted to this phenomenon, called synergism, and also to the search for effective inhibitor compositions.

A number of monographs[1-3] and reviews[4-6] published in recent years deal with the mechanism by which inhibitors of free-radical processes act but the problem of the mechanism of the action of phosphites and sulphur-containing compounds has been hardly touched upon. The mechanisms of the synergism of mixtures comprising inhibitors of free-radical processes and agents decomposing hydroperoxides have been very incompletely treated in the monographs and reviews published hitherto.

The present review deals with the mechanism by which inhibitors terminate kinetic oxidation chains (phenols and amines) and inhibitors suppressing chain branching (phosphites and sulphur-containing compounds); the possible mechanisms of the action of their mixtures, which exhibit synergistic effects, are also discussed.

II. THE MECHANISM OF THE ACTION OF INHIBITORS

1. Phenols and Amines

The oxidation of carbochain organic compounds and in particular of polymers involves a radical chain mechanism with degenerate branching[2], which can be described as follows[7]. Initiation takes place as a result of the reaction of oxygen with the hydrocarbon:

$$RH + O_2 \xrightarrow{w_u} \dot{R} + H\dot{O}_2$$

or

$$2RH + O_2 \xrightarrow{w_u} 2\dot{R} + H_2O_2 \,.$$

The kinetic chain is propagated and branches via the reactions

$$1.\ \dot{R} + O_2 \xrightarrow{k_1} R\dot{O}_2 \,,$$

$$2.\ R\dot{O}_2 + RH \xrightarrow{k_2} \dot{R} + ROOH \,,$$

$$3.\ ROOH \xrightarrow{k_3} R\dot{O} + H\dot{O} \,,$$

$$3'.\ ROOH + RH \xrightarrow{k_3'} \dot{R} + R\dot{O} + H_2O \,.$$

The chains are destroyed as a result of the recombination of the radicals $R\dot{O}_2$, since in the presence of oxygen $[\dot{R}] < [R\dot{O}_2]$:

$$4.\ R\dot{O}_2 + R\dot{O}_2 \xrightarrow{k_4} ROOR + O_2 \,.$$

In the presence of inhibitors of free-radical processes (phenols and amines), there is linear termination of the $R\dot{O}_2$ radicals by the inhibitor[8-10]:

$$5.\ R\dot{O}_2 + InH \xrightarrow{k_5} ROOH + I\dot{n} \,,$$

with formation of a hydroperoxide and a relatively inactive inhibitor radical, as shown in subsequent studies using ESR[11,12].

Semenov[7] showed that, when the above process mechanism operates, there should exist a critical inhibitor concentration defined by the equation

$$[InH]_{cr} = \frac{k_2[RH]}{k_5} \,. \qquad (1)$$

The presence of critical inhibitor concentrations has been established in a number of studies on the oxidation of liquid hydrocarbons[13,14] and polypropylene[15].

Eqn. (1) was derived on the assumption that reaction (5) yields stable products; nevertheless, the hydroperoxide formed is a branching agent in the chain process. When this is taken into account, then, as shown by Neiman[2], there should be no critical inhibitor concentration. Since the critical concentration is in fact observed experimentally and, within the framework of the oxidation process mechanism adopted by Semenov, Eqn. (1) is not entirely exact, it has been suggested[15] that the hydroperoxide reacts with the hydrocarbon[16] and ultimately the radicals $R\dot{O}_2$ are formed with a probability δ by the reaction

$$ROOH + RH \begin{cases} R\dot{O} + \dot{R} + H_2O \\ ROR + H_2O \end{cases} \xrightarrow{RH,O_2} \delta R\dot{O}_2 \; .$$

After this modification, the following expression was obtained[2,17] for the critical inhibitor concentration:

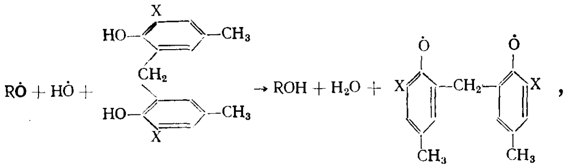
$$[InH]_{cr} = \frac{\delta}{(1-\delta)}\frac{k_2}{k_5}[RH] \; , \qquad (2)$$

from which it follows that the critical concentration of the antioxidant can obtain only when $\delta < 1$. Up to the critical antioxidant concentration the oxidation reaction takes place under non-steady-state conditions and above it under steady-state conditions[13-15,17].

Hydroperoxides are known to react with phenols and amines at a higher rate than with hydrocarbons. Ingold showed that phenols and amines accelerate the decomposition of the hydroperoxides formed in the oxidation of mineral oil[18]. It has also been established[19,20] that amines sharply reduce the activation energy for the decomposition of polypropylene hydroperoxide: in the absence of amines the activation energy for the decomposition of the hydroperoxide is 25 kcal mole^{-1}, while in the presence of diphenylamine it is 17 kcal mole^{-1} and in the presence of *N*-cyclohexyl-*N*'-phenyl-*p*-phenylenediamine it is only 14 kcal mole^{-1}. Consequently, in the presence of such inhibitors the hydroperoxide reacts not with the hydrocarbon but with the inhibitor to form ultimately active $R\dot{O}_2$ radicals with a probability δ according to the mechanism

$$ROOH + InH \begin{cases} R\dot{O} + \dot{In} + H_2O \\ RO-In + H_2O \end{cases} \xrightarrow{RH,O_2} \delta R\dot{O}_2 \; .$$

It is easy to show that, when account is taken of this reaction, the preceding equation (2) is obtained for the critical antioxidant concentration. The antioxidants in whose presence $\delta \geqslant 1$ cannot at any concentration ensure a slow steady-state occurrence of the inhibited reaction. In their presence the reaction always takes place under non-steady-state conditions with appreciable acceleration. This acceleration cannot be detected from the absorption of oxygen, since it is too slight, but it can be observed from the decrease of the molecular weight of the polymer. If the antioxidant does not have a critical concentration, in its presence the molecular weight of the polymer falls sharply during the induction period. Thus in the presence of monohydric phenols, which do not have a critical concentration, the molecular weight of polypropylene falls much more appreciably than in the presence of bisphenols which do have a critical concentration[21]. Moreover, monophenols are much less effective than bisphenols (several times and not by a factor of two as would be expected on the basis of the number of hydroxy-groups). The different effectiveness of monophenols and bisphenols in the inhibited oxidation of polypropylene is probably associated with the participation of antioxidants in chain branching. It has been suggested[22] that effective antioxidants should have two active groups located close to one another in order to react simultaneously with the two radicals formed in the decomposition of the hydroperoxide, for example in a cage according to the mechanism



where X is a t-butyl group.

This process results in the formation of a single relatively inactive biradical. If the antioxidant has one active group, then in the cage it can react with only one radical. The second radical cannot recombine, which increases the probability of chain branching.

The dependence of the induction period (τ) in the oxidation of polypropylene on the concentration of 2,2'-methylenebis-(6-t-butyl-4-methylphenol) as an antioxidant in the presence and absence of 4-methyl-2,6-di-t-octylphenol has been investigated[23]. It was shown that in the presence of the monophenol τ for the bisphenol diminishes and the critical concentration increases. Other monophenols had a similar effect.

According to the authors, the increase of the critical concentration of the bisphenol in the presence of the monophenol is due to an enhanced probability of chain branching in the oxidation of polypropylene. However, the increase of the critical concentration and the decrease of τ for the bisphenol can also be caused by the reaction of the monophenoxy-radical with polypropylene:

$$\dot{In} + RH \rightarrow InH + \dot{R} \; .$$

If the monophenoxy-radical participates in chain propagation, then, as shown by Likhtenshtein and Urman[24,25], the critical concentration of the inhibitor increases. Possibly the inhibitor (monophenol) radicals are more active in the initiation of oxidation than the bisphenol radicals[12] and consequently increase the critical concentration of the latter. Under the conditions of identical reactivities of the monophenol and bisphenol inhibitor radicals, theoretical calculations show that the critical concentration is increased by the enhanced probability of branching. At low oxidation temperatures the inhibitor radicals are destroyed by recombination; at an elevated temperature there is a greater probability of their participation in chain propagation.

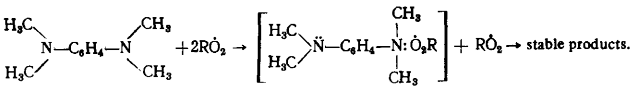
Thus it has been shown[26] that the critical concentration of an effective bisphenol increases both in the presence of an ineffective monophenol and an ineffective bisphenol (monohydroxybenzophenone and dihydroxybenzophenone). Probably chain transfer to the photostabiliser radicals plays an appreciable role.

Oxidation may be initiated also as a result of the direct oxidation by oxygen of an antioxidant molecule, for example, a monophenol, via the mechanism $InH + O_2 \rightarrow \dot{In} + H\dot{O}_2$ with formation of the relatively active radical $H\dot{O}_2$. On interaction with the hydrocarbon, the latter yields hydrogen peroxide, which breaks down into radicals and causes chain branching. As a result of this reaction, the critical concentration of the inhibitor should increase, as shown theoretically by Likhtenshtein and Urman[24]. Thus the increase of the critical concentration of the bisphenol in the presence of a monophenol can be caused both by the participation of the monophenol in degenerate branching and by the initiation of the oxidation process by the inhibitor radical and the inhibitor oxidation products.

It has been established in a number of investigations that the mechanism of inhibition by amines which contain a mobile hydrogen atom in the amino-group consists in linear termination of radicals:

$$R\dot{O}_2 + R''NHR' \rightarrow R'\dot{N}R'' + ROOH \; .$$

This mechanism of inhibition by amines is confirmed by the formation of inhibitor radicals[11,12] and the expected final oxidation products[1-6]. Thus in the oxidation of cumene in the presence of *NN*'-diphenyl-*p*-phenylenediamine, the latter is 80–95% converted into *NN*'-diphenyl-*p*-quinone-di-imine. However, it is known that tertiary amines also strongly inhibit the oxidation. It has been shown that in the oxidation of cumene in chlorobenzene solution each tetramethyl-*p*-phenylenediamine molecule terminates two oxidation chains:



This involves the intermediate formation of a radical complex[27]. Probably aromatic hydrazines which do not have mobile hydrogen atoms should fulfil a similar role. Further study of such compounds will undoubtedly be of great interest.

2. Sulphur-containing Compounds

Sulphur-containing compounds without amino- and phenolic groups inhibit the oxidation process by the decomposition of hydroperoxides with formation of stable molecules[28-31]:

$$6.\ \mathrm{ROOH} + \mathrm{R'_2S} \xrightarrow{k_4} \mathrm{ROH} + \mathrm{R'_2SO}\ .$$

In a study of the kinetics of the reaction of a hydroperoxide with sulphides, it was shown that the reaction is of first order with respect to the hydroperoxide[32]. Sulphides are oxidised further to sulphones[33-35]:

$$\mathrm{ROOH} + \mathrm{R'_2SO} \rightarrow \mathrm{ROH} + \mathrm{R'_2SO_2}\ .$$

Apart from the reactions mentioned above, sulphides are oxidised by peroxy-radicals without chain termination[28,30,31]:

$$\mathrm{R\dot{O}_2} + \mathrm{R'_2S} \rightarrow \mathrm{R\dot{O}} + \mathrm{R'_2SO}\ .$$

In this secondary reaction sulphides are consumed, which reduces their effectiveness.

Mercaptans inhibit oxidation via the mechanism

$$\mathrm{\dot{R}O_2} + \mathrm{R'SH} \rightarrow \mathrm{ROOH} + \mathrm{R'\dot{S}}\ .$$

Thiyl radicals can probably also interact with peroxy-radicals in the following way[36]:

$$\mathrm{R\dot{O}_2} + \mathrm{R'\dot{S}} \rightarrow \mathrm{R'\,(O)-S-O-R},$$

and can recombine with formation of disulphides. Aryl disulphides are as a rule more effective than aryl sulphides. However, in the presence of certain disulphides the molecular weight of polypropylene was found to diminish sharply during the induction period[37]. Probably at 200°C the aromatic disulphide breaks down into thiyl radicals which in the presence of oxygen cause the breakdown of the polymer.

In the first oxidation stage disulphides and hydroperoxides form intermediate thiosulphoxides:

$$\mathrm{R'S-SR''} + \mathrm{ROOH} \rightarrow \mathrm{R'S\,(O)\,SR''} + \mathrm{ROH},$$

which on further oxidation are converted into thiosulphones[35,38,39]. The sulphides themselves are rarely used to stabilise mineral oils and polymers, since their effectiveness is low but, when mixed with inhibitors of free-radical processes, they sharply increase the effectiveness of the latter. Among sulphur-containing compounds, sulphides, mercaptans, polysulphides, etc. are used in mixtures with phenols and amines. The most powerful synergistic effect is produced by esters of thiocarboxylic acids such as dilauryl and distearyl thiodipropionates and esters of thiovaleric acid. The synergistic effect of mixtures of free-radical process inhibitors with sulphides is widely used to stabilise various organic substances, including polymers.

3. Phosphites

Phosphite esters are widely used to stabilise polymers both in a pure form and in mixtures with phenols. In contrast to amines and phenols, phosphites do not colour polymers and therefore may be used in the manufacture of light-coloured articles. The mechanism of their action and the effectiveness of aromatic phosphites as a function of the structure of their phenoxy-residues have been little investigated.

It is known that aliphatic phosphites, like sulphides, break down hydroperoxides virtually without the formation of free radicals[40,41]:

$$7.\ \mathrm{ROOH} + (\mathrm{RO'})_3\mathrm{P} \rightarrow \mathrm{ROH} + (\mathrm{RO'})_3\mathrm{PO}\ .$$

Therefore it is suggested that phosphites inhibit oxidation only by suppressing chain branching. Furthermore, it has been shown[42] that at 130°C aliphatic phosphites are oxidised by peroxy- and oxy-radicals to phosphates without chain termination:

$$8.\ \begin{array}{l} \mathrm{R\dot{O}_2} + (\mathrm{\dot{R}'O})_3\mathrm{P} \rightarrow \mathrm{\dot{R}O} + (\mathrm{R'O})_3\mathrm{PO}\ , \\ \mathrm{R\dot{O}} + (\mathrm{\dot{R}'O})_3\mathrm{P} \rightarrow \mathrm{\dot{R}} + (\mathrm{R'O})_3\mathrm{PO}\ . \end{array}$$

Table 1. Effectiveness of phosphites in the oxidation of polypropylene at 200°C and an oxygen pressure of 200 mmHg [43].

No.	Phosphite	Induction period at a concn. of 0.05 mole kg^{-1} min
1	Tri(nonylphenyl) phosphite	30
2	Iso-octyl diphenyl phosphite	35
3	Phenyl *o*-phenylene phosphite	60
4	Tri-(4-t-butylphenyl) phosphite	90
5	α-Naphthyl *o*-phenylene phosphite	190
6	2,6-Di-t-butyl-4-methylphenyl *o*-phenylene phosphite	260
7	2,4,6-Tri-t-butylphenyl *o*-phenylene phosphite	400
8	2,6-Di-isobornyl-4-methylphenyl *o*-phenylene phosphite	1000

The effectiveness of action of the phosphites by this mechanism must be low. Indeed, it follows from the data in Table 1 [43-46] that aliphatic and aromatic phosphites without alkyl substituents in the phenoxy-residue have a low antioxidant activity.

Table 1 shows that the introduction of a t-butyl and particularly an isobornyl group into the *ortho*-position of phenol in *o*-phenylene phosphite sharply increases the induction period. A study of the kinetics of the absorption of oxygen in the oxidation of polypropylene in the presence of phosphites showed that relatively ineffective phosphites do not have a critical concentration (Fig. 1) [37]. Consequently they inhibit the oxidation, like sulphides, by breaking down the hydroperoxides without linear termination of peroxy-radicals[1,7]. On the other hand, effective phosphites have a critical concentration and therefore they inhibit the oxidation process by linear termination of radicals and possibly by breaking down the hydroperoxides (Fig. 2)[37].

The kinetics of the reactions of aromatic phosphites with the diphenylpicrylhydrazyl radical and with t-butyl hydroperoxide at room temperature have been investigated[47,48]. It was found that phosphites (6) and (7) (see Table 1) react rapidly, compound (4) much more slowly, and compound (3) and triphenyl phosphite hardly react at all with the diphenylpicrylhydrazyl radical[47]. Thus the reactivity towards radicals and the effectiveness of phosphites increase sharply on introduction of alkyl substituents into the phenoxy-residue. On the other hand, the reactivity of aromatic phosphites towards hydroperoxides bears an inverse relation, i.e. the lower the antioxidant activity of phosphites the faster they react with the hydroperoxide[48].

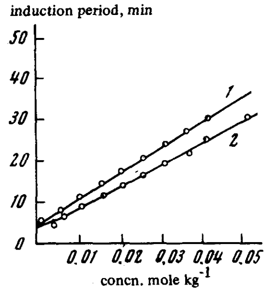


Figure 1. Variation of the induction period in the oxidation of polypropylene with the concentration of tri(nonylphenyl) phosphite (*1*) and iso-octyl diphenyl phosphite (*2*) at 200°C and P_{O_2} = 200 mmHg.

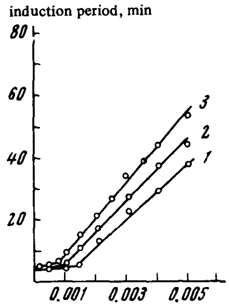

Figure 2. Variation of the induction period in the oxidation of polypropylene with the concentration of α-naphthyl *o*-phenylene phosphite (*1*), 2,6-di-t-butyl-4-methylphenyl *o*-phenylene phosphite (*2*), and 2,4,6-tri-t-butylphenyl *o*-phenylene phosphite (*3*) at 200°C and P_{O_2} = 200 mmHg.

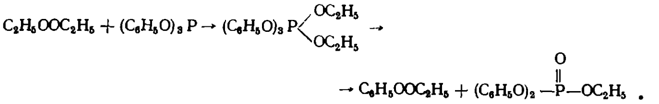
The reaction of peroxy- and oxy-radicals with aromatic phosphites has not been investigated at all. Walling and coworkers suggested[49] that in the reaction of aromatic phosphites with aliphatic RȮ radicals a double decomposition reaction is possible:

$$R\dot{O} + (R'O)_3P \rightarrow (R'O)_2POR + R'\dot{O}$$

in consequence of the formation of the more stable phenoxy-radical. Almost simultaneously it was shown[50] that in the reaction of diethyl peroxide with triphenyl phosphite at 130°C ethyl phenyl ether ($C_2H_5OC_6H_5$) and a phosphate with the probable structure $C_2H_5OP(O)(OC_6H_5)_2$ are formed. These products may be formed by the exchange of radicals via an intermediate quadrivalent phosphorus compound:

$$C_2H_5O + (C_6H_5O)_3P \rightarrow C_2H_5O\dot{P}(OC_6H_5)_3 \xrightarrow{C_2H_5\dot{O}}$$
$$\rightarrow (C_6H_5O)_2P(O)(OC_2H_5) + C_2H_5OC_6H_5$$

and probably in the reaction of the undecomposed diethyl peroxide with triphenylphosphite via an intermediate quinquevalent phosphorus compound:



$$C_2H_5OOC_2H_5 + (C_6H_5O)_3P \rightarrow (C_6H_5O)_3P\begin{matrix}\diagup OC_2H_5\\ \diagdown OC_2H_5\end{matrix} \rightarrow$$
$$\rightarrow C_6H_5OOC_2H_5 + (C_6H_5O)_2-\overset{\overset{\displaystyle O}{\|}}{P}-OC_2H_5\ .$$

Probably the reaction of pentoxy-radicals with aromatic *o*-phenylene phosphite esters with t-butyl groups in the phenoxy-residue can occur at an elevated temperature via a radical exchange mechanism with formation of a phosphate and a stable phenoxy-radical[43]:

9. 
This mechanism is consistent with the high reactivity of these phosphites towards diphenylhydrazyl radicals and their enhanced antioxidant effectiveness compared with other phosphites[37,43]. However, this mechanism is inconsistent with the experimental studies on the kinetics of the reaction of $R\dot{O}_2$ radicals with aromatic phosphites in ethylbenzene at 60°C using a chemiluminescence technique[51]. In these experiments it was shown that aromatic phosphites (5), (6), and (7) (Table 1) cause chain termination, but fifty phosphite molecules are required for the termination of a single $R\dot{O}_2$ radical. Possibly at the experimental temperature the phosphites only react slowly with peroxy-radicals and therefore do not affect the effectiveness of the luminescence. On the other hand, it would appear that the weak termination of peroxy-radicals in the presence of aromatic phosphites might be explained by the presence of hydrolysis products. On this basis, it was suggested that phosphites inhibit oxidation by the hydrolysis products formed in the oxidation process[5]. Nevertheless, this hypothesis is inconsistent with a number of observations. The hydrolysis products of *o*-phenylenephosphite esters do not have a critical concentration under the experimental conditions in the oxidation of polypropylene, like screened phenols, α-naphthols, and *o*-phenylene phosphorous acid, while the phosphite itself does have such a concentration (Fig. 2). Moreover, the effectiveness of phosphites (6), (7), and (8) (Table 1) would be almost the same if the oxidation of polypropylene were inhibited by the hydrolysis products, since the effectiveness of the latter differs little. It was further established that the effectiveness of phosphite (7) is much higher than that of any equimolar mixture of the hydrolysis products[37]. Probably at a high temperature phosphites enter into reactions (7), (8), and (9) with different probabilities (depending on the structure). Possibly aliphatic and aromatic phosphites with unscreened phenoxy-groups inhibit oxidation only by suppressing chain branching [reaction (7)] and are mainly consumed in reaction (8). On the other hand, aromatic phosphites with screened phenoxy-groups in the molecule may inhibit oxidation by radical termination via reaction (9). If the phenoxy-radicals formed propagate the oxidation chain via the reaction $\dot{\mathrm{In}} + \mathrm{RH} \rightarrow \mathrm{InH} + \dot{\mathrm{R}}$ with a lower probability, then the effectiveness of the phosphite will be high, and conversely. Moreover, at an elevated temperature effective aromatic phosphites, like aliphatic phosphites, probably react with hydroperoxides to form stable products. Experiments on the oxidation of polypropylene in the presence of a mixture of 2,6-di-t-butyl-4-methylphenyl-*o*-phenylene phosphite and dilauryl thiodipropionate showed that this mixture exhibits a synergistic effect, which, however, is much smaller than that of a mixture of phenols with the same sulphide[37]. Consequently, such sulphides inhibit chain branching to some extent as well. Moreover, effective phosphites can probably be partially consumed also by reaction (8).

The above mechanism of inhibition by screened phosphites is consistent with their high antioxidant activity and the critical concentrations observed in experiments on the oxidation of polypropylene.

III. THE MECHANISM OF THE SYNERGISM OF INHIBITOR COMPOSITIONS

When two or more inhibitors are introduced into the substance being oxidised, an antioxidant effect in excess of the additive value is frequently observed. Such an effect of the mixture is usually called synergism and is defined by the expression $\tau_{1,2} < \tau_1 + \tau_2$, where $\tau_{1,2}$, τ_1, and τ_2 are the induction periods for the mixture and the individual components respectively. Furthermore, the synergistic effect should be defined as one in which the antioxidant efficiency of the induction period for the mixture are higher than for any one component taken separately at a concentration equal to the overall concentration of the mixture (Fig. 3) [37,52]. On the other hand, strictly speaking, the phenomenon of synergism should be understood as the enhancement of the effectiveness of the active component by a completely inactive component.

With this definition of synergism, it is possible to establish both the magnitude of the effect and its maximum as a function of the molar ratio of the components. The synergistic effect for mixtures of inhibitors is observed in those cases where the mixture components inhibit oxidation by different mechanisms. Therefore we shall consider the possible mechanisms of the action of inhibitor compositions for which the synergistic effect is known to apply or may be postulated.

1. Mixtures of Inhibitors of Free-radical Processes with Sulphides.

The most powerful synergistic effect is usually shown by mixtures of two inhibitors one of which terminates the oxidation chain and the other breaks down hydroperoxides[15,32–34,36,37,52–55]. The considerable enhancement of the inhibiting effect can be explained in terms of this mechanism by the fact that one of the inhibitors reduces the yield of hydroperoxides, which, on decomposing into radicals cause chain branching, while the second breaks down the hydroperoxides and thereby both inhibitors protect one another from rapid consumption. However, hydroperoxide decomposing agents are evidently themselves oxidised by peroxy-radicals in the inhibition process.

This mechanism was confirmed[15] by kinetic data. Thus, when polypropylene is stabilised by a mixture of a chain terminating oxidant and a sulphide which decomposes hydroperoxide, the critical concentration of the antioxidant diminishes as that of the sulphide is increased, according to the equation

$$[\mathrm{InH}]_{\mathrm{cr}} = \frac{\delta k_2 k_4 [\mathrm{RH}]^2}{(1-\delta) k_4 k_5 [\mathrm{RH}] + k_6 [\mathrm{R_2S}]} \ . \qquad (3)$$

In the absence of the sulphide or another hydroperoxide decomposing agent, Eqn. (3) transforms into Eqn. (2) derived above.

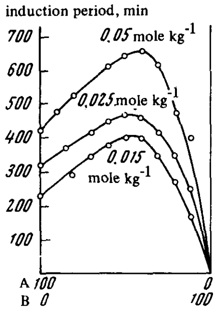


Figure 3. Variation of the induction period in the oxidation of polypropylene with the composition of a mixture of 2,2'-methylenebis-(6-t-butyl-4-methylphenol) (*A*) and dilauryl thiodipropionate (*B*) at different overall concentrations, 200°C, and P_{O_2} = 200 mmHg.

In the same investigation it was shown that 2,4,6-tri-t-butylphenol does not have a critical concentration in the oxidation of polypropylene (200°C, oxygen pressure 300 mmHg); in this case the induction period is short. However, in the presence of a sulphide[15] or a phosphite[46] (at a sufficiently high concentration) a critical concentration is observed and the effectiveness of the monophenol increases sharply. If the antioxidant has a critical concentration, then in the presence of a hydroperoxide decomposing agent it diminishes and the effectiveness of the antioxidant increases[15,46].

Mixtures of monophenols, bisphenols, and thiobisphenols with hydroperoxide decomposing agents show a marked synergistic effect[15,37,54,55–58]. Fig. 3 shows as an example the variation of the induction period of the oxidation of polypropylene as a function of the molar composition of a mixture of 2,2,-methylenebis-(6-t-butyl-4-methylphenol) and dilauryl thiodipropionate at different overall concentrations. It is seen that the induction period for the mixture is much longer than for the bisphenol at the concentration equal to the overall concentration of the mixture. It is interesting that the sulphur in the thiobisphenol molecule does not decompose the hydroperoxide, since thiobisphenols in a mixture with a sulphide exhibit an appreciable synergistic effect. The synergistic effect depends on the activity of the synergist. The most active synergist among the sulphides investigated proved to be dilauryl thiodipropionate[54], but, as shown by the present authors' experiments, thiovaleric esters are also active synergists; thioacetic esters are less active. The activity of thioacid esters increases with the number of carbon atoms in the aliphatic residue[58].

Synergistic mixtures of phenols with sulphur-containing compounds are widely used to stabilise polymers, largely polyolefins. There are more than 200 patents for the application of these synergistic mixtures. Certain mixtures effectively protect polyolefins during processing at a high temperature and under the conditions of their use[55-57]. Synergistic mixtures of phenols with thiophosphoric compounds and phosphites do not colour polymers or weaken them appreciably and they are very important in the manufacture of light-coloured high-quality articles.

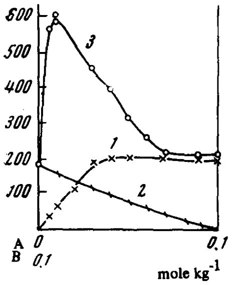

Figure 4. Variation of the induction period in the oxidation of polypropylene with the composition of a mixture of *p*-hydroxyphenyl-β-naphthylamine (*A*) and mercaptobenzimidazole (*B*) (*3*) and with the concentrations of the components (*1* and *2*) at 200°C and P_{O_2} = 200 mmHg.

Beside phenols, amines mixed with agents which decompose hydroperoxide exhibit a synergistic effect. For example (Fig. 4), the effectiveness of a mixture of *p*-hydroxyphenyl-β-naphthylamine with mercaptobenzimidazole (MBIA) is three times greater than the effectiveness of the most active component at the concentration equal to the overall mixture concentration[52]. It is interesting that the maximum effect is observed when MBIA is present in the mixture in an appreciable excess.

The synergistic effect is observed in different ways depending on the activity of the inhibitor of free-radical processes. Fig. 5 shows that a mixture of β-naphthylphenylamine with MBIA is not more effective than the initial amine[53]. A synergistic effect in respect of additivity is observed only at a low amine concentration. Probably at a high concentration the amine suppresses chain branching.

The different synergistic effects of the last two mixtures evidently depend also on the different rates of the direct oxidation of the amines employed according to the mechanism

$$\mathrm{InH} + \mathrm{O_2} \rightarrow \dot{\mathrm{In}} + \mathrm{H\dot{O}_2} \xrightarrow{\mathrm{RH}} \dot{\mathrm{In}} + \mathrm{H_2O_2} + \dot{\mathrm{R}} \ .$$

Indeed the curves relating τ to the antioxidant concentration (curves *1* in Figs. 4 and 5) show in the first place the attainment of a limiting induction period as the concentration is increased, while in the second case a limit is not reached. This shows that *p*-hydroxyphenyl-β-naphthylamine is vigorously oxidised by oxygen as the concentration increases[32]. The presence of an agent which decomposes hydroperoxide sharply decreases the yield of free radicals $\dot{\mathrm{R}}$, leading to an appreciable enhancement of the effectiveness of the mixture.

Thus certain mixtures consisting of a weak inhibitor and a synergist may be as effective as compositions comprising a strong inhibitor and the same synergist, i.e. the synergistic effect is greater the weaker is the inhibitor free radical process.

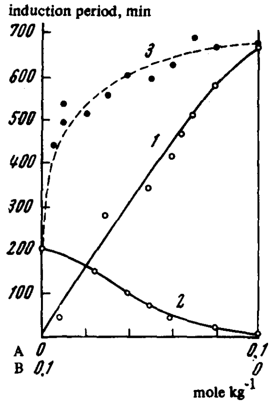

Figure 5. Variation of the induction period in the oxidation of polypropylene with the composition of a mixture of β-naphthylphenylamine (*A*) and mercaptobenzimidazole (*B*) (*3*) and with the concentrations of the components (*1* and *2*) at 200°C and P_{O_2} = 200 mmHg.

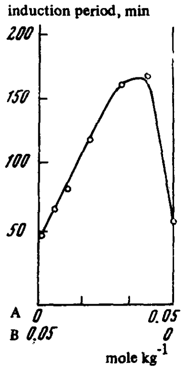

Figure 6. Variation of the induction period in the oxidation of polypropylene with the composition of a mixture of 2,4,6-tri-t-butylphenol (*B*) and dilauryl thiodipropionate (*A*) at 200°C and P_{O_2} = 200 mmHg.

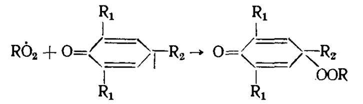
If a strong inhibitor, for example a bisphenol or a diamine, binds both free radicals on interaction with the hydroperoxide in a cage, in the presence of a hydroperoxide decomposing agent the synergistic effect should be absent or small. However, Fig. 3 shows that a mixture of a bisphenol with dilauryl thiodipropionate exhibits an appreciable synergistic effect. Consequently bisphenols do not bind in a cage all the free radicals formed on decomposition of the hydroperoxide. Comparison of the synergistic effect of a mixture of a monophenol and a sulphide (Fig. 6) with that of a mixture of a bisphenol with the same sulphide (Fig. 3) shows that it is greater in the first mixture[15,37,46]. This finding evidently shows that in the presence of the bisphenol, the yield of radicals in the decomposition of the hydroperoxide is lower than in the presence of the monophenol. In principle, it is possible that polyphenols and polyamines which have either adjacent functional groups or well separated ones capable of approaching one another in space may completely suppress chain branching. Thus certain tetraphenols (for example Irganox 1010 produced by the Geigy Co., Switzerland) mixed with sulphides and oxides do not exhibit a synergistic effect, which probably shows that they suppress chain branching. Inhibitors capable of chain termination and suppression of chain branching should exhibit a high antioxidant activity provided that they are not oxidised by oxygen under these conditions. The search for such inhibitors is of considerable interest both from theoretical and practical points of view.

2. Mixtures of Phenols with Phosphites

It is known that aliphatic and aromatic esters of phosphorous acid, like sulphides, interact with hydroperoxides to form stable products[40,41]. Moreover, it has been shown[42] that phosphites react with peroxy-radicals without chain termination by reaction (8) and therefore are rapidly consumed. In the presence of inhibitors of free-radical reactions the consumption of phosphites by reaction with peroxy-radicals should diminish, which should increase the importance of phosphites in the suppression of chain branching. As a result of the above reactions, the effectiveness of the mixture components increases significantly and the mixture may exhibit a synergistic effect. However, this general inhibition mechanism probably depends on the structure of the alkoxy- and phenoxy-residues of the phosphite esters. Aliphatic phosphites mixed with phenols are relatively ineffective, although they rapidly decompose hydroperoxides with a low yield of free radicals[59]. Evidently this can be explained by the more rapid consumption of phosphites by reaction (8) so that they suppress chain branching only to a small extent. Nevertheless, mixtures of monophenols and bisphenols with iso-octyl diphenyl phosphite (Figs. 7 and 8) and with tri(nonnylphenyl) phosphite show a powerful synergistic effect[46], whose magnitude is greater for monophenols. Probably this is because bisphenols are more likely to suppress chain branching than monophenols. As mentioned above, this is also observed in mixtures of monophenols and bisphenols with dilauryl thiodipropionate.

The structure of phosphites has a very pronounced effect on the synergistic effect in mixtures of phenols with *o*-phenylene phosphite esters. Thus a mixture of a monophenol with 2,4,6-tri-t-butylphenyl *o*-phenylene phosphite does not show an appreciable additional effect[37], in contrast to the mixture of the same monophenol with iso-octyl diphenyl phosphite (Fig. 7). At the same time an appreciable synergistic effect is observed in mixtures of *o*-phenylene phosphite esters with bisphenols and thiobisphenols[37,44,60]. The absence of the synergistic effect from mixtures of monophenols with *o*-phenylene phosphite esters and conversely its occurrence in mixtures with bisphenols and thiobisphenols indicate a complex inhibition mechanism. In the inhibition of oxidation phosphite esters, like sulphides[15], do not exhibit a critical concentration[46]. Therefore both inhibit oxidation by suppressing chain branching and at the same time are oxidised by the peroxy-radicals with formation of stable products and an oxy-radical, i.e. without chain termination[31,42]. On the other hand, *o*-phenylene phosphite esters do have a critical concentration, which shows that they are responsible for linear termination of peroxy-radicals. The mechanism of the action of these phosphites was examined above and it was postulated that at a high temperature *o*-phenylene phosphite esters undergo reaction (9) with peroxy-radicals to form a phosphate and a phenoxy-radical. On the other hand, the phenoxy-radical can react with another peroxy-radical:



forming a peroxide, which, on decomposing at an elevated temperature into radicals, gives rise to chain branching.

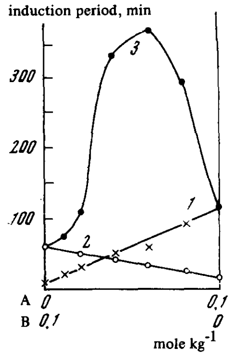


Figure 7. Variation of the induction period in the oxidation of polypropylene with the composition of a mixture of 2,4,6-tri-t-butylphenol (*A*) and iso-octyl diphenyl phosphite (*B*) (*3*) and with the concentrations of the components (*1* and *2*) at 200°C and P_{O_2} = 300 mmHg.

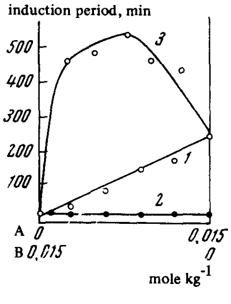

Figure 8. Variation of the induction period in the oxidation of polypropylene with the composition of a mixture of 2,2'-methylenebis-(6-t-butyl-4-methylphenol) (*A*) and iso-octyl diphenyl phosphite (*B*) (*3*) and with the concentrations of the components (*1* and *2*) at 200°C and P_{O_2} = 300 mmHg.

The different effects observed in the presence of bisphenols and monophenols can probably be explained by the different probabilities of the suppression of chain branching by these compounds. Bisphenols, which have two functional groups, are more likely to bind both radicals formed from the peroxide and thereby suppress chain branching, while monophenols can bind only one radical, the other continuing the chain propagation process.

This mechanism of the synergistic effect is consistent with the finding that it is a maximum at a high concentration of the bisphenol. However, for the final determination of the mechanism by which mixtures of screened *o*-phenylene phosphite esters with bisphenols act, it is necessary to investigate the elementary reactions of the peroxy-radical with these phosphites at an elevated temperature.

3. Mixtures of Inhibitors of Free Radical Processes

When mixtures of inhibitors of free radical processes inhibit only by linear termination of peroxy-radicals, they cannot exhibit a synergistic effect. However, such mixtures may have an antioxidant effect greater than the additive value in consequence of the hydrogen transfer reaction from the weaker inhibitor to the radical of the stronger inhibitor after the latter has given up its hydrogen to the peroxy-radical, according to the reaction

$$\dot{In}_1 + In_2H \rightarrow In_1H + \dot{In}_2 .$$

Such a reaction is possible, since even the least active inhibitor will then give rise to a resonance-stabilised radical. Reactions of this class have been observed between 2,4,6-tri-t-butylphenoxy-radicals and phenols, naphthols[61], and also 4-substituted phenols[62].

When the concentrations of both components are equal, the effectiveness of the mixture, which increases only by virtue of the hydrogen transfer reaction, cannot exceed the effectiveness of the strongest inhibitor at twice its concentration. Consequently this mechanism of the action of a mixture shows no synergistic effect. The mechanism shows that the concentration of the strong inhibitor component in the mixture should not alter in the oxidation process as long as the weaker inhibitor is not completely consumed.

Indeed, it has been shown[63] in the sensitised oxidation of ethylbenzene, that in the presence of β-naphthylphenylamine and 2,6-di-t-butylphenol at 60°C the concentration of the first compound remains constant and begins to fall only after the phenol has been completely consumed. It has also been shown[63] that the induction period is higher than the additive value, but does not exceed the value corresponding to the amine at the total inhibitor concentration.

Thus at a low oxidation temperature in the absence of chain branching, the interaction of inhibitors with the peroxide and of the inhibitor radicals with the hydrocarbon, i.e. in the absence of chain propagation reactions, the enhanced activity of the inhibitors is caused only by the transfer of hydrogen from the phenol to the amine.

In the oxidation of ethylbenzene at 120°C and in the presence of the same inhibitor, the authors observed a synergistic effect: the induction period for the mixture proved to be longer than that corresponding to the amine at the total inhibitor concentration[64]. At this temperature, the termination of peroxy-radicals by the inhibitor and the transfer of hydrogen from the phenol to the inhibitor radical may be accompanied by the decomposition of the hydroperoxide and chain propagation due to the reaction of the radical derived from the inhibitor (amine) with ethylbenzene: $\dot{In} + RH \rightarrow InH + \dot{R}$.

However, in the presence of the phenol, the chain propagation reaction is suppressed because of the lower activation energy for the reaction of the inhibitor radical with the phenol ($\dot{In} + PhOH \rightarrow InH + Ph\dot{O}$) than with ethylbenzene. Since chain propagation by the inhibitor radical sharply reduces the effectiveness of the inhibitor, suppression of this reaction does greatly enhance the effectiveness of the mixture. To establish the influence of the chain propagation reaction on the effectiveness of the mixture, a kinetic calculation was made on the branched chain mechanism of inhibited oxidation in the absence of the chain propagation reaction. The computer calculation showed that the suppression of the chain propagation reaction leads to the appearance of a synergistic effect. Nevertheless, it has been noted[6] that this effect can appear also due to the interaction of the hydroperoxide with the amine, evidently as a result of the suppression of chain branching.

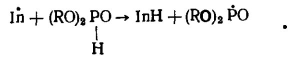
According to published work, many mixtures of free radical process inhibitors are more effective than would be expected from additivity, but until the publication of the studies described above a synergistic effect was not observed in any of the investigations.

The experimental observation of the synergistic effect and the theoretical explanation of its mechanism in mixtures of inhibitors of free radical processes opens up new prospects in the search for synergistic compositions.

The synergistic effect observed in the oxidation of alimentary fats and oils between phenols and certain organic and inorganic acids, which, while lacking antioxidant properties, nevertheless increased the effectiveness of the phenols, can also be accounted for by the hydrogen transfer reaction from the acid to the phenoxy-radical[65-67]. However, fairly strong acids such as phosphoric, succinic, and citric can decompose hydroperoxides catalytically without the formation of free radicals and thus suppress chain branching[68].

In a study of the combined action of phenols and dialkyl phosphites in the oxidation of a mineral oil it was shown that the effectiveness of phenols greatly increases although the activity of dialkyl phosphites is very low[69].

According to the authors, the enhancement of the activity of phenols is due to the reduction of the phenoxy-radical by the hydrogen of the phosphonic acid ester produced by the isomerisation of the dialkyl phosphite:



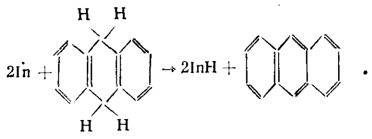
$$\dot{In} + (RO)_2\underset{\displaystyle H}{\underset{|}{P}}O \rightarrow InH + (RO)_2\dot{P}O .$$

This involves the formation of quadrivalent phosphorus. However, phosphites are known to decompose hydroperoxides and thereby suppress chain branching so that the synergistic effect of this mixture may be a consequence of both hydrogen transfer from the phosphonate ester to the phenoxy-radical and the suppression of chain branching. The reduction of the phenoxy-radical by the hydrogen of diethyl phosphite has been demonstrated using the ESR method[70]. It was also shown[70] that the concentration of phenoxy-radicals diminishes with increase in the concentration of diethyl phosphite. However, when the diethyl phosphite concentration is raised further, that of the radicals does not change, probably because of the formation of a phosphonate ester dimer.

A synergistic effect was also observed in the oxidation of a polyamide stabilised by naphthol and a diaryl phosphite[71] and in the oxidation of polypropylene in the presence of tri-t-butylphenol and *o*-phenylenephosphorous acid[37]. Thus, the synergistic effect observed in the oxidation of mineral oil, polyamide, and polypropylene in the presence of phenols and phosphonate esters is probably due to the hydrogen transfer reaction[70] and evidently the suppression of chain branching[46].

Apart from the mechanisms of the synergistic effect examined above, there can be yet another mechanism, which has been little investigated but which is important for the increased effectiveness of inhibitors and their mixtures at elevated temperatures.

The inhibitor radicals formed in the high-temperature inhibited oxidation initiate a new reaction chain by reacting with the substrate[64,72,73]; therefore, for example at temperatures above 250°C, inhibitors of free radical processes (phenols and amines) have only a weak inhibiting effect on the oxidation process. Initiation by the inhibitor radical may be sharply reduced, by adding to normal inhibitors or their synergistic compositions, compounds capable of combining with inhibitor free radicals, for example aromatic polymers with a system of conjugated bonds[24,74,75]. For this purpose, one can also use condensed aromatic compounds such as dihydroanthracene, which reacts with the inhibitor radical as follows:



The inhibitor radical is then reduced to the inhibitor molecule and dihydroanthracene is converted into anthracene, which is probably also capable of forming complexes with the radicals and thereby reducing their reactivity. However, dihydroanthracene may be oxidised by oxygen with formation of anthracene and $\dot{HO}_2$ radicals, which propagate the oxidation chain. Therefore the greatest effect should be shown by additives with a system of conjugated bonds, which do not initiate the oxidation reaction but are capable of inhibiting the chain propagation reaction. The study of inhibitors and their mixtures to which substances capable of binding inhibitor radicals have been added is probably important in solving the problem of stabilising polymers at a high temperature[74].

The effectiveness of a mixture of inhibitors changes when two components form a complex. Then the rate of reaction of the peroxy-radical with the complex may prove to be greater or smaller than that with any of the components. Moreover, in the reaction of the complex with the hydroperoxide there is a possibility of a decreased yield of free radicals. Thus the formation of complexes from the components may lead to either an increase and a decrease of their effectiveness. However, this mechanism of the action of mixtures has not been investigated. The effectiveness of inhibitor mixtures also changes when the components form a new chemical compound. It has been shown[76,77] that the oxidation of polyoxymethylene in the presence of α-naphthol and β-naphthylamine involves the interaction of the components with the formaldehyde formed, which leads to the formation of a new compound—1-(2-hydroxynaphthyl)-1-(2-aminonaphthyl)methane. It has been shown experimentally that this compound is more effective than any component present at the overall mixture concentration.

Table 2 lists the mechanisms of the action of inhibitor compositions examined together with their possible antioxidant effects. These effects of the mixtures evidently change when the components participate in processes other than the reactions quoted.

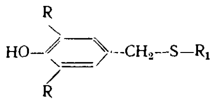
Table 2. Mechanism of the action of inhibitor compositions in the oxidation process in the presence of the reaction $In_1H + R\dot{O}_2 \rightarrow ROOH + \dot{In}_1$.

Type	Mechanism of action	Possible antioxidant effect	Refs.
Free-radical process inhibitor	$R\dot{O}_2 + In_2H \rightarrow \dot{In}_2 + ROOH$	additive effect	
Hydroperoxide decomposing agent	$ROOH + R'XR'' \rightarrow ROH + R'X(O)R''$	mutual enhancement of effectiveness by inhibitors (synergism)	15, 33, 46, 52, 53, 54
Hydrogen donor	$\dot{In}_1 + In_2H \rightarrow In_1H + \dot{In}_2$	enhancement of effectiveness (weak synergism)	63, 64
Radical acceptors. Polymers with conjugated bonds, condensed aromatic compounds	$\dot{In}_1 + A \rightarrow In_1 - A$	enhancement of effectiveness	24, 74
Complexones	$In_1H + In_2H \rightarrow In_1H - In_2H$	enhancement or decrease of effectiveness	
Chemical interaction between components	formation of a new compound	enhancement or decrease of effectiveness	76, 77

4. Polyfunctional Stabilisers (PFS)

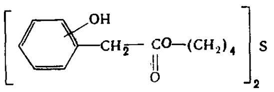
Polyfunctional stabilisers contain in their molecules several reactive groups capable of terminating chains and suppressing chain branching, i.e. capable of inhibiting individual elementary steps in a branched chain oxidation reaction. The application of polyfunctional stabilisers has a number of advantages compared with synergistic compositions, which usually consist of two components, one of which terminates the chain and the other decomposes the hydroperoxide with formation of stable molecules. Moreover, photostabilisers and deactivators of metals are introduced into these mixtures. In order to obtain the maximum synergistic effect, it is necessary to combine the components in appropriate proportions and mix them uniformly with the polymers, which requires complicated and laborious preliminary operations. Nor can one exclude the possibility of chemical interaction between the individual mixture components in the course of the high-temperature processing of the polymer, which may change their antioxidant activity.

All these disadvantages may be removed by employing universal polyfunctional stabilisers capable of inhibiting all the elementary steps in the oxidation and photodegradation. In recent years chemists have endeavoured to synthesise such ideal polyfunctional stabilisers. Among the known inhibitors, thiobisphenols should have polyfunctional properties (owing to the presence of the OH group and the sulphur atom), but their sulphur atoms are relatively inactive and therefore when they are mixed with sulphides they exhibit a synergistic effect[54]. Thioethers with the structure



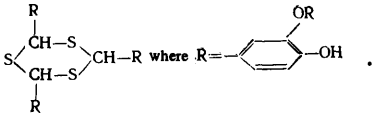
are regarded as the simplest polyfunctional stabilisers. Their effectiveness is higher than that of the corresponding phenols, but lower than that of the bisphenols[78,79].

Thioethers of aromatic hydroxy-carboxylic acids have a higher stabilising effect, for example:



and also mixed esters of two carboxylic acids containing sulphur or phosphorus atoms in the molecule[80].

Various heterocyclic compounds containing sulphur atoms in the ring are effective antioxidants for polyolefins, for example 2,4,6-tri(hydroxyphenyl)-1,3,5-trithianes[81-83]:



These compounds protect the polymer from oxidation and reduce the catalytic effect of multivalent metals. The effectiveness of aromatic derivatives of 1,3,5-trithianes is much higher than that of phenolic antioxidants and depends strongly on the substituents in the benzene ring. Trithianes with an alkoxy-group attached to the ring in the *ortho*-position relative to the hydroxyl show the best antioxidant properties. The addition of a sulphide is stated not to increase the antioxidant effectiveness of trithianes[83], but this needs to be verified.

In recent years reports have appeared on polyfunctional stabilisers which are active thermo- and photo-stabilisers. These data show that the most effective photo- and thermo-stabilisers are phosphorodithioic acid salts of various multivalent metals[84]. Complex chelate quinoxaline compounds appear to be particularly effective photostabilisers[85]. The study of the mechanism and effectiveness of the action of polyfunctional stabilisers constitutes a new field and, as shown by the first results, may lead to the discovery of more effective inhibitors than those known at present.

In conclusion we may note that the stabilisation of polymers at high temperatures still remains an unsolved problem. Possibly one of the ways for its solution will be the application of polyfunctional stabilisers resistant to oxidation by oxygen and capable of chain termination and suppression of chain branching.

Frost Resistance of Polymers

V.I.Popov and V.A.Voskresenskii

Papers by Soviet and foreign authors on the problem of frost resistance are surveyed, and definitions are suggested for the concepts of the technical and the theoretical frost resistance of polymers. Existing qualitative methods for determining the frost resistance of various types of polymeric materials are discussed, together with quantitative methods proposed by Soviet authors, in particular those based on the thermomechanical method of investigation. Data are reported on the dependence of frost resistance on the previous history of the production and processing of polymers, the nature and duration of aging, the action of plasticisers, fillers, etc. The bibliography contains 91 references.

CONTENTS

1. History of Problem

The value of polymers in technology is continually increasing, and in the near future the volume of the production and consumption of polymers will exceed that of the manufacture and use of metals and alloys. In spite of their many valuable properties, however, polymers are not devoid of defects in several respects, one being the partial or complete loss of working properties at low temperatures, i.e. limited frost resistance. The experimental data show that the mechanical, dielectric, relaxation, and other properties of linear polymers vary substantially with temperature. Little work has been done on the behaviour of polymers at low temperatures, which is frequently an obstacle to their use in goods operating in the cold.

The tendency of polymers to crack when deformed below the brittle point is explained by the growth of stresses resulting from the retardation of processes in the macromolecular chains which lead to stress relaxation. It is therefore concluded that the frost resistance of polymers may be improved by the introduction of plasticisers[1] and by suitable chemical modification[2], since this enables the rate of relaxation processes to be increased and the development of cracks to be largely suppressed.

The ability of polymers themselves to retain their flexibility and elasticity at low temperatures is usually the main prerequisite for high frost resistance in polymeric materials based on them[2-5].

Aleksandrov[6] defines frost resistance as the ability of polymers to maintain their mechanical and other properties at low temperatures. A quantitative index of frost resistance is the temperature below which articles made of the given type of polymeric material disintegrate or suffer a sharp diminution in their physicomechanical properties under the influence of specified deforming forces. Brittle fracture of polymers thus begins with the finest inhomogeneities (microcracks), which are foci of considerable overstressing. When the overstresses become equal to the tensile strength of the material, a crack begins to grow at these sites, and leads to brittle fracture of the specimen at a specified frequency of deformation[7]. A roughly similar definition of the frost resistance of polymers is given in the relevant Soviet Standard[8].

Chernaya and Vol'chenko[9] and also Tager[10] regard the workability of a polymer at a definite low temperature limit of operation for a specified time as the main criterion of frost resistance. Sedlis[11] defines frost resistance as the ability of a polymer to retain flexibility and elasticity at low temperatures. Tinius[12] characterises frost resistance by the temperature at which specimens of the polymer become brittle with a given temperature–time operating schedule.

A provisional Soviet Standard for artificial leather and for film materials[13] notes that the temperature of frost resistance serves only for the comparison of these materials under given test conditions: it does not determine the lower temperature limit for goods to function, since this limit is determined by the actual conditions of operation.

In fact existing definitions of frost resistance are qualitative and applied in character, and to some extent serve merely as an indication of the technical (relative) frost resistance of a given polymeric material.

In addition to the concept of technical frost resistance it is useful to introduce that of the theoretical frost resistance, which should provide a more accurate measure of the true frost resistance of a polymer. The definition of frost resistance as the temperature threshold for the occurrence of segmental mobility in polymer chains, given by Kargin and Shteding[14], may correspond in considerable measure to the concept of theoretical frost resistance. In this case a thermomechanical method of investigation enabled the authors to find a boundary temperature between two zones—that in which segmental mobility appeared in practice and that in which it was absent—which was interpreted as the temperature of frost resistance.

The temperature of technical frost resistance of a polymer should obviously always lie somewhat above the level of theoretical frost resistance, since structural defects, foreign inclusions, internal and surface cracks, and residual stresses present in the material will promote the appearance of brittleness and disintegration of the material at higher temperatures than that at which segmental mobility disappears in the chain macromolecules. In view of the above, technical and theoretical frost resistance can obviously be defined as follows.

Technical frost resistance must be regarded as the ability of a polymeric material to maintain its operating properties at low temperatures for a certain length of time, i.e. to retain the ability to develop specified deformations or withstand disintegration.

Theoretical frost resistance is the lower temperature limit for the start of segmental mobility of the macromolecular chains, i.e. at which minute relaxation processes appear in the polymer for given rates of action of deforming forces of given magnitude, which prevent fracture of the polymer specimens.

2. Methods for Determination of Frost Resistance

Because of the very broad technical importance of frost resistance and the great difference in the conditions of operation of polymers a large number of test methods have been proposed. These methods differ significantly in the character, degree, and rate of deformation of the specimens, so that data on frost resistance obtained for the same material by different methods often differ considerably and are difficult to compare. The frost resistance of polymers is determined mainly from test results obtained by impact, single and multiple flexing, stretching, compression, torsion, etc.

Existing methods of testing polymers for frost resistance have been divided[15] into those based on determining the temperature at which a sample undergoes brittle fracture under the influence of a certain type of load (mostly impact) and those in which the temperature is determined at which a specimen under load acquires a predetermined deformation. The former type are most often used, and can usefully be further divided according to the type of load.

In an early form of apparatus proposed[16,17] for impact tests at low temperatures a weight of ~200 g fell on the frozen test specimen from different controlled heights. In an analogous instrument the weight was dropped from a constant height, but there were separate chambers for cooling and for testing the specimen. The limiting frost resistance of the polymer specimen was assessed from the appearance of cracks.

In test methods for rubbers[18] the brittle point is determined by bending the cooled specimen, fixed horizontally at one end, by the application of an impulsive load to the free end. The temperature at which cracks become visible to the naked eye or at which the specimen fractures is regarded as the brittle point.

In a study of the plasticising action on poly(vinyl chloride) of certain low-molecular-weight substances the frost resistance was determined[19] in a pendulum instrument by the impact on the frozen specimen of a weight of 500 g falling from a height of 300 mm. Specimens were regarded as withstanding the test if after impact no cracks were visible under a lens giving tenfold magnification.

In England polymeric film-forming materials are tested for frost resistance at low temperatures by Williams' method[20], in which a specimen 0.58 mm thick, made up of two halves, is frozen and then subjected to impact from a hammer driven by a spring.

A review[21] of existing methods and equipment for testing polymers for frost resistance divides the methods into those in which specimens may undergo disintegration and those in which the modulus of elasticity is measured. Such tests of films for frost resistance are made in a special impact apparatus.

The frost resistance of a new modification of polypropylene (poprolin), obtained by plasticising with dioctyl sebacate and applying a cross-linking agent to the polymer, was determined[22] from the brittle point at which 50% of the test specimens break down. A specimen was cooled to a definite temperature, and bent to a specified deflection by application of an impact load.

An impact method of loading has been used[23] to determine the frost resistance of films at temperatures from −73°C and above. In a test specimens were mounted on a frame, brought to the specified temperature, and punctured by a loaded rod moving at different speeds (from 14 to 38100 cm min^{-1}) depending on the test conditions. The load necessary to pierce the film, the corresponding deformation, the critical speed, and the brittleness of the specimens were determined. The results were rather high compared with values obtained by other methods.

Standards adopted in several countries for measuring frost resistance are based on determining impact strength at low temperatures: i.e. tests are made in which a specimen is subjected under standard conditions to the action of a falling weight of definite size. This technique is described, for example, in a Dutch Standard[24] for cables having poly(vinyl chloride) insulation and in other standards[25,26]. Turner[27] suggested a method for determining the frost resistance of polymers which had several advantages over the standard method[25]. A rapid method for determining the brittleness of rubber at low temperatures has also been suggested[28].

A German patent[29] proposed a special method for testing cable insulation. A piece of wire 1.5 m long is covered with the insulation and slowly cooled. After every 5 deg the wire is swung sharply (to imitate a whiplash). The frost-resistance temperature of the polymeric coating is then determined from the appearance of cracks.

Sorokobatkina[30] suggested apparatus for determining frost resistance from the brittle point in which the main variables—temperature and rate and magnitude of deformation—could be controlled.

There are several methods other than those involving impact for testing the frost resistance of polymers. For example, a Soviet standard[31] uses two ways—bending a specimen (fixed horizontally at one end) a specified amount, and compressing a loop of a polymer film 0.5 mm thick—for determining the brittle point. The frost resistance is taken to be the temperature at which 50% of the specimens tested yield cracks or break down at the specified deformation.

The principle of flexing a film through 180° is used also in testing cable rubber and resin on an ergometer[32] and in a small bath[33].

In the test for leathercloth[8] the specimen is not only bent through 180° but also smoothed out by weights totalling 1 kg. In another method[8] a loop of the film is pulled through a slit (1 mm wider than twice the thickness of the film) at 100 mm min^{-1}. The frost resistance is found from the load required to draw the loop through the slit at a certain temperature without rupture of the specimen or the appearance of cracks.

Schulz and Mehnert[34] suggest that the frost resistance of a film can be measured by the temperature at which a specimen in the form of a loop of precisely defined dimensions can still be pulled without breaking, through a slit of standard size, by a sharp jerk.

A method of testing frost resistance is often used in which a sample of the polymeric film is wound in the form of a tape at a specified rate on a spindle of definite diameter, without the appearance of cracks or breaks. This method is known as "cold bending". A British standard[35] provides that a poly(vinyl chloride) plastic tape 1.27 mm thick should be wound on a 0.5-cm spindle at a rate of 1 rev/sec. This method is widely used for testing cable insulation. The diameter of the spindle can be varied according to the thickness of the specimen, which enables more or less comparable results to be obtained when different samples of the same material are tested. Another test method is also given: the specimen is cooled to the specified temperature, and subjected to a constant load (105.5 kg cm^{-2}) for 30 s, after which the elongation of the specimen is measured.

A method of testing rubber for frost resistance is also based on comparing the elongation of a specimen at normal and low temperatures[36]. In this case a coefficient of frost resistance is obtained by dividing the elongation at normal temperature under a definite load into the elongation of the working part of the specimen cooled to a particular temperature.

Sedlis and Lel'chuk[37,38] suggested that the frost resistance should be measured by the temperature at which a specimen of a polymer film extends by a definite amount under the influence of a load for a controlled period of time. These workers suggested both a method for determining frost resistance and empirical formulae for calculating this temperature.

In another method[39] a sample of artificial leather was kept in a cold chamber for 1 h, after which its bending strength was tested in a Herfeld apparatus. Hofman[40] pointed out that a single flexing of a sample of artificial leather will lead to erroneous conclusions on frost resistance, so that more prolonged bending tests are necessary.

The frost resistance of polymer films can be determined also from the number of double flexings required for the appearance of cracks or destruction of the specimen[41]. Tests by this method showed that the frost resistance of polymer films is increased by raising the plasticiser content and increasing the extent of gel formation.

Wormald[42] used a specially designed apparatus to determine the number of flexings (external diameter of curved specimen six times the thickness) leading to destruction of a poly(vinyl chloride) film at a specified temperature, as a function of the type and content of plasticiser. This method established that tritolyl phosphate was not effective in the production of frost-resistant plastics. It was concluded that the frost resistance is improved by partial replacement of dioctyl phthalate in the film by a linear plasticiser—dioctyl sebacate.

Several papers recommend the use of compressive forces for determining the frost resistance of plastics. For rubber under compression the method[43] consists in measuring the deformation of specimens in a special instrument at normal temperature and comparing the results with the deformation obtained under the same applied load at low temperatures. The temperature at which the frost-resistance coefficient of the rubber is 0.1 is adopted as the index of frost resistance. This method is applicable only to block specimens: to determine the frost resistance of film materials a specimen in the form of a cylinder (a roll of film 20–200 μm thick) can be deformed under a definite compressive load[44]. The deformed sample is removed from the chamber and inspected with the naked eye. The presence of cracks is the criterion from which the frost resistance of the material is assessed.

Several workers[45] recommend testing artificial leather for frost resistance in an attachment to a Schopper cold chamber. It is characterised by the load required to compress a cooled specimen of the film in the form of a tube (of diameter 65 mm and length 100 mm) fixed in special clamps in a deformometer.

Since fracture of a material is a more critical indication than a temporary increase in rigidity in the cold, tests of frost resistance in which the brittle point is determined are employed more often than methods involving determination of the limiting "temperature of cold twisting"[46]. The method consists in measuring the angle of rotation of the upper portion of a standard specimen, firmly attached to a movable upper clamp, under the action of a definite rotating moment about a fixed lower clamp, and hence calculating the modulus of elasticity at a specified temperature. These tests yield the temperature at which a standard modulus of rigidity is reached. When published results are considered, however, it must be remembered that in many cases different values are used for the standard modulus of rigidity. The frost resistance characterised by the torsional modulus is determined according to the standards.[47,48]

However, a modified method was used in several investigations[50]. Although the tests were made according to the standard[48], the frost resistance was measured by the temperature at which the specimen breaks down when twisted through 360°, not 200°. The frost resistance was shown to have considerably diminished in specimens which had aged under natural conditions.

Hayes and Lannon[51] proposed a method for determining the flexibility of plasticised poly(vinyl chloride) by measuring the angles through which specimens were twisted by a definite twisting moment (5.68×10^5 dyn cm). The frost resistance was characterised by the temperature which a specimen should have for the angle of twist produced by the given moment to be 200°.

Study of frost resistance from the increase in rigidity has established[52] that the thickness and linear dimensions of specimens influence the rigidity of film materials.

Since the flexibility of a polymer can be measured by the apparent modulus of elasticity in bending and twisting tests, and since a linear relation exists between the plasticiser concentration and the temperature at which a specified Young's modulus is reached, it is possible to find[53] the temperature at which a specified modulus will be achieved with a given plasticiser content: i.e. a qualitative determination of frost resistance can be made by this method.

Bartenev and Zuev[54] studied the relation between the frost-resistance coefficient and the maximum mechanical losses of rubberlike polymers during multiple deformations in the region of vitrification (the coefficient of frost resistance was defined[55,56] as the ratio of the amplitude of deformation at the specified temperature to the amplitude of vibration at +20°C).

It is evident from the above discussion that methods of determining frost resistance employed in various branches of technology are qualitative in character, insensitive, cumbersome, laborious, and applicable only to quite specific conditions of use of the articles made from polymers. The type of deforming force, its rate of application, and other test conditions are chosen purely empirically. The result produced by the deforming force—the appearance of cracks or other defects in the specimens—is usually determined visually. According to the above methods specimens are brought to destruction, which is not always possible or advisable.

Several new methods have recently been proposed for studying the frost resistance of polymers. Kanavets and Yartsev[57] have suggested adopting the reversible elastic deformation on stretching, characteristic of the intact internal structure of the material, as index of frost resistance. In this case the temperature of frost resistance is found from the plot of percentage elastic deformation against temperature.

Shteding and Kargin[14] have shown the theoretical possibility of determining the frost resistance of polymers by means of the thermomechanical deformation—temperature characteristics obtained by the uniaxial stretching of specimens in a special instrument, a deformometer[58]. As noted above, this method involves finding the temperature of the boundary between the zone in which segmental mobility of the chain macromolecules is absent and the zone in which it is present, an external indication of this being the observed appearance of a minimum deformation. This temperature was taken to be an index of the frost resistance of polymeric film materials. The proposed method represents a considerable advance in determining frost resistance, but it necessitates the construction of a special and quite complicated instrument—the deformometer.

Kargin and Shteding's suggested principle has been used[59,60] to determine the frost resistance of polymer films, but the instrument was a specially adapted version of apparatus used in industry to determine the frost resistance of rubbers[36], certain changes and additions being introduced into its design and especially into the method of measurement[59], which improved the accuracy and permitted the use of an existing manufactured instrument. With our proposed modifications[60] to the Kargin–Shteding method not only can the absolute frost resistance of polymeric films be determined more accurately but also the effect on polymers of various external factors (type and amount of plasticiser, processing schedule, aging, etc.) can be followed quantitatively. The experimental results correlate well with those obtained by other physical methods of investigation, e.g. thermomechanical and rheological.

3. Dependence of the Frost Resistance of Polymers on Various Factors

An early qualitative observation[11] was that the frost resistance of polymeric materials depends primarily on the physicomechanical parameters of the polymers themselves. The higher the flexibility and extensibility of the polymers at room temperature the higher is usually the frost resistance of materials based on them. A high degree of polymerisation and great uniformity of molecular weight, a low content of fractions of low molecular weight, and the necessary flexibility of the macromolecular chains also favour the production of frost-resistant polymeric materials.

The most important procedures for improving frost resistance are plasticisation with polymeric plasticisers and with low-molecular-weight plasticisers for amorphous polymers, and copolymerisation and modification for crystalline polymers, i.e. changing the properties of the polymers by chemical reaction with modifiers of low molecular weight[9], e.g. by processing mixtures together on rolls, in mixers, etc. Simultaneous enhancement of frost resistance and lowering of the glass point of crystalline polymers usually requires the introduction of mixtures of plasticisers and modifiers or the use of copolymerisation followed by plasticisation of the resulting copolymers. The frost resistance of polymers depends very substantially on the content of plasticisers[61] and obviously on their chemical structure.

Nevertheless, Bauer and Cox[62] who examined the main classes of plasticisers usually employed to increase the elasticity of vinyl polymers at low temperatures, detected no dependence of efficiency on the type of plasticiser (at contents below 50%), and suggested that plasticisers should be selected only on the basis of their compatibility with the polymer, incombustibility, low volatility, etc. These workers found that mixtures of plasticisers possess no synergic action, but this is disproved by later work: the frost resistance of poly(vinyl chloride) cable insulation can be improved appreciably[63] by the use of mixtures of plasticisers—a monoester of low molecular weight and a polyester of high molecular weight, obtained from phthalic anhydride, triethylene glycol, sebacic acid, and an aliphatic alcohol.

Experiments by other workers[19,64] have shown that the frost resistance of samples of plasticised poly(vinyl chloride) depends substantially on the chemical structure of the plasticisers. With equimolecular contents of tributyl phosphate and tritolyl phosphate in the polymer, for example, films with the former plasticiser, which has linear side-chains, are the more frost-resistant.

The use of a plasticiser having a low freezing point does not always guarantee improved frost resistance in a polymer[65]. For example, the frost resistance of a p.v.c. film plasticised with dioctyl adipate (f.p. −75°C) is lower than that of films having an equimolecular content of dioctyl sebacate (f.p. −48°C).

Forman[66] showed that non-volatile plasticisers of higher viscosity, higher boiling point, and low vapour pressure exert a greater plasticising effect on neoprene rubbers at low temperatures.

Fedotova and Karp[67] used a mixture of a gel-forming plasticiser and a grease to improve the frost resistance of plasticised p.v.c.

Kozlov et al.[68] discovered an interesting phenomenon in a study of the action of mixed plasticisers on polystyrene. A mixture of a plasticiser of low molecular weight (phenyltributoxysilane) and an oligomer (polydiphenyloxysilane) gives a significant synergic plasticising effect: a mixture of such plasticisers produces a considerably greater shift in the glass and flow points.

Plasticisers of different types are obtained depending on the presence of polarisable groups[69]: those containing polar and aliphatic groups (e.g. trioctyl phosphate) are not readily compatible with poly(vinyl chloride), but raise the frost resistance of the polymer substantially; those of polar–aromatic structure (tritolyl phosphate) form gels readily with p.v.c., but improve its frost resistance only very slightly. The frost-resistant plasticisers which are normally widely employed[15,70–73] are diesters of aliphatic dicarboxylic acids, such as adipic, sebacic, etc.

The quantity of frost-resistant plasticisers in a composition is determined by the elasticity which the plasticised material should possess at low temperatures. With a given total quantity of added plasticiser a linear relation exists between the quantity in the mixture and the softness of the poly(vinyl chloride) plastic, the limiting temperature of "cold twisting", and the logarithm of the bulk resistance.

Plasticisers prepared from linear alcohols[74] have recently become widely used, as also have epoxystearates[15], for the production of frost-resistant compositions. Polymers were shown[75] to acquire the greatest frost resistance when esters of organic acids containing 6–8 carbon atoms in the chain were used as plasticisers. Esters containing a larger number of carbon atoms in the chain are not so compatible with polymers and tend to freeze out of the compositions at low temperatures. The degree of branching in the structure of the initial alcohol also has a great effect on the frost resistance of the polymer material, lowering it substantially[76]. For example, the frost resistance of p.v.c. diminished in the sequence—*n*-octyl > isohexyl > 2-ethylhexyl > iso-octyl > 2-ethyl-2-methylpentyl—on the introduction of different esters of phthalic acid with alcohols containing eight carbon atoms. The presence of several aromatic rings or polar groups in phthalic esters has an adverse effect on the frost resistance of the plasticised polymer[77]. Isophthalic diesters confer high frost resistance on p.v.c.[78]. Although phthalates are widely used to plasticise p.v.c., they are not sufficiently frost-resistant, and are also flammable[79]. Phosphates having aromatic side-chains are characterised by low flammability but low frost resistance. Linear plasticisers—sebacates and adipates—confer fairly high frost resistance on p.v.c., but are flammable. To obtain frost-resistant polymeric materials, even in this case it is advisable to use mixtures of plasticisers, including chloroalkanes and other halogenated compounds. The frost resistance of p.v.c. containing nitrophthalic esters is higher than with equivalent molar quantities of phthalates.

Fillers and pigments usually lower the frost resistance of plastics[11,42,81,82] and require additional quantities of plasticisers. From an examination of the viscoelastic properties of poly(vinyl chloride) plasticised with tritolyl phosphate and dioctyl adipate, however, Eirich has shown[83] that small amounts of a very finely disperse limestone filler act as an additional plasticiser, somewhat lowering the moduli and increasing the relative elongation under tension.

The frost resistance of polymers is improved by orientation and by preliminary drawing. Aleksandrov[6] notes that highly oriented polymers retain their flexibility at temperatures several tens of degrees below the glass point. Drawn poly(vinyl chloride) acquires flexibility which varies little with fall in temperature[11]. The effect of drawing is greater the lower the plasticiser content. The greatest effect was achieved by combining a frost-resistant mixture with a softener and mechanical drawing. Several other workers[84,19] have observed an improvement in frost resistance on drawing.

Orientation is especially valuable in the manufacture of films. Compared with unoriented p.v.c. films, oriented films possess superior mechanical properties and good frost resistance[85,86].

Several workers have established[87] that atmospheric aging influences the temperature of impact brittleness more than other mechanical properties. Atmospheric conditions have a greater effect on the frost resistance of films plasticised with a single plasticiser the greater the plasticiser content. All methods aimed at stabilising polymers usually maintain also the frost resistance of materials based on them. On the whole, however, insufficient study has been made of the variation in the frost resistance of polymers during aging.

The increase in the frost resistance of linear polymers due to the introduction of a sufficient quantity of gel-forming plasticisers is usually accompanied by a decrease in strength. In some cases, however, the frost resistance of materials can be enhanced with a simultaneous increase in strength by partial "cross-linking" of the polymers[88,89].

Kargin et al.[90] have established that several properties of polymers depend on the character of the supermolecular secondary structures. Conferring the optimum structure on polymers[91] will probably enable their physical properties to be influenced, including the frost resistance of materials obtained from them. Such investigations would be of great scientific interest.

Advances in the Chemistry of Adamantane

V.V.Sevost'yanova, M.M.Krayushkin, and A.G.Yurchenko

The review deals with the latest data on the chemistry of adamantane and its nearest homologues—noradamantane and homoadamantane. A systematic account is given of the methods for the preparation of adamantane derivatives. The reactivities of the bridgehead and bridge sites in the adamantane structure have been considered in detail.
The bibliography includes 192 references.

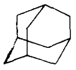
CONTENTS

I. INTRODUCTION

In the last two decades there has been an increase of interest in the chemistry of skeletal compounds. Adamantane occupies a special place among them—it was the first hydrocarbon which proved to have a diamond-like structure and it has in fact served as a touchstone for the investigation of the chemical and physicochemical properties of substances of this type. In the 1960's several reviews on the chemistry of polyhedral compounds were published[1-6].

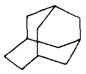
The number of reports on the chemistry of adamantane increases sharply each year. In the last 2–3 years interesting and fundamentally new methods for synthesising adamantane and its derivatives have been developed. There has been an increase of interest in adamantane derivatives as biologically active substances.

The aim of the present review is to give a general account of the latest data on the chemistry of adamantane(I) and its nearest homologues—noradamantane (II) and homoadamantane (III).



(I)

(II)



(III)

On the basis of quantitative physicochemical data for adamantane and their comparison with data for other carbocyclic compounds, an attempt is made to estimate quantitatively the characteristics of the chemical behaviour of adamantane and to determine its position in the series of other cyclic systems.

Heteroadamantanes are not considered in the review; as far as possible, the literature up to July 1969 is included.

II. SYNTHESIS OF THE ADAMANTANE STRUCTURE

1. Synthesis of Adamantane by the Isomerisation of Organic Compounds of Various Classes

The range of compounds capable of isomerisation to the adamantane structure has been extended so much that the term "adamantisation"[7] now appears quite natural and valid. While initially polycyclic perhydroaromatic hydrocarbons containing ten and more carbon atoms were subjected to adamantisation[8-11], nowadays a much wider range of compounds, including derivatives with different functional groups, has been investigated in this reaction. The isomerisation of cholesterol, cholestane, abietic acid, cedrene, caryophyllin, cyclohexane, squalene, squalane, and dodecane leads to the formation of a mixture of alkyladamantanes in 2–45% yield[12]. The reaction is carried out under pressure in the presence of aluminium halides at 110–130°C for 2–5 days. The solvents employed are cyclohexane and carbon disulphide or the reaction is carried out without a solvent. It is interesting to note that adamantane itself has not been detected in the isomerisation products—the main products were 1,3,5,7-tetramethyl-, 1,3,5-trimethyl-, and 1,3-dimethyl-adamantanes; 1-methyl- and 3-ethyl-1-methyl-adamantanes were isolated only in small amounts.

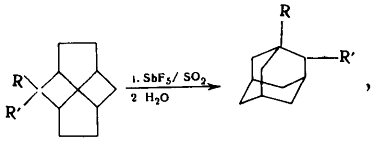
Possibly the above study will serve as the starting point of the search for industrial methods for the synthesis of polyalkyladamantanes. The isomerisation of cedrane[12,13] is already the best method for the synthesis of 7-ethyl-1,3,5-trimethyladamantane.

1,3-Dimethyladamantane is formed in the isomerisation of 1-ethyladamantane[14] and *endo*- and *exo*-2,2-dimethyltetrahydrodicyclopentadiene[15] in the presence of aluminium chloride.

An effective isomerisation catalyst proposed by Robinson[11] consists of a mixture of t-butyl bromide and aluminium bromide; the catalyst is employed in the form of a suspension in the hydrocarbon to be isomerised.

Schneider et al.[16] made a detailed study of the conversion of a mixture of isomeric C_{14} perhydroanthracenes and perhydrophenanthrenes into the adamantane system. The experimental data convincingly show that alkyladamantanes, particularly those substituted at the nodal sites (methyladamantanes), are stable final isomerisation products. Careful calculations by the authors of the enthalpies and entropies of the initial hydrocarbons and various products of their skeletal isomerisation showed that adamantane homologues are thermodynamically the most stable isomers. For example, in the isomerisation of perhydrophenanthrene four carbon atoms are "squeezed" out of the ring structure and the spherical 1,3,5,7-tetramethyladamantane, with the lowest energy among all the isomers investigated, is formed.

Twistane and several of its derivatives are very easily adamantised[7]. Apart from Lewis acids, SbF_5 or an SbF_5/SO_2 mixture were investigated as catalysts; the reaction was carried out at -80°C for 30 min:

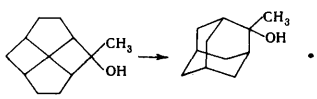


(IVa, b)

where R = R' = H in (IVa) and R = H and R' = OH in (IVb).

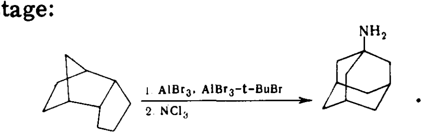
The transition from the twistane structure to the adamantane structure, which includes the "untwisting" of one methylene bridge, takes place via the initial formation of a cation. Experiments with deuterated compounds showed that the removal of hydrogen takes place during the rearrangement and the adamantyl cation formed is stable in relation to hydrogen exchange.

2-Methyl-2-adamantanol was obtained under the same conditions in the isomerisation of 2-methyl-2-twistanol (V):



(V)

The recently developed method for the synthesis of 1-aminoadamantane from tricyclo[5,2,1,$0^{2,6}$]decane (VI)[17,18] undoubtedly merits attention. The isomerisation and amination with nitrogen trichloride may be carried out in a single stage:



(VI)

The above reaction is interesting because it made it possible for the first time to introduce a functional group in the isomerisation process and to obtain a high yield of 1-aminoadamantane (amantidine), which is now in the stage of comprehensive clinical tests.

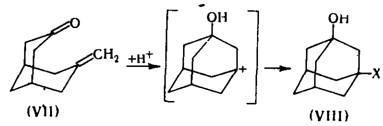
Thus the isomerisation conditions developed at the present time permit the synthesis with fairly high yields of adamantane, its homologues, and certain functional derivatives from a wide range of organic compounds.

All these studies are of undoubted theoretical interest also in another connection; they throw light on the origin of skeletal and in particular adamantane compounds in petroleum[4,19]. A number of studies have been made on the development of methods for the isolation of adamantane and its homologues from petroleum[20-22].

2. Synthesis of the Adamantane Nucleus from Bicyclic Systems.

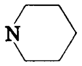
The greatest number of studies have been made on the synthesis of adamantane derivatives from compounds containing the bicyclo[3,3,1]nonane system. Although the methods for the synthesis of bicyclo[3,3,1]nonane derivatives as a rule involve many stages, they make it possible to obtain adamantane derivatives with substituents which are difficult to introduce by direct procedures.

Alkaline hydrolysis of (3-bromo-1-adamantyl)urethane, carried out by Stetter and coworkers[23], is accompanied by fragmentation which results in the formation of 3-methylenebicyclo[3,3,1]-7-nonanone (VII). Cyclisation of this compound[24], which is a modification of the Prins reaction, takes place in an acid medium with the initial formation of the 3-hydroxy-1-adamantylcarbonium ion, capable of further addition with formation of compound (VIII):



(VII) (VIII)

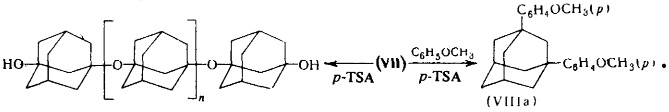
where X = OH, OC_2H_5, SC_2H_5, Cl, $NHCOCH_3$, NH_2, or



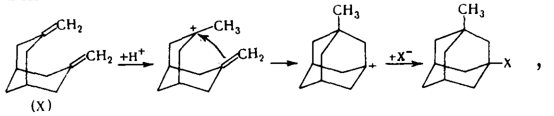
.

Compound (VII) undergoes ring closure to adamantane not only in an acid medium but also in the reaction with ammonia and amines (piperidine). The authors suggest that in this case the reaction initially involves the carbonyl group and that on heating a carbonium ion is formed, which subsequently undergoes further ring closure to adamantane[24].

When (VII) is heated with anisole, (VIIIa) is readily formed and heating of (VII) in a solvent (benzene, chlorobenzene, or carbon tetrachloride) leads to the formation of the polyester (IX); both reactions are catalysed by *p*-toluenesulphonic acid (*p*-TSA)[24]:

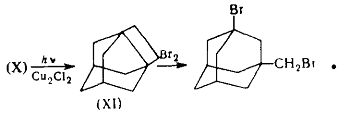


3,7-Dimethylenebicyclo[3,3,1]nonane (X), which undergoes ring closure to adamantane derivatives under the action of electrophilic reagents[25,26], is formed from (VII) by the Wittig reaction. The conversion of (X) into adamantane derivatives undoubtedly involves an ionic mechanism:

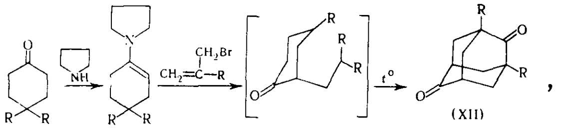


where X = Cl, Br, I, OH, OCH_3, $NHCOCH_3$, or *p*-$C_6H_4OCH_3$.

Photoinitiation of the cyclisation of (X)[27] leads to the formation of tetracyclo[$4,3,1,1^{4,8},0^{1,4}$] undecane (XI), a highly strained compound, which on refluxing in bromine combines with one mole of the latter:

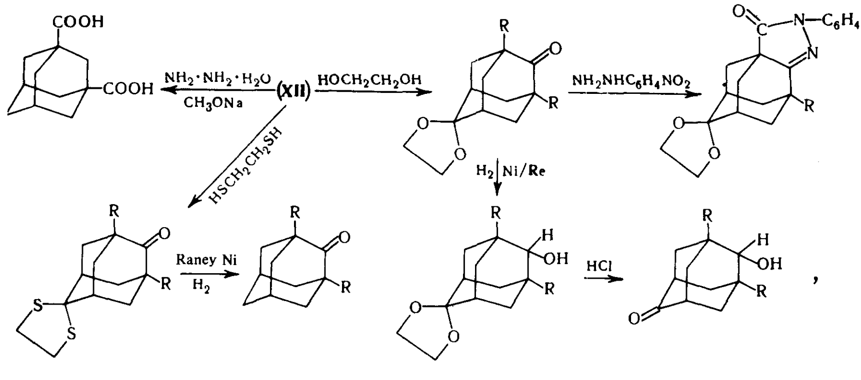


The recently developed method for the synthesis of the diethyl ester of 2,6-dioxa-adamantane-1,3-dicarboxylic acid (XII) is attractive because of the ready availability of the starting material, high yields at all stages, and the possibility of obtaining polysubstituted adamantanes[28,29]:



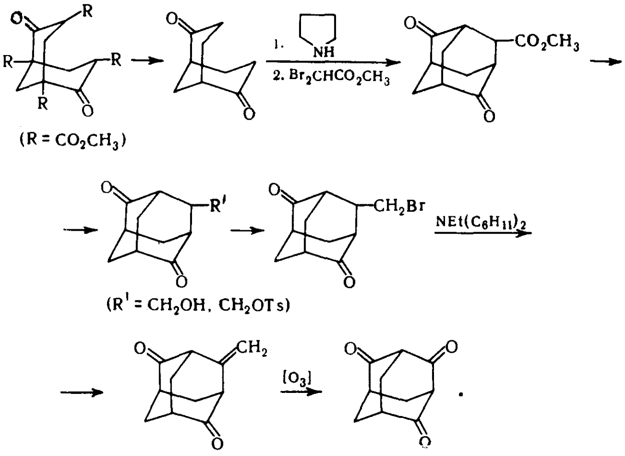
where R = $CO_2C_2H_5$.

Starting from compound (XII), the authors carried out the following series of reactions[29]:

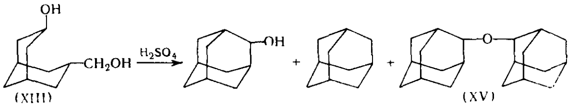


where R = $CO_2C_2H_5$.

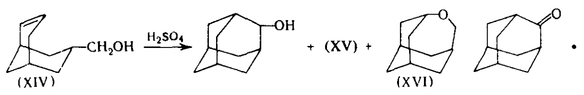
The methyl ester of 2,6-dioxoadamantane-4-carboxylic acid was obtained from Meerwein's ester and some of its reactions have been investigated[30]:



In contrast to the cyclisation of 3,7-disubstituted bicyclo[3,3,1]nonanes, which leads to the formation of 1,3-disubstituted adamantanes, the cyclisation of 3-hydroxymethylbicyclo[3,3,1]-7-nonanol (XIII) and 3-hydroxymethylbicyclo[3,3,1]non-2-ene (XIV) in the presence of sulphuric acid gives 2-monosubstituted adamantanes[31]. On treatment with 48% sulphuric acid in dioxan, a mixture of 2-hydroxyadamantane (39%), adamantane (17%), and 2-adamantyl ether (XV) (26%) is formed from (XIII):

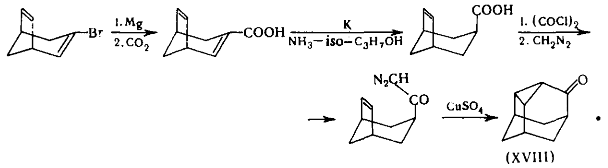


The cyclisation of (XIV) under the same conditions leads to the formation of 2-hydroxyadamantane (80%), small amounts of (XV), 2-oxatricyclo[$4,3,1,1^{4,8}$]undecane (XVI) and adamantanone:



The idea of the possible synthesis of adamantane derivatives by the ring closure in the 3- and 7-positions of bicyclo[3,3,1]nonane was already put forward in the first studies on the synthesis of the adamantane nucleus. The novel feature of the studies quoted above consists in the fact that the adamantane system is formed as a result of intramolecular condensation; a methylene bridge is formed from the carbon atom already present in the bicyclo[3,3,1]nonane ring.

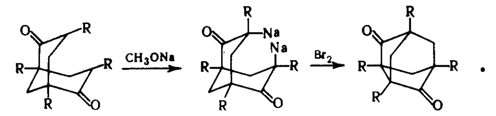
An interesting scheme for the synthesis of the adamantane structure was recently proposed by Baldwin and Foglesong[32]. They started with 3-bromobicyclo[3,2,1]-octa-2,6-diene (XVII), which was converted into 8,9-dehydro-2-adamantanone (XVIII) by the mechanism below:



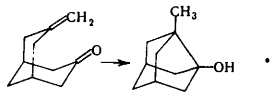
III. SYNTHESIS OF NEAREST HOMOLOGUES OF ADAMANTANE.

In this review we are considering only two nearest homologues of adamantane: tricyclo[3,3,1,0^{3,7}]nonane (noradamantane) and tricyclo[4^{3},1,1^{3,8}]undecane (homoadamantane).

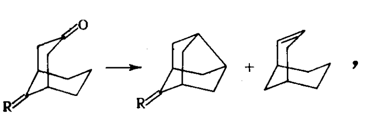
Meerwein was the first to obtain the noradamantane system by the cyclisation of the Meerwein ester[33]:



Many years later disubstituted noradamantane was obtained by the reduction of 3-methylenebicyclo[3,3,1]-7-nonanone with sodium in wet ether[34]:

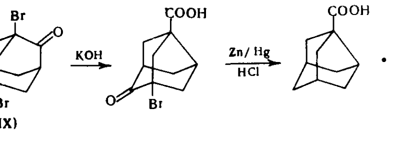


The noradamantane structure is formed on dry distillation of salts of the tosylhydrazone of bicyclo[3,3,1]-3-nonanone[35]:



where R = H_2 or $-OCH_2CH_2O-$. In both cases the transannular cyclisation of the bicyclo[3,3,1]nonane system to the noradamantane system takes place extremely readily.

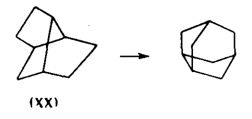
A completely different approach to the synthesis of the noradamantane system was achieved by Vogt and Hoover, who started with 1,5-dibromoadamantane-2,6-dione (XIX), which was converted by the Favorskii reaction into substituted noradamantane[36]:



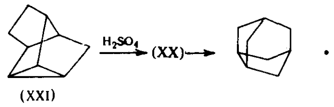
This method merits attention for two reasons: firstly, there is no doubt about the noradamantane structure obtained in this way and, secondly, the presence of three functional substituents permits the preparation of a wide variety of derivatives.

Noradamantane as well as adamantane may be obtained by the isomerisation of tri- and tetra-cyclic hydrocarbons in the presence of Lewis acids. Hitherto this isomerisation has been investigated only for a few isolated examples.

Brexane—tricyclo[4,3,0,0^{3,7}]nonane (XX)—isomerises very readily to noradamantane in the presence of aluminium bromide; the reaction is carried out for 30 min in carbon disulphide at 25°C, the yield of noradamantane being 75%[37]:



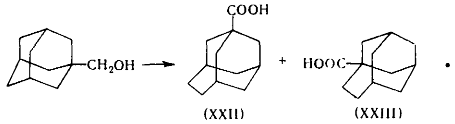
Deltacyclane (XXI), which is a convenient starting material for the formation of the brexane skeleton, can isomerise to noradamantane under the action of 96% sulphuric acid[38]:



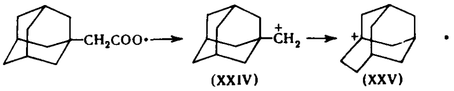
Depending on the method of treatment of the product, after isomerisation it is possible to obtain noradamantane with various substitutents in the 2-position.

Noradamantane is a white crystalline substance melting at 203–204°C and readily subliming. Its chemical and physical properties have so far been little investigated.

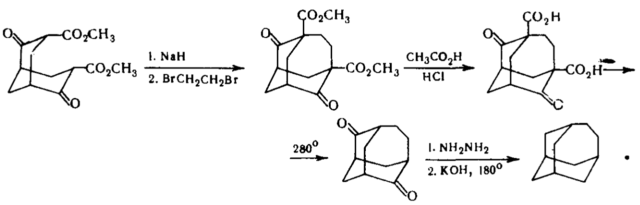
The principal method for the preparation of homoadamantane derivatives involves the expansion of one of the rings in the adamantane nucleus. In 1959 Stetter and coworkers[39] obtained homoadamantane-3-carboxylic acid from 1-hydroxymethyladamantane by the Koch–Haaf reaction. A more detailed study of the properties of this compound[40,41] showed that the substance obtained by Stetter consisted of a mixture of 80% of homoadamantane-1-carboxylic acid (XXII) and 20% of homoadamantane-3-carboxylic acid (XXIII):



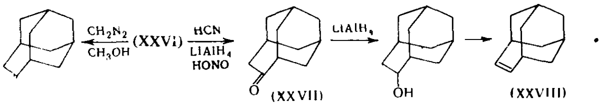
When the sodium salt of adamantane-1-acetic acid is electrolysed, the radical AdCH$_2$COO$^{\cdot}$, which is formed at the anode, loses carbon dioxide and is oxidised further to the cation (XXIV), which then rearranges to the 3-homoadamantyl cation (XXV)[42,43]:



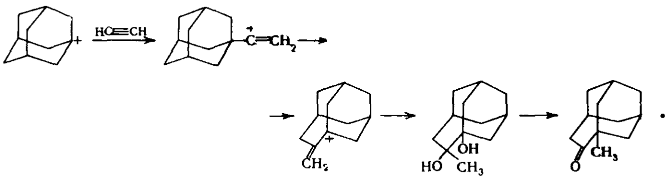
A specific synthesis of homoadamantane was achieved by Vogt[44] from bicyclo[3,3,1]nonane:



Promising methods for the synthesis of the homoadamantane system have been demonstrated[45,46]. In both cases the authors started with the readily available adamantanone (XXVI):

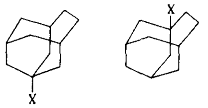


Subsequent reduction of 4-homoadamantanone (XXVII) leads to the formation of the corresponding alcohol, the dehydration of which gives 4,5-dehydrohomoadamantane (XXVIII). The formation of small amounts of homoadamantyl derivatives has been noted in the reaction of adamantane with acetylene[47]. The author suggested the following mechanism:



Other cases of the formation of the homoadamantane structure have also been observed but the reactions described are not unsuitable for preparative purposes[4].

The electrolysis of homoadamantanecarboxylic acids was investigated in the studies already mentioned[42,43]. Electrolysis of homoadamantane-1-carboxylic acid in methanol gives 1-methoxyhomoadamantane and homoadamantane-3-carboxylic acid is converted under the same conditions into 3-methoxyhomoadamantane. Two series of homoadamantane derivatives with substituents in the 1- or 3-position have been synthesised from the methoxy-derivatives[42]:



where X = OCH_3, Br, Cl, OH, $NHCOCH_3$, NH_2, COOH, $COOCH_3$, or CN.

The position of the substituents in the 1- and 3-bromo-derivatives of homoadamantane is confirmed also by a comparison of the relative rates of solvolysis. 1-Bromohomoadamantane is solvolysed only three times faster than 1-bromoadamantane, while 3-bromohomoadamantane is solvolysed 500 times faster[42].

IV. PHYSICOCHEMICAL PROPERTIES OF ADAMANTANE.

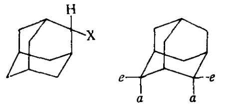
The principal physicochemical properties of adamantane have been very thoroughly described in the review mentioned above[3]. Subsequent studies dealt mainly with the revision and checking of results already published. Thus Nordman and Schmitkons[48] assert that at room temperature adamantane has a disordered face-centred cubic structure, probably belonging to the F_m3_m group rather than $F\overline{43}m$ suggested previously. The same workers confirmed the occurrence of a phase transition at −65°C and determined the parameters of the low-temperature unit cell.

A phase transition to the tetragonal structure at 208.62°K was established by Resing[49] using the "spin echo" method. The phase behaviour of adamantane was also investigated at elevated temperatures and pressures[50].

It has been noted[3] that an experimental test of the lack of strain in adamantane is impossible without knowing the enthalpy of sublimation. Bratton and Szilard measured the vapour pressure of adamantane in the range 40−80°C and calculated the enthalpy of sublimation from the integral form of the Clausius−Clapeyron equation. It proved to be 14.0 kcal $mole^{-1}$. Subsequent calculations by the authors confirmed the conclusion that adamantane has a low strain energy[51]. The results of Bower et al.[54], who reported the formation of an adamantane radical-anion, were checked by Jones[52] and Gerson et al.[53], who showed that these data are erroneous. The signals in the ESR spectra assigned to the adamantane radical-anion are in fact due to contamination by benzene.

The NMR spectra of adamantane substituted at the bridgehead positions were already partly discussed in the review of Fort et al.[3] A detailed publication[55] showed that the NMR spectra yield much information about the structure of adamantane derivatives by virtue of the additivity of the chemical shifts of all the protons in the adamantane nucleus. The spectra of polysubstituted adamantanes may be calculated by the algebraic summation of the chemical shifts of the β-, γ-, and δ-protons of the corresponding monosubstituted adamantane derivatives in relation to unsubstituted adamantane. The relatively large difference between the chemical shifts, the absence of geminal spin−spin coupling, and the low vicinal coupling constant made the interpretation of the spectra easy. When the lines overlap, the use of benzene as a solvent makes it possible to elucidate all the structural detail. The effect of aromatic solvents on the NMR spectra of adamantane derivatives was studied in detail by Fort and Lindstrom[56], who postulated the presence of a 1 : 1 complex with the solvent in solutions of 1-halogenoadamantanes in benzene, which, however, is so unstable that it could not be detected by any method other than NMR spectroscopy.

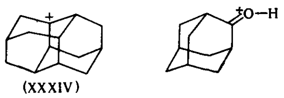
The symmetry of adamantane derivatives with the substituent in the 2-position is much lower than that of 1-derivatives and therefore analysis of the spectra of such compounds is much more complicated. The NMR spectra of 2-derivatives of adamantane consist of a series of poorly resolved lines which do not show appreciable vicinal splitting. Analysis of the spectra recorded at a 100 MHz using double resonance established that J_{vic} = 2.6 Hz and J_{gem} = 12 Hz for compounds (XXIX)−(XXXIII). The chemical shifts for the majority of protons have also been determined[57]:



where X = Cl for (XXIX), X = Br for (XXX), X = I for (XXXI), X = OH for (XXXII), and X = NH_2 for (XXXIII).

2,4-Dihalogeno-derivatives of adamantane can exist in three stereoisomeric forms—2a, 2e; 2a, 4e; 2e, 4a. Analysis of the NMR spectra[58] of 2,4-dichloro-, 2,4-dibromo-, and 2,4-di-iodo-adamantanes established the configuration of these compounds and it was found that the chemical shifts of the protons of adamantane derivatives with substituents at the secondary carbon atoms are additive.

In individual NMR studies adamantane derivatives were also investigated among other compounds. Thus Olah and Lucas[59], who studied the behaviour of cycloalkanes in "magic" acid (a mixture of fluorosulphonic acid and antimony pentafluoride), found that, on dissolution in this mixture, adamantane loses a hydride ion and forms the adamantyl cation. Trimethylenenorbornane is also converted under these conditions into the adamantyl cation with loss of a hydride ion. Diadamantane (“congressane”) behaves analogously, losing a hydride ion from the tertiary position in the “belt” [(XXXIV)]. Adamantanone forms an oxonium species in “magic” acid[60]:

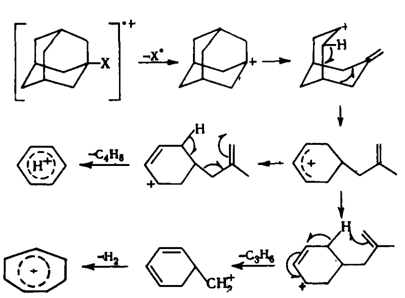


(XXXIV)
diamantane (“congressane”)

Oleneva et al.[61] examined the infrared and Raman spectra of mono- and 1,3-di-substituted derivatives of adamantane. They noted that the absorption bands of the C–H and CH_2 groups are located in the regions characteristic of cyclohexane structures. The skeletal vibrations of the adamantane structure differ appreciably from those of the corresponding cyclohexane vibrations but they are not characteristic and probably cannot be used to identify the adamantane nucleus.

A combined approach to the study of alkyladamantanes has been demonstrated[62,63]. The authors characterise alkyladamantane on the basis of its infrared and Raman spectra and gas–liquid chromatography.

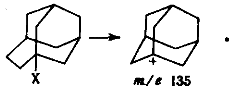
A detailed study of the behaviour of adamantane derivatives on electron impact has been made only for 1-substituted adamantanes[64]. Depending on their behaviour under electron impact, 1-derivatives of adamantane can be divided into two groups: compounds whose molecular ions split off the substituent in the form of a neutral fragment, while the remaining fragment $C_{10}H_{15}^{+}$ is further cleaved according to the mechanism



where X = Cl, Br, NO_2, CH_2OH, $COCH_3$, COOH, $COOCH_3$, C_6H_{11}, or $C_{10}H_{15}$, and compounds (X = OH, NH_2, $NHCOCH_3$, C_6H_5, or OCH_3) which split off olefin molecules, forming charged fragments where the substituent is retained. Adamantane itself gives a very intense peak due to the molecular ion which decomposes with elimination of olefins.

In contrast to adamantane, the molecular ion of homoadamantane[41] fragments into neutral radicals, forming thereby significant ionic species with odd masses. Like the 1-derivatives of adamantane, homoadamantane derivatives containing a substituent both in the 1-position and the 3-position can be divided into two groups differing in the nature of the mass spectra. The 1- and 3-derivatives of homoadamantane with Cl, Br, COOH, and $COOCH_3$ substituents give rise on electron impact to a molecular ion which splits off the substituent in the form of a neutral fragment and breaks down further with elimination of olefins.

Thermal rearrangement of the Wagner–Meerwein type to adamantane derivatives, leading to the formation of a fragment with $m/e = 135$ ($C_{10}H_{15}^{+}$) is characteristic of 3-substituted homoadamantanes of this group.



.

The presence or absence of the ion with $m/e = 135$ makes it possible to distinguish the 1- and 3-substituted homoadamantane derivatives.

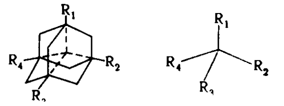
The molecular ions of 1- and 3-derivatives of homoadamantanes containing OH, OCH_3, NH_2, and $NHCOCH_3$ substituents split off neutral radicals and all the principal ions retain the substituent. The most intense peak in the mass spectra of compounds of this group is that corresponding to the $M - C_5H_{11}$ ion. The ratio of the intensity of this ion to that of the $M - C_4H_9$ ion in the case of the 1-substituted derivatives is 10 : 1 or above, while in the case of 3-substituted derivatives it is not more than 3 : 1, which makes it possible to distinguish these series of isomers.

In a study of the mass spectra of adamantane-1-acetic and homoadamantane-3-carboxylic acids deuterated in the carboxy-group, it was found that vigorous deuterium exchange with the nucleus takes place. Probably the 2-position of the adamantane or homoadamantane nucleus is capable of exchange.

Other spectroscopic methods were used to study adamantane derivatives to a much lesser extent. Chadwick et al.[65] calculated from the parameters of microwave spectra the carbon–halogen bond length in 1-halogenoadamantanes.

Certain properties of the ultraviolet and circular dichroism spectra have been investigated for β-substituted adamantanones[66].

Adamantane with four different substituents at the bridgehead carbon atoms may be regarded as a formal analogue of a compound with an asymmetric carbon atom:



.

The attempts to separate into optical isomers 3,5 and 3,5,7-substituted adamantane-1-carboxylic acids were unsuccessful[67]. By fractional crystallisation, Hamill and McKervey isolated an optically active dehydroabietylammonium salt of 5-bromo-3-methyladamantane-1-carboxylic acid[68]. The bromo-acid isolated from the salt proved to be optically inactive, but after conversion into 5-bromo-3-methyl-1-adamantylurethane and subsequent fragmentation, the optically active 1-methyl-3-methylenebicyclo[3,3,1]-7-nonanone ($[\alpha]_D^{23} = 10.4°$) was obtained.

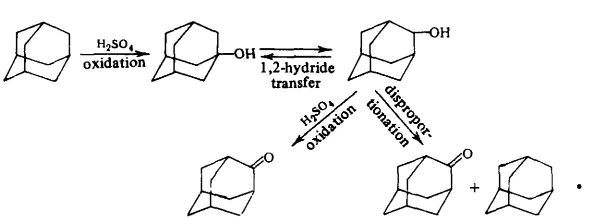
V. CHEMICAL PROPERTIES OF ADAMANTANE

During the last five years the chemistry of adamantane has developed very rapidly. The hydride transfer reactions, which permit the interchange of functional groups between bridgehead and bridge positions in the adamantane ring, must be regarded as the most important achievements in this field. Notable advances have been made in the synthesis of adamantane derivatives with substituents in the bridge positions. Finally, the increasing interest in the radical reactions of adamantane may be noted.

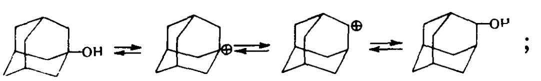
1. Hydride Transfer Reactions in the Adamantane Ring

These include in the first place oxidation of adamantane by sulphuric acid and the disproportionation of its hydroxy- and halogeno-derivatives.

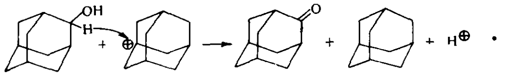
In 1967 Geluk and Schlatmann reported the direct oxidation of adamantane to adamantanone by sulphuric acid[69,70]. The mechanism of this multistage process is as follows:



They established that the individual stages in the conversion of adamantane into adamantanone are: (a) oxidation of adamantane to 1-adamantanol; (b) 1,2-hydride transfer leading to the equilibrium

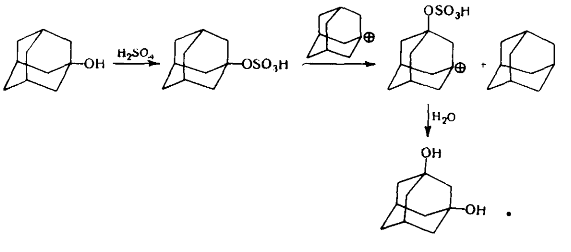


(c) intermolecular hydride transfer in which the adamantyl cation functions as a hydride ion acceptor:

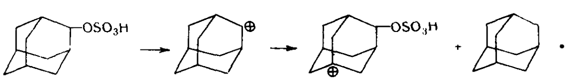


Adamantanone is formed also in the oxidation of 2-adamantanol by nitric acid.

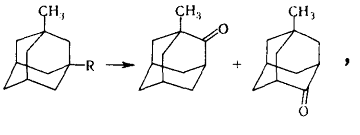
The composition of the products formed in the reaction of 1-hydroxy- or 2-hydroxy-adamantane with sulphuric acid depends to a considerable degree on the concentration of sulphuric acid, temperature, and duration of reaction. The 1,2-hydride transfer mentioned above [process (b)] takes place readily in 96% acid, while in 70% acid 1,3-hydride transfer takes place[71]:



Here too the acceptor is the adamantyl cation and the donor the sulphate ester of 1-adamantanol formed in sulphuric acid. In 70% sulphuric acid 2-adamantanol is similarly converted into an equimolar mixture of adamantane and 1,4-dihydroxyadamantane:

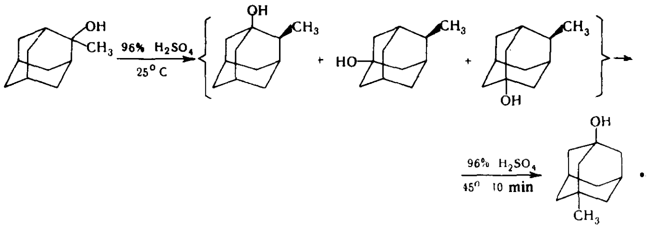


The structure of 1,4-dihydroxyadamantane obtained in the form of a mixture of two stereoisomers was rigorously demonstrated by the authors and on its basis a series of 1,4-disubstituted adamantanes were obtained. 1-Methyladamantane, 3-bromo-1-methyladamantane, and 3-hydroxy-1-methyladamantane as well as unsubstituted adamantane are oxidised by sulphuric acid to a mixture of isomeric 1-methyladamantanones[72]:

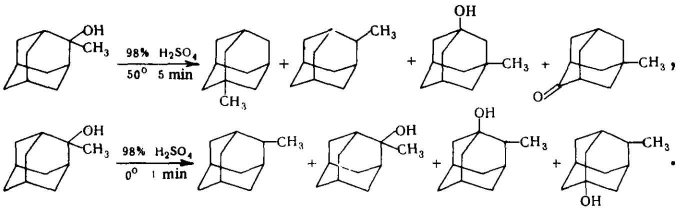


where R = Br, H, or OH.

The behaviour of 2-hydroxy-2-methyladamantane in sulphuric acid is fairly complex, which is probably the reason for a somewhat contradictory nature of the available literature data on its reaction products. At room temperature 2-hydroxy-2-methyladamantane[73] is immediately isomerised in 96% sulphuric acid to a mixture of 3 isomeric hydroxymethyladamantanes, the hydroxy-group being located at a bridgehead carbon atom. At 45°C the methyl group is also located at a tertiary carbon atom, as shown in the mechanism below:



The isomerisation of 2-hydroxy-2-methyladamantane in concentrated sulphuric acid at 0° and 50°C is likewise accompanied by intermolecular hydride transfers[73]:



The authors believe that the 2-methyl-2-adamantyl cation formed initially rapidly isomerises to a mixture of all other tertiary cations.

Patent data have also been published on the ready isomerisation of 2-hydroxyadamantane derivatives to the corresponding 1-hydroxyadamantanes[74]. 2-Hydroxyadamantane disproportionates under the influence of phosphoric and perchloric acids or Lewis acids[70].

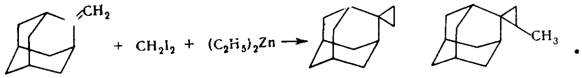
The rate of isomerisation of 2-hydroxy-2-methyladamantane is apparently sharply reduced when the temperature is decreased, since the only product of the isomerisation of 2-hydroxy-2-methyltwistane in an SbF_5/SO_2 mixture at −78°C is 2-hydroxy-2-methyladamantane[7].

2. Reactions Involving the Bridge Positions in the Nucleus.

Starting with adamantanone, which is now readily available, the following derivatives have been obtained by standard methods: 2-hydroxy-, 2-chloro-, 2-bromo, 2-carboxy-, 2-amino-, 2-cyclopentyl-, and 2-methylene-adamantanes[75,76].

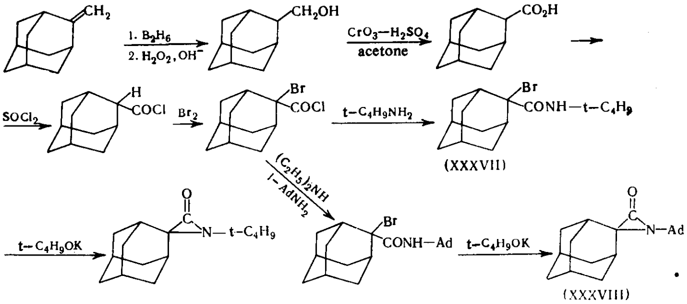
Methyleneadamantane also serves as a starting material for the synthesis of adamantanes substituted in the 2-position.

Like other olefins, methyleneadamantane reacts with methylene iodide and diethylzinc, forming spiro[adamantane-2,1′-cyclopropane] (XXXV) [77]; under the same conditions, 2-methylspiro[adamantane-2,1′-cyclopropane] (XXXVI) is formed from ethylideneadamantane:



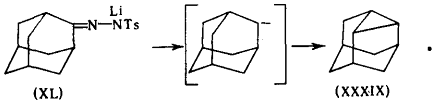
(XXXV) (XXXVI)

The α-lactams (XXXVII) and (XXXVIII) can also be obtained from methyleneadamantane by the following mechanism[78]†:



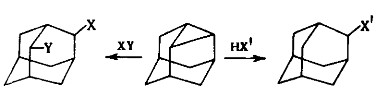
The lactams (XXXVII) and (XXXVIII) thus obtained are quite stable despite containing β-hydrogen atoms, since the latter are located at the bridgehead positions and the isomerisation of lactams with ring opening is blocked.

A fundamentally new method for the synthesis of adamantanes with substituents in bridge positions was developed starting from 2,4-dehydroadamantane (XXXIX) obtained by the pyrolysis of the dry lithium salt of the *p*-tosylhydrazone of adamantone (XL) at 130−140°C [79]:



(XL) (XXXIX)

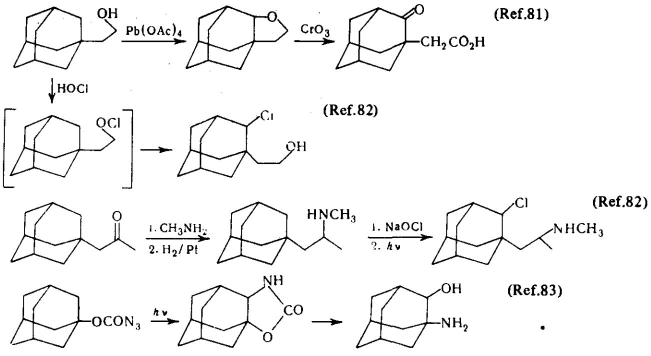
Compound (XXXIX), which is a readily available hydrocarbon with m.p. 202.5−203.5°C, is a very convenient starting material for the synthesis of 2-monosubstituted and 2,4-disubstituted adamantane derivatives[80]:



where X = Cl, H, Br, I, OH, =O, or $NHCOCH_3$, Y = Cl, Br, I, C_6H_5, OH, or H, and X′ = $OCOCH_3$, OCH_3, C_6H_5, (*o* + *p*)-$C_6H_4CH_3$, or (*o* + *p*)-$C_6H_4OCH_3$.

Reactions with the opening of the three-membered ring proceed under mild conditions and lead to the synthesis of the final products in high yields. A series of new 2-monosubstituted and 2,4-disubstituted adamantanes have been obtained by this reaction.

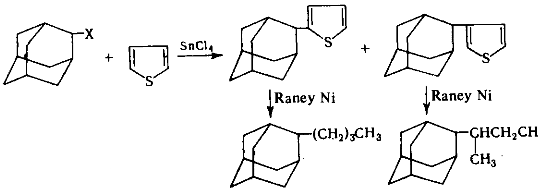
A general method for the preparation of 1,2-disubstituted adamantane derivatives is intramolecular cyclisation with participation of the vicinal carbon atoms of the adamantane nucleus with subsequent ring opening and the formation of 1,2-derivatives[81-83]:



The intramolecular ring closure to give 1-substituted adamantanes has so far been very little investigated; the use of photolysis in the ring closure stage appears to be promising.

The Koch synthesis of carboxylic acids from 2-hydroxyadamantane yields a mixture of adamantane-1-carboxylic and adamantane-2-carboxylic acids, the greatest yield of the latter being obtained when the ratio 2-hydroxyadamantane:H_2SO_4 = 1 : 1500. A series of adamantane derivatives substituted in the 2-position has been obtained from adamantane-2-carboxylic acid[84].

Hock and coworkers developed an interesting method for the introduction of butyl and isobutyl groups into the adamantane nucleus[85]. This method consists in the alkylation of halogenoadamantanes with thiophen and subsequent hydrogenolysis of the resulting compounds. 2-Halogenoadamantanes are less readily alkylated than 1-halogeno-derivatives, but the final products can nevertheless be obtained in a yield of about 40%:



where X = Cl or Br.

2-Butyladamantane was also obtained in a high yield by the reaction of adamantanone with butyl-lithium[86].

In an overall assessment of this section on the chemistry of adamantane, the striking progress in this new field is noteworthy. It is sufficient to recall that only a few years ago even the synthesis of adamantanone was an extremely laborious process. It is to be expected that in the near future the study of the reactivity of polyhedranes at the bridgehead and bridge positions will lead to many applications of this unusual type of compounds in the solution of important synthetic and applied problems.

3. Free-radical Reactions

The first chemists who began a comparative study of the stability of skeletal radicals were Applequist and Kaplan[86]. A convenient reaction for such study is decarbonylation of aldehydes. The authors investigated the ease of the loss of carbon monoxide by the acyl radicals

---

† Here and henceforth Ad = 
$\dot{R}CO$, where R is subject to different degrees of limitation of skeletal coplanarity:

$$\begin{tikzcd}R\dot{C}O \arrow[r, "k_1"] \arrow[d, "CCl_4"', "k_2"] & R\cdot + CO \arrow[d] \\ RCOCl & RH, RCl\end{tikzcd} .$$

The stability of the radicals is estimated in terms of the ratio k_1/k_2, since the rate of capture of the $R\dot{C}O$ radicals by the solvent (carbon tetrachloride) is less sensitive to the nature of R (i.e. k_2 is almost constant). Data for the relative stabilities of the radicals investigated‡ and the relative rates of solvolysis of the corresponding bromides§ are presented below:

		$(CH_3)_3CR$			
Relative stability of radicals k_1/k_2	R=CHO	1.00	2.5	1.2	0.007
Relative rate of solvolysis	R=Br	1.00	10^{-3}	10^{-6}	10^{-14}

Although these data do demonstrate a real difference between the stabilities of the t-butyl and 1-adamantyl radicals, when account was taken of the energies of the dissociation of the corresponding hydrocarbons into radicals, the authors concluded that the 1-adamantyl radical is more stable approximately to the extent of [only] 1 kcal than the t-butyl and 1-bicyclo[2,2,2]octyl radicals. The significant difference between the relative stabilities of the free radicals and carbonium ions is noteworthy. Probably steric factors play a greater role in ionic reactions than in radical reactions.

On the other hand, Chick and Ong[87] believe that the 1-adamantyl radical is less stable than the t-butyl radical, but unfortunately they do not quote quantitative data.

Free-radical substitution in adamantane was investigated in detail by Oda and coworkers[88-90]. They studied the fundamental problem of the relative reactivities of the 1- and 2-positions in radical reactions. While the 1-position is subject to steric limitations (the 1-adamantyl radical cannot be planar), the 2-position can give rise to a normal secondary free radical (sp^2-hybridisation is possible). Experiments on the radical halogenisation of adamantane[88,89] led the authors to the following conclusions:

1. In radical reactions the 1-adamantyl radical is formed more readily than the 2-adamantyl radical.
2. The bridgehead adamantyl radical is less stable than the bridge radical; the selectivity in this reaction (the ratio of the reactivities in the 1- and 2-positions) is 4.

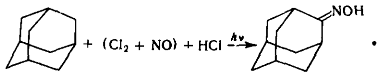
The different selectivities of the adamantyl radicals are also shown in the Hünsdiecker reaction[88]: in chlorine-containing solvents (carbon tetrachloride) the 1-adamantyl radical abstracts chlorine preferentially from the solvent molecule relative to the 2-adamantyl radical.

In the radical chlorocarbonylation of adamantane[90] the 1- and 2-isomers are formed in proportions of 55:45. Among other advantages, this reaction provides a convenient method for the preparation of adamantane-2-carboxylic acid or its ester:

$$Ad + (COCl)_2 \xrightarrow{(C_6H_5COO)_2} \underset{55\%}{AdCOCl\ (1)} + \underset{45\%}{AdCOCl\ (2)} .$$

In a recent paper Gleicher et al.[91] described the effect of atomic bromine (generated photochemically from *N*-bromosuccinimide) on adamantane and some of its 1-substituted derivatives; the reactions were carried out in carbon tetrachloride at 40°C. In each case a complex mixture of products is formed since both bridgehead and bridge positions are substituted by chlorine (from carbon tetrachloride) and bromine.

An interesting observation was made when deuterated adamantane was subjected to direct photochemical hydroximation with a mixture of chlorine and nitric oxide[92]. This reaction, which in all probability has a radical mechanism[93], does not involve the bridgehead positions in adamantane:



Peroxides of the adamantane series constitute a new little investigated class of compounds and therefore it is appropriate to mention here a study of the kinetics of the decomposition of the t-butylperoxy-ester of adamantane-1-carboxylic acid, which takes place via the intermediate formation of the adamantyl radical according to the mechanism[94]

$$Ad\text{-}\!\!\!\!\!\!\!\quad\overset{O}{\overset{\|}{C}}O\text{-}OC(CH_3)_3 \longrightarrow Ad\cdot + CO_2 + (CH_3)_3CO\cdot .$$

4. Reactions Involving the Bridgehead Positions

A large number of studies on the reactivity of adamantanes in the bridgehead positions have been made. The present review quotes all the investigations in this field, but only the most interesting and original of these are considered in detail.

Again much attention is devoted to the problem of the halogenation of adamantane. In the presence of aluminium chloride adamantane is readily chlorinated by agents such as acetyl chloride, propyl and isopropyl chlorides[95], and thionyl chloride[96]. The replacement of substituents in certain adamantane derivatives by bromine takes place readily on refluxing with anhydrous bromine[97]:

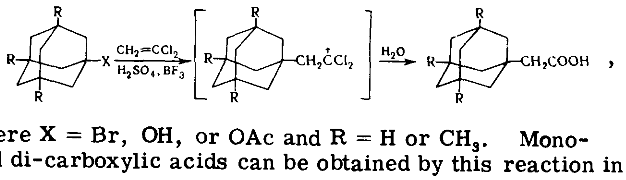
$$Ad - X \xrightarrow{Br_2} AdBr ,$$

where X = H, F, Cl, or OH. The reaction does not occur when X = CN, CO_2H, CH_3, or p-$NO_2C_6H_4$. The interchange of halogens of the bridgehead positions of adamantane is also possible using hydrogen halides[98]:

$$\begin{tikzcd}& AdBr \arrow[dl, shift right, "HF"'] \arrow[dr, shift left, "HCl"] & \\ AdF \arrow[ur, shift right, "HBr"'] \arrow[rr, shift left, "HCl"] & & AdCl \arrow[ul, shift left, "HBr"] \arrow[ll, shift left, "HF"]\end{tikzcd}$$

A number of studies have been made on the bromination catalysts[99,100]. The bromination of the side chain in adamantanes does not present difficulties; bromine in this position exhibits its normal mobility[100].

Bott extended his previously developed method for the synthesis of carboxylic acids using 1,1-dichloroethylene[101] to compounds of the adamantane series[102]:



where X = Br, OH, or OAc and R = H or CH_3. Mono- and di-carboxylic acids can be obtained by this reaction in

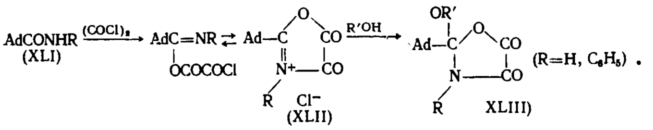
---

‡ The decarbonylation reactions were carried out at 135°C in carbon tetrachloride using di-t-butyl peroxide as an initiator.

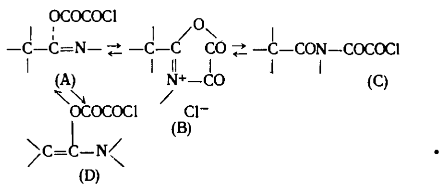
§ The solvolysis was carried out in 80% ethanol at 25°C.

high yields. When 1,1,2-trichloroethylene is introduced into this reaction, the same series of acids is formed with the chlorine atom in the α-position[103].

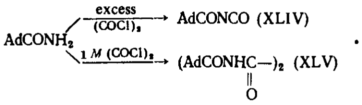
While the reactions of adamantylacetic acid involving the carbonyl group take place in the usual way and lead to a series of derivatives[104], the reactions of adamantane-1-carboxamides with oxalyl chloride have a mechanism different from that which usually obtains[105]. The reaction of adamantane-1-carboxamide (XLI) with oxalyl chloride at 0°C results in the intermediate formation of the unstable oxazoline-4,5-dione (XLII), which on treatment with protic solvents gives rise to substances with the general formula (XLIII):



The previously described reactions of carboxamides with oxalyl chloride lead to the formation of open-chain compounds (of types C or D):



The reaction of adamantane-1-carboxamide with oxalyl chloride in various molar proportions at a temperature above 20°C leads to the formation of adamantane-1-carbonyl isocyanate (XLIV) and *NN*-bis(adamantane-1-carbonyl) oxamide (XLV):



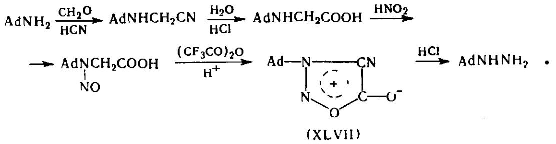
1-Aminoadamantane and its derivatives formed using the amino-group continue to attract the attention of chemists and biochemists as physiologically active substances. This concentration on the chemistry of 1-aminoadamantane proved very fruitful not only from the standpoint of medical chemistry but is also extremely interesting in its synthetic aspect. There are very many relevant examples and some of them will be considered.

For instance, the application of the Ritter reaction to 1-bromoadamantane and its subsequent development gave high yields of various *N*-(1-adamantyl)amides (XLVI)[106]:

$$AdBr \xrightarrow{H_2SO_4} Ad^+HSO_4^- \xrightarrow{RCN} AdN{=}\overset{+}{C}RHSO_4^- \xrightarrow{H_2O} \underset{(XLVI)}{AdNHCOR}\ .$$

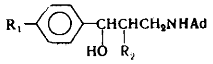
The alkylation of aliphatic and aromatic amines with 1-bromoadamantane has been investigated[107,108]; the reaction takes place under severe conditions.

1-Hydrazinoadamantane cannot be obtained directly but only via the intermediate formation of the sydnone (XLVII)[109]:



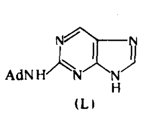
(XLVII)

The synthesis of 1-(3-aryl-3-hydroxypropylamino)adamantanes (XLIX)[110], 1-(3-aryl-3-hydroxypropylamino)adamantanes (XLVIII)[110], and adamantyl derivatives of aminopurines (L), aminopyrimidines (LI)[111], *p*-aminobenzamide, and *p*-aminobenzenesulphonamide[112] also required far-reaching development:

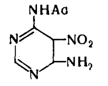


(XLVIII)

(XLIX)



(L)



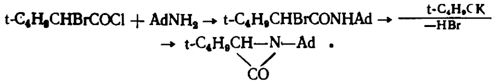
(LI)

This applies equally to the synthesis of adamantane compounds containing in the side chains, diethylamine, piperidine, morpholine, and pyrrolidine residues[113].

For biochemists, the reactions of aminoadamantanes in the organism are of primary interest; the microbiological oxidation of some of these compounds has been studied[114].

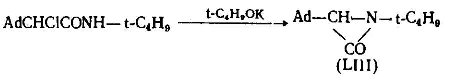
The synthesis, and chemical and physical properties of α-lactams of the adamantane series are of considerable interest. This is due to the fact that the α-lactams are the only class of three-membered heterocycles with a carbonyl group; a disadvantage of these reactive compounds is their low thermal stability, which of course hinders the study of their properties.

1-(1-Adamantyl)-3-t-butylaziridinone (LII), synthesised by the mechanism presented below, proved to be very stable[115,116], which made possible a detailed study of the chemical properties and spectroscopic characteristics of compounds of this class:



(LII)

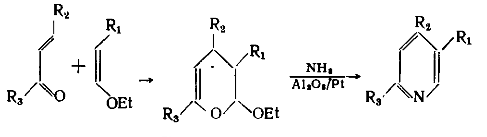
The α-lactam (LIII) was obtained by the same mechanism[117]:



(LIII)

The behaviour of 1-aminoadamantane in the Dem'yanov reaction has been investigated[118]. Numerous derivatives have been synthesised from aldehydes and ketones of the adamantane series. Aldehydes derived from adamantane have been obtained by the oxidation of the corresponding alcohols with lead tetra-acetate[119], by the reaction of organomagnesium derivatives of bromoalkyladamantanes with orthoformic ester[120], and also by other methods[117,121].

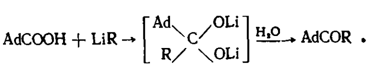
Unsaturated aldehydes are formed as a result of crotonic condensation[120] or by the condensation of acetals with ethyl vinyl ether via 1,1,3-triethoxyalkanes[122]. The acetals of adamantane aldehydes are converted into 1-adamantyl vinyl ethers when pyrolysed on magnesium phosphate[122]. Glutaric aldehydes of the adamantane series[123] and adamantylpyridines[124] have been obtained from unsaturated aldehydes or vinyl ethers via the corresponding pyrans:



where R_1 = H, Ad, or CH_2Ad, R_2 = H or CH_2Ad, and R_3 = H or Ad.

Aldehydes of the adamantane series form cyanohydrins which are hydrolysed to α-hydroxyacids, undergo the crotonic condensation, and are very readily oxidised (unusually so for aliphatic aldehydes) to the corresponding carboxylic acids on standing in air[120].

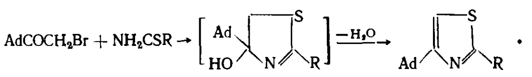
A convenient method for the synthesis of adamantyl ketones consists in the reaction of adamantane-1-carboxylic acid with alkyl-lithium[125]:



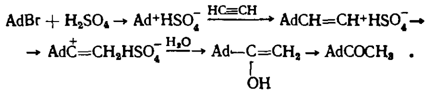
$$\mathrm{AdCOOH + LiR} \rightarrow \left[\begin{matrix}\mathrm{Ad}\diagdown & & \diagup\mathrm{OLi}\\ & \mathrm{C} & \\ \mathrm{R}\diagup & & \diagdown\mathrm{OLi}\end{matrix}\right] \xrightarrow{\mathrm{H_2O}} \mathrm{AdCOR}\ .$$

where R = CH_3, C_2H_5, or iso-C_3H_7.

Adamantyl methyl ketone enters into the Reformatskii reaction with bromosuccinic ester and the Mannich reaction with formaldehyde and dimethylamine[126]. The introduction of bromine into the α-position relative to the carbonyl group is possible by direct bromination or by the decomposition of the diazoketone obtained from the chloride of adamantanecarboxylic acid and diazomethane. The bromoketone can condense with acid thioamides to form thiazoles[127]:



The interest in derivatives of adamantane with multiple bonds, which is the most recent and little investigated group of substances of this type, can be readily understood. Sasaki et al.[128] reported the formation of a vinyl cation and its rearrangement on addition of the adamantyl cation to acetylene. The reaction proceeds as follows:

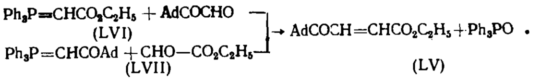


$$\mathrm{AdBr + H_2SO_4 \rightarrow Ad^+HSO_4^- \xrightarrow{HC\equiv CH} AdCH{=}CH^+HSO_4^- \rightarrow}$$
$$\mathrm{\rightarrow Ad\overset{+}{C}{=}CH_2HSO_4^- \xrightarrow{H_2O} Ad{-}\underset{\displaystyle OH}{\underset{|}{C}}{=}CH_2 \rightarrow AdCOCH_3}\ .$$

1-Vinyladamantane was obtained by the thermal cleavage of β-(1-adamantyl)ethyl-S-methylxanthate (LIV) in the Chugaev reaction[129]:

$$\underset{\mathrm{(LIV)}}{\mathrm{AdCH_2CH_2O{-}CS{-}SCH_3}} \rightarrow \mathrm{AdCH{=}CH_2 + CH_3SH + COS}\ .$$

The ethyl ester of β-(1-adamantoyl)acrylic acid (LV) may be synthesised either from 1-adamantylglyoxal and ethoxycarbonylmethylenetriphenylphosphorane (LVI) or from ethyl glyoxalate and (1-adamantoylmethylene)triphenylphosphorane (LVII) [130]:



$$\left.\begin{matrix}\mathrm{Ph_3P{=}CHCO_2C_2H_5 + AdCOCHO}\\ \mathrm{(LVI)}\\ \mathrm{Ph_3P{=}CHCOAd + CHO{-}CO_2C_2H_5}\\ \mathrm{(LVII)}\end{matrix}\right] \rightarrow \mathrm{AdCOCH{=}CHCO_2C_2H_5 + Ph_3PO}\ .\qquad \mathrm{(LV)}$$

Unfortunately the literature information about polyadamantanes is very scanty. It is noteworthy that the polyadamantane obtained by the Wurtz condensation of 3,3-dibromo-1,1-diadamantane is crystalline to the extent of more than 80% [131].

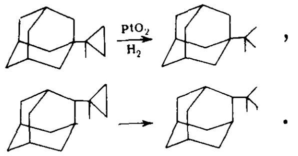
Alkylation of benzene with bromoadamantanes takes place readily[132,133] and, depending on the conditions, yields either adamantane containing several phenyl groups[134] or benzene containing up to three adamantyl residues[135]. These compounds are interesting because they comprise the adamantane nucleus with a tendency towards nucleophilic substitution reactions and the benzene ring which undergoes the characteristic electrophilic substitution reactions. Experiments have shown[132,133] that both nuclei exhibit their characteristic reactivities.

Alkylation of adamantane with olefins takes place readily in the presence of aluminium halides[136]. Under the same conditions 1-adamantylacetaldehyde is formed from 1-hydroxyadamantane[47].

It is very remarkable that the reaction of oestrone with adamantol did not yield an alkylation product; in this case adamantol reacted as a dehydrated agent and $\Delta^{9(11)}$-oestrone was isolated[137].

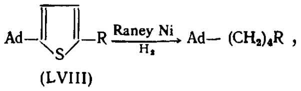
Organometallic derivatives of adamantane in which the metal is directly linked to the nucleus for a long time remained a "blank spot" in the chemistry of substances of this class. In 1965 Landsbury and Sidler[138] described for the first time the preparation of lithioadamantane by the action of t-butyl-lithium on iodoadamantane[138]. Bromoadamantane and alkyl-substituted adamantanes containing bromine in the side chain form Grignard reagents[139]. The synthesis of 1-(3-aryl-3-hydroxypropylamino)ada-bromo-derivatives of adamantane and zinc leading to the formation of 3,7-dimethylenebicyclo[3,3,1]nonane and 1,3,5,7-tetramethylenecyclo-octane.

Among new trends, one may include the study of the catalytic reactions and the pyrolysis of adamantane compounds. Hydrogenolysis of adamantanes containing the cyclopropane ring in the side chain takes place under mild conditions and yields compounds with a t-butyl substituent[140]:



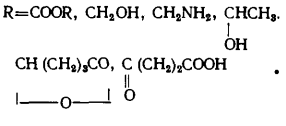
Pyrolysis of adamantane and its catalytic reactions in the presence of aluminosilicate or aluminium–chromium catalysts were investigated by Kazanskii and coworkers[141,142]; it was shown that the composition of the products in the catalytic reaction and pyrolysis is similar (mainly monocyclic aromatic hydrocarbons).

The catalytic desulphuration of adamantane derivatives of type (LVIII) is a convenient method for the synthesis of adamantanes containing a functional group in the side chain[143]:



(LVIII)

where



$$\mathrm{R{=}COOR,\ CH_2OH,\ CH_2NH_2,\ \underset{\displaystyle OH}{\underset{|}{C}H}CH_3,}$$
$$\mathrm{\underbrace{CH(CH_2)_3CO}_{O},\ \underset{\displaystyle O}{\underset{\|}{C}}(CH_2)_2COOH}\ .$$

The oxidation of adamantane and its homologues takes place smoothly when chromium oxide in an acid medium is employed as an oxidising agent. Then, depending on the amount of oxidant employed, mono- or di-hydroxyderivatives of adamantane are formed[144].

A number of studies[145–151] illustrate the usual course of the reaction in the adamantane side chain.

VI. QUANTITATIVE STUDY OF THE REACTIVITY OF ADAMANTANE.

Much work has been done on the reactivity of adamantane. One of the promising studies in the field is the comparative investigation of the stability of the adamantyl cation in a series of other polycyclic structures. Using the concept of the preferential planar configuration of the cations, Schleyer, Fort, and Gleicher proposed an elegant theory to account for the differences in the rates of solvolysis of the tertiary bromo-derivatives of adamantane, homoadamantane, bicyclo[2,2,2]octane, bicyclo[3,2,1]-nonane, bicyclo[2,2,1]heptane, bicyclo[2,1,1]hexane, and bicyclo[3,3,1]nonane and t-butyl bromide[3,6,152]. An undoubted achievement of their investigations is a satisfactory agreement between the experimental rate constants for the solvolysis of 1-chlorobicyclo[3,3,1]nonane and 1-bromobicyclo[3,3,1]nonane and the constants predicted by the theory[153,154].

Nucleophilic substitution reactions of bromine in 1-bromoadamantane take place exclusively by a unimolecular S_N1 mechanism. From this point of view, 1-bromoadamantane is exceptionally convenient for a detailed study of the structure of the transition state in unimolecular reactions. In this connection the problem of the involvement of the solvent in the activated complex is of interest. The studies in which the kinetics of the solvolysis of 1-bromoadamantane in aqueous ethanol and dimethyl sulphoxide were investigated[155,156] are probably the first stage of such investigations.

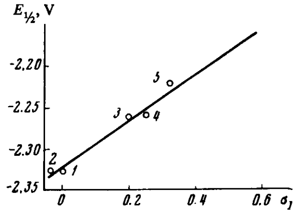


Figure 1. Variation of the half-wave potential $E_{1/2}$ with the σ_I constants of the substituents for 3-substituted 1-bromoadamantanes with the following substituents: 1) H; 2) CH_3; 3) CH_2COOCH_3; 4) OH; 5) $COOCH_3$.

The effect of substituents on the stability of the adamantyl and adamantylmethyl cations has been studied[157-159]. As was to be expected, the introduction of electronegative groups lowers the stability of the cation. It is remarkable that the presence of methyl groups at the bridgehead positions retards the solvolysis of bromoadamantane. Similar "anomalies" in the effect of the methyl group were also noted earlier[160]. Schleyer and coworkers suggest that in this case the anomaly is associated with some deformation of the cation in the transition state due to the presence of the methyl group. However, the problem remains open, because in other processes involving the formation of a cation the methyl groups exhibit electron-donating properties or have no effect[139].

The results obtained in the solvolysis of 3-substituted 1-bromoadamantanes were compared[157] with the σ^* constants and a fairly high correlation coefficient ($r = 0.996$) was obtained. In an analogous study[158] carried out using a large number of polar constituents, a correlation between the rate constants and the pK_a for the corresponding adamantanecarboxylic acid ($r = 0.986$) was obtained. The existence of such correlation is evidence that the substituents do not influence the geometrical structure of the adamantyl cation during its formation or their effect is negligibly small.

The mutual effects of the substituents in the adamantane nucleus are clearly shown in the hydrolysis of substituted acylamino-derivatives of adamantane. Depending on the nature of the substituent, the nitrogen–adamantane or the nitrogen–acyl group bond is cleaved[161,162]. In a number of studies a quantitative estimation of the influence of the substituents was undertaken. As usual, the first step was to investigate the ionisation constants of adamantanecarboxylic acids[163,165].

The correlation coefficient between the pK_a of 3-substituted adamantane-1-carboxylic acids and σ^* constants is 0.950–0.987 depending on whether account is taken of all the substituents or whether part of the points deviating to the greatest extent are rejected. The coefficient of sensitivity for this series $\rho^* = 0.263$. For bicyclo[2,2,2]-octane and *trans*-1,4-cyclohexane systems, these quantities are respectively 0.295 (in 50 wt.% ethanol) and 0.247. Such close values of ρ^* for systems where the substituents and the reaction centres are separated by different numbers of carbon atoms are evidence in favour of the hypothesis that the effect of substituents is transmitted mainly through space[160,166].

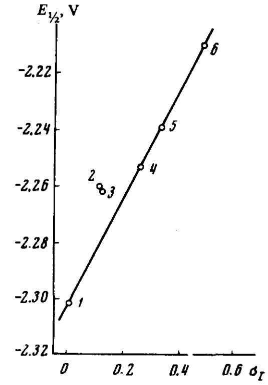

Figure 2. Variation of the half-wave potential $E_{1/2}$ with the σ_I constants of the substituents for 3-substituted 1-bromomethyladamantanes with the following substituents: 1) H; 2) C_6H_5; 3) CH_2COOCH_3; 4) OH; 5) $COOCH_3$; 6) Cl.

The effect of substituents on the reactivity has also been demonstrated by Leibzon et al.[167], who investigated the polarographic behaviour of derivatives of 1-bromoadamantane and 1-bromomethyladamantane. Bromine was reduced in 90% aqueous dimethylformamide at room temperature. Figs. 1 and 2 show the variation of the half-wave potentials $\epsilon_{1/2}$ with the σ_I constants of the substituents.

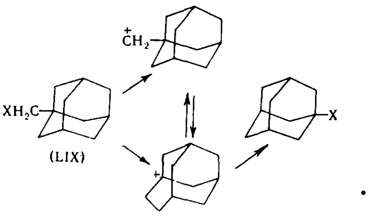
The sensitivities ρ_I of the reaction series for 1-bromomethyladamantanes and 1-bromoadamantanes were respectively 0.168–0.196 and 0.284–0.294. The correlation coefficient varied from 0.947 to 0.999. The low sensitivities of this reaction series are due to the considerable distance of the substituents from the reaction centre.

Using Palm's method[166], Leibson et al. estimated the contribution of the effect of substituents transmitted through space as 25% of the total effect. For the ionisation of adamantanecarboxylic acids, in which unit charge is produced, this quantity amounts to as much as 50% {57% for the bicyclo[2,2,2]octane system and 70% for the *trans*-1,4-cyclohexane system}.

In an overall assessment of studies concerned with the quantitative estimation of the effect of substituents, a similarity between the behaviour of cyclohexane, bicyclooctane, and adamantane systems may be noted.

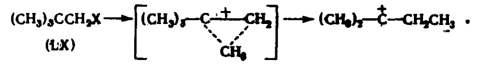
The exceptional properties of the adamantane structure—freedom from Baeyer and Pitzer strain—led to extensive application of adamantane derivatives as models for the solution of theoretical problems in organic chemistry.

Reactions with formation of 1-adamantylmethyl cations are known to involve a rearrangement of the adamantane structure to the homoadamantane structure, which is sterically more strained:



This finding has been used to elucidate the mechanism of the neopentyl rearrangement[168]. The problem of whether the neopentyl rearrangement takes place by the stepwise mechanism (1) or whether the ionisation process and the rearrangement occur simultaneously [mechanism (2)] is still controversial.

$$(CH_3)_3CCH_2X \longrightarrow (CH_3)_3C\overset{+}{C}H_2 \longrightarrow (CH_3)_2\text{—}\overset{+}{C}\text{—}CH_2CH_3\ , \qquad (1)$$



$$\underset{(LX)}{(CH_3)_3CCH_2X} \longrightarrow \left[(CH_3)_2\text{—}C\overset{+}{\text{—}}CH_2 \cdots CH_3\right] \longrightarrow (CH_3)_2\text{—}\overset{+}{C}\text{—}CH_2CH_3\ . \qquad (2)$$

To solve this problem, some investigators suggest the use of a model compound of the neopentyl type, which, reacting by the ionic mechanism, would undergo rearrangement with greater difficulty than the neopentyl derivative. 1-Adamantylmethyltoluene sulphonate $AdCH_2OTS$ (LIX) has been suggested as a compound of this kind. It was postulated that the rates of solvolysis of neopentyltoluene sulphonate (LX) and of compound (LIX) should be similar if the rate-limiting step involves simple ionisation with formation of $Ad\overset{+}{C}H_2$ and $(CH_3)_3C\overset{+}{C}H_2$ respectively.

If, on the other hand, the rate-limiting step involves simultaneous ionisation and rearrangement, then neopentyltoluene sulphonate should be solvolysed faster (the migration of the methyl group takes place more readily than the rearrangement of the adamantane to the homoadamantane system, which is sterically more strained). It was found that the rate constants for the solvolysis of adamantylmethyltoluene sulphonate are actually somewhat higher than the corresponding rate constants for the neopentyl derivative (evidently owing to the inductive effect of the adamantane nucleus). According to the authors, these results are evidence in favour of the stepwise mechanism of the neopentyl rearrangement [mechanism (2)], in which ions (ion pairs) are formed in the first stage.

Grob and coworkers[169,170] investigated the mechanism of the fragmentation of γ-amino- and γ-alkyl-halogeno-derivatives using as an example the solvolysis of the amino- and alkyl derivatives of 1-bromoadamantane in 80% aqueous ethanol. They showed that the rate constants for the solvolysis of 3-amino-1-bromoadamantane and its *N*-methyl derivatives greatly exceed those for the corresponding 3-alkyl-1-bromoadamantanes. The activation entropy is lower in the first case than in the second. Moreover, whereas the sole products of the solvolysis of 3-alkyl-1-bromoadamantanes are their hydroxy-derivatives, in the case of the amino-compounds products indicating the fragmentation of the initial compounds were detected.

This led the authors to the conclusion that the solvolysis of alkyl-substituted 1-bromoadamantanes takes place by the usual unimolecular nucleophilic substitution mechanism.

The data on the solvolysis of the amino-derivatives are evidence in favour of the synchronous fragmentation of γ-amino-substituted halides of the following type:

$$R_2N\text{—}\underset{|}{\overset{|}{C}}\text{—}\underset{|}{\overset{|}{C}}\text{—}\underset{|}{\overset{|}{C}}\text{—}X \rightarrow R_2\overset{+}{N}\text{=}C\langle + \rangle C\text{=}C\langle + X^- \ .$$

The authors attribute the reason for the synchronous occurrence of this type of five-centre reaction to the exceptionally favourable geometrical disposition of all the components of the structure.

Owens et al.[171] investigated the abstraction of hydrogen from 1-substituted adamantanes by the trichloromethyl radical. They noted that the reaction involves mainly bridgehead positions. The yield of side products does not exceed 10%. Treatment of the results using the Taft equation leads to $\rho^* = -0.40 \pm 0.04$ with a high correlation coefficient ($r = 0.980$).

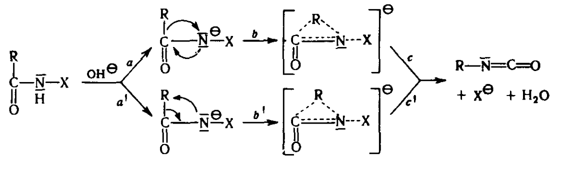
Using the Kirkwood–Westheimer equation describing the interaction between a dipole and a point charge, the authors described the transition state by a set of canonical structures:

$$RH \cdot CCl_3 \leftrightarrow R \cdot H\text{—}CCl_3 \leftrightarrow R^+H\text{—}CCl_3$$

and determined the amount of ionic character of the transition state as 10–12%.

An analogous approach to the determination of the transition state was employed by Gleicher et al.[91] They investigated the reaction of 1-substituted adamantanes with atomic bromine generated from *N*-bromosuccinimide. The sensitivity of this reaction $\rho^* = -0.59$, i.e. is somewhat greater than in the reaction with the trichloromethyl radical. The authors determined the "degree of ionic character" of this process as 17%.

The pronounced electron-donating properties of the adamantane nucleus threw light on the hitherto not entirely clear mechanism of rearrangements at the nitrogen atom (the Hofmann, Curtius, and Lossen rearrangements)[172]. On the basis of the available experimental data, the mechanism of these rearrangements may be represented thus:



Strictly speaking, the experimental data do not allow a choice between pathways *a–c* or *a′–c′*, although the majority of workers adopt the first without any stipulation. The above rearrangements take place readily and with high yield also in the adamantane series[161,172,173], although it is known that adamantane readily forms the 1-adamantyl cation and the formation of the 1-adamantyl anion is not typical for this compound, i.e. the adamantyl group cannot migrate to the nitrogen atom with its electron pair. Therefore the mechanism of the rearrangement via the pathway $a'-b'-c'$ must be regarded as more likely.

Kevill and Weitl[174] attempted to revise the mechanism of the decomposition of alkyl formates using 1-adamantyl formate as an example. They assert that, of the two alternative mechanisms of the decomposition of alkyl formates

(I)

$$ROCOCl \longrightarrow R^{+}Cl^{-} + CO_2 \longrightarrow RCl \qquad \text{(II)}$$

mechanism (II) is more likely.

Baldwin and Foglesong[175,176] adduced the results obtained in the solvolysis of 8,9-dehydro-2-adamantyl 3,5-dinitrobenzoate as a model compound to account for the unexpectedly high reactivity of cyclopropylmethyl derivatives. They concluded that in the transition state both structures give rise to a non-classical carbonium ion and in the case of adamantane the 2-, 8-, and 9-positions are approximately equivalent.

In conclusion we may note certain purely theoretical studies dealing with adamantane.

The high symmetry of adamantane, which greatly simplifies calculations, was used by Kitaigorodskii et al.[177], who attempted to calculate the Debye temperature θ for the face-centred cubic crystal of adamantane, having adopted intermolecular interaction as a basis. The values of θ obtained are quite reasonable, but it is so far difficult to test the results experimentally.

Quantum-chemical calculations on adamantane by the LCAO-MO method permit the calculation of the energies of the highest occupied molecular orbital (usually set equal to the ionisation potential with the sign reversed) and the charges at the carbon atom[178]. The latter proved to be −0.09 for the carbon atoms of the methylene (CH_2) groups and +0.18 for the methylidyne (C−H) groups. It is so far difficult to decide whether such calculations have any practical value, particularly since the differences between the reactivities at the bridgehead and bridge positions in adamantanes are quite definitely caused by the geometry of the transition state.

Maksic and Klasinc[179] employed the maximum overlap method proposed by Murrell[180] to calculate the degree of hybridisation of the carbon atoms in adamantane. They found that the hybridisation is somewhat different from sp^3 hybridisation, which they believe to be consistent with the slight deviations of the valence angles from the tetrahedral values.

VII. APPLICATIONS¶

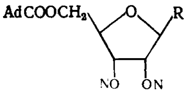
Adamantane derivatives have found the widest application as physiologically active substances.

1-Aminoadamantane (amantidine) is an effective prophylactic agent against diseases due to viruses of groups A, A′, and A-2. Amantidine does not act directly on the virus but prevents its penetration into the cell[181-183]. For the same reason amantidine prevents the development of sarcoma centres on a nucleated culture[184]. Amantidine is relatively non-toxic (λD_{50} = 700 mg kg^{-1}), but can have a side effect on the functioning of kidneys[185].

A number of adamantane derivatives of the type 1-R-Ad, where R = NH_2, NHEt, $NHCONH_2$, NCO, NCS, NHCONO, NHCOHN, or NHCONHPh sensitise the contraction of the smooth muscle initiated by 5-hydroxytryptamine[186].

Esters of adamantane-1-carboxylic acid readily dissolve in lipids and are resistant to hydrolysis owing to steric hindrance. This makes possible specific changes in the properties of testosterone[187].

The esters of adamantanecarboxylic acid and certain nucleosides with the general structure where R = 6-azauracil, 6-mercaptopurine,



adenine, or hypoxanthine, exhibit antineoplastic activity[188].

$(CH_3)_3AdCON(^{14}CH_3)_2$ has been used to investigate the rate of oxidative *N*-demethylation[189].

Substituted amides of adamantane carboxylic acid,

$AdCONR_1R_2$	R_1	H	H	CH_3	H	H	H	H	H
	R_2	H	CH_3	CH_3CH_2	CH_2OH	$COCH_3$	CHO	COPh	CO_2Et

may serve as sedatives[190].

The introduction of the adamantyl residue into 2-hydroxynaphthoquinone yields antimalarial preparations[191]. Polychloro- and polyfluoro-derivatives of adamantanecarboxylic acid exhibit insecticidal activity[192].

The Structure of Aliphatic Diazo-compounds and Their Isomers

O.P.Studzinskii and I.K.Korobitsyna

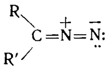
The review describes the modern concepts concerning the electronic fine structure of aliphatic diazo-compounds based on experimental data (from infrared, ultraviolet, and PMR spectroscopy) and also quantum-mechanical calculations by the LCAO-MO method. These concepts explain many chemical properties of diazoalkanes and sometimes make it possible to predict them. Apart from "classical" aliphatic diazo-compounds, the structures and properties of the isomers—linear (*N*-isocyanamine) and cyclic (diazirines)—are considered.
The bibliography comprises 99 references.

CONTENTS

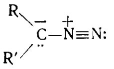
I. INTRODUCTION

About ten years have elapsed since the publication of extensive reviews [1] and monographs [2,3] on the structure and properties of diazoalkanes. During this period many papers have appeared on the fine structure of aliphatic diazo-compounds and their isomers. In the present review an attempt is made to give a general account of these new data, which are important for theoretical organic chemistry. The literature up to 1969 inclusive has been compiled.

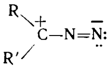
The problem of the structure of aliphatic diazo-compounds arose soon after their discovery by Curtius [4-10] in 1883. It was not until 50 years later that Boersch [11,12] demonstrated by physical methods and subsequently Clusius [13] by chemical methods the linear structure of diazo-compounds. In 1920–1930 it was suggested that the structure of diazoalkanes by represented by formulae (I), (II), and (III):[14-18]



(I)



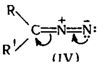
(II)



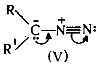
(III)

Usually in the discussion of the structure of the CN_2 group of diazoalkanes in the ground state formulae (I) and (II) only are employed with the coordinate bonds $N\rightleftharpoons N$ and $C\leftarrow N$ respectively. This is because formula (III) corresponds to a less stable molecular state compared with (I) and (II), since it contains fewer covalent bonds and the charges are removed to a greater distance [2].

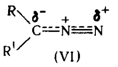
The interatomic distances in diazomethane measured by Boersch by electron diffraction are inconsistent with the values calculated for these formulae on the basis of the additivity of the covalent radii even after correction for the atomic charges [19,20]. The experimental interatomic distances are intermediate between the values calculated for structures (I) and (II). This deviation is explained by the equalisation of electron density in the CN and NN bonds. The CN and NN bonds are non-integral: the CN bond is intermediate between a double and a single bond and the NN bond is intermediate between a double and triple bond. The negative charge of the CN_2 group is in fact distributed between the α-carbon and β-nitrogen atoms, which can be expressed by formulae (IV), (V), and (VI):[2]



(IV)



(V)



(VI)

The most correct representation of diazoalkanes is by a combination of the limiting formulae (I) and (II) each making a definite contribution to the resonance hybrid. However, partly because these contributions are not known and partly for the sake of simplicity, only one of them is employed. Formulae (IV)–(VI) are somewhat more rigorous.

Some data on the distribution of electron density in diazoalkane molecules can be derived by studying their chemical properties. In many reactions diazoalkanes exhibit nucleophilic properties, since the carbon and the β-nitrogen atoms of the CN_2 group are negatively charged and the positively charged α-nitrogen atom has already formed the maximum number of covalent bonds and cannot serve as a source of electrophilic activity [2].

It follows from the above considerations that the nucleophilic properties of diazoalkanes become weaker on introduction of electron-accepting substituents (for example, carbonyl or alkoxycarbonyl groups) and the thermal stability and the resistance to acids of diazo-compounds increase, while the introduction of electron-donating substituents (for example alkyl groups) make diazoalkanes more nucleophilic, reducing their stability at the same time. These problems are described in detail in Huisgen's review [1] and the monographs of D'yakonov [2] and Zollinger [3].

A more thorough study of the fine structure of diazoalkanes and the elucidation of the problem of the distribution of electron density in aliphatic diazo-compounds became possible only as a result of the application of spectroscopic and quantum-mechanical research methods.

II. ELECTRONIC FINE STRUCTURE OF ALIPHATIC DIAZO-COMPOUNDS

1. Diazohydrocarbons and Diazocarbonyl Compounds (Structural Studies by Spectroscopic Methods)

In structures (I) and (II) different electron densities arise at the α-carbon atom and in substituents R and R′, to that the chemical shifts of the protons at the α-carbon atom or in its substituents are then different depending on which particular form predominates. It is to be expected that the greater is the contribution of structure (II), i.e. the greater the negative charge at the α-carbon atom, the greater will be the chemical shift of the protons (on the τ scale) and conversely.

In 1964 Ledwith and Friedrich[21] measured the PMR spectra of a series of diazo-compounds and interpreted the results. Table 1 lists the chemical shifts of the protons at the α-, β-, and γ-carbon atoms and the protons in the aromatic rings of the substituents. The results show that the chemical shift of the protons in diazomethane is much greater than in allenes, olefins, and aldehydes[21], which suggests a higher degree of screenings of the methylene protons and consequently a greater contribution of the carbanion structure (II) compared with structure (I).

Table 1. Chemical shifts of the protons in diazoalkanes.

Diazo-compound	Chemical shift of protons on τ scale, p.p.m*	Multiplicity of signal
CH_2N_2	α 6.92	
CH_3CHN_2	α 6.78 β 8.30	 doublet
$CH_2{=}CH{-}CHN_2$	α 5.42 β 6.71 γ 8.93	multiplet quartet triplet
$C_2H_5OOCCHN_2$ $CH_3OOCCHN_2$	α 5.04 α 5.04	
	α 3.38 β 4.14	quartet quartet
$PhCHN_2$	α 5.42 Ar 3.10	multiplet
Ph_2CN_2	Ar 2.74	singlet

*The operating frequency was 40 MHz and the following solvents were employed: carbon tetrachloride, methylene chloride, and trichlorotrifluoroethane. The effect of the solvent on the chemical shift is slight.

Koster[22], who made a thorough study of the PMR spectra of diazomethane in various solvents, holds similar views. However, one cannot exclude the possibility that such increase in the screening of α-protons in diazomethane and its alkyl-substituted derivatives can be partly accounted for also by the diamagnetic anisotropy of the diazo-group, as happens in acetylenes and nitriles[23,24].

The chemical shift of the α-protons of diazoethane is similar to that of the protons in diazomethane and therefore diazoethane is best described by formula (VIIa):

$$CH_3{-}\overset{-}{C}H{-}\overset{+}{N}{\equiv}N: \leftrightarrow CH_3{-}CH{=}\overset{+}{N}{=}\overset{-}{N}: \leftrightarrow CH_3{-}\overset{+}{C}H{-}N{=}\overset{-}{N}: .$$

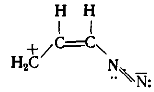
(VIIa) (VIIb) (VIIc)

One of the limiting structures (VIIc) is probably not achieved at all, since any appreciable contribution by this formula to the resonance hybrid would result in descreening of the β-protons, while their experimental chemical shift has the normal value for a methyl group joined to an unsaturated system.

Among all the protons of vinyldiazomethane, the greatest chemical shift (τ = 8.93 p.p.m.) corresponds to the protons at the γ-carbon atom. This finding is analogous to the increase of the screening of the carbanion methylene protons in allylmagnesium halides[25-27]:

$$CH_2{=}CH{-}\overset{-}{C}H{-}\overset{+}{N}{\equiv}N: \leftrightarrow \overset{-}{C}H_2{-}CH{=}CH{-}\overset{+}{N}{\equiv}N: .$$

(VIIIa) (VIIIb)

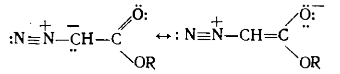


(IX)

The relative chemical shifts of the α-, β-, and γ-protons might lead to the conclusion that structure (VIIIb), in which there is the greatest negative charge at the γ-carbon atom, makes the most appreciable contribution to the real state of the molecule. However, this kind of interpretation of the PMR spectra of vinyldiazomethane must be treated with caution, since such appreciable screening of the γ-methylene protons is possible also when vinyldiazomethane exists in the *cis*-form (IX); it is then postulated that the screening effect of the NN bond is similar to that of the C=C and C=O bonds[28].

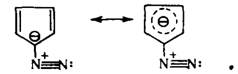
The chemical shifts of the α-protons of phenyldiazomethane and diazoacetic ester also indicate a greater contribution by the carbanion structure (II) compared with structure (I); the carbanion forms (Xa) and (XIa) of these diazo-compounds can be additionally stabilised by the transfer of the negative charge from the α-carbon atom to the phenyl or alkoxycarbonyl group [structures (Xb) and (XIb)].

(Xa) (Xb)



(XIa) (XIb)

In diazocyclopentadiene the chemical shift of the β-ring proton is similar to the shift of the proton in cyclopentadienyl-lithium, which suggests that diazocyclopentadiene (XII) has almost entirely the carbanionic structure in the ring which thus has the properties of a non-benzenoid aromatic system[29,30]†.



(XIIa) (XIIb)

Thus the carbanionic and nucleophilic nature of diazoalkanes, which is assessed on the basis of their chemical properties, are consistent with qualitative PMR spectroscopic data.

It must be emphasised that the terms "carbanionic" nature and "carbanionic" structure should not be understood solely as implying the transfer of the negative charge of the CN_2 group to the α-carbon atom (which can in fact occur only in diazomethane). They should be understood in a wider sense as the transfer of a major fraction of the negative charge to the α-carbon atom and to the substituents linked to it, which in fact occurs in all diazomethane derivatives

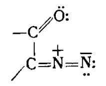
---

†Another aliphatic diazo-compound, which is also representative of a non-benzenoid aromatic system—diazocyclononatetraene—has been recently reported[31]. Its properties are being investigated.

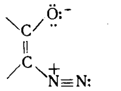
It follows from the above that the PMR spectroscopic method is used mainly to investigate the electronic structure of diazo-compounds with hydrogen atoms or hydrocarbon groups linked directly to the α-carbon atom. On the other hand, the interpretation of PMR spectroscopic data for α-diazocarbonyl and particularly α-diazo-$\beta\beta'$-dicarbonyl compounds is difficult and therefore infrared spectroscopy is widely employed to investigate the structures of these diazo-compounds.

α-Diazocarbonyl and α-diazo-$\beta\beta'$-dicarbonyl compounds occupy a somewhat special place among aliphatic diazo-compounds. They have a number of unusual properties for diazoalkanes: high resistance to the action of acids and heat, the absence of characteristic carbonyl reactions in many cases, and the capacity of individual compounds to form derivatives similar in type to aromatic diazonium salts[32].

Two limiting structures have been proposed for aliphatic diazocarbonyl compounds, for which the terms "diazo-oxide" (XIIIa) and "diazoanhydride" (XIIIb) have become established in the literature[32]:



(XIIIa)



(XIIIb)

The contributions by these structures to the resonance hybrid are estimated on the hypothesis that the transition from structure (XIIIa) to (XIIIb) will entail corresponding changes in the infrared spectrum. In consequence of the decrease of the double bond character in the carbonyl group, a shift of the absorption band to the long-wavelength region compared with the usual frequency for the keto- (or alkoxycarbonyl) group is to be expected. In the diazo-group there will be a change from a system of cumulative bonds in (XIIIa) to the NN triple bond of the diazonium structure in (XIIIb), which should give rise in the infrared spectrum to a shift of the absorption band associated with the NN stretching vibrations towards shorter wavelengths compared with diazohydrocarbons. These shifts of the absorption bands due to CO and NN stretching vibrations in fact characterise the contributions by structures (XIIIa) and (XIIIb) to the real state of the molecule[32-37].

In order to discover the region in which the absorption bands of the diazo-group in diazocarbonyl compounds may be located, we shall consider the aromatic diazonium salts (XIV) and the azides (XV):

(XIV)

$$R{-}\overset{+}{N}{=}\overset{-}{N}{=}\ddot{N}{:} \leftrightarrow R{-}\overset{=}{\ddot{N}}{-}\overset{+}{N}{\equiv}N{:}$$

(XV)

The real state of diazonium salts can be quite justifiably expressed by structure (XIV), the diazo-group absorbing in the region 2200–2300 cm^{-1}; on the other hand, the absorption by azides (XV), where the contributions by both structures are approximately equal, is observed in the region 2100–2160 cm^{-1}.[38,39]

Thus the diazo-group in diazocarbonyl compounds should absorb in the region 2000–2300 cm^{-1}. The greater is the shift within these limits towards higher frequencies, the greater is the contribution by structure (XIIIb) to the resonance hybrid, and the greater is the shift towards lower frequencies, the greater is the contribution by structure (XIIIa) (Table 2).

Naturally, the contribution by the diazoanhydride structure is particularly large in those compounds where the transition to the diazo-oxide form is impossible for some reason; an example of this is 5-diazouracil (ν_{N_2} = 2190 cm^{-1}).[32]

Absorption by the CO groups in diazocarbonyl compounds is to be expected in the region between 1720 cm^{-1} (absorption by the carbonyl group in ordinary ketones) and 1600 cm^{-1} (absorption by the carbonyl group in enolised β-dicarbonyl compounds with an intramolecular hydrogen bond)[32]. The greater is the shift towards lower frequencies, the greater is the contribution of the CO group to the formation of structure (XIIIb) and conversely (Table 3).

Table 2. The colour of aliphatic diazo-compounds and the frequencies of the absorption bands due to the diazo-group[32-37,40-42].

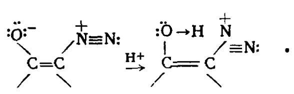
Diazo-compound	ν_{N_2}, cm^{-1}	Colour
Cyclic diazodicarbonyl compounds	2150-2190	colourless
R'-CO-CN$_2$-CO-R	2140-2160	colourless, yellow
R-CO-CN$_2$-R' (linear and cyclic)	2080-2130	greenish-yellow
Diazohydrocarbons	2020-2120	greenish-yellow, red

It was found[33,34] that not only the magnitude of the shift of the absorption band of the NN stretching vibrations but also the molar integral absorption corresponding to this band may serve as a criterion of the involvement of the limiting forms (XIIIa) and (XIIIb) in the resonance hybrid. The greater is the contribution by the diazoanhydride form (XIIIb) and therefore the greater is the high-frequency shift of the NN stretching vibration band, the lower is the molar integral absorption corresponding to this band. For example, for diazodicarbonyl compounds with an enhanced contribution of the diazoanhydride form, it is smaller by a factor of 1.5–2 than for diazomonocarbonyl compounds, amounting to (3.2–4.1) × 10^{-4} litre mole^{-1} cm^{-1} for the former and (4.6–5.2) × 10^{-4} litre mole^{-1} cm^{-1} for the latter[33-35].

Table 3. Absorption by the CO group in carbonyl and diazocarbonyl compounds[32].

Diazocarbonyl compound	$\nu_{C=O}$ in diazocarbonyl compounds, cm^{-1}	$\nu_{C=O}$ in carbonyl compounds, cm^{-1}
R—CN$_2$—CO—R'	1640—1670	1705—1725
R—CN$_2$—COOR'	1670—1720	1735—1750
R—CN$_2$—CH$_2$—COOR'	1735—1750	1735—1750
H—CN$_2$—CO—R'	1620—1630	1705—1725
H—CN$_2$—COOR'	1690	1735—1750

The structure of diazocarbonyl compounds approaches more closely the diazonium structure the greater is the number of carbonyl groups adjacent to the diazo-group. Then in the series of aliphatic diazo-compounds there is an increase in stability; thus diazoketones, which usually have a yellow or a greenish-yellow colour, are decomposed slowly by acetic and benzoic acids and fairly rapidly by inorganic acids. Diazodicarbonyl compounds are much more resistant to the action of acids. They can be frequently dissolved in concentrated sulphuric acid and be isolated unchanged on dilution with water. They are decomposed by concentrated acids only on heating. The explanation is that in diazodicarbonyl compounds, where the structure (XIIIb) makes a particularly large contribution, the proton is attached to the strongly electronegative oxygen atom and not to the α-carbon atom [form (XIIIa)] with formation of an unstable diazonium ion:



For this reason, the greater is the contribution by structure (XIIIb), the more resistant is the diazocarbonyl compound to the action of acids[32].

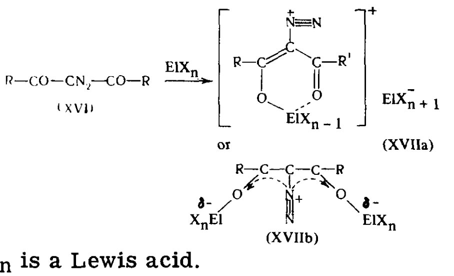
All the findings described above hold also for α-diazocarbonyl compounds; the carbonyl group in the β-position relative to the diazo-group makes no contribution to the formation of the diazoanhydride structure (Table 3). The contribution by structure (XIIIb) to the real state of the molecule increases when electron-accepting substituents (halogens and carbonyl or alkoxycarbonyl groups) are present next to the carbonyl or diazo-groups and decreases on introduction of electron-donating groups (for example, alkyl groups), which is confirmed by the spectroscopic and chemical properties in the series of diazocarbonyl compounds[33-35].

The decrease of the quantum yield of the photolysis of diazocompounds on passing from diazohydrocarbons to diazocarbonyl compounds is also explained by the increased contribution of the more stable diazonium structure (XIIIb)[43] (Table 4).

Table 4. Quantum yields of the photolysis of diazo-compounds[43].

Diazo-compound	Quantum yield
Ph_2CN_2	0.78
$C_2H_5OOCCHN_2$	0.66
$PhCOCHN_2$	0.46
$(PhCO)_2CN_2$	0.31
p-$(N_2CHCO)_2C_6H_4$	0.15

There exist also derivatives of aliphatic diazo-compounds whose structure is very close to that of diazonium salts; these are adducts of diazodicarbonyl compounds with Lewis acids—(XVIIa) or (XVIIb):[44-48]



where ElX_n is a Lewis acid.

Colourless crystalline compounds are formed as a result of the addition of the Lewis acid to the oxygen atom, which entails additional withdrawal of the negative charge from the carbon atom of the CH_2 group and the structure acquires the properties of an aromatic diazonium salt. This is indicated by the shift of the absorption band of the diazo-group of the adduct to the region 2180–2140 cm^{-1} relative to the absorption by the initial diazodicarbonyl compounds (XVI) (2130–2150 cm^{-1}).

Thus α-diazocarbonyl and particularly α-diazo-$\beta\beta'$-dicarbonyl compounds are intermediate as regards their chemical properties and spectroscopic characteristics between diazohydrocarbons and aromatic diazonium salts. A group of very interesting compounds—*o*- and *p*-quinone diazides and *p*-iminoquinone diazides[49], the discussion of which is outside the scope of the present review—also belong to this class.

The spectroscopic characteristics of aliphatic diazo-compounds examined in this section suggest with a fair degree of certainty that either the carbanion form or the diazoanhydride form similar to it (in the case of diazocarbonyl compounds) make the greatest contribution to the real state of these compounds. However, it must be emphasised that these conclusions are purely qualitative, whereas for some time now it has been necessary to examine the structures of diazo-compounds also on a quantitative basis‡.

2. LCAO-MO Calculations for Aliphatic Diazo-compounds

Calculations on the π-electron structure of diazoalkanes by the LCAO-MO method have been carried out by Schuster and Polansky[50] and by Simon and Badilescu[51]. They found the values of π-electron energy, delocalisation energy, the bond orders, and atomic charges. On this basis, attempts were made to establish to what extent the calculated data agree with experiment and what additional information about the structure and properties of aliphatic diazo-compounds may be obtained with their aid.

The delocalisation (E_D) and combination (E_C) energies of diazoalkanes may be used as criteria of their relative resistance to the action of acids and heat[50]. The combination energy is regarded as the energy contribution when diazo-compounds are formed from the π-electron system of the CN_2 group and the π-electron systems of the substituents. Table 5 lists the values of E_D and E_C for a number of diazoalkanes. It shows that, with decrease if the resistance to the action of acids and heat in the series diazomethane, diazoethane, and dimethyldiazomethane[2], there is a parallel decrease of the E_D values for these compounds. However, on passing from diazomethane and its alkyl-substituted derivatives to diazoalkanes, where the substituents exhibit a conjugation as well as an inductive effect, E_D ceases to be a good criterion of the stability of diazo-compounds, becoming inconsistent with experimental data.

In order to account for the difference in the resistance of these diazoalkanes to the action of acids, it is best to

---

‡For a quantitative estimation of the contributions by the diazonium and diazohydrocarbon structures to the resonance hybrid of diazo-compounds, Fahr attempted to employ the difference between the frequencies of the NN stretching vibrations of the diazo-group and molecular nitrogen (ν_{NN} = 2331 cm^{-1}): the smaller the difference the closer is the structure to the diazonium form and conversely the greater the difference the closer is the structure to the diazohydrocarbon form. There are corresponding changes also in the chemical properties of the compounds (private communication).

employ the values of E_C: the increase of the resistance of diazo-compounds to acids in most cases agrees with the increase of their E_C values. Table 5 shows that only diphenyldiazomethane, which is in fact more stable than phenyldiazomethane, deviates from this series. The authors explain this by the fact that the angle of rotation of both phenyl groups relative to the plane of the diazo-group was chosen arbitrarily to facilitate the calculation.

Table 5. Delocalisation energies (E_D), combination energies (E_C), and the losses of the delocalisation energy ($E_D^* - E_D$) of diazoalkanes[50,51].

Diazo-compound	E_D, β	E_C, β	$\lvert E_D^* - E_D \rvert$, β

Diazofluorene	6.3709	1.2201	—
Diazocyclopentadiene	2.8653	1.6258	—

If one remembers that diazoalkanes are nucleophilic agents whose reactivity should be determined to a first approximation by the localisation of the negative charge in the CH_2 group (without taking into account steric and certain other factors), then we should have the following general tendency: a decrease of the reactivity of diazoalkanes with increasing E_D and E_C. In fact in the series of diazomethane and its alkyl-substituted derivatives the increase of nucleophilic activity is accompanied by a decrease of E_D; there is a similar decrease of E_C in the series of diazo-compounds whose substituents are conjugated with the diazo-group.

Another criterion of the reactivity of diazo-compounds, proposed by Simon[51], is the loss of delocalisation energy ($E_D^* - E_D$). Its value characterises the decrease of E_D on transition from the ground state of the molecule to the activated complex in which the conjugation is weakened at the CN bond to be dissociated. It is believed[51] that $E_D^* - E_D$ can be usefully employed only to characterise adiabatic reactions, i.e. reactions in which the radical formed is in a singlet state. On the other hand, when the reaction is non-adiabatic, i.e. there is a change in electron spin in the activated complex with subsequent formation of a triplet ground state, this criterion is no longer valid.

Table 5 lists the values of $E_D^* - E_D$; in general (with the exception of diazomethane) there is an increase of the thermal and photolytic stability of diazoalkanes with increase of $E_D^* - E_D$.

Schuster and Polansky[50] determined the π-electron contribution to the enthalpy of decomposition of diazonium cations (ΔH_π) characterising the change in π-electron energy on passing from the diazonium cation to a carbanion cation and nitrogen: $RN_2^+ \rightarrow R^+ + N_2$. The results are presented in Table 6.

It is seen that the phenyldiazonium cation is more stable than the methyldiazonium cation to the extent of 0.63 β. Such quantum-mechanical examination of diazo-compounds permits the solution of many problems, in particular the problem of the structure of the simplest representative of this class—diazomethane.

The dipole moment of diazomethane (μ = 1.5 D) does not provide unambiguous information about the relative contributions of the two forms [(I) and (II)] to the real state of the molecule[52]. The dissociation energy of the CN bond in diazomethane found from mass-spectrometric data is low (1.9 eV)[53] and closer to the energy of a single than a double bond, i.e. this suggests that structure (II) predominates. The above results (p. 835) of the study of the PMR spectra of diazomethane also confirm its carbanionic structure.

Table 6.

R	CH_3	C_6H_5	p-$(CH_3)_2N—C_6H_4$
$\Delta H_\pi \beta$	−0.2463	+0.3831	+0.4056

The molecular diagram (XVIII) of diazomethane calculated by Schuster and Polansky[50] also confirms the greater contribution by the carbanionic structure, as can be inferred from the negative charges at the α-carbon and β-nitrogen atoms and the bond orders:

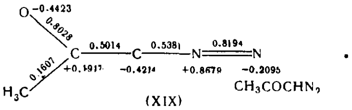
$$\underset{-0.4995}{H_2C}\overset{0.6491}{—}\underset{+0.8418}{N}\overset{0.7441}{\equiv}\underset{-0.3423}{N} \,.$$

(XVIII)

The molecular diagrams of other diazo-compounds[50] also confirm their carbanionic structure, deduced experimentally in earlier studies, and agree well with qualitative data derived from their PMR spectra.

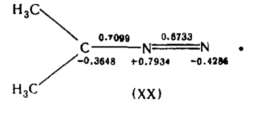
The PMR spectroscopic data suggested a transfer of part of the negative charge from the α-carbon atom of the CN_2 group to the substituents linked to it. This assumption is consistent with the molecular diagrams of phenyl- and diphenyl-diazomethane, diazoacetic ester, and others, and also with their chemical behaviour (for example, in reactions with ketones and α-diketones[54-58]).

The molecular diagrams of diazocarbonyl compounds likewise confirm that the diazoanhydride structure predominates to a considerable extent over the diazo-oxide structure, which is reflected in a transfer of the negative charge from the diazo-group to the carbonyl oxygen and an increase of the C–C bond order between the carbonyl and the diazo-group approximately to 1.5 units [see, for example, diagram (XIX)]:



(XIX)

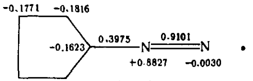
The calculated data show that only in dimethyldiazomethane, where the two methyl groups have a considerable +*I* effect, the contribution of the carbanionic structure is somewhat less than that of the non-carbanionic structure (XX):



(XX)

In all the remaining cases the carbanionic form with delocalisation of the negative charge over the α-carbon atom and the substituents linked to it makes the major contribution.

Diazocyclopentadiene is known to be very stable; it does not enter into typical reactions of diazoalkanes, but is capable of electrophilic substitution. These properties are consistent with the high value of E_C; it follows from the molecular diagram (XXI),



(XXI)

that electrophilic substitution should take place preferentially in the 2- and 5-positions; however, the difference between the charges in these positions compared with the 3- and 4- positions is not very great. When diazocyclopentadiene is nitrated, α- and β-nitrodiazocyclopentadienes are formed in proportions of 3 : 2.

Until recently it was believed that the α-nitrogen atom in diazo-compounds transmits electron density but its own charge remains unchanged. The calculated data[50] show that this is probably not entirely true and the positive charge of the α-nitrogen atom changes, albeit not very greatly [see, for example, the molecular diagrams (XVIII)–(XXI)].

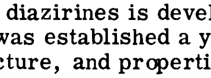
The data quoted show that the qualitative description of the structure of aliphatic diazo-compounds based on the study of the PMR and infrared spectra is confirmed quantitatively when quantum-mechanical computational methods are applied to diazo-compounds. Altogether the experimental and calculated data make it possible to describe accurately not only the fine structure of aliphatic diazo-compounds, which explains their behaviour in chemical reactions, but sometimes it is also possible to predict such behaviour.

III. ISOMERS OF ALIPHATIC DIAZO-COMPOUNDS

1. Cyclic Isomers (Diazirines)

Cyclic isomers of diazoalkanes (diazirines) were discovered in 1960–1961 independently by Paulsen[59] and Schmitz and Ohme[60]. The discovery of this new class of compounds was highly unexpected, since in earlier investigations[7,61] cyclic structures were discussed as possible alternatives for aliphatic diazo-compounds, but it was never suggested that the cyclic isomers can exist as a separate class of compounds.

However, it was found that frequently it is easier to obtain the more stable cyclic isomers than the less stable linear diazo-compounds. The usual method of preparation of diazirines (XXIII) is by oxidising diaziridines (XXII):



(XXII) (XXIII)

The chemistry of diazirines is developing very rapidly and their structure was established a year after discovery. The synthesis, structure, and properties of diazirines have been described in detail in a monograph by Schmitz[62] and therefore here we shall consider them very briefly.

The bond lengths in diazirine were determined from its microwave spectra: 1.48 Å (C–N) and 1.23 Å (N–N). Its dipole moment is 1.59 D, i.e. very close to the dipole moment of diazomethane (see p. 838).[63-65]

The PMR spectrum of diazirine in carbon tetrachloride has a singlet at τ = 9.60 p.p.m. The signal of the protons at the ring carbon atom is located in a relatively high field, which indicates the presence of a strained three-membered ring[66].

The equivalence of both nitrogen atoms was demonstrated in pentamethylenediazirine as an example using a tracer atom method[67].

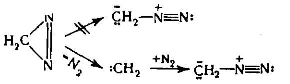
The ultraviolet spectra of diazirines have an absorption maximum at 340 nm, which is close to the absorption of azomethane (λ_{max} = 343 nm) but differs sharply from the absorption by the isomeric compounds diazomethane (λ_{max} = 412 nm) and *N*-isocyanamine (λ_{max} = 247 nm).[68,69]

In the infrared spectra the absorption band of the azo-group at 1580–1600 cm^{-1} is observed instead of the absorption band of the linear diazo-group in the region of 2000–2200 cm^{-1}.

The difference between the structures leads also to a sharp difference between the chemical properties; diazoalkanes are some of the most reactive substances known in organic chemistry, while diazirines are much more stable. Thus diazirine is more stable that diazomethane to the extent of 30 kcal mole^{-1} (according to mass-spectrometric data, the heats of their formation are respectively 79 and 49 kcal mole^{-1}).[53,70-72] Aliphatic diazo-compounds are extremely sensitive to acids, while alkyl-substituted diazirines decompose only when treated with concentrated inorganic acids (80–90% sulphuric acid).

In almost all reactions of diazoalkanes new C–C bonds are formed, while in the case of diazirines Thiele's view that the N=N bond is more reactive is confirmed. For example, hydrogen and Grignard reagents readily add to the nitrogen–nitrogen double bond. However, there are also similarities between the reactions of these two classes of compounds: both diazoalkanes and diazirines decompose on photolysis and thermolysis with evolution of nitrogen and the formation of carbenes.

Diazirines can be converted into linear diazo-compounds: it has been shown by infrared spectroscopy that, when diazirine is irradiated in a solid nitrogen matrix at 20°K, diazomethane is formed[72]. Experiments using labelled nitrogen suggest that the mechanism involving the splitting off of molecular nitrogen and its subsequent addition to the carbene with formation of the linear diazomethane is more likely than the cleavage of the three-membered ring and direct formation of diazomethane:



It has also been shown[73] that diazomethane is formed in the photolysis of diazirine in the gas phase too. In the liquid phase the formation of the linear diazo-compound is observed in the photolysis of pentamethylenediazirine[74]. Studies dealing with the conversion of diazirines into linear diazo-compounds and designed to determine the mechanism of this process are being continued.

2. Linear Isomers (*N*-Isocyanamines)

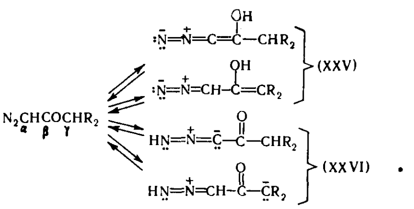
For a long time there existed the hypothesis of a possible tautomeric equilibrium between two linear structures, namely between diazomethane and isodiazomethane[75,76]:

$$\ddot{\bar{C}}H_2-\overset{+}{N}\equiv N: \rightleftarrows CH\equiv\overset{+}{N}-\ddot{\bar{N}}H$$

(XXIV)

Only in recent years, as a result of Koster's work[22] on the PMR spectra of diazomethane at different temperatures and a careful study of the infrared spectra of 12 diazomethane specimens prepared in different ways[77], was the absence of diazo–isodiazo tautomerism in diazomethane demonstrated.

The absence of tautomerism in diazohydrocarbons did not allow an *a priori* rejection of such isomerism in diazocarbonyl compounds, where the mobility of the α- and γ-hydrogen atoms should be enhanced owing to the influence of the carbonyl group. In this case two types of tautomerism could be postulated: keto–enol (XXV) and diazo–isodiazo (XXVI):[78]



However, Fahr[79] made a detailed study in 1959 of the ultraviolet spectra of diazocarbonyl compounds and showed that the change in the spectroscopic characteristics of these substances on passing from hydrocarbon to hydroxylated solvents, which had been previously explained by a shift of the tautomeric equilibrium (XXV)–(XXVI), is in fact due to the formation of a hydrogen bond:

Thus it has now been rigorously demonstrated that there is no tautomerism in aliphatic diazo-compounds. However, there exists a linear isomer of diazomethane, discovered more than 30 years ago[80–82]. It was obtained by Müller[80–83] by the action of an aqueous solution of ammonium chloride on the compound formed by the reaction of diazomethane with methyl-lithium. Three limiting structures [(XXVIIa)–(XXVIIc)] were suggested for the very unstable compound (called "isodiazomethane") isolated after vacuum distillation of the solvent:

$$\underset{a}{\underset{..}{\overset{-}{C}}H=\overset{+}{N}=\underset{..}{N}H} \leftrightarrow \underset{b}{\overset{+}{C}H=\underset{..}{N}-\underset{..}{\overset{-}{\ddot{N}}}H} \leftrightarrow \underset{c}{CH\equiv\overset{+}{N}-\underset{..}{\overset{-}{\ddot{N}}}H}\ .$$

(XXVII)

Thus, on the basis of the electronic configuration, the isomeric diazomethane, whose properties differ appreciably from those of the usual diazomethane, was regarded[82] as an analogue of hydrazoic acid (XXVIII). This analogy was apparently confirmed by the instability of both compounds and the similarity of their ultraviolet spectra.

$$:N\equiv\overset{+}{N}-\underset{..}{\overset{-}{\ddot{N}}}H \leftrightarrow \underset{..}{\overset{-}{\ddot{N}}}=\overset{+}{N}=\underset{..}{N}H\ .$$

(XXVIII)

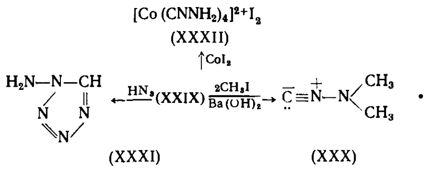
However, the latest studies have shown quite rigorously that "isodiazomethane" is in fact *N*-isocyanamine (the amide of fulminic acid) (XXIX):

$$\underset{..}{\overset{-}{C}}\equiv\overset{+}{N}-\underset{..}{N}H_2 \leftrightarrow :C=\underset{..}{N}-\underset{..}{N}H_2\ .$$

(XXIX)

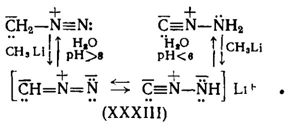
This structure of the isomeric diazomethane is also confirmed by infrared and PMR spectroscopic data[83]. The infrared spectrum of compound (XXIX), like that of cyanamide[84], contains absorption bands associated with the NH stretching vibrations (3170 and 3290 cm^{-1}) and deformation vibrations (1630 cm^{-1}) and also a weak absorption at 2130 cm^{-1} attributed to the isonitrile group. The PMR spectrum of the isomeric diazomethane contains only one broad band (τ = 3.6 p.p.m.) which is not split when the temperature is sharply reduced and resembles in shape and position the corresponding signal from carboxylic acid amides (τ = 3.5–3.8 p.p.m.). The compound readily exchanges both hydrogen atoms for deuterium and under the action of alkali is rapidly converted into diazomethane. In the first case the signal in the PMR spectrum completely disappears and in the second it is replaced by the signal due to the protons in the diazomethane molecule (τ = 6.8 p.p.m.).[21]

The chemical reactions of the isomeric diazomethane are satisfactorily consistent with the spectroscopic data, confirming that its structure is (XXIX). Thus it proved possible to carry out a reaction involving the aminogroup: *N*-isocyanodimethylamine (XXX), previously described in the literature, was obtained[85]:



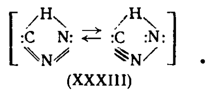
Like other isonitriles, *N*-isocyanamine readily forms the corresponding tetrazole (XXXI) by reaction with hydrazoic acid and complexes (XXXII) with cobalt and iron salt. Other reactions of compound (XXIX) characteristic of isonitriles have also been investigated[83,85–87]. Consequently both physical and chemical research methods fairly clearly demonstrate that the isomeric diazomethane is the first member of the series of *N*-isocyanoalkylamines and *N*-isocyanodialkylamines, which were described for the first time quite recently[88].

Compared with diazirine, *N*-isocyanamine shows somewhat greater similarity to diazomethane. This is shown by the instability of both isomers and by their capacity for ready interconversion, whereas diazomethane is not converted into diazirine. The diazomethane–fulminic acid amide interconversions do not take place directly but only via their deprotonated form—the diazomethyl anion (XXXIII)—which is readily obtained by the action of methyl-lithium on diazomethane or its isomer (XXIX). On hydrolysis in an acid medium, diazomethyl-lithium forms the amide (XXIX) and on hydrolysis in an alkaline medium diazomethane is formed:



(XXXIII)

The tautomeric conversion of the anion is apparently facilitated by the hydrogen bond in the transition state (XXXIII):[83]

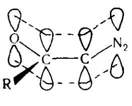


(XXXIII)

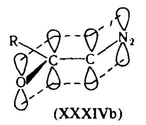
Nor can one exclude the possibility that the protonation of the diazomethyl anion involves the formation of isodiazomethane proper (XXIV), which is an extremely unstable intermediate in the transformation of diazomethane into *N*-isocyanamine (and conversely). However, this hypothesis requires rigorous tests.

3. *cis*-*trans*-Isomerism of Diazocarbonyl Compounds

It follows from the above (pp. 836–837) that whatever the contribution of structure (XIIIb) to the real state of the molecule of the diazocarbonyl compound, the C—C bond between the carbonyl and the CN_2 group will always exhibit a certain amount of double bond character. This should prevent free rotation about the C–C bond and consequently the existence of two forms of diazocarbonyl compounds may be expected: *cis* - [(XXXIVa)] and *trans*- [(XXXIVb)]. In this case the terms "*cis*" and "*trans*" refer to the relative positions of the π-electron clouds of the carbonyl group and diazo-group, while the group linked to the carbonyl is located in the *trans*-position relative to the diazo-group in the *cis*-form (and conversely):



(XXXIVa)
cis-



(XXXIVb)
trans-

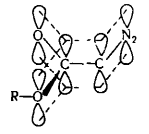
The hypothesis of conformational isomerism of α-diazoketones was put forward by Pecile et al.[89] and later by Leveson and Thomas[90] to account for certain characteristics of their infrared and ultraviolet spectra. However, the evidence which they adduced in favour of this assumption was not sufficiently rigorous.

A decisive proof of the real existence of the conformational isomerism of α-diazoketones was obtained by Kaplan and Melloy who investigated the PMR spectra of diazocarbonyl compounds (XXXV) at different temperatures[91–93]:

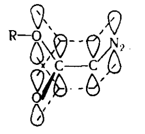
$RCOCHN_2$ a. R=H; d. R= t-C_4H_9; g. R=C_2H_5O;
(XXXV) b. R=CH_3; e. R=Ph—CH_2; h. R=Ph;
c. R=C_2H_5; f. R=CH_3O; i. R=*p*=NO_2—C_6H_4.

They made the following observations: in the majority of the diazocarbonyl compounds investigated (XXXVa, b, c, e, f, g) the signal of the methylidyne proton is gradually broadened as the temperature is reduced and finally splits into two components. This type of change in the PMR spectra is characteristic of an equilibrium mixture of two substances: the average signal is observed at high rates of interconversion and two signals are observed at low rates. The constancy of the spin–spin coupling constant for the methylidyne proton ($J_{^{13}C-H}$) corresponding to the average signal and the signals of each of the substances undergoing conversion is evidence that any type of tautomerism involving the methylidyne proton is impossible. Consequently in this case only a *cis*–*trans* isomeric equilibrium can exist and the two peaks in the low-temperature spectra correspond to the *cis*- and *trans*-forms of the diazocarbonyl compound. On the basis of analogies in the literature[94,95], the signal in the stronger field was attributed to the *trans*-form, whence the ratio of the *cis* - and *trans* -conformers may be obtained from the ratio of the signal intensities.

Table 7 shows this ratio for the diazocarbonyl compounds (XXXV) investigated varies markedly as a function of the group R. The high content of the *cis*-conformer in compounds (XXXVb, c, e) compared with diazoacetaldehyde can probably be explained by the steric hindrance to the formation of the *trans*-forms of these diazocarbonyl compounds. In general, one may expect that the *cis*/*trans* ratio will increase as the steric requirements of the substituents become more stringent. However, this factor is not always decisive. Thus, on the basis of steric considerations, an appreciable predominance of the *cis*-form might have been expected in diazoacetic esters (XXXVf, g), but the *cis*/*trans* ratio is in fact only a little in excess of unity. This can probably be accounted for by the fact that the π-electron systems of both forms have the same geometry (XXXVIa, b), which leads to identical interactions: as a result, the difference between the free energies ΔF of the two conformers is insignificant.



(XXXVIa)



(XXXVIb)

Table 7. Compositions in, and activation energies E_a for, the *cis*–*trans* interconversion of diazocarbonyl compounds[92].

Compound	Fraction		E_a, kcal mole^{-1}(°C)
	cis	*trans*	
(XXXVa)	0.690	0.310	
(XXXVb)	0.924	0.076	15.5±0.9 (11.8)
(XXXVc)	0.941	0.059	16.1±0.6 (6.5)
(XXXVd)	0.990	0.010	
(XXXVe)	0.962	0.038	18.1±0.6 (1)
(XXXVf)	0.538	0.462	12.5±0.9 (—25)
(XXXVg)	0.540	0.460	9±0.8 (—32)

For a number of compounds (XXXVd, h, i), only one signal is observed over the entire temperature range investigated. Among the explanations proposed for this experimental finding, the most acceptable is the hypothesis that all these diazoketones exist mainly in the *cis*-form owing to the strong steric interaction between the diazo-group and the bulky R radical in the *trans*-form.

The activation energy E_a which determines the barrier to free rotation, varies from 9 to 18 kcal mole^{-1} (Table 7)§. Comparison of the values of E_a and the orders of the central C–C bond[50] shows that a decrease of the double bond character of this linkage lowers the barrier to free rotation.

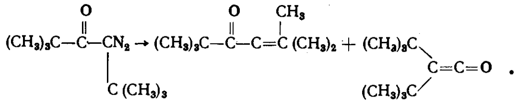
The existence of diazoketones in the *cis*- and *trans*-forms can be used to explain some of their reactions (in particular, their decomposition processes); it is then of course necessary to take into account the relative rates of the reaction and of the *cis*–*trans* transition. Naturally, the possibility of the formation of the reaction products from the preferred conformation must be considered only when the rate of interconversion of the two forms is lower than the rate of the decomposition reaction.

Assuming that the formation of ketens in the Wolff rearrangement takes place as a concerted synchronous process[97] and only via the *cis*-form of the diazoketone, which is the most favourable for this purpose, Kaplan and Melloy made a fairly successful attempt to account for the results of certain reactions of α-diazoketones[92,98,99].

---

§E_a for the interconversion of the *cis*- and *trans*-conformers of diazoacetone was recently calculated[96] by Hückel's molecular orbital method. The calculated value (about 14 kcal mole^{-1}) agrees well with the experimental activation energy found by Kaplan and Melloy (Table 7).

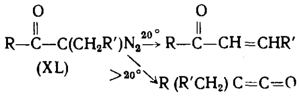
Thus, owing to the powerful repulsion of the two t-butyl groups, the diazoketone (XXXVII) cannot exist in the *cis*-form and therefore its photolytic, thermal, and catalytic decomposition results in the formation of compound (XXXVIII) and only traces of the keten (XXXIX):



$$(CH_3)_3C-\overset{\overset{O}{\parallel}}{C}-\underset{\underset{C(CH_3)_3}{|}}{C}N_2 \rightarrow (CH_3)_3C-\overset{\overset{O}{\parallel}}{C}-C=\overset{\overset{CH_3}{|}}{C}(CH_3)_2 + ((CH_3)_3C)_2C=C=O\ .$$

(XXXVII) (XXXVIII) (XXXIX)

At low temperatures the diazoketones (XL) also exist mainly as the *trans*-conformers. However, the formation of the *cis*-form is less sterically hindered and on raising the temperature the energy received by the molecules is apparently sufficient for the formation of appreciable amounts of the *cis*-conformer. For this reason, the photolytic and catalytic decomposition of diazoketones (XL) at 20°C leads mainly to compounds (XLI). At higher temperatures the ketens (XLII) are mainly obtained:



$$R-\overset{\overset{O}{\parallel}}{C}-C(CH_2R')N_2 \xrightarrow{20^\circ} R-\overset{\overset{O}{\parallel}}{C}-CH=CHR' \quad (XLI)\ .$$
$$\xrightarrow{>20^\circ} R(R'CH_2)C=C=O \quad (XLII)$$

(XL)

Thus the study of the conformational isomerism of diazoketones, which is itself of considerable theoretical interest, will undoubtedly prove useful also for a better understanding of the mechanism of the reactions of this class of compounds.

Dual Reactivity of Ambident Anions

S.A.Shevelev

The present state of the problem of the dual reactivity of ambident anions, i.e. anions with two reactive centres, is reviewed. The factors influencing the reactions of such anions are discussed and certain relations are interpreted from the standpoint of the principle of hard and soft acids and bases.
The bibliography includes 120 references.

CONTENTS

I. INTRODUCTION

Ambident anions are those which have two reactive centres linked into a single conjugated (mesomeric) system[†]. Ambident anions are capable of forming two series of derivatives in reactions with electrophilic agents, i.e. according to Nesmeyanov and Kabachnik[3] they exhibit dual reactivity. Examples of anions of this kind are the enolates of β-dicarbonyl compounds, phenoxides, cyanide, thiocyanate, and nitrite ions, the anions of nitro-compounds, oximes, carboxylic acid amides, dialkyl phosphorothioites, and dialkyl phosphorothioates, the anions of heterocyclic aromatic compounds or their derivatives (pyrrole, indole, 2-hydroxypyridine, hydroxypyrimidine, etc.), and others.

The capacity of such anions to react in two ways has been known for a long time but the factors influencing the mode of reaction have been virtually unknown and only in the last fifteen–twenty years have studies illuminating this problem been carried out.

Although there exist two modern reviews on the dual reactivity of ambident anions, published in 1964[2] and 1965[4] respectively, this field is developing so rapidly that a new review of the literature is required, particularly since during the period which has elapsed new hypotheses, which can be applied to this problem, have appeared and become established in chemistry. On the other hand, a fairly large number of contradictory data have accumulated in the literature and require a detailed discussion.

Therefore the author's aim is not to review the entire enormous literature on the dual reactivity of ambident anions, particularly since extensive literature data, apart from the reviews already mentioned[2,4], have been compiled also in a number of earlier publications[1,3,5,6], but merely to give a general account of the present state of the problem in the light of the work carried out in recent years.

II. RELATIONS BETWEEN THE STRUCTURE AND DUAL REACTIVITY OF AMBIDENT ANIONS

As already stated, both reactive centres of the ambident anion form a single mesomeric system and therefore the negative ionic charge is distributed between the two atoms which can be involved in the formation of a covalent bond on reaction with electrophilic agents. However, as a rule the main bulk of the charge is concentrated at one of the nucleophilic atoms and usually the atom which is more electronegative (according to Pauling's electronegativity scale of atoms); at the same time the less electronegative donor atom is more polarised[1,3,7][‡]. Thus the bulk of the negative charge in enolate anions and the anions of nitro-compounds is concentrated at the oxygen atom, while the carbon atom is more polarised; a similar relation obtains between the oxygen and nitrogen atoms in the nitrite ion and the anion of 2-hydroxypyridine, and between the nitrogen and carbon atoms in the pyrrole and cyanide anions.

Despite the fact that one donor atom has a higher electron density than the other, the reactions with electrophilic agents by no means always take place at the point with the highest electron density; very often the covalent bond is formed with the less electronegative atom. Nesmeyanov and Kabachnik[3] call this phenomenon reactive centre transfer[§]. They note[3] that the capacity of ambident anions to react with reactive centre transfer is related not so much to the distribution of the negative charge in the anions as to the capacity of the conjugated system for the electromeric shift of electron density necessary for the reaction, for example:

[†] The term “ambident anion” was proposed by Kornblum[1]. Gompper[2] suggests that such compounds be called “ambifunctional”, but this name is less widely used. The term “polydent anions” is employed to designate anions with three and more reactive centres.

[‡] The high polarisability of the less electronegative atom is probably due either to the considerable double bond character of its linkage, as in the case of the α-carbon atom in enolates, or a significant polarisability of the atom as such (phosphorus, sulphur, etc. atoms).

[§] The old concept that the reason for the dual reactivity of ambident anions is the existence of two anionic tautomers, each of which gives rise to its own series of derivatives, was disproved in the same investigation[3].

Thus the problem of the relation between the structure of the ambident anion and its capacity to react in different ways reduces largely to finding the relation between the structural parameters of the anion and the ease of the electromeric shift of electron density.

It is well known that certain ambident anions show a greater tendency to react in a particular way than others even though their structures are similar. Thus the anions of acetoacetic ester and acetylacetone exhibit a much greater tendency to react via the oxygen atom, than the anion of malonic ester; the anion of phenol also tends to react much more readily via the oxygen atom than the anion of β-naphthol (see, for example, Kornblum and Lurie[8]). In contrast to the anions of monobasic carboxylic acids, the phthalimide ion is alkylated virtually only at the nitrogen atom[3]. More such examples may be quoted. At the same time it must be emphasised that these data are purely qualitative, since so far very few studies have been made in which the dual reactivities of various ambident anions, including those with similar structures, were compared in sufficient detail under standard conditions using electrophiles of different types.

Unfortunately there are no reliable criteria which would relate the electron structure or some other parameters of ambident anions (or their conjugate acids) to their capacity to react with transfer of the reaction centre.

An attempt has been made[9] to relate the dual reactivity of the anions of β-dicarbonyl compounds to the distribution of π-electron density and certain other electronic parameters, obtained by the LCAO-MO method (in the Hückel approximation). However, as stated above, the capacity of the ambident anion to react in a particular way is not directly related to the distribution of electron density. At the same time one cannot exclude the possibility that this approach will prove fruitful in the case of electrophiles with significant positive charges, which usually react at the site with the greatest electron density (see Section V). Moreover, the tendency to react via the oxygen atom can probably be estimated using data for the variation of the electron density at this atom in a series of related anions[9]. However, we believe that in the general case the electron density at a carbon atom cannot be correlated with its reactivity (as was done by Gren and Vanag[9]) (see also Klopman[10]).

This does not of course imply that in principle the quantum-chemical approach is inapplicable to the estimation of the dual reactivity. The recent study by Klopman[10], where the possibility in principle of a quantum-mechanical calculation of the reactivity of ambident systems (by the method of polyelectron perturbation) was demonstrated, has attracted attention from this standpoint.

Thus the relation between the structure and dual reactivity of ambident anions constitutes one of the least investigated problems.

III. THERMODYNAMICALLY AND KINETICALLY CONTROLLED REACTIONS

In the discussion of the factors influencing the mode of the reactions of ambident anions, it is necessary to distinguish clearly thermodynamically and kinetically controlled reactions. In kinetically controlled reactions the composition of the products is determined by the relative nucleophilicity of each of the donor atoms in the ambident anion in relation to the given electrophilic agent. On the other hand, in thermodynamically controlled reactions the most stable compound is the final product regardless of the reaction mechanism. The energy (heat) of formation of the compound, which can be estimated from the bond and conjugation energies[2], is a measure of its stability.

The reaction is thermodynamically controlled when the interaction of the electrophilic agent with the ambident anion is reversible. When the relative amounts of the reaction products are not determined by the nucleophilicity of the donor atoms but by their basicity in relation to the atom at which the substitution takes place—for example in alkylation by the basicity in relation to a saturated carbon atom[11].

It has been noted[2] that in many cases conclusions concerning the products of thermodynamically controlled reactions can be drawn from the basicity of particular donor atoms in relation to the proton: an electrophilic agent will form a bond preferentially with the atom of the ambident anion which is most basic in relation to the proton (the basicity in relation to the proton usually decreases in the series C > N > O > S).

The available data confirmed this hypothesis. For example, the product of the alkylation of the enolates of β-dicarbonyl compounds at the more basic atom (the carbon atom) is thermodynamically more stable than the O-alkylation product[12]. Similarly the product of the N-alkylation of the nitrite ion (nitroalkane) is more stable than the O-alkylation product (the corresponding alkyl nitrite)[13].

The question arises: in which cases should one expect the reaction with electrophilic agents to be thermodynamically controlled? In other words, in which cases are the reaction products capable of decomposing into the starting materials? Gompper[2] noted that this occurs frequently when the experiments are carried out with stable cations or when relatively stable cations (for example triarylcarbonium ions, the carbonium ions formed in the Mannich reaction, and aryldiazonium ions) are formed as intermediates. Thermodynamic control is also observed in reactions with electrophilic agents containing multiple bonds (for example, aldehydes and ketones—the addition of ambident anions to the carbonyl group). Moreover the tendency to undergo thermodynamically controlled reactions should increase with the stability of the anion. Thermodynamically controlled reactions are dealt with in greater detail by Gompper[2].

Henceforth in the discussion of factors influencing the dual reactivity of ambident ions, we shall consider only kinetically controlled reactions, although one must bear in mind that the possibility of thermodynamic control was not fully excluded in all the investigations considered.

IV. NUCLEOPHILIC PROPERTIES OF THE REACTIVE CENTRES OF AMBIDENT ANIONS

The problem of the dual reactivity of ambident anions in kinetically controlled reactions is the problem of the relative nucleophilicity of each of the donor atoms of the anion linked into a single mesomeric system.

The reactivity of the electron donor (nucleophilic agent) in substitution reactions (nucleophilicity) is determined by a number of factors[7,14-16]. The principal of these are the basicity and polarisability of the given nucleophilic atom and also the α-effect (the presence of an unshared electron pair at an adjacent atom)[7,17]. It follows that the contribution of each of these parameters to the overall reactivity of the nucleophilic agent depends to a considerable degree on the nature of electrophilic atoms at which the substitution takes place[7,14].

However, in the case of ambident anions it is impossible to determine the polarisability and basicity of each reaction centre independently of one another and consequently it is impossible to estimate in this way their nucleophilicity, since the two nucleophilic atoms are not independent but are linked into a single mesomeric system. Indeed in order to determine a parameter such as polarisability, it is necessary to know the molecular refraction of each of the donor atoms of the anion[7,17], whereas in fact it is only possible to determine the refraction of the anion as a whole. As regards the basicity (in relation to the proton), it is found that the protonation of the anion necessary to determine the basicity takes place with very significant redistribution of electron density in the conjugated system and consequently the equilibrium position does not reflect the "independent" basicity of each donor atom in the anions, particularly the atom with the lower electron density.

At the same time, although it is impossible to estimate quantitatively (or semiquantitatively) the reactivity of the donor centres of the ambident anion, it is possible to make a purely qualitative estimate of the relative nucleophilicities of both atoms of the anion in relation to a specific type of electrophilic agent. The principle of hard and soft acids and bases recently put forward by Pearson[13,18–21] is particularly suitable in this context. According to this principle, all Lewis bases (electron donors or nucleophilic agents) can be divided into two classes: hard and soft bases (some of these bases occupy an intermediate position). Similarly Lewis acids (electron acceptors or electrophilic agents) are also divided into two classes—hard and soft acids—some occupying an intermediate position.

Hard bases are Lewis bases with a high electronegativity, low polarisability, and resistant to oxidation, i.e. hard bases firmly retain their valence electrons.

Soft bases are Lewis bases with a low electronegativity, high polarisability, and readily oxidised, i.e. they retain their valence electrons less firmly.

Hard acids are Lewis acids with a high electronegativity, and a low polarisability; these properties correspond to a high positive charge and a small size of the acceptor atom and the absence from it of an unshared electron pair.

Soft acids are Lewis acids with a low electronegativity and a high polarisability; this property corresponds to a low positive charge (or absence of charge), a large size of the acceptor atom, and the presence of an unshared electron pair (*p* or *d* electrons) at this atom. It has been noted that not all the properties enumerated must necessarily be present together to assign an acid to a particular class[20].

The fundamental postulate of the concept of hard and soft acids and bases is as follows: hard bases are preferentially coordinated to hard acids and soft bases to soft acids.

According to Pearson, organic and inorganic molecules are regarded as acid–base complexes. For example, CH_3I is a complex of the acid CH_3^+ and the Lewis base I^-, CH_3COCl is a complex of the acid CH_3CO^+ and the base Cl^-, etc.[13,20] Consequently, it is possible to estimate the hardness (softness) of a given molecule in particular reactions, i.e. to estimate the hardness or softness of a particular reaction centre (atom) and of course it is necessary to take into account the mutual effects of all components of the complex.

Pearson enumerates the most widespread hard and soft acids and bases[19,20]. Examples of hard bases are: OH^-, H_2O, RO^-, ROH, R_2O, F^-, Cl^-, $CH_3CO_2^-$, SO_4^{2-}, NO_3^-, and RNH_2; soft bases: RS^-, RSH, R_2S, I^-, R_3P, C_2H_4, H^-, R_3C^-, and others.

Examples of hard acids are: the proton, cations of alkali and alkaline earth metals, aluminium, the carbonyl carbon atom (RCO^+), the phosphorus atom in the phosphoryl group (R_2PO^+), the sulphur atom in the sulphonyl group (RSO_2^+), and the hydrogen atom involved in the formation of a hydrogen bond; soft acids: cations of univalent copper, silver, univalent and divalent mercury, the sulphenyl sulphur atom (RS^+) and selenium and tellurium atoms in analogous groupings (RSe^+, $ReTe^+$), iodine, bromine, and oxygen atoms in those molecules where they behave as electrophilic centres (I^+, Br^+, HO^+, RO^+), BH_3, carbenes, and others. Among acids with intermediate properties mention should be made of the saturated carbon atom (R_3C^+) and the aromatic carbon atom ($C_6H_5^+$). For a more detailed list of soft and hard acids and bases, see Pearson[19,20] (and also Pearson and Songstad[13]).

It should be noted that the principle of hard and soft acids and bases is empirical and in fact constitutes a generalisation of experimental data. However, recently Klopman[10] gave a theoretical explanation of the principle of hard and soft acids and bases using the quantum-mechanical perturbation theory. He showed that[10] the softness (hardness) of a particular acid (acceptor atom) is determined by the energy of the lowest vacant orbital and the softness of a base (donor atom) by the energy of the highest occupied orbital, and, apart from the energies of orbitals themselves, account must be taken also of the solvation energy, i.e. the softness (hardness) is influenced by the solvent.

We shall now consider the applications of the concept of hard and soft acids and bases to ambident anions. As shown in Section II, one of the atoms of the ambident anion is usually more electronegative and the major part of the negative ionic charge is concentrated there, while the second atom is more polarisable.

Comparison of these data with the characteristic features of hard and soft bases (see above) leads to the conclusion that usually the less electronegative and more polarisable donor atom of the anion is a soft base while the more electronegative atom is a hard Lewis base[7,10,13,22]¶.

Thus in enolate anions the oxygen atom is hard and the carbon atom is soft[10,22]; in the thiocyanate anion the nitrogen atom is hard and the sulphur atom is soft[10]; in the nitrite ion the oxygen atom is hard and the nitrogen atom is soft[10]; etc.

The application of the principle of hard and soft acids and bases to ambident anions makes it possible to predict the preferential mode of reaction of these anions with various electrophilic agents: the soft donor atom of the ambident anions will be preferentially bound to a soft electrophilic agent, while the harder atom will be bound to a hard electrophilic agent. As will be shown below, this useful principle is confirmed by numerous experimental data.

¶ There are of course sometimes also ambident anions where both donor atoms have similar electronegativities and are included, according to Pearson's classification in a common series of bases (soft or hard). However, in this case too one of the atoms will be softer than the other. Such a situation will arise when, for example, both donor atoms are the same and differ only in substituents, as in the anions of *OO*-dialkyl-*NN'*-diarylphosphamidines (see Kabachnik and Gilyarov[23] and the references quoted by them):

.

An important conclusion, which may be derived from this principle, is as follows: the order of the relative nucleophilicities of the donor atoms of ambident anions can be decisively influenced by the nature of the electrophilic atoms at which substitution takes place. Therefore subsequently the principal features of the behaviour of ambident anions will be examined for each type of electrophilic centre separately. In the first place we shall examine substitution at a saturated carbon atom for which there are most data and then at other electrophilic centres (a carbonyl carbon atom, certain heteroatoms, etc.). This does not, of course, imply that the relative nucleophilicities of the donor atoms are the sole factors which influence the mode of reaction of ambident anions. As will be shown in subsequent sections, factors such as steric effects, solvent effects, the state of the salt in solution, and certain others frequently play a very considerable and sometimes a decisive role.

V. BEHAVIOUR OF AMBIDENT ANIONS IN SUBSTITUTION REACTIONS AT A SATURATED CARBON ATOM (ALKYLATION)

The factors which influence the mode of reactions of ambident anions have been investigated in greatest detail for the alkylation of these anions (substitution reactions at a saturated carbon atom). These data will be examined in the present section.

1. Electronic Effects in the Alkylating Agent

In 1955 two papers appeared almost simultaneously and proved to have a very significant influence on the understanding of the dual reactivity in ambident systems at the present time. In the first of these by Nesmeyanov and Kabachnik[3], apart from the general postulates concerning the causes of dual reactivity and the relation between the phenomenon with tautomerism, mentioned above, the fundamental relations determining the mode of reaction of ambident anions were generalised insofar as it was possible on the basis of the experimental data available at the time.

In particular it was pointed out that the mode of reaction is very significantly influenced by the electrophilic properties of the alkylating agent. Thus in salts of keto-enols or carboxylic acid amides where the bond between the oxygen atom of the anion and the metal cation is highly ionised and the alkylating agent is a cation or a strongly electrophilic molecule, a reaction involving the oxygen atom frequently takes place; on the other hand, when the electrophilic properties of the reactant are weak, the reaction takes place at the carbon atom of the enolate anion or correspondingly at the nitrogen atom of the amide anion.

Thus the electronic structure of the alkylating agent has a very significant influence on the mode of reaction of ambident anions.

In another paper, by Kornblum et al.,[1] it was shown that, when silver nitrite reacts with alkyl halides, the tendency towards alkylation at the atom with the maximum electron density, i.e. at the oxygen atom of the ambident nitrite ion, increases sharply on passing from primary to secondary and then to tertiary halides. This behaviour is related to the finding that the reaction of silver nitrite with alkyl halides takes place via an intermediate S_N2–S_N1 mechanism and, with increasing S_N1 character (the carbonium character) of the transition state, there is an increase in the tendency towards *O*-alkylation of the nitrite ions; on the other hand, the carbonium character of the transition state increases in the above series of alkyl halides.

Indeed, the silver ion coordinated to the halogen atom of the alkyl halide polarises the carbon–halogen bond, induces at the carbon atom a partial positive charge, and thereby increases the S_N1 character of the transition state, the ease of polarisation of the carbon–halogen bond increasing on passing from primary to secondary and further to tertiary alkyl halides and consequently the carbonium character of the transition state also increases in this series†.

Kornblum et al.[1] quoted a number of other data confirming his idea of the decisive effect of the nature of the transition state on the mode of alkylation of the nitrite ion; in particular, it was shown for the reaction of substituted benzyl bromides with $AgNO_2$ that the proportions of *O*- and *N*-alkylation of the nitrite ion are not associated with steric effects.

Generalising their own and the literature data, Kornblum et al.[1] put forward an extremely important rule, the essential feature of which may be formulated as follows: when an ambident anion reacts with electrophilic agents, an increase in the S_N1 character of the transition state increases the tendency towards the reaction at the most electronegative atom, i.e. the atom with the highest electron density. Conversely, an increase in the S_N2 character of the transition state leads to an increase of the tendency towards the formation of a bond with the less electronegative atom (that is, the more polarisable atom with a lower electron density).

In the light of this rule, the difference in the behaviour of silver and alkali metal salts of ambident anions becomes understandable. Silver ions are a very effective means of increasing the carbonium character of the transition state, polarising the carbon–halogen bond by electrophilic interaction with the halogen atom, while alkali metal atoms do not have this property.

Hence, when silver salts are employed, there should be an increase in the tendency towards reactions at the atom with the maximum electron density (compared with alkali metal salts). Conversely, when silver salts are replaced by alkali metal salts, there is an increase in the tendency towards the formation of a covalent bond with the atom of the ambident anion where the electron density is lower.

Kornblum et al. quote a number of examples confirming this conclusion. Thus in the reaction of nitrite ions with alkyl halides, the replacement of silver nitrite by sodium nitrite (or other alkali metal nitrites) leads to a sharp increase in the fraction of *N*-alkylation products and a corresponding decrease of the fraction of *O*-alkylation products[1,24]. Similarly in the alkylation of the anion of 2-hydroxypyridine by ethyl iodide the silver salt gives mainly the *O*-derivative, while the potassium salt gives only *N*-ethylpyridone[25,26]. Alkylation of the silver salts of carboxylic acid amides by alkyl halides favours *O*-alkylation in a similar manner, while the alkali metal salts give the *N*-derivatives (for the literature, see Kornblum et al.[1]). Alkali metal cyanides react with alkyl halides to form mainly nitriles, while silver cyanide forms isonitriles[27,28], etc.

---

† This is associated with the fact that the more stable the carbonium ion which the alkyl halide can form the greater is the degree of polarisation of the carbon–halogen bond under the influence of the silver ion.

It should not of course be thought that the use of silver salts will always lead solely to alkylation products at the site of maximum electron density. The capacity to react in a particular way is in the first place the function of the structure of the alkyl halide. In the case of alkyl halides which are incapable of undergoing a significant polarisation of the carbon–halogen bond under the influence of silver ions, the reaction at the less electronegative centre may prevail. For example, in the interaction of the esters of α-iodocarboxylic acids with silver nitrite the yield of N-alkylation products reaches 80–85%.[29] In the methylation of the silver salt of 2-hydroxypyridine by methyl iodide (in dimethylformamide) the yield of the N-alkylation product is 74% and that of the O-alkylation products only 12%.[30]

Moreover, the ratio of the products will also depend on the nature of the anion: in the case of anions which are particularly apt to undergo reactions at the more polarisable centre, even in the presence of silver ions, the reaction involves virtually exclusively this centre, as happens, for example, in the alkylation of the silver salts of 2-hydroxypyrimidine and 2-hydroxy-5-nitropyrimidine by primary alkyl halides (the N-alkylation products are mainly formed)[31].

Apart from silver ions, the carbonium ion character in the transition state can of course be effectively increased also by other metal ions, for example those of mercury and copper, which are capable of polarising the carbon–halogen bond and inducing a positive charge at the carbon atom. Similarly other well known factors promoting the occurrence of the S_N1 process will increase the tendency towards reactions at the centre with the maximum electron density.

Kornblum et al.[1] quote certain examples of this kind. Thus the sodium salt of acetoacetic ester is alkylated by primary alkyl halides only at the carbon atom (in solvents of relatively low polarity) while chloromethyl ether, which usually reacts with nucleophilic agents by an S_N1 mechanism, forms only the O-derivative[32]. Certain other examples of the greater tendency of α-chloroethers towards reactions at the oxygen atom, compared with alkyl halides, are quoted by Nesmeyanov and Kabachnik[3].

It should be borne in mind that the nature of the transition state is by no means always as clear as in the case of silver salts. Even when electrophiles with a high tendency towards reaction by an S_N1 mechanism are employed, the nature of the process is quite obscure, since the reaction mechanism is influenced, apart from the structure of the alkylated agent, also by other factors, the nature of the solvent being decisive in most cases‡.

One should also be on one's guard against a misunderstanding of Kornblum's rule. From the standpoint of present-day knowledge, this rule should not be interpreted as implying that, when a reaction takes place via an S_N2 mechanism, the product resulting from the attack on the least electronegative atom is always formed. Kornblum's rule implies only that, for a given specific ambident anion, the transition from the S_N2 mechanism to an intermediate mechanism S_N2–S_N1 (and further to S_N1) will be accompanied by an increase of the fraction of the products of the alkylation of the centre with the maximum electron density and that, other conditions being equal, this increase will be greater the more pronounced is the carbonium ion character of the transition state. Conversely, for a given anion the transition from an S_N1 mechanism to an S_N2 mechanism will lead to a decrease of the fraction of this product. On the other hand, the relative amounts of the products in an S_N2 process will depend on other factors (see below) including the structure of the anion itself and its capacity for a transfer of reaction centre. Kornblum's rule can be readily interpreted in terms of Pearson's principle of hard and soft acids and bases (see Section IV). Indeed the increase of carbonium ion character of the transition state under the influence of the solvent or an electrophilic catalyst (for example, silver ions) implies that the C–X bond is polarised in the alkylating agent R_3C–X, in consequence of which a partial positive charge appears (or increases) at the carbon atom and hence its polarisability diminishes. This implies that the carbon atom at which the substitution takes place becomes harder. On the other hand, an increase in the hardness of an electrophilic centre will increase, in accordance with the principle of hard and soft acids and bases, the tendency towards reactions at the harder atom of the ambident anion, i.e. the atom with the maximum electron density (usually the more electronegative atom).

The interpretation with the aid of the principle of hard and soft acids and bases extends the scope of Kornblum's rule. In the first place it should be noted that the appearance of a significant positive charge at the carbon atom of the electrophile and the decrease of the polarisability of this atom (increase of its hardness) may be related not only to the effect of particular reagents (electrophilic catalysts or the solvent) but also to the effect of highly electronegative polar groups or atoms in the electrophile itself. Examples of this kind will be quoted below in connection with the problem of the effect of the substituting group on the mode of reaction.

Moreover, factors which increase the hardness of the saturated carbon atom will of course operate also in relation to other electrophilic centres.

Consequently Kornblum's rule can be formulated as follows in a general form: an increase in the positive charge at an electrophilic centre (for example a carbon atom) and also a decrease in its polarisability will increase the tendency towards the reaction at the atom in the ambident anion with the greatest electron density§. The converse postulate holds for the donor atom with the lowest electron density.

It must be emphasised that the effect of the electrophilic properties of the substrate on the mode of reaction of ambident anions (see above), noted by Nesmeyanov and Kabachnik[3], agrees well with the above postulate, since an increase in the electrophilic properties of the substrate is identical with an increase in the hardness of the acceptor atom.

Indeed, although the order of the electrophilic reactivities depends on the nature of the nucleophilic agent, one usually has in mind the electrophilicity in relation to highly basic nucleophiles with little tendency towards polarisation, i.e. hard Lewis bases. Consequently in this sense an increase in electrophilicity implies a higher reactivity in relation to the harder donor atom of the ambident anion.

Since its publication (1955), Kornblum's rule became generally recognised. However, recently a number of papers have been published in which the rule is criticised.

---

‡ Usually the reaction mechanism is strongly affected also by electrophilic catalysts: for example Ag^+ and Hg^{2+} ions or compounds such as $AlCl_3$, SbF_5, AsF_6, and certain others.

§ That is, the contribution of electrostatic forces to the overall reactivity increases.

Thus Cardillo et al.[33] found that, in the alkylation of the sodium derivative of indole in tetrahydrofuran (THF), the yield of *C*-alkylation products increases and that of *N*-alkylation products falls on transition from primary to secondary and further to tertiary alkyl bromides. Hence the authors conclude that, contrary to Kornblum's rule, an increase in the S_N1 character of the process favours attack at the least electronegative atom (carbon atom).

However, we believe that the observed relations, are not associated with a change in mechanism (the reaction is carried out in a relatively non-polar aprotic solvent which does not favour S_N1 processes) but merely with steric effects, since models show that in indoles alkylation at the nitrogen atom is sterically more difficult than at a carbon atom (in the 3-position of the pyrrole ring).

Cardillo et al.[33] and Le Noble and Puerta[34] consider that another contradiction with Kornblum's rule is the fact that allyl and benzyl halides, which the authors believe should impart to the transition state an appreciable S_N1 character, show a considerable tendency to alkylate the centre with the minimum electron density, greatly exceeding in this property the corresponding saturated alkyl halide.

This type of behaviour is general, since it is observed in the alkylation of various ambident systems: the enolates of acetoacetic ester[34] and acetophenone derivatives[35], the β-naphthoxide anion[36,37], salts of 2-hydroxypyridine[30], 2-hydroxypyrimidine[31], pyrrole[38], indole[33], etc. In all these examples the fraction of *O*- or correspondingly *N*-alkylation in the presence of benzyl and allyl derivatives is much less than when the corresponding n-propyl and ethyl halides are employed and is approximately at the level for methyl halides.

However, the widely held view that allyl and benzyl halide derivatives react preferentially by a unimolecular nucleophilic substitution mechanism (S_N1) is erroneous. Indeed, despite the fact that these halides are capable of forming relatively stable carbonium ions even in media favouring S_N1 processes (water, alcohols), the reaction with nucleophilic agents takes place only via an S_N2 mechanism[39]. Alkylation of the ambident phenoxide anions by halides of this kind in water is also an S_N2 process[40,41]. Moreover, allyl and benzyl halides are greatly superior in their reactivity in typical S_N2 reactions to the corresponding saturated halides[42].

Thus the contradiction with Kornblum's rule is only apparent, particularly since in the studies quoted above the alkylation was investigated in the majority of cases in aprotic dipolar solvents for which S_N1 processes are relatively a typical[43].

It is noteworthy that the reactivities of nucleophiles towards a particular electrophile in S_N2 reactions may be expressed by the equation[44,45]

$$\lg (k_N/k_0) = \alpha E_n + \beta H,$$

where k_N is the rate constant for the given nucleophilic agent, k_0 the rate constant for a standard nucleophilic agent (usually the solvent), E_n and H are constants characterising the nucleophiles, and α and β are constants characterising the electrophiles; α is the polarisability of the atom at which the substitution takes place[46] and β is a measure of the positive charge at this atom[47].

In substitution at a saturated carbon atom the β constant is so low that the term βH may be neglected[48] (see also Palm[49]) and the reactivity of the electrophilic agent in S_N2 reactions can be measured simply by the polarisability of its acceptor atom (in the absence of significant steric effects).

Consequently the higher reactivity of allyl and benzyl halides in S_N2 reactions compared with the corresponding saturated halogeno-derivatives is related to the higher polarisability of the allyl (benzyl) carbon atom. This implies in turn that the allyl (benzyl) carbon atom is a softer Lewis acid than the acceptor carbon atom of the corresponding saturated halide, which we believe to account for the very high tendency of allyl and benzyl derivatives to react at the more polarised, i.e. the softer centre in the ambident anion.

If this view is correct, then in general an increase in the reactivity of the alkylating agent in bimolecular nucleophilic substitution reactions will increase the tendency towards reactions involving the more polarised atom in the ambident anion¶.

Indeed, the available data confirm that the tendency to react at the more polarised (less electronegative) atom decreases in the series (see, for example, Refs. 30, 34, 35, 50) $CH_3X > C_2H_5X > n\text{-}C_3H_7X > iso\text{-}C_3H_7X$ (for the same groups X and identical conditions), which corresponds to the variation of reactivity in S_N2 processes.

In many cases this relation can of course be explained by steric effects, particularly for branched-chain halides. In addition, particularly strong steric effects, which prevent the attack on one of the centres of the ambident anion, may reverse this series. Such examples will be quoted in the next subsection.

It has now become clear that the nature of the substituted group X in the alkylating agent RX has a significant influence on the mode of reaction of ambident anions. Thus in the alkylation of the anion of the acetoacetic ester in solvents of a wide variety of polarities the fraction of *O*-alkylation products increases when X† is varied in the series $RI < RBr < RCl < (RO)_2SO_2$, i.e. the tendency towards reaction at the atom with the maximum electron density increases with increase of the electronegativity of X[34,51–54].

A similar relation was observed also in the alkylation of certain other anions. For example, in the ethylation of the anions of the series of monocarbonyl compounds the fraction of *O*-alkylation products increases sharply on transition from C_2H_5Br to $p\text{-}CH_3C_6H_4SO_2OC_2H_5$.[35] In the alkylation of the pyrrole anion the fraction of the *N*-alkylation product increases on passing from allyl bromide to allyl toluenesulphonate[38]. In the reaction of salts of p-toluenesulphinic acid with CH_3I the *S*-methylation product (sulphone) is mainly formed, and, when dimethyl sulphate, methyl toluenesulphonate or alkoxyphosphonium salts are employed as alkylating agents, the *O*-methylation product is formed (ester of sulphinic acid)[55].

The question arises how the effect of the substituted group on the mode of reaction of ambident anions may be explained‡. One of the explanations was given by Beletskaya, Reutov, and coworkers[53]: when the electronegativity of the X group increases, there is a simultaneous increase of the partial positive charge at the carbon atom at which the substitution takes place and a decrease in its polarisability[47], which indicates an increase in the electrophilicity of the alkylating agents. In other words, there is an increase in the hardness of the acceptor carbon atom

---

¶ The same idea was put forward by le Noble and Puerta[34] albeit without any explanation.

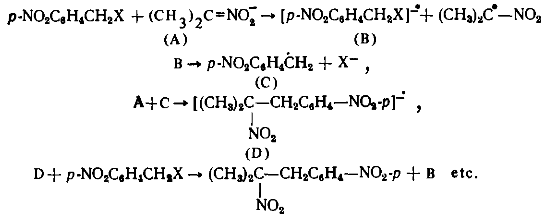
† When R and the reaction conditions remain constant.

‡ This effect is not related to a change in mechanism, since in the studies quoted the reactions were carried out under the conditions of an S_N2 process.

and consequently an increase in the tendency towards reaction at the harder centre of the ambident anion.

Another explanation of this phenomenon in terms of the principle of hard and soft acids and bases was given by Pearson and Songstad[13,22]. By considering the transition state of S_N2 processes, these workers concluded that the grouping of several soft or several hard bases around the carbon atom at which substitution takes place stabilises the transition state and hence increases the rate of reaction (the so called symbiotic effect). Hence it follows that, when the substituting group X is eliminated as an anion which is a hard Lewis base (X = Cl or OSO_2OR), the electrophilic agent reacts at a higher rate at the harder centre of the ambident anion. Conversely, when X^- is a soft base (X = Br or I), then the reaction at the softer centre predominates. It must be emphasised that not all ambident anions are equally sensitive to changes in the substituted group. Thus in the anions of 2-hydroxypyridine[30] and particularly 2-hydroxypyrimidine and its derivatives[31] the change in the group eliminated has little effect on the mode of reaction.

An apparent contradiction with the above relations in the alkylation of certain ambident anions by *p*-nitrobenzyl derivatives ($p\text{-}NO_2C_6H_4CH_2X$) should be pointed out. Thus in the reaction of these derivatives with the lithium salt of 2-nitropropane the fraction of the *O*-alkylation product decreases in the following sequence as X is varied: $I > Br > p\text{-}CH_3C_6H_4SO_2O > Cl$, with a corresponding increase in the fraction of *C*-alkylation[56,57]. However, subsequently it was found that in this case *C*-alkylation is a radical-anion chain process and not a nucleophilic substitution reaction[58-61]:



$$p\text{-}NO_2C_6H_4CH_2X + \underset{(A)}{(CH_3)_2C{=}NO_2^-} \rightarrow \underset{(B)}{[p\text{-}NO_2C_6H_4CH_2X]^{-\bullet}} + (CH_3)_2\overset{\bullet}{C}{-}NO_2$$

$$B \rightarrow \underset{(C)}{p\text{-}NO_2C_6H_4\dot{C}H_2} + X^-\,,$$

$$A + C \rightarrow \underset{(D)}{[(CH_3)_2\underset{\substack{|\\NO_2}}{C}{-}CH_2C_6H_4{-}NO_2\text{-}p]^{-\bullet}}\,,$$

$$D + p\text{-}NO_2C_6H_4CH_2X \rightarrow (CH_3)_2\underset{\substack{|\\NO_2}}{C}{-}CH_2C_6H_4{-}NO_2\text{-}p + B \quad \text{etc.}$$

On the other hand, nucleophilic substitution leads solely to *O*-alkylation.

The ratio of the *C*- and *O*-alkylation products reflects merely the competition between two different reactions. When nucleophilic substitution is faster than the radical-anion process, then *O*-alkylation predominates (X = I); on the other hand, when nucleophilic substitution is slow (for example, when X = Cl), the radical reaction predominates and consequently *C*-alkylation takes place preferentially. The anion of 2-ethoxycarbonyl-3-coumaranone reacts by a similar mechanism with *p*-nitrobenzyl derivatives[62,63].

In connection with the problem of the effect of the substituted group, the alkylation of ambident anions by trialkyloxonium salts should be examined. The trialkyloxonium cation R_3O^+ is strongly electrophilic, i.e. it should be fairly hard and should exhibit an appreciable tendency towards reactions involving the centre with the highest electron density. The available literature data largely confirm this conclusion.

For example, the anions of acetoacetic ester and of acetylacetone are usually alkylated by primary alkyl halides at a carbon atom in media of low polarity[6,50], while in the reaction where the triethyloxonium salt (in ether) is employed *C*-alkylation is accompanied by appreciable *O*-alkylation[64]. The triethyloxonium salt reacts similarly with the diethyl phosphorothioate anion (a mixture of *S*- and *O*-derivatives is formed; with alkyl halides, only *S*-alkylation takes place[65]), the anion of 2-hydroxypyridine (both *O*- and *N*-alkylation take place)[66], and certain other ambident systems. The anions of nitroalkanes give only *O*-alkylation products[67-69].

However, in the alkylation of the anion of acetoacetic ester in hexamethylphosphoramide (HMP) the triethyloxonium salt gives an unexpectedly lower amount of the *O*-alkylated product than the less electrophilic diethyl sulphate[52,53]. The authors suggest that in this case the alkylating agent is not the triethyloxonium cation itself but its complex with HMP, which reduces significantly its electrophilicity.

It is noteworthy that in the general case the interaction of an ambident anion with an alkylating agent of opposite sign need not by any means necessarily lead to products of attack on the centre with the maximum electron density. According to Kornblum[1], for reaction at the most electronegative atom to occur, it is more important that the bond between the alkyl residue and the group to be eliminated should break readily, which is not always so with 'onium salts. Moreover, examples are known where 'onium salts show a lower tendency towards reactions involving the centre with the maximum electron density than other alkylating agents.

Thus, in the alkylation of the anion of acetoacetic ester with a benzyldimethylphenylammonium salt, the *C*-alkylation product is formed in high yields[70]. The anions of mononitroalkanes usually give only *O*-alkylation products, but in the reaction with diphenyliodonium salts they are phenylated at a carbon atom[71,72]. Other examples are also known.

Carbonium ions are harder Lewis acids than oxonium salts and consequently in kinetically controlled reactions they should alkylate preferentially the centre of maximum electron density. However, the available data, although extremely limited, show that this is not always the case.

Thus for the most reactive carbonium ion selectivity may be lost owing to the extremely high reactivity; a decrease in the energy of the carbonium ion may lead to an increase of selectivity. Relations of this kind are observed in reactions of phenoxide ions with carbonium ions[8]: on passing from $(CH_3)_3C^+$ via $(C_6H_5)_2\overset{+}{C}H$ to $(C_6H_5)_3\overset{+}{C}$, the fraction of *O*-alkylation increases. While the trimethylcarbonium ion gives about 25% of the *O*-alkylated isomer and about 75% of the *C*-alkylated isomer, the percentages of the two isomers produced by the triphenylcarbonium ion are about 95% and about 5% respectively.

Diazomethane, which is rather an unusual alkylating agent, in many cases methylates preferentially the centre with the maximum electron density in reactions with the conjugate acids of ambident anions (see, for example Refs. 55, 73, and 74).

Kornblum[1] explained this phenomenon by the following sequence of reactions:

$$R{-}\underset{\substack{\|\\O}}{C}CH_2COOC_2H_5 \xrightarrow{CH_2N_2} R{-}\underset{\substack{|\\-O}}{C}{=}CHCOOC_2H_5 + \overset{+}{C}H_3N_2 \rightarrow R{-}\underset{\substack{|\\CH_3-O}}{C}{=}CHCOOC_2H_5 + N_2\,.$$

i.e. in the first stage of the process diazomethane behaves as a base, which results in the formation of an ambident anion and a methyldiazonium ion. The latter, which exhibits an appreciable tendency towards *O*-alkylation reactions, methylates the centre with the maximum electron density.

The amount of data on the application of other diazoalkanes is much less. It is known that in the alkylation of α-pyridones diazoethane gives a much higher yield of the *O*-alkylation product than diazomethane[75].

In conclusion of this section, we may note that according to Pearson a saturated carbon atom is an intermediate (boundary) Lewis acid (see Section IV) and therefore, as can be seen from the data quoted above, even relatively slight changes in the structure of the alkylating agent and also in the reaction conditions (see below) lead to appreciable alteration in the mode of alkylation of ambident anions.

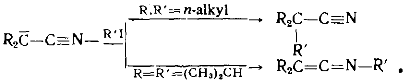
2. Steric Effects

In those cases where one of the reaction centres of the ambident anion is sterically more accessible than the other, steric factors have a very appreciable influence on the mode of reaction, frequently surpassing in this respect the electronic effect, particularly when the steric requirements of the alkylating agent are also stringent.

Thus, in the alkylation of potassium phenoxide by alkyl iodides (in a mixture of t-butyl alcohol and the dimethyl ether of tetraethylene glycol), only the *O*-alkylation product is formed, while in the case of 2,6-di-(t-butyl)phenoxide both *O*- and *C*-alkylated derivatives are formed under these conditions, the fraction of the *C*-alkylation products (mainly in the *p*-position) increasing sharply on passing from methyl iodide to ethyl and further to isopropyl iodide (in the latter case *C*-alkylation takes place exclusively)[76].

Thus a decrease in the steric accessibility of the oxygen atom compared with a carbon atom (particularly in the *para*-position) has a very significant effect on the mode of reaction. This effect increases with steric hindrance in the alkyl halide and leads to results opposite to those which would have been expected from purely electronic effects in the alkyl halide (see p. 6).

Alkylation of α-cyanocarbanions usually leads only to *C*-alkylated isomers:



However, when R and R′ are isopropyl groups, appreciable amounts of the *N*-alkylation product are formed[77].

In the enolates of carbonyl compounds the oxygen atom is sterically more accessible than the carbon atom[78]. For this reason, the fraction of *O*-alkylation increases significantly both with the size of the substituent at the carbon reaction centre of the anion and with increasing steric hindrance in the alkyl halide.

Thus alkylation of the anions of acetoacetic ester and acetylacetone by primary alkyl halides in alcohols or non-polar solvents usually takes place exclusively at the carbon atom, while in the presence of secondary alkyl halides under the same conditions, appreciable amounts of enolic ethers are produced[50].

In the alkylation of the anion of acetoacetic ester in polar aprotic solvents the fraction of *O*-alkylation also increases significantly with the branching of the hydrocarbon group in the alkyl halide[34,78]; for example, with neopentyl chloride only the *O*-alkylated isomer is formed[78].

In the alkylation of the enolates of α-substituted acetophenones the amount of the *O*-alkylated product increases sharply with the size of the α-substituents[35], which indicates a significant effect of steric hindrance in the enolate on the mode of reaction. The alkylation of the anions of 2-hydroxypyrimidine and its derivatives is hardly affected by the nature of the solvent, the cation, and the group substituted. The structure of the alkyl halide has the main influence: on passing from methyl to isopropyl halide, the fraction of *O*-alkylation increases, which the authors attributed solely to steric effects, since models show that alkylation at the nitrogen atom imposes more stringent steric requirements than attack on the oxygen atom[31]. A similar conclusion was reached also for the anion of 2-hydroxypyridine[30].

Steric effects have also been used to account for the increase of the fraction of *O*-alkylation of the anion of benzophenone oxime and its derivatives on passing from methyl bromide to benzyl bromide[79].

3. Effects of the Solvent

The solvent usually has a very significant influence on the mode of reaction of ambident anions. Earlier (see p. 5) the effect of the solvent on the behaviour of alkylating agents was already noted. Here we shall consider the interaction of the solvent with the ambident anion–counterion system and the influence of such interaction on the mode of alkylation.

In a study of the behaviour of ambident anions in aprotic solvents the following general feature was observed: an increase in the polarity of the aprotic solvent favours alkylation at the centre with the maximum electron density. For example, in the alkylation of the anions of 2,6-dimethylphenol the fraction of *O*-alkylated products decreases in the following sequence as the solvent is varied: ethyl ether > isopropyl ether > toluene > benzene[80]. The fraction of the *N*-alkylation products of the anion of pyrrole decreases in the sequence tetrahydrofuran > dioxan > isopropyl ether > ethyl ether > benzene, toluene, n-heptane, methylcyclohexane[81].

The tendency towards reactions at the centre with the maximum electron density increases even more when dipolar aprotic solvents are employed—dimethylformamide (DMF), dimethylacetamide (DMAA), dimethyl sulphoxide (DMSO), hexamethylphosphoramide (HMP), and others.

Such behaviour is observed in the alkylation of a wide variety of ambident anions: the enolates of β-dicarbonyl compounds (see, for example Kurts et al.[54]), β-naphthoxides[36], salts of pyrrole[38], indole[33], 2-hydroxypyridine[30], and others. The effect of aprotic solvents was investigated in greatest detail during recent years[36,54,78,81]. It is noteworthy that dipolar aprotic solvents also differ significantly among one another in terms of their influence on the mode of alkylation of ambident anions. Thus in the alkylation of the anions of acetoacetic ester and acetylacetone the greatest yield of the *O*-alkylated isomers is observed in hexamethylphosphoramide and the tetramethyldiamide of methylphosphonic acid. These are followed by aprotic solvents of the amide type: DMF, DMAA, tetramethylurea, etc., and also dimethyl sulphoxide in which the fraction of the *O*-alkylated isomer is lower; the amount of *O*-alkylated derivatives is reduced still further in acetone, acetonitrile, and tetramethylene sulphone. These are followed by solvents of the ether type which are of relatively low polarity and also certain halogeno-derivatives in which the amount of *O*-alkylated products is as a rule close to zero[54] (see also Refs. 34, 51–53, 78, 82).

This does not of course imply that the use of dipolar aprotic solvents always leads to preferential alkylation of the centre with the maximum electron density. The final result depends both on the properties of the anion itself, and on the relative importance for the given anion of particular factors which influence the mode of reaction.

For example, silver nitrite in a relatively non-polar solvent (ethyl ether) is appreciably alkylated at the oxygen atom[1], while the use of alkali metal nitrites in a dipolar aprotic solvent (DMF) significantly increases the fraction of *N*-alkylation[1,24], i.e. in the case of nitrite ions, the alkylating agent (or more correctly its form produced by modification under the influence of silver ions) has a greater effect than the solvent. On the other hand, the solvent has virtually no influence on the mode of reaction of the anions of 2-hydroxypyrimidine on some of its derivatives[31].

The question arises of the reasons for the influence of aprotic solvents on the mode of reaction of ambident anions. Aprotic solvents, including dipolar solvents, as a rule solvate anions only very slightly[43] and therefore the change in the mode of reaction is probably not associated to any appreciable extent with the interaction between the aprotic solvent and the anion.

Kornblum[36] attributed the effect of aprotic solvents to their dielectric properties. However, subsequently, it was found that the effect of such solvents is not determined by their dielectric constants[54,78] but by their capacity to solvate cations[35,38,54,78,81].

This type of relation can be explained as follows. Like other electrolytes[83,84], the salts formed by ambident anions and their counterions are associated to some extent in the majority of organic solvents to ion pairs (or more highly aggregated species). In view of the electrostatic orientation of ions, it is likely that the cation will be preferentially coordinated to the atom in the ambident anion with the maximum electron density§ (hard nucleophilic atom)[2], i.e. in the association of the ambident anion and the counterion the centre with the highest electron density is screened, which hinders the reaction at this site; in consequence, the relative reactivity of the second nucleophilic centre increases (an approach to this problem, in many ways similar to that described, was employed by Nesmeyanov and Kabachnik[3]). The increase in the degree of solvation of the cation by the solvent, for example on passing from solvents of low polarity to dipolar aprotic solvents, leads to a weakening of the coordination of the cation to the ambident anion and hence facilitates the reaction at the atom with the maximum electron density.

The increase in the degree of solvation of cations by the solvent can probably lead both to a weakening of the bond between the cation and anion within the ion pair and to an increase of the degree of dissociation of the ion pair. Both these effects will facilitate attack on the harder atom of the ambident anion. However, at present the available experimental data are insufficient to estimate in a specific case which of these effects is responsible for the change in the mode of reaction.

It is noteworthy that the determination of the capacity of the solvent to solvate cations is not a simple problem although such estimates have been made for a series of the most widely used solvents[43]. In this connection the correlation[78] between the relative amounts of both *O*- and *C*-alkylated isomers in the alkylation of the anion of acetoacetic ester and the basicity of the solvent (the increase of the fraction of the *O*-alkylated isomer with the basicity of the solvent) merits attention. However, at present there are too few data to arrive at a conclusion concerning the applicability of such correlations to a wide range of systems.

Protic solvents—alcohols, unsubstituted amides, and others—behave as hydrogen bond donors and, in contrast to aprotic solvents, usually readily solvate anions[43].

Kornblum found for phenoxides[40,41] and β-naphthoxides[36] that, despite the fact that protic solvents effectively solvate cations[43], alkylation in them greatly promotes reactions involving the most polarised (soft) centre of the ambident anion and prevents attack on the centre with the maximum electron density.

The effectiveness of protic solvents as media promoting reactions at the softer nucleophilic atom of the ambident anion very greatly increases when solvents capable of forming stable hydrogen bonds are employed. For example, phenol salts in aprotic solvents (dimethylformamide, tetrahydrofuran, ethyl ether, and even toluene) are alkylated exclusively at the oxygen atoms; the use of protic solvents such as methyl, ethyl, and t-butyl alcohols also does not alter the mode of reaction. However, in solvents such as water, fluorinated alcohols, and phenol, which form significantly stronger hydrogen bonds than simple aliphatic alcohols[85,86], *C*-alkylation of phenoxide anions takes place to a considerable degree (the yield of *C*-alkylated isomers approaches 80% in some cases)[40,41]. It has been noted that in this case both *C*- and *O*-alkylation takes place via an S_N2 mechanism.

According to Kornblum[40,41], the effect of protic solvents can be accounted for as follows: owing to hydrogen bonding, these solvents selectively and effectively solvate the centre with the maximum electron density (for example, the oxygen atom)¶, as a result of which the accessibility of this centre is greatly reduced and substitution at the other centre (a carbon atom) may successfully compete with that at the oxygen atom. Hence it becomes clear why the solvent capable of forming the strongest hydrogen bonds (water, phenol, fluorinated alcohols) are especially effective: an increase in the strength of the hydrogen bond will increase the energy required to desolvate the atom with the maximum electron density and hence will increase the activation energy for reaction at this atom.

Kornblum[41] suggested the name "selective solvation" for the capacity of protic solvents to solvate selectively the centre with the maximum electron density and thereby prevent the reaction at this centre. This type of effect of protic solvent on the mode of reaction is observed also for other ambident anions. For example, in the alkylation of the anion of acetoacetic ester the yield of the *O*-alkylated isomer falls sharply on passing from dipolar aprotic solvents to alcohols (ethyl and t-butyl alcohols) and to a substituted amide (*N*-methylacetamide) and in alcohols the yield of the *O*-alkylated isomer falls almost to zero[54].

In the alkylation of the enolates of monocarbonyl compounds[35] and 2-hydroxypyridine salts[30] transition from polar aprotic solvents to alcohols also leads to a significant decrease of the amount of the *O*-alkylated isomer. It is noteworthy that even relatively small amounts of added protic solvents influence the mode of reaction[34,52,53,87]. Thus in the ethylation of the enolate of acetoacetic ester in hexamethylphosphoramide the addition of equimolar amounts of protic solvents (water, t-butyl alcohol) significantly increases the fraction of *C*-alkylation[52,53,87].

---

§ At least in the case of alkali and alkaline earth metal cations and also ammonium ions, i.e. hard Lewis acids (see Section IV). For metal cations which are soft Lewis acids (for example Hg^{2+}), there is a possibility of coordination at the most polarised atom in the ambident system.

¶ We may recall that the hydrogen atom behaves as a hard Lewis acid in the formation of a hydrogen bond (see Section IV).

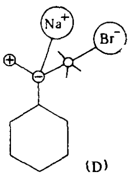
At the present time the explanation of the effect of protic solvents on the mode of reaction given by Kornblum is generally accepted, (see, for example, Refs. 30, 35, 52, 54, 87)†.

Factors such as the heterogeneity or homogeneity of the medium in which the reaction is carried out are closely related to the influence of solvents.

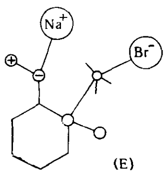
In 1959, Kornblum and Lurie[8] found that the alkylation of phenol and *p*-t-octylphenol salts under truly heterogeneous conditions, i.e. on the surface of the crystals of the salts, leads exclusively to *C*-alkylation products, while the same reaction in solution yields only *O*-alkylation products. Their explanation of these results is as follows[8]. The alkylation of the oxygen atom should involve a linear transition state (D) in which the negative charge of oxygen is transmitted to the halogen atom of the alkylating agent. There are two factors which make such a transition state energetically unfavourable. In the non-polar solvents employed for the heterogeneous reaction the halide ion eliminated is solvated to only a very slight extent. However, a still more important factor is that the transfer of electron density from the oxygen atom will lead to electrostatic repulsion between the positively charged metal ions and to a sharp increase of the energy of the system, since in the crystal lattice the metal ions cannot move apart.

In a homogeneous medium the formation of the ether (the *O*-alkylation product) does not give rise to difficulties of this kind even if the entire salt is present in the form of ion pairs or larger aggregates, since in solution metal ions can readily move apart.

In contrast to the formation of ethers, *C*-alkylation takes place via a non-linear transition state (E) where the halide ions is "solvated" owing to the formation of an ion pair with the metal ion; moreover, the formation of this ion pair will prevent electrostatic repulsion between the metal ions when the oxygen atom loses its negative charge. Consequently, under heterogeneous conditions *C*-alkylation takes place preferentially:



(D)



(E)

It is at present impossible to state whether this factor ("heterogeneity") does indeed have such an appreciable influence also in the case of other ambident anions or whether it applies only to phenol and similar systems, since there have been no studies of dual reactivity showing clearly that the "heterogeneous" reaction investigated takes place only on the surface of the crystal and not in solution.

4. Effect of the Cation and the State of the Salts in Solution

The nature of the counterion (cation) frequently has an appreciable effect on the mode of reaction of ambident anions. Above (see pp.4 – 5) the specific effect of the silver cation and similar ions (electrophilic catalysts) has already been reported. Here we shall examine the effect of other cations.

In a study of the alkylation of ambident anions in aprotic solvents a single general relation was observed: the tendency of the ambident anions to react at the centre with the maximum electron density increases in the following sequence of cations: $Li^+ < Na^+ < K^+ < Rb^+ < Cs^+ < NR_4^+$. Moreover, it has been shown in a number of cases that the Li^+ ion promotes the reaction at the centre with the maximum electron density more than the Mg^{2+} ion (β-naphthoxides[37], pyrrole salts[38]).

This type of relation has been observed in a wide variety of ambident systems: enolates of β-dicarbonyl[34,51-53,87] and monocarbonyl compounds[89], salts of naphthols[36,37], phenols[80], pyrrole[38,81], 2-hydroxypyridine[30], and others. The effect of the cations obtains both in relatively non-polar aprotic solvents and in dipolar aprotic solvents. Thus the tendency towards reactions involving the centre with the maximum electron density diminishes with decreasing radius of the cation and, for equal radii (Li^+ and Mg^{2+}), with increase of the charge, i.e. with increase of the hardness of the cation (see Section IV).

As already stated (see p. 9), salts formed by ambident anions and their counterions in solution are to some extent associated into ion pairs and the alkali metal or alkaline earth metal cation is preferentially coordinated to the hard nucleophilic atom of the ambident anion, which hinders the reaction at this atom. With increase of the hardness of the cation (decrease of the radius and increase of the charge), the degree of association of the cation with the centre having the maximum electron density will become more pronounced (a more "closely linked" ion pair will be formed) and thereby the reaction at this centre will be hindered. In consequence, the relative reactivity of the second, softer nucleophilic centre will increase.

The strengthening of the bond between the cation and anion leads to both an increase of the energy required to descreen the hard reaction centre and to a decrease of the degree of dissociation of the ion pairs. Both these factors will hinder the reaction at the atom with the maximum electron density. At the present time it is impossible to say in a specific case which of these factors is responsible for the change in the mode of reaction as the cation is varied.

It is important to note that, in contrast to Kornblum's hypothesis[36], the effect of the change of the cation can be followed also in dipolar aprotic solvents (dimethylformamide, dimethyl sulphoxide, and others), for example in the case of the anions of acetoacetic ester[34,51-53,87] and pyrrole[81], i.e. even in these solvents there is some association of the ambident anions with their counterions to form ion pairs‡. Only in solvents such as hexamethylphosphoramide, which very strongly solvates cations, have cases been found where a change of the cation does not affect the mode of reaction (the acetylacetonate anion[54] and also the anion of acetoacetic ester at elevated temperatures[78]). Probably in such cases the reactive species is the anion not combined in an ion pair[54,78] and the mode of reaction is determined solely by the mesomerism of the anion itself[54].

The postulate of the strengthening of the bond between the cation and the centre in the ambident anion having the

---

† Recently the hypothesis of the selective solvation by protic solvents of the hard centre in ambident anions was proved by spectroscopic methods for salts of phenols and certain nitro-compounds as examples[88].

‡ It has been shown by ultraviolet spectroscopy that the salts of phenol and acyclic β-dicarbonyl compounds are in most cases associated in dimethylformamide even at concentrations in the range 10^{-4}–10^{-5} M.[90]

maximum electron density as the radius of the cation is reduced was confirmed by spectroscopic methods for alkali metal salts of phenols and β-dicarbonyl compounds in 1,2-dimethoxyethane and dimethylformamide solutions [90]. It was also shown [90] that in these aprotic solvents association of the alkali metal cations with the anions of phenols and enols does not involve the formation of covalent bonds even for the most "closely linked" ion pairs and the interaction is purely ionic.

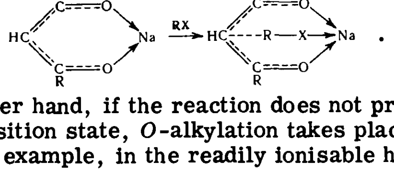
The effect of the cation in protic solvents has been investigated to a very limited degree. However, the available data show that, despite the high solvation capacity of polar protic solvents in relation to cations and anions [43], in many cases a cationic effect is observed [37,80,91], although examples may be quoted when the effect of the cation is insignificant [79]. Nevertheless there is no doubt that more detailed studies will lead to the discovery of ambident systems where the effect of the cation will be significant even in such media, particularly since in many cases association into ion pairs of ambident anions and their counterions has been observed even in a solvent such as water (see, for example, Zaugg and Schaefer [90]).

Thus the data presented show that association with cations reduces the tendency of the ambident anion towards reaction at the centre with the maximum electron density, at least in aprotic solvents. An example of direct experimental proof of this hypothesis is provided by the study by Smith and Milligan [92] of the effect of ion pair association on the mode and rate of alkylation of the fluorinone oxime anion.

However, in protic solvents in those cases where the centre with the maximum electron density in the ambident anion is more firmly solvated via hydrogen bonding than via association with the cation there is also a possibility of the opposite relation: a greater tendency towards reactions at this centre in ion pairs than in the unassociated anion [36,93].

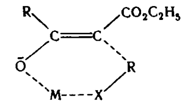
It must be emphasised that the state in solution of salts formed by ambident anions with their counterions (degree of association into ion pairs as a function of the solvent and the cation, the nature of the ion pairs formed—with the two ions in direct contact or separated by solvent species, the size of the ionic aggregates, etc.) has so far been clearly inadequately investigated, which hinders a quantitative estimation of the dual reactivities of both the associated species and the "free" anions.

According to Brändström [5,94], the formation of chelate compounds, for example by metal derivatives of β-dicarbonyl compounds, has a very significant influence on the mode of reaction. The chelates have a ring structure and have pseudoaromatic properties; according to Brändström's hypothesis [5,94], *C*-alkylation of these systems is a multicentre process and proceeds via the energetically favourable six-membered transition state:



On the other hand, if the reaction does not proceed by a cyclic transition state, *O*-alkylation takes place. This happens, for example, in the readily ionisable halogenoderivatives (RX), where the coordination with a metal ion or the effect of the solvent lead to the formation of a carbonium cation, which reacts at the site with the maximum electron density—at the oxygen atom.

It has recently been suggested that [95] the formation of a six-membered transition state (owing to coordination between the metal ion and the "nucleophilic" part of the alkylated agent), promoting *C*-alkylation, is possible also in the case of non-chelate structures, as can be seen from the scheme below:



This type of transition state should be promoted by solvents which cause least dissociation of the enolate and ionisation of the alkylated agent (protic and aprotic media of low polarity).

5. Effect of Certain Other Factors

Comparatively few data are available on the effect of factors other than those described above on the mode of reaction of ambident anions. In a number of examples it has been shown that, as the concentration of the "ambident" salts in aprotic solvents is reduced, the yield of the product of the alkylation of the centre with the maximum electron density increases [35,38,80,81,87]. Whereas in dipolar aprotic solvents [87] this phenomenon can be accounted for by an increase of the degree of dissociation of the ion pair, in aprotic media of low polarity (ethyl ether, tetrahydrofuran, and others [38,80,81]) the existence of unassociated anions is extremely doubtful; possibly in these media dilution leads to the dissociation of highly aggregated species into smaller aggregates, which increases the accessibility of the hard centre.

It has been found for the anions of monocarbonyl compounds that, in contrast to aprotic media, in protic solvents the fraction of *O*-alkylation diminishes with dilution [35], which the authors attribute to enhanced effectiveness of the hydrogen bond§.

Even fewer data are available on the effect of temperature. In the alkylation of pyrrole salts in dioxan and toluene the fraction of the *N*-isomer increases with temperature [38]. In the case of the enolates of acetoacetic ester an increase of temperature entails an increase of the fraction of *O*-alkylation when the reaction is carried out in dimethyl sulphoxide [51].

The observed behaviour can be accounted for by an increase of the degree of dissociation of ion pairs (or larger aggregates) with increasing temperature, particularly since for the acetoacetic ester anions in hexamethylphosphoramide, where the reacting species is believed to be the "free" anion, a temperature effect is not observed [78]. However, this view does not explain the decrease of the fraction of *O*-alkylation of the enolate of acetoacetic ester with increasing temperature in N^1-methylpyrrolidinone [51].

A change in hydrostatic pressure does not usually affect the mode of alkylation, particularly when the reaction is performed in aprotic solvents [96,97]. However, in the alkylation of phenoxide and β-naphthoxide ions in protic media, an increase of pressure (to several thousand atmospheres) causes some increase in the fraction of *C*-alkylation [96-99], which is explained by an enhancement of the "selective" solvation of the oxygen atom (via hydrogen bonding) as the pressure rises [97-99].

---

§ Apparently in this case "selective" solvation has a greater influence on the mode of reaction than association with the cation.

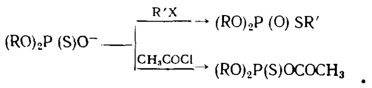
VI. BEHAVIOUR OF AMBIDENT ANIONS IN SUBSTITUTION REACTIONS AT AN UNSATURATED CARBON ATOM AND AT HETEROATOMS

In contrast to substitution at a saturated carbon atom, the behaviour of ambident anions in substitution reactions at an unsaturated carbon atom has been much less investigated; there are even fewer data on substitution at heteroatoms. It is reasonable to suppose that many of the factors which influence the mode of alkylation will operate also in the case of other electrophilic agents. However, here one should take into account in the first place the nature of the electrophilic agent itself and its tendency to react at a particular centre of the ambident anion. The examples quoted below show that the principle of hard and soft acids and bases (see Section IV) is very useful for the estimation of such properties of electrophilic agents.

Substitution at an unsaturated carbon atom has been investigated mainly in acylation reactions (substitution at a carbonyl carbon atom). Since the carbonyl carbon atom is a hard Lewis acid,[13] (see also Section IV), it is to be expected that in acylation the reaction will take place to a considerable degree at the harder atom of the ambident anion (at the centre with the maximum electron density), and the tendency to react at this centre should be much greater than in alkylation (a saturated carbon atom is an intermediate Lewis acid).

The available data fully confirm this hypothesis, at least when carboxylic acid anhydrides and halides are employed as the acylating agents. Thus in the acylation of the enolates of monocarbonyl compounds, *O*-acylated isomers are formed preferentially, whereas under the same conditions alkylation gives either *C*-alkylated products or a mixture of the *C*-alkylated and *O*-alkylated isomers[89,100–102]. The enolates of β-dicarbonyl compounds are capable of giving both *C*- and *O*-acyl derivatives but in acylation they tend to undergo reaction at the oxygen atom more than in alkylation (see, for example, Refs. 3, 5, 94, and 103). Acylation of the phenoxide anion by acid halides probably takes place only at the oxygen atom under these conditions[2].

The salts of phosphorothioic acids are alkylated at the sulphur atom[104–106]; on the other hand, the acylation of these salts by acyl halides takes place preferentially at the oxygen atom[105,107]:



$$(RO)_2P(S)O^- \begin{cases} \xrightarrow{R'X} (RO)_2P(O)SR' \\ \xrightarrow{CH_3COCl} (RO)_2P(S)OCOCH_3 \end{cases} .$$

Thiocyanate ions are acylated by acetyl chloride at the nitrogen atom, while alkylation takes place at the softer sulphur atom[13].

The mode of acylation of ambident anions is probably influenced by the same factors as in alkylation. Thus in the acylation of the anions of β-diketones an increase of the carbonium character of the transition state leads to an increase of the fraction of the *O*-acylated isomer[108]. The use of silver salts instead of alkali metal salts (with acyl chlorides as acylating agents) increases the tendency towards the acylation of the more electronegative atom[37,109].

An increase in electrophilicity (and consequently in the hardness) of the acylating agent increases the tendency towards reactions at the harder centre of the ambident anion. For example, in the acylation of the anions of 2-ethoxycarbonylcyclanones the fraction of *O*-acylation increases in the series[110]

$$ClCOOEt < ClCH_2COCl < CH_3COCl < CH_3COClO_4$$

Steric effects can also have a significant influence. Thus despite the fact that the salts of phenol are acylated only at the oxygen atom, the 2,6-di-t-butylphenoxide anion, the oxygen atom of which is strongly screened by bulky groups, is acylated by benzoyl chloride to give a *C*-acyl derivative[111].

As in alkylation, an increase of the polarity of the aprotic solvent favours the reaction at the centre with the maximum electron density (see, for example, Ferris et al.[110]). A change of the cation probably has the same effect as in alkylation[37,110].

The formation of chelates has a significant influence on the mode of acylation, as in alkylation reactions. It has been shown for the chelates of β-diketones that *C*-acylation is promoted when the reaction proceeds via a six-membered transition state (owing to the coordination of the "nucleophilic" part of the acylating agent to the metal ion and of the "electrophilic" part to the carbon reaction centre)[108,112].

The behaviour of ambident anions in substitution reactions at an olefinic carbon atom is illustrated using an example the substitution of the β-carbon atom in compounds of the type $RCOCH = CHX$, where X is the group eliminated (the β-ketovinylation reaction). The ketovinylation of the anions of β-dicarbonyl compounds and nitrocompounds and cyanide, thiocyanate, and nitrite ions takes place at the most polarised (softest) centre of the ambident anion[113]. At the same time the phenoxide anion is ketovinylated only at the oxygen atom even in water[113,114]. Thus the behaviour of ambident anions in the β-ketovinylation reaction is apparently in many respects similar to the behaviour of these anions in alkylation.

The information about the behaviour of ambident anions in substitution reactions at heteroatoms is extremely limited. However, the general tendency of electrophilic agents of this type to react at a particular centre of the ambident anion may be predicted by estimating the properties of the electrophilic agent as a Lewis acid (hard or soft).

Thus the phosphorus atom in the phosphoryl group is a hard Lewis acid (see Section IV), which is reflected in the behaviour of this electrophilic agent in relation to ambident anions. For example, the phosphorylation of phosphorothioate salts takes place, as in acylation, at the harder atom (the oxygen atom)[115]:

$$(RO)_2P(S)O^- + R_2P(O)X \rightarrow (RO)_2P(S)O\underset{\underset{O}{\|}}{P}R_2 + X^- .$$

Similarly the phosphorylation of the thiocyanate ion takes place at the harder centre (the nitrogen atom)[16].

The silylation of enolates by chlorotrimethylsilane takes place only at the oxygen atom[116] (while alkylation takes place only at the carbon atom[101]), which is consistent with the classification of the silicon atom as a hard Lewis acid[20].

The sulphur atom in the sulphenyl group is a soft Lewis acid (see Section IV), which is confirmed by the marked tendency of this electrophilic agent to react at the softer (more polarised) atom of the ambident system. Thus in the reaction of the anions of mononitroalkanes with sulphenyl chlorides, only the corresponding *C*- substituted derivatives (α-nitrosulphides) are formed[117,118]; on the other hand, the alkylation of these anions as a rule leads only to *O*-substituted products[119].

The capacity of perchloryl fluoride ($FClO_3$) to fluorinate the anions of ketoenols, phenols, and nitroalkanes, at the carbon atom[120] suggests that the fluorine atom in this compound may be classified as a soft Lewis acid[7].

---o0o---

The data, in their entirety, show that certain general relations controlling the dual reactivity of ambident anions can now be traced and knowledge of them can help the investigator in many cases to control the process in a particular way.

At the same time many problems still await solution. The author attempted to indicate these unsolved problems throughout the review. One of the most important problems of this kind is the relation between structure and dual reactivity of the anion. It is difficult to solve because the "true" reactivity of the ambident system is frequently subject to very marked changes under the influence of various factors (association with the cation, selective solvation, and others). Hence another problem arises—that of estimating the relative sensitivities of various anions to particular effects.

However, purely experimental data for the reactions of the various anions with a wide variety of electrophilic agents under comparable conditions are at present quite inadequate for the solution of these problems. Moreover, in connection with the introduction of precise methods of analysis and improved research techniques, many old data require revision.

In conclusion, we may note that one cannot exclude the possibility that in future, following a more detailed study of the reactivity of ambident anions and their structure, new concepts may appear, providing a deeper and more complete explanation of certain characteristics of the behaviour of ambident systems.

Prototropic Isomerisation of Olefins with Functional Groups and Its Use in Organic Synthesis

L.A.Yanovskaya and Kh.Shakhidayatov

The characteristics and mechanism of the prototropic isomerisation of olefins with functional groups in the presence of bases, acids, metal carbonyls, and other catalysts and also by thermal and photochemical activation have been examined together with its application in organic synthesis.
The bibliography includes 180 references.

CONTENTS

I. INTRODUCTION

In recent years there has been a considerable growth of interest in the problem of the migration of double bonds in olefins with functional groups. A number of new effective isomerisation catalysts have been proposed and novel methods of synthesis based on prototropic isomerisation have been developed. This review gives a general account of the advances in the study of the mechanism and use in syntheses of the prototropic shift in olefins with functional groups achieved in the last 10–15 years.

A brief review of the literature on this problem up to 1960–1961 is given in "The Chemistry of Alkenes",[1] but it does not deal at all with isomerisation in the presence of metal carbonyls and with thermal and photochemical isomerisation. Information about base-catalysed isomerisation of olefins including some with functional groups is given in the review by Hubert and Reimlinger[2].

II. ISOMERISATION IN THE PRESENCE OF BASES

The prototropic shift under the influence of bases in olefins with functional groups takes place by a carbanionic mechanism[3,4]:

The reaction is reversible. The position of equilibrium depends on the structure of the olefin and the nature of the functional group X, as shown already in the classical work of Kon and Linstead[2,3] on the prototropic isomerisation of unsaturated acids, their esters, and nitriles, and confirmed in subsequent investigations.

For the system $CH_2{=}CHCH_2X \rightleftharpoons CH_3CH{=}CHX$, where X may be conjugated with an $\alpha\beta$-double bond via an unshared electron pair (X = OR, SR, NR$_2$, etc.) or p electrons (X = COOH, COOR, CN, CHO, COR, etc.), the equilibrium is usually displaced towards the conjugated system. For example, alkyl allyl[5], allyl aryl[6], and allyl vinyl[7] ethers are almost completely converted into propenyl ethers on heating with potassium t-butoxide. Similarly, under the influence of alkoxides and other bases, alkyl allyl sulphides[8] and allyl aryl sulphides[9] form equilibrium mixtures where the ratio of the propenyl and allyl forms is 99 : 1. Allyl phenyl selenide isomerises quantitatively to phenyl propenyl selenide in the presence of potassium t-butoxide[10]. The isomerisation of *NN*-disubstituted allylamines[11-13] to enamines goes to completion in the presence of bases and in most cases the equilibrium constants cannot be determined. Under the action of alkalis, vinylacetic acid is converted into an equilibrium mixture containing 98% of crotonic acid[14]. The equilibrium in mixtures of vinylacetonitrile with crotononitrile or of ethyl vinylacetate with ethyl crotonate is also almost completely displaced towards the $\alpha\beta$-isomer[15].

If the group X is incapable of conjugation with the $\alpha\beta$-double bond (X = SO, SO$_2$, etc.), then the equilibrium mixture contains an appreciable amount of the $\beta\gamma$-isomer. Thus the equilibrium mixture of allyl methyl sulphoxide and methyl propenyl sulphoxide contains 17–20% of the $\beta\gamma$-isomer[16] and a mixture of allyl methyl sulphone and methyl propenyl sulphone contains 44% of the $\beta\gamma$-isomer[17]. The equilibrium position in alkyl cycloalkyl sulphones[18] and in cyclic sulphones[18,19] is likewise shifted towards the $\beta\gamma$-isomer.

Substitution (in the first place in the γ-position) in a three-carbon system has an enormous influence on the equilibrium position (Table 1). Table 1 shows that substituents in the γ-position displace the equilibrium towards the $\beta\gamma$-isomer, which may actually predominate. For alkyl groups, this can be explained by the competition between the effect of the conjugation of the functional groups with the double bond, which stabilises the $\alpha\beta$-form, and the effect of the hyperconjugation of the alkyl group with the double bond, which stabilises the $\beta\gamma$-form. If the latter effect prevails, then the $\beta\gamma$-isomer predominates in the equilibrium mixture. The decrease of the hyperconjugation effect in the sequence $H < (CH_3 > C_2H_5 > \text{iso-}C_3H_7 > \text{t-}C_4H_9)$ results in a somewhat smaller effect of higher alkyl groups on the equilibrium position. An alkyl group in the α-position additionally stabilises the $\alpha\beta$-isomer owing to hyperconjugation and therefore the $\alpha\beta$-isomer predominates in the equilibrium mixture even in the presence of a substituent in the γ-position. In βγ-disubstituted derivatives the content of the αβ-form is also somewhat increased. The presence of a substituent in the α- or β-position only has hardly any influence on the equilibrium. Thus mesityl oxide contains only 1.3% of the βγ-form[22,23].

The stabilisation of the βγ-isomer by hyperconjugation has been confirmed by a number of investigations. Thus in the system $n\text{-}C_4H_9C(R){=}CHCH(CH_3)COOC_2H_5 \rightleftharpoons n\text{-}C_4H_9CH(R)CH{=}C(CH_3)COOC_2H_5$ the fraction of the αβ-isomer in the equilibrium mixture increases from 45 to 86% on passing from $R = CH_3$ to $R = t\text{-}C_4H_9$, in agreement with the decrease of the hyperconjugation effect[21]. Analogous results were obtained for ethyl *trans*-2-methyl-4-*p*-R-phenylbutenoates, where the effect of steric factors is excluded and there is no *cis–trans* isomerisation during the attainment of equilibrium[24] (Table 2).

Table 2. $p\text{-}RC_6H_4CH{=}CHCH(CH_3)COOC_2H_5 \rightleftharpoons p\text{-}RC_6H_4CH_2CH{=}C(CH_3)COOC_2H_5$.

R	αβ-Isomer, %	βγ-Isomer, %	R	αβ-Isomer, %	βγ-Isomer, %
H	59.2	40.8	iso-C_3H_7	50	50
CH_3	39.8	60.2	t-C_4H_9	52.4	47.6
C_2H_5	45.9	54.1			

In the equilibrium mixture $C_6H_5CH_2SO_2CH{=}CHSO_2R \rightleftharpoons C_6H_5CH_2SO_2CH{=}CH{-}CH_2SO_2R$ the content of the first isomer also depends on the inductive effect of R, increasing in the series C_2H_5 (39%) < $n\text{-}C_3H_7$ (40%) < $n\text{-}C_4H_9$ (53%) < < $t\text{-}C_4H_9$ (60%).[25] The hyperconjugation effect accounts for the shift of equilibrium towards the second sulphone in the system $(C_2H_5)_2NO_2SCH{=}CHCH(CH_3)SO_2N(C_2H_5)_2 \rightleftharpoons (C_2H_5)_2N{-}O_2SCH_2CH{=}C(CH_3)SO_2N(C_2H_5)_2$.[26]

Apart from the conjugation and hyperconjugation effects, the inductive effect of the functional group plays a major role in the stabilisation of the αβ- and βγ-forms. This is evident from a comparison of the equilibrium constants *K* for mixtures of certain unsaturated sulphides, sulphoxides, and sulphones[8] (Table 3).

Table 3 shows that the stability of the αβ-form decreases in a series $SO_2R > SOR > SR$, i.e. in order of increasing inductive effects. It should be borne in mind that in the system $RCH_2{-}CH{=}CHX \rightleftharpoons RCH{=}CHCH_2X$ the effect of the substituent X is greater than that of CH_2X.

Table 3. Equilibrium constants for mixtures of certain unsaturated sulphides, sulphoxides, and sulphones $RCH_2CH{=}CHX \rightleftharpoons RCH{=}CHCH_2X$.

R	X	*K*	R	X	*K*
H	SCH_3	0.01	$n\text{-}C_3H_7$	SO_2CH_3	99.0
H	$SOCH_3$	0.2—0.25	$n\text{-}C_9H_{19}$	SCH_3	0.5
H	SO_2CH_3	0.78	$n\text{-}C_9H_{19}$	$SOCH_3$	24.0
$n\text{-}C_3H_7$	SCH_3	0.51	$n\text{-}C_9H_{19}$	SO_2CH_3	24.0
$n\text{-}C_3H_7$	$SOCH_3$	24.0			

Electron-accepting substituents increased the mobility of the α-hydrogen atom in $RCH{=}CHCH_2X$ and favour the prototropic shift in accordance with the magnitude of the $-I$ effect. However, such substituents at the double bond destabilise the αβ-form, provided that they cannot show a $+M$ or a $-M$ effect. Accordingly, the SR group stabilises the αβ-form and the SOR and SO_2R groups destabilise it in accordance with the magnitude of their $-I$ effects.

The equilibrium relations among nitro-olefins and phosphorus-containing olefins have been little investigated. According to the available data[27-30], regardless of substitution, an equilibrium mixture of nitro-olefins contains appreciable amounts of βγ-isomers (13–19% for the systems $CH_2{=}CHCH(CH_3)NO_2 \rightleftharpoons CH_3CH{=}C(CH_3)NO_2$[27] or $CH_2{=}C(CH_3)CH_2NO_2 \rightleftharpoons (CH_3)_2C{=}CHSO_2$).[29,30] This indicates a lower stabilisation of the αβ-form by the nitro-group compared with OR, SR, NR_2, COOR, CN, etc., possibly owing to the greater $-I$ effect.

Diallylphosphine is converted on refluxing with C_2H_5ONa into dipropenylphosphine in 90% yield[31]; similarly, when potassium hydroxide in methanol is employed, diallylphosphine oxide and allyl phenylphosphinic acid isomerise to dipropenylphosphine oxide and phenylpropenylphosphinic acid respectively (yield 90–95%). However, allylphosphonic acid is stable under these conditions.

Diethyl allylphosphonate isomerises completely to the propenyl isomer in the presence of sodium ethoxide even at room temperature, whereas under these conditions diethyl 3-phenylprop-2-enylphosphonate does not change and diethyl but-2-enylphosphonate gives an equilibrium mixture containing only 25% of the αβ-isomer[32]. Thus the phenyl and even the methyl group interacts with the double bond more strongly than the $P(O)(OC_2H_5)_2$ group. It is quite possible that in phosphine oxides and phosphinic acids the prototropic shift is due solely to the inductive effect of the PO and P(O)OH groups. Nor can one exclude in phosphines of the type R_3P the possible stabilisation of the propenyl form by the overlapping of the *p* orbitals of carbon with the *d* orbitals of phosphorus.

The capacity of various functional groups for stabilising the αβ-form may be estimated by comparing the equilibrium positions in systems with two different functional groups. Thus in the presence of $(C_2H_5)_3N$ an equilibrium mixture of 34% of 1-cyano-1-ethoxy-3,3-dichloroprop-2-ene and 58% of *trans*- and 8% of *cis*-1-cyano-1-ethoxy-3,3-dichloroprop-1-ene is formed[33-35]. The equilibrium mixture of ethyl 4,4-dichlorobutenoate contains different amounts of the αβ- and βγ-isomers[35].

Under the influence of potassium ethoxide in t-butyl alcohol at 35°C, methyl *trans*-3-methoxycrotonate is almost completely converted into methyl *cis*-4-methoxybut-3-enoate[36]:

$$CH_3OCH_2CH{=}CHCOOCH_3 \rightarrow CH_3OCH{=}CHCH_2COOC_2H_5\,.$$

The isomer where the double bond is conjugated to the SR group predominates slightly in an equilibrium system incorporating the SCH_3 and $COOC_2H_5$ groups[36]:

$$\underset{42\%\ (trans)}{CH_3SCH_2CH{=}CHCOOC_2H_5} \rightleftarrows \underset{24\%\ (cis)\ +\ 34\%\ (trans)}{CH_3SCH{=}CHCH_2COOC_2H_5}\,.$$

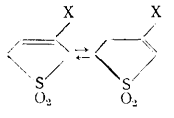
Thus the alkoxy and sulphide groups stabilise the conjugated isomer to a greater extent than the alkoxycarbonyl group. It is interesting to note that, when diethylamine acts upon the *trans*-isomer of ethyl 3,4-di(ethylthio)but-2-enoate, the latter is converted quantitatively into ethyl 3,4-di(ethylthio)but-3-enoate (a mixture of 80% of the *trans*-isomer and 20% of the *cis*-isomer), i.e. the double bond is fully displaced from conjugation with the $COOC_2H_5$ group[37].

On heating with potassium t-butoxide in dimethyl sulphoxide, an equilibrium mixture of 1% of *cis*- and 2% of *trans*-4-methoxy-1-methylthioprop-1-ene and of 32% of *cis*- and 65% of *trans*-4-methoxy-1-methylthioprop-2-ene is formed[36]:

$$CH_3OCH_2CH{=}CHSCH_3 \rightleftarrows CH_3OCH{=}CHCH_2SCH_3\,.$$

Thus in this case too the isomer with the double bond conjugated with the OR group is more stable, which is consistent with the relative +*M* effects of the OR and SR groups.

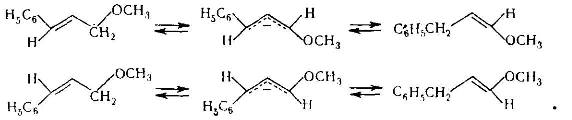
In the system



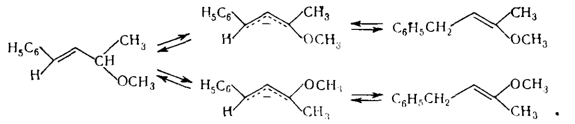
the content of the αβ-isomer increases in the sequence of substituents X = H ~ Cl < CH_3 ≪ OCH_3, n-C_4H_9S and in the last two cases the αβ-isomer predominates entirely. This can be accounted for by a donor–acceptor interaction between the substituent X, which has a free electron pair, and the sulphur atom in the SO_2 group[38].

Prototropic isomerisation is very greatly complicated by *cis–trans* isomerisation and this is why there is contradictory information in the literature about the stereochemistry of the prototropic shift. At the present time, however, it is known that prototropic isomerisation can be either stereospecific or lead to mixtures of *cis*- and *trans*-isomers depending on the structure of the olefin. It has been established that allyl ethers, for example, undergo a rigorously stereospecific isomerisation on heating with potassium t-butoxide to *cis*-propenyl ethers[5,39]. Under the reaction conditions, n-propyl *trans*-propenyl ether is not converted into the *cis*-isomer, i.e. the *cis*-isomer is indeed the primary isomerisation product.

It has recently been established[40] that the presence of substituents in the β-position has an appreciable influence on the stereochemistry of the isomerisation of allyl ethers to vinyl ethers. Thus, when potassium t-butoxide in dimethoxyethane acts at 25°C on the methyl ether of *trans*-cinnamyl alcohol, the latter gives predominantly the *cis*-isomer of 1-methoxy-3-phenylprop-1-ene (the content of the *trans*-isomer does not exceed 10%), while the methyl ether of *cis*-cinnamyl alcohol gives largely the *trans*-isomer (the content of the *cis*-isomer is about 25%):

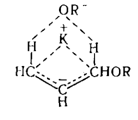


In the case of the methyl ether of 1-methylcinnamyl alcohol the isomerisation in the presence of potassium t-butoxide in dimethyl sulphoxide takes place non-stereospecifically, a mixture of different amounts of stereoisomeric vinyl ethers being formed[40]:

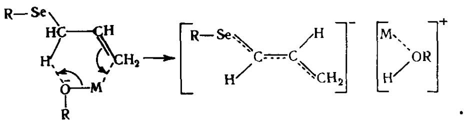


Allyl aryl selenides also isomerise stereospecifically, but in this case the *trans*-isomers are formed[10].

On the other hand, the isomerisation of allyl sulphides always leads to mixtures of 60–80% of the *cis*-isomer and 20–40% of the *trans*-isomer[8]. The differences in the stereochemistry of the isomerisation of allyl ethers, allyl sulphides, and allyl selenides are probably due to the differences in the geometry of the transition state. The formation of a stable *cis*-allyl carbanion incorporating the cation (K)[39]



has been postulated for allyl ethers. It is believed that, by virtue of the lower electronegativity and greater radius of the selenium atom, in allyl selenides the formation of a *cis*-transition complex is sterically hindered and the carbanion assumes a transoid configuration, where delocalisation of the carbanionic charge is facilitated by conjugation with the electrons in the *d* orbitals of selenium[10]:



The non-stereospecificity of the isomerisation of allyl sulphides can be explained by the fact that in this case there is a possibility of both a *cis*- and a *trans*-transition state, since sulphur is intermediate in its characteristics between oxygen and selenium.

It has been shown that, under the action of a solution of sodium in liquid ammonia, *N*-allyl-*N*-methylaniline, *N*-allyl-*N*-ethyl-*p*-toluidine, *NN*-diallylamine, etc. isomerise stereospecifically to *cis*-propenylamines. However, the compounds obtained rapidly isomerise to the thermodynamically stable *trans*-isomers even on storage in nitrogen; admixtures of alcohols or acids accelerate this process[12] and therefore in the majority of cases the isomerisation of allylamines leads to mixtures of *cis*- and *trans*-isomers (see also Riviere and Lattes[41]).

The isomerisation of $CH_2{=}CHCH(R)X$ in acetonitrile in the presence of $(C_2H_5)_2NH$ leads entirely to the formation of $CH_3CH{=}C(R)X$; there is no *cis–trans* isomerisation.

The data on the stereochemistry of this isomerisation are presented in Table 4.[15]

The stereochemistry of the reaction is independent of both the solvent (hexamethylphosphoramide, dimethyl sulphoxide, dimethylformamide, acetone, tetrahydrofuran, ether, dioxan, and others) and of the catalyst (piperidine, diethylamine, n-butylamine, isopropylamine, triethylamine, etc.) and is determined solely by the stereochemistry of the intermediate carbanion:

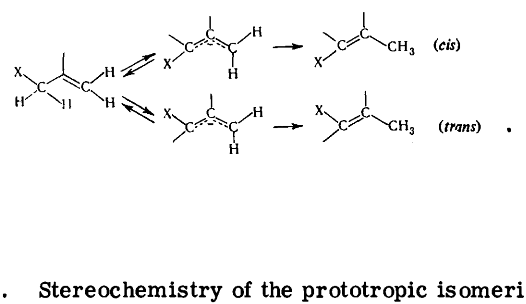


Table 4. Stereochemistry of the prototropic isomerisation $CH_2=CYCH(R)X \rightleftharpoons CH_3CY=C(R)X$.

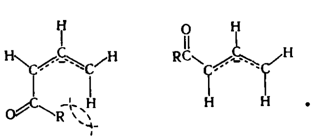
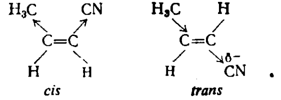
R	X	Y	*trans*-Form, %	R	X	Y	*trans*-Form, %
H	CN	H	35	Cl	COOH	H	100
H	$COOC_2H_5$	H	85	SC_2H_5	$COOC_2H_5$	H	90
H	COOH	H	94	H	CN	Cl	6
H	COC_2H_5	H	100	H	$COOC_2H_5$	Cl	0
Cl	CN	H	90	H	COOH	Cl	0
Cl	$COOC_2H_5$	H	100				

The relative amounts of the *cis*- and *trans*-isomers in the final product are determined by the ratio of the *cis*- and *trans*-carbanions, i.e. the free energies of the carbanions, the thermodynamically more stable carbanion being formed more rapidly. Evidently the thermodynamic stability of the carbanion is not necessarily the same as that of the final product. The stability of the carbanion depends on the electronic interaction between the substituents in the $\alpha\beta$- and $\alpha\gamma$-positions and on steric factors. In systems of the type $CH_2=CHCH_2X \rightleftharpoons CH_3CH=CHCHX$ the stability of the carbanion is controlled by the interaction of the $\alpha\gamma$-substituents (i.e. the H and X groups); when $X = COOC_2H_5$, COR, or COO^-, a greater stability of the *trans*-carbanion is to be expected:



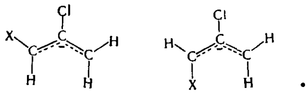
cis *trans*

By virtue of the smaller bulk of the CN group, in nitriles the interaction of the α-CN group and the γ-H atom plays a less important role; moreover, in this case the *cis*-form is stabilised by dipole–dipole interaction to a greater extent than the *trans*-form and therefore there is a possibility of the formation of a mixture of *cis*- and *trans*-isomers in proportions corresponding to the stabilities of the intermediate carbanions:



cis *trans*

For a system of the type $CH_2=OClCH_2X \rightleftharpoons CH_3CCl=CHX$, the interaction of the substituents in the $\alpha\beta$-positions promotes the formation of the *cis*-carbanion:



cis *trans*

These considerations proved to be valid also in the study of other systems, for example $CH_2=C(SR)CHClCOOC_2H_5 \rightleftharpoons CH_3(SR)=CClCOOC_2H_5$ or $CH_3=C(SR)CH(SR')COOC_2H_5 \rightleftharpoons CH_3C(SR)=C(SR')COOC_2H_5$.[42]

The carbanionic mechanism of prototropic isomerisation has been confirmed by a number of experimental findings. Thus the isomerisation of allyl or propenyl derivatives in deuteroalcohols always leads to the formation of α- or γ-deutero-derivatives respectively[17,43–45]. For example, the following reaction takes place on refluxing in deuterobutanol in the presence of potassium t-butoxide[43]:

$$\underset{}{CH_2=CHCH_2OR} \rightarrow \underset{27.8\%}{CH_3CH=CHCH_2OR} + \underset{69.7\%}{CH_2DCH=CHCH_2OR} + \underset{2.5\%}{CHD_2CH=CHCH_2OR}\ .$$
$$(R=C_9H_{19})$$

Similarly at room temperature we have the reaction[44]

$$C_9H_{19}CH_2CH=CHS(O)CH_3 \rightarrow C_9H_{19}CH=CHCD_2S(O)CH_3\ .$$

At 175 °C deuterium exchange takes place and an equilibrium is established[43]:

$$CH_2=CHCH_2OR \rightleftarrows \underset{47\%}{CH_3CH=CHOR} + \underset{40\%}{CH_2DCH=CHCHOR} + \underset{11\%}{CHD_2CH=CHOR} + \underset{1.3\%}{CD_3CH=CHOR}\ .$$

All these data are consistent with a carbanionic mechanism:

$$CH_2=CHCH_2X \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} CH_2\text{---}\bar{C}H\text{---}CHX \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} CH_3CH=CHX$$
$$k_1 > k_2,\ k_{-1} > k_{-2}\ .$$

Kinetic studies on prototropic isomerisation[15,46,47] also confirm the carbanionic mechanism. The rate of isomerisation depends on the affinity of the catalyst for the proton[47]. For the system

$$CH_2=C(R)CH(R')X \rightleftarrows CH_3C(R)=C(R')X \quad {}^{15}$$

the reaction obeys second-order kinetics. Certain data on the effect of the nature of the base on the rate of isomerisation in this system are presented in Table 5, which shows that the catalytic activity of amines depends on the degree of substitution at the nitrogen atom (the rate of isomerisation increases with decreasing steric hindrance at the nitrogen atom) and on solvation [the more solvated primary amines are less active than the less solvated $(C_2H_5)_2NH$].

The basicity of the catalyst is also of great importance. Thus 1,3-diphenylprop-2-en-1-ol isomerises only under the action of alcoholic alkali but not pyridine or triethylamine[48], while the isomerisation of 1,3,3-triphenylprop-2-en-1-ol requires the use of potassium t-butoxide in dimethyl sulphoxide but not aqueous alkali[49].

The rate of reaction depends very markedly on the nature of the solvent, reaching a maximum in aprotic polar solvents (hexamethylphosphoramide, dimethylformamide, dimethyl sulphoxide, acetonitrile, etc.)[15], which is typical of reactions with a carbanionic mechanism. Table 6 presents certain data on the effect of solvents on the rate of isomerisation.

The rate of reaction is determined by the formation of the carbanion. All factors facilitating the formation of the carbanion increase the rate of reaction. Thus in the $CH_2=CHCH_2X$ system the rate of isomerisation increases in the following sequence of X: $COOH < COOC_2H_5 < CN < COR$, which is the same as the familiar series of substituents with increasing $-M$ effects[15] and can be accounted for by the facilitation of the heterolysis of the α-C–H bond. The introduction of a chlorine atom into the α-position of the system increases the rate of isomerisation owing to the –*I* effect and the acceleration of the reaction in the presence of chlorine in the β-position is due to the additional stabilisation of the carbanion by the involvement of lone-pair electrons of the chlorine atom in delocalisation[15]. The systems examined above are characterised by low activation energies (about 10 kcal) and highly negative activation entropies (about –35 e.u.), which indicates a high degree of order in the transition state. It has been suggested[15] that in the transition state the formation of the B–H bond preceeds the heterolysis of the highly polarised α-C–H bond and the transition state itself is a highly solvated still incompletely dissociated ion pair.

Table 5. Rate of isomerisation and the nature of the base $CH_2{=}CRCHR'COOC_2H_5 \rightarrow CH_3CR{=}CR'COOC_2H_5$*.

**Only the *trans*-isomer is formed.

***Only the *cis*-isomer is formed.

Prototropic isomerisation in the presence of bases has found wide application in organic synthesis. Several novel methods are based on the isomerisation of unsaturated alcohols where the alcoholic group is converted into a carbonyl group as a result of prototropic shift:

$$RCH{=}CHCH(OH)R' \rightarrow RCH_2CH{=}C(OH)R' \rightarrow RCH_2CH_2COR' \ .$$

The conversion of allyl alcohols themselves into carbonyl compound has found only limited application in the synthesis of aliphatic-aromatic ketones stable to alkalis (for example, see Refs. 46–48). However, a prototropic shift in substituted allyl alcohols constitutes the foundation of several preparative syntheses.

Thus when hot dilute alkalis act upon the cyanohydrin of ββ-diphenylacrolein or the amide of 2-hydroxy-4,4-diphenylbut-3-enoic acid, prototropic isomerisation is accompanied by the hydrolysis of the nitrile and amide groups and the formation of α-oxo-γγ-diphenylbutyric acid in high yields[50]:

$$(C_6H_5)_2C{=}CHCH(R)OH \rightarrow (C_6H_5)_2CHCH{=}C(R)OH \rightarrow (C_6H_5)_2CHCH_2COCOOH \ ,$$

where R = CN or $CONH_2$. This method is of general importance for the synthesis of α-ketoacids.

A prototropic shift is the rate-determining stage in the synthesis of succinic acid by refluxing β-formylacrylic acid with a solution of potassium cyanide, which takes place according to the following mechanism[51]:

$$HOOCCH{=}CHCHO \xrightarrow{CN^-} HOOCCH{=}CHCH(CN)OH \rightarrow HOOCCH_2CH{=}C(CN)OH \rightarrow$$
$$\rightarrow HOOCCH_2CH_2COCN \xrightarrow{OH^-} HOOCCH_2CH_2COOH \ .$$

A similar mechanism constitutes the basis of a simple method for the synthesis of esters of β-substituted propionic acids by the action of an excess of acetone cyanohydrin and triethylamine on αβ-unsaturated aldehydes with electron-accepting substituents in the β-position[52]. The intermediate cyanohydrin isomerises to a β-ketonitrile, which in the presence of an excess of acetone cyanohydrin or alcohol (as a solvent) gives an ester of propionic acid:

$$RCH{=}CHCHO \xrightarrow{CN^-} RCH{=}CHCH(CN)OH \rightarrow RCH_2CH{=}C(CN)OH \rightarrow$$
$$\rightarrow RCH_2CH_2COCN \xrightarrow{R'O^-} RCH_2CH_2COOR' \ .$$

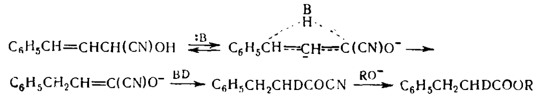
Table 6. Effect of solvents on the rate of isomerisation. $CH_2{=}CHCHClCOOC_2H_5 \rightarrow CH_3CH{=}CClCOOC_2H_5$*.

Solvent	*k*, litre $mole^{-1}\ s^{-1}$	Solvent	*k*, litre $mole^{-1}$ s^{-1}
Hexamethylphosphoramide	instantaneous reaction	Tetrahydrofuran	0.35
Dimethylformamide	reaction ends after 5 min	Monoglyme	0.084
Acetonitrile	2.47	Ether	0.0136
Acetone	1.99		

*The base is $(C_2H_5)_2NH$; temperature 0.2° ± 0.2°C.

The intermediate formation of the cyanohydrin is confirmed by the fact that, when acetone cyanohydrin and triethylamine act on the cyanohydrin of cinnamaldehyde, an ester of β-phenylpropionic acid is also formed[53].

In the reaction of cinnamaldehyde and α-methylcinnamaldehyde with deuteroacetone cyanohydrin in the presence of triethylamine, 75–80% of the deuterium enters into the α-position of the ester. Thus the transfer of hydrogen in this case takes place largely intramolecularly:



$$C_6H_5CH{=}CHCH(CN)OH \overset{:B}{\rightleftharpoons} C_6H_5CH{\cdots}\underline{C}H{\cdots}C(CN)O^- \rightarrow$$
$$C_6H_5CH_2CH{=}C(CN)O^- \xrightarrow{BD} C_6H_5CH_2CHDCOCN \xrightarrow{RO^-} C_6H_5CH_2CHDCOOR \ .$$

When polyene aldehydes take part in the reaction, the process involves only the αβ-double bond[54]; in this way, it is possible to synthesise αβ-dihydro-derivatives:

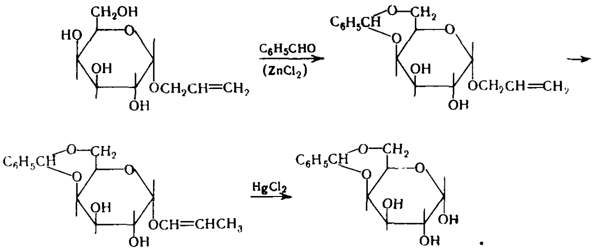
$$R(CH{=}CH)_nCHO \rightarrow R(CH{=}CH)_{n-1}CH_2CH_2COOR' \ ,$$

where R = CH_3, C_6H_5, or $COOC_2H_5$, and *n* = 2 or 3.

The isomerisation of allyl ethers has found fairly wide application in the synthesis of propenyl ethers (for examples, see Refs. 5–7 and 55–59). Among the catalysts proposed, potassium t-butoxide is particularly effective when dimethyl sulphoxide is used as a solvent[5,6,58]. The isomerisation of allyl ethers by heating with potassium t-butoxide is a convenient preparative method for the synthesis of propenyl ethers especially those which are difficult to obtain by other methods—ethers derived from polyhydric alcohols. For example, tetrapropenylpentaerythritol was obtained from tetra-allylpentaerythritol in about 83% yield[5]:

$$C(CH_2OCH_2CH{=}CH_2)_4 \rightarrow C(CH_2OCH{=}CHCH_3)_4 \ .$$

The easy isomerisation of allyl ethers to propenyl ethers suggested the use of the allyl group as a protecting group in carbohydrate chemistry[60–65]. After the necessary operations, the allyl ether isomerises to the propenyl ether and its protecting group is removed in a suitable way (by acid hydrolysis, ozonolysis, oxidation by alkaline potassium permanganate, and by treatment with $HgCl_2$). The allyl protecting group is particularly convenient in the synthesis of benzyl and benzylidene derivatives of sugars. Thus 4,6-*O*-benzylidene-D-galactose can be obtained from 1-allyl-D-galactopyranoside[65]:



An interesting method for the synthesis of esters of $\beta\gamma$-unsaturated sulphonic acids otherwise difficult to obtain is based on the alcoholysis of $\alpha\beta$-unsaturated sulphonyl chlorides in the presence of triethylamine[66]. The reaction involves a mechanism with prototropic isomerisation via sulphenes.

$$CH_3CH{=}CHSO_2Cl \rightarrow \left[\overset{-}{\overbrace{CH_2{\cdots}CHCH{\cdots}SO_2}}\right] \rightarrow \left[CH_2{\cdots}CH\bar{C}HSO_2\overset{+}{O}\begin{smallmatrix}R\\H\end{smallmatrix}\right] \rightarrow CH_2{=}CHCH_2SO_3R$$

In the presence of triethylamine, allyl aryl sulphones isomerise smoothly to propenyl sulphones[67,68]. Thus on heating allyl β-naphthyl sulphone in dioxan or alcohol with triethylamine for 15–17 h, β-naphthyl propenyl sulphone was obtained:

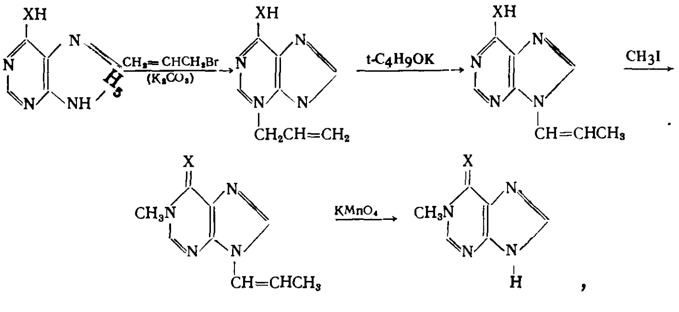
$$\beta\text{-}C_{10}H_7SO_2CH_2CH{=}CH_2 \rightarrow \beta\text{-}C_{10}H_7SO_2CH{=}CHCH_3\ .$$

The isomerisation of allylamines in the presence of potassium t-butoxide in dimethyl sulphoxide[11,12], a dispersion of sodamide on alumina in pentane or hexane[69], or a solution of sodium in liquid ammonia[70] at room temperature is a very convenient method for the synthesis of *NN*-disubstituted enamines in high yields (60–100%):

$$CH_2{=}CHCH_2NRR' \rightarrow CH_3CH{=}CHNRR'\ .$$

A method has been developed for the synthesis of *N*-propenylpyrrolidinone and *N*-propenylcaprolactam in 50–80% yield by the isomerisation of the corresponding allyl derivatives at 165–180°C in the presence of potassium t-butoxide[71]. *N*-Allylthiolactams isomerise in the presence of potassium t-butoxide in dimethyl sulphoxide even at room temperature[72].

The use of the allyl group to protect the amino-group in purine bases has been suggested[73]. 1-Methyladenine and 1-methylhypoxanthine have been obtained using such protection via the 9-allyl derivatives by the mechanism



where X = O or NH.

A prototropic shift constitutes the basis of a new method for the synthesis of iminoethers by the action of potassium cyanide and primary amines on $\alpha\beta$-unsaturated aldehydes in the presence of potassium hydroxide or sodium methoxide in methanol at room temperature[74]. The reaction takes place by the mechanism

$$RCH{=}CHCHO \rightarrow RCH{=}CHCH(CN)NHR' \rightarrow RCH_2CH{=}C(CN)NHR' \rightarrow$$
$$\rightarrow RCH_2CH_2C(OCH_3){=}NR'\ .$$

$\alpha\beta$-Unsaturated aldehydes react by a similar mechanism with acetone cyanohydrin and primary or secondary amines with formation of α-cyanoimines or α-cyanoenamines respectively[75]:

$$RCH{=}CHCHO \rightarrow RCH{=}CHCH(CN)NR' \rightarrow RCH_2CH{=}C(CN)\,NHR' \rightarrow RCH_2CH_2C(CN){=}NR'$$
$$RCH{=}CHCHO \rightarrow RCH{=}CHCH\,(CN)\,NR'R'' \rightarrow RCH_2CH{=}C(CN)NR'R''\ .$$

The intermediate formation of aminonitriles has been demonstrated by their synthesis in the reaction of cinnamaldehyde with acetone cyanohydrin and piperidine, morpholine, or aniline[75,76]:

$$C_6H_5CH{=}CHCHO \rightarrow C_6H_5CH{=}CHCH\,(CN)\,R\ ,$$

where R = NCH_6H_5 diagrams.

When potassium cyanide in methanol was allowed to react with cinnamaldehyde cyanohydrin, methyl β-phenylpropionate was obtained[77].

1-Cyano-1-piperidino-3-phenylprop-1-ene isomerises smoothly to an enaminonitrile on being passed through an alumina column[76]; a product with the hydrogen atom and the amino-group in *cis*-positions is formed.

The product of a prototropic shift was obtained on refluxing 3-chloro-3-*p*-nitrophenylprop-1-ene in benzene with triethylamine[78]:

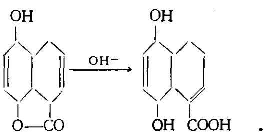
$$p\text{-}O_2NC_6H_4CHClCH{=}CH_2 \rightarrow p\text{-}O_2NC_6H_4CCl{=}CHCH_3\ .$$

The formation of small amounts of an ester of but-1-enylmethylphosphinic acid on methylation of but-2-enylphosphonic ester can also be accounted for by a prototropic shift[79]:

$$CH_3CH{=}CHCH_2P(O)\,(OC_3H_7\text{-iso})_2 \xrightarrow{CH_3I} CH_3CH{=}CHCH_2P(CH_3)\,(O)\,(OC_3H_7\text{-iso})$$
$$CH_3CH_2CH{=}CHP(CH_3)(O)(OC_3H_7\text{-iso})$$

The formation of methyldiphenyl-(1-phenylprop-1-enyl)-phosphonium iodide on methylation of diphenyl-(1-phenylallyl)phosphine can be interpreted similarly[80].

Isomerisation in the presence of bases is used for the synthesis of $\alpha\beta$-unsaturated acids, esters, nitriles, lactones, ketones, etc. from the corresponding $\beta\gamma$-derivatives (for examples, see Refs. 81–86). For instance, *cis*-5,8-dihydroxy-1,4,5,8,9,10-hexahydronaphthoic acid is obtained by refluxing with aqueous alcoholic alkali the 1,8-lactone of *cis*-5,8-dihydroxy-3,4,5,8,9,10-hexahydronaphthoic acid[86]:



When nucleophilic agents act upon $CHCl{=}CHCH_2X$,[87] $CH_2{=}CClCH_2X$,[80,81] or $CH_2{=}CHCHClX$,[87] other reactions, apart from prototropic isomerisation, can occur depending on the reactant, the position of the chlorine atom, and the reaction conditions. Thus, regardless of the configuration of the initial compound, hydrolysis of $CHCl{=}CHCH_2COOC_2H_5$ by aqueous alkali leads to the formation of *trans*-3-chlorocrotonic acid, i.e. the isomerisation and hydrolysis take place with retention of the chlorine atom:

$$CHCl{=}CHCH_2COC_2H_5 \rightarrow CH_2ClCH{=}CHCOOH \quad .$$

When the reaction is carried out in alcoholic solution, isomerisation with simultaneous addition of the alcohol and retention of the chlorine atom takes place:

$$CHCl{=}CHCH_2COOC_2H_5 \rightarrow CH_2ClCH(OC_2H_5)CH_2COOC_2H_5 \quad .$$

However, on refluxing with an aqueous solution of sodium carbonate, the shift of the double bond is accompanied by the exchange of the chlorine atom for a hydroxy-group:

$$CHCl{=}CHCH_2X \rightarrow CH_2(OH)CH{=}CHX \quad ,$$

where X = CN or $COOC_2H_5$.

In the case of $CH_2 = CClCH_2X$ the isomerisation takes place with retention of the chlorine atom or its replacement, depending on the nature of X; moreover, in a number of instances an elimination reaction is observed[87,88]:

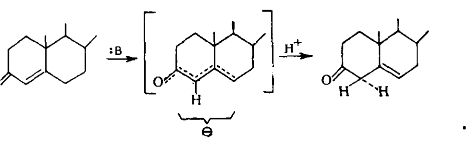
$$CH_2{=}CClCH_2COOC_2H_5 + C_2H_5O^- \rightarrow CH_3C(OC_2H_5){=}CHCOOC_2H_5 \quad ,$$
$$CH_2{=}CClCH_2N + C_2H_5O^- \rightarrow CH_3CCl{=}CHCN + CH_3C(OC_2H_5){=}CHCN \quad .$$

Isomerisation with or without replacement of the chlorine atom and sometimes the formation of addition products occur with $CH_2{=}CHCHClX$:[87]

$$CH_2{=}CHCHClCOOC_2H_5 + (C_2H_5)_2NH, \rightarrow CH_3CH{=}CClCOOC_2H_5 \quad ,$$
$$CH_2{=}CHCHClCOOC_2H_5 + C_2H_5ONa \rightarrow CH_3CH{=}CClCOOH + CH_3CH{=}CClCOOC_2H_5 +$$
$$+ CH_3CH(OC_2H_5)CHClCOOC_2H_5 \quad .$$

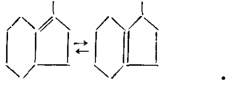
Base-catalysed isomerisation is used to convert Δ^5-3-oxosteroids into Δ^4-3-oxosteroids. Thus Δ^5-pregnenedione has been converted in high yield into progesterone[89].

A method has also been developed for the conversion of Δ^4-3-oxosteroids into Δ^5-3-oxosteroids. For this purpose, Δ^4-3-oxosteroids are heated with potassium t-butoxide in t-butyl alcohol and the resulting carbanions are then protonated by acetic acid, forming Δ^5-3-oxosteroids[90]:

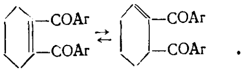


The reaction is based on the fact that in this case protonation at the C_4 atom is faster than at the C_6 atom. This possibility is confirmed by the fact that, on refluxing, for example, 6,6-dimethylcyclohex-2-enone with deuterium oxide, the vinyl hydrogen atom is exchanged 170 times faster than the allyl hydrogen atom[91]. This method has been used to prepare 17α-methyl-Δ^5-androst-17β-en-2-one from 17-methyltestosterone. Ketones with several conjugated bonds remain unchanged when treated in this way[90].

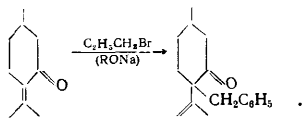
It is interesting that on heating (for 24 h) 1-acetyl-$\Delta^{1,8}$-perhydroindane with potassium methoxide in methanol, an equilibrium mixture is formed containing 80% of the $\Delta^{8,9}$-isomer[92]:



Similarly, on heating (72 h) with a potassium hydroxide solution, 1,2-diaroylcyclohexene is converted to the extent of 90% into 1,6-diaroylcyclohexene[93]:

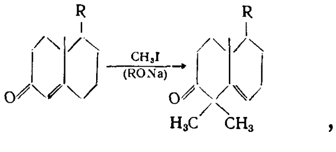


The different reactivities of the α- and β-positions of carbanions with functional groups are used in the synthesis of α-alkyl and αα-dialkyl-substituted βγ-unsaturated acids, esters, ketones, etc. by alkylating the αβ-unsaturated isomers in an alkaline medium (for examples, see Refs. 94–109). Thus the alkylation of sorbic acid in liquid ammonia with CH_3I in the presence of potassamide leads to 2,2-dimethylhexa-3,5-dienoic acid[94]. The alkylation of ketones with a tetrasubstituted ethylene bond by alkyl halides in the presence of sodium alkoxides gives α-monoalkyl derivatives[96,97]. For example:



α-Monoalkyl derivatives can also be obtained by maintaining specially selected reaction conditions[98,99]. Thus, a 44% yield of 4-methyltestosterone is obtained by the gradual addition of 1.2 equivalents of methyl iodide to testosterone in boiling t-butyl alcohol in the presence of 1.5 equivalents of potassium t-butoxide.

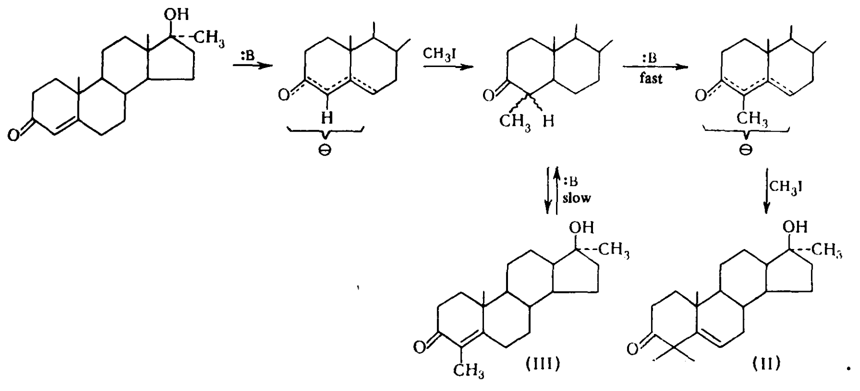
Dialkylation of αβ-unsaturated cyclic ketones has found extensive application in the chemistry of terpenes and steroids. Thus bicyclic ketones, which are necessary for the synthesis of terpenes of the labdanolic acid type[100] or triterpenes of the β-amyrin type[101], were obtained via the mechanism



where R = H or OH.

Alkylation of cholestenone with CH_3I in t-butyl alcohol in the presence of potassium t-butoxide leads to 4,4-dimethylcholest-5-en-3-one[102,105]; 4,4-dimethylandrost-3-ene[106] and 4,4-dimethylergosta-5,7,22-trien-3-one[107] were obtained in this way from testosterone and ergosterone respectively; 3-oxo-Δ^4-derivatives of androstene and pregnane are methylated similarly[108].

The formation of dialkyl derivatives is explained by the fact that secondary alkylation and (or) the formation of a tertiary carbanion are faster than the primary alkylation and (or) the formation of a secondary carbanion. In fact, the reaction of CH_3I with the carbanion formed from the ketone (I) by brief treatment with potassium t-butoxide leads to the ketone (II) in 74% yield, while methylation of the α-methyl ketone (III) under the same conditions gives the ketone (II) in a yield of only 6%:[110]



When alcohols are allowed to react with the chlorides of $\alpha\beta$-unsaturated acids in the presence of tertiary amines, the main reaction products are esters of vinylacetic acid[111,112]:

$$RCH_2CH{=}CHCOCl + R'OH\,(R_3'N) \rightarrow RCH{=}CHCH_2COOR' + RCH_2CH{=}CHCOOR'\,.$$

The nature of the amine and the structure of the acid chloride (Table 7) affect the ratio of the $\alpha\beta$- and $\beta\gamma$-isomers.

Table 7. Effect of the nature of the amine and the structure of the acid chloride on the ratio of the $\alpha\beta$- and $\beta\gamma$-isomers $CH_2{=}C(R)CH_3COOCH_2(IV) \rightleftharpoons CH_3C(R){=}CHCOOCH_3(V)$.

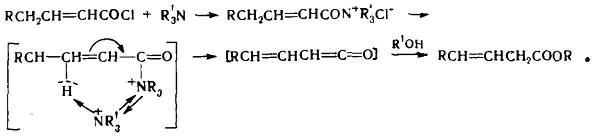
N-Ethylpiperidine	10.4	83.5	16.4	89.6	10.4
Triallylamine	8.3	47.5	52.5	44.1	55.9
N-Ethylmorpholine	7.7	65.3	34.7	69.1	30.9
Pyridine	5.2	1.6	98.4	0.6	99.4

The results show that the ratio of the reaction products is controlled by the initial abstraction of a proton. It has been suggested that, when highly basic amines (p$K > 10$) are employed, the reaction takes place via the following mechanism[112]:



$$RCH_2CH{=}CHCOCl + R_3'N \rightarrow RCH_2CH{=}CHCON^+R_3'Cl^- \rightarrow$$

$$\left[\begin{array}{c} RCH{-}CH{=}CH{-}C{=}O \\ \quad H \qquad\quad {}^+NR_3 \\ \overset{+}{N}R_3' \end{array}\right] \rightarrow [RCH{=}CHCH{=}C{=}O] \xrightarrow{R'OH} RCH{=}CHCH_2COOR\,.$$

Thus the reaction consists in the prototropic isomerisation of the intermediate acylammonium salt with elimination of an NR_3 group and the formation of a keten, which then combines with the alcohol.

It has been shown in recent years[113-116] that prototropic isomerisation is also the basis of the Varrentrapp reaction, which is carried out by heating *cis*- or *trans*-unsaturated acids with central double bonds at 300–360°C with potassium hydroxide in an inert atmosphere; this results in the formation of acetic and a saturated acid containing two carbon atoms less than the initial unsaturated acid:

$$CH_3(CH_2)_nCH{=}CH(CH_2)_mCOOH \rightarrow CH_3(CH_2)_{n+m}COOH + CH_3COOH + H_2\,.$$

Thus palmitic acid was obtained from oleic or petroselinic acid in yields of 80–85% and 78% respectively, nonanoic acid was obtained from undec-10-enoic acid in 80% yield, and heptanoic acid was obtained from non-2-enoic acid in 80% yield also.

A detailed study of the Varrentrapp reaction using oleic acid as an example showed that the prototropic shift plays the main role and that in the initial stages the migration of double bonds takes place to an equal extent on either side. However, when, as a result of a series of reversible shifts, the double bond reaches the $\alpha\beta$-position, a reversible cleavage takes place and the entire system of equilibria is displaced towards the carboxy-group. The overall reaction mechanism may be represented thus:

$$R(CH_2)_{n-1}CH{=}CH(CH_2)_{n+1}COO^- \rightleftharpoons R(CH_2)_{n-1}CH\cdots\bar{C}H\cdots CH(CH_2)_mCOO^- \rightleftharpoons$$

$$R(CH_2)_nCH{=}CH(CH_2)_mCOO^- \rightleftharpoons R(CH_2)_nCH\cdots\bar{C}H\cdots CH(CH_2)_{m-1}COO^- \rightleftharpoons$$

$$R(CH_2)_{n+1}CH{=}CH(CH_2)_{m-1}COO^- \rightleftharpoons \ldots\ldots\ldots\ldots \rightleftharpoons$$

$$R(CH_2)_{n+m-1}CH\cdots\bar{C}H\cdots CHCOO^- \rightleftharpoons R(CH_2)_{n+m}CH{=}CHCOO^- \rightarrow$$

$$R(CH_2)_{n+m}COOH + CH_3COOH + H_2\,.$$

III. ISOMERISATION IN THE PRESENCE OF ACIDS

It has been known for a long time that the prototropic shift of the double bond in olefins can be induced by acids. The reaction involves the intermediate formation of a carbonium cation and is frequently accompanied by allyl isomerisation and structural changes. For this reason, acid-catalysed isomerisation has found much less application than base-catalysed isomerisation. The overall process mechanism can be represented as follows:

$$H^+ \rightarrow \overset{|}{\underset{|}{C}}{=}\overset{}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}H \rightleftharpoons H{-}\overset{|}{\underset{|}{C}}{-}\overset{+}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}H \rightleftharpoons H{-}\overset{|}{\underset{|}{C}}{-}\underset{|}{C}{=}\overset{|}{\underset{|}{C}} + H^+\,.$$

The acid-catalysed isomerisation of allyl alcohols to carbonyl compounds[117], which has found industrial application for the synthesis of isobutyraldehyde from 2-methylprop-2-en-1-ol[118], has been most thoroughly investigated. It has been shown that, as in base-catalysed isomerisation, the reaction depends appreciably on the structure of the allyl alcohol. The allyl alcohol itself and its linear homologues of the type $RCH{=}CHCH_2OH$ are hardly isomerised on refluxing with 0.44 *N* sulphuric acid solution[110,111]. On the other hand, β-alkylallyl alcohols are smoothly converted in high yields (88–92%) into aldehydes:

$$CH_2{=}CH(R)CH_2OH \rightarrow CH_3CH(R)CHO\,,$$

where $R = CH_3$, C_2H_5, iso-C_3H_7, or t-C_4H_9.

$\beta\gamma$-Substituted allyl alcohols undergo simultaneously a prototropic shift (the formation of aldehydes) and oxotropic isomerisation (formation of ketones), the latter predominating judging from the yields:

$$RCH{=}C(R')CH_2OH \rightarrow RCH_2CH(R')CHO + RCOCH(CH_3)R'$$

R	R′	Yield of aldehyde, %	Yield of ketone, %	R	R′	Yield of aldehyde, %	Yield of ketone, %
CH_3	CH_3	25	63	CH_3	C_2H_5	36	52
C_2H_5	CH_3	15	71	n-C_3H_7	C_2H_5	19	69 .

Alcohols of the type $RR'C{=}CR''CH_2OH$ are readily dehydrated. Secondary alcohols of the type $CH_2{=}C(R)CH(R')OH$ are smoothly converted into ketones:

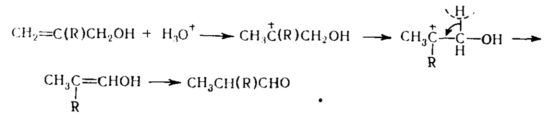
$$CH_2{=}C(R)CH(R')OH \rightarrow CH_3CH(R)COR' \text{ (yield 86–92\%)} .$$

Only traces of aldehydes—products of oxotropic rearrangement with a subsequent prototropic shift—are observed.

The prototropic isomerisation of secondary alcohols of the type $RCH{=}C(R')CH(R'')OH$ also takes place without complications:

$$RCH{=}C(R')CH(R'')OH \rightarrow RCH_2CH(R')COR'' .$$

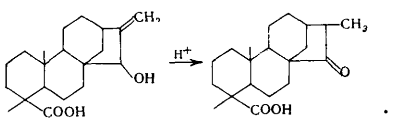
The study of the kinetics and the effect of the acidity of the medium on the rate of conversion of β-alkylallyl alcohols into aldehydes and of the kinetics of the conversion of the glycols $CH_3C(R)(OH)CH_2OH$ into the same aldehydes confirms the carbonium ion mechanism of the acid isomerisation of allyl alcohols[119-121]:



$$CH_2{=}C(R)CH_2OH + H_3O^+ \longrightarrow CH_3\overset{+}{C}(R)CH_2OH \longrightarrow CH_3\underset{R}{\overset{+}{C}}{-}\underset{H}{\overset{H}{C}}{-}OH \longrightarrow CH_3\underset{R}{C}{=}CHOH \longrightarrow CH_3CH(R)CHO .$$

Thus the proton adds to the double bond with subsequent elimination of a proton from the α-position. This mechanism is consistent with the results of the isomerisation of 1-[^{14}C]methylallyl alcohol, which leads to the formation of isobutyraldehyde labelled with carbon-14 at the carbonyl group[122].

The acid-catalysed isomerisation of alcohols has found limited application in the synthesis of certain cycloalkanones[123] and certain complex cyclic ketones[124,125]. For example:

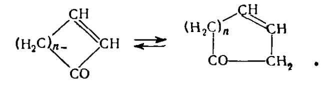


Little is known about the effect of the structure of the olefin on the equilibrium position in acid-catalysed isomerisation in $RCH_2CH{=}CHX \rightleftharpoons RCH{=}CHCH_2X$ systems. It has been noted that the $\alpha\beta$-isomer predominates in the equilibrium mixture of aliphatic ketones[126]:

$$\underset{\sim 93\%}{(CH_3)_2C{=}CHCOCH{=}C(CH_3)_2} \rightleftarrows \underset{\sim 7\%}{(CH_3)_2C{=}CHCOCH_2C(CH_3){=}CH_2} \rightleftarrows \underset{\text{traces}}{CH_2{=}C(CH_3)CH_2COCH_2C(CH_3){=}CH_2} .$$

However, in the hydrolysis of *cis*-β-chlorocrotononitrile with sulphuric acid at room temperature, the amide of *cis*-β-chlorovinylacetic acid was obtained in high yield[83].

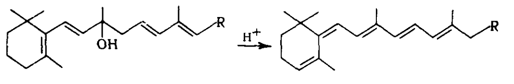
The equilibrium between cycloalk-2-enones and cycloalk-3-enones on refluxing in benzene in the presence of p-$CH_3C_6H_4SO_3H$ depends on ring size[127]:



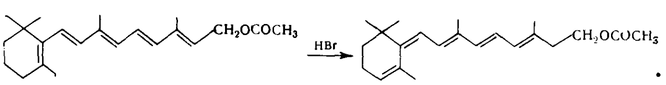
n	Time of attainment of equilibrium, h	Composition of equilibrium mixture, %	
		$\alpha\beta$-isomer	$\beta\gamma$-isomer
3	fast.	99.0	1.0
4	1	73.0	27.0
5	2	20.0	80.0
6	22	0.3	99.7

The shift of equilibrium towards the $\beta\gamma$-isomer with increasing number of units is probably associated with the fact that the double bond and the carbonyl group become non-coplanar. This leads to the destabilisation of the $\alpha\beta$-isomer, which in the absence of conjugation is thermodynamically less stable than the $\beta\gamma$-isomer. An approximate estimation of the angle of rotation Θ between the planes of the CO group and the double bond on the hypothesis that the difference between the chemical shifts in the H NMR spectrum of cyclononones $\gamma_B - \gamma_A$ (A = H at C_2 and B = H at C_3) is proportional to cos Θ, showed that Θ increases progressively with the number of units in the ring[127]. Possibly this is due to the fact that, on increasing the number of units, the conformations where the CO group and the double bond are located in the same plane become hindered, as shown, for example, by the conformational analysis of cyclo-oct-2-enone, in which full coplanarity of the CO group and the double bond is achieved only in the model where there should be strong *trans*-annular interaction between the H atom at C_4 and the *cis*-H atom at C_8.

In connection with the problem of the synthesis of biologically active preparations of the type of vitamin A, a detailed study was made of the acid-catalysed prototropic isomerisation in the vitamin A series, which has been called retroionylidene rearrangement. This rearrangement takes place in the acid-catalysed dehydration of hydroxy-derivatives and when acidic reagents act upon compounds where the side chain is fully conjugated with the ring double bond and consists in the shift of the entire conjugated bond system from the functional group towards the ring[128-131]:

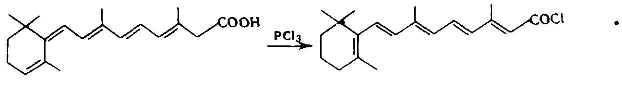


where R = CH_2OCH_3, CHO, COOR, etc.;



This results in the formation of biologically inactive species—the so called retroionylidene structures. The rearrangement is due to the fact that in a molecule of the vitamin A type there is appreciable steric interaction between the methyl groups of the ring and the side chain; when acted upon by acids, such compounds should be converted into the thermodynamically more stable retroionylidene compounds. The transition from such structures to ionylidene compounds is possible on treatment with alkaline agents (potassium hydroxide, sodium hydroxide, alkoxides, etc.) or by chromatography on aluminosilicate columns[130,132,133].

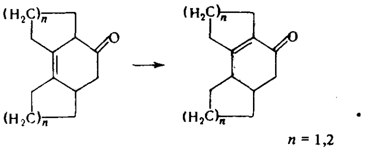
Acids with the retroionylidene structure are converted into straight-chain acid chlorides on treatment with specially purified phosphorus trichloride[132]. For example:



Acid-catalysed prototropic isomerisation may complicate many processes. Thus the hydration of divinylacetylenes in aqueous solutions in the presence of sulphuric acid and mercuric sulphate results in the formation of divinyl ketones instead of the expected allyl vinyl ketones[134]:

$$RCH{=}CHC{\equiv}CCH{=}CHR' \rightarrow RCH{=}CHCOCH{=}CHCH_2R' \ .$$

A method has been proposed for the synthesis of $\alpha\beta$-unsaturated tricyclic ketones by refluxing the $\beta\gamma$-isomers with a 3% methanol solution of hydrogen chloride or a 0.1% benzene solution of p-$CH_3C_6H_4SO_3H$.[135] 4-Oxo-$\Delta^{8a(8)}$-decahydro-*as*-indacene and 9-oxo-$\Delta^{4(8a)}$-dodecahydrophenanthrene were obtained in this way:



A method has also been proposed for the synthesis of aryl propenyl sulphones by heating allyl aryl sulphones with a solution of boron trifluoride in sulphuric acid[136]:

$$ArSO_2CH_2CH{=}CH_2 \rightarrow ArSO_2CH{=}CHCH_3 \ (43\text{–}50\%) \ .$$

IV. ISOMERISATION IN THE PRESENCE OF METAL CARBONYLS

It has been established by investigations in recent years that metal carbonyls [$Fe(CO)_5$,[137-141] $CoH(CO)_4$,[142] or $Co(CO)_8$[143]] are effective catalysts of the prototropic isomerisation of substituted olefins with functional groups; they may contain functional groups with free electron pairs (allyl alcohols[137-140,142] and allyl ethers[140,141]) or they are esters of unsaturated acids capable of π–π conjugation[141]. The principal advantage of metal carbonyls is the fact that in their presence the reaction may be carried out in a neutral medium (although examples are also known where the reaction was carried out in the presence of alkalis).[137] Thus this method may be used to achieve the shift of double bonds when the initial or final products are sensitive to acids and alkalis.

The isomerisation of unsaturated alcohols has been most thoroughly investigated. Secondary allyl alcohols isomerise particularly smoothly on heating with 10–20 mole % $Fe(CO)_5$ without a solvent at 110–125°C or on refluxing in octane. The yields of ketones reach 60–80%:[140]

$$CH_2{=}C(R)\,CH(OH)\,R' \rightarrow CH_3CH(R)COR' \ .$$

Alcohols of the type $CH_2{=}CH(CH_2)_nCH(OH)R$ enter into the reaction with equal success[140].

However, primary alcohols and cyclohex-2-enol gives low yields of products under these conditions. The yield increases to 29–54% when the reaction is carried out in pentane at room temperature in the presence of 3–5 mole % $Fe(CO)_5$ with simultaneous ultraviolet irradiation[140]. For example:

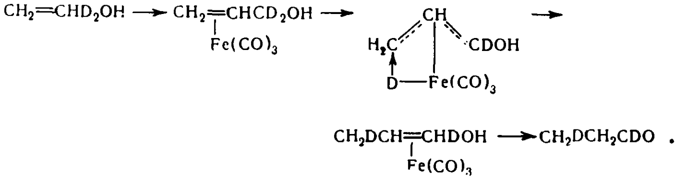
$$RCH{=}CH\,(CH_2)_n\,CH_2OH \rightarrow R\,(CH_2)_{n+2}\,CHO \ ,$$

where $n = 1$ and $R = C_2H_5$ (*cis*-isomer) (29%) or $n = 7$ and $R = H$ (54%).

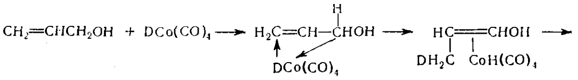
The isomerisation of allyl, crotyl, and other unsaturated alcohols in the presence of $CoH(CO)_4$ is complicated by hydroformylation and leads to low yields (3–21%) of carbonyl compounds[142].

On heating (to 130–160°C) with $Fe(CO)_5$, cyclo-oct-3-enol and cinnamyl alcohol give cyclo-octanone and 3-phenylpropionaldehyde in yields of 90 and 100% respectively.

As regards the reaction mechanism, it is suggested that initially the allyl system and the metal carbonyl form a π-complex[138,142,144,145], within which a 1,3-hydrogen transfer takes place. This is confirmed by the fact that, in the isomerisation of 1,1-dideuteroallyl alcohol in the presence of $Fe(CO)_5$, only 1,3-dideuteropropionaldehyde is formed[144]:



This mechanism is also confirmed by the formation of 3-deuteropropionaldehyde in the isomerisation of allyl alcohol in the presence of $CoD(CO)_4$:[142]

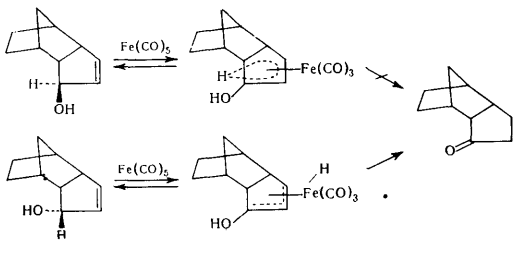


$$CH_2{=}CHCH_2OH + DCo(CO)_4 \longrightarrow \underset{\uparrow\ DCo(CO)_4}{H_2C{=}CH{-}\overset{H}{C}HOH} \longrightarrow \underset{DH_2C\quad CoH(CO)_4}{HC{=}CHOH} \longrightarrow$$

$$HCo(CO)_4 + CH_2DCH{=}CHOH \longrightarrow CH_2DCH_2CHO \ .$$

Possibly the π-complex exists in equilibrium with a δ-complex.

Additional confirmation of the mechanism of the rearrangement via the formation of a π-complex between the allyl system and the metal carbonyl was obtained in a study of the isomerisation of *endo*-α-1-hydroxy-5,6-dihydrocyclopentadiene to *endo*-β-1-hydroxy-5,6-dihydrocyclopentadiene. It was found that the first compound does not isomerise on heating with iron pentacarbonyl even at 160°C, while the second gives the ketone in about 40% yield on heating to 130°C for 16 h with 10% of iron pentacarbonyl in an atmosphere of nitrogen[145]:



This shows that the rearrangement takes place via a π-complex, since in both cases the attack by the iron carbonyl can take place from the least screened *exo*-side, but only in the second case is there a possibility of the formation of a transition state in which a hydrogen atom can be readily transferred.

The isomerisation of allyl ethers takes place quantitatively in the presence of 5 mole % $Fe(CO)_5$ in pentane under ultraviolet illumination[140,146]. This leads to the formation of a mixture of approximately equal amounts of the *cis*-isomer (44–52%) and the *trans*-isomer (48–56%). Under these conditions, diallyl ether gives a mixture of 26%, 42%, and 31% of *cis*, *cis*-; *cis*, *trans*-; and *trans*, *trans*-dipropenyl ethers respectively[146] and 1-methoxybut-3-ene forms a mixture of products of complete and partial isomerisation:

$$CH_2{=}CHCH_2CH_2OCH_3 \rightarrow \underset{25\%}{CH_3CH{=}CHCH_2OCH_3} + \underset{34\%\ cis + 41\%\ trans}{CH_3CH_2CH{=}CHOCH_3} \ .$$

The stability of the tautomers was estimated by studying their relative amounts in isomerisation mixtures of different types derived from unsaturated ethers (Table 8).[140] The Table shows that the $\alpha\beta$-isomers of ethers in which the double bond is conjugated to the ether group are the most stable. The ratio of the Δ^3-isomer and the Δ^2-isomer is 1.5 : 1 both for open-chain and cyclic ethers, which indicates an important role of the inductive destabilisation of the $>CHOCH_3$ group.

Table 8. Relative amounts of tautomers in isomerisation mixtures of ethers.

Initial ether	Total yield, %	Relative amounts of isomers, %			
		Δ^1	Δ^2	Δ^3	Δ^4
$CH_3OCH{=}CH(CH_2)_2CH_3$	91	84.0	6.0	9.0	1
$CH_3O(CH_2)_3CH{=}CH_2$	90	85.0	5.0	9.0	1
—OCH$_3$	93	93.5	3.9	3.6	
—OCH$_3$	96	95.0	2.0	3.0	

In the isomerisation of ethers of the type $CH_2{=}CH(CH_2)_nOCH_3$ (n = 1, 2, 3, 4, 8, 9) there is an increase of the overall amount of isomers with more remote double bonds and a decrease of the content of the $\alpha\beta$-isomer in the equilibrium mixture. The ratio of the vinyl ether to each non-conjugated isomer (with the exception of the $\beta\gamma$-isomer) is approximately 10 : 1. Calculation shows that the replacement of the alkyl group by a methoxy-group at the vinyl carbon atom increases the stability of the isomer by 1.5 kcal.

Table 9. Relative amounts of tautomers in isomerisation mixtures of esters.

Ester	Relative amounts of esters in mixture, %						
	Δ^1	Δ^2	Δ^3	Δ^4	Δ^5	Δ^6	Δ^7
$C_5H_{11}CH{=}CHCOOCH_3$	...	18.1	8.1	20.4	23.6	28.5	1.5
$C_2H{=}CH(CH_2)_5COOCH_3$	...	17.8	7.3	20.8	24.2	28.7	1.2
—COOCH$_3$	88.8	3.6	7.6	—	—	—	—
—COOCH$_3$	86.8	4.4	8.8	—	—	—	—

Table 9 presents certain data on the relative amounts of tautomers obtained in the isomerisation of esters by refluxing in octane in the presence of 10–20 mole % $Fe(CO)_5$.[141] The equilibrium ratio of the $\alpha\beta$- and $\beta\gamma$-isomers of the octenoates is 2.5 : 1 according to the data obtained. However, the overall sum of the Δ^4-, Δ^5-, and Δ^6-isomers exceeds the content of the $\alpha\beta$-isomer, because the $-M$ and $-I$ effects of the $COOCH_3$ group do not affect the stability of the internal isomers stabilised mainly by hyperconjugation.

Among cyclic isomers, the $\alpha\beta$-isomer stabilised by the $-M$ affect of the $COOCH_3$ group and hyperconjugation is the most stable. It has recently been established that $Fe(CO)_5$ is an effective catalyst of the isomerisation of N-allylimides to N-propenylimides[147].

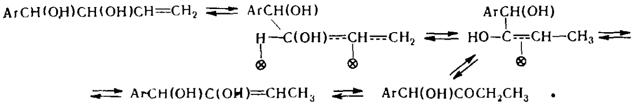
V. ISOMERISATION IN THE PRESENCE OF VARIOUS CATALYSTS

The catalytic isomerisation of olefins with functional groups can be of preparative or industrial value, but, although it was described long ago[117], it has not been adequately investigated. The literature quotes almost exclusively examples of isomerisation under conditions of heterogeneous catalysis. Thus it has been noted that allyl and crotyl alcohols are converted into propionaldehyde and butyraldehyde respectively when the alcohol vapours are passed over copper or cobalt at 150–400°C.[148–150] Vinyl glycols of the type $ArCH(OH)CH(OH)CR{=}CHR'$ (Ar = C_6H_5 or α-furyl) passed in the vapour phase at 200°/15 mmHg over Cu/Cr_2O_3 [151,152] or 5–10% $Pd/CaCO_3$ [153] give the ketols $ArCH(OH)COCHRCH_2R'$ in yields of 30 to 65% in addition to other products. Similarly, when the vapour of the glycol $CH_3CH{=}CHCHOHCHOHCH{=}CHCH_3$ is passed over Cu/Cr_2O_3 at 130°/15 mmHg, dibutyryl is formed in 45% yield[154].

A promising method has been proposed for the catalytic isomerisation of N-alkylallylamines to N-alkylpropenylamines in 26–50% yield when the vapour is passed at 260 to 270°C over alumina promoted by potassium hydroxide; at the same time 5–15% of N-alkylidenealkylamines is formed[155]:

$$CH_2{=}CHCH_2NHR \rightarrow CH_3CH{=}CHNHR + CH_3CH_2CH{=}NR\ .$$

Vinyl glycols of the type $ArCH(OH)CH(OH)CH{=}CH_2$ are also isomerised on simple distillation over $Pd/CaCO_3$ [156] or reduced copper[152], forming the ketols $ArCH(OH)COC_2H_5$ (yield 62–75%). The following possible mechanism of the formation of ketols under the conditions of heterogeneous catalysis, the first stage of which is adsorption of the unsaturated molecule on the catalyst metal, has been proposed:



The isomerisation of allyl alcohols and glycols takes place also on distillation over Raney nickel. Thus n-valeraldehyde was obtained in 80% yield from pent-3-enol[157] and methyl 12-oxostearate was obtained from methyl ricinoleate[158]. It is suggested that in this case the alcohol may be dehydrogenated with subsequent hydrogenation of the double bond.

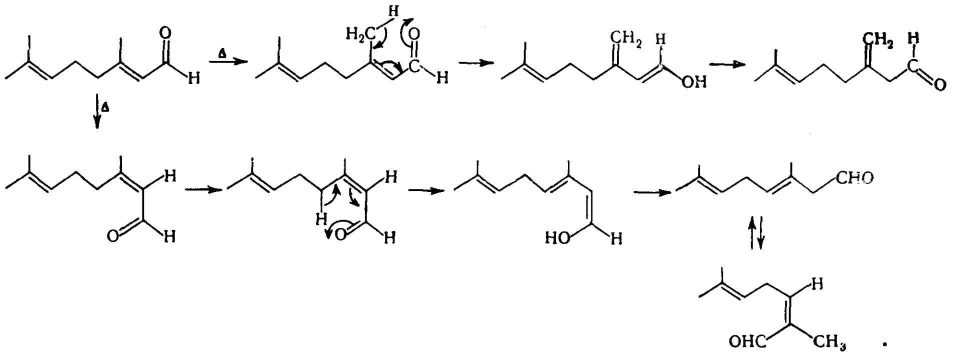
The conversion of allyl alcohols into aldehydes was observed in the reduction by zinc treated with alkali[159] or by the Zn/Cu couple[160]. In some cases there is a possibility of isomerisation under conditions of homogeneous catalysis. Thus phenylvinylglycol is converted into 1-hydroxy-1-phenylbutan-2-one on heating in solution with *cis*-$PdCl_2[P(C_6H_5)_3]_2$:[151]

$$C_6H_5CH\,(OH)\,CH\,(OH)\,CH{=}CH_2 \rightarrow C_6H_5CH\,(OH)\,COC_2H_5\ .$$

The yield greatly depends on the nature of the solvent, reaching 85–100% in dimethylformamide. In benzene, diglyme, and nitromethane the reaction scarcely occurs, in chloroform the yield of the ketol is 10–12%, and in ethylene glycol and hexamethylphosphoramide the yield is 20–30%. Saturated glycols do not change under the experimental conditions. Probably the isomerisation takes place via the formation of a π-complex.

VI. THERMAL ISOMERISATION

The thermal prototropic isomerisation has been little investigated. For example, citral (a mixture of *cis*- and *trans*-isomers in proportions of 2 : 1) isomerises on heating (130–175°C) in a vacuum (15–130 mmHg) to isocitral (also a mixture of the *cis*- and *trans*-isomers) in yields up to 70% and 3-methylene-7-methyloct-6-enal in yields up to 30%. An intramolecular cyclic electron transfer mechanism has been proposed for the thermal isomerisation of citral, isocitral being formed from the *cis*-form of citral and 3-methylene-7-methyloct-6-enal from the *trans*-form of citral[162]:



The thermal isomerisation of nitro-olefins at 110–140°C, which leads to the formation of equilibrium mixtures[163] (Table 10), was investigated in greater detail. The data in Table 10 show that in the case of unsubstituted nitro-olefins or derivatives substituted only in the α-position the equilibrium is wholly displaced towards the αβ-isomer. The effect of substituents in the β- or γ-positions results in the appearance in the equilibrium mixture of appreciable amounts of the βγ-isomer. The equilibrium position is also influenced by the nature of the solvent: polar aprotic solvents promote a shift of equilibrium towards the βγ-isomer (Table 11).

Table 10. Thermal isomerisation of nitro-olefins $RCH_2C(R')=C(R'')NO_2 \rightleftharpoons RCH=C(R')CH(R'')NO_2$.

R	R′	R″	Content in equilibrium mixture, %	
			αβ-isomer	βγ-isomer
H	H	H	100	0
CH_3	H	H	86	14
H	CH_3	H	75	25
H	H	CH_3	100	0
H	CH_3	CH_3	90	10

The study of the thermal isomerisation of vinylnitriles[164] showed that unsubstituted nitriles or derivatives with substituents in the α- or β-positions only do not isomerise. In the presence of two methyl groups or electron-accepting substituents (C_6H_5, C_6H_5O) in the γ-positions the equilibrium is displaced towards the βγ-isomer:

$$RR'CHC(R'')=C(R''')CN \rightleftarrows RR'C=C(R'')CH(R''')CN\ .$$

R	R′	R″	R‴	αβ-isomer %	βγ-isomer %
H	H	H	H	100	0
H	H	$CH_3(C_6H_5)$	H	100	0
H	H	H	$CH_3(C_6H_5)$	100	0
CH_3	CH_3	H	CH_3	100	0
CH_3	CH_3	H	H	28	72
C_6H_5	H	H	H	36	64
C_6H_5O	H	H	H	5	95

However, the γ-substituted nitrile does not isomerise when there is a methyl group in the α-position.

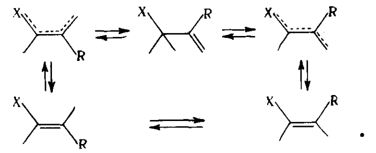
The stereochemistry of the thermal isomerisation of nitriles is independent of temperature and solvent. In the initial stages of the process the *cis*-isomer predominates and the *trans*/*cis* ratio increases only in the course of the reaction, which can be readily accounted for by the *cis*–*trans* isomerisation occurring simultaneously. As a result, the ratio of the *cis*- and *trans*-isomers established is approximately 1.4.

Table 11. Effect of solvents on the position of equilibrium in the system $(CH_3)_2C=CHNO_2 \rightleftharpoons CH_2=C(CH_3)CH_2NO_2$.

Solvent	Temp., °C	Content in equilibrium mixture, %	
		αβ-isomer	βγ-isomer
Cyclohexane	140	83	17
Benzene	140	80	20
Toluene	140	75	25
Acetonitrile	140	75	25
Dioxan	140	67	33
Dimethyl sulphoxide	25	68	32
Hexamethyl-phosphoramide	25	52	48

The rate of reaction increases in the following series of solvents: toluene < dioxan < acetonitrile < dimethyl sulphoxide ≪ hexamethylphosphoramide[164].

The stereochemistry of the reaction and the effect of solvents on the rate of reaction and also the effect of substituents and solvents on the position of equilibrium are consistent with a carbanion mechanism of the thermal isomerisation[163,164]:

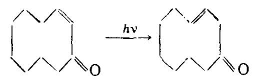


VII. PHOTOCHEMICAL ISOMERISATION

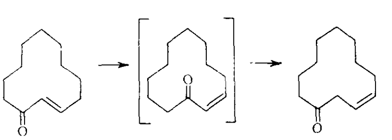
A fairly large number of examples of the migration of the double bond in carbonyl compounds under the influence of ultraviolet light have now been described. The principal feature of the photochemical isomerisation is that in this case the shift of the double bond takes place always from a conjugated to a non-conjugated position, i.e. the $\beta\gamma$-isomer is formed from the $\alpha\beta$-isomer. Thus, on irradiation of 4,5,5-trimethylhex-3-en-2-one, the product is pure 4-methylene-5,5-dimethylhexan-2-one, which on standing is spontaneously partially converted into vinyl ketone, giving an equilibrium mixture in proportions of 1 : 1.[165]

The study of the photochemical isomerisation of aliphatic $\alpha\beta$-unsaturated ketones of the type $RR'C=C(R'')COCH_3$ in ether showed[166] that ketones without substituents or containing substituents in the α- or β-positions only or simultaneously in the γ- and α- or β-positions do not isomerise. On the other hand, γ-substituted ketones readily enter into the reaction. Thus 5-methylhex-4-en-2-one was obtained in 75% yield from 5-methylhex-3-en-2-one, while hex-3-en-2-one gave a mixture of the *cis*- and *trans*-isomers of hex-4-enone[166]. When phorone is irradiated in methanol or hexane, 2,6-dimethylhepta-1,5-diene-4-one is formed in high yield[167,168] together with traces of 2,6-dimethylhepta-1,6-diene-4-one.

The results of the photolysis of $\alpha\beta$-unsaturated cyclic ketones are related to ring size[169]. In the case of cyclodec-2-enone[170] and cyclododec-2-enone[171] the double bond migrates from the $\alpha\beta$- to the $\beta\gamma$-position:



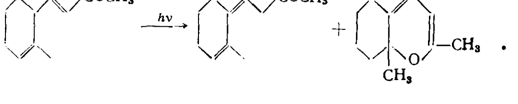
cis-isomer 59% (mixture of *cis*- and *trans*-isomers) ,



trans-isomer *cis*-isomer 92% .

Before isomerisation *trans*-isomers are converted into the *cis*-form. After prolonged irradiation of *cis*-cyclodec-2-enone, 2-vinylcyclo-octanone was formed in a yield up to 35% in addition to the cyclodec-3-enone.

Several examples of the photochemical shift of the double bond in the α-ionone series have been described[172,173]. However, the reaction is frequently complicated by the formation of bicyclic structures. For example:



Photochemical isomerisation has been used to convert 7-oxocholesteryl acetate into 3β-acetoxycholest-4-en-7-one[174] and 10α-testosterone into 17α-hydroxy-3-oxo Δ^5-10α-androstene[175].

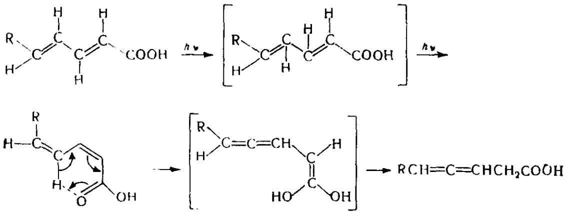
It has been noted that, when crotonaldehyde vapour is irradiated at 30°C with light at 245–400 nm, vinylacetaldehyde is formed[176].

Esters of crotonic, pent-2-enoic, 4-methylpent-2-enoic, and 2-methylcrotonic acids are smoothly isomerised on illumination with ultraviolet light, giving quantitative yields of vinylacetic ester and its substituted derivatives[177]. Under the same conditions, ethyl 1,3-dimethylcrotonate gives ethyl 2,3-dimethylbut-3-enoate with a yield of only 7%. The reaction is promoted by polar solvents, low concentrations of the reactants, and high temperatures.

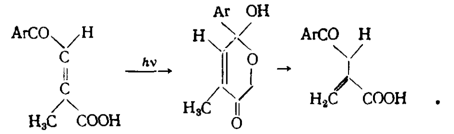
An interesting method for synthesising allenic acids of the type $RCH=C=CHCH_2COOH$ is based on the photochemical reaction of dienoic acids (sorbic and penta-2,4-dienoic) in ether in the presence of traces of formic acid[178]. The yield of the final product is 20–32%:

$$RCH=CHCH=CHCOOH \rightarrow RCH=C=CCH_2COOH \quad .$$

Salts of the acids do not isomerise under these conditions, which indicates an important role of the unionised carboxy-group in the reaction. The following mechanism has been proposed for the isomerisation:

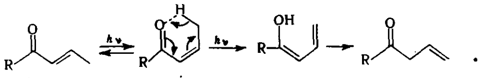


The isomerisation of α-methyl-β-aroylacrylic acids under the influence of sunlight takes place with deconjugation of the aroyl group[179]:



The process proceeds via the lactone, which can be isolated when the reaction is interrupted at the initial stage.

In accordance with all available data for the mechanism of photochemical reactions[169,180], it is believed that the photochemical isomerisation of $\alpha\beta$-unsaturated carbonyl compounds to $\beta\gamma$-isomers takes place by the mechanism (for the *trans*-isomers)



trans *cis*

This mechanism has been confirmed by the fact that the isomerisation of $(CH_3)_2CHCH=CHCOCH_3$ in deuteromethanol (CH_3OD) resulted in 90% conversion into deuterated $\beta\gamma$-unsaturated ketone, where 90% of the hydrogen in the 3-position was replaced by deuterium, which is possible only when the process proceeds via the enol [$(CH_3)_2C=CHCH_2COCH_3$ does not exchange hydrogen in the 3-position for deuterium under identical conditions].[166]

Investigation of Rapid Proton Exchange by Proton Magnetic Resonance

V.K.Pogorelyi and I.P.Gragerov

The review presents a critical compilation and a general account of the published data on rapid proton exchange processes obtained by proton magnetic resonance (PMR). An attempt has been made to establish wherever possible the dependence of the rate and mechanism of the exchange on the chemical structure of the reactants, particularly on the properties of the hydrogen bonds formed by them.
The bibliography includes 163 references.

CONTENTS

I. INTRODUCTION

Many of the most important types of chemical reactions reduce to proton transfer between molecules or ions. This group includes, for example, the dissociation of acids and bases, neutralisation, acid–base catalysis, a number of cases of solvolysis, various tautomeric transformations, rapid isotope exchange of hydrogen, and other processes. One of the central problems of theoretical chemistry involves understanding the driving forces, kinetics, and mechanisms of such processes as a function of the structure of the reactants and the experimental conditions.

Advances in this field are due to the application of relaxation methods[1,2], which allow, in particular, the study of the kinetics of rapid protolytic reactions in ions of different charge types, and the PMR method. The latter proved particularly convenient in the investigation of the detailed mechanism of protolytic reactions and the role of solvation processes in them.

This review deals with studies on rapid proton exchange reactions by the PMR method. In order to supplement several review articles already available[3–8], the relevant literature is considered up to the end of 1968. Particular attention has been concentrated on the dependence of the rate and mechanism of exchange on the chemical structure of the reactants and especially on the properties of the hydrogen bonds formed by them. The role of these bonds in proton exchange was discussed in some studies (see, for example, Refs. 9–16), but has usually been underestimated in the treatment of the experimental data obtained by the PMR method.

We shall not consider in detail the theory of the nuclear magnetic resonance (NMR) method and its application in the study of rapid reactions; the treatment will be restricted to the formulation of certain concepts needed here, the description of the fundamental principles involved in calculating the rates of exchange, and the references to appropriate sources.

The application of the NMR method to problems of chemical kinetics is based on the study of the form of spectral lines. The multiplet structure of the spectrum and the width and intensity of the lines are partly determined by dynamic processes, which can be divided into two types: intermolecular exchange of atoms, groups of atoms, or electrons, and intramolecular processes, for example hindered rotation of atomic groups, inversion of configuration, and rearrangements. We shall examine here the exchange of protons between two molecules:

$$AH^{*}+BH \leftrightarrows AH+BH^{*}\,. \qquad (1)$$

When the exchange is very slow [the lifetimes of the proton in the molecules AH and BH (τ_A and τ_B) are greater than 1 second], the PMR spectrum of such a system shows two narrow resonance signals associated with the magnetic non-equivalence of the two hydrogen nuclei. With increase of the rate of exchange (decrease of τ_A and τ_B), the magnetic environment of the protons in the A–H and B–H bonds becomes averaged, the absorption lines therefore broaden and at a certain exchange frequency merge into a single signal, which becomes narrower on further acceleration of the exchange.

The first approximate relations between the change in line shape and the rate of exchange were proposed by Gutowsky and coworkers[17–19], who used a solution of the Bloch equations[20] in which the time variation of the nuclear magnetisation vector was taken into account by introducing an exponential multiplier, which depends on the lifetime of the proton in a given state. In these studies it was also shown that exchange processes whose frequency is comparable to the difference between the chemical shifts ($\Delta\nu = \nu_A - \nu_B$) of the protons undergoing exchange may be observed by the PMR method.

A more rigorous treatment was proposed by McConnell[21], who introduced into the Bloch equation a number of additional terms, characterising the exchange. The following assumptions were made: (a) proton exchange is a reversible process in which hydrogen nuclei are transferred from one electronic environment to another; (b) the lifetime of the protons in positions AH and BH is much greater than the time necessary for the transfer of protons from A to B and conversely; (c) the probability of finding the protons in the equilibrium positions P_A and P_B and the equilibrium exchange time τ are related to τ_A and τ_B as follows in accordance with the principle of detailed balance:

$$P_A=\frac{\tau_A}{\tau_A+\tau_B};\ P_B=\frac{\tau_B}{\tau_A+\tau_B};\ \tau=\frac{\tau_A\cdot\tau_B}{\tau_A+\tau_B}\ .$$

He also regards the quantities P_A and P_B as the statistical weight fractions of the protons in the corresponding positions. We shall consider in greater detail certain special cases of proton exchange.

1. Under conditions of "slow" exchange when τ_A and $\tau_B \gg \Delta\nu^{-1}$, PMR spectra show two separate signals. Their width Δ increases with decrease of τ (acceleration of exchange). These quantities are related by the equation[22]

$$\pi\Delta_A = T_{2A}^{-1} + \tau_A^{-1} ,$$

which allows the lifetime of the proton (duration of the exchange) τ_A to be determined from the width of the signal when exchange is absent ($T_{2A}^{-1} = \pi\Delta_0$).

2. In the case of "rapid" exchange, where τ_A and $\tau_B \ll \Delta\nu^{-1}$ the spectrum shows a single common signal, whose position depends on the ratio of P_A and P_B and whose width is related to τ_A and τ_B by the equation[23]

$$\pi\Delta = T_2^{-1} + P_A^2 P_B^2 (\tau_A + \tau_B) ,$$

from which τ is found. At very high rates of exchange the contribution of the second term to line width may be negligible and the above formula becomes unsuitable for the determination of τ. In these cases τ may be found from the change in the intensity of the combined signal[24].

3. In the region of intermediate rates of exchange where τ_A and τ_B are comparable to $\Delta\nu^{-1}$, τ may be determined in several ways. One of these consists in comparing the absorption curves calculated for different τ with the experimental spectra. The most general solution of this problem was obtained by Rogers and Woodbrey[25]. Gutowsky and Holm[19] obtained the following expression for the signal intensities q_ν on the assumption that $P_A = P_B$, $\tau_A = \tau_B = 2\tau$, and $T_{2A} = T_{2B} = \infty$ (in the absence of exchange the absorption lines are infinitely narrow):

$$q_\nu = \frac{K\tau\,(\nu_A - \nu_B)^2}{\left[\left(\frac{\nu_A + \nu_B}{2}\right) - \nu\right]^2 + 4\pi^2\tau^2\,(\nu_A - \nu)^2(\nu_B - \nu)^2} .$$

They also derived an equation for the more general case where $T_{2A} = T_{2B}$ is finite and $P_A \neq P_B$. The determination of the rate of exchange can be significantly simplified by obtaining a universal curve (suitable for any values of $\Delta\nu$ and T_2) which relates τ to line width at half the height or to the ratio of the maximum and minimum signal intensities. This problem has been solved for a doublet of lines of equal intensity[26,27] and for the case where $P_A \neq P_B$[28]. A method has also been developed for the determination of τ from the distance between the maxima ($\Delta\nu_{max}$) of the signals due to the states involved in the exchange[19]. The resulting equation is simplest for an infinitely narrow line ($T_{2A} = T_{2B} = \infty$):

$$\tau^{-1} = \sqrt{2}\,\pi\,(\Delta\nu^2 - \Delta\nu_{max}^2)^{\frac{1}{2}} .$$

It shows that the signals merge when $\tau^{-1} = \sqrt{2}\pi(\nu_A - \nu_B)$. Such merging is characteristic of these systems and may serve for the estimation of τ.

In contrast to the two-centre exchange described above, the derivation of analytical expressions for many-centre exchange is fairly complex and has been achieved only in the simplest cases[29-33]. The general expression for an n-centre exchange in the absence of spin–spin coupling between non-equivalent protons was obtained by Piette and Anderson[22].

When the absorption lines corresponding to the mobile protons in the molecules A–H and B–H have a multiplet structure due to spin–spin coupling, the exchange of protons (both equivalent and non-equivalent) leads to a broadening and merging of the components of the multiplet. The rate of exchange may be assessed from these changes. Thus Solomon and Bloembergen[34] solved the problem of the broadening of the lines of the multiplet in "rapid" exchange. Kaplan[35,36] developed a general theory which includes "rapid" and "slow" exchange as limiting cases. Kaplan's method was used by Alexander[37,38] for exchange between different molecules. General methods for the calculation with a spin doublet have been put forward[39-43]. Equations relating the rate of proton exchange to changes in the form of a triplet[29,30,44] and quartet[42] are also available.

More detailed information about the calculation of the rate of proton exchange from NMR spectra may be found in monographs by Pople et al.[45] and Emsley et al.[46]

The lifetime τ_A of the proton in the HA molecule is related to the rate constant k for proton exchange. Evidently the relation between τ_A, the concentration of the substance HA, and the rate of exchange is of the form

$$\tau_A = [\mathrm{HA}]/-\frac{d[\mathrm{HA}]}{dt} \quad \text{or} \quad \tau_A^{-1} = -[\mathrm{HA}]^{-1}\cdot\frac{d[\mathrm{HA}]}{dt} .$$

On the other hand,

$$-\frac{d[\mathrm{HA}]}{dt} = k\,[\mathrm{HA}]^m\,[\mathrm{HB}]^n .$$

Consequently

$$R = \tau_A^{-1} = k\,[\mathrm{HA}]^{m-1}\,[\mathrm{HB}]^n ,$$

where R is the relative rate of proton exchange.

With the aid of NMR it is possible to measure τ in the range 1–10^{-4} s. When the values outside this range are encountered, the rate of exchange is altered by varying the concentration, temperature, or the solvent, in order to make it measurable.

The NMR method has advantages over other procedures for the investigation of rapid reactions—it permits a more detailed study of their mechanism and yields more accurate values of the rate constants. It is significant that, in contrast to relaxation methods, equilibrium in the test system is not displaced or hindered during the measurement. The disadvantages of the NMR method include low sensitivity, which makes it difficult to investigate dilute solutions or gases at a low pressure.

2. PROTON EXCHANGE IN OH GROUPS

The exchange in water has been investigated in several studies by Meiboom, Loewenstein, and their coworkers[23,47,48]. Oxygen contains a certain amount of the ^{17}O isotope, which has a nuclear spin. Spin–spin coupling with protons should lead to a multiplet structure of the PMR spectrum of water in the absence of exchange. However, the spectrum consists of a single line, which is explained by a rapid exchange reaction. Its rate increases in the presence of acid or alkali, which is evident from the narrowing of the line. These small changes in line form cannot be observed under the usual steady-state conditions. They have been measured by the spin–echo method[49] in water specimens enriched in oxygen-17 as a function of the pH and the rate constants for the processes leading to exchange have been found:

$$H_2O + OH^- \overset{k_1}{\rightleftarrows} HO^- + OH_2 , \qquad (2)$$

$$H_2O + H_3O^+ \overset{k_3}{\rightleftarrows} H_3O^+ + H_2O , \qquad (3)$$

$$H_2O + H_2\overset{*}{O} \overset{k_5}{\leftleftarrows} H_2\overset{*}{O} + H_2O . \qquad (4)$$

At 25°C they have the following values: $k_1 = 3.8 \times 10^9$ litre mole^{-1} s^{-1}, $k_3 = 10^{10}$ litre mole^{-1} s^{-1}, and $k_5 = 2.2 \times 10^5$ s^{-1}. The activation energies E and the preexponential factors A for the reactions were determined from the temperature variation of the rate of exchange in the range 20–80°C: $E_1 = 4.8$ kcal mole^{-1} and $E_3 = 2.6$ kcal mole^{-1}, $A_1 = 2 \times 10^{12}$ and $A_3 = 10^{12}$. The values of E were later revised[50] to $E_1 = 2.1$ kcal mole^{-1} and $E_3 = 2.4$ kcal mole^{-1}, which agree well with the values calculated from the anomalous mobility of these ions in water. It is of interest to compare these data with $k = 1.4 \times 10^{11}$ litre mole^{-1} s^{-1}, $E = 2$–3 kcal mole^{-1}, and $A = 9 \times 10^{12}$ found by Eigen and de Maeyer[51–53] by a relaxation method for proton transfer between H_3O^+ and OH^- ions.

The above results are important for the understanding of the mechanism of proton transfer and the anomalous mobility of the ions in water. The rate constants quoted agree with the values found from the anomalous mobilities of hydrogen and hydroxide ions based on electrical conductivity data. The rate constant for the reaction between H_3O^+ and OH^- corresponds to the value calculated for a process which is diffusion-controlled with a distance of approach of the ions of about 7 Å, which corresponds to their separation by 2–3 layers of water molecules. Hence it is concluded that, when the ions approach one another as a result of diffusion to this distance, the reaction occurs rapidly by the migration of protons along hydrogen bond chains:

$$H_2O^+{-}H \ldots \overset{\displaystyle H}{\overset{|}{O}}{-}H \ldots \overset{\displaystyle H}{\overset{|}{O}}{-}H \ldots \bar{O}H \rightarrow H_2O \ldots H{-}\overset{\displaystyle H}{\overset{|}{O}} \ldots H{-}\overset{\displaystyle H}{\overset{|}{O}} \ldots HOH\ . \quad (5)$$

An analogous mechanism accounts for the anomalous mobility of hydrogen ions in water. The reaction proceeds in two stages. The first consists in the formation of a chain of hydrogen bonds with a suitable orientation of the molecules achieved by their rotation. In the second protons are transferred along this chain. The rate is limited by that of the first step. Probably a mechanism of this type obtains in all rapid reactions with participation of H_3O^+ and OH^- ions†.

It is noteworthy that in alcohols (see below) the rate constants for proton exchange are smaller by several powers of ten than in water and the mobility of hydrogen ions is also much lower. Since the strength of hydrogen bonds in alcohols and in water is almost the same[55], which implies that the activation energy for proton exchange is also almost the same (see Section VII), it may be supposed that the rate of exchange in alcohols, as in water, is limited by the rate of formation of hydrogen bond chains of type (5), which is hindered by bulky hydrocarbon groups.

Data have been published on the rate of proton exchange between water molecules in various organic solvents[56]. The exchange proved to be slower the greater the electron-donating capacity of the solvent. These observations were explained by the fact that the solvent dissociates the hydrogen bond between water molecules and forms hydrogen bonds with the water protons, which reduces their mobility.

Rapid proton exchange in alcohols was discovered by Zimmerman and coworkers[57,58], but the first quantitative study was made by Arnold[29], who estimated the values of τ from the change in the form of the triplet due to the hydroxyl protons in ethanol as the pH was changed.

A detailed study of the exchange in ethanol and methanol has been made[59–61]. In neutral ethanol the reaction is slow and the PMR spectrum consists of a triplet due to CH_3, two overlapping quartets due to CH_2, and a triplet due to OH. When the ethanol contains water, the single signal due to the latter appears between the multiplets of the CH_2 and OH groups. In acidified alcohol or in the presence of alkali the signal due to methylene protons is converted into a simple quartet, the hydroxyl triplet is converted into a singlet, and the separate water peak is not observed. These changes in the spectrum are caused by a decrease in the lifetime of the proton in the hydroxy-group due to two consecutive processes.

In anhydrous alcohol only the protons of the OH group undergo exchange and the values of τ found from the analysis of the form of the CH_2 and OH signals are the same. On the other hand, when the alcohol contains water, two exchange reactions take place—between alcohol molecules and between alcohol and water. The rate of the overall process R was found from the change in the form of the methylene signals and the rate of exchange with water R_W from the width of the water line. The rate of the alcohol–alcohol exchange R_A was determined from the equation $R_A = R - R_W$. It was found that R_A and R_W depend linearly on the concentration of acid or alkali. The rate constants for the reactions leading to exchange were found from the slope of the straight line obtained and the equilibrium constants which determine the values of the ratios $[H_3O^+]/[ROH_2^+]$ and $[OH^-]/[RO^-]$:

$$ROH + OH^- \overset{k_1}{\rightleftarrows} RO^- + H_2O\ , \qquad (6)$$

$$ROH^* + HOH + RO^- \rightleftarrows RO^- + H^*OH + ROH\ ,$$

or

$$ROH + RO^- \overset{k_2}{\rightleftarrows} RO^- + ROH\ , \qquad (7)$$

$$ROH + H_3O^+ \overset{k_3}{\rightleftarrows} ROH_2^+ + H_2O\ ,$$

or

$$ROH_2^+ + HOH^* + ROH \rightleftarrows ROH + HOH + RO^+HH^*\ , \qquad (8)$$

$$ROH + RO^+H_2 \overset{k_4}{\rightleftarrows} RO^+H_2 + ROH\ , \qquad (9)$$

$$ROH^* + HOH \overset{k_5}{\rightrightarrows} ROH + HOH^*\ . \qquad (10)$$

We may note that in the system isopropyl alcohol–water[62] the mechanism of the exchange in an acid medium was found to depend on the relative amounts of the alcohol and water. The reaction takes place via mechanism (8) when the solvent is the alcohol and via the mechanism

$$H_3O^+ + ROH^* + OH_2 \rightrightarrows H_2O + ROH + H^*O^+H_2$$

when the solvent is water.

In contrast to ethanol, even in highly purified methanol the doublet due to the methyl protons and the quartet due to the hydroxyl are broadened. In aqueous solution the water line appears in the vicinity of the broadened quartet. The overall rate of exchange was found from the change in the form of the doublet and R_W from the broadening of the water line. The results proved to be analogous to those obtained for ethanol with the sole difference that in neutral anhydrous methanol the reaction

$$ROH^* + ROH \rightleftarrows ROH + ROH^*\ ,$$

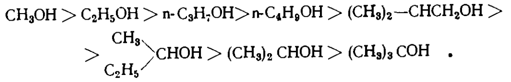
which in ethanol is too slow to be investigated by the NMR method, makes an appreciable contribution to the overall rate of exchange. The activation energy for methanol proton exchange in an acid or alkaline medium is 2–3 kcal mole^{-1}, which corresponds to the activation energy for a diffusion process. There are data[63] showing an increased activation energy for the exchange in degassed methanol, compared with the alcohol saturated by oxygen.

---

† An analogous mechanism was recently proposed for the exchange between $H_2PO_4^-$ and HPO_4^{2-} ions in water[54].

The rate constants for the exchange reactions in ethanol and methanol and also in isopropyl and isobutyl alcohols[64] and in water are compared in Table 1.

The kinetics of proton exchange between various alcohols and water in a neutral solution have been investigated[64-66] as a function of the concentration of water; the rate of exchange decreases in the following sequence:



$$CH_3OH > C_2H_5OH > n\text{-}C_3H_7OH > n\text{-}C_4H_9OH > (CH_3)_2{-}CHCH_2OH > \left.\begin{matrix}CH_3\\ C_2H_5\end{matrix}\right\rangle CHOH > (CH_3)_2\,CHOH > (CH_3)_3\,COH\ .$$

Table 1. Rate constants for proton exchange in alcohols and water.

R—OH	k_1	k_2	k_3	k_4	k_5
H—OH	$3.8\cdot10^{9}$*	—	$1\cdot10^{10}$*		$2.2\cdot10^{5}$*
CH_3—OH	$2.6\cdot10^{6}$	$7.4\cdot10^{8}$*	10^{8}	$3.5\cdot10^{9}$*	3
C_2H_5—OH	$2.8\cdot10^{6}$	$1.4\cdot10^{6}$	$2.8\cdot10^{6}$	$1\cdot10^{8}$	0.8
n-C_3H_7—OH	—	$0.6\cdot10^{6}$	—	$8\cdot10^{6}$	—
$(CH_3)_2CHCH_2$—OH	—	$2.7\cdot10^{6}$	—	$2\cdot10^{7}$	—

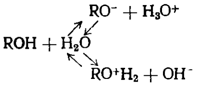
Note. The designations of the constants k (litre mole^{-1} s^{-1}) are the same as in Eqns. (2)–(4) and (6)–(10). The temperatures are 20° ± 2°C but 25°C for the values distinguished by an asterisk.

As already mentioned, the decrease of the rate of catalysed exchange in alcohols compared with water is due to the steric effect of the hydrocarbon residues, which hinder the orientation of the molecules and screen the hydroxy-group, and this inhibits the formation of complexes of type (5), the rate-limiting step in the exchange process. The data in Table 1 confirm this idea, since the rate decreases in the series of alcohols as the bulk of the hydrocarbon group increases. Possibly the decreased acidity of alcohols, which weakens the hydrogen bond formed by them, plays a certain role. This factor is probably not of decisive importance, since the changes in acidity (and in the strength of the hydrogen bond) are small compared with the changes in the rate of exchange. The above relation fails for isobutyl alcohol.

In a neutral medium the rate constants for the exchange are lower by many powers of ten than when catalysed by an acid or alkali. Bearing in mind that the rates of formation of the reaction complex in the neutral alcohol and in catalysis by an acid or alkali should be similar, one may suppose that the rate of neutral exchange is limited by the migration of protons along the hydrogen bonds in the complex. A synchronous mechanism of exchange in the cyclic association complex

(11)

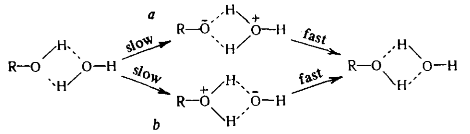
or a mechanism including slow dissociation into ion pairs and their rapid recombination,



(12)

have been proposed for this case[65].

The second mechanism is unlikely because of the high energy expenditure on the separation of the ions. The formation of "close" ion pairs linked by hydrogen bridges is more acceptable:



(13)

Among the pathways described, only pathway *a* accounts for the observed acceleration of exchange with increasing acidity of the alcohol. It is difficult to reconcile this acceleration with mechanism (11), according to which the rate should be independent of the acidity of the alcohol. We may also note that the formation of four-centre complexes assumed in mechanisms (11) and (13) is unlikely. It is unfavourable on energetic grounds[13-15] and has not been confirmed by determinations of the reaction order.

We have already noted that in the PMR spectrum of pure neutral methanol both multiplets are broadened. It has been found[67] that the addition of acetone to alcohols leads to a narrowing of the lines of the multiplet due to localisation of the hydroxyl proton in the hydrogen-bonded alcohol–acetone complex. This localisation hinders the exchange between the alcohol molecules, distorting the form of the spectrum. Such an effect of complex formation on the rate of proton exchange has already been noted in the discussion of studies on water. As will be shown below, it is of general importance.

We may refer to two studies on proton exchange in hydrated acetaldehyde[68] and its hemiacetal[69], in which a rapid exchange between the hydrogen atoms of the OH groups of the hydrate, hemiacetal, alcohol, and water is observed.

Proton exchange between hydrogen peroxide and water has been investigated[70]. The spectrum of a mixture of these substances consisted at room temperature of a single line whose width depended on the hydrogen peroxide concentration and the pH. In the pH range 2.5–4 the rate of exchange was proportional to the concentration of H_3O^+ ions and at 27°C $k = 1.6 \times 10^7$ litre mole^{-1} s^{-1}. The rate-limiting stage is probably

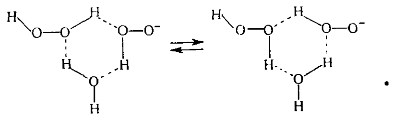
$$H_2O_2 + H_3O^+ \rightleftarrows H_3O_2^+ + H_2O\ . \qquad (14)$$

At pH 5.0–6.5 the rate proved to be proportional to the concentration of OH^- and the peroxide and was determined by the rate of the reaction

$$HO_2H + H^*OH + HO_2^- \rightleftarrows HO_2^- + HOH + H^*O_2H \qquad (15)$$

with $k = 7.3 \times 10^7$ litre mole^{-1} s^{-1} at 27°C.

Since the collision of three molecules is improbable and cannot lead to rapid reactions, it was assumed[70] that the process proceeds via a stage of complex formation between the peroxide or the HO_2^- ion and water and occurs in a cyclic activated complex:



(16)

We note that the rate of exchange between hydrogen peroxide and water is lower by several powers of ten than in water itself but is close to the rate of exchange in alcohols.

The exchange between t-butyl hydroperoxide and water has been investigated[71]. In an acid medium a mechanism analogous to mechanism (14) was established and it was found that the rate of reaction is virtually the same as for hydrogen peroxide: $k = 1.1 \times 10^7$ litre mole^{-1} s^{-1} at 23°C. On the other hand, in an alkaline medium the mechanism proved to be different. The relative rate no longer depended on the concentration of the peroxide and was proportional to the concentration of alkali alone ($k = 6.5 \times 10^6$ litre mole^{-1} s^{-1} at 23°C). The observed change in the mechanism may be due to the fact that the hydroperoxide cannot form a cyclic complex of type (16).

A series of studies have been made on the proton exchange in phenols. The exchange between phenol and water catalysed by sodium phenoxide[72] is characterised by a rate constant $k_B = 7.1 \times 10^8$ litre mole^{-1} s^{-1} at 25°C and an activation energy $E_B = 4.2$ kcal mole^{-1}. The rate of reaction is proportional to the concentration of phenol and alkali; the equation for the exchange reaction includes one or several water molecules:

$$\mathrm{PhOH} + (\mathrm{H_2O})_n + \bar{\mathrm{O}}\mathrm{Ph} \rightleftarrows \mathrm{Ph}\bar{\mathrm{O}} + (\mathrm{H_2O})_n + \mathrm{PhOH} \quad . \qquad (17)$$

Grunwald and Puar[73] studied the exchange between phenols and water catalysed by acids and alkalis. Somewhat different characteristics are obtained for reaction (17): $k_B = 5.7 \times 10^8$ litre mole^{-1} s^{-1} at 25°C. $E_B = 3.2$ kcal mole^{-1} and it was shown that one water molecule is involved. The following mechanism was proposed for an acid medium:

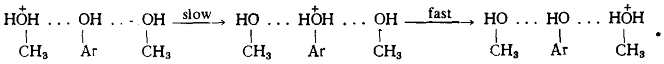
$$\mathrm{H_3O^+} + \mathrm{PhOH} + \mathrm{H_2O} \rightleftarrows \mathrm{H_2O} + \mathrm{PhOH} + \mathrm{H_3O^+} \quad , \qquad (18)$$

where $k_A = 1.5 \times 10^7$ litre mole^{-1} s^{-1} at 25°C and $E_A = 5.5$ kcal mole^{-1}.

Studies on the exchange between substituted phenols and methanol[74,75] led to a more profound understanding of the mechanism of processes of type (17) and (18). It was found that in an alkaline medium the rate of reaction for a series of phenols varies in parallel with their acidity. These data were explained by an exchange process involving a dissociative mechanism in a trimolecular complex. The proton is transferred from the phenol to the alcohol in the slow stage:

$$\underset{\mathrm{Ar}}{\mathrm{OH}} \ldots \underset{\mathrm{CH_3}}{\mathrm{OH}} \ldots \underset{\mathrm{Ar}}{\bar{\mathrm{O}}} \xrightarrow{\text{slow}} \underset{\mathrm{Ar}}{\bar{\mathrm{O}}} \ldots \underset{\mathrm{CH_3}}{\mathrm{H\overset{+}{O}H}} \ldots \underset{\mathrm{Ar}}{\bar{\mathrm{O}}} \xrightarrow{\text{fast}} \underset{\mathrm{Ar}}{\bar{\mathrm{O}}} \ldots \underset{\mathrm{CH_3}}{\mathrm{HO}} \ldots \underset{\mathrm{Ar}}{\mathrm{HO}} \ . \qquad (19)$$

In the acid-catalysed process the rate varies inversely with the acidity of the phenols. Consequently the slow stage in the exchange is protonation of the phenol:



$$\underset{\mathrm{CH_3}}{\mathrm{H\overset{+}{O}H}} \ldots \underset{\mathrm{Ar}}{\mathrm{OH}} \ldots \underset{\mathrm{CH_3}}{\mathrm{OH}} \xrightarrow{\text{slow}} \underset{\mathrm{CH_3}}{\mathrm{HO}} \ldots \underset{\mathrm{Ar}}{\mathrm{H\overset{+}{O}H}} \ldots \underset{\mathrm{CH_3}}{\mathrm{OH}} \xrightarrow{\text{fast}} \underset{\mathrm{CH_3}}{\mathrm{HO}} \ldots \underset{\mathrm{Ar}}{\mathrm{HO}} \ldots \underset{\mathrm{CH_3}}{\mathrm{H\overset{+}{O}H}} \ . \qquad (20)$$

Analogous results were obtained[76] for the reactions of a series of other phenols with water in dioxan or dimethyl sulphoxide solutions. It was noted[75] that the rate of exchange between phenols and methanol in an acid medium is lower the greater is the bulk of the substituents in the *ortho*-position in the phenol molecule. This observation may be explained by steric hindrance to the transfer of protons to the phenol in the slow stage of process (20) due to the substituent. Such interpretation is consistent with the results of studies on the hydrogen bond in sterically hindered phenols[77-82]. We may note that a less marked steric effect of substituents may be expected for exchange in an alkaline medium, since steric hindrance has a smaller effect on the acid dissociation of phenols, the rate-limiting stage in process (19), than on the protonation of phenols in reaction (20). The effect of steric hindrance on the exchange between 2,6-disubstituted phenols and methanol in a neutral medium has been investigated[82].

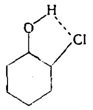
The rate of exchange decreases in the following series of substituents: $\mathrm{H} > \mathrm{CH_3} > (\mathrm{CH_3})_2\mathrm{CH} > (\mathrm{CH_3})_3\mathrm{C}$; since the activation energy is constant, this was explained by an increase in the entropy of activation in the above series.

The study of association in and the proton exchange between a series of *para*-substituted phenols and ethanol showed[83] that the activation energy for the exchange is lower the stronger is the hydrogen bond in the association complex of the phenol and alcohol. This provided one of the first experimental proofs of the predicted relation[14] between the height of the potential barrier to the exchange and the energy of the hydrogen bond in the reaction complex.

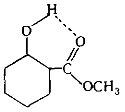
An intramolecular hydrogen bond has a significant influence on the rate of proton exchange in phenols. Thus the uncatalysed exchange between *o*-chlorophenol (I) and methanol is much slower than the exchange between phenol and the same alcohol. Probably the rate is determined by the stage involving the formation of an ion pair:

$$\mathrm{PhOH} + \mathrm{CH_3OH} \rightarrow \mathrm{PhO^-} + \mathrm{CH_3O^+H_2} \quad .$$

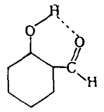
The rate constant is 9×10^2 s^{-1} and the activation energy is 4.6 kcal mole^{-1}. The relatively low rate of exchange is explained by the fact that, despite its low energy ($\Delta H = -2.4$ kcal mole^{-1}), the intramolecular hydrogen bond OH...Cl lowers significantly the capacity of compound (I) to form intermolecular-hydrogen bonds. This interpretation was confirmed by the fact that methyl salicylate (II), salicylaldehyde (III), and *o*-hydroxyacetophenone (IV),



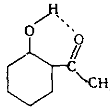
(i)



(II)



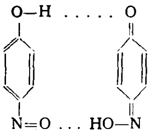
(III)



(IV)

which form stronger intermolecular hydrogen bonds, undergo exchange at a much lower rate than compound (I)[84]. Compounds (III) and (IV) were investigated in greater detail[85]. It was found that (III) undergoes exchange faster than (IV), because the latter has a stronger intramolecular hydrogen bond by virtue of the electron-donating effect of the methyl group.

The interesting case of proton exchange between tautomeric forms of *p*-nitrosophenol has been studied[86]. The relative rate of reaction in a neutral medium is proportional to the concentration and therefore two molecules, probably the molecules of both tautomeric forms, are involved in the elementary step. It is natural to suppose that the exchange takes place in hydrogen-bonded complexes, for example:



In the presence of acids or bases the rate of exchange increases. Catalysis by bases has been explained by the ionisation of the substrate:

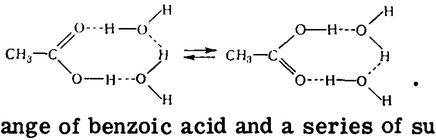
$$\mathrm{HOC_6H_4NO} + [\mathrm{OC_6H_4NO}]^- \rightleftarrows [\mathrm{OC_6H_4NO}]^- + \mathrm{OC_6H_4NOH} \quad ,$$
$$\mathrm{OC_6H_4NOH} + [\mathrm{OC_6H_4NO}]^- \rightleftarrows [\mathrm{OC_6H_4NO}]^- + \mathrm{HOC_6H_4NO} \quad .$$

The catalysed reaction takes place with a lower activation energy than the uncatalysed reaction.

Proton exchange in organic acids was investigated in a number of cases. Thus Luz and Meiboom[87] studied the system acetic acid–water enriched in oxygen-17. The rate proved to be too high to be accounted for by the dissociation of acid:

$$CH_3COOH + H_2O \rightleftarrows CH_3COO^- + H_3O^+ \ .$$

The limiting rate of dissociation may be calculated from the dissociation constant and the rate of reaction between the ions CH_3COO^- and H_3O^+, which cannot exceed the limit set by diffusion. The upper limit to the rate of dissociation found in this way proved to be below the observed rate of exchange by several powers of ten. For this reason, a synchronous cyclic reaction mechanism was proposed:



(21)

The exchange of benzoic acid and a series of substituted benzoic acids (HA) with methanol was investigated by Grunwald and coworkers[88–90], who found that the expression for the rate of reaction in an alkaline medium includes two terms corresponding to an uncatalysed and a catalysed process:

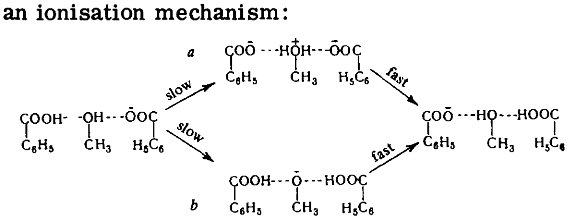
$$R = k_1 + k_B [A^-] \ . \qquad (22)$$

The values of k_1 and k_B for benzoic acid proved to be 1.3×10^5 s^{-1} and 1.2×10^8 litre mole^{-1} s^{-1} at 24.8°C. It was established that in the uncatalysed process two alcohol molecules participate together with an acid molecule and in the catalysed process the reactants are an acid and an alcohol molecule and an acid anion. The rate of the first reaction is much higher than the limiting value which could be accounted for by the dissociation of the acid and has a negative entropy of activation. Therefore the authors proposed a mechanism analogous to that given in equation (21). The displacement of protons in this complex can take place both synchronously and asynchronously with formation of "close" ion pairs in the slow stage. In the catalysis by alkali the exchange in the open-chain trimolecular complex can also take place via mechanisms of two types—a synchronous mechanism:

(23)

$$C_6H_5COOH \ldots \underset{\displaystyle CH_3}{OH} \ldots \bar{O}OCC_6H_5 \rightleftarrows C_6H_5COO \ldots \underset{\displaystyle CH_3}{HO} \ldots HOOCC_6H_5 \qquad (23)$$

or an ionisation mechanism:

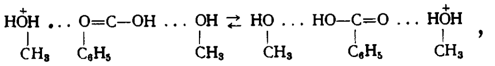


(24)

The rate of reaction by these mechanisms should depend in different ways on the acidity of HA. The ratio $d\ \lg k/d.\lg K_A$, which Grunwald and coworkers used to infer the mechanism, is a measure of the sensitivity of the rate to changes in acid strength. The ratio should be +1 if the rate is limited by acid dissociation [mechanism (24 a)] and −1 when it is determined by the protonation of the base [mechanism (24 b)]. In the synchronous mechanism the ratio should be independent of acid strength, since an increase in the acidity of HA is fully compensated by a decrease in the basicity of A^-. It was found that $d\ \lg k_1/d.\lg K_A = 0.53$ and $d\ \lg k_B/d\ \lg K_A = 0.26$. Therefore it was concluded that the uncatalysed and base-catalysed exchange involves both synchronous and ionisation mechanisms [formula (24 a)]. We believe that these conclusions have little justification, since they do not take into account a number of factors which influence the exchange. We may point, for example, to the fact that a change in acidity alters the strength of hydrogen bonds in complexes of types (21) and (23), on which depends not only the ease of migration of protons in the complexes but also their concentration. Other criteria whereby synchronous and ionisation mechanism may be distinguished are formulated below (see Section V).

Results analogous to those presented above were obtained in a study of the base-catalysed exchange between neopentyl alcohol and acetic, cyanoacetic, and trichloroacetic acids[91]. In this case the ratio $d\ \lg k_1/d\ \lg K_A$ proved to be 0.55. However, the authors concluded that a synchronous exchange mechanism of type (23) operates, since they did not observe a variation of the ratio $d\ \lg k/d.\lg K_A$ with the dielectric constant of the solvent, which would have been expected for a mechanism of type (24 a).

Grunwald and Jumper[90] obtained a rate constant $k_A = 2.52 \times 10^8$ litre mole^{-1} s^{-1} for the exchange between benzoic acid and methanol in an acid medium and proposed a termolecular reaction complex:



(25)

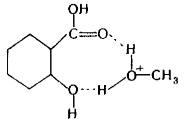
$$\underset{\displaystyle CH_3}{H\overset{+}{O}H} \ldots \underset{\displaystyle C_6H_5}{O{=}C}{-}OH \ldots \underset{\displaystyle CH_3}{OH} \rightleftarrows \underset{\displaystyle CH_3}{HO} \ldots HO{-}\underset{\displaystyle C_6H_5}{C{=}O} \ldots \underset{\displaystyle CH_3}{H\overset{+}{O}H} \ , \qquad (25)$$

but the reaction order with respect to the alcohol was not determined.

The effect of the intramolecular hydrogen bond in salicylic acid on the rate of proton exchange between carboxy- and hydroxy-groups on the one hand and methanol on the other in an acid medium at −80°C was studied by Puar and Grunwald[92]. The following kinetic equations were derived:

$$R_{COOH} = k_1 + k_A [HCl] \text{ and } R_{OH} = k'_A [HCl]$$

with $k_1 = 440$ s^{-1}, $k_A = 1.35 \times 10^5$ litre mole^{-1} s^{-1}, and $k'_A = 5.8 \times 10^3$ litre mole^{-1} s^{-1}. These equations are analogous to the expressions describing the exchange between benzoic acids and phenols on the one hand and acidified methanol on the other. Therefore mechanisms of types (21) and (25) were proposed for the reaction involving the carboxyl and mechanism (20) for the exchange involving the hydroxyl. The constant k_1 for salicylic acid is much higher than for benzoic acid, because the former is a stronger acid and the intramolecular hydrogen bonds in salicylic acid dissolved in methanol are probably disrupted and do not interfere with the formation of complexes of type (21). On the other hand, the constants k_A and k'_A are lower than for benzoic acid and phenols, which was explained by the stability of the complex



whose formation lowers the concentration of termolecular complexes and thereby retards the reactions via mechanism (20) and (25).

The exchange of protons between the OH and COOH groups of *p*-hydroxybenzoic acid was studied in various solvents[27]. The reaction was found to be retarded on passing from acetone to dimethylformamide and dimethyl sulphoxide. This is due to the increased electron-donating capacity of the solvent and the stability of its association complexes with the acid. Association with the solvent hinders the formation of acid dimers in which the exchange takes place.

In a series of isomeric hydroxybenzoic acids the rate of the uncatalysed reaction in dimethyl sulphoxide solution increased in the *ortho* > *para* > *meta* series. The exchange of *m*-hydroxybenzoic acid was studied in greater detail in a later investigation[93].

III. PROTON EXCHANGE IN NH GROUPS

The study of proton exchange in NH groups was begun by Ogg[94,95] using ammonia. The PMR spectrum of thoroughly dried liquid or gaseous ammonia consists of a triplet with a splitting of about 46 Hz. It arises as a result of spin–spin coupling between the proton and the ^{14}N nucleus, the spin of which is unity. In the presence of traces of water in liquid ammonia the triplet merges into a singlet owing to the rapid reaction

$$NH_3 + H_2O \rightleftarrows NH_4^+ + OH^- .$$

This conclusion contradicts the results of other investigations[96–98], in which separate NH and OH peaks were observed ("slow" exchange) for solutions containing less than 50% of water. The explanation offered for the discrepancy[98] is that Ogg observed a reaction catalysed by traces of ammonium ions generated in the reaction between ammonia and the protons adsorbed on glass. The exchange in liquid ammonia is also catalysed by potassamide. The following reaction probably occurs:

$$NH_3 + NH_2^- \rightleftarrows NH_2^- + NH_3 \ .$$

Its rate constant is close to 10^9 litre mole^{-1} s^{-1}. In the gas phase the form of the spectrum is independent of the presence of water vapour and therefore the rapid reaction with water does not take place.

The exchange between ammonium salts and water was investigated in a large series of studies. We shall consider these studies using methylammonium chloride as an example[41,99–101]. In an acid medium (pH ~ 1) the rate of exchange is low and the spectrum shows a quartet due to the methyl protons, arising by virtue of the spin–spin coupling with the protons of the NH_3^+ group, a triplet due to the NH_3^+ protons generated by coupling with ^{14}N, and a singlet corresponding to water. With increase of the pH, the rate of exchange rises. The peaks of the methyl quartet are broadened and merge into a single broad line, which then becomes narrower, while the NH_3^+ triplet continues to become broader and finally disappears.

Both these effects may serve as a measure of the average lifetime of the protons in NH_3^+. The water singlet broadens, merges with the signal due to the NH protons, and the combined peak becomes narrower. A study of the above spectral changes provided evidence for the following exchange reactions:

$$R_3NH^+ + H_2O \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} R_3N + H_3O^+ \ , \tag{26}$$

$$R_3NH^+ + OH^- \overset{k_2}{\rightleftarrows} R_3N + H_2O \ , \tag{27}$$

$$R_3NH^+ + R_3N \overset{k_3}{\rightleftarrows} R_3N + R_3NH^+ \ , \tag{28}$$

$$R_3NH^+ + \overset{\overset{\displaystyle H}{|}}{O}H + NR_3 \overset{k_4}{\rightleftarrows} R_3N + H\overset{\overset{\displaystyle H}{|}}{O} + H\overset{+}{N}R_3 \ , \tag{29}$$

and made possible the determination of the corresponding rate constants. The overall rate of exchange is determined by the relation

$$R = k_1 + \frac{1}{[H^+]}\{k_2\ K_w + (k_3 + k_4) \cdot K_A [R_3\overset{+}{N}H]\} \ ,$$

where K_W is the ionic product of water and K_A is the acid dissociation constant of R_3NH^+. The constants k_1, k_2, and $k_3 + k_4$ were determined from the relation between R (calculated from the change in the form of the CH_3 quartet) and the pH and the R_3NH^+ concentration. The individual values of k_3 and k_4 were obtained by analysing the broadening of the water line. It was found that at a low pH the contribution by reactions (26) and (27) to the overall rate is low and that k_4 for any ratios of the reactant concentrations is approximately 1.5 times greater than k_3. In a later study[99] the rate constants were revised to allow for changes in the viscosity. The results are listed in Table 2.

Table 2. Rate constants for the proton exchange of ammonium salts in water at 22°C*.

R_3NH^+	k_1	$k_{-1} \cdot 10^{-10}$	$k_2 \cdot 10^{-11}$	$k_3 \cdot 10^{-8}$	$k_4 \cdot 10^{-8}$	$K_A \cdot 10^{10}$
NH_4^+	25	4.4	10	11.7	0.9	5.68
$CH_3NH_3^+$	—	—	1	4.0	5.3	0.242
$(CH_3)_2NH_2^+$	—	—	1	0.5	9.0	0.168
$(CH_3)_3NH^+$	4.7	3.0	1	0.3	3.4	1.57
$(C_2H_5)_3NH^+$ **	0.31	2.0	0.17	—	1.8	0.155
$CH_3\overset{+}{N}H_2CH_2COOH$	1.10	3.2	—	—	—	30

* The units of k_1 are s^{-1} and of k_{-1} and k_2–k_4 are litre mole^{-1} s^{-1} respectively.

** Temperature 25–30°C.

Ammonium[102–104], dimethyl- and trimethyl-ammonium[42,105–107], triethylammonium[108], and $CH_3\overset{+}{N}H_2CH_2COOH$[109] ions were investigated similarly and their exchange was explained by the same mechanisms (26)–(29). The rate constants obtained are compiled in Table 2, which shows that, as was to be expected, the constants k_1 vary in parallel with the acidity of the ammonium ions. The rate constants for the reverse reaction k_{-1} have values characteristic of processes whose rate is limited by diffusion and which apparently occur in almost every collision.

The values of k_1 proved to be sensitive to the presence of neutral salts and the pH. They decrease on addition of salts and strong acids[103–105,110]. The study of the effect of the acidity of the medium made it possible to refine the mechanism of reaction (26). The new mechanism[110] includes two stages: reversible ionisation in which the amine molecule does not initially lose its bond with the proton being eliminated:

$$R_3NH^+ \ldots (HOH)_n \underset{k_-}{\overset{k_+}{\rightleftarrows}} R_3N \ldots (HOH)_m + \overset{+}{H}(OH_2)_{n-m} \tag{26a}$$

and the exchange of water molecules between the hydration shell of the amine and the bulk of the solvent:

$$HOH \ldots NR_3 + H\overset{*}{O}H \overset{k_H}{\rightarrow} HOH + R_3N \ldots H\overset{*}{O}H \ . \tag{26b}$$

Reaction (26a) alone does not lead to the exchange of protons bound to the nitrogen as long as reaction (26b) does not occur. In an acid medium the first reaction plays the role of a pre-equilibrium stage and the rate of exchange is determined by stage (26b). The kinetic equation for the overall process is of the form[104]:

$$R = k_+ [R_3NH^+] \frac{k_H}{k_H + k_- [H^+]} \ .$$

When the acidity is fairly high, $k_H \ll k_-[H^+]$ and

$$R = \frac{k_+ k_H [R_3NH^+]}{k_-[H^+]} = \frac{K_A k_H [R_3NH^+]}{[H^+]} \qquad (26c)$$

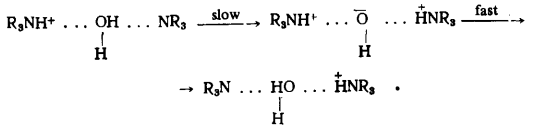
i.e. under certain conditions the rate of exchange is inversely proportional to the concentration of hydrogen ions. The consistency of the exchange kinetics with the equations quoted above implies that in very acid media the amine remains hydrated. When allowance is made for the hydration of the proton, it becomes clear that not less than two water molecules participate in reaction (26a)[110].

The values of k_H which can be found by Eqn. (26c) are of great interest, since these are the rate constants for the dissociation of the hydrogen bond between amines and water. They are listed in Table 3 together with the reciprocal quantities (τ_H), which define the average lifetime of the hydrogen bonds. The data in Table 3 suggest that τ_H is not determined by the basicity of the amine alone but also by steric factors on which depends the ease of the mutual approach of the amine and water and also other characteristics of the structure of the amines.

Table 3. Dissociation rate constants (k_H) and average lifetimes (τ_H) of the hydrogen bonds $R_3N...HOH$ at 25°C.

R_3N	$k_H \cdot 10^{-10}$, s^{-1}	$\tau_H \cdot 10^{11}$, s	$K_A \cdot 10^{10}$
NH_3	50	0.2	5.68
CH_3NH_2	8	1.25	0.242
$(CH_3)_3N$	1.1	9	1.57
$(C_2H_5)_3N$	0.38	26.3	0.155
CH_3NHCH_2COOH	0.8	12.5	30

In contrast to the values of K_A, k_3 (Table 2) decreases steadily from ammonium to trimethylammonium ions, which Loewenstein and Meiboom[42] suggest is caused mainly by steric hindrance. The ratio k_4/k_3 decreases steadily in the same series. The constants k_4 are correlated with K_A: the rate of reaction (29) increases as the acidity of the ammonium ions falls. This relation breaks down only for trimethylammonium ions, probably due to steric hindrance. The mechanism of reaction (29) was examined in detail by Grunwald and Kromhout[99]. Table 2 shows that reactions (26) are so slow that proton transfer from ammonium ions to water cannot ensure the occurrence of the rapid reactions (29). Therefore it was suggested that the rate is limited by proton transfer from the water in the hydration shell of the alkylammonium ions to the amine molecules in the hydrogen-bonded complexes:



$$R_3NH^+ \ldots \underset{\underset{H}{|}}{OH} \ldots NR_3 \xrightarrow{\text{slow}} R_3NH^+ \ldots \underset{\underset{H}{|}}{\bar{O}} \ldots \overset{+}{H}NR_3 \xrightarrow{\text{fast}} R_3N \ldots \underset{\underset{H}{|}}{HO} \ldots \overset{+}{H}NR_3 \; . \qquad (30)$$

The electrostatic field of the cation promotes the slow stage of reaction (30), since it increases the acidity of water by several powers of ten. The field is almost identical for different ammonium ions. Therefore, when the substituents are not unduly bulky, the rate of reaction is determined by the basicity of the amine, which explains the experimental data.

Meiboom[26] revised mechanism (30). He investigated the kinetics of proton exchange in the system trimethylammonium chloride–trimethylamine–water enriched in oxygen-17 as a function of the concentration of water and showed that reaction (30) involves only one water molecule. Water molecules may participate also in reactions of type (27).

The temperature variation of the rate of exchange between ammonium salts and water has been investigated by several workers[100,105,106,110]. In the first study it was found for NH_4^+ and $(CH_3)_3NH^+$ ions that the activation energies of reactions (28) and (29) are close to zero. This result appears to be doubtful, since the activation energy for the reaction between the H_3O^+ and OH^- ions, whose rate is limited by diffusion, is 2–3 kcal mole^{-1}.[51,52]

In a later investigation[105] the plausible value $E = 3.3$ kcal mole^{-1} was obtained for the exchange involving $(CH_3)_3NH^+$ via mechanism (29). The activation energy for reaction (26) with NH_4^+ ions proved to be $E = 12.2$ kcal mole^{-1}. Since the enthalpy change is 12.4 kcal mole^{-1}, one must assume that the activation energy for the reverse process

$$NH_3 + H_3O^+ \rightarrow NH_4^+ + H_2O$$

is close to zero, which is consistent with its very high rate (see above).

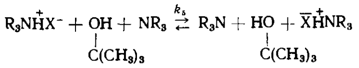
Several studies have been made of proton exchange between aminoacids and polypeptides on the one hand and water on the other in an acid medium. The mechanisms of the exchange processes involving glycine[111], sarcosine[109], glycylglycine[112], triglycine[113], and ammonium salts proved to be similar.

In contrast with acetamidinium salts[114] only the reaction of type (27) is significant. This was explained by the low acid dissociation constant of the ion $[CH_3C(NH_2)_2]^+$ which keeps the concentration of the amidine so low that reactions of type (28) and (29) scarcely occur.

Interesting results were obtained by comparing the proton exchange of ammonium salts in water and other solvents[115]. The changes in the kinetics and mechanism of the exchange could be observed as a function of the properties of the solvents and the structure of the salts. These data are of general importance in understanding the effect of the solvent on the mechanism of protolytic reactions.

In methanol[116–119], which like water has a high dielectric constant ($D = 33.7$ at 20°C), the mechanism of the exchange is similar to mechanism (26)–(29) and the mechanisms of the individual processes are only slightly different from those in water, as can be seen from a comparison of the data in Tables 2 and 4.

In contrast, in t-butyl alcohol, which has a much lower dielectric constant ($D = 12.5$ at 25°C), the mechanism of the exchange is different and the rate of the process is much lower[120–122]. The reason for the differences is that in this solvent ammonium salts exist in the form of ion pairs[123] and not free (solvated) ions. Under these conditions, processes of type (29) play the main role in the exchange, but they involve ion pairs and not free ions:



$$R_3N\overset{+}{H}X^- + \underset{\underset{C(CH_3)_3}{|}}{OH} + NR_3 \overset{k_5}{\rightleftarrows} R_3N + \underset{\underset{C(CH_3)_3}{|}}{HO} + \bar{X}\overset{+}{H}NR_3 \; . \qquad (29a)$$

Table 5 presents the experimental data and the ratios of the rate constants for reactions (29) and (29a). It shows that methylammonium salts differ sharply from trimethylammonium salts. The ratio k_4/k_5 for the former is close to 25 and depends little on the nature of the X^- anion, while for the latter the ratio varies from several thousand to several hundred and depends significantly on X^-. The difference is probably due to the fact that the single hydrogen atom at the nitrogen in $(CH_3)_3N^+HX^-$ molecules is linked to the anion by a strong hydrogen bond, which lowers the rate of exchange by mechanism (29a) and to a greater extent with increasing strength of this bond. In $CH_3NH_3^+X^-$ only one hydrogen atom is linked to the anion and the other two form hydrogen bonds with the solvent and undergo exchange at a much higher rate, which depends little on the nature of the anion.

Table 4. Rate constants for the proton exchange of ammonium salts in methanol at 24°C.

Ammonium ion	k_1, s^{-1}	$k_{-1} \times 10^{-10}$, litre $mole^{-1}$ s^{-1}	$k_4 \times 10^{-8}$, litre $mole^{-1}$ s^{-1}	$K_A^* \cdot 10^{10}$
p-$CH_6H_4NH_3^+$	$2.9.10^3$	1,04	0.81	2800
$(CH_3)_3NH^+$	0.6	0.5	3.25	1.2
2-Picoline.H^+	$9.1 \cdot 10^3$	1.2	2.89	7580
4-Picoline.H^+	$10.6 \cdot 10^3$	1.2	3.44	8830
2,4-Lutidine.H^+	$1.32 \cdot 10^3$	0.97	2.97	1360
2,6-Lutidine.H^+	$1.15 \cdot 10^3$	0.75	0.85	1530

* K_A was measured in methanol at 25°C.

In anhydrous acetic acid solution (D = 6.2 at 25°C) ammonium salts also form ion pairs and not free ions. The exchange reactions probably take place in two stages of type (26a) and (26b):

$$R_3N\overset{+}{H}\overset{-}{O}Ac \rightleftarrows R_3N \ldots HOAc \quad , \qquad (26d)$$

$$AcOH \ldots NR_3 + H\overset{*}{O}Ac \overset{k_6}{\rightleftarrows} AcOH + R_3N \ldots H\overset{*}{O}Ac \quad , \qquad (26e)$$

where reaction (26d) differs from (26a) in that the proton transfer takes place within an ion pair. The analogy with the dissociation and exchange processes in water is confirmed by a parallelism between the enthalpies and entropies of acid dissociation of ammonium ions in water and the corresponding activation parameters for proton exchange between ammonium salts and acetic acid. The experimental data[124-126] are presented in Table 6.

Table 5. Rate constants for the proton exchange between ammonium salts and t-butyl alcohol at 35°C.

R_3NH^+	X^-	$k_5 \times 10^{-5}$, litre $mole^{-1}$ s^{-1}	k_4/k_5
$(CH_3)_3NH^+$	Cl^-	1.1	3500
$(CH_3)_3NH^+$	Br^-	5.3	740
$(CH_3)_3NH^+$	$CH_3C_6H_4SO_2O^-$	7.0	560
$CH_3NH_3^+$	Cl^-	260	23
$CH_3NH_3^+$	$CH_3C_6H_4SO_2O^-$	240	25

These data show that the values of k_6 for acetate salts depend on the acid dissociation constants of ammonium ions in water (K_A). They are almost proportional to the K_A, in accordance with the above exchange mechanism which includes an ionisation stage. Of its two stages, stage (26e) is probably rate-limiting[124,125]. Table 6 shows that the rate of exchange greatly depends on the anion. In accordance with mechanism (26d)–(26e), the rate for salts with the same cation proved to be proportional to the basicity of the anion in acetic acid. Similar results were obtained in a study on the proton exchange of NN-dialkylanilinium salts in acetic acid[127].

In some cases the solvent alters the rate of exchange, while the mechanism and the components undergoing exchange remains the same. Thus the reaction between NH_4^+, H_2O, and NH_3 in water is faster by two powers of ten than in liquid ammonia, probably because water has a lower dielectric constant[98].

Table 6. Rate constants for the proton exchange between ammonium salts and acetic acid at 25°C.

R_3NH^+	X^-	k_6, s^{-1}	$K_A \cdot 10^{10}$
NH_4^+	CH_3COO^-	6080	5.69
$CH_3NH_3^+$	CH_3COO^-	230	0.238
$(CH_3)_3NH^+$	CH_3COO^-	945	1.58
$(HOCH_2)_3CNH_3^+$	CH_3COO^-	41000	84.0
NH_4^+	$C_6H_2(NO_2)_3O^-$	30	
NH_4^+	CCl_3COO^-	2	
NH_4^+	Cl^-	too low for measurement by NMR method	
$CH_3NH_3^+$	Cl^-		
$(CH_3)_3NH^+$	Cl^-		

In several studies the kinetics and mechanisms of protolytic reactions with participation of carboxylic acid hydrazides[128] and amides[43,129] were investigated. For example, it was established that in an aqueous solution of N-methylacetamide at pH 5 the PMR spectrum consists of a singlet due to C-methyl protons, a doublet due to N-methyl protons, a singlet due to water, and a broad line due to the amide hydrogen. It was found from the form of the doublet that the half-life of the exchange exceeds 1 s. On increasing or decreasing the pH, the N-methyl doublet is converted into a single line and the water singlet becomes broader, which is evidence that both acids and alkalis catalyse the exchange. The following reaction mechanisms have been proposed:

$$CH_3{-}CONHCH_3 + OH^- \overset{k_1}{\rightleftarrows} (CH_3{-}CON{-}CH_3)^- + H_2O \quad ,$$

$$CH_3{-}CONHCH_3 + H_3O^+ \overset{k_2}{\rightleftarrows} (CH_3{-}CONH_2CH_3)^+ + H_2O \quad ; \qquad (31)$$

$k_1 = 5.2 \times 10^6$ litre $mole^{-1}$ s^{-1} at 21°C and $k_2 = 3.8 \times 10^2$ litre $mole^{-1}$ s^{-1} at 23°C. The activation energy for the acid-catalysed exchange is in the range 14–16 kcal $mole^{-1}$.[130,131]

In a strongly acid solution the doublet structure of the signal due to the N-methyl protons persists in the presence of dioxan which retards the exchange. This observation shows that protonation involves mainly the oxygen atom, since the protonation of the nitrogen atom would convert the signal of the N-methyl protons into a triplet. The competition of reaction (31) with the protonation of the oxygen atom accounts for the relatively small value of k_2.

The protonation of amides at the oxygen atom was confirmed in a number of studies[132-134]. In the first of these the reaction of formamide, acetamide, and their NN-dimethyl derivatives with fluorosulphonic acid was investigated and it was found that at low temperatures a new line due to the $=C\overset{+}{O}H$ group appears in the spectrum.

Thioamides and sulphonamides are also protonated at the sulphur or oxygen atom. Thiourea and *N*-methylthiourea in fluorosulphonic acid give rise to diprotonated forms[135]. Data have been obtained from the protonation of sodium sulphamate[136].

It is noteworthy that NMR is the only reliable procedure for the investigation of the mode of protonation of acid amides and their analogues.

IV. PROTON EXCHANGE IN HYDROGEN FLUORIDE

Liquid hydrogen fluoride contains the ions HF_2^- and H^+ which are formed by the mechanism

$$2\,HF \rightleftarrows HF_2^- + H^+ \ .$$

The concentration of protons increases in the presence of BF_3 and when the system contains water, H_3O^+ ions appear:

$$HF + H_2O + BF_3 \rightleftarrows H_3O^+ + BF_4^- \ .$$

In this case the PMR spectrum consists of a single peak at room temperature and two peaks, due to HF and H_3O^+, below −50°C. The merging of the peaks on warming was explained[137] by the following proton exchange reaction:

$$H_3O^+ + HF_2^- \rightleftarrows H_2O + 2\,HF \ .$$

Its rate constant proved to be close to 10^{11} litre $mole^{-1}$ s^{-1} and the temperature coefficient was found to be small. In view of the closeness of the above values to the diffusion-limited rate constant for the reaction of hydrogen and hydroxide ions in water, it was suggested that there is an analogy also between the exchange mechanisms, the following scheme being suggested:

$$H_2\overset{+}{O}H \ldots FH \ldots F^- \rightarrow H_2O \ldots HF \ldots HF \ .$$

Possibly not one but several hydrogen fluoride molecules are involved in this reaction.

V. PROTON EXCHANGE IN PH AND SH GROUPS

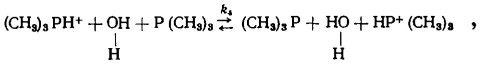
We have emphasised more than once the effect of the acidity of the reactants in protolytic reactions and of the strength of the hydrogen bonds formed by them on the rate of proton transfer. However, so far, it has been impossible to separate the roles of these factors, since for many compounds of a particular type they vary in parallel. Such an estimate can be made by comparing the rates of proton exchange in a series of analogous nitrogen- and phosphorus-containing compounds and hydroxy- and mercapto-derivatives, since the replacement of nitrogen by phosphorus and of oxygen by sulphur increases the acidity but lowers the strength of hydrogen bonds. Therefore the study of exchange in PH and SH groups is of particular interest. The available data are fairly scanty, but they nevertheless allow certain definite conclusions.

A detailed study has been made of proton transfer from PH bonds in aqueous solutions of trimethylphosphonium ions[138]. In an acid medium (pH < 6) the rate of exchange is low and the PMR spectrum consists of a septet due to the hydrogen atom in PH, a double doublet due to methyl hydrogen atoms, resulting from spin–spin coupling with the PH proton and with ^{31}P, and a single line due to water. With increase of the pH, the rate of reaction rises and the septet merges into a very broad singlet, the signal due to the methyl protons is converted into a broadened doublet, and the water line is also slightly broadened. Analysis of the form of the methyl signal led to the determination of the overall rate of exchange involving trimethylphosphonium ions and the rate of the processes with participation of water could be found from the width of the water signal. Reaction mechanisms analogous to those adopted for ammonium salts were proposed:

$$(CH_3)_3PH^+ + H_2O \overset{k_1}{\rightrightarrows} (CH_3)_3P + H_3O^+ \ , \tag{32}$$

$$(CH_3)_3PH^+ + OH^- \overset{k_2}{\rightleftarrows} (CH_3)_3P + H_2O \ , \tag{33}$$

$$(CH_3)_3PH^+ + P(CH_3)_3 \overset{k_3}{\rightleftarrows} (CH_3)_3P + HP^+(CH_3)_3 \ , \tag{34}$$



$$(CH_3)_3PH^+ + \underset{\substack{|\\H}}{OH} + P(CH_3)_3 \overset{k_4}{\rightleftarrows} (CH_3)_3P + \underset{\substack{|\\H}}{HO} + HP^+(CH_3)_3 \ , \tag{35}$$

but the values of k_3 and k_4 were not determined separately.

Table 7. Rate constants for the proton exchange of $(CH_3)_3\overset{+}{N}H$ and $(CH_3)_3\overset{+}{P}H$ in water at 22°C.

$(CH_3)_3\overset{+}{X}H$	k_1, s^{-1}	k_2, litre $mole^{-1}$ s^{-1}	$(k_3 + k_4)$ litre $mole^{-1}$ s^{-1}	pK_A
$(CH_3)_3\overset{+}{P}H$	7.9	$4.6 \cdot 10^7$	$1.2 \cdot 10^2$	8.8
$(CH_3)_3\overset{+}{N}H$	4.7	$<10^{11}$	$3.4 \cdot 10^8$	9.8

The corresponding exchange rate constants for trimethylammonium and trimethylphosphonium ions in water are compared in Table 7. These data cannot be explained in terms of the acid–base properties of the ions undergoing exchange. Thus the higher value of k_1 for $(CH_3)_3PH^+$ is consistent with its higher acidity, but it remains obscure why k_2 for this species is a thousand times lower than for $(CH_3)_3NH^+$ although trimethylphosphonium ions behave as proton donors also in reaction (33). The authors accounted for the relative values of the combined constants $k_3 + k_4$ by the fact that in reaction (35), as in reaction (29), the rate is limited by proton transfer from water to the phosphine. However, it is still not clear why a difference between the basicities of the amine and phosphine by only one power of ten causes an enormous change in $k_3 + k_4$ (by six powers of ten).

On the other hand, the data in Table 7 can be explained if it is postulated that the ratio of the rates under consideration is determined by the ratio of the strengths of the hydrogen bonds. For phosphorus, these bonds are much weaker than for nitrogen and one must suppose that they are particularly weak in those cases where the phosphorus atom behaves as a proton acceptor. This in fact accounts for the lowering of k_2 and the even greater lowering of $k_3 + k_4$ on passing from ammonium to phosphonium ions. However it still remains obscure why k_1 increases slightly under these conditions.

A comparison, similar to that carried out above, cannot be made for dimethylphenylphosphonium ions in methanol[116], since their nitrogen-containing analogue has not been investigated. One can only assert that reactions of types (34) and (35) are much slower with these ions than with ammonium salts, which is consistent with the much weaker proton-accepting character of phosphorus in hydrogen bonds.

The exchange in SH bonds has been investigated on a somewhat larger scale. The study of phenylmethanethiol showed[139] that the rate of reaction is proportional to the concentration of the alkaline or acid catalyst. On this basis, the following mechanisms have been proposed for the exchange:

$$\mathrm{C_6H_5CH_2SH_2^+ + C_6H_5CH_2SH \overset{k_1}{\rightleftarrows} C_6H_5CH_2SH + C_6H_5CH_2SH_2^+}\ , \qquad (36)$$

$$\mathrm{C_6H_5CH_2SH + C_6H_5CH_2S^- \overset{k_2}{\rightleftarrows} C_6H_5CH_2S^- + C_6H_5CH_2SH}\ ; \qquad (37)$$

$k_1 = 1.35 \times 10^2$ litre mole^{-1} s^{-1} and $k_2 = 6 \times 10^5$ litre mole^{-1} s^{-1}. The uncatalysed process is so slow that its rate cannot be determined by the NMR method.

The rate of exchange of protons in the SH group of 2-mercaptoethanol has been studied[140]. The PMR spectrum of a solution of this substance in carbon tetrachloride consists of a triplet due to the thiol hydrogen, a quartet due to S–CH$_2$, a triplet due to O–CH$_2$, and a singlet due to OH. The spectrum retains the same form in an acidified aqueous medium, but in a neutral solution or solutions made alkaline with sodium acetate the SH triplet and the OH singlet merge into a common signal. Analysis of these changes as a function of the catalyst concentration, taking into account the acid–base equilibrium constants in the system, made it possible to determine (at 27°C) the rate constants for the uncatalysed exchange ($k_0 = 32$ s^{-1}) and the reactions catalysed by acetate ions ($k = 2 \times 10^3$ litre mole^{-1} s^{-1}). The equilibrium constant for the reaction

$$\mathrm{HOCH_2CH_2SH + CH_3COO^- \rightleftarrows HOCH_2CH_2S^- + CH_3COOH}$$

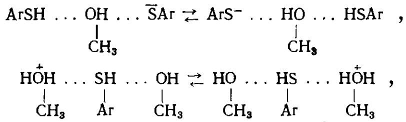
was found and the rate constant for the process

$$\mathrm{HOCH_2CH_2S^- + CH_3COOH \rightarrow HOCH_2CH_2SH + CH_3COO^-}\ ,$$

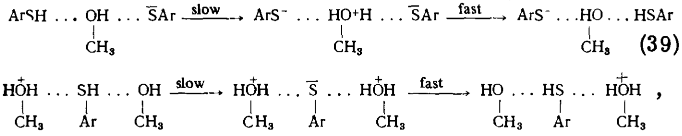
was calculated to be 10^8 litre mole^{-1} s^{-1}. The absence of the acid catalysed proton exchange in the SH group of 2-mercaptoethanol was explained by the low basicity of the thiol group.

It is interesting to compare the above data with the results for alcohols, for example it is instructive to compare k_1 and k_2 from Eqns. (36) and (37) with k_4 and k_2 from Eqns. (9) and (7) (Table 1). The comparison shows that the rate of exchange in SH groups is smaller by several powers of ten than in OH. We explained this difference by the lower strength of SH...S hydrogen bonds compared with OH...O. This interpretation was confirmed in the present author's studies[141,142] of proton exchange of thiophenols.

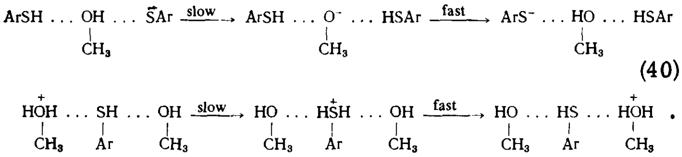
A study was made of the exchange between a series of thiophenols and methanol catalysed by hydrogen chloride or sodium methoxide. The rate of reaction was found to be proportional to the concentration of the thiophenol, alcohol, and the catalyst. It increased (and the activation energy fell) in parallel with the acidity on introducing electron accepting substituents into the thiophenol nucleus. For *para*- and *meta*-substituted compounds, a linear relation was observed between the activation energy and the logarithm of the rate constants for the exchange in alkaline and acid media (E_B, E_A, lgk_B, and lgk_A), on the one hand, and Hammett's σ constants, on the other, the values of ρ in the correlation equations proving virtually identical in both series. These data confirmed the exchange mechanism. Three most probable mechanisms were considered, in which the reactants were combined by hydrogen bonds into a single reaction complex:



$$\mathrm{ArSH}\ldots\underset{\mathrm{CH_3}}{\mathrm{OH}}\ldots\overline{\mathrm{S}}\mathrm{Ar}\rightleftarrows\mathrm{ArS^-}\ldots\underset{\mathrm{CH_3}}{\mathrm{HO}}\ldots\mathrm{HSAr}\ , \qquad (38)$$
$$\underset{\mathrm{CH_3}}{\mathrm{H\overset{+}{O}H}}\ldots\underset{\mathrm{Ar}}{\mathrm{SH}}\ldots\underset{\mathrm{CH_3}}{\mathrm{OH}}\rightleftarrows\underset{\mathrm{CH_3}}{\mathrm{HO}}\ldots\underset{\mathrm{Ar}}{\mathrm{HS}}\ldots\underset{\mathrm{CH_3}}{\mathrm{H\overset{+}{O}H}}\ ,$$



$$\mathrm{ArSH}\ldots\underset{\mathrm{CH_3}}{\mathrm{OH}}\ldots\overline{\mathrm{S}}\mathrm{Ar}\xrightarrow{\text{slow}}\mathrm{ArS^-}\ldots\underset{\mathrm{CH_3}}{\mathrm{HO^+H}}\ldots\overline{\mathrm{S}}\mathrm{Ar}\xrightarrow{\text{fast}}\mathrm{ArS^-}\ldots\underset{\mathrm{CH_3}}{\mathrm{HO}}\ldots\mathrm{HSAr} \qquad (39)$$
$$\underset{\mathrm{CH_3}}{\mathrm{H\overset{+}{O}H}}\ldots\underset{\mathrm{Ar}}{\mathrm{SH}}\ldots\underset{\mathrm{CH_3}}{\mathrm{OH}}\xrightarrow{\text{slow}}\underset{\mathrm{CH_3}}{\mathrm{H\overset{+}{O}H}}\ldots\underset{\mathrm{Ar}}{\overline{\mathrm{S}}}\ldots\underset{\mathrm{CH_3}}{\mathrm{H\overset{+}{O}H}}\xrightarrow{\text{fast}}\underset{\mathrm{CH_3}}{\mathrm{HO}}\ldots\underset{\mathrm{Ar}}{\mathrm{HS}}\ldots\underset{\mathrm{CH_3}}{\mathrm{H\overset{+}{O}H}}\ ,$$



$$\mathrm{ArSH}\ldots\underset{\mathrm{CH_3}}{\mathrm{OH}}\ldots\overline{\mathrm{S}}\mathrm{Ar}\xrightarrow{\text{slow}}\mathrm{ArSH}\ldots\underset{\mathrm{CH_3}}{\mathrm{O^-}}\ldots\mathrm{HSAr}\xrightarrow{\text{fast}}\mathrm{ArS^-}\ldots\underset{\mathrm{CH_3}}{\mathrm{HO}}\ldots\mathrm{HSAr} \qquad (40)$$
$$\underset{\mathrm{CH_3}}{\mathrm{H\overset{+}{O}H}}\ldots\underset{\mathrm{Ar}}{\mathrm{SH}}\ldots\underset{\mathrm{CH_3}}{\mathrm{OH}}\xrightarrow{\text{slow}}\underset{\mathrm{CH_3}}{\mathrm{HO}}\ldots\underset{\mathrm{Ar}}{\mathrm{H\overset{+}{S}H}}\ldots\underset{\mathrm{CH_3}}{\mathrm{OH}}\xrightarrow{\text{fast}}\underset{\mathrm{CH_3}}{\mathrm{HO}}\ldots\underset{\mathrm{Ar}}{\mathrm{HS}}\ldots\underset{\mathrm{CH_3}}{\mathrm{H\overset{+}{O}H}}\ .$$

The data showing the acceleration of the exchange with increasing acidity of thiophenols contradict mechanism (40), which requires the opposite relation, but are consistent with mechanism (39). The choice between the latter and mechanism (38) was made on the basis that only reactions (39) explain the observed equality of the values of ρ in the correlation equations, since only in mechanism (39) is the slow exchange stage the same in both alkaline and acid media, namely proton transfer via the hydrogen bond in the SH...OH dimers. Hence it was concluded that there should be a quantitative relation between the kinetic parameters of the exchange and the thermodynamic characteristics of the hydrogen bond. Such a relation does indeed exist.

Table 8. Kinetic parameters of the proton exchange between thiophenols and methanol and the thermodynamic parameters of the hydrogen bonds between thiophenols and acetone.

ArSH	Proton exchange				Hydrogen bond		
	k_B (27°), litre mole^{-1} s^{-1}	k_A (27°) litre mole^{-1} s^{-1}	E_B, kcal mole^{-1}	E_A, kcal mole^{-1}	K (27°), mole fraction^{-1}	$-\Delta H$, kcal mole^{-1}	$-\Delta S$, e.u.
p-Methoxythiophenol	$4.2 \cdot 10^3$	$1.2 \cdot 10^2$	9.0	12.5	2.3	2.6	7.1
p-Thioxylenol	$3.3 \cdot 10^3$	—	8.3	—	2.1	2.9	8.2
Tetraline-2-thiol	$5.5 \cdot 10^3$	—	8.5	—	2.6	2.8	7.8
p-Thiocresol	$5.8 \cdot 10^3$	$1.7 \cdot 10^2$	8.2	12.0	2.6	2.9	7.8
Thiophenol	$14.0 \cdot 10^3$	$2.8 \cdot 10^2$	7.5	11.0	2.9	3.2	8.6
p-Chlorothiophenol	$28.3 \cdot 10^3$	$7.8 \cdot 10^2$	6.3	10.0	3.3	3.8	10.0
3,4-Dichlorothiophenol	$112.0 \cdot 10^3$	$33.3 \cdot 10^2$	5.5	8.5	4.5	4.1	10.4

We used NMR to investigate[143] the thermodynamics of hydrogen bond formation between acetone and the same series of thiophenols for which the exchange had been investigated and found a linear relation between E_B and E_A, on the one hand, and the enthalpy of formation of the hydrogen bond ΔH, on the other, and also between k_B and k_A, on the one hand, and the association constants K, on the other. It is significant that this relation holds also for *ortho*-substituted thiophenols. The kinetic and thermodynamic data obtained in these studies are compiled in Table 8.

The total set of results shows that the characteristics of the hydrogen bond formed by sulphur play a decisive role in the kinetics and mechanism of proton exchange of thiophenols. The weakness of these bonds explains, in particular, the relatively high activation energies and the low rates of exchange (much lower than in the phenols–methanol systems[75]). The proton-accepting power of sulphur is apparently much weaker. This hypothesis accounts for the observation that the exchange involving thiophenol in an acid medium does not take place by mechanism (40) in which sulphur serves as a proton acceptor, in contrast to the exchange involving phenols, which takes place by reaction (20), analogous to mechanism (40). We may recall that in the case of hydrogen bonds formed by phosphorus the proton-accepting character of phosphorus is apparently much weaker than that of nitrogen.

VI. EXCHANGE IN C–H GROUPS.

Rapid proton exchange in C–H bonds of hydrocarbons and their derivatives takes place only in catalysis by bases and only in those cases where the acidity of the hydrogen is particularly enhanced. Like the other exchange processes examined here, these reactions probably take place in hydrogen-bonded complexes. Hydrogen bonds are less typical for carbon, which explains the rare occurrence of rapid exchange in C–H groups.

Several studies have been made on substituted acetylenes $R-C\equiv CH$.[144,145] It was found that with $R = C_6H_5$, CH_2CH_2OH, CH_2OCH_3, $C(CH_2)_2OCH_3$, $C(CH_3)_2OH$, and $CH(OC_2H_5)_2$ the rate of base-catalysed exchange with aqueous t-butyl alcohol is proportional to the concentrations of the substrate and the catalyst; the logarithm of the rate constants varies linearly with σ^*. The mechanism can be represented as follows:

$$R-C\equiv CH + OH^- \rightleftarrows R-C\equiv C^- + H_2O\ .$$

A study was also made of the exchange in compounds with $R = SC(CH_3)_3$, OCH_3, $C(CH_3)_3$, $SCH=CH_2$ and $OCH=CH_2$ catalysed by $(CH_3)_4NOH$.[146] The rate proved to be a maximum for sulphur-containing substances and a minimum for t-butylacetylene, and is lower the higher the dielectric constant of the solvent. These data were explained by the fact that only in compounds containing sulphur is there conjugation of the type

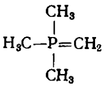
$$\overline{C}\equiv C-SR \leftrightarrow :C=C=\overline{S}R\ ,$$

which stabilises the anion, lowers the energy of the transition state for the reaction, $R-C\equiv C^{-\delta}...H...OH^{-\delta}$, and increases the rate of exchange. The transition state is less solvated than OH^- ions, which in fact explains the decrease of the exchange rate with increasing dielectric constant of the solvent.

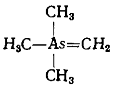
In certain systems a rapid exchange was observed between the hydrogen in C–H groups and carbanions. Thus it has been established[147] that the rate constants for the reaction between dimethyl sulphoxide and Na^+ or $Li^+CH_3SOCH_2^-$ (determined from the change in the form of the ^{13}C satellites of the signal due to the CH_3 group) are 12 and 7 litre $mole^{-1}\ s^{-1}$ respectively at 37°C.

In another study[148] it was shown by a double resonance method that the rate of exchange between fluorene and 9-fluorenyl-lithium in dimethyl sulphoxide solutions at 38°C is characterised by the constant $k = 0.5$ litre $mole^{-1}\ s^{-1}$. These results are inconsistent with the much higher rate of exchange in the analogous system comprising 9-methylfluorene and the 4,5-methylenephenanthryl anion[149] observed in a very dilute dimethyl sulphoxide solution by the stop-flow method. The difference is probably due to self-association of the organometallic compound in concentrated solution.

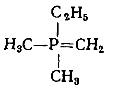
Rapid proton exchange was observed recently in phosphoranes and their analogues. Thus at room temperature the PMR spectra of the pure compound (I) or its benzene solution show doublets due to the methyl and methylene protons (the splitting is caused by interaction with the ^{31}P nuclei), but the rapid exchange induced by heating deprives the hydrogen atoms of their individual characteristics, which leads to a broadening of the signals, smearing out of the doublet structure, and merging of the signals into a singlet at a temperature above 100°C. In the presence of proton-donating compounds, for example traces of an alcohol, the singlet is observed even at room temperature[150,151]. A similar behaviour was noted for compounds (II)[152] and (III)–(V)[153]. In the latter compounds only the α-hydrogen atoms become indistinguishable. Variation of the form of the signal of the $\equiv P=CHR$ group with temperature was observed also for compounds having the general formula (VI) with R = H, CN, $CO(CH_2)_2C_6H_5$, $COCH_3$, $COOCH_3$, or CHO,[154] it too was explained by rapid proton exchange



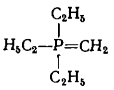
$H_3C-\underset{CH_3}{\overset{CH_3}{P}}=CH_2$
(I)



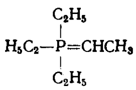
$H_3C-\underset{CH_3}{\overset{CH_3}{As}}=CH_2$
(II)



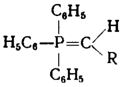
$H_3C-\underset{CH_3}{\overset{C_2H_5}{P}}=CH_2$
(III)



$H_5C_2-\underset{C_2H_5}{\overset{C_2H_5}{P}}=CH_2$
(IV)



$H_5C_2-\underset{C_2H_5}{\overset{C_2H_5}{P}}=CHCH_3$
(V)



(VI)

The mechanisms of the above processes were investigated in several studies[154–156], the authors concluded that the exchange takes place between phosphoranes and catalytic amounts of phosphonium salts present in the solutions and formed by the interaction of the phosphorane with proton-donating molecules:

$$\begin{aligned} &(a)\quad R_3\overset{+}{P}-\overset{-}{C}R_2 + HX \rightarrow [R_3\overset{+}{P}-CR_2H]X^-\ , \\ &(b)\quad R_3\overset{+}{P}-\overset{-}{C}R_2 + [R_3\overset{+}{P}-CR_2H]X^- \rightleftarrows [R_3\overset{+}{P}-CR_2H]X^- + R_3P^+-\overset{-}{C}R_2\ . \end{aligned} \qquad (41)$$

This mechanism explains the catalysis of the exchange by proton-donating compounds mentioned above. It is confirmed by the inhibition of the reaction by bases, which decompose the phosphonium salts.

The rapid exchange by mechanism (41) probably explains the broadening of the signal due to the methylidyne hydrogen in the PMR spectra of the sulphoranes (VII) and (VIII)[156]:

(VII)

(VIII)

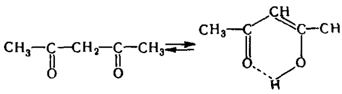
(IX)

$[(CH_3)_3\overset{+}{S}=O]X^-$.
(X)

Recently rapid exchange was observed in dimethyloxosulphonium methylide (IX).[157] It makes all the hydrogen atoms in this substance indistinguishable in solutions even at a temperature as low as −30°C. The exchange is probably catalysed by impurities. One cannot exclude the possibility that it proceeds by a mechanism analogous to mechanism (41) and is catalysed by compounds of type (X). This hypothesis is confirmed indirectly by data[158] for the rapid proton exchange of compounds of type (X) in aqueous alkaline solutions.

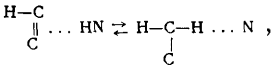
We may note that reactions of type (41b) constitute acid–base interactions. Their rate is high because the ylide structure of phosphorane and their analogues leads to high basicity of the methylene hydrogen and the positive charge at the phosphorus, arsenic, or sulphur atom increases the acidity at the hydrogen at the adjacent carbon atom.

An interesting case of proton exchange in CH groups associated with the tautomerism of acetylacetone has been investigated[159,160]. The PMR spectrum of pure acetylacetone shows individual signals corresponding to the enol and keto-forms; however, in the presence of diethylamine the equilibrium

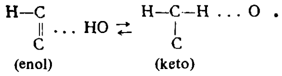


is displaced towards the formation of the enol and a common signal for the protons in OH, NH, and =CH– appears in the spectrum. To explain the involvement of the enolic methylidine hydrogen in the proton exchange, mechanisms were proposed with the intermediate participation of the keto-tautomer (only the atoms or groups between which protons migrate are indicated):

$$\text{O—H} \ldots \text{N} \rightleftarrows \text{O} \ldots \text{H—N}\ , \tag{42}$$



$$\underset{\text{C}}{\overset{\text{H—C}}{\|}} \ldots \text{HN} \rightleftarrows \text{H—}\underset{\overset{|}{\text{C}}}{\text{C}}\text{—H} \ldots \text{N}\ , \tag{43}$$



$$\underset{\substack{\text{C}\\ \text{(enol)}}}{\overset{\text{H—C}}{\|}} \ldots \text{HO} \rightleftarrows \underset{\substack{|\\ \text{C}\\ \text{(keto)}}}{\text{H—C—H}} \ldots \text{O}\ . \tag{44}$$

We may note that reaction (44) represents the usual keto-enol transformation.

Special experiments showed that the exchange in =CH– is much slower than in OH and NH. This is consistent with the finding that the hydrogen-bond bridges with participation of π-bond electrons are usually weaker than those formed with participation of unshared electron pairs.

VII. CERTAIN GENERAL PROBLEMS OF PROTON EXCHANGE

In this section we shall give a general account of the role of hydrogen bonds in the mechanism of proton exchange and of the nature of the reaction complexes by which the exchange takes place; we will also examine certain considerations concerning the acidity of compounds with SH and PH bonds, which we proposed when comparing the data for the rate and mechanism of proton exchange.

The entire information presented in the review and probably all other published data are consistent with the hypothesis that in rapid exchange reactions the protons always migrate along hydrogen bonds and the ease of such migration is greater the stronger the bonds. Some time ago this hypothesis enabled Brodskii[161] to give a general treatment of the vast experimental data for hydrogen isotope exchange, to devise a classification for such data which has since been generally adopted, and to explain why hydrogen bound to atoms with non-bonding electron pairs is involved in the exchange. Using this hypothesis, Miklukhin[162,163] predicted the variation of the rate of hydrogen isotope exchange (and proton exchange) with the strength of the hydrogen bonds in reaction complexes. These predictions were later confirmed experimentally (see Section V). The hypothesis explains the usually observed parallel variation of the rate of exchange and the acidity of the protons being exchanged by the fact that the acidity and the strength of the hydrogen bonds vary in the same sense in series of related compounds. It also explains the higher rates of exchange between ions of opposite sign, frequently noted above, compared with the exchange between an ion and a molecule, or between neutral molecules, since the hydrogen bonds between ions of different signs are stronger than in the other two cases. It can also explain the rapid exchange in C–H bonds (see Section VI). This exchange is observed only in the system comprising compounds with highly acid hydrogen atoms and a strong base (X) with unshared electron pairs or π electrons. Probably isotope exchange in such systems takes place via hydrogen bonds of the type C–H...X. We may recall finally that in certain cases (see Sections II and V) a linear relation was established between the activation energy for proton exchange and the strength of hydrogen bonds. Thus, there are good reasons for the belief that rapid proton exchange always takes place via hydrogen-bonded reaction complexes.

The nature of these complexes was investigated only in rare cases and as a rule remains unknown. Thus the cyclic structures for these complexes proposed in many investigations of uncatalysed exchange processes are usually unsupported by any evidence. The number of members of the ring (4, 6, 8 and above) is also chosen arbitrarily since in the majority of cases the number of molecules participating in the slow reaction step is unknown.

In the interpretation of the mechanisms of reactions of different types cyclic complexes are sometimes preferred to open-chain complexes because the former can ensure a higher rate of reaction (see, for example, Syrkin[15]). We may note, however, that, for the formation of hydrogen-bonded cyclic complexes in the rapid exchange processes in which we are interested, it is necessary that each molecule forming part of the complex should be capable of behaving simultaneously as a hydrogen donor and acceptor. This condition does not as a rule hold in catalysed exchange, since the acid catalyst blocks the free electron pairs and frequently leads to the loss of acceptor capacity by the molecule, while the base usually leads to the conversion of molecules into ions, which lack labile hydrogen. Thus many of the very rapid catalysed proton exchange reactions undoubtedly involve open-chain complexes. We suggest that one cannot exclude the possibility that many uncatalysed exchange reactions also proceed via open-chain complexes.

In Section V it was already stated that the low rate and the relatively high activation energy of proton exchange in the PH and SH groups compared with NH and OH can be accounted for by the low strength of the hydrogen bond formed by phosphorus and sulphur. Generalising the findings, one can postulate, following Miklukhin[163], that the exchange in AsH, SbH, SeH, and TeH should be even slower and the activation energy should be still higher.

We have also noted (see Section V) that the properties of the hydrogen bond formed by sulphur and phosphorus determine the mechanism of the exchange involving mercapto-compounds and phosphonium salts and that the proton-accepting functions of sulphur and phosphorus are probably even weaker (compared with oxygen and nitrogen) than their proton-donating functions. We suggest that these characteristics of the hydrogen bond are responsible also for the acid properties of mercapto-compounds and phosphonium salts. The greater weakness of hydrogen bonds formed by sulphur and phosphorus compared with oxygen and nitrogen usually results in the retardation of both the forward and reverse reactions in the acid–base equilibrium of the type

$$\text{X—H} \ldots \text{B} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \text{X}^- \ldots \text{HB}^+\ .$$

This is because, as already stated above, the proton-accepting functions of sulphur and phosphorus are very much weaker. As a result, the acid dissociation constants $K = k_1/k_{-1}$ prove to be higher than for the corresponding oxygen- and nitrogen-containing substances.

This treatment is probably of general validity. It explains, for example, the higher acidity of phosphines compared with amines and the increase of the acidity in the series

$$H_2O < H_2S < H_2Se < H_2Te \text{ and } HF < HCl < HBr < HI\ .$$

Evidently this approach to the problem of acidity is applicable only in those cases where the hydrogen in the X–H bonds has partial positive charge sufficient for the formation of the hydrogen bond X–H...B.

Application of Flash Photolysis in the Study of the Triplet State of Organic Substances

A.K.Chibisov

Flash photolysis is a relaxation method for the investigation of the mechanism of rapid photochemical reactions. The fundamental design and constructional features of spectroscopic apparatus for flash photolysis have been examined. Considerable attention has been devoted to the description of the sources for flash photolysis. The application of flash photolysis in the study of triplet states of organic substances in solutions is considered. The results obtained for the quantum yields and the triplet-triplet absorption spectra of aromatic hydrocarbons, carbonyl compounds, dyes, and pigments have been presented. The mechanisms and the kinetics of the deactivation of triplet states, the quenching mechanisms, and the role of the triplet state in photochemical reactions have been discussed.
The bibliography includes 197 references.

CONTENTS

1. INTRODUCTION

The study of excited electron states in chemical and biological processes constitutes an extremely urgent task. Primary photochemical reactions are known to take place with participation of both excited singlet and triplet states. Terenin[1] and Lewis and coworkers[2-4] put forward and justified experimentally the hypothesis that the transition from the excited singlet to the triplet state is due to the inversion of the spin of the optically excited electron. The longer lifetimes of triplet molecules (10^{-3}–10^{-4} s) compared with those in the excited singlet state (10^{-8}–10^{-9} s) in solutions are responsible for the dominant role of triplet states in the majority of photochemical reactions.

Until comparatively recently the sole source of direct information about triplet states of polyatomic molecules were data on the spectra and decay of phosphorescence[5]. Since most substances are not phosphorescent in liquid solutions, i.e. under conditions where diffusion processes take place, there was no information about triplet states of substances in solution. With the appearance of pulse excitation methods and in particular the method of flash photolysis† it became possible to follow directly processes involving the population and deactivation of the triplet states of substances in condensed and gaseous phases.

Recently many papers have been published on the triplet states of organic substances in solutions investigated under conditions of intense flash photolysis. Therefore it has become necessary to give a systematic account of the information and the properties of triplet states and their role in primary photochemical processes. The available reviews[6-8] by no means fully reflect the data on the physicochemical properties of the triplet states of organic substances. The present review deals exclusively with the results obtained in the study of the triplet states of organic substances by the method of flash photolysis. The aim of the review was also to illustrate the scope of the method of flash photolysis in the investigation of intermediate short-lived products of rapid reactions.

2. METHOD OF FLASH PHOTOLYSIS

Flash photolysis is one of the relaxation methods employing powerful brief light pulses which act on the given substance to give rise to a considerable non-equilibrium concentration of metastable states. The relaxation of the system to the initial or a new equilibrium state is "followed" from the absorption spectrum or some other characteristic recorded over a period of time after the pulse initiation.

Pulse illumination is achieved as a result of a pulse discharge, preferably in an inert gas (xenon, argon, and krypton)[9]. The source of the electrical energy of the flash ($E = CU^2/2$) is a battery of high-voltage condensers of capacity C (μF) charged to a potential U (kV). One or several gas-discharge flash tubes connected in series or in parallel serve as a source of the flash. The flash source connected by heavy leads to the battery of condensers constitutes the electrical circuit.

In the design of apparatus for flash photolysis much attention has been devoted to the electrical circuit and particularly to the flash source. The requirements which must be met by the source reduce to minimum duration and selectivity of the emission and also to maximum light yield. The electrical discharge in the circuit is oscillatory or shows simple decay depending on the relation between the resistance R, the inductance L, and the capacitance C of the circuit elements. When the relation $R = 2\sqrt{L/C}$ holds, the critical damping conditions are achieved, the duration of the emission τ is then a minimum which is most suitable for photoexcitation. A decrease of τ is obtained by lowering L and C ($\tau \propto \sqrt{LC}$). However, one must bear in mind that the compensation of the electrical energy of the flash on lowering C by increasing U is restricted by the load factor

---

† In the Russian literature this method is also referred to as pulse photolysis, pulse photoexcitation, and pulse spectroscopy.

($F \propto CU^4$), which determines the duration of the serviceability of the flash tubes. For electrical circuits with a low value of C (several microfarads), the duration of τ is determined largely by the self-inductances of the flash tubes. The inductance L of a circuit consisting of two series-connected elongated flash tubes (interelectrode distance 20 cm; 250 nH) connected to a condenser (5 μF; 6 nH) by a low-inductance circuit of the "sandwich" type (length 100 cm; 8 nH) is 264 nH.[10] The duration of the flash in this version $\tau = 2\pi\sqrt{LC}$ (according to the current) is 7.2 μs at $E = 1000$ J. The reduction of τ to 1.8 μs is achieved using a coaxial design for the flash tubes with $L = 6$ nH.[11]

Ultrashort (10^{-7}–10^{-12} s) light pulses are obtained by employing a self-contracting (the Z-pinch effect) pulse discharge ($\tau = 2 \times 10^{-7}$ s, $E = 4850$ J)[12] or lasers operating under giant pulse conditions[13–15].

In order to determine the time resolution of the spectrophotometric apparatus with flash photolysis, it is necessary to consider the flash duration τ_{light} in contrast to τ_{current}. Due to the afterglow recombination process $\tau_{\text{light}} \geq \tau_{\text{current}}$. For $\tau_{\text{current}} = 5$ μs, the duration of the recombination afterglow τ_{light} may reach 150 μs (for 0.1 of the peak light amplitude) depending on the type of gas employed, the pressure, and the wavelength of the emission. The duration of afterglow can be reduced by increasing the internal surface area of the flash tube[16], by decreasing the length of the mean free path of the excited molecules[17], and by introducing quenching gases (N_2 and O_2).[18,19]

In the practical application of flash photolysis, flash lamps filled with both inert and molecular gases (O_2, N_2, and H_2) and their mixtures have found the greatest use[18–20]. Depending on the type of gas and its pressure (5 mm–10 atm‡), the spectral distribution of the pulse emission changes appreciably[21–23]. The emission maximum shifts towards the ultraviolet part of the spectrum when the energy of the flash increases as a result of the increase in U.[24] The application of flash lamps filled with various gases in combination with narrow-band light filters interposed between the source of radiation and the test object ensures the selectivity of excitation.

The number of quanta n emitted by the flash lamp during the flash depends on E, the type of gas, and the wavelength of the emission. According to actinometric measurements, $n = 1 \times 10^{20}$ quanta per flash in the range 220–440 nm at $E = 3000$ J ($\tau_{0.1} = 9.5$ μs; tube filled with O_2 at 20 mmHg).[19] With such high light intensity, the molecules of the light-absorbing substance (10^{-5}–10^{-6} mole litre^{-1}) undergo repeated (10^2–10^3) excitation during a single light pulse. A high concentration of intermediate, for example triplet, photoexcitation products is thereby achieved. Thus 100% population of the phosphorescent triplet level (5×10^{-7} mole litre^{-1}) is attained when an aqueous solution (0.01 N NaOH) of the dye is irradiated by a flash with $E = 6000$ J [25] (the probability of the transition to the triplet state is about 0.05)[26]. The high concentration of the intermediates generated by the photon excitation permits the use of spectroscopic methods for their recording and identification.

For semiquantitative measurements of the intermediate products of a reaction initiated by a light pulse, a spectrographic method of recording, described in the first version of the flash photolysis apparatus[27], is employed. Fig. 1 shows schematically the positions of the principal constructional elements of the flash photolysis apparatus with spectrographic recording[10]. The flash initiating the photochemical reaction is produced by the discharge of a high-voltage condenser (*1*) via two cylindrical flash lamps connected in series (*4*). The lamps are connected to the condenser via low-inductance leads (*2*) of the "sandwich" type. The flash is initiated by an electric pulse applied to the trigger (*3*) (a thyratron, ignitron, etc.). The test object is put in a cuvette (*5*) and is initially excited by light from photolysis flash lamps (*4*). The absorption spectrum of the intermediate product is "instantaneously" (about 10^{-6} s) recorded with the aid of a low-power monitoring flash lamp (*6*) and a spectrograph (*7*). The absorption spectrum of the intermediates is photographed an arbitrarily fixed delay time $\Delta\tau$ after the initiation of the excitation.

A series of absorption spectra of the intermediates are obtained in repeated measurements with variable delay times $\Delta\tau$. The change in the blackening of the photographic plate, which serves as a receiver of the radiation of the monitoring source, is proportional to the change in the optical density of the solution of the test substance, provided that the degree of blackening and the exposure are linearly related. The use of the spectrographic method for the recording of intermediates is valid for substances whose absorption spectra show fine (for example vibrational–rotational) structure. In this case the application of photoelectric recording requires many repetitions of the irradiation of the substance by light pulses, which frequently leads to its decomposition. In this respect the spectrographic method of recording is convenient for the study of the mechanism of irreversible photochemical processes.

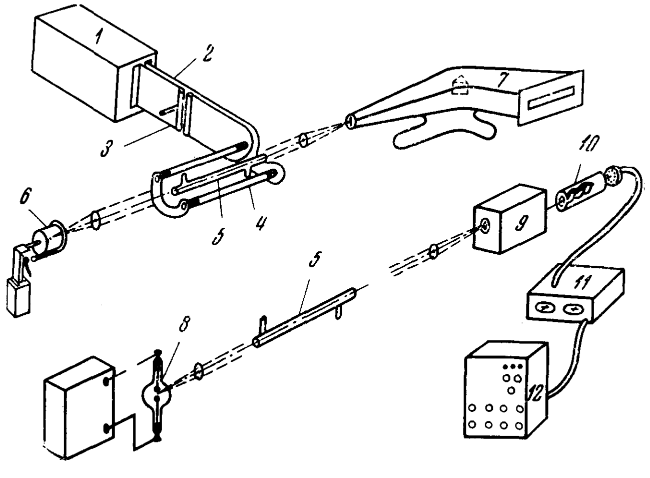

Figure 1. Diagram of flash photolysis apparatus[10] (for explanation, see text).

For accurate measurements of concentrations, the extinction coefficients of intermediates, and the kinetics of their reactions, the more sensitive photoelectric method of recording is employed. Photoelectric detectors cover a much wider range of wavelengths compared with the photographic plate, which in turn yields more information about short-lived products of photochemical reactions. Fig. 1 also shows schematically the positions of the principal elements of a flash photolysis apparatus with photoelectric

---

‡ For spherical flash lamps.

recording. In this version the monitoring flash lamp (*6*) is replaced by a source of continuous radiation (*8*)—an incandescent lamp or an ultrahigh pressure arc lamp filled with xenon or mercury. The spectrograph (*7*) is replaced by a monochromator (*9*) with a photomultiplier cell (*10*), a power source (*11*), and an oscilloscope (*12*). The spectral changes under the influence of the flashes from the photolysis lamp are recorded "point by point", the monochromator being set before each flash to a fixed wavelength in the relevant wavelength range.

The differential resolving power (on the basis of the change in the optical density ΔD) of the flash photolysis apparatus with photoelectric recording is determined by the level of fluctuation interference (noise) of the recording system. An increase of the signal-to-noise ratio is achieved by employing the maximum possible illumination of the photocathode of the photomultiplier by the continuous monitoring source, by using a low supply voltage for the photomultiplier, and with the aid of electric filters (*RC*) which limit the high frequency components of the transmitted signal[28-30]. CAT's combined with a source of pulse photoexcitation and operating under stroboscopic conditions have been employed recently to increase the signal-to-noise ratio[29,31]. When the illumination of the reaction system is repeated many times, the signal-to-noise ratio increases by a factor of $\sqrt{n}$, where n is the number of exciting light pulses.

As well as the above two methods for the recording of the absorption spectra of intermediates, fast scanning spectroscopy is employed[32-35]. In this method the absorption spectrum of the intermediates is scanned at a high speed with simultaneous oscilloscopic recording of the spectrum. In the single-beam high-speed spectrometer with a rotating system of three mirrors (optical accelerator) the range 400–1100 nm is scanned over a period of 4×10^{-5} s.[34]

The majority of the measurements of the absorption spectra of the intermediates have been made with flash energies in the range 100–1000 J. Approximate calculations show that an energy of 1000 J is sufficient for most photochemical studies[36]. As already mentioned, the time resolution of the flash photolysis apparatus is determined by the duration of emission from the photochemical flash source. The limiting rate constants for rapid reactions may be estimated from the resolution time of the apparatus and its sensitivity. For a first-order reaction, the maximum rate constant k_1 is estimated as $k_1 \simeq 10^5$ s^{-1} when the duration of the flash $\tau_{0.5}$ is several microseconds. For a second-order reaction, for example a reaction between radicals, $k_2 = \epsilon l \tau_{0.5}^{-1} \Delta D^{-1}$ is found from the relations $k_2 = \tau_{0.5}^{-1} C^{-1}$ and $\Delta D = \epsilon C l$, where ϵ is the extinction coefficient of the intermediate product (radical), C its concentration, and l the thickness of the absorbing layer (in the direction of the probing beam). For $l = 10$ cm, $\Delta D = 0.1$, and $\tau_{0.5} = 10^{-5}$ s, we have $k_2 = 10^7 \epsilon$. Consequently the maximum value is $k_2 = 10^{11}$ litre mole^{-1} s^{-1} when $\epsilon = 10^4$ litre mole^{-1} cm^{-1}.[36]

The reaction intermediates may be recorded in ways other than from absorption spectra. The charged species (ions) generated by the light pulse can be recorded from the change in electrical conductivity[37]; free radicals can be recorded using ESR spectra[38].

However, in the practical application of flash photolysis, the spectroscopic method for recording intermediate products, and in particular triplet states, has found the greatest use. In principle, this method can be used to solve two problems: the elucidation of the structure of intermediates from their absorption spectra, and of the mechanism and kinetics of the transformation of intermediates in rapid reactions.

3. QUANTUM YIELD OF THE TRIPLET STATE

Many molecules of aromatic hydrocarbons, carbonyl compounds, dyes, and pigments are effectively converted into the triplet state in liquid and solid solutions under the action of flash photolysis. The possibility of directly observing the population and deactivation processes of triplet states is determined, on the one hand, by the relatively long lifetime of triplet molecules and, on the other hand, especially by the capacity of triplet molecules to absorb from the triplet level (the triplet–triplet absorption spectrum). The last factor is a consequence of the transitions between states of the same multiplicity being allowed and constitutes the foundation of the spectroscopic recording of triplet molecules using pulse illumination.

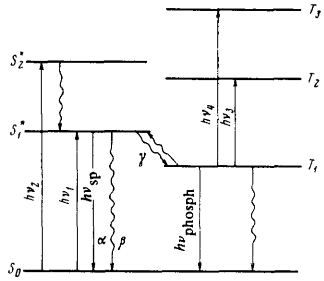

Figure 2. Schematic representation of the energy levels of the molecule: S_1^* and S_2^*—excited singlet levels; T_1, T_2, and T_3—excited triplet levels; for other explanations, see text.

The energy of the lowest excited singlet state is known to be degraded by several processes including fluorescence, non-radiative degradation, and transition to the triplet state[39-42]. Fig. 2 shows schematically the positions of the energy levels of the molecules, where α, β, and γ denote the probabilities of transitions giving rise to fluorescence (α), non-radiative degradation (internal conversion) (β), and transition to the triplet state (γ). There are simple relations between the probability of the γ transition, the quantum yield Φ_T in the formation of the triplet state, and the lifetime τ of the molecules in the S_1^* state: $\Phi_T = \gamma/(\alpha + \beta + \gamma)$ and $\Phi_T = \gamma\tau$. Using flash photolysis, it is possible to find Φ_T by the following two procedures. The first, the direct determination of $\Phi_T = C_\gamma / C_a = \Delta D / (\epsilon_T - \epsilon_S)\theta C_0 l$, is based on the direct determination of the concentrations of the triplet molecules C_γ and the molecules C_a excited by the light pulse[26,43-45]. ΔD is the change in optical density on formation of the triplet state, $\epsilon_T - \epsilon_S$ the difference between the extinction coefficients of the molecules in the triplet and singlet stage respectively, θ the fraction of light quanta absorbed by the molecules of the substance at an initial concentration C_0, and l the thickness of the absorbing layer. The expression for θ is $\theta = \int I_f(\nu) R(\nu) [1 - I_M(\nu)] d\nu / \int I_f(\nu) R(\nu) d\nu$, where I_f and I_M are the fractions of the light pulse transmitted by the light filter and the substance respectively and R is the relative light yield of the flash excitation source[26]. The accuracy of such determinations of Φ_T could be within 20–30%.[46]

The second method for the determination of Φ_T[47,48] is based on the perturbation by heavy atoms of the spin-orbital coupling in the molecule[49]. The effect of heavy or paramagnetic atoms in one molecule leads to an increase of the probability of the transition to the triplet state of another[50] and the quenching of the fluorescence[51]. Thus in the presence of heavy atoms the relative yield F/F^0 of fluorescence falls with a parallel increase of the yield D_T/D_T^0 of the triplet molecules of the substance. The quantitative relation between the two processes is expressed by $F^0/F = (D_T F^0/D_T^0 F - 1)(1 + k_1/k_2)\Phi_T + 1$, where k_1 and k_2 are the rate constants for the quenching process:

$$S_1^* + Q \rightarrow S_0 + Q \quad , \tag{1}$$

$$S_1^* + Q \rightarrow T_1 + Q \quad . \tag{2}$$

Bromobenzene[47], potassium and sodium iodide and bromide, p-iodophenol, bromocyclohexane, p-dibromobenzene[52], and also gaseous xenon[48], etc. are used as heavy-atom quenching agents Q. Table 1 presents a number of values of Φ_T determined by one of the two methods. It shows that the values of Φ_T for xanthene dyes (fluorescein, eosin, and erythrosine) increase sharply on introduction of a heavy atom (bromine and iodine) into the fluorescein molecule. This is due to the effect of the heavy atom bound chemically to the molecular skeleton on the probability of transition to the triplet state[55].

Table 1. The quantum yields Φ_T of the transition to the triplet state determined by the method of flash photolysis.

A knowledge of Φ_T and the fluorescence quantum yield Φ_{fl} permits the determination of $\Phi_{n.d}$ for non-radiative degradation of many of the compounds listed in Table 1. Thus for pyrene[48] and also anthracene and its derivatives[47,52], $\Phi_T + \Phi_{fl} = 1$, which indicates the absence of a non-radiative degradation process. A value of $\Phi_{n.d}$ close to zero was also observed for xanthene dyes[44], chlorophylls[44,45], and etioporphyrins[57]. An appreciable contribution (⩾ 50%) of non-radiative degradation to the deactivation of the excited singlet state was observed for mesoporphyrins[45] and 6-hydroxy-9-phenylfluorescein[3]. In the latter case $\Phi_{n.d} = 0.8$, while for fluorescein $\Phi_{n.d} \simeq 0.1$.[53] The difference between the values of $\Phi_{n.d}$ for the two compounds indicated above, which differ by the charge of the carboxy-group (in an alkaline solution), is due to the structure-forming effect of water molecules (solvent), which lowers the probability of the deformation of the molecular skeleton and hence of non-radiative degradation[41,53].

The values of Φ_T listed in Table 1 and determined indirectly, for example from the sensitisation of the *cis–trans* isomerism[56], are in good agreement with one another.

4. TRIPLET-TRIPLET ABSORPTION

In 1953 Porter and Windsor[58] observed the appearance in the spectrum of anthracene in hexane of a short-lived triplet absorption at 398 and 420 nm under the influence of pulse illumination. Subsequently the same workers[59] recorded the absorption spectra of the triplet molecules of 32 substances including aromatic hydrocarbons, ketones, and other compounds. The triplet–triplet absorption spectrum arises as a result of the absorption of light quanta by triplet molecules ($T_1 \xrightarrow{h\nu_3} T_2$; $T_1 \xrightarrow{h\nu_4} T_3$; etc., Fig.2). Fig. 3 shows the absorption spectra of the triplet states of condensed aromatic hydrocarbons ranging from benzene to pentacene. The triplet–triplet absorption of benzene was observed only in a solid matrix at 77°K[60], while the spectra of the triplet absorption of naphthalene, anthracene, naphthacene, and pentacene were measured at room temperature in liquid solution[59]. The wavelengths of the triplet absorption maxima of certain aromatic hydrocarbons (anthracene and its derivatives, naphthalene and its derivatives, naphthacene, pentacene, phenanthrene, chrysene, pyrene, rubrene, and others) have been given in a number of papers[59,61–65].

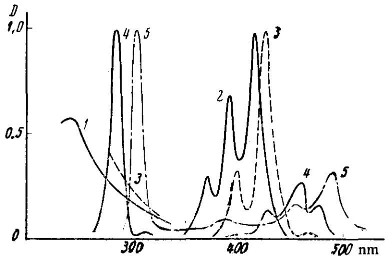

Figure 3. Triplet–triplet absorption spectra: *1*) benzene; *2*) naphthalene; *3*) anthracene; *4*) naphthacene; *5*) pentacene.

An important characteristic of absorption spectra is the oscillator strength f,[66] which is related to the experimental extinction coefficient ϵ: $f = 4.32 \times 10^{-9} \int \epsilon(\nu) d\nu$. The ϵ_T for a triplet–triplet absorption is determined in several ways. One of them is based on the fact that the transition of a molecule to the triplet state is accompanied by the depletion of the singlet S_0 level. This method of determination of ϵ_T is convenient for those substances whose singlet–singlet and triplet–triplet absorption spectra do not overlap.

The degree of attenuation (decolorisation) of the singlet absorption band under the influence of pulse illumination is a measure of the concentration of triplet molecules. In this case $\epsilon_T^{\lambda_2} = \epsilon_S^{\lambda_1}(\Delta D^{\lambda_2}/\Delta D^{\lambda_1})$, where λ_1 and λ_2 correspond to the maxima in the singlet and triplet absorption. In the case of overlapping singlet–singlet and triplet–triplet absorption spectra, ϵ_T is found from the variation of ΔD with flash energy E. The limiting value ΔD^0, which is independent of E, corresponds to 100% conversion into the triplet state[25,67]. ϵ_T can also be estimated from the kinetic data for the deactivation of the triplet molecule. In this case one finds experimentally the relative rate constant for triplet–triplet annihilation: $\varphi = k/\epsilon_T$.[34] The rate constant k is usually close to the diffusion constant $k_D = 8RT/3000\eta$, where η is the viscosity of the medium[68]. Consequently $\epsilon_T = 8RT/3000\eta\varphi$. The values of ϵ_T for certain aromatic hydrocarbons found by one of the above methods and also the values of the calculated oscillator strength f are listed in Table 2. The high extinction coefficient ϵ_T for the triplet–triplet absorption of aromatic hydrocarbons is evidence of a high probability of the transitions $T_1 \rightarrow T_2$, $T_1 \rightarrow T_3$, etc. According to the literature[59,71], T_1, T_2, T_3, T_4, and T_5 are identified with the states ${}^3B^+_{2u}$, ${}^3A^-_{1g}$ (lower), ${}^3B^-_{1g}$ (lower), ${}^3B^-_{1g}$ (upper), and ${}^3A^-_{1g}$ (upper) respectively. The positions of the excited triplet levels T_2, T_3, etc. are found from the positions of the lower triplet levels T_1 for polyacenes[2,50,72] and triplet–triplet absorption data[59]. The experimental values of T_2, T_3, T_4, and T_5 proved to be in good agreement with calculation[71].

* Measurements at 77°K.

** Measurements at 113°K.

The measurement of the triplet–triplet absorption spectra of aromatic compounds containing heteratoms, for example ketones, and also dyes and pigments, is in many cases more difficult than the measurement of the triplet spectra of aromatic hydrocarbons. In contrast to aromatic hydrocarbons, the flash photolysis of many hetero-compounds yields both triplet and intermediate products (radicals, ions, isomers, etc.) as a result of the photo-excitation of the molecules. In many cases the absorption spectra of the intermediates are very similar to the triplet absorption spectra; moreover, radicals may be formed as a result of the reaction of triplet molecules with those of the medium, which leads to a considerable shortening of the lifetimes of the triplet states. Therefore, in order to identify the triplet absorption spectra, certain auxiliary procedures (triplet–triplet transfer, the method of matrix isolation, phosphorescence, etc.) are employed.

The absorption spectrum of the intermediate in the flash photolysis of benzophenone in liquid paraffin, identified as of the triplet type, was first reported by Porter and Windsor[59]. However, subsequently on the basis of data for the triplet–triplet energy transfer in the system benzophenone–naphthalene, it was shown[73] that the spectrum of the intermediate product of benzophenone is due to a ketyl radical and not to the triplet state. Probably the most reliable observations of the triplet state of benzophenone are reported by Bell and Linschitz[74] and by Melhuish[75]. Using a flash source with a duration of several microseconds, they observed the appearance of a short-lived (10^{-5} s) absorption in the photoexcitation of benzophenone in benzene[74]. Comparative data for the spectra of the triplet state of benzophenone and its ketyl radical were obtained using a poly(methyl methacrylate) matrix[75]. The difficulty of recording the spectrum of the triplet absorption of benzophenone is caused, on the one hand, by the short lifetime of the triplet in solution (10^{-5}–10^{-7} s[76–79]) and, on the other hand, by the similarity of the spectra of the triplet state of benzophenone and the ketyl radical. The short lifetime of the triplet state of benzophenone is due to its high reactivity for abstraction of hydrogen atoms from the molecules of the medium[74], and also to the quenching of the benzophenone triplet state by the photochemical reduction products[80]. Qualitatively analogous results were obtained from benzaldehyde and acetophenone[81]. The triplet states of carbonyl derivatives of naphthalene (naphthaldehyde, acetonaphthone, and naphthyl phenyl ketone) are less reactive in solutions in respect of photochemical reduction. This is indicated indirectly by the low quantum yield of the conversion into pinacols observed on irradiation in isopropyl alcohol[82]. For example, 2-acetonaphthone is not photochemically reduced in secondary alcohols[83]. This made it possible to record the triplet absorption spectrum of 2-acetonaphthone in benzene with a maximum at 430 nm[84]. Measurements have also been made of the triplet absorption spectra of certain aromatic alcohols. The maximum in the triplet absorption of 1-naphthol in benzene was observed at 390 nm[84] and that of 2-naphthol in water at 432 nm[85] and in a gelatine film at 443 nm[86].

The lower triplet level of aromatic hetero-compounds may be n,π^*, or π,π^*, or CTS (the charge-transfer state) depending on the nature of the substituents in the aromatic ring (amino-, hydroxy-, methoxy-groups, etc.) and the medium (hydrocarbons or solvents tending to form hydrogen bonds). For p-aminobenzophenone, the lower triplet level in isopropyl alcohol is CTS (T_1) and in cyclohexane n,π^*[87] (see Section 7 of this review).

The triplet absorption spectra of dyes have been investigated in less detail compared with aromatic hydrocarbons and oxygen-containing compounds. As in the case of aromatic ketones, the triplet molecules of dyes are capable of reversible electron-transfer reactions in the absence of external electron donors or acceptors[25]. In many cases this leads to the masking of the triplet absorption spectra of dyes by those of radicals. Moreover, in view of the tendency of dye molecules towards the formation of dimers and more complicated association complexes, triplet absorption measurements must be made in dilute dye solutions (10^{-6}–10^{-7} M). In order to detect triplet molecules at a low concentration, highly sensitive flash photolysis apparatus is necessary.

The study of the triplet states of dyes using their absorption spectra is important in elucidating the mechanism of the sensitising action of dyes. Measurements have been made of the triplet absorption spectra of individual examples of xanthene[25,88–91], acridine[92], phenazine[93,94], thiazine[95–99], and polymethine[100] classes§. Fig. 4 presents the triplet absorption spectra of phenosafranine in aqueous solution at different pH; Table 3 lists the wavelengths λ_{max} of the maximum triplet–triplet absorption and the extinction coefficient ϵ_T for certain dyes. The dyes listed in Table 3 are characterised by an intense $S_0 \rightarrow S_1^*$ absorption band in the visible part of the spectrum. The transition to the triplet state is accompanied by a weakening of the $S_0 \rightarrow S_1^*$ band. Acridine Orange in triethylamine solution is an exception[92]. In the triplet state there are a number of transitions, $T_1 \rightarrow T_2$, $T_1 \rightarrow T_3$, etc., which appear experimentally as several triplet absorption bands usually located at the short-wavelength and long wavelength limits of the singlet absorption. A change in the pH of the medium leads to a displacement of the triplet absorption bands as a result of the shift of the acid–base equilibrium of the triplet molecule.

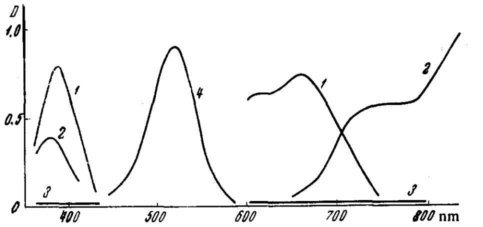

Figure 4. Triplet–triplet absorption spectra of phenosafranine in aqueous solution; *1*) pH 3–5; *2*) pH 5–7; *3*) pH 12; *4*) singlet–singlet absorption spectrum of phenosafranine at pH 7.[94]

The triplet absorption spectra of pigments of the type of chlorophyll and also porphyrins and phthalocyanines have been investigated in greater detail than those of dyes. This is due to the important role of chlorophyll as a sensitiser in the primary photosynthetic process. The triplet absorption spectra of chlorophylls a and b have been measured in a number of studies[67,101–110] on solutions of the pigment in various solvents (benzene, toluene, pyridine, ether, and others) with different flash energies (ranging from hundreds to several thousand joules) and in different excitation wavelengths ranges (blue and red). The principal findings in these investigations are that the triplet absorption spectrum of the pigments is independent of the exciting wavelength (blue or red), that the extinction coefficient is high ($\epsilon_T \simeq 10^4$ litre mole^{-1} cm^{-1}; π,π^* triplet absorption), and the triplet level of chlorophyll is readily populated (a high quantum yield Φ_T). The triplet absorption spectrum of chlorophyll is presented in Fig. 5; this shows that the most intense triplet absorption band of chlorophyll is located in the blue-green region; then in the region of the first transition $S_0 \rightarrow S_1^*$ (645 nm) the extinction coefficient $\epsilon_T^{645} \ll \epsilon_S^{645}$. This latter finding may be used to determine the "yield of triplet molecules per flash" and to find the values of ϵ_T. A triplet absorption with a maximum in the blue-green part of the spectrum is characteristic also of metal-free analogues of chlorophylls—phaeophytins a and b[67,102,104,108–110], chlorophyllin a[111], methyl chlorophyllide a[112], phaephorbide a + b[112], bacteriochlorophyll[107], and also certain porphyrins[102,104,107,113,114], and magnesium-phthalocyanine[104,113,115,116].

Table 3. The values of λ_{max} and ϵ_T for the triplet–triplet absorption of dyes.

Dye	Medium	λ_{max}, nm	ϵ_T, litre mole^{-1} cm^{-1}	Refs.

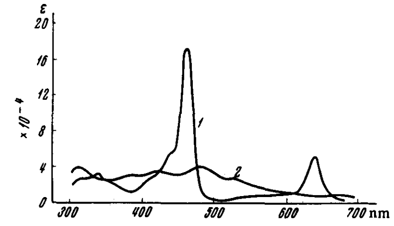

Figure 5. Triplet–triplet (curve *2*) and singlet–singlet (curve *1*) absorption spectra of chlorophyll b in benzene[106].

Study of the triplet–triplet absorption spectra of tetrapyrrole pigments made it possible to determine the effect of the structure of the molecule on triplet–triplet transitions. Even very considerable changes in the structure of pigments[46] have little effect on the nature of the triplet spectrum. The triplet absorption spectra of pigments are diffuse, differing significantly from the characteristic singlet–singlet absorption spectra. Moreover the triplet absorption spectra of chlorophylls are very similar to those of short-lived radicals—intermediate products of the photochemical oxidation-reduction reactions of chlorophylls[108,117] which makes it difficult to interpret the experimental results unambiguously using only spectroscopic data. In the latter case data for the kinetics of the deactivation of triplet states are valuable.

In many studies[108,118] the effect of "impurity" amounts of water on the spectroscopic properties of the triplet

---

§ Phthalocyanine dyes will be examined below together with pigments.

state of chlorophyll was investigated, and it was shown that the introduction of traces of moisture to a carefully dried solution of chlorophyll in toluene leads to an increase of the "yield of triplets per flash". The results did not confirm the hypothesis[119] that polar compounds affect the relative probabilities of fluorescence and the transition of chlorophyll to the triplet state. The familiar effect of the "activation" of the fluorescence of carefully dried solutions of chlorophyll in hydrocarbons (for example 3-methylpentane) in the presence of polar compounds[120,121] could not be explained by a decrease of the quantum yield Φ_T. The "activation" of the fluorescence of chlorophyll has been explained by the inversion of the positions of the n,π^* and π,π^* excited singlet levels[122,123]. To account for the results quoted by the present author[108] and Livingston[118], one must suppose firstly that the non-radiative degradation of energy in the n,π^* state is several times faster than the transition to the triplet state and secondly that the lifetime of the molecules in the π,π^* triplet state is much longer than in the n,π^* state. The latter assumption is probably unsound[40]. A more soundly based explanation of the observed effect has been put forward by Evstigneev et al.[124] and by Amster and Porter[125], who state that the absence of the fluorescence of chlorophyll in dried solutions is caused by the dimerisation of the pigment molecules. The introduction of moisture into the chlorophyll solution leads to the formation of monosolvates of the pigment as a result of the deaggregating effect of the water molecules and hence an increased concentration of "normal" (fluorescent) chlorophyll molecules.

In a number of studies measurements have been made of the triplet absorption spectra of retinene (the *trans*-form), which is one of the components of the visual pigments. A triplet–triplet absorption of retinene has been recorded in methanol[126,127], methylcyclohexane[128], toluene[129], and hexane[129] with a maximum at 440–450 nm. A triplet absorption was not observed for a solution of retinene in water containing 1% of digitonin or in 1 : 1 methanol–water mixtures. The quantum yield of the transition of retinene to the triplet state in methylcyclohexane decreased on addition of methanol to the solution, which is due to the formation of a complex between triplet retinene and methanol[128]. The triplet state of retinene is populated as a result of a transition from the n,π^* excited singlet level. The presence of water in the retinene solution leads to a change in the relative positions of the n,π^* and π,π^* excited singlet levels, accompanied by a decrease of the probability of the transition to the triplet state.

In connection with the postulated importance of the triplet state of chlorophyll in primary photosynthetic processes[130–132], repeated attempts have been made to detect the triplet–triplet absorption of chlorophyll *in vivo*[133,134]. Flash photolysis of photosynthetically active chloroplasts leads to eight types of spectral changes caused by electron and ion migration[135]. However, the triplet–triplet absorption spectrum of chlorophyll in photosynthesising organisms has not so far been observed. The likely explanation may be an effective transfer of energy from excited chlorophyll molecules to photochemically active centres[136]. The short-lived (about 10^{-5} s) absorption at 520 nm, observed on flash illumination of the cells of the alga *Chlorella*, was interpreted as due to the triplet state of carotenoids[137,138] as a result of energy transfer through triplet states with participation of chlorophyll. The triplet absorption spectrum of chlorophyll was observed only for chloroplasts[134] disrupted by surface-active substances (digitonin) and also for artificially isolated chlorophyll–protein complexes[139] and monomolecular layers of chlorophyll deposited on a glass support in the presence of aliphatic acid salts[140].

5. KINETICS OF THE DEACTIVATION OF TRIPLET STATES

The study of the mechanism and kinetics of the deactivation of triplet states is based on the direct measurement of the rate of decay of the triplet–triplet absorption bands. Numerous kinetic measurements of the decrease of the intensity of the triplet absorption of aromatic hydrocarbons, dyes, and pigments in a liquid solution have shown that the rate of deactivation of triplet molecules obeys the general equation

$$-\frac{dT}{dt} = k_1T + k_2T^2 + k_3TS \;, \qquad [1]$$

where

$$k_1 = k_0 + \sum_i k_{Q_i}Q_i \qquad [2]$$

in accordance with the following deactivation processes:

$$T \to S \;, \qquad (0) \quad (k_0)$$

$$T + T \to S^* + S \;, \qquad (2) \quad (k_2)$$

$$T + S \to S + S \;, \qquad (3) \quad (k_3)$$

$$T + Q_i \to S + Q_i \;, \qquad (i) \quad (k_{Q_i})$$

where k_0 is the rate constant for the unimolecular deactivation, k_2 the rate constant for triplet–triplet annihilation, k_3 the rate constant for the self-quenching process, and k_{Q_i} the rate constant for the quenching of the triplet state by extraneous (impurity) molecular quenching agents Q_i.

The unimolecular reaction [reaction (0)] includes the following deactivation processes: phosphorescence (k_{phosph}), non-radiative degradation ($k_{\text{n.r}}$), and delayed fluorescence ($k_{\text{r.fl}}$)[¶]. The first two processes are shown schematically in Fig. 2 by straight and wavy arrows between T_1 and S_0 and the third is represented by a wavy arrow directed from T_1 to S_1^* and is due to the thermal excitation of the triplet molecule with its transition to the S_1^* level. Thus the expression for k_0 is written in the form $k_0 = k_{\text{phosph}} + k_{\text{n.r}} + k_{\text{r.fl}}$. In liquid solutions at room temperature the majority of complex molecules do not phosphoresce. The effect of heavy atoms on the spin–orbit coupling has been used[62] to elucidate the relation between the radiative and non-radiative degradation of the energy of the triplet state. On the basis of the dependence of k_0 and k_{phosph} on the nature of the heavy atom in the anthracene and its derivatives (anthracene, 9,10-dichloroanthracene, and 9,10-dibromoanthracene), it was concluded that the non-radiative degradation process makes a considerable contribution to the kinetics of the unimolecular deactivation of the triplet state.

The quenching of the triplet state by impurity molecules competes with unimolecular non-radiative degradation (according to Eqn. [2]) and is responsible for the discrepancies in the experimental values of k_1 (see Table 4). The minimum value of k_1 listed in Table 4 is closest to k_0. The constant k_0 may be determined in several ways. One of these is based on the Arrhenius relation between k_1 and temperature:

$$k_1 + k_0 + A\,\exp(-\Delta E/RT)[Q].$$

[¶] This type of fluorescence is also called delayed fluorescence of the first kind[41].

As the temperature or the viscosity of the medium changes, k_1 is altered due to the largely variable contribution by k_{Q_i}. The rate of deactivation of the triplet state is measured at different temperatures[145,146,149–151] and k_0 is found from the temperature variation of k_1.[150] Another procedure is based on measurements in a solid matrix where there are virtually no diffusion-dependent quenching processes. Thus the values of k_0 for anthracene in a polystyrene film[86] and in a poly(methylmethacrylate) matrix[152] are respectively 38 s^{-1} and 54 s^{-1}.

Table 4. The rate constants k_1 for the deactivation of the triplet state of anthracene.

Solvent	k_1, s^{-1}	Refs.	Solvent	k_1, s^{-1}	Refs.
Acetone	14 000 ± 3000	59	Hexane	350	63
Hexane	13 000	142	Glycerol	180 ± 20	59
Hexane	11 900 ± 1500	141	Hexane	160	146
Cyclohexane	8000	62	Hexane	130	145
Bromobenzene	1600	143	Tetrahydrofuran	110	146
Ethylene glycol	1300 ± 200	59	Isopentane	69	147
Cyclohexane	500	144	Glycerol	58	61
Cyclohexane	440	62	Hexane	56 ± 76	148

Since oxygen is an extremely effective quenching agent for triplet states, the rate constants for the deactivation process must be measured in a carefully degassed solution. It has been shown[148] that k_1 for anthracene in tetrahydrofuran can be reduced to 40 s^{-1} on eliminating the oxygen remaining after degassing by allowing it to react with NaK. Small (trace) amounts of vacuum grease, which inevitably contaminate the solution during the degassing process, can also behave as quenching impurities. It has been shown[153] that the use of a vacuum grease at $p \geqslant 10^{-10}$ mmHg leads to the contamination of the solvent during degassing even under conditions excluding direct contact between the grease and the solvent. Traces of oxygen can be effectively removed from aqueous solution by "washing" the latter with an inert gas (argon)[25]. However, this method is ineffective for organic solvents[106].

In a number of studies[62,74,86] it has been shown that k_1 decreases with the number of flashes (from 8000 s^{-1} for anthracene in cyclohexane after the first flash to 440 s^{-1} after the fiftieth flash[62]) owing to irreversible reactions of the triplet molecules with the residual O_2. The procedure involving repeated preliminary flash illumination of the substance ("flash purification"[74]) can also be recommended for the determination of k_0 (provided that the substance is stable under repeated flash photolysis).

The constant k_0 is almost independent of the viscosity of the medium and temperature. Thus for anthracene the k_0 measured in hexane ($\eta = 0.320$ cP) and glycerol ($\eta =$ 1499 cP at 20°C) are 45 ± 25 s^{-1} and 30 ± 3 s^{-1} respectively[145]. A decrease of temperature leads to a slight decrease of k_0. The activation energy for the non-radiative degradation of triplet anthracene in a poly(methyl methacrylate) matrix is 60 cal $mole^{-1}$.[152] The constant k_0 depends significantly on molecular structure. For example, the experimental constants $k_0 + \sum_i k_{Q_i} Q_i$ for fluorescein are 220 s^{-1} (cation, 9 M H_2SO_4), 600 s^{-1} (neutral molecule, 0.1 N H_2SO_4), 600 s^{-1} (univalent anion, pH 5.5), and 50 s^{-1} (divalent anion, 0.01 M NaOH)[25,154]. The significant differences between the rate constants obtained for the neutral molecule and the divalent anion of fluorescein are not a result of the quenching effects of impurities[154].

The quenching of the triplet states by microimpurities and also triplet–triplet annihilation and self-quenching are bimolecular deactivation processes of triplet states. Triplet–triplet annihilation is due to the interaction of two triplet molecules with transition of one of them to an excited singlet state with subsequent fluorescence†. The value of k_2 is close to the diffusion constant and amounts to 10^9–10^{10} litre $mole^{-1}$ s^{-1} for non-viscous media. The activation energy for triplet–triplet annihilation, determined from the temperature variation of the rate of deactivation of the triplet state, agrees with ΔE_η.[149,150] The rate-limiting stage of the triplet–triplet annihilation is the diffusion of triplet molecules in the medium, and therefore the lifetime of triplet molecules in the gas phase is lower than in solution (when there is no quenching by impurities)[155]. For the triplet state of anthracene in the gas phase at 140°C, $k_2 = (1.4 \pm 0.4) \times 10^{11}$ litre $mole^{-1}$ s^{-1}. The constant k_2 is close to 3.8×10^{11} litre $mole^{-1}$ s^{-1} calculated on the basis of collision theory, whence it follows that triplet–triplet annihilation is extremely effective and occurs at every collision between triplet molecules[155]. The experimental observation of delayed fluorescence as a result of triplet–triplet annihilation has been reported by Parker[156] and Kikuchi et al.,[157] who employed flash photolysis.

The self-quenching process, i.e. the deactivation of triplet molecules as a result of their interaction with non-excited molecules of the same substance, has been observed only for dyes[25,158] and pigments of the type of chlorophyll[105,109]. For triplet molecules of aromatic hydrocarbons, we have $k_3 \ll k_1 + k_2T$, and for dyes and pigments, $k_3 \simeq 10^7$–10^8 litre $mole^{-1}$ s^{-1}. It follows from Eqn. [1] that the dominant processes in the kinetics of the deactivation of triplet states immediately after the flash are non-radiative degradation and triplet–triplet annihilation (under the conditions of 100% excitation to the triplet state). The self-quenching process is observed from the instant of the regeneration of non-excited molecules and makes an appreciable contribution to the deactivation kinetics only at high initial concentrations (10^{-4} M) of the substance.

6. MECHANISMS OF THE QUENCHING OF TRIPLET STATES

Depending on the form of the decay of the concentration of triplet molecules of a given substance, static and dynamic quenching of triplet states can be distinguished. Another classification is into "physical" and "chemical" quenching of triplet states depending on the products and on the nature of the quencher. In the static quenching of triplet states a decrease of the concentration of triplet molecules ("yield per flash") is not accompanied by a change in their lifetime. Static quenching is characterised by an equilibrium between molecules unperturbed by the quenching agent and those altered under its influence (a complex with a quenching agent in the ground or excited state, aggregate, etc.) and associated with a lower quantum yield for populating the triplet state. Thus when water is added to an alcoholic solution of chlorophyll, the observed fall of the yield of the triplet molecules of the pigment is caused by a decrease in the concentration of chlorophyll monosolvates as a result of the shift of the monomer–dimer equilibrium towards dimers.

---

† This type of delayed fluorescence is also called fluorescence of the second kind[41].

Dynamic quenching of the triplet state occurs in the collisions between triplet molecules and those of the quenching agent and is accompanied by a decrease of the lifetime of the triplets. Such quenching can yield the original molecules in the ground or excited state (physical quenching) or intermediate products, for example free radicals, ions, etc. (chemical quenching). Physical quenching processes include triplet–triplet and triplet–singlet energy transfer, paramagnetic quenching, quenching by heavy atoms, etc; among chemical quenching processes, one may include quenching by oxygen‡, by electron donors and acceptors, by transition metal ions, etc.

Table 5. Variation of the rate constants $k_{D,A}$ for the triplet–triplet energy transfer over a distance ΔE between a donor and an acceptor[162].

Donor	Acceptor	Solvent	$k_{D, A}$, litre $mole^{-1}$ s^{-1}	ΔE, cm^{-1}
Diacetyl	1,2-benzanthracene	benzene	$3.0 \cdot 10^9$	3200
Benzophenone	naphthalene	benzene	$2 \cdot 10^9$	3100
Triphenylene	naphthalene	hexane	$1.3 \cdot 10^9$	2200
Phenanthrene	1-iodonaphthalene	hexane	$7.0 \cdot 10^9$	1100
Phenanthrene	1-bromonaphthalene	hexane	$1.5 \cdot 10^8$	900
Phenanthrene	naphthalene	hexane	$2.9 \cdot 10^6$	300
Naphthalene	phenanthrene	hexane	$2 \cdot 10^4$	—300

Triplet–triplet transfer was first observed in sensitised phosphorescence at low temperatures[159,160]. In liquid solutions the quenching of the phosphorescence by energy transfer was observed for diacetyl[161]. Triplet–triplet transfer between an energy donor (D) and acceptor (A) (which do not phosphoresce in liquid solutions) is accompanied by the quenching of the triplet state of D and the appearance of the triplet absorption spectrum of A. Measurements with different triplet energy donors and acceptors, including aromatic hydrocarbons[162–165], carbonyl compounds[73,84,166], and pigments[167–170] established in the first place that the effectiveness of the energy transfer (the rate constant $k_{D,A}$ for the quenching of the triplet donor) depends on the distance ΔT between the triplet levels of the energy donor and acceptor and in the second place that a diffusion mechanism obtains in the triplet–triplet transfer in liquid solutions. Table 5 lists the values of ΔT and $k_{D,A}$ for various triplet energy donor–acceptor pairs. It follows from the data in Table 5 that the rate constant for the transfer is close to the diffusion constant (10^9–10^{10} litre $mole^{-1}$ s^{-1}) when $\Delta T \geqslant 1000$ cm^{-1}. The decrease of $k_{D,A}$ for smaller ΔT is probably due to the reverse energy transfer (from the acceptor triplet to the donor triplet)[171,172]. Using triplet–triplet transfer, the positions of the triplet levels in a number of non-phosphorescing compounds have been determined by flash photolysis. The positions of the triplet levels of *trans*-stilbene (17 500 cm^{-1}), *cis*-stilbene (20 200 cm^{-1})[164], phaeophytin a (> 11 300 cm^{-1})[169], thionine (13 640 cm^{-1})[173], and others have been estimated on the basis of the correlation between $k_{D,A}$ and ΔT for various acceptor (the position of the triplet level unknown)–donor (the position of the triplet level known) pairs. Triplet energy transfer combined with flash photolysis is used also to elucidate the role of excited singlet and triplet states in photochemical reactions. By comparing the yields of products of a reaction initiated in one case by direct and in another by sensitised (transfer via triplet states) excitation, the important role of the triplet state of anthracene in the reaction with carbon tetrachloride in bromobenzene was demonstrated[163]. Using triplet–triplet transfer, evidence was obtained proving the participation of triplet and ground singlet tetramethylbenzoquinone molecules in the formation of semiquinone radicals in alcohol[174,175]. The participation of the triplet states was also demonstrated in the photochemical reduction of 2-acetophenone by tributyltin[84], the photochemical reduction of benzophenone by isopropyl alcohol[73,166], the photochemical oxidation of chlorophyll a by *p*-benzoquinone[169,170], etc.

The heavy atom effect (the "external" and "internal" effects of the heavy atom) on spin–orbital coupling in molecules increases the probability of forbidden intercombination transitions and consequently leads to a shortening of the lifetime of triplet molecules. The internal effect of the heavy atom has been demonstrated[62] in the kinetics of the deactivation of the triplet states of anthracene and its dichloro- and dibromo-derivatives. On passing from anthracene to 9,10-dichloroanthracene and 9,10-dibromoanthracene, the deactivation rate constant k_0 increases from 110 s^{-1} to 23 000 s^{-1}. The external effect of the heavy atom is shown in the quenching of the triplet state of safranine T by potassium iodide (quenching constant 1.0×10^8 litre $mole^{-1}$ s^{-1})[93] and also of the triplet state of anthracene and its phenyl and methyl derivatives by bromobenzene[47]. The inhibiting effect of potassium iodide in the photochemical reduction of riboflavine has also been explained by the quenching of the triplet state of riboflavine by potassium iodide[176].

In a number of studies[105,142,177] it was observed that transition metal ions with paramagnetic properties are capable of quenching triplet states§. However, since Porter and Wright[142] did not find a correlation between the quenching rate constant and the magnetic susceptibility of transition metal ions, the shortening of the lifetime of triplet molecules in the presence of ions cannot be accounted for solely by "paramagnetic" quenching. On the basis of the effect of water on the rate constant for the quenching of the triplet states of anthracene and porphyrins (tetraphenylporphin and its zinc derivative) by Ni^{2+}, Co^{2+}, and Cu^{2+} ions[177] and also the effect of the ligand in the Ni^{2+}, Co^{2+}, and Cu^{2+} complexes of ethylenediamine, ethylenediaminetetra-acetate, pyridine, *o*-phenanthroline, and others[182,183], it was suggested that the quenching is due to the formation of a charge-transfer complex (CTC) between the excited molecule and the quenching agent. The excited complex $(S.MX_n)^*$ may be deactivated via the following pathway:

$$\begin{tikzcd}[column sep=small] T + MX_n \arrow[r] & (S \cdot MX_n)^* \arrow[r] \arrow[d] & S + MX_n^*, \\ & (S \cdot MX_n) \arrow[r] & S + MX_n. \end{tikzcd} \tag{4}(k_4)$$

Measurements of the rate of quenching of the triplet state by oxygen showed that the quenching rate constant is close to the diffusion constant. Probably diffusion is the rate-limiting step for the quenching of the triplet states by oxygen only in moderately viscous media. In very viscous media, for example solid matrices at 77°K, the presence of O_2 at a concentration of 10^{-4} M does not affect the rate

---

‡ Quenching by oxygen can also be classified as physical quenching owing to the paramagnetic properties of O_2.

§ Quenching by oxygen which is paramagnetic, has been demonstrated for aromic hydrocarbons[59,63,142,143], dyes[25,89,96,178–180], and pigments[181].

of deactivation of triplet states[152]. The current view on the mechanism of the deactivating effect of oxygen involves paramagnetic quenching[142] and energy transfer from the triplet molecule to O_2 [1] and also the formation of a moloxide—the labile product of the addition of O_2 to the excited molecule[41]. At the same time it has been shown[25,178] that the quenching of the triplet state of fluorescein by oxygen leads to one-electron oxidation of the dye:

$$T + O_2 \rightarrow \dot{R}^+ + O_2^{\dot{-}}, \qquad (5)(k_5)$$

which takes place simultaneously with physical quenching:

$$T + O_2 \rightarrow S + O_2 . \qquad (6)(k_6)$$

The rate constants k_5 and k_6 are respectively[25,178] $k_5 = 1 \times 10^7$ litre mole^{-1} s^{-1} (pH 2.0), $k_5 = 1.4 \times 10^8$ litre mole^{-1} s^{-1} (pH 12.0), $k_6 = 1.2 \times 10^9$ litre mole^{-1} s^{-1} (pH 2.0), and $k_6 = 1.7 \times 10^9$ litre mole^{-1} s^{-1} (pH 12.0). Physical quenching is independent of the acidity of the medium, while chemical quenching is negligible in an acid medium (triplet cation of fluorescein) and increases with the pH (neutral triplet molecules and triplet anions).

As shown above in the discussion of the kinetics of the deactivation of triplet states, the rate of depletion of the triplet level depends on the rate of bimolecular triplet–triplet annihilation and self-quenching processes. Formally, these processes can also be regarded as quenching of the triplet state as a result of the collision of the triplet molecule with another such molecule or a ground state molecule (k_2 or k_3). In many cases the quenching of a triplet molecule by another triplet molecule or a ground state molecule leads to the formation of radicals produced by electron transfer and therefore quenching may be classified as being of the chemical type:

$$T + T \rightarrow R^{\dot{-}} + \dot{R}^+, \qquad (7)(k_7)$$

$$T + S \rightarrow R^{\dot{-}} + \dot{R}^+. \qquad (8)(k_8)$$

Table 6. The rate constants for the quenching of the triplet state by electron donors and acceptors.

Object	Medium	Quenching agent.	$k_9 + k_{11}$ litre mole^{-1} s^{-1}	k_9, litre mole^{-1} s^{-1}	$k_{10} + k_{12}$, litre mole^{-1} s^{-1}	k_{10}, litre mole^{-1} s^{-1}
Fluorescein	H_2O[185]	ethylenediamine tetra-acetate	$1.5 \cdot 10^5$	—	—	—
Fluorescein	H_2O[185]	Fe^{III} ethylenediamine tetra-acetate	—	—	$8 \cdot 10^8$	$1 \cdot 10^8$
Fluorescein	H_2O[25]	*p*-phenylenediamine	—	$5 \cdot 10^9$	—	—
Eosin	H_2O[158]	$K_3Fe(CN)_6$	—	—	$2.5 \cdot 10^8$	$1.5 \cdot 10^8$
Eosin	H_2O[89]	phenol	$1.5 \cdot 10^5$	—	—	—
Chlorophyll a	pyridine[187]	ascorbic acid	$\approx 10^4$	—	—	—
Chlorophyll a	ethanol[188]	methylviologen	—	—	$2.0 \cdot 10^9$	—
Phaeophytin a	ethanol[189]	phenylhydrazine	$3.0 \cdot 10^7$	—	—	—
Phaeophytin a	ethanol[189]	Methyl Red	—	—	$1.7 \cdot 10^8$	—

Reactions (7) and (8) were observed in aqueous solutions of xanthene[25,88,158,185], thiazine[91,98,186], and phenazine[93] dyes. The constants k_7 and k_8 were determined from the rate of accumulation of the radicals $R^{\cdot}$ and R^+. For fluorescein (pH 12), in particular, $k_7 = 6 \times 10^8$ litre mole^{-1} s^{-1} and $k_8 = 5 \times 10^7$ litre mole^{-1} s^{-1}.[25] The results show that electron transfer is most probable between two triplet molecules.

The quenching of triplet state by electron donors or acceptors is a consequence of a photochemical oxidation–reduction reaction with participation of triplet molecules. However, the quenching of the triplet state of the reducing agent (DH_2) or the oxidising agent (A) does not always lead to the formation of radical-ions:

$$T + \mathrm{DH}_2 \rightarrow R^{\dot{-}} + \dot{\mathrm{D}}\mathrm{H}_3^+, \qquad (9)(k_9)$$

$$T + \mathrm{A} \rightarrow \dot{R}^+ + \mathrm{A}^{\dot{-}}. \qquad (10)(k_{10})$$

Chemical quenching of triplet molecules [reactions (9) and (10)] is accompanied by physical quenching, revealed experimentally by an inconsistency between the rate of quenching of the triplet state and the rate of accumulation of $R^{\cdot}$ and R^+:

$$T + \mathrm{DH}_2 \rightarrow S + \mathrm{DH}_2 , \qquad (11)(k_{11})$$

$$T + \mathrm{A} \rightarrow S + \mathrm{A} . \qquad (12)(k_{12})$$

Table 6 lists the rate constants for the quenching of the triplet molecules of dyes and pigments by various electron donors and acceptors. The mechanism of the quenching of triplet states by donors and acceptors is likely to include the formation of charge-transfer complexes as an intermediate stage in electron transfer. For instance, the probability of the conversion of charge-transfer complexes into radical-ions in the quenching of the triplet state of eosin by potassium hexacyanoferrate(III) is 0.6. [158]

7. PROPERTIES OF TRIPLET STATES AND THEIR ROLE IN PHOTOCHEMICAL REACTIONS

In contrast to the excited singlet state, a molecule in the triplet state is paramagnetic, which suggests that the triplet and phosphorescent states are identical[3,4]; this is supported by data on the kinetics of phosphorescence and photomagnetism[190]. Together with the optical properties of triplet molecules, the paramagnetic properties of triplet states are responsible for the ability of triplet molecules to absorb microwave radiation (ESR spectrum)[191].

Apart from the spectroscopic and kinetic properties and the characteristics of triplet states discussed above, triplet molecules exhibit a definite affinity for protons (the acid–base properties of triplets). The proton affinity of a molecule in an excited state may differ significantly from the affinity in the ground state. In a number of studies[192,193] this effect was investigated for aromatic acids and bases in terms of the changes in the absorption and fluorescence spectra with the acidity of the solvent. It was shown that aromatic acids dissociate in the excited singlet state over a period less than 10^{-9} s. The change in pK is then about 6. The measurements designed to determine pK_T for molecules in the triplet state by flash photolysis reveal a significant difference between pK_S (for the excited singlet state) and pK_T[85,194] together with a similarity between pK_g (for the ground singlet state) and pK_T. Similar values of pK_g and pK_T were obtained for a number of alcohols, acids, and amines[85,194]. However, for dyes of the thiazine (Methylene Blue, Methylene Green, Novomethylene Blue, Azur) and azine (safranine and phenosafranine) classes, pK_g differs from pK_T by more than 6 units[93,94,98,100,186]. Consequently the proton affinity of thiazine and azine dyes in the triplet state differs significantly from the affinity in the ground and excited singlet states.

The properties and reactivity of molecules in the triplet state depend in many respects on the distribution of electron density on excitation. For aromatic carbonyl compounds of the type  $X-C_6H_4-C(=O)-R$, the lower excited triplet state (T_1) may be n,π^*, or π,π^*, or the charge-transfer state (CTS)[87]. A characteristic feature of the n,π^* triplet state of carbonyl compounds is a high quantum yield γ of the reaction involving the abstraction of a hydrogen atom from alcohols, hydrocarbons, and related compounds ($\gamma = 1$), which ultimately yields pinacols and also the occurrence of addition to the double bond of olefins and other unsaturated compounds[195], Moreover, the n,π^* triplet level is characterised by a short-lived phosphorescence in the solid matrix at 77°K (10^{-3} s)[196], a small singlet–triplet splitting (< 3000 cm^{-1}), and a deficiency in electron density at the oxygen atom of the carbonyl group ($>C=\overset{+\delta}{O}$) [87]. The appreciably lower reactivity of the π,π^* triplet state is shown by a low quantum yield of the pinacol formation reaction ($\gamma = 0.1$). The π,π^* triplet level is then characterised by a greater singlet–triplet splitting (10 000 cm^{-1}) and also by the absence of an electron deficiency at the carbonyl group ($>C=O$) [87]. Thus the reactivity of molecules in the triplet state, and in particular of carbonyl compounds, depends on the distribution of electron density in the lower triplet state.

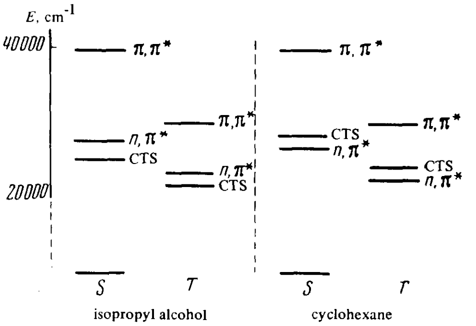

Figure 6. Schematic energy level diagram for p-aminobenzophenone in isopropyl alcohol and in cyclohexane[195].

The electron density distribution depends in turn on the nature of the substituents (X, R) and the effect of the solvent. For substituted benzophenones (R = C_6H_5 and X = a halogeno-, phenyl-, amino-, hydroxy-, and methoxy-groups in the *meta*- and *para*-positions), the quantum yield γ depends on the nature and positions of the X substituents and also on the polarity of the solvent. For benzophenone and also its *para*-substituted halogen derivatives, $\gamma \simeq 1$ (isopropyl alcohol, cyclohexane), which shows that the T_1 state is of the n,π^* type. *m*- and *p*-phenylbenzophenones have a low quantum yield of the pinacol-formation reaction ($\gamma = 0.1$) owing to the inversion of the positions of n,π^* and π,π^* triplet levels, the lower triplet level being π,π^*. The introduction of electron-donating (amino- and hydroxy-groups) substituents in the *para*-position of benzophenone leads to a variation of γ with the solvent. For amino- and hydroxy-derivatives of benzophenone, a long-wavelength absorption due to a charge-transfer state together with $n\rightarrow\pi^*$ and $\pi\rightarrow\pi^*$ transitions was observed[195]. For p-aminobenzophenone, with the CTS configuration,

$\gamma = 0.00$ in isopropyl alcohol but in a non-polar solvent (cyclohexane) $\gamma = 0.02$. Similarly, for p-hydroxybenzophenone an increase of γ from 0.02 (isopropyl alcohol) to 0.9 (cyclohexane) was observed. The increase in γ on passing from a polar to a non-polar solvent is due to the reversal of the CTS and n,π^* triplet levels (Fig. 6).

Using direct or sensitised (triplet–triplet energy transfer) flash photolysis, the involvement of triplet molecules of organic and biologically important substances in many photochemical reactions has been demonstrated experimentally. Much information on the chemistry of triplet states has also been obtained by non-pulse excitation methods[197]. There is no doubt that the triplet state participates in various photochemical reactions but one must bear in mind that the real pathway of a photochemical reaction is not determined solely by the reactivity of the excited state. A significant factor which determines the primary photochemical step is the excitation conditions (pulse or stationary conditions and the density and duration of emission), the effect of the environment [the presence of extraneous molecules (additives) and the nature of the solvent], etc. In a consideration of the real pathway of a photochemical reaction involving excited singlet or triplet molecules, one must bear in mind the probability of transition to the triplet state, the lifetime in the triplet level, and also the concentration of the reacting (excited) molecules.

---o0o---

The method of flash photolysis is undoubtedly one of the powerful modern procedures for the investigation of rapid reactions initiated by light. The applications of this method in the study of triplet states discussed above illustrate one of the possibilities of flash photolysis in the study of photochemical and photobiological processes. The present state of the experimental technique permits a considerable extension of the scope of the method in the investigation of the properties of the primary products formed under the action of radiation on matter (pulse radiolysis, lasers). This constitutes a stimulus for intensive research in the chemistry of excited states, short-lived products, and rapid processes.

Cationic Boron Complexes

O.P.Shitov, S.L.Ioffe, V.A.Tartakovskii, and S.S.Novikov

The review deals with studies on an interesting class of boron compounds constituting a very rapidly developing field at the boundary between inorganic and "organoelemental" chemistry.
The bibliography includes 189 references.

CONTENTS

I. INTRODUCTION

The chemistry of cationic boron complexes[†] began with the work of Diltey, who obtained in 1906 the first boronium cations by the interaction of β-diketones with boron trichloride[1].

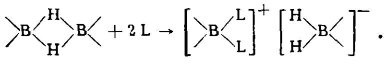
In the last decade, after the work of Parry and coworkers[2-9] who determined the structure of "diammoniate of diborane", this field in boron chemistry has developed extensively.

A number of fundamental monographs[10-21] dealing with various aspects of boron chemistry have now been published. In the first place mention must be made here of the books by Mikhailov[17], Zhigach[19], Steinberg[15], and Muetterties[18]. These monographs contain isolated data on the methods of synthesis and the properties of boronium salts but they do not provide complete information about these compounds. Moreover, in recent years many new results have accumulated, which have not been reviewed anywhere. This review gives a compilation of the literature on the cationic boron complexes up to the middle of 1969.

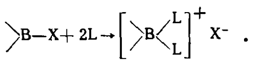
II. PREPARATION OF CATIONIC BORON COMPLEXES

The methods of preparation of numerous boron complexes with a wide variety of structures may be divided into four principal groups.

1. Asymmetric cleavage of boranes by Lewis bases:

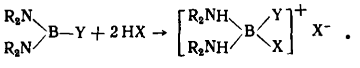


2. Conversion of substituted boranes under the action of amines:



[†] Boron complexes with boron as the central atom of the cation are called cationic boron complexes or boronium salts. In the present review both terms are used.

3. Addition of hydrogen halides to aminoboranes:



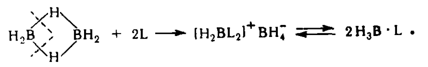
$$\begin{matrix}R_2N\\R_2N\end{matrix}\!>\!B-Y+2HX\rightarrow\left[\begin{matrix}R_2NH\\R_2NH\end{matrix}\!>\!B\!<\!\begin{matrix}Y\\X\end{matrix}\right]^+X^-\ .$$

4. Reaction of boranes with aminoboranes at elevated temperatures:

$$2L\cdot BH_3+B_2H_6\rightarrow[H_2BL_2]^+X^-\ .$$

1. ASYMMETRIC CLEAVAGE OF BORANES BY LEWIS BASES

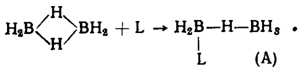
At the present time there exist two views on the mechanism of the formation of cationic boron complexes by the reaction of Lewis bases with diborane. According to Beachley[22], at a low temperature bases always cause an asymmetric cleavage of diborane and the cationic boron complexes can rearrange to the corresponding aminoboranes when the latter are thermodynamically more stable at a given temperature:



(1)

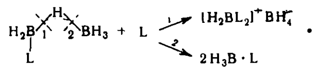
However, Shore and Parry[3] and also Inoue and Kodama[23] showed that in liquid amines and in ether there is no equilibrium between cationic boron complexes and the corresponding aminoboranes.

According to another view[5,24] the reaction of diborane with Lewis bases begins with the dissociation of one bridge bond and the formation of an intermediate product (A):



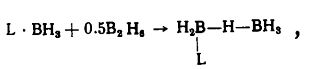
(2)

The nature of the final compound is determined by the mode of dissociation of the three-centre bond $H_2B-H-BH_3$ as a result of the attack by a second molecule of the base on product (A):



(3)

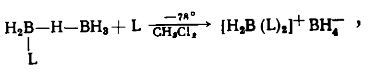
The mode of attack depends both on the structure of the reactants and on the reaction temperature. In many cases the reaction can proceed via both pathways simultaneously. This mechanism of the formation of boronium salts was confirmed by the preparation of compounds of type (A) in the tensimetric titration of aminoboranes by diborane at −78°C in methylene chloride[24,25]:



$$L\cdot BH_3+0.5B_2H_6\rightarrow \underset{\displaystyle L}{\underset{|}{H_2B}}-H-BH_3\ , \qquad (4)$$

where L = NH_3, CH_3NH_2, or $N(CH_3)_3$. The presence of H_2B and BH_3 groups in these compounds was established by ^{11}B NMR spectroscopy‡.

The addition of a second mole of the amine leads to compounds indicated below:



$$\underset{\displaystyle L}{\underset{|}{H_2B}}-H-BH_3+L\xrightarrow[CH_2Cl_2]{-78°}[H_2B(L)_2]^+BH_4^-\ , \qquad (5)$$

where L = NH_3 or CH_3NH_2;

$$\underset{\displaystyle N(CH_3)_3}{\underset{|}{H_2B}}-H-BH_3+N(CH_3)_3\xrightarrow[CH_2Cl_2]{-78°}H_3B\cdot N(CH_3)_3\ . \qquad (6)$$

Thus the same products were obtained in reactions (5) and (6) as in the reaction between diborane and an excess of the corresponding amine at a low temperature.

It is interesting to note the effect of the degree of methylation of amines on the proportions of the final products in the reaction with diborane. Whereas in the reaction with ammonia[28-32] the boronium salt is mainly formed§, in the reaction with trimethylamine the product was exclusively a neutral complex[39]. Methylamine and dimethylamine[22,23,39] form mixtures of both possible compounds, with the boronium salt predominating in the first case and the neutral complex in the second:

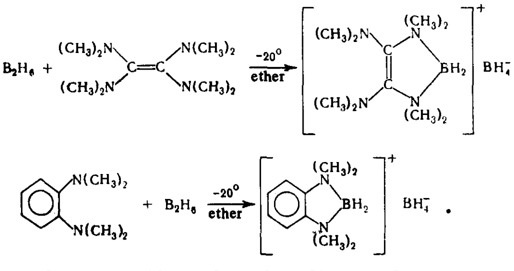
$$B_2H_6+2NH_3\rightarrow[H_2B(NH_3)_2]^+BH_4^-\ , \qquad (7)$$

$$B_2H_6+2(CH_3)_nNH_{3-n}\rightarrow\{H_2B[NH_{3-n}(CH_3)_n]_2\}^+BH_4^-+(CH_3)_nNH_{3-n}\cdot BH_3\ ,$$

$$(n=1-2)$$

$$B_2H_6+2N(CH_3)_3\rightarrow 2(CH_3)_3N\cdot BH_3\ .$$

Apparently the cleavage of the intermediate (A) is determined mainly by steric factors. This is confirmed by Wiberg's data[40] on the synthesis of boronium salts in the reaction of tertiary diamines with diborane:



(8)

The ease of preparation of such salts has been explained by the formation of a sterically favourable cyclic system[14].

Other Lewis bases can also react with diborane via mechanism (2)–(3) with formation of cationic boron complexes. In a tensimetric study of the reaction of diborane with dimethyl sulphoxide in methylene chloride at −78°C, McAchran and Shore[41] showed that in this case a boronium salt is formed:

$$B_2H_6+2(CH_3)_2SO\rightarrow\{H_2B[OS(CH_3)_2]_2\}^+BH_4^-\ . \qquad (9)$$

The formation of the hydrated ion BH_2^+ has been postulated in the reaction between diborane and 8 N hydrochloric acid at −70°C:[42,43]

$$B_2H_6+2H^++4H_2O\rightarrow 2[H_2B(H_2O)_2]^++2H_2\ . \qquad (10)$$

The cation may be formed as a result of the asymmetric cleavage of diborane by water¶:

$$B_2H_6+2H_2O\rightarrow[H_2B(H_2O)_2]^+BH_4^-\ . \qquad (11)$$

On the basis of the electrical conductivity of diborane solutions in tetrahydrofuran (THF) and diglyme, Brown and Wallace[44] and Mikhailov et al.[45] concluded that the corresponding cationic boron complexes exist in such

---

‡ Eastham[26] suggests that compounds (A) have the structure  i. e. the diborane molecule is linked to the ligand by a π-bond formed by a free orbital of diborane and the electron pair of the amine. However, this structure was rejected on the basis of tracer atom studies and the determination of the heats of reaction[27].

§ For the structure of "diammoniate of diborane" $[H_2B(NH_3)_2]^+BH_4^-$, see the appropriate literature[2-9,28,33-38].

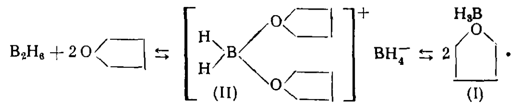
¶ However, one cannot exclude also other mechanisms of this reaction, for example:

$$B_2H_6+2H_2O\rightarrow 2H_3B\cdot H_2O\ ,$$

$$2H_3B\cdot H_2O+2HCl\rightarrow 2H_2BCl\cdot H_2O+2H_2\ ,$$

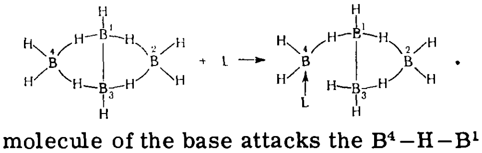
$$2H_2BCl\cdot H_2O+2H_2O\rightarrow 2[H_2B(H_2O)_2]^+Cl^-\ .$$

solutions. Mikhailov et al.[45] believe that in a tetrahydrofuran solution of diborane there is an equilibrium between the neutral complex (I) and the cationic boron complex (II):



(12)

Apart from diborane, higher boranes can also undergo asymmetric cleavage by Lewis bases. The mechanism of the reaction of tetraborane with Lewis bases is similar to that of the cleavage of diborane and consists in the dissociation of one of the bridge bonds in the first stage of the reaction[46]:



(13)

A second molecule of the base attacks the B^4-H-B^1 bond, which is ruptured with the formation of the cation $(H_2BL_2)^+$ and the anion $B_3H_8^-$ (asymmetric cleavage) or the complexes $H_3B.L$ and $B_3H_7.L$ (symmetrical cleavage).

Stock et al.[47], who investigated the reaction of tetraborane with ammonia, concluded that its products are unstable compounds with the compositions $B_4H_{10}.4NH_3$ and $B_4H_{10}.2.5NH_3$. However, Kodama and Parry[48,49] showed that the product of the reaction of an ethereal solution of tetraborane with ammonia at −78°C is diammineboronium octahydrotriborate:

$$B_4H_{10} + 2NH_3 \rightarrow \left[\begin{matrix}H\\H\end{matrix}{>}B{<}\begin{matrix}NH_3\\NH_3\end{matrix}\right]^+ B_3H_8^- . \quad (14)$$

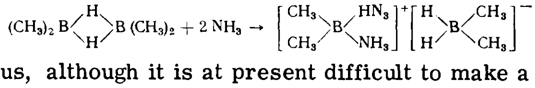
Schaeffer et al.[50] detected by ^{11}B NMR spectroscopy the anion $B_3H_8^-$ in solutions of tetraborane in tetrahydrofuran at −53°C, which is evidence of the formation of the boronium salt:

$$B_4H_{10} + 2C_4H_8O \rightarrow [H_2B(OC_4H_8)_2]^+ B_3H_8^- . \quad (15)$$

However, they did not detect the corresponding cation $[H_2B(OC_4H_8)_2]^+$.

These data are somewhat inconsistent with earlier studies, where it was found that the reactions of tetraborane with amines, ethers, or dialkyl sulphides lead exclusively to the formation of products of the symmetrical cleavage of tetraborane[51-53].

Moews and Parry[54] described the asymmetric cleavage of tetramethyldiborane by ammonia at −78°C†:

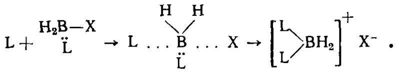


$$(CH_3)_2B{<}\begin{matrix}H\\H\end{matrix}{>}B(CH_3)_2 + 2NH_3 \rightarrow \left[\begin{matrix}CH_3\\CH_3\end{matrix}{>}B{<}\begin{matrix}HN_3\\NH_3\end{matrix}\right]^+ \left[\begin{matrix}H\\H\end{matrix}{>}B{<}\begin{matrix}CH_3\\CH_3\end{matrix}\right]^- . \quad (16)$$

Thus, although it is at present difficult to make a reliable *a priori* prediction of the structure of the final products of the reaction of boranes with Lewis bases, the published data makes it possible to follow fairly clearly the effect of the structure of the reactants on the process.

2. THE CONVERSION OF SUBSTITUTED BORANES UNDER THE ACTION OF AMINES

The reaction of substituted boranes with bases is the most widely used method for the synthesis of cationic boron complexes. In most cases the formation of such complexes by this method may be regarded as nucleophilic substitution by the base of an electronegative substituent X at the boron atom, probably via an S_N2 mechanism[56-58]:



$$L + \underset{L}{H_2B-X} \rightarrow L\ldots\overset{H\ H}{\underset{L}{B}}\ldots X \rightarrow \left[\begin{matrix}L\\L\end{matrix}{>}BH_2\right]^+ X^- . \quad (17)$$

In many cases in the presence of bulky substituents in the amine–borane molecule or when charged intermediate species may be stabilised, one cannot exclude also the possibility of a reaction by an S_N1 mechanism. This possibility was discussed by Ryschkewitsch and coworkers[59], who investigated the reaction of $(CH_3)_3N.BH_2I$ with methylpyridines and also by Nöth et al.[56] in the case of pyridine-chloroborane, for which there is a possibility of the formation of a cation stabilised by mesomerism. However, in a later study of Nainan and Ryschkewitsch[58] the ionisation of iodoboranes in non-polar solvents and the formation under these conditions of boronium salts by an S_N1 mechanism was fully excluded.

In the synthesis of boronium salts via mechanism (17) it is necessary to take into account a number of factors which influence the stability of boronium salts under the reaction conditions: (1) the dimensions and nature of the anion; (2) the steric and electronic effects of the substituents at the boron atom; (3) the structure of the bases.

An increase in the size of the anion leads to considerable stabilisation of the boronium salt. Thus, when trimethylamine-iodoborane was used instead of trimethylamine-chloroborane[56,58,60], it was possible to obtain boronium salts containing tertiary aliphatic amines in the cation:

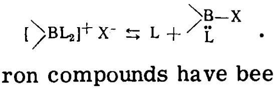
$$(CH_3)_3N \cdot BH_2I + L \rightarrow \left[\begin{matrix}(CH_3)_3N\\L\end{matrix}{>}BH_2\right]^+ I^- , \quad (18)$$

where L = $(CH_3)_3N$, $(C_2H_5)_3N$, or 4-methylpyridine.

The salts formed by the anions of weak acids (SR^-) are stable only in the presence in the cation of relatively small ligands[61]. An increase of the bulk of the substituents at the boron atom or the heteroatom of the base leads to a decrease of the stability of the boronium cation, the decomposition of which in the reaction may be represented by two mechanisms: (1) in the case of primary and secondary amines the final reaction products may be aminoboranes:

$$\left[{>}B{<}\begin{matrix}NHR_2\\NHR_2\end{matrix}\right]^+ X^- + HNR_2 \xrightarrow{-HNR_2\cdot HX} \left[{>}B{<}\begin{matrix}NR_2\\NHR_2\end{matrix}\right] \xrightarrow{-NHR_2} {>}B-NR_2 , \quad (19)$$

where R = H, alkyl, or aryl; (2) in the case of tertiary amines we believe that there is a possibility of the regeneration of the initial complex:



$$[{>}BL_2]^+ X^- \rightleftarrows L + \underset{L}{{>}B-X} . \quad (20)$$

A number of boron compounds have been used to synthesise cationic boron complexes by the substitution method: (a) complexes of halogenoboranes with Lewis bases; (b) amine-boranes; (c) mercaptoboranes and their amine complexes; (d) aryl-, alkyl-, amino-, and alkoxy-boron halides; (e) boron trihalides BX_3 (X = Cl, Br, I, or F).

a. Preparation of Boronium Salts from Complexes of Halogenoboranes with Lewis Bases

Nöth and coworkers[56,62-64] observed in a study of the reaction of ether and amine complexes of chloroboranes

---

† This reaction was investigated for the first time by Schlesinger et al.[55], but they did not establish the composition and the structure of the reaction product.

with amines that the latter takes place with formation of boronium salts‡:

$$H_2BCl\cdot OR_2+2\,L\rightarrow\left[H_2B\begin{smallmatrix}\diagup L\\ \diagdown L\end{smallmatrix}\right]^+Cl^-+R_2O;\ H_2BCl\cdot L+L'\rightarrow\left[H_2B\begin{smallmatrix}\diagup L'\\ \diagdown L\end{smallmatrix}\right]^+Cl^-,\qquad(21)$$

where L and L′ = NH_nR_{3-n} (n = 1–2) or C_5H_5N.

Ryschkewitsch and coworkers[58–60,66] obtained boronium salts containing various tertiary amines in the cation:

$$L\cdot BH_2I+L'\rightarrow\left[H_2B\begin{smallmatrix}\diagup L\\ \diagdown L'\end{smallmatrix}\right]^+I^-\ ,\qquad(22)$$

where L = R_3N (R = CH_3 or C_2H_5) or pyridine and L′ = substituted pyridines, quinoline, or *NN*-dimethylaniline.

Douglass et al.[67] isolated boronium salts with alkyl substituents at the boron atom:

$$R'R''B\cdot I\cdot NC_5H_5+C_5H_5N\rightarrow[R'R''B\,(NC_5H_5)_2]^+I^-\ ,\qquad(23)$$

where R′ = 1,1,2-trimethylpropyl and R″ = H or R′ = R″ = cyclohexyl.

It has also been observed that the bis(pyridine)boronium cation is formed when pyridine-iodoborane is refluxed in an ether–benzene solution at 40°C.[68] The authors quote the following reaction mechanism:

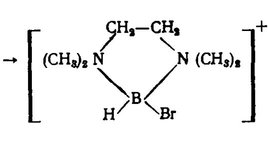
$$\begin{gathered}C_6H_5N\cdot BH_2I+(C_2H_5)_2\,O\rightarrow[C_5H_5NBH_2O\,(C_2H_5)_2]^+\,I^-,\\ [C_5H_5NBH_2O\,(C_2H_5)_2]^++I^-\rightarrow C_5H_5N\cdot BH_2OC_2H_5+C_2H_5I\ ,\\ C_5H_5N\cdot BH_2OC_2H_5\leftrightarrows C_5H_5N+H_2BOC_2H_5\ ,\\ C_5H_5N\cdot BH_2I+C_5H_5N\rightarrow[(C_5H_5N)_2\,BH_2]^+\,I^-\ .\end{gathered}\qquad(24)$$

The preparation of cationic boron complexes containing in the cation alkylthio-groups linked directly to the boron atom has been described[69]:

$$\begin{gathered}(CH_3)_3\,N\cdot BH_2SCH_3+BH_2I\cdot N\,(CH_3)_3\rightarrow\left[(CH_3)_3\,NBH_2\overset{CH_3}{\overset{|}{S}}BH_2N\,(CH_3)_3\right]^+I^-,\\ (CH_3)_3\,NBH_2SCH_3+(CH_3)_3\,N\cdot BH_2\overset{CH_3}{\overset{|}{S}}BH_2I\rightarrow\left\{\left[(CH_3)_3\,NBH_2\overset{CH_3}{\overset{|}{S}}\right]_2BH_2\right\}^+I^-,\end{gathered}\qquad(25)$$

and also the synthesis of boronium salts with polyfunctional bases[70,71], tertiary amines, phosphines, arsines, sulphides[72], and their oxides[73].

A monobrominated boronium cation was obtained by the reaction of trimethylamine-dibromoborane with *NNN′N′*-tetramethylethylenediamine[72]:



$$(CH_3)_3\,N\cdot BHBr_2+(CH_3)_2\,NCH_2CH_2N\,(CH_3)_2\rightarrow\left[(CH_3)_2\overset{CH_2-CH_2}{N\quad\ \ N}(CH_3)_2\ \text{(ring via }\underset{H\ \ Br}{B}\text{)}\right]^+Br^-.\qquad(26)$$

b. Preparation of Boronium Salts from Amine-boranes

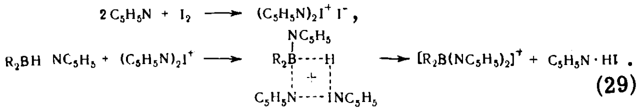
Douglass[74,75], who investigated the reaction of amine complexes of borane or its derivatives with iodine in an excess of the amine isolated cationic boron complexes:

$$RBH_2\cdot L+I_2+2\,L\rightarrow[RBHL_2]^+\,I^-+L+HI\cdot L\ ,\qquad(27)$$

where (a) R = phenyl or cyclohexyl and L = C_5H_5N and (b) R = H and L = $(CH_3)_3N$ or C_9H_7N. Initially a two-stage reaction mechanism was proposed: in the first stage an amine complex of iodoborane is formed and is then converted further into a boronium salt under the influence of the excess amine:

$$\begin{gathered}RBH_2\cdot L+I_2+L\rightarrow RBHI\cdot L+HX\cdot L\ ,\\ RBHI\cdot L+L\rightarrow[RBHL_2]^+\,I^-\ .\end{gathered}\qquad(28)$$

However, further study of the reaction[67] showed that amine-boranes containing bulky substituents at the boron atom do not react with iodine in the excess amine. Therefore Douglass suggested another mechanism with a four-membered transition complex:



$$\begin{gathered}2\,C_5H_5N+I_2\longrightarrow(C_5H_5N)_2I^+\,I^-,\\ R_2BH\ \ NC_5H_5+(C_5H_5N)_2I^+\longrightarrow\left[\begin{matrix}&NC_5H_5&\\ &R_2B\cdots H&\\ &C_5H_5N\cdots INC_5H_5&\end{matrix}\right]^+\longrightarrow[R_2B(NC_5H_5)_2]^++C_5H_5N\cdot HI\ .\end{gathered}\qquad(29)$$

This mechanism agrees better with the experimental data, since it is known that cyclic transition states are very sensitive to steric factors.

Ryschkewitsch[76] obtained dipyridineboronium salts by the reaction of sodium borohydride or trimethylamine-borane with iodine in the presence of an excess of pyridine. The author believes that the formation of the dipyridineboronium cation from sodium borohydride may be represented by the following sequence of reactions:

$$\begin{gathered}BH_4^-+I_2+2\,C_5H_5N\rightarrow C_5H_5N\cdot BH_3+C_5H_5NH^++2\,I^-,\\ BH_4^-+C_5H_5NH^+\rightarrow C_5H_5N\cdot BH_3+H_2\ ,\\ C_5H_5N\cdot BH_3+I_2+C_5H_5N\rightarrow(C_5H_5N)_2\,BH_2^++C_5H_5NH^++2\,I^-\ .\end{gathered}\qquad(30)$$

The author concludes from the measurements of the rates of reaction of deuterated and normal trimethylamine-borane with iodine that the rate-determining stage of the reaction [Eqn. (31)] is hydride transfer from trimethylamine-borane to iodine:

$$H_3B\cdot N\,(CH_3)_3+I_2+2\,C_5H_5N\rightarrow[H_2B\,(NC_5H_5)_2]^+\,I^-+(CH_3)_3\,N\cdot HI\ .\qquad(31)$$

A similar boronium cation is formed when trimethylamine-borane is refluxed with mercury(I) chloride in pyridine[76].

Borane complexes with phosphorus and arsenic derivatives can also be introduced into the Douglass reaction[70]:

$$(CH_3)_3\,SiCHL\cdot BH_3+I_2+N\,(CH_3)_3\rightarrow\{(CH_3)_3\,N\cdot BH_2CH\,[Si\,(CH_3)_3]\,L\}^+\,I^-,\qquad(32)$$

where L = $P(CH_3)_3$ or $As(CH_3)_3$.

$$(C_6H_5)_3\,PCH_2BH_3+I_2+N\,(CH_3)_3\rightarrow[(CH_3)_3\,NBH_2CH_2P\,(C_6H_5)_3]^+\,I^-.$$

c. Preparation of Boronium Salts from Mercaptoboranes

Mikhailov and coworkers[61,77] showed that in the reaction of trimers of alkylthioboranes with primary amines bis-(alkylamine)boronium mercaptides are formed regardless of the proportions of the reactants:

$$(RSBH_2)_3+6\,RNH_2\rightarrow3\,[H_2B\,(NH_2R)_2]^+\,SR^-\ ,\qquad(33)$$

where R = CH_3, C_2H_5, or n-C_4H_9. When the reaction is carried out with higher amines in the presence of benzyl chloride, bis(alkylamine)boronium chlorides are formed:

$$(RSBH_2)_3+R'NH_2+3\,C_6H_5CH_2Cl\rightarrow3\,[H_2B\,(NH_2R')_2]^+\,Cl^-+C_6H_5CH_2SR\ ,\qquad(34)$$

where R = CH_3, C_2H_5, or n-C_4H_9 and R′ = iso-C_3H_7, n-C_3H_7, iso-C_4H_9, n-C_4H_9, t-C_4H_9, n-C_5H_{11}, n-C_6H_{13}, or $C_6H_5CH_2$.

---

‡ Nöth and coworkers[56] initially isolated the boronium salts as side products in the reduction of benzoyl chloride by the complexes $H_3B.NH_2R$ (R = CH_3, n-C_3H_7, or t-C_4H_9). The formation of these salts may be represented by the following equations[17]:

$$\begin{gathered}C_6H_5COCl+H_3B\cdot NH_2R\rightarrow H_2BCl\cdot NH_2R+C_6H_5CHO\ ,\\ C_6H_5CHO+H_3B\cdot NH_2R\rightarrow C_6H_5CH_2OBH_2+RNH_2\ ,\\ H_2BCl\cdot H_2NR+RNH_2\rightarrow[H_2B\,(NH_2R)_2]^+\,Cl^-\ .\end{gathered}$$

The authors proposed two schemes for the formation of bis(alkylamine)boronium chlorides without giving preference to either. The first is a modification of Nöth's method, based on the use of a halogenoborane as the initial component:

$$\begin{gathered} {}^1/_3\,(RSBH_2)_3 + 3\,R'NH_2 \rightarrow RSBH_2\cdot NH_2R', \\ RSBH_2\cdot NH_2R' + C_6H_5CH_2Cl \rightarrow ClBH_2\cdot NH_2R' + C_6H_5CH_2SR, \\ H_2BCl\cdot NH_2R + RSBH_2\cdot NH_2R' \rightarrow [H_2B(NH_2R')_2]^+Cl^- + {}^1/_3\,(RSBH_2)_3. \end{gathered} \tag{35}$$

The second scheme presupposes the partial conversion in ether of alkylamine-alkylthioborane into bis(alkylamine)-boronium mercaptide, which then reacts further with benzyl chloride:

$$\begin{gathered} 2\,R'NH_2\cdot BH_2SR \leftrightarrows [H_2B(NH_2R')_2]^+SR' + RSBH_2, \\ [H_2B(NH_2R')_2]^+SR^- + C_6H_5CH_2Cl \rightarrow [H_2B(NH_2R')_2]^+Cl^- + C_6H_5CH_2SR. \end{gathered} \tag{36}$$

We believe that the second scheme [Eqn. (36)] is less likely, because, as stated above[5,23], complexes of amine-boranes and their boronium salts are probably not interconverted in ether.

Cationic boron complexes are also formed when hydrogen chloride and halogeno-derivatives of hydrocarbons react with dimethylamine-alkylthioborane complexes[78,79]:

$$2\,RSBH_2\cdot NH(CH_3)_2 + R'X \rightarrow \{H_2B[NH(CH_3)_2]_2\}^+X^- + RSR' + {}^1/_3\,(RSBH_2)_3, \tag{37}$$

where R = CH_3 or C_2H_5, H′ = CCl_3, $CHBr_2$, C_2H_5, $C_6H_5CH_2$, or H, and X = Cl or Br. Similar reactions take place with pyridine-alkylthioboranes under the action of carbon tetrachloride:

$$2\,RSBH_2\cdot NC_5H_5 + CCl_4 \rightarrow [H_2B(NC_5H_5)_2]^+Cl^- + {}^1/_3\,(RSBH_2)_3 + RSCCl_3. \tag{38}$$

Only the amine complexes of halogenoboranes and dialkyl sulphides were isolated in the reactions of trialkylamine-alkylthioboranes with halogeno-derivatives of hydrocarbons[79]:

$$RSBH_2\cdot NR''_3 + R'X \rightarrow R''_3N\cdot BH_2X + RSR'. \tag{39}$$

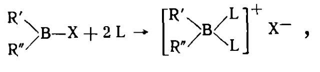
However, later a boronium salt was also obtained[80]:

$$(CH_3)_3N\cdot BH_2SCH_3 + CH_3I \rightarrow [(CH_3)_3NBH_2S(CH_3)_2]^+I^-. \tag{40}$$

Evidently, the formation of boronium salts in all the examples quoted takes place via mechanism (35).

d. Preparation of Boronium Salts from Alkyl-, Aryl-, Amino-, and Alkoxy-boron Halides

Many cationic boron complexes were synthesised by Mikhailov and coworkers[78,81-86] in a study of the reaction of diaryl- and dialkyl-boron halides with amines:



$$R'R''B{-}X + 2\,L \rightarrow [R'R''BL_2]^+X^-, \tag{41}$$

where R′ and R″ = alkyl or aryl, X = Cl, or Br, and L = amine.

Similar boronium salts were also obtained by Nöth[63,87,88] and other investigators[89,90] by mixing the reactants in an inert solvent (ether, benzene, pentane) at room or a lower temperature.

It is noteworthy that one can undoubtedly include among the boronium salts also the ternary complexes of dibutylboron chloride and bromide with pyridine, $(C_4H_9)_2BX.2C_5H_5N$ (X = Cl or Br), [91] and a group of complexes of alkoxyarylboron chlorides[92-94], alkoxyboron dichlorides[95-97], and dialkoxyboron dichlorides[98] with two moles of pyridine, the preparation of which was reported by Gerrard, Lappert, and coworkers.

Diphenyl-(αα′-dipyridyl)boronium chloride was obtained in 50% yield by refluxing diphenylboronic acid or its 2-aminoethyl ester with αα′-dipyridyl in 5 *N* solution of hydrochloric acid for 2–3 h: [89]

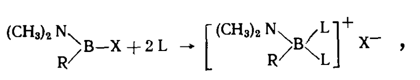
$$(C_6H_5)_2BOR + (NC_5H_4)_2 + HCl \rightarrow [(C_6H_5)_2B(NC_5H_4)_2]^+Cl^-, \tag{42}$$

where R = H or $OCH_2CH_2NH_2$.

A unique case of the synthesis of a cationic boron complex from borate has been described[98]:

$$(C_6H_5O)_3B + NH_3 \rightarrow [(C_6H_5O)_2B(NH_3)_2]^+OC_6H_5^-. \tag{43}$$

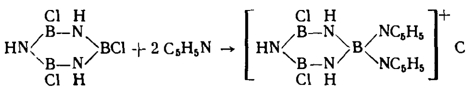
It proved possible also to obtain boronium salts by the reaction of aminoboron halides with amines[89,99]:



$$(CH_3)_2N(R)B{-}X + 2\,L \rightarrow [(CH_3)_2N(R)BL_2]^+X^-, \tag{44}$$

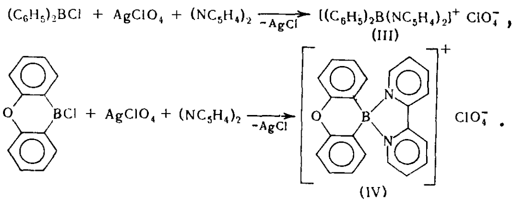
where R = $(CH_3)_2N$ or Cl, X = Cl, and L = pyridine, 4-$CH_3C_5H_4N$, or αα′-dipyridyl.

An unusual boronium salt is formed in the reaction of *B*-trichloroborazine with pyridine[99]:



(45)

The boronium salts (III) and (IV) were synthesised by Davidson and French by the reaction of a stoichiometric amount of αα′-dipyridyl with an equimolar mixture of diphenylboron chloride or 10-chloro-9-hydroxy-10-bora-anthracene with silver perchlorate in nitromethane[100,101]:



$$(C_6H_5)_2BCl + AgClO_4 + (NC_5H_4)_2 \xrightarrow[-AgCl]{} [(C_6H_5)_2B(NC_5H_4)_2]^+ClO_4^-,$$

(III)

(IV)

(46)

They showed[100,101] that, depending on the amount of αα′-dipyridyl taken, diphenylboron chloride forms 1 : 1 and 2 : 1 complexes, to which ionic structures are attributed:

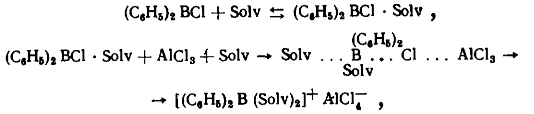
$$[(C_6H_5)_2B(NC_5H_4)_2]^+Cl^- \quad [(C_6H_5)_2B(NC_5H_4)_2]^+[Cl_2B(C_6H_5)_2]^-.$$

On the basis of the conductivities of $(C_6H_5)_2BCl$, $AlCl_3$, and $(C_6H_5)_2Br-AlCl_3$ solutions in nitrobenzene and also the ultraviolet spectra of these systems in ethyl methyl ketone, Davidson and French[102] believe that the boronium cation $(C_6H_5)_2B^+$, isoelectronic with the diphenylmethylcarbonium cation $(C_6H_5)_2CH^+$, is formed from $(C_6H_5)_2BCl$ in ionising solvents in the presence of ionic additives.

However, Moodie and coworkers[103], having analysed the ^1H NMR spectra of the products of the reaction of diphenylboron chloride and silver perchlorate in sulpholane, concluded that in solution the $(C_6H_5)_2B^+$ ion is coordinated to two solvent molecules and is therefore a boronium cation $[(C_6H_5)_2B\,(\text{sulpholane})_2]^+$.

Armstrong and Perkins[104] arrived at a similar conclusion in view of the agreement between the electronic transition calculated by the Pariser–Parr–Pople method with the absorption observed in the ultraviolet spectrum of the diphenylboron cation.

Thus Davidson and French's conclusion that the $(C_6H_5)_2B^+$ ion is present must be evidently regarded as erroneous and the appreciable increase of the conductivity of the diphenylboron chloride solution in nitrobenzene following the addition of aluminium chloride may be accounted for by the formation of a cationic boron complex according to the following mechanism:



$$(C_6H_5)_2BCl + Solv \leftrightarrows (C_6H_5)_2BCl \cdot Solv, \qquad (47)$$

$$(C_6H_5)_2BCl \cdot Solv + AlCl_3 + Solv \rightarrow Solv \ldots \underset{Solv}{\overset{(C_6H_5)_2}{B}} \ldots Cl \ldots AlCl_3 \rightarrow$$

$$\rightarrow [(C_6H_5)_2B(Solv)_2]^+ AlCl_4^-,$$

where Solv = $C_6H_5NO_2$.

Mikhailov and coworkers[45] observed that ethereal solutions of certain diarylboron chlorides [$(C_6H_5)_2BCl$, (o-$CH_3C_6H_4)_2BCl$, (p-$CH_3C_6H_4)_2BCl$, (α-$C_{10}H_7)_2BCl$, and $(C_4H_9)_2BCl$] conduct electricity and explain this phenomenon by the existence in ether of an equilibrium between organoboron chlorides and the corresponding boronium salts:

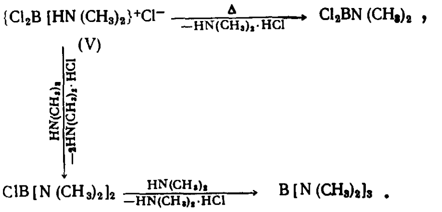
$$R_2BCl + 2(C_2H_5)_2O \leftrightarrows \{R_2B[O(C_2H_5)_2]_2\}^+ Cl^-. \qquad (48)$$

However, Moodie et al.[103] demonstrated by ^1H NMR spectroscopy that the cation of the boronium salt $\{(C_6H_5)_2B[O(C_2H_5)_2]\}^+ClO_4^-$ § is insufficiently stable and is fully decomposed in several hours via the following mechanism:

$$\{(C_6H_5)_2B[O(C_2H_5)_2]_2\}^+ \rightarrow (C_6H_5)_2BOC_2H_5 + (C_2H_5)_3O^+. \qquad (49)$$

e. Preparation of Boronium Salts from Boron Trihalides

A number of cationic boron complexes have been obtained by the reaction of boron trihalides with amines. The reaction consists of many stages and the final products depend on many factors[105-111]. Thus Nöth et al.[112] showed in a study of the reaction of boron trichloride with dimethylamine that the aminolysis of boron trichloride proceeds via a stage involving the formation of a boronium salt—dichlorobis(dimethylamine)boronium chloride (V) and dimethylaminoboron dichloride is formed only in the thermal decomposition of (V) in the course of aminolysis:



$$BCl_3 \xrightarrow{HN(CH_3)_2} Cl_3B \cdot HN(CH_3)_2 \xrightarrow{HN(CH_3)_2}$$

$$\begin{tikzcd}
\rightarrow \{Cl_2B[HN(CH_3)_2]\}^+Cl^- \arrow[r, "\Delta", "-HN(CH_3)_2\cdot HCl"'] \arrow[d, "HN(CH_3)_2"', "-2HN(CH_3)_2\cdot HCl"] & Cl_2BN(CH_3)_2, \\
ClB[N(CH_3)_2]_2 \arrow[r, "HN(CH_3)_2", "-HN(CH_3)_2\cdot HCl"'] & B[N(CH_3)_2]_3.
\end{tikzcd} \qquad (50)$$

(V)

Boronium salts containing various amines in the cation have been prepared by the reaction of dimethylamine–boron trichloride with amines in ether or benzene[112,113]:

$$Cl_3B \cdot NH(CH_3)_2 + L \rightarrow \left[Cl_2B\begin{matrix}NH(CH_3)_2\\L\end{matrix}\right]^+ Cl^-, \qquad (51)$$

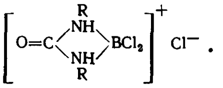
where L = NH_3, iso-$C_3H_7NH_2$, $C_4H_9NH_2$, $(CH_3)_2NH$, $(C_2H_5)_2NH$, $N(CH_3)_3$, pyridine, or 4-methylpyridine.

When trimethylamine-boron tribromide was refluxed with 3-chloropyridine, a boronium salt were also isolated: $[Br_2B(NC_5H_4Cl)_2]^+Br$.[114] Similar salts were obtained by the action of amines on solutions of boron trihalides in benzene or chloroform[115-118]¶:

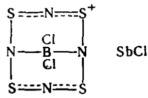
$$BX_3 + 2L \rightarrow [X_2BL_2]^+X^-, \qquad (52)$$

where (a) X = Cl or Br and L = $NH(CH_3)_2$, RNH_2, or C_5H_5N and (b) X = I and L = C_5H_5N.

On the basis of conductimetric data, Greenwood and Robinson[120] attributed an ionic structure to the adducts formed by the reaction of boron trichloride with urea derivatives:



We may mention that the infrared spectrum of the compound isolated in the reaction between $SbCl_5$ and the adduct of sulphur nitride and boron trichloride corresponds very closely to the structure of a boronium salt[121]:



A similar cationic boron complex was detected in a study of BCl_3–$SbCl_5$–CH_3CN phase diagrams at 25°C:[122]

$$BCl_3 + SbCl_5 + 2CH_3CN \rightarrow [Cl_2B(CH_3CN)_2]^+SbCl_6^-. \qquad (53)$$

Analysis of the spectroscopic characteristics and conductimetric data for solutions of boron trichloride and tribromide in acetonitrile led Schmulbach and Ahmed[123,124] to the conclusion that the ion pairs $[(CH_3CN)_2BX_2]^+BX_4^-$ exist in solution. However, the authors' conclusion probably requires confirmation. The same workers[125] suggest that the boronium cation $[I_2B(CH_3CN)_2]^+$ is formed on dissolution of $(C_2H_5)_4NBI_4$ in acetonitrile:

$$(C_2H_5)_4NBI_4 \xrightarrow{CH_3CN} (C_2H_5)_4N^+ + [I_2B(CH_3CN)_2]^+ + 2I^-. \qquad (54)$$

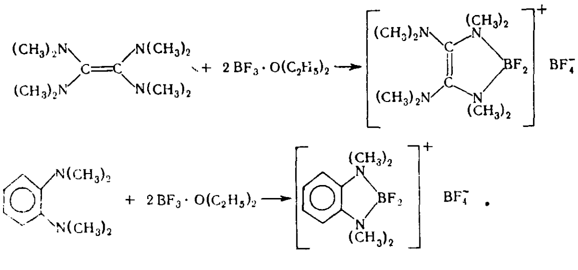
The formation of a boronium cation was postulated in the synthesis of arylboron halides from aromatic hydrocarbons and boron trichloride in the presence of aluminium and aluminium trichloride[126,127]:

$$ArH + BCl_3 \rightarrow ArH \cdot BCl_3 \xrightarrow{AlCl_3} ArHBCl_2^+ AlCl_4^-, \qquad (55)$$

$$ArHBCl_2^+ \rightarrow ArBCl_2 + H^+,$$

$$3H^+ AlCl_4^- + Al \rightarrow {}^3/_2 H_2 + 4AlCl_3.$$

The sole example of the preparation of cationic boron complexes from boron trifluoride is the reaction of boron trifluoride-ether with tertiary diamines[40,128]:



(56)

The majority of investigators assume a covalent structure for the boron trihalide complexes with amines: $R_{3-n}H_nN \rightarrow BX_3$. However, in a number of studies ionic structures were attributed to the amine complexes of boron trichloride:

$$[R_{3-n}H_nNBCl_2]^+Cl^- \quad [(R_{3-n}H_nN)_2BCl_2]^+BCl_4^-.$$

Thus the formation of an ionic complex in the dimethylamine–boron trichloride system was suggested by Brown and Osthoff[111], who concluded on the basis of a study of the vapour pressure of dimethylamine–boron trichloride that the following equilibrium exists in the gas phase:

$$(CH_3)_2NH \cdot BCl_3 \leftrightarrows (CH_3)_2NBCl_2 \cdot HCl \leftrightarrows (CH_3)_2NBCl_2 + HCl. \qquad (57)$$

---

§ It is noteworthy that Mikhailov and coworkers[45] considered salts with the anion Cl^-, while boronium salts with the anion ClO_4^- are as a rule more stable[67].

¶ It is interesting that, in an ^1H NMR spectroscopic study of solutions of boron trihalides in pyridine derivatives in the temperature range between −50° and +35°C, the formation of boronium salts was not observed[119].

This observation enabled them to formulate the structure of amine-borane also in the form of the salt

The reaction of this complex with iron(III) chloride, which leads to the formation of $[Cl_2BNH(CH_3)_2]^+FeCl_4^-$, may be regarded as a confirmation of the ionic structure[129]. Moreover, dimethylamine–boron trichloride is readily hydrolysed in aqueous silver nitrate with formation of AgCl, this being in sharp contradiction with the behaviour of trimethylamine-boron trichloride, which is difficult to hydrolyse and which does not react with $FeCl_3$. At the same time the low conductivity of solutions of this complex in chloroform indicates a non-ionic structure[130].

Gerrard et al.[131] suggested that complexes of boron trichloride with aliphatic secondary amines be regarded as dichlorobis(dialkylamine)boronium tetrachloroborates:

$$[Cl_2B(NHR_2)_2]^+\ BCl_4^- ,$$

where $R = CH_3$ or iso-C_4H_9. This hypothesis is based on an analysis of the infrared spectra of these compounds, which contain absorption bands characteristic of the BCl_2 group and also frequencies corresponding to the anion BCl_4^-.

In a study of the viscosity and conductivity of melts of boron trichloride complexes with pyridine and piperidine over a wide range of temperatures, Greenwood and Wade[132] concluded that these complexes dissociate into ions to the extent of approximately 1%. On this basis, the following equilibrium between covalent and ionic forms was proposed:

$$2\,BCl_3 \cdot NC_5H_x \leftrightarrows [Cl_2B(NC_5H_x)_2]^+\,BCl_4^- , \qquad (58)$$

where $x = 5$ or 11.

The infrared spectra of the solid complex of pyridine with boron trichloride and its solutions in benzene[132] and also the ^{11}B NMR spectra of complexes of pyridine with BX_3 (X = Cl or Br) in acetonitrile and methylene chloride correspond to the covalent structure $C_5H_5N.BX_3$.[118,123] Boronium salts with ether ligands in the cation were synthesised by Mikhailov and coworkers[115–117] by the reaction of iron(III) or tin(IV) chloride with ethereal solutions of boron trichloride:

$$BCl_3 + 2\,L + FeCl_3 \xrightarrow{-70^\circ} [Cl_2BL_2]^+\ FeCl_4^- , \qquad (59)$$

where $L = (C_2H_5)_2O$ or C_4H_8O;

$$2\,BCl_3 + 4\,C_4H_8O + SnCl_4 \xrightarrow{-70^\circ} [Cl_2B(OC_4H_8)_2]_2^+\ SnCl_6^{2-} .$$

The results of this reaction and also the determinations of the molecular weights of boron trihalide-ether compounds in ether by Singer's method† and the capacity of ethereal solution of boron trihalides to conduct electricity led to the conclusion[45] that in ether there is an equilibrium between the neutral complex (VI) and the boronium salts (VII) and (VIII):

$$\underset{(VI)}{X_3B \cdot O(C_2H_5)_2} + (C_2H_5)_2O \leftrightarrows \underset{(VII)}{\{X_2B[O(C_2H_5)_2]_2\}^+}\,X^- \xrightleftharpoons{BX_3 \cdot O(C_2H_5)_2}$$

$$\rightarrow \underset{(VIII)}{\{X_2B[O(C_2H_5)_2]_2\}^+\,BX_4^-} , \qquad (60)$$

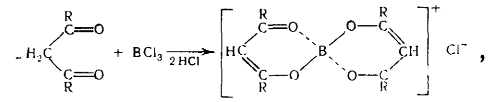
where X = Cl, Br, or F.

However, these results can be accounted for also from other standpoints. For example, the conductivity of the complex of boron trifluoride with anisole was explained by Pechalin and Panchenko by the formation of a charge-transfer complex[133]. Fratiello et al.[134] observed that ethereal solutions of the complexes $BCl_3.OC_4H_8$ and $BBr_3.O(C_2H_5)_2$ are unstable and therefore their conductivity may be caused by the presence of decomposition products. Moreover, the NMR spectra of the ether complexes of boron trihalides, which always contain one ^{11}B signal and one signal corresponding to each of the protons in the ether bound in the complex, are also inconsistent with the presence of ionic structures[134]. Bearing in mind the results of Fratiello et al.[134], structures of the type $[(R_2O)_2BX_2]^+X^-$ for the ether complexes of boron trihalides can be rejected altogether. The reaction of ethereal solutions of boron trichloride with Lewis acids need not necessarily be accompanied by their ionisation but may involve an S_N2 mechanism:

$$R_2O \cdot BCl_3 + FeCl_3 \xrightarrow{R_2O} R_2O \ldots \overset{Cl_2}{\underset{\ddot{R}_2O}{B}} \ldots Cl \ldots FeCl_3 \rightarrow [(R_2O)_2BCl_2]^+\,FeCl_4^- . \qquad (61)$$

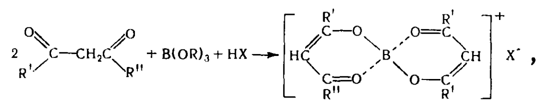
All these findings show that the problem of the existence of an equilibrium in ethereal solutions of boron trihalides cannot be regarded as finally solved.

Boron trichloride may react with β-diketones to form cationic boron complexes. Diltey in fact obtained in 1906 the first cationic boron complexes precisely by this reaction[1]:



(62)

where $R = CH_3$ or C_6H_5. Subsequently the method was improved by Barabas et al.[135] and extended to other β-diketones:



(63)

where $R' = R'' = CH_3$ or C_6H_5, R = H or n-C_4H_9, and X = Cl or ClO_4^-.

Cationic chelate complexes of boron containing tropone derivatives as ligands were synthesised by Muetterties and coworkers[136–142] by the reaction between the tropone derivatives and BBr_3 in chloroform or methylene chloride:

$$BBr_3 + 2\,T \xrightarrow[-HBr]{} [BT_2]^+\,Br^- , \qquad (64)$$

where T = tropolone, thiotropolone, or the lithium salt of *NN*-dimethylaminotroponimine and *N*-methylaminothiotropone.

In the case of tropolone the chelate complexes of boron can be obtained from boric acid and tropolone in aqueous solution in the presence of inorganic acids.

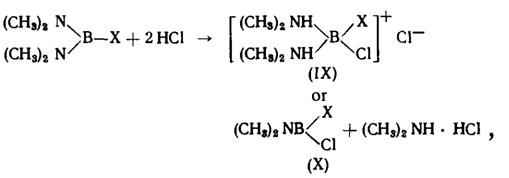
3. PREPARATION OF CATIONIC COMPLEXES BY THE ADDITION OF HYDROGEN HALIDES TO AMINOBORANES

The reaction of aminoboranes with hydrogen halides was investigated in greatest detail by Nöth and coworkers[63,87,143–147], who established that the reaction can lead to two different products, the structure of the compound depending mainly on the nature of the substituents at the boron atom. In the presence of bulky substituents,

---

† The molecular weights determined for the other compounds of boron trichloride, trifluoride, and tribromide exceed the values for the neutral complexes by 50, 40, and 20% respectively[45].

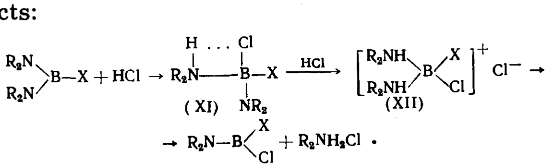
aminoborane derivatives are formed, but when the substituents are small the products are boronium salts:



(IX) or (X) (65)

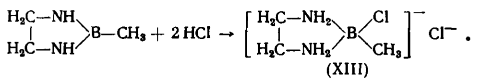
where in compound (IX) X = H, CH_3, C_2H_5, C_6H_5, Cl[‡], F, or $N(CH_3)_2$ and in compound (X) X = C_3H_7, C_4H_9, $Si(CH_3)_3$, $Si(C_6H_5)_3$, $B[N(CH_3)_2]_2$, or $N(C_2H_5)_2$.

The mechanism of the reaction of aminoboranes with hydrogen chloride probably consists in the addition of HCl to the B–N bond of the aminoborane with formation of compound (XI). Subsequent addition of a second HCl molecule leads to the formation of the boronium salt (XII), the cation of which is unstable in the presence of bulky substituents and decomposes with formation of substitution products:



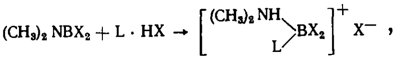
(XI) (XII) (66)

The reactions of hydrogen chloride with aminoboranes have been investigated in a number of studies. Thus, the preparation of the cationic boron complex (XIII) by the reaction of *B*-methyldiazaboroline with hydrogen chloride has been described[148]:



(XIII) (67)

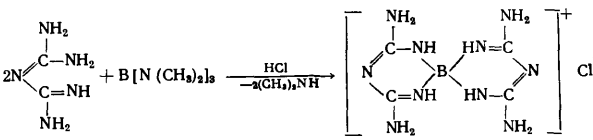
Mikhailov and coworkers[115–117] showed that the reaction of dimethylaminoboron dihalides with amine hydrogen halides in chloroform leads to the formation of boronium salts:



(68)

where X = Cl or Br and L = $(CH_3)_2NH$ or C_5H_5N.

The cationic boron complex (XIV) was synthesised by the reaction of biguanidine with tris(dimethylamino)borane in boiling pyridine followed by treatment with 0.5 *N* hydrochloric acid[149]:

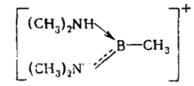


(XIV) (69)

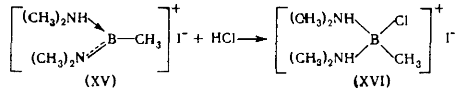
The unusual behaviour of hydrogen iodide in relation to aminoboranes is noteworthy. In contrast to the reactions with hydrogen chloride and bromide, methyl bis(dimethylamino)borane combines in toluene with only one mole of hydrogen iodide forming the insoluble complex (XV):

$$[(CH_3)_2N]_2B{-}CH_3 + HI \rightarrow \underset{(XV)}{[(CH_3)_2N]_2B{-}CH_3 \cdot HI} \,. \qquad (70)$$

On the basis of infrared spectroscopic data, Nöth and coworkers[145] attribute to (XV) the structure

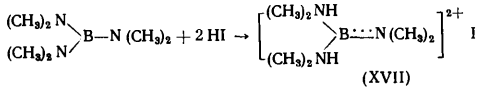


in which the cation is stabilised by the formation of a π-bond between the boron and nitrogen atoms. Additional confirmation of this structure is provided by the reaction of (XV) with hydrogen chloride, which leads to the formation of the boronium salt (XVI) and the disappearance from the infrared spectrum of the 1576 cm^{-1} absorption band characteristic of the B...N bond:



(XV) (XVI) (71)

Hydrogen iodide reacts similarly also with tris(dimethylamino)borane:



(XVII) (72)

The structure of compound (XVII) is based on infrared spectroscopic data.

4. INTERACTION OF BORANES WITH AMINE-BORANES AT ELEVATED TEMPERATURES

One of the general methods for the preparation of cationic boron complexes is the reaction proposed by Miller, Muetterties, and coworkers[70,138,140,150] between borane complexes and 'onium salts at an elevated pressure and a temperature in the range 100–180°C:

$$L\cdot BH_3 + L\cdot HX \rightarrow [H_2BL_2]^+X^- + H_2\,. \qquad (73)$$

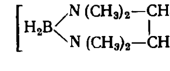
A wide variety of boronium salts have been synthesised by this method, containing in the inner sphere of the cation amines, phosphines, arsines, and dialkyl sulphides and with various acid residues as the anions. Equivalent amounts of a base and an acid may be employed instead of the 'onium salts.

Cationic boron complexes are also obtained by the reaction of borane–base complexes with diborane or higher boranes at 100–250°C: [138,151–155]

$$L\cdot BH_3 + B_2H_6 \rightarrow [H_2BL_2]^+X^- \qquad (74)$$

where X = $B_{12}H_{12}^{2-}$, $B_{12}H_{11}L^{1-}$, etc. and L = $(CH_3)_3N$, $(CH_3)_3P$, $(CH_3)_3As$, or $(CH_3)_2S$.

Boronium salts containing the cation



are formed when adducts of pentaborane(9) with *NNN'N'*-tetramethylethylenediamine (TMED) and B_4H_8.TMED are decomposed at 140–150°C.[156]

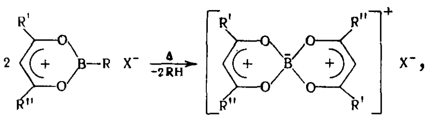
Beachley, who investigated the pyrolysis of the amine complexes of borane both in the presence of bis(methylamine)boronium chloride and in its absence, isolated boronium salts with cations containing several boron atoms[157,158]:

$$\begin{gathered} H_3B\cdot NH(CH_3)_2 + [H_2B(NH_2CH_3)_2]^+Cl^- \,|\, \xrightarrow[20\ h]{110°} \\ \rightarrow [CH_3NH_2BH_2NHCH_3BH_2NH_2CH_3]^+Cl^- + H_2 + [H_2BN(CH_3)_2]_2 , \\ H_3B\cdot NH_2CH_3 + [H_2B(NH_2CH_3)_2]^+Cl^- \xrightarrow[19\ h]{85°} \\ \rightarrow [CH_3NH_2BH_2NHCH_3BH_2NH_2CH_3]^+Cl^- + H_2 + \\ + \underset{(XVIII)}{[CH_3NH_2BH_2NHCH_3BH_2NHCH_3BH_2NH_2CH_3]^+Cl^-} + H_3B_3N_3(CH_3)_3\,. \end{gathered} \qquad (75)$$

[‡] It is interesting to note that Weiberg and Schuster[109] described a product with the same composition more then 30 years before the work of Nöth.

The same products were obtained on partial pyrolysis of 1,3,5-trimethylcyclotriborazane in the presence of methylamine hydrochloride. The structure of the boronium salt (XVIII) was proposed by Beachley on the basis of infrared and ^{1}H NMR spectroscopic data.

The preparation of bis(1,3-diketonato)boronium salts by the decomposition of 1,3-dioxaborinium salts at 100°C both in the solid state and in inert solvents (toluene and acetonitrile) has been described[159,160]:



(76)

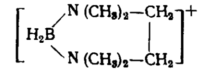
where X = Cl^- or ClO_4^-, R = C_6H_5, R′ = CH_3 or C_6H_5, and R″ = CH_3 or C_6H_5.

5. OTHER METHODS OF PREPARATION

A method for the synthesis of boronium salts with the composition $[H_2BL_2]^+X^-$, where L = tertiary amine, phosphine, or nitrile and X^- = ClO_4^- or BF_4^-, consisting in the treatment of borohydrides or amine-boranes with triphenylmethyl perchlorate or fluoroborate in the presence of bases, has been patented[161,162]:

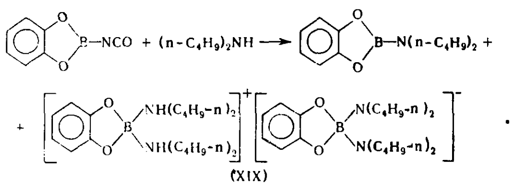
$$(C_6H_5)_3CBF_4 + (CH_3)_4NBH_4 + 2C_5H_5N \xrightarrow[CH_3CN]{-55^\circ} [H_2B(NC_5H_5)_2]^+BF_4^- + (C_6H_5)_3CH + (CH_3)_4NBF_4 \,. \qquad (77)$$

The acid hydrolysis of the adducts of pentaborane(9) with TMED and B_4H_8.TMED leads to the formation of the cation



in quantitative yield. The same cation is obtained by the hydrolysis of the adducts under neutral conditions[156].

After allowing two moles of dibutylamine to react with one mole of 2-isocyanato-1,3,2-benzodioxaboronate, Lappert and coworkers[163] isolated a complex with the composition $C_{22}H_{41}O_2N_2B$, which proved to be resistant to pyrolysis and alcoholysis. On the basis of infrared spectroscopic data, the structure of a boronium salt (XIX) was attributed to the complex:



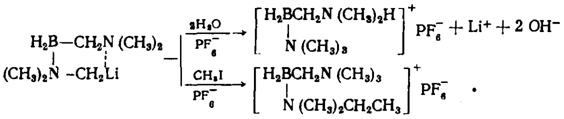
(XIX) (78)

The boronium salts $[C_5H_5NBH_2N(CH_3)_3]^+I^-$ and $\{[(CH_3)_3NBH_2]_2SCH_3\}^+I^-$ were isolated after treating $H_3BN(CH_3)_2CH_2SCH_3$ with methyl iodide and pyridine or with methyl iodide and water respectively[80].

The preparation of ionic compounds of boron (the authors regard them as boronium salts) by the reaction of trimethylamine-dimethylaminomethylborane with ethyl bromoacetate or hydrogen chloride has been described[71,164]:

$$(CH_3)_3N\cdot BH_2CH_2N(CH_3)_2 + HCl \xrightarrow{PF_6^-} [(CH_3)_3NBH_2CH_2N(CH_3)_2H]^+PF_6^- \,. \qquad (79)$$

Similar compounds are also formed in the methylation with methyl iodide or in the hydrolysis of the lithio-derivative of borane (XX):[71,164]

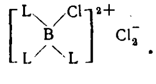


(XX) (80)

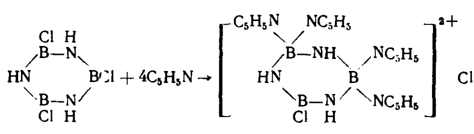
Di- and Tri-valent Cationic Complexes of Boron

The data presented above show that considerable advances have been achieved in the development of methods for the synthesis of singly charged cationic boron complexes. Until recently almost nothing was known about cationic boron complexes with charges greater than +1. The first mention of this class of compound dates back to 1951 when Sowa[165] reported the preparation of a series of boronium cations with charges ranging from +1 to +3. However, he did not prove the structure of these compounds. Only in the last three years has a series of papers appeared on the preparation of doubly and triply charged cationic boron complexes in which the structural data for the compounds are confirmed by the results of elemental analyses, infrared spectra, and conductimetric data.

When boron trichloride reacts with various primary, secondary, and tertiary amines in benzene, complexes with the composition $BCl_3.3L$ (L = amine) are obtained[166-168]; the structure of a divalent cationic complex was attributed to them:



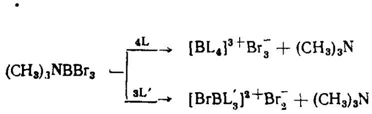
Similar complexes were prepared by the reaction of *B*-trichloroborazine and diethylaminoboron dichloride with an excess of pyridine in benzene or petroleum ether at 0°C:[99]



(81)

$$(C_2H_5)_2NBCl_2 + 3C_5H_5N \rightarrow [(C_2H_5)_2NB(NC_5H_5)_3]^{2+}Cl_2^- \,.$$

Tri- and divalent boron complexes were synthesised by refluxing $(CH_3)_3N.BBr_3$ with an excess of pyridine or its derivatives[114]:



(82)

$$(CH_3)_3NBBr_3 \xrightarrow{4L} [BL_4]^{3+}Br_3^- + (CH_3)_3N$$
$$(CH_3)_3NBBr_3 \xrightarrow{3L'} [BrBL'_3]^{2+}Br_2^- + (CH_3)_3N \,,$$

where L = 4-ethylpyridine and L′ = pyridine or 3-bromopyridine.

It is noteworthy that the complexes $3C_5H_{10}NH.BBr_3$ and $3(C_6H_5)_2NH.BBr_3$ obtained in reactions of boron tribromide with aromatic and cyclic amines and also the complexes $[(CH_3)_2N]_3B.3HI$ and $3(CH_3)_2NH.BCl_3$ should probably be regarded as divalent cationic boron complexes[112,145,169].

A divalent cationic complex has been synthesised by the reaction of tris-2,4,6-trichlorophenyl borate with ammonia[98]:

$$(Cl_3C_6H_2O)_3B + 3NH_3 \rightarrow [Cl_3C_6H_2OB(NH_3)_3]^{2+}[Cl_3C_6H_2O]_2^- \,. \qquad (83)$$

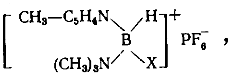
III. PHYSICAL PROPERTIES OF CATIONIC BORON COMPLEXES

Cationic boron complexes are crystalline substances. Most of them are insoluble in hydrocarbon solvents, carbon tetrachloride, and ethers. Boronium salts with small anions (Cl^-, NO_3^-, SO_4^-, etc.) are hygroscopic. They dissolve appreciably in halogenohydrocarbons (chloroform, methylene chloride, and dichloroethane), acetonitrile, acetone, alcohols, and water§, some salts crystallising as hydrates from the last solvent[89,150]. The water of hydration is readily eliminated by drying in a vacuum over phosphorus pentoxide or by recrystallisation from acetonitrile or chloroform. Boronium salts with large anions (PF_6^-, $B_{12}H_{12}^{2-}$, etc.) are much less soluble in organic solvents and water.

The boronium salts isolated from reactions in chloroform or carbon tetrachloride frequently contain between 0.2 and 0.9 mole of the solvent[75,76,136].

The saltlike nature of the cationic complexes of boron is confirmed by their capacity to conduct electricity in aqueous solutions[89,114], organic solvents[56,99,102,125,145], or amines[54]. The ionic structure of diammineboronium chloride $[H_2B(NH_3)_2]^+Cl^-$ and "diammoniate of tetraborane" $[H_2B(NH_3)_2]^+B_3H_8^-$ was also confirmed by X-ray diffraction data[170-172]. The molecular weights of these complexes have been determined in liquid ammonia[49,173,174].

Cationic boron complexes with an asymmetric boron atom should exist in optically active forms. After a number of unsuccessful attempts[135,150] optically active cationic complexes were isolated[60,66,175]:



where X = Cl or Br.

NMR Spectra of Cationic Boron Complexes

The ^{11}B NMR spectra of cationic boron complexes with 2 BH bonds consist of triplets with intensity ratios of 1 : 2 : 1 and J_{BH} constants in the range 90–120 Hz, [39,40,58-60,67,72,75,76,150,176,177] and the spectra of cations with only one BH bond consist of symmetrical doublets with J_{BH} = 134–160 Hz.[60,66,67,150]. The spectrum of bis(trimethylphosphine)-boronium consists of a quintet (0.5 : 4.4 : 5.5 : 4.4 : 0.5).[150] The ^1H NMR spectra of various cationic boron complexes have also been described[40,58-60,66,67,69-73,76,88,103,128,135,147,150,151,178].

Infrared and Ultraviolet Spectra of Cationic Boron Complexes

In the infrared spectra of boronium salts of the type $[H_2BL_2]^+X^-$ (where L is a Lewis base) there is a doublet in the region of 2380–2600 cm^{-1} associated with the stretching vibrations of the BH bonds. It is symmetrical for bisarsine and bisphosphine cations and asymmetric for bisamine cations, the band with the lower intensity lying at higher wavelengths. The frequencies due to the deformation vibrations of the BH_2 group are in the region of 1065–1170 cm^{-1}. In the deuterium-substituted cation $[D_2BL_2]^+$ the stretching and deformation vibration frequencies of the BD_2 group are displaced to 1900–1760 and 915 cm^{-1} respectively. In the region of 2430–2600 cm^{-1} cations of the type $[HB(R)L_2]^+$ have a singlet with a much lower intensity than the doublet of the BH_2 group[22,23,40,56-59,67,69-76,143,150,158].

The Raman spectra of diammineboronium and bis(dimethyl sulphoxide)boronium borohydrides each have two bands associated with the BH_2 group (2371–2315 and 2437–2422 cm^{-1} [8,41]).

The infrared spectra of the boronium salts $(R'R''BL_2)^+X^-$ containing various substituents at the boron atom (R′ and R″ = halogen, alkyl, aryl, etc.)[40,54,67,88,90,99-101,114,123,128,144,145,163], the infrared spectra of Diltey's complexes[135,159,178,179], and the ultraviolet spectra of various boronium cations[40,59,76,101,102,104,114,118,135,179] have been described.

IV. CHEMICAL PROPERTIES OF CATIONIC BORON COMPLEXES

The chemical reactions of cationic boron complexes can be divided into three groups.

1. Reactions with breakdown of the boronium salt (pyrolysis, hydrolysis, alcoholysis, and reactions with bases).

2. Reactions involving changes in the boronium cation but not resulting in its breakdown (substitution reactions and ligand exchange reactions).

3. Reactions of the anions of the boronium salts.

1. REACTIONS WITH BREAKDOWN OF THE BORONIUM SALT

a. Thermal Stability and Pyrolysis of Boronium Salts

The thermal stability of boronium salts depends both on the nature of the ligand and the substituents at the boron atom in the cation and on the nature and dimensions of the anions. Mikhailov[46] quotes the following series of bases bound in a complex with boron in terms of decreasing stability of the boronium cations: diamines > amines > phosphines > arsines > ethers > sulphides. Within the limits of each of the above types of bases, the stability of the boronium cation is determined mainly by steric factors. For example, for amine ligands it is possible to establish the following series in terms of decreasing thermal stability of boronium salts[56]:

$$[(C_6H_5)_2B\,(NH_3)_2]^+Cl^- > [(C_6H_5)_2B\,(NH_2CH_3)_2]^+Cl^- > \{(C_6H_5)_2B\,[HN\,(CH_3]_2\}^+Cl^- .$$

While diammineboronium borohydride is stable up to 80°C, the borohydrides of bis(methylamine)boronium and bis(dimethylamine)boronium are stable at room temperature only in a vacuum[10,23].

The stability of boronium salts is appreciably influenced also by the dimensions of the substituent at the boron atom, the stability as a rule decreasing with increase in the size of the substituent. Thus ethylbis(dimethylamine)boronium chloride decomposes at room temperature and methylbis(dimethylamine)boronium remains unchanged at the same temperatures in the absence of moisture[145].

The dimensions and the nature of the anion also have a significant effect on the thermal stability of the salts. The boronium salts formed with the anions of weak acids are stable only when small ligands are present in the inner sphere of the cation (NH_3, CH_3NH_2).[61] Boronium salts with anions of strong acids are distinguished by greater stability. While the boronium salt $[(CH_3)_2B(NH_3)_2]^+[H_2B.(CH_3)_2]^-$ decomposes at 10°C, its chloride is stable under

---

§ The solubilities of a number of boronium salts in water have been determined[90].

the same conditions[54]. When salts with strong acid anions and bulky ligands are formed, the dimensions of the anion become of decisive importance for their stability, since small anions are capable of displacing the ligand from the cation at elevated temperatures:

$$[H_2BL_2]^+Cl^- \xrightarrow{\Delta} H_2BCl \cdot L + L \, , \tag{84}$$

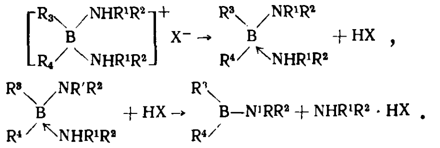
On the other hand, large anions ($B_{12}H_{12}^{2-}$, PF_6^-) permit the synthesis of stable boronium salts with ligands such as trimethylamine, ethyldimethylamine, triethylamine, and 2,6-dimethylpyridine[58,59,140,150].

Two types of thermal transformations are characteristic of boronium salts, depending on the nature of the ligand. The pyrolysis of boronium salts with tertiary amines as ligands and small anions leads to the displacement of the amine from the inner sphere of the cation by the anion and formation of complexes of the amine with boron derivatives[138,140,150,180]:

$$\{H_2B[N(CH_3)_3]_2\}^+X^- \xrightarrow{125-195^\circ} H_2B{-}X \cdot N(CH_3)_3 + N(CH_3)_3 \, , \tag{85}$$

where X = Cl, Br, or N_3.

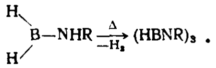
Another type of thermal transformation is characteristic of boronium salts containing primary and secondary aliphatic amines in the cation. When these salts are heated, aminoboranes and derivatives of cycloborazanes and borazines are produced, and their formation may be represented by the following equations:



(86)

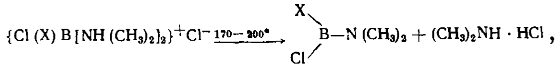
(XXI)

When R^3 and R^4 = C_nH_{2n+1}, C_6H_5, or Cl, the pyrolysis stops at this stage. When $R^1 = R^3 = H$, the product (XXI) may cyclise with formation of cycloborazanes $(H_2BNHR)_3$ or undergoes further reactions leading to borazine derivatives:



$$H_2B{-}NHR \xrightarrow[-H_2]{\Delta} (HBNR)_3 \, . \tag{87}$$

This mechanism may be illustrated by the examples of the reactions of boronium salts on heating quoted below. The wide melting point range of the boronium salts $\{Cl(X)B[NH(CH_3)_2]_2\}^+Cl^-$ can probably be accounted for by their partial decomposition on heating. This reaction, which leads to the formation of aminoboranes, occurs smoothly at 170–200°C:[63,88,112,143–145]



$$\{Cl(X)B[NH(CH_3)_2]_2\}^+Cl^- \xrightarrow{170-200^\circ} X(Cl)B{-}N(CH_3)_2 + (CH_3)_2NH \cdot HCl \, , \tag{88}$$

where X = H, Cl, Br, CH_3, or C_6H_5.

It is noteworthy that the introduction of bulky substituents linked to boron into the cation of the boronium salt leads to a lowering of the temperature at which the transformation takes place[81,84]:

$$[(C_6H_5)_2B(NH_2R)_2]^+Cl^- \xrightarrow{200-250^\circ} (C_6H_5)_2B{-}NHR + RNH_2 \cdot HCl \, , \tag{89}$$

where R = CH_3, C_2H_5, or iso-C_4H_9;

$$[(p\text{-}CH_3C_6H_4)_2B(NH_2R)_2]^+Cl^- \xrightarrow{150-170^\circ} (p\text{-}CH_3C_6H_4)_2BNH_2 + RNH_2 \cdot HCl \, ,$$

where R = C_2H_5 or iso-C_4H_9.

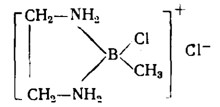
The decomposition of the salts $[H_2B(NH_2CH_3)_2]^+X^-$ and $[CH_3NH_2BH_2NHCH_3BH_2NH_2CH_3]^+X^-$, where X = BH_4 or Cl, at 100–125°C results in the formation of 1,3,5-trimethylcyclotriborazane and 1,3,5-trimethylborazine[157,158,181].

The pyrolysis of the "diammoniates" of diborane and tetraborane at 180–190°C leads to the formation of borazine[47,182]. *N*-Tri-n-burylborazine, bis-(n-butylamino)borane, and n-butylamine-borane were isolated in the thermal decomposition of bis-(n-butylamine)boronium ethylmercaptide[77].

A completely different type of thermal decomposition was observed on heating dicyclohexylbis(pyridine)boronium perchlorate in chloroform. This results in the formation of cyclohexene and cyclohexylbis(pyridine)boronium perchlorate[67]:

$$[(C_6H_{11})_2B(NC_5H_5)_2]^+ClO_4^- \xrightarrow{\Delta} [C_6H_{11}(H)B(NC_5H_5)_2]^+ClO_4^- + C_6H_{10} \, . \tag{90}$$

The pyrolysis of the boronium salt



at 300°C in the presence of hydrogen chloride results in the formation of methane and CH_3BCl_2 in low yields[148].

The decomposition of diphenylbis(ethyl ether)boronium[103]:

$$\{(C_6H_5)_2B[O(C_2H_5)_2]_2\}^+ \rightarrow (C_6H_5)_2B{-}OC_2H_5 + (C_2H_5)_3O^+ \tag{91}$$

and the transformation[99] on vacuum sublimation of the divalent cationic complex  $2Cl^-$ into the univalent complex  Cl^- have also been described.

b. Hydrolysis and Alcoholysis

The hydrolysis and alcoholysis of boronium salts are the most important reactions of cationic boron complexes. It is noteworthy that the majority of boronium salts are stable in relation to water and acids but are fairly rapidly decomposed by alkalies[39,56,58,66,67,69–71,73–76,88,89,114,158]. Thus this reaction evidently reduces to nucleophilic attack on the boronium cation.

Although there has been no systematic study of the behaviour of boronium salts in hydrolysis, examination of the literature data permits the isolation of a number of factors which determine the stability of cationic boron complexes in relation to hydrolysis.

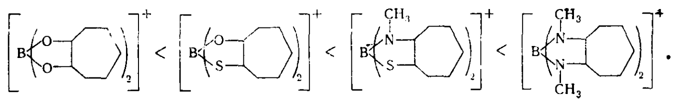
The hydrolytic stability of boronium salts is determined primarily by the basicity of the ligands in the cation. The salts become more stable with increase in the basicity of the ligands. Thus boronium cations containing thioether ligands with a relatively low basicity, $[H_2B(SR_2)_2]^+$, are readily hydrolysed by water¶.

¶ However, a boronium cation containing the S–CH_3 group, $[(CH_3)_2NBH_2SBH_2N(CH_3)_3]^+$, which is resistant to acids and alkalies, has been described. Rowatt and Miller[69] explain its enhanced hydrolytic stability by the screening of the sulphur atom by $H_2BN(CH_3)_3$ groups, which are isoelectronic with the neopentyl group. The cation

in which the sulphur atom is less screened, is hydrolysed by water.

Bis(trialkylarsine)boronium salts, $[H_2B(AsR_3)_2]^+X^-$, in which the ligands are more basic, can be actually recrystallised from water, but water hydrolyses them slowly. Cations with even more basic tertiary phosphines, $[H_2B(PR_3)_2]^+$, are stable even in relation to boiling inorganic acids but are slowly decomposed in hot alkalies. Diamineboronium cations, $[H_2B(NR_3)_2]^+$, are not susceptible to the action of concentrated acids (HCl, HNO_3, H_2SO_4), and 10% alkali even on heating[70,140,150]. However, the replacement of NR_3 in the boronium cation by 4-methylpyridine leads to a sharp lowering of the hydrolytic stability of the salt[58].

An analogous variation of hydrolytic stability in relation to alkalies on passing to more basic ligands was observed by Muetterties[136-138,140-141] also for chelate cationic boron complexes:



The rate of hydrolysis of the boronium cations $[H_2BL_2]^+$, where L is a pyridine derivative, is inversely proportional to the relative strength of the base[114]. Boronium salts with weakly basic ligands such as dimethylformamide and dimethylacetamide[70] and the *N*-oxides of tertiary bases[73], exhibit an unexpectedly high stability in relation to hydrolysis.

On the basis of data for the solvolysis of a number of bis(alkylamine)boronium chlorides, Mikhailov and coworkers[183] established that, with increase in the bulk of the molecules of nitrogen-containing bases, the hydrolytic stability of the salts decreases in the series

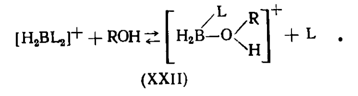
(a) $NH_3 > CH_3NH_2 > C_2H_5NH_2 > n\text{-}C_3H_7NH_2 > C_4H_9NH_2 > n\text{-}C_5H_{11}NH_2 > n\text{-}C_6H_{13}NH_2$;
(b) $NH_3 > CH_3NH_2 > (CH_3)_2NH$;
(c) $n\text{-}C_3H_7NH_2 > iso\text{-}C_3H_7NH_2$;
(d) $n\text{-}C_4H_9NH_2 > iso\text{-}C_4H_9NH_2 > t\text{-}C_4H_9NH_2$.

Bulky or electronegative substituents at the boron atom reduce the hydrolytic stability of boronium salts[54,56,61,112]. Thus the stability of salts of the type $\{(Cl)XB[NH(CH_3)_2]_2\}^+ . Cl^-$ decreases with increase in the bulk of the substituent X in the following sequence[88,143,147]: $H > F > Cl \sim C_6H_5$.

The nature of the anion of the boronium salt probably also influences its hydrolytic stability. Boronium salts with anions of weak acids $[(CH_3)_2BH_2^-, SR^-]$ are fairly readily hydrolysed[23,151], while the anions of strong acids, particularly large anions ($B_{12}H_{12}^{2-}$, PF_6^-), increase the hydrolytic stability of the salts[140,150].

The hydrolytic stability of the cationic boron complexes depends on the magnitude of the positive charge of the cation and decreases as it is diminished[114].

The mechanism of the hydrolysis of boronium salts is still obscure. According to the data of Mikhailov and coworkers[46,183], in the first stage of the solvolysis of the boronium salts $(H_2BL_2)^+Cl^-$ (where L are primary and secondary aliphatic amines) one amine molecule is replaced by water or an alcohol molecule:



$$[H_2BL_2]^+ + ROH \rightleftarrows \underset{\text{(XXII)}}{\left[H_2B\overset{L}{\diagup}\!\!-O\begin{smallmatrix} R \\ H \end{smallmatrix} \right]^+} + L \quad . \qquad (92)$$

(XXII)

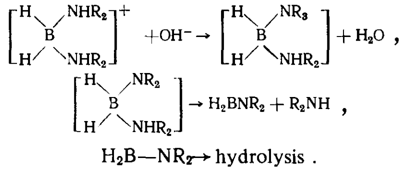
The mixed cation (**XXII**) formed dissociates at the O–H bond with formation of a neutral complex of the hydroxy- or alkoxy-borane:

$$\textbf{XXII} + ROH \rightarrow \underset{\text{(XXIII)}}{H_2B}\begin{smallmatrix} L \\ OR \end{smallmatrix} + ROH_2^+ \quad . \qquad (93)$$

Compounds of type (**XXIII**) are solvolysed at a high rate with evolution of hydrogen.

The mechanism shows that the possibility of the displacement of the ligand in the first stage is determined both by the basicity of the hydrolysing agent and the strength of the boron–ligand bond. On the other hand, the ease of the acid-catalysed dissociation of the cation (**XXII**) in the second stage depends both on the nature of the amine incorporated in it and on the basicity of the medium. In addition, the rate of alcoholysis decreases with increasing bulk of the alcohol molecule.

In the alkaline hydrolysis of the boronium salts $(H_2BL_2)^+X^-$ (where L are primary or secondary amines), one cannot of course exclude the possibility of the reaction of the hydroxide ion with NH protons:

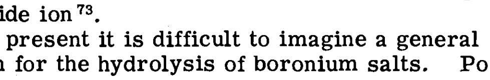


(94)

However, this last mechanism has been questioned by Mikhailov et al.[117]

Muetterties[140,150] proposed a different mechanism for the alkaline hydrolysis of boronium salts with the cations $[H_2BL_2]^+$ (where L = PR_3, AsR_3, or SR_2), according to which the initial stages of the process involves the attack by the hydroxide ion on the positively charged heteroatom of the ligand.

It is interesting to note that in certain cases there is a possibility of a nucleophilic attack by the hydroxide ion also on an atom more remote from boron[136,137]. In the alkaline hydrolysis of the boronium cation with tropolone molecules as ligands in a medium containing $H_2^{18}O$, tropolone becomes enriched in oxygen-18 to an extent corresponding to 50% of the possible maximum. On this basis, Muetterties suggests that the initial stage of the hydrolysis consists in the attack by the OH^- ion not on the central boron atom but on the carbon atom linked to oxygen:



(95)

An analogous mechanism of hydrolysis was proposed for the boronium cation $[(CH_3)_3NBH_2O \leftarrow P(CH_3)_3]^+$:

$$[(CH_3)_3NBH_2O \leftarrow P(CH)_3]^+ + OH^- \rightarrow (CH_3)_3NBH_2O \leftarrow \overset{OH^-}{\overset{\vdots}{P}}(CH_3)_3 \xrightarrow{-H^+} (CH_3)_3NBH_2O^- + PO(CH_3)_3 . \qquad (96)$$

This reaction is of third order: of first order with respect to the boronium cation and of second order with respect to the hydroxide ion[73].

Thus at present it is difficult to imagine a general mechanism for the hydrolysis of boronium salts. Possibly the reaction mechanism varies with the type of hydrolysing agent and the nature of the boronium salt.

c. Effect of Bases on Boronium Salts Containing Amines as Ligands

A number of communications have been published on the preparation of aminoboranes or their polymerisation products by reaction of strong bases with cationic boron complexes. Probably the reactions can be described in all cases by a general mechanism including as the first stage the elimination by the base A^- of a proton from the amine in the boronium cation:

$$[H_3NBH_2NH_3]^+ + A^- \rightarrow HA + \underset{(XXIV)}{H_3NBH_2NH_2}\ , \qquad (97)$$

where A^- is the base [$C{\equiv}CH^-$, NH_2, H^-, NH_2R (R = H or alkyl)]. The ammine-aminoborane (**XXIV**) formed dimerises with loss of an ammonia molecule:

$$\begin{matrix} H_3NBH_2NH_2 \\ \uparrow \\ H_2NBH_2NH_3 \end{matrix} \rightarrow \underset{(XXV)}{H_2NBH_2NH_2BH_2NH_3} + NH_3\ . \qquad (98)$$

The ammine-aminoborane (**XXV**) formed or the product of its further condensation may cyclise with elimination of an NH_3 molecule:

$$H_3N(BH_2NH_2)_n \rightarrow (H_2BNH_2)_n + NH_3\ . \qquad (99)$$

Another pathway for the formation of cycloborazanes $(H_2NBH_2)_n$ includes attack on the boron atom in the diammineboronium cation by the ammine-aminoborane (**XXIV**):

$$\underset{(XXIV)}{\begin{matrix} [H_3N\cdot BH_2NH]_3^+ \\ \uparrow \\ H_2NBH_2\cdot NH_3 \end{matrix}} \rightarrow \underset{(XXVI)}{[H_3NBH_2NH_2BH_2NH_3]^+} + NH_3\ . \qquad (100)$$

The boronium cation (**XXVI**) can be lengthened by mechanism (98) quoted above with transfer of a proton to the base A^- [reaction (97)] or can cyclise with loss of an ammonia molecule according to reaction (99).

The examples below illustrate the formation of aminoboranes in the reaction of boronium salts with bases. Sodium acetylide reacts with diammineboronium borohydride forming aminoboranes in two different modifications, one of which is cyclotriborazane (n = 3):[185]

$$[H_2B(NH_3)_2]^+BH_4^- + NaC{\equiv}CH \xrightarrow{NH_3\,(liq.)} (H_2BNH_2)_n + NaBH_4 + CH{\equiv}CH + NH_3\ . \qquad (101)$$

Cycloborazanes with the composition $(H_2BNH_2)_n$, where n = 2, 3, or 5, were synthesised by the reaction of sodamide with diammineboronium borohydride[184]:

$$[H_2B(NH_3)_2]^+BH_4^- + NaNH_2 \xrightarrow{NH_3\,(liq.)} (H_2BNH_2)_n + NaBH_4 + 2NH_3\ . \qquad (102)$$

The "diammoniate of diborane", which is stable in dry ether at room temperature, decomposes rapidly in the presence of small amounts of ammonia with formation of a polymeric aminoborane[3]:

$$[H_2B(NH_3)_2]^+BH_4^- + NH_3 \xrightarrow{(C_2H_5)_2O} (H_2BNH_2)_n + H_3B\cdot NH_3 + H_2\ . \qquad (103)$$

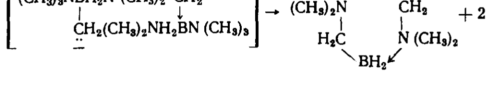
Probably bis(ethylamine)boronium ethylmercaptide decomposes similarly in ether under the influence of traces of an amine[61]:

$$[H_2B(NH_2C_2H_5)_2]^+SC_2H_5^- \xrightarrow{H_2NC_2H_5} H_2BNHC_2H_5 + C_2H_5SH + C_2H_5NH_2\ . \qquad (104)$$

The reaction of bis(trimethylamine)boronium chloride with sodium hydride[186] and butyl-lithium[164] and also the reactions of a number of boronium salts with metallic sodium[2,50,54] take place with initial elimination of a proton from the nitrogen atom or from the alkyl group of the amine.

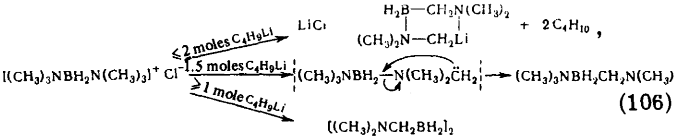
The reaction with sodium hydride gives rise to a six-membered boron-containing heterocycle in 5% yield. The formation of this product may be represented by the following mechanism

$$[(CH_3)_3NH_2BN(CH_3)_3]^+Cl^- + NaH \rightarrow NaCl + H_2 + [(CH_3)_3NBH_2N(CH_3)_2\ddot{C}H_2^{\ominus}]\ ,$$



(105)

In the reaction with butyl-lithium a number of products are formed depending on the proportions of the reactants[71,164]:



(106)

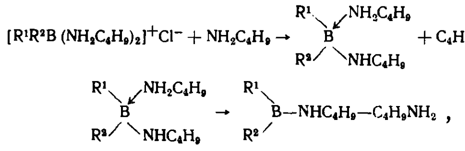
The reactions of the boronium salts $[H_2B(NH_3)_2]^+X^-$ and $[(CH_3)_2B(NH_3)_2]^+[H_2B(CH_3)_2]^-$ with sodium in liquid ammonia lead to the formation of aminoboranes†[2,49,54]:

$$[H_2B(NH_3)_2]^+X^- + Na \xrightarrow{NH_3\,(liq.)} H_2NBH_2 + NH_3 + NaX + {}^1/_2H_2\ ,$$

where $X^- = Cl^-$, Br^-, BH_4^-, or $B_3H_8^-$:

$$[(CH_3)_2B(NH_3)_2]^+[H_2B(CH_3)_2]^- + Na \xrightarrow{NH_3\,(liq.)} Na[H_2B(CH_3)_2] + (CH_3)_2B{-}NH_2 + NH_3 + {}^1/_2H_2\ . \qquad (107)$$

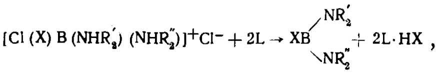
Boronium salts with substituents at the boron atom can also decompose under the influence of amines with formation of aminoboranes[84,86]:



(108)

where (1) $R^1 = R^2 = p\text{-}CH_3C_6H_4$ and (2) $R^1 + R^2 = (CH_2)_6$.

It is noteworthy that hexamethylenebis(n-butylamine)-boronium chloride does not react either with CH_3NH_2 or $(C_2H_5)_3N$. Unfortunately there is no explanation in the literature[86] of this phenomenon. At the same time it is known that dichlorobis(dialkylamine)boronium chloride[112] and chlorophenylbis(dimethylamine)boronium chloride[88] decompose smoothly under the influence of $(C_2H_5)_3N$ and $(CH_3)_2NH$:



$$[Cl(X)B(NHR'_2)(NHR''_2)]^+Cl^- + 2L \rightarrow XB\begin{matrix} \diagup NR'_2 \\ \\ \diagdown NR''_2 \end{matrix} + 2L\cdot HX\ , \qquad (109)$$

where X = Cl or C_6H_5 and L = $(C_2H_5)_3N$ or $(CH_3)_2NH$.

It is also noteworthy that reactions of a different type, leading to a transformation of the boronium cation, have also been described. Thus the complex $Cl_3B.3NH(CH_3)_2$, which is evidently the divalent cationic boron complex $\{ClB[NH(CH_3)_2]_3\}^{2+}Cl^-$, is converted by triethylamine into the univalent boronium salt $\{Cl_2B[NH(CH_3)_2]_2\}^+Cl^-$.[112]

d. Oxidation of Boronium Salts

Boronium salts containing tertiary amines as ligands are extremely resistant to oxidation. They remain unchanged under the action of oxidising agents such as Ag^+, Cu^{2+}, Hg^+, and Au^{3+} salts, potassium dichromate, and 30% hydrogen peroxide solution. Even "aqua regia" at 100°C does not decompose the cation $[H_2B(NR_3)_2]^+$ but merely converts it into the monochloro-derivative $HB(Cl)B(NR_3)_2$.[58,140,150,164] Cases of the oxidation of boronium salts by potassium permanganate[58,128] and trimethylamine-*N*-oxide[106] have been described.

---

† In these reactions the acidic protons of ammonia serve as a source of hydrogen. This was confirmed by Parry and coworkers[6] in a study of the reaction of various deutero-derivatives of the "diammoniate of diborane" with sodium in liquid ammonia.

e. Reduction of Boronium Salts

Very few examples of the reduction of boronium salts are known at present. The preparation of borazanes by the reaction of $LiBH_4$ with $[H_2B(NH_2R)_2]^+Cl^-$ has been reported[4,56,62]. The only product isolated in the reduction of $[(CH_3)_2B(NH_3)_2]^+Br^-$ by hydrogen at 120°C and a pressure of 3200 atm proved to be ammonium bromide[54].

The reduction of a cationic boron complex containing tropolone as a ligand has been described

$$[(C_7H_5O_2)_2B]^+Br^- \xrightarrow{BH_4^-} (C_7H_6O_2)\,B\,(O_2C_7H_5)\ . \tag{110}$$

Bis-(*NN*-dimethylaminotropolonimine)boronium bromide is reduced similarly by lithium aluminium hydride:

$$[(C_9H_{11}N_2)_2B]^+Br^- \xrightarrow{LiAlH_4} (C_9H_{12}N_2)\,B\,(C_9H_{11}N_2)\,. \tag{111}$$

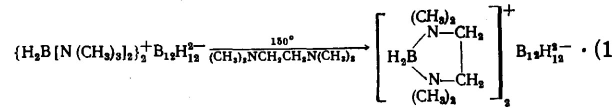
Both these boronium cations are resistant to polarographic reduction[136,140].

2. REACTIONS IN THE CATION

a. Ligand Exchange Reactions

The ligands in the boronium cation may be displaced by stronger bases without decomposing the complex. Miller and Muetterties[140,150] quote the following series of bases arranged in order of decreasing ease of exchange of the ligand in boronium salt cations: sulphides ≫ arsines > phosphines > amines > diamine. The electron-donating properties of these bases increase in the same sequence.

The steric effects of the substituents in the bases also have a significant effect on the possibility of the displacement of ligands from the cation. For example, substitution of dimethyl sulphide in $\{H_2B[S(CH_3)_2]_2\}^{2+}B_{12}H_{12}^{2-}$ by trimethylamine, *αα'*-dipiridyl and *NN*-dimethylpiperazine is rapid at room temperature, while *N*-methylpiperidine and ethyldimethylamine are incapable of displacing dimethyl sulphide. The displacement of tertiary amines by diamines takes place at an elevated temperature (up to about 150°C):

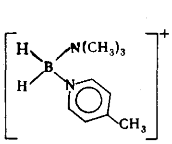


· (112)

Muetterties suggests that the first stage of the reaction is dissociation

$$[H_2B\,(NR_3)_2]^+ \rightleftarrows [H_2BNR_3]^+ + NR_3\,, \tag{113}$$

because the formation of the transition state by an S_N2 mechanism is unlikely owing to steric hindrance. However, the absence of the racemisation of the optically active boronium cation



both at room temperature and at 100°C throws doubt on the possibility of the reversible dissociation of one of the ligands at the boron atom[66].

Examples of the substitution of trimethylamine in the cation by pyridine or its derivatives at 100–110°C have been described[58]. A weak base (4-acetylpyridine) proved to be incapable of displacing a molecule of trimethylamine from the cation on refluxing in benzene for 4 h.[58] It is interesting to note that the trimethylamine, a comparatively strong base, does not displace pyridine *N*-oxide from the boronium cation at 50°C.[73]

The exchange of primary and secondary amine ligands in boronium salts with small anions (Cl^-, BH_4^-) takes place under mild conditions[54]. Thus the cations $[H_2B(NH_2CH_3)_2]^+$ and $\{H_2B[NH(CH_3)_2]_2\}^+$ undergo ligand exchange reactions on dissolution in liquid ammonia or liquid amines[23]

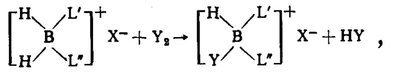
$$\begin{tikzcd}
{[H_2B(NH_2CH_3)_2]^+Cl^-} \arrow[rr, shift left, "(CH_3)_2NH\ (liq.)"] \arrow[dr, "NH_3\ (liq.)"'] & & {\left\{H_2B[HN(CH_3)_2]_2\right\}^+Cl^-\ .} \arrow[ll, shift left, "CH_3NH_2\ (liq.)"] \arrow[dl, "NH_3\ (liq.)"] \\
& {[H_2B(NH_3)_2]^+Cl} &
\end{tikzcd} \tag{114}$$

Since in these salts the amine is not dissociated from the boronium cation at a low temperature, one may assume that here the ligand exchange reactions have an S_N2 mechanism.

The attempts to substitute the ligand in di- or trivalent boronium cations by other amines led to the decomposition of the products or the recovery of the initial compounds[114].

b. Hydrogen Substitution Reactions in the Cation $[H_2BL_2]^+$

When chlorine or bromine is allowed to act on solutions of the boronium salts $[H_2BL_2]^+X^-$ in water[138,140,150,154] or methylene chloride[60,66], one hydrogen atom linked to boron is replaced by halogen. However, the chlorination in water is slow even at 90°C:



(115)

where X = I or Cl and Y = Cl or Br.

When the boronium salts $[H_2B(NR_3)_2]^+Cl^-$ are acted upon by reactants such as "aqua regia", NCl_3, and SF_5Cl, the monochloro-substituted cations $[H(Cl)B(NR_3)_2]^+$ are formed.

The iodination of boronium salts does not take place either with iodine or iodine monochloride. In the latter case at 80°C both hydrogen atoms are replaced by chlorine:

$$\{H_2B\,[N\,(CH_3)_3]_2\}^+Cl^- \overset{ICl}{\rightarrow} \{Cl_2B\,[N\,(CH_3)_3]_2\}^+. \tag{116}$$

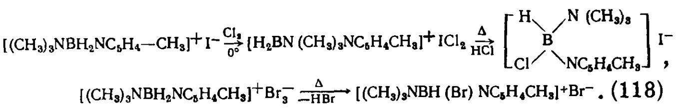
When fluorine in a stream of nitrogen is passed through an aqueous solution of $\{H_2B[N(CH_3)_3]_2\}^+$ at 0°C, the mono- and di-fluorinated cations $\{(F)HB[N(CH_3)_3]_2\}^+$ and $\{F_2B.[N(CH_3)_3]_2\}^+$ are obtained. Fluorination in the presence of chloride ions gives the mixed cation $\{Cl(F)B[N(CH_3)_3]_2\}^+$.

Peroxydisulphuryl fluoride substitutes both hydrogen atoms in the boronium salt cation:

$$\{H_2B\,[N\,(CH_3)_3]_2\}^+PF_6^- \xrightarrow{S_2O_6F_2} \{(FSO_3)_2B\,[N\,(CH_3)_3]_2\}^+PF_6^-\,. \tag{117}$$

Miller and Muetterties suggest that the above reactions have a radical mechanism. However, on the basis of data for the chlorination of the boronium salt $[(CH_3)_3NBH_2NC_5.H_4CH_3]^+I^-$ in methylene chloride at a low temperature and in the absence of light, Ryschkewitsch and Garrett[66] suggest that the mechanism of the halogenation of boronium cations consists in the electrophilic attack on the BH bond by a halide molecule.

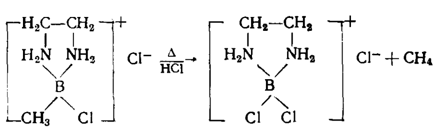
Halogeno-substituted cations are obtained also on heating boronium polyhalide salts[66]:



$$[(CH_3)_3NBH_2NC_5H_4{-}CH_3]^+I^- \xrightarrow[0^\circ]{Cl_2} [H_2BN(CH_3)_3NC_5H_4CH_3]^+ICl_2 \xrightarrow[HCl]{\Delta} \left[\begin{matrix} H & & N(CH_3)_3 \\ & B & \\ Cl & & NC_5H_4CH_3 \end{matrix}\right] I^- ,$$

$$[(CH_3)_3NBH_2NC_5H_4CH_3]^+Br_3^- \xrightarrow[-HBr]{\Delta} [(CH_3)_3NBH(Br)NC_5H_4CH_3]^+Br^- . \quad (118)$$

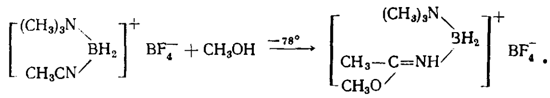
The substitution by chlorine of a methyl group bound to the boron atom in a cationic complex on heating the latter with hydrogen chloride has also been described. However, the reaction conditions and the properties of the final product have not been indicated[148]:



(119)

The reaction of $[(CH_3)_3NBH_2N(CH_2)_2CH_2SCH_3]^+$ with hydriodic acid results in the formation of $\{[(CH_3)_3N]_2BH_2\}^+$.[70]

It is noteworthy that the reactions of the cations in boron complexes containing only amine molecules in the cation as ligands have now been described. The sole exception appears to be the reactions with methyl alcohol of the boronium salt (XXIX) containing acetonitrile as a ligand[187]:



(XXIX)

(120)

3. REACTIONS OF BORONIUM SALT ANIONS

Reactions involving the exchange of the anions in boronium salts are widely used to identify these compounds and to modify their properties. Thus when diammineboronium borohydride was treated with ammonium chloride or bromide in liquid ammonia, diammineboronium chloride and bromide were obtained[2]:

$$[H_2B(NH_3)_2]^+BH_4^- + NH_4X \rightarrow [H_2B(NH_3)_2]^+X^- + NH_3BH_3 + H_2 , \quad (121)$$

where X = Cl or Br.

When ethereal or aqueous solutions of hydrogen halides (HCl, HBr) react with boronium salts containing the anions BH_4^-,[2,3,22,41] $B_3H_8^-$,[49] and $H_2B(CH_3)_2^-$,[54] the corresponding halides are obtained. The reverse reaction—the replacement of the chloride ion by the borohydride ion—was achieved by allowing sodium borohydride to react with boronium chloride salts in liquid amines[23,158]:

$$[H_2BL_2]^+Cl^- + NaBH_4 \xrightarrow[-45^\circ-(-78^\circ)]{L(liq.)} [H_2BL_2]^+BH_4^- + NaCl , \quad (122)$$

where $L = CH_3NH_2(CH_3)_2NH$;

$$[CH_3NH_2BH_2NHCH_3BH_2NH_2CH_3]^+Cl^- + NaBH_4 \xrightarrow[-30^\circ]{CH_3NH_2}$$

$$\rightarrow [CH_3NH_2BH_2NHCH_3BH_2NH_2CH_3]^+BH_4^- + NaCl .$$

The mercaptide ion is replaced by the chloride ion when boronium mercaptides are treated with hydrogen chloride[61] or benzyl chloride[61,79]. Boronium halides are converted into the corresponding perchlorates on treatment with ammonia or metal (Ag^+, K^+, and Na^+) perchlorates both in water and in organic solvents[67,74-76,90,100,101,103,135]. Hexafluorophosphates[58-60,67,70-73,76,80,114,136,139,141,150,151], hexafluoroarsenite salts[58,66,114], and tetraphenylborate salts[56,58,59,89] are precipitated when aqueous or alcoholic solutions of boronium halides are acted upon by the corresponding ammonium, sodium, and potassium salts.

Boronium chlorides react with the chlorides of iron[56,78,88,115,116,135,143-145,158], aluminium[56,135], tin[1,83,116,135], antimony[63,135], gold[1,150,152], platinum[1,145], zinc, cadmium, and mercury[1,58,66,188], forming salts with complex anions. Treatment of alcoholic solutions of boronium salts containing the anions $FeCl_4^-$ and $SnCl_6^{2-}$ with 70% perchloric acid leads to the formation of the corresponding perchlorates[135] and in reactions of KPF_6 or $NaB(C_6H_5)_4$ with boronium salts having the anions BF_4^- and BH_4^-, the hexafluorophosphates or tetraphenylboronates are formed[40,128].

When ion-exchange resins or the reactions of boronium chlorides with silver oxide in water are employed, the products are cationic complexes of boron containing hydroxide ions and behaving as strong bases. When these complexes were acted upon by acids, boronium salts with different anions were synthesised[89,150,152,155,180]. Boronium salts containing the anions $B_9H_{14}^-$, Br^-, I^-, I_3^-, Br_3^-, N_3^-, $SSP(SH_3)_2^{2-}$, NO_3^-, HSO_4^-, $C(SCN)_4(NH_3)_2^-$, $(NC)_2C{-}CHC{-}(CN)_2^-$, etc. have also been obtained by exchange reactions[58,136,150,189]. Several reactions of boronium salts involving transformations in the anion have been described too. When SO_2 is passed through an alcoholic solution of bis-(1,3-diketonato)boronium di-iodoiodate, the corresponding iodide was obtained[135]. A quantitative conversion of boronium salts with the anions I_3^-, Br_3^-, and I_2Cl^- into the corresponding halides takes place when they are treated with $Na_2S_2O_5$, acetone, or an olefin[66]. The reaction of difluoro[tetrakis(dimethylamino)ethylene]boronium tetrafluoroborate with phenylmagnesium bromide results in the formation of the tetraphenylboronate of the cation[40].

Advances in the Chemistry of 1,2,5-Thiadiazoles and 1,2,5-Selenadiazoles

V.G.Pesin

Published information on 1,2,5-thiadiazoles, 1,2,5-selenadiazoles, their derivatives, and fused systems formed by these heterocycles is summarised. A list of 322 references is included.

CONTENTS

I. INTRODUCTION

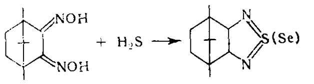
Although benzo- and naphtho-1,2,5-thia- and -selenadiazoles were described by Hinsberg in 1889,[1-4] no interest was taken in this group of compounds for more than sixty years. In 1950 the Reviewer and his coworkers began systematic investigations in this field[5]. Papers by other workers soon appeared, mainly devoted to the study of fused 1,2,5-thia- and -selena-diazole ring systems. Research in this field has been stimulated also by the discovery, among 1,2,5-thia- and -selena-diazole derivatives, of compounds which show promise of practical application in various fields. Research on monocyclic derivatives of these heterocycles began only in 1958.

Although an imense amount of information has now been accumulated on the chemistry of 1,2,5-thia- and -selena-diazoles, it has not been examined systematically or critically, apart from a short review of two or three pages[6]. The present survey covers the literature to 1968 inclusive.

II. MONOCYCLIC 1,2,5-THIADIAZOLES AND 1,2,5-SELENADIAZOLES

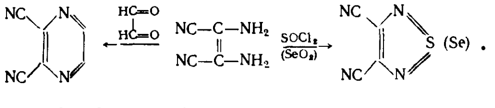
1. Synthesis

Until quite recently it proved impossible to synthesise monocyclic 1,2,5-thia- or -selena-diazoles from aliphatic compounds. The preparation of bornylene-1,2,5-thiadiazole by treating β-camphorquinone dioxime with hydrogen sulphide[7]

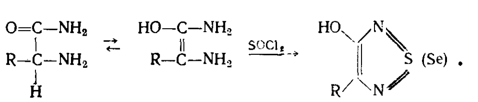


suggested that monocyclic 1,2,5-thiadiazoles might be obtained from aliphatic dioximes. However, neither dimethylglyoxime[8] nor cyclohexane-1,2-dione dioxime[9] reacts with hydrogen sulphide under similar conditions. Yet phosphorus pentasulphide or boiling sodium sulphide solution dehydrates the dioximes to the corresponding oxadiazoles. Only dimethylglyoxime has been isolated from the action of potassium sulphide on diacetyldimethylglyoxime in boiling alcohol[10].

It seemed obvious that difficultly accessible alkenediamines would be necessary for the synthesis of monocyclic 1,2,5-thiadiazoles by treatment with thionyl chloride. This was confirmed by the synthesis of the 3,4-dicyanothiadiazole from thionyl chloride and the tetramer of hydrogen cyanide[10]†, and of the selenium analogue by conducting the reaction with selenium dioxide[10]:



Drawing a further analogy with the synthesis of pyrazine derivatives, Collins and other workers[12-15] obtained hydroxy-derivatives of 1,2,5-thiadiazole from amides of α-amino-acids or their nitriles‡:

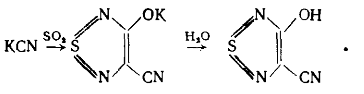


The cyclising agents used were thionyl chloride[14], sulphinylaniline[15], and sulphur monochloride[17]. Use of the *NN*-diphenylamide of sulphurous acid in a nitrogen atmosphere has been claimed[14] instead of thionyl chloride. Weinstock and his coworkers have established[16,17] that 1,2,5-thiadiazole and its derivatives are easily formed by reaction between sulphur monochloride and aliphatic compounds containing an N–C–C–N chain. Sulphur dichloride has also been employed in this reaction[18-20]. Sulphur dibromide yields bromo-derivatives of thiadiazole[18].

Thiadiazole derivatives have been obtained also by the action of sulphur dichloride on diethyloxalimide[21] or cyanogen[22].

The synthesis from sulphur nitride S_4N_4 and aliphatic compounds is of theoretical interest[23,24].

A fundamentally different method is the reaction between potassium cyanide and sulphur dioxide[19,25-28]:



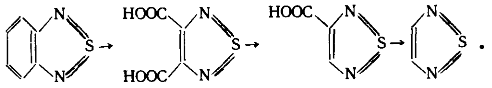
---

†Replacement of thionyl chloride by glyoxal yielded 2,3-dicyanopyrazine[11].

‡Replacement of thionyl chloride by a 1,2-diketone gave hydroxypyrazines[16].

1,2,5-Selenadiazole, unknown until recently, has been obtained by the reaction between ethylenediamine and selenium monochloride [29,30,32]. Higher yields of this compound and its mono- and di-methylated derivatives have been synthesised from ethylenediamine (or propylenediamine), dimethylglyoxime, and selenium dioxide [30-32].

A method of obtaining monocyclic 1,2,5-thiadiazoles and 1,2,5-selenadiazoles which is of practical importance is the degradation of fused ring systems incorporating these heterocycles. In benzo-1,2,5-thiadiazole (I) the benzene ring is less resistant than the thiadiazole ring to the action of oxidants. This permits the oxidative cleavage of (I) to 1,2,5-thiadiazole-3,4-dicarboxylic acid, which is converted by successive decarboxylation into the monocarboxy-acid and then into unsubstituted 1,2,5-thiadiazole [9,10,33-40]:



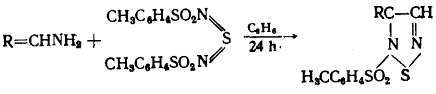
(I)

The pyrimidine ring in pyrimido-1,2,5-thia(and selena)-diazoles is readily cleaved by basic or acidic reagents under mild conditions [41-46], with the formation of various derivatives of 4-amino-1,2,5-thia(or selena)diazole-3-carboxylic acid.

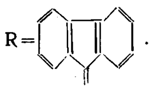
Hydrogenated 1,2,5-thiadiazoles. Michaelis [47] and more recently Shew [10] made unsuccessful attempts to obtain di- and tetra-hydro-1,2,5-thiadiazoles by treating ethylenediamine and its *NN'*-diethoxycarbonyl derivative with thionyl chloride; indeterminate results were obtained by the action of thionyl chloride on *NN'*-diethoxycarbonyl- and -dibenzoyl-vinylenediamines under various conditions [10].

1,2,5-Thiadiazolidines are obtained by treating ethylenediamines with sulphur dichloride [48]. According to Peyron [49] such thiadiazolidines and also benzothiadiazolines can be obtained by the successive action of chlorine and sodium sulphide on *NN'*-diacylethylenediamines or *NN'*-diacyl-*o*-phenylenediamines. Attempts to reproduce this synthesis and also to obtain similar heterocycles by treating dipotassium ethylenediamine-*NN'*-ditoluene-*p*-sulphonate with sulphur monochloride, sulphur dichloride, or thionyl chloride were also unsuccessful [9].

A synthesis of 1,2,5-thiadiazolines by the cycloaddition of alkeneamines to "sulphodi-imides" has been described recently [50]: e.g.

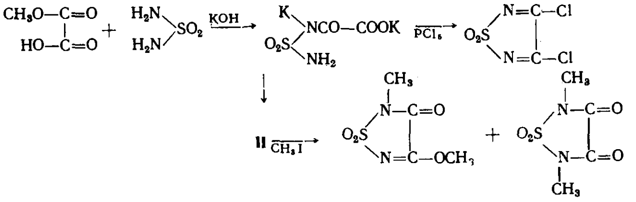


where



1,2,5-Thiadiazolidine 1,1-dioxide ("ethylenesulphamide") has been synthesised in good yield from ethylenediamine and sulphuric diamide under various conditions [51,52]. Dehydro-derivatives of this compound have been obtained by the reaction of sulphuric diamide with α-dicarbonyl compounds [53-57].

Wen [21], studying the structure of a product of the oxidation of benzo-1,2,5-thiadiazole by potassium permanganate, obtained the dipotassium salt of *N*-sulphamoyloxamic acid by the reaction of sulphuric diamide with methyl oxalate in the presence of caustic potash, and from it the disilver salt (II). He obtained two isomeric thiadiazolidine dioxides by the action of methyl iodide on this latter salt. With phosphorus pentachloride the dipotassium salt gave 3,4-dichloro-1,2,5-thiadiazole 1,1-dioxide, in which the chlorine atoms were so labile that they could easily be replaced by amino- and alkoxy-groups by known methods.



2. Properties

1,2,5-Thiadiazole (m.p. −50.1°, b.p. 94°C) is distinguished by great thermal stability (it remains unchanged when heated to 360°C [1,19]), and resists the action of acids, alkalis, and oxidants, but not reductants. It is an extremely weak base, its salts being easily hydrolysed by water [35]. The hydrochloride, nitrate, and picrate cannot be prepared; the sulphate and chlorate are extremely unstable [35]. It forms complex compounds with mercury chloride and silver nitrate [35] (analogy with pyrazine) [58].

1,2,5-Thiadiazole is extremely inert to electrophilic substitution and addition. It does not react with bromine either on irradiation or in the presence of iron(III) bromide [9,10]. It does not undergo the Friedel–Crafts reaction§.

Deuterium exchange takes place only in the presence of heavy-metal salts, but the ring then undergoes reductive cleavage with the evolution of hydrogen sulphide. Deuteration has been achieved by means of orthophosphoric acid under extremely severe conditions (in sealed tubes at 250°C for 37 h [35]). Deuteration has been effected also by decarboxylating mono- and di-carboxylic acids of 1,2,5-thiadiazole in which the carboxy-groups has previously been deuterated.

Nucleophilic substitution, on the other hand, takes place quite easily. For example, 1,2,5-thiadiazole itself is immediately aminated by sodamide. 3-Amino-1,2,5-thiadiazole has been obtained also by a different method [13,59].

The above results indicate the electron-acceptor character of the heterocycle, which is confirmed by various reactions of 1,2,5-thiadiazole derivatives. For example, the 3-methyl compound reacts similarly to 2-methyl- and 2,5-dimethyl-pyrazines with *p*-dimethylaminobenzaldehyde [60]. A 3-chloro-substituent is highly labile, and has enabled 3-sulphanilamido-derivatives to be prepared [18,61,62]. A 3-hydroxy-group has a well developed phenolic character [15], and 3-cyano-4-hydroxy-1,2,5-thiadiazole is a stronger acid than acetic [19]. They form salts with lithium, copper, and silver. These compounds are not acylated by acetic anhydride, benzoyl chloride, or toluene-*p*-sulphonyl chloride; nor can the hydroxyl be replaced by a mercapto-group or chlorine [15,19].

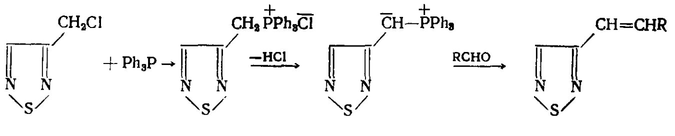
The electron-acceptor influence of the thiadiazole ring is especially clearly developed in the inertness of chlorine

---

§However, 3-amino-1,2,5-thiadiazole undergoes halogenation in acetic acid at 20°C. [278] (Note added in proof.)

in chloromethyl and 1′-chloroethyl derivatives. These compounds do not react with aqueous silver nitrate even on boiling. On the other hand, 3-α-chlorobenzyl-1,2,5-thiadiazole yields a precipitate of silver chloride and the corresponding carbinol even when shaken in the cold[60]. In this case the intermediate carbonium cation is probably stabilised by interaction with the π-electron cloud of the benzene ring. This effect is prevented in the first two cases by the acceptor influence of the heterocycle.

It has recently proved possible[63] to detach chlorine from chloromethylthiadiazole by the action of a stronger nucleophilic reagent—triphenylphosphine:



where R = Ar, Het.

Many papers have been published on reactions, in which the ring is preserved, of 1,2,5-thia- and -selena-diazole derivatives containing various substituents in the side-chain[10,13,19,21,25,26,35-39,42,43,59-66]. In fused benzo-systems the thiadiazole ring is stable to the action of oxidising agents[9,10,21,33,34,36-40,67], but the heterocyclic ring may, depending on the conditions, be cleaved on oxidation with permanganate[9,10,19,21,25,33-40]. One of the products of the oxidation of benzo-1,2,5-thiadiazole with permanganate has a cyclic structure according to Shew[10], whereas Wen[21] has attributed the acyclic structure KOOC.CO.NK.SO_2NH_2 to the same compound. Ross[19] assumes that both compounds are formed by permanganate oxidation.

The thiadiazole ring is not stable towards reducing agents. Either reductive cleavage occurs or else the ring is not affected at all depending on the derivatives, the reductant, and the conditions. For example, 1,2,5-thiadiazole-3,4-dicarboxylic acid remains unchanged on hydrogenation (with palladium–carbon)[37]; 3-hydroxy-1,2,5-thiadiazole, when boiled with 50% alcohol in the presence of Raney nickel, undergoes fission with the formation of diethylaminoacetamide[19]. 3-Cyano-4-hydroxy-1,2,5-thiadiazole is only partly cleaved by sodium in alcohol (hydrogen sulphide is evolved), and is unaffected by sodium tetrahydroborate[19]. Other examples are known in which the thiadiazole ring is stable towards reduction by metal hydrides[60]. The thiadiazole ring is cleaved by sodium hydrogen sulphite, which readily attacks electron-deficient carbon atoms[25].

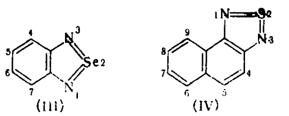
1,2,5-Selenadiazole and its methyl derivatives are cleaved by hydrogen sulphide[30,31], being reduced to the corresponding alkylenediamines and elementary selenium. 1,2,5-Selenadiazole is unaffected by treatment either with 14% NaOD in D_2O (at 60°C for 5 days) or 15% D_2SO_4 in D_2O (at 50°C for 40 min). Alkaline or ammoniacal hydrogen sulphide solution converts 3,4-dimethylselenadiazole into tetramethylpyrazine. 3,4-Diphenylselenadiazole is stable to the action of hydrogen sulphide; with sodium in alcohol it undergoes reductive cleavage to form 1,2-diphenylethylenediamine[32].

III. BENZO-1,2,5-THIADIAZOLES AND BENZO-1,2,5-SELENADIAZOLES

Many systems are now known in which these heterocycles are fused to other rings. The benzo-ring systems have been most thoroughly investigated, and the pyrimido- and naphtho-derivatives to a less extent.

1. Synthesis

The main method for synthesising benzo-1,2,5-thiadiazole (I) and benzo-1,2,5-selenadiazole (III) derivatives is the cyclisation of *o*-diamines. It was in this way that Hinsberg[1-4] first obtained (I), (III), and naphtho[1,2-*c*]-[1,2,5]-thiadiazole (IV) by treating *o*-phenylenediamines and 1,2-naphthylenediamines with concentrated sulphurous acid or with sodium hydrogen sulphite (in sealed tubes at 180–200°C for 8 h). Study of Hinsberg's reaction has shown that it can be conducted under milder conditions: several derivatives of (I) have been obtained in yields up to 40% by passing sulphur dioxide into solutions of *o*-diamines in dimethylformamide[68].



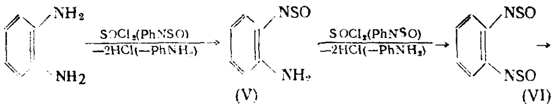
Weinstock[9] synthesised (I) in ~60% yield by heating *o*-phenylenediamine with sodium metabisulphite in ethylene glycol at 140°C for 6 h. It has been shown recently[69,70] that benzo- and naphtho-1,2,5-thiadiazoles are formed in almost theoretical yields when sulphur dioxide is passed into solutions of *o*-diamines in dichloromethane with triethylamine as catalyst.

Michaelis and his coworkers[71,72] used thionyl chloride as cyclising agent. When pyridine or triethylamine is present to combine with the hydrogen chloride formed, the reaction takes place rapidly (within a few minutes instead of many hours) and with almost quantitative yields[73-75].

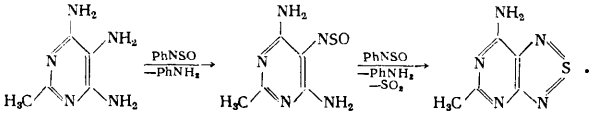
These results disprove the statement[76,77] that 4-nitro-1,2-phenylenediamine is less active than the 3-nitro-isomer in forming a thiadiazole ring.

Since thionyl chloride cannot be used for the cyclisation of *o*-diamines in which the benzene ring is substituted by hydroxyl, carboxyl, sulpho, and other groups, a study has been made of the reaction of diamines with sulphinylaniline[73-75,78,79], which Michaelis[71] had used for the preparation of (I). This reaction takes place exceptionally easily with various aromatic and heterocyclic diamines and their salts, in almost theoretical yield.

With both thionyl chloride and sulphinylaniline the reaction involves the intermediate formation of *o*-sulphinylaminoaniline (V) and *NN′*-disulphinyl-*o*-phenylenediamine (VI):[9,80]

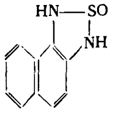


From the products of the reaction of 4,5,6-triamino-2-methylpyrimidine with sulphinylaniline Shealy and Clyton[81] isolated 4,6-diamino-2-methyl-5-sulphinylaminopyrimidine, which is converted by sulphinylaniline into 7-amino-5-methylpyrimidothiadiazole:

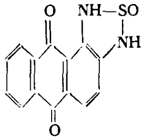


Beecken[70] has shown that *o*-arylenediamines and 1,2-naphthylenediamine react with sulphinylaniline to give high yields of the corresponding *o*-disulphinylamines.

The use of *p*-sulphinyltoluenesulphonamide instead of sulphinylaniline produces a similar effect[82].



(VII)

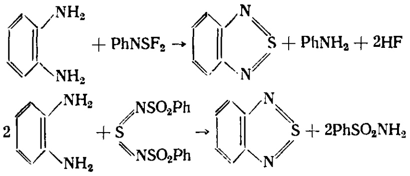


(VIII)

Dietz[83] isolated the sulphurous diamide (VII) from the products obtained by the reaction of 1,2-naphthylenediamine with sulphinylaniline. It has recently been shown[84] that the action of alkali on 6,11-dihydro-6,11-dioxoanthra[1,2-*c*]-[1,2,5]-thiadiazole at 20°C yields the analogous diamide (VIII), which, depending on the experimental conditions, can be converted into the original thiadiazole, into the *o*-diamine, or into a mixture of the two.

Thus the mechanism of the formation of (I) from *o*-arylenediamines and thionyl chloride involves the intermediate formation of an *o*-sulphinylaminoarylamine, an *o*-disulphinylaminoarene, and a cyclic sulphurous diamide.

Benzothiadiazole (I) is formed also by the use of "sulphinylaniline difluoride"[85] or *NN'*-diphenylsulphonyl-"sulphur di-imide":[86]



Derivatives of (I) are obtained by the action of sulphur monochloride on *o*-phenylenediamines or *o*-nitroanilines[87].

Schrage and Hitchings[88] obtained 7-amino-5-chloropyrimido[4,5-*c*]-[1,2,5]-thiadiazole by the action of sulphuryl chloride on 4,5,6-triamino-2-methylthiopyrimidine, but the reaction was complicated by several side-reactions. A method consisting in fusing 4-amino-5-nitrosopyrimidines with thiourea, which yields pyrimido-1,2,5-thiadiazoles, is of theoretical interest[89]. These compounds can also be synthesised[90-92] from *o*-aminonitrosopyrimidines and sodium thiosulphate.

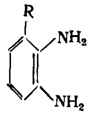
A fundamentally new method was proposed by Weinstock[9]: he synthesised naphtho-1,2,5-thiadiazole by the action of sulphur nitride S_4N_4 on 1- or 2-naphthylamine. 1,8-Naphthylenediamine yields 9-aminonaphthothiadiazole. Attempts to extend this method to aniline and other amines were unsuccessful.

Benzo-1,2,5-thiadiazole oxide was presumably obtained by the action of sulphur dichloride on *o*-benzoquinone dioxime[93]; however, it could not be obtained by treating the latter or benzofuroxan with hydrogen sulphide, sulphinylaniline, or phosphorus pentasulphide[8,93]. Unsuccessful attempts have been made[3,8,93] to replace oxygen in benzo- and naphtho-furazans by sulphur by means of various sulphurising agents.

A general method for obtaining the selenium analogues is to treat *o*-diamines with selenium dioxide[1,4,94-99]. Since this reaction takes place readily and also gives high yields, it can be used for the identification of *o*-diamines[94,99].

2. Properties

Synthesis of the polycyclic derivatives (I) and (III) from *o*-diamines is restricted by the relative inaccessibility of the latter. The preparation of many of them, in particular 1,2,3-derivatives of the type



(IX)

presents considerable difficulties. Therefore substitution in (I) and (III) is of considerable interest for preparation purposes.

(*a*) Electrophilic Substitution

Nitration. Benzothiadiazole can be nitrated as readily as can benzene (with nitric acid of density 1.35 at 0°C) to give a 95% yield of 4-nitrobenzothiadiazole[75,100,101].

The fact that the nitro-group enters the 4-position shows that the greatest electron density is located on carbon atom 4(7) and that the electron cloud is drawn towards the heterocycle. However, the acceptor effect of the latter is relatively small, since it hardly impedes the reaction at all, and is shown only in the orientation of the nitro-group [position 5(6) is less reactive]. But even this effect is considerably weakened or completely absent in the nitration of derivatives of (I) containing donor substituents (methyl, methoxy, hydroxy) at position 4.

The nitration of 5-methylbenzothiadiazole gives 94% yield of the 4-nitro-derivative. Under similar conditions 4-methylbenzothiadiazole yields a mixture of the 5- and 7-nitro-derivatives in the proportions 35 : 65,[98,102] which indicates that the influence of the methyl group predominates over that of the heterocycle. Similar proportions of *ortho* and *para* substitutions (but with the *ortho*-isomer predominating) are observed in the nitration of toluene.

The presence of two methyl groups—at positions 5 and 6—has little effect on the direction of nitration by a nitrating mixture: the 4-nitro-derivative is formed exclusively, and is converted into the 4,7-dinitro-compound on further nitration with a mixture of sodium nitrate and sulphuric acid. It is also formed in 96% yield directly from 5,6-dimethylbenzothiadiazole[103,104].

4-Acetamidobenzothiadiazole, as well as its 5(6)-mono- and 5,6-di-methyl derivatives, is easily nitrated at position 7; 5-acetamidobenzothiadiazole is readily nitrated at position 4.[105]

Stronger electron donors, such as alkoxyl and hydroxyl, weaken the influence of the heterocycle on the orientation of nitration[102,106]. Thus 4-ethoxybenzothiadiazole yields equal quantities of the 5- and 7-nitro-derivatives, which indicates that in this case these positions in the benzene ring have closely similar electron densities. On nitration with excess of nitric acid the reaction product is the 4-ethoxy-5,7-dinitro-derivative (in almost quantitative yield).

Under these conditions 4-hydroxybenzothiadiazole gives only the 5-nitro-derivative (in 95% yield), which on subsequent nitration is converted into the 5,7-dinitro-compound. Hence a 4-hydroxy-group completely suppresses the electron-acceptor effect of the thiadiazole ring and produces maximum electron density at position 5.

The nitration of 5-hydroxy- and 5-ethoxy-benzothiadiazole gives almost quantitative yields of the corresponding 4-nitro-derivatives[106,107]. In the case of the 4-hydroxy-5-methyl compound nitration yields the 7-nitro-derivative exclusively[108].

Bromomethyl derivatives of (I) are more difficult to nitrate[109]. Under the usual conditions for the nitration of aromatic compounds 5-bromomethylbenzothiadiazole gives a 58% yield of the 4-nitro-compound; a quantitative yield of this compound can be obtained by using fuming nitric acid. Under these conditions the 4-bromomethyl derivative is nitrated at position 7 in almost quantitative yield. A 4-cyanomethyl group exerts an analogous orientating effect[109]. The presence of chlorine atoms in the side-chain of toluene has a similar retarding influence on nitration.

In the nitration of a 4-halogenobenzothiadiazole the nitro-group goes mainly to position 7. Only the use of more severe conditions (a mixture of sodium nitrate and sulphuric acid at 100°C) makes it possible to obtain the 5,7-dinitro-derivatives[104,110]. The 5-halogeno-derivatives are nitrated at position 4, and the 4,6-dihalogeno-compounds at position 7. Both mononitro-products undergo further nitration by a mixture of sodium nitrate and sulphuric acid to the 4,7- and 5,7-dinitro-compounds respectively. The 7-nitro-derivative is obtained from a 4-halogeno-5-methyl compound[104,111].

The accumulation of halogen substituents in the benzene ring of (I) strongly deactivates it to attack by the nitronium cation. The 4,5- and 4,7-dihalogeno-compounds are nitrated at positions 7 and 5 respectively with comparative difficulty, especially in the latter case. When the 4,5,7-trihalogeno-compounds are nitrated under similar conditions, the nitro-group enters the vacant 6-position. Depending on the nitrating agent the 5,6-dihalogeno-compounds yield either 4-mono- or 4,7-di-nitro-derivatives[103,104,112,113]. Two nitro-groups can be introduced into the *ortho* (5,6) positions by the action of sodium nitrate in sulphuric acid on 4-halogeno-7-methyl compounds. Under similar conditions 4- and 5-nitrobenzothiadiazoles are converted into the same 4,6-dinitro-derivative.

Both 5-methyl-4-nitro- and 5-methyl-6-nitro-derivatives are nitrated to the 4,6-dinitro-compound. The 4-methyl-5-nitro- and 4-methyl-7-nitro-isomers are likewise nitrated to the 5,7-dinitro-product[98,102].

Benzo-1,2,5-selenadiazole (III) and its many derivatives are easily nitrated under the usual conditions for aromatic compounds, the yields being high and often close to theoretical[97,98,102,114-120]. Substitution is oriented in the same way as in the corresponding thia-analogues. Nitration of unsubstituted (III) gives a 98% yield of the 4-nitro-derivative[115]. A 97% yield of a mixture of the isomeric 5- and 7-nitro-derivatives in the proportions 45 : 55 is formed from the 4-methyl compound. With identical substituents in positions 5 and 6, a mixture of sodium nitrate and sulphuric acid, depending on the nature of the substituents, either gives mono- or di-nitrobenzoselenadiazole or does not nitrate the compound at all (as e.g. in the case of the 5,6-dinitro-compound).[120]

All the nitrobenzothiadiazoles and nitrobenzoselenadiazoles obtained can be reduced to the corresponding amines, which appear in high yields in the former case[98,103,104,106,110,111,121], but in considerably lower yields in the latter case[98,115,122], owing to the lower resistance of the selenadiazole ring to the action of reducing agents (e.g. degradation under the influence of hydriodic acid[123]).

Sawicki and Carr[114] showed that the nitro-group in 5-methyl-4-nitrobenzoselendaiazole activates the adjacent methyl group, which is evident in the condensation of the latter with benzaldehydes.

Nitrosation. Like 1- and 2-naphthols, 4- and 5-hydroxybenzothiazoles are easily nitrosated, the nitroso-group entering positions 5 and 4 respectively[106,107]. The 4-hydroxy-5-methyl compound is nitrosated at position 7. Thus the nitrosation of hydroxy-derivatives of (I) proceeds similarly to their nitration[106]. From a study of the nitrosation of 5-hydroxybenzothiazole Efros and his coworkers concluded[96] that the nitroso-group in the 5-hydroxy-4-nitroso-derivative possesses no hydroxyimino-function. This conclusion is inconsistent with the behaviour of the 4-hydroxy-5-nitroso- and 5-hydroxy-4-nitroso-derivatives under the conditions of the Bucherer reaction[124], which indicates that these compounds can exist in the tautomeric quinone oxime form. The hydroxynitroso-derivatives of (I) are easily reduced to the amines[107,124].

Azo-coupling. The 4- and 5-amino- and 4- and 5-hydroxy-derivatives of benzothiazole are readily coupled with diazonium salts to form the 7- and 4-azo-derivatives respectively[90,105,122,125-127]. If position 7 in the 4-hydroxy-derivative is occupied by methyl or methoxyl, the azo-group enters position 5.[127,128] This is the way in which azo-coupling occurs in the naphthalene series.

Halogenation. Chlorination and bromination in the benzothiadiazole series do not always take place in the same way, which can be explained only by the difference in the nature of the halogens. The catalytic effect of heterolysis of the interatomic bond in the molecule is less necessary for bromine than for chlorine. This is evident in the fact that, in the bromination of benzothiadiazole, electrophilic substitution takes place equally readily in the presence and in the absence of a catalyst. Bromine differs from chlorine in showing no tendency to add to benzothiadiazoles [except in the bromination of (I) itself].

Catalysed chlorination of benzo-1,2,5-thiadiazoles[110,111,131-135]. The chlorination of (I) was first studied by Efros and his coworkers[76], who concluded that this compound was incapable of addition and that no reaction took place in the absence of a catalyst. They reported also that benzothiadiazole is chlorinated in the presence of iron to the 4,7-dichloro-derivative having m.p. 57.5°C. These data were later found to be incorrect[129,130], when a 91% yield of this compound was obtained with m.p. 182°C. Further rise in temperature to 190–200°C yields successively 4,5,7-trichloro- and 4,5,6,7-tetrachloro-benzothiadiazole. Under similar conditions the 4,7-dibromo-compound is chlorinated to the 4,7-dibromo-5,6-dichloro-derivative[112].

Methyl group present at positions 4 and 5 have hardly any effect on the direction of the chlorination of melts in the presence of iron, when di- and tri-chlorinated derivatives are mainly formed. Only from the 4-methyl compound is it possible to isolate the 7-monochloro-derivative. The coincident orientating effects of heterocycle and substituents in 5,6-dimethylbenzothiadiazole result in the occurrence of chlorination under milder conditions (not only in the melt but also in acetic acid), with the formation mainly of the 4,7-dichloro-derivative. In acetic acid 4,5,6,7-tetrachlorotetrahydrobenzothiadiazole has also been isolated.

If an electron-withdrawing substituent (nitro, sulpho) is present at position 4 in benzothiadiazole, its strong deactivation of the benzene ring probably results initially in its displacement by chlorine, after which catalytic chlorination takes place in the usual way[134]. These substituents are also readily replaced by chlorine under similar conditions in nitro- and sulpho-derivatives of naphthalene and benzene.

5-Nitrobenzothiadiazole is catalytically chlorinated at position 7, as a consequence of concerted orientation by the heterocycle and by the nitro-group [134].

Uncatalysed chlorination of benzo-1,2,5-thiadiazoles. Like naphthalene, benzo-1,2,5-thiadiazole is chlorinated exothermically in chloroform, carbon tetrachloride, or dichloroethane at 60°C or in the melt at 80–90°C, four chlorine atoms being added. Alcoholic alkali eliminates two molecules of hydrogen chloride from the adduct with the formation of 4,7-dichlorobenzothiadiazole [112,129,130]. In acetic acid, chlorination gives a mixture of the tetrachloro-adduct and the substituted 4,7-dichloro-derivative. The latter is the sole product if chlorination is conducted in formic acid [133].

Neither a 4- or 5-methyl group, a 4-ethyl group, nor a 5-methoxy-group prevents the addition of four chlorine atoms under the conditions given above for (I). Alcoholic alkali splits off hydrogen chloride from the tetrachloro-adducts, converting them respectively into 4,6-dichloro-7-methyl (or ethyl)- and 4,7-dichloro-5-methyl (or methoxy)-benzothiadiazole [98,112,113]. The chlorination of 4- and 5-methylbenzothiazole in acetic acid yields in both cases a mixture of the tetrachloro-adduct and a monosubstituted product (at positions 7 and 4 respectively). Only monosubstitution takes place in formic acid.

The action of excess of sulphuryl chloride on 4- and 5-methylbenzothiadiazole yields only the corresponding 7- and 4-monochlorinated compounds. Nor do two methyl groups at positions 5 and 6 have any significant effect on the direction of chlorination [133], which occurs similarly to that of monomethyl derivatives. In the melt four chlorine atoms are added, but in acetic acid a mixture of this adduct and the dichlorinated dimethyl compound is formed.

The presence of amino, hydroxyl, and alkoxycarbonyl groups activates (I) towards chlorinating agents [78,79,111,136,137], and the reactions occur under milder conditions. The action of chloramine or sulphuryl chloride in chloroform or in acetic acid on 5-hydroxy- or 5-amino-benzothiadiazole results in the entry of chlorine at position 4. Chlorination of 4-amino-, 4-hydroxy-, and 4-methoxycarbonyl-benzothiadiazole under the same conditions yields 5,7-dichlorobenzothiadiazole: it proves impossible to limit the process to monochlorination.

Thus the heterocycle does not influence the direction of the chlorination of (I), substituents in the benzene ring being of decisive importance. The activating effect of substituents on position 5 falls in conformity with the decrease in nucleophilic character in the sequence $NH_2 > OH \gg CH_3$.

Bromination of benzo-1,2,5-thiadiazoles. Bromination results *only* in substitution, independently of the presence or the absence of a catalyst (contrast to chlorination). This can be explained by the different characters of these halogens.

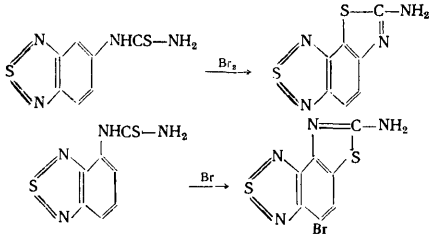
The action of excess of bromine on molten benzothiadiazole in the presence of reduced iron yields almost exclusively the 4,7-dibromo-derivative. With an equimolecular quantity of bromine under the same conditions about half the initial compound remains unchanged, and the above dibromo-derivative is accompanied by a minute amount of 4-bromobenzothiadiazole [131]. As with chlorination, the process cannot in practice be limited to monosubstitution.

In the absence of a catalyst four bromine atoms are added [112,129,130]. Subsequent treatment with alcoholic alkali yields 4,7-dibromobenzothiadiazole.

Bromination is considerably facilitated by the presence of methyl, hydroxyl, or an amino-group. The 4- and 5-methyl derivatives are brominated in the melt: the former at position 7 and in the side-chain (homolytically), and the latter to 4,7-dibromobenzothiadiazole [98]. When the reaction is conducted in the presence of reduced iron, only substitution in the benzene ring takes place, with the formation respectively of the 7-bromo- and the 4,7-dibromo derivatives [131-133].

Molten 5,6-dimethylbenzothiadiazole is brominated quantitatively to the 4,7-dibromo-derivative. In acetic-acid solution either the same product or the 4-monobromo-derivative is obtained depending on the quantity of bromine [133]. The latter product is formed also by replacing the amino-group in the 4-amino-5,6-dimethyl derivative by means of the Sandmeyer reaction. Amino-, hydroxy-, and methoxycarbonyl-benzothiadiazoles are brominated with the same orientation as in chlorination [78,78,111,136,137]. The thiocyanation of 4- and 5-amino-derivatives occurs similarly [78,79,131].

Acylated amines of (I) are brominated similarly to the amino-derivatives. The bromination of 5-thioureidobenzothiadiazole in chloroform yields 7-aminothiazolo-[5,4-*d*]benzothiadiazole; however, bromination of the isomeric 4-thioureido-compound under similar conditions results in cyclisation accompanied by the entry of bromine into the benzene ring [78,79,131].



5-Bromo- and 4,6-dibromo-benzothiadiazoles are brominated to the 4,5,7-tribromo-derivative [132]. 4- and 5-Nitrobenzothiadiazoles do not react with boiling bromine in the presence of iron.

Halogenation of benzo-1,2,5-selenadiazoles. Substitution alone occurs in the chlorination of benzo-1,2,5-selenadiazole, with formation of the 4,5,6,7-tetrachloro-derivative [98]. The 4-methyl compound, molten or dissolved in carbon tetrachloride, dichloroethane, or acetic acid, is chlorinated at position 7; in formic acid the 5,7-dichloro-derivative is also obtained. The 5-methyl compound is converted into the 4-chloro-, 4,7-dichloro-, and 4,6,7-trichloro-derivatives respectively in carbon tetrachloride, dichloroethane, or acetic acid, in the melt, and in formic acid. Sulphuryl chloride in carbon tetrachloride converts the 4- and 5-methyl compounds into the 7- and 4-chloro-derivatives respectively. The chlorination of benzoselenadiazole in the presence of silver sulphate in concentrated sulphuric acid yields a mixture of the 4-chloro- and 4,7-dichloro-derivatives [119]. The latter compound is formed also from the 4-chloro-derivative under similar conditions; 5-chlorobenzoselenadiazole gives the 4,5-dichloro-derivative [119].

Thus, in contrast to the thia-analogues, benzoselenadiazole is unable to add chlorine. In its derivatives, also, the reactivities of positions 4–7 are more alike than in the thia-analogues, in which substitution takes place preferentially at positions 4 and 7. All this provides evidence of the more aromatic character of (III) compared with (I), probably resulting from the better ability of selenium than of sulphur to transmit conjugation.

As with chlorination, bromination produces only substitution in the benzene ring of (III).[98,119] In the presence of silver sulphate in concentrated sulphuric acid the 4,7-dibromo-derivative is formed[119]. The action of bromine on the molten 4- and 5-methyl compounds produces resinification[98]. In acetic acid the 4-bromo-7-methyl and the 4-bromo-5-methyl and 4,7-dibromo-5-methyl derivatives are formed respectively[98].

In the presence of silver sulphate in concentrated sulphuric acid, crystalline iodine acts on benzoselenadiazole to give a low yield of a mixture of the 4-iodo- and 4,7-di-iodo-derivatives[119].

Sulphonation. Benzo-1,2,5-thiadiazoles are more difficult than naphthalenes to sulphonate. Under sufficiently severe conditions (17% oleum at 150°C for 1 h) a 78% yield of the 4-sulphonic acid is obtained from (I).[76,138,139] The use of 22% oleum raises the yield to 90%, when a minute amount of the 4,7-disulphonic acid also separates[140]. Under similar conditions benzo-1,2,5-selenadiazole gives an 83% yield of its 4-sulphonic acid[119] (or a 71.5% [141]). The isomeric 5-sulphonic acid of (III) is obtained[140] by the Hinsberg reaction[4].

4- and 5-Methylbenzothiadiazoles are sulphonated more easily (with 20% oleum at 110°C for 2 h), high yields of the 7- and 4-sulphonic acids respectively being obtained[142]. The use of chlorosulphuric acid instead of oleum gives the corresponding sulphonyl chlorides. The 4-sulphonyl chloride can also be obtained directly from benzothiadiazole and chlorosulphuric acid (in the presence of thionyl chloride[143]) or by the action of phosphoryl chloride on the corresponding sulphonic acid[135,136].

Hydroxy- and amino-benzothiadiazoles are sulphonated under milder conditions. Only the 5,7-disulphonic acids are formed by the 4-hydroxy- and 4-amino-derivatives[138,139].

Thus in the presence of an active electron donor position 5 readily undergoes electrophilic attack, as is observed in halogenation and nitration. No influence of the heterocycle is apparent.

On chlorination sulpho-groups in benzothiadiazoles are replaced by chlorine. Bromination of 5-hydroxybenzothiadiazole-4-sulphonic acid yields the 4-bromo-5-hydroxy-derivative. Benzothiadiazole-4-sulphonic acid can also be converted into the 4-chloro-derivative under similar conditions, but the yield does not exceed 5–8% owing to oxidative degradation[141]. In this respect the properties of naphthalenesulphonic acids are repeated by sulphonic acids both of benzothiadiazoles and of benzoselenadiazoles.

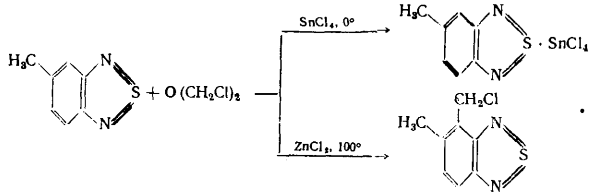
(*b*) Alkylation and Acylation at Carbon and Nitrogen

Chloromethylation. Conditions usual in the aromatic series have been applied to study the chloromethylation of benzothiadiazole and its derivatives. Attempts to chloromethylate (I) itself by the combined action of hydrogen chloride, paraformaldehyde, and zinc chloride were unsuccessful[144,145]. Negative results were obtained also when bischloromethyl ether was used in the presence of zinc chloride hydrate[146]. Only by the action of bischloromethyl ether in the presence of aluminium chloride[147,148] has it been possible to obtain 4,7-bischloromethylbenzothiadiazole (in 76% yield). The process cannot be restricted to monosubstitution even when a double excess of benzothiadiazole is used[147,148].

Chloromethylation does not take place with bischloromethyl ether in the presence of electron-donor compounds, e.g. in dimethylformamide or with a considerable excess of paraformaldehyde or hexamethylenetetramine. In the presence of a minute amount of paraformaldehyde¶ the main product is 4,7-bischloromethylbenzothiadiazole. If bischloromethyl ether prepared as in Ref. 150† is used, a mixture of the 4-chloromethyl and 4,7-bischloromethyl derivatives is formed, the ratio of which cannot be controlled[147,148,151,152].

The above results suggest that chloromethylation, in both benzothiadiazoles and aromatic compounds, is especially sensitive to the slightest changes in the reaction conditions, which cannot always be rationally taken into account.

Chloromethylation is facilitated by the introduction of an electron-donor substituent into the benzothiadiazole molecule. Thus 4- and 5-methyl compounds and the corresponding methoxy-derivatives react readily with paraformaldehyde and hydrogen chloride in the presence of zinc chloride as catalyst if the reaction is conducted in acetic acid[144]. With bischloromethyl ether the process depends[145] on the nature of the catalyst and on the temperature:



The 4-chloromethyl-5-methyl derivative is formed also with chlorosulphuric acid (at 100°C for 9 h) or aluminium chloride (at 65°C for 2 h) as catalyst, the yield being ~60%.

4-Methylbenzothiadiazole is chloromethylated at position 7 in the presence of chlorosulphuric acid, or with formation of the 5,7-disubstituted product in the presence of aluminium chloride[151]. The 5-methyl compound is chloromethylated under more severe conditions and with a lower yield than in the case of the 4-methyl compound.

Entry of a chloromethyl group is still more facilitated by the presence of a second methyl group in the benzene ring. The 4,5-dimethyl compound is chloromethylated at position 7, and the 5,6-isomer forms the 4,7-disubstituted product exclusively[135,151].

4- and 5-Chlorobenzothiadiazoles are not chloromethylated by bischloromethyl ether in the presence of chlorosulphuric acid. By using a more vigorous catalyst—aluminium chloride—it has proved possible[148] to introduce a chloromethyl group at positions 7 and 4 respectively. Nitrobenzothiadiazoles are not chloromethylated even in the presence of active catalysts under severe conditions.

When heated above 70°C with bischloromethyl ether in the presence of chlorosulphuric acid, unsubstituted benzo-1,2,5-selenadiazole is decomposed with the separation of selenium[153]. Aluminium chloride as catalyst forms a complex after 5 min, but on prolonged heating a 85–90°C small yields can be isolated of either the 4-mono- or the 4,7-bis-chloromethyl derivative depending on the extent of contamination of the initial bischloromethyl ether with paraformaldehyde[149,150].

¶Present in bischloromethyl ether prepared as in Ref. 149.

†Contaminated with a considerable quantity of paraformaldehyde.

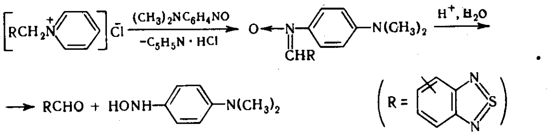
The methyl derivatives are more easily chloromethylated[153]. With bischloromethyl ether slightly contaminated with paraformaldehyde[149] 5-methylbenzoselenadiazole forms in the presence of chlorosulphuric acid the 4-chloromethyl-5-methyl compound. Under similar conditions bischloromethyl ether containing a considerable amount of paraformaldehyde gives a mixture of all three possible isomers—the 4-, 6-, and 7-chloromethyl-5-methyl derivatives (Ref. 150). The 4-methyl compound gives predominantly the 4-chloromethyl-7-methyl derivative, independently of the paraformaldehyde content of the bischloromethyl ether.

The 4- and 5-chloro-derivatives of benzoselenadiazole are more difficult to chloromethylate than are their thia-analogues under the same conditions. Processes involving degradation of the heterocycle predominate.

The chlorine in chloromethyl derivatives of benzothiadiazole and benzoselenadiazole is readily replaced by hydroxyl, alkoxyl, cyano, thiocyano, and amino: *o*- and *p*-methyl groups in chloromethylated benzothiadiazole facilitate, whereas chlorine impedes, nucleophilic substitution of the chloromethyl chlorine[140,144,145]. This shows an analogy with the behaviour of nuclear-substituted benzyl chlorides. However, the acceptor character of the heterocycle has hardly any effect.

The behaviour of chloromethylbenzothiadiazole has been studied under the conditions of the Sommelet reaction, which is employed for the synthesis of aldehydes. The acceptor influence of the heterocycle is not apparent in the preparation of the hexamethylenetetramine salt from the 4-chloromethyl-7-methyl compound. However, hydrolysis of the salt results in a low yield of the aldehyde. Similarly, the 4-formyl-5-methyl compound has been obtained in insignificant yield[144] by decomposition of the corresponding hexamethylenetetramine salt with very dilute hydrochloric acid.

Under the conditions of the Kröhnke reaction[113,147,148,154] chloromethylbenzothiadiazoles are converted fairly smoothly into aldehydes. This reaction, unlike the Sommelet reaction, is favoured by electron-accepting substituents. *p*-Nitrosodimethylaniline reacts with 1-benzothiadiazol-4′-ylmethylpyridinium chloride or the corresponding 4′,7′-dipyridinium salt in the presence of piperidine or a solution of caustic soda as catalyst to form the corresponding nitrones, acid hydrolysis of which gives high yields of 4-formyl- and 4,7-diformyl-benzothiadiazoles respectively[113,147,148]:



The resulting formyl derivatives were converted into the corresponding acids by means of hydrogen peroxide or silver oxide.

The mobility of the chlorine in a chloromethylated benzothiadiazole is unaffected by a *para*-methyl group, whereas the yield of aldehyde obtained by the Kröhnke reaction is considerably diminished by an *ortho*-methyl group, apparently because of steric hindrance. With *N*-methylformamide and phosphoryl chloride 4- and 5-methoxybenzothiadiazoles give the 4-formyl-7-methoxy- and 4-formyl-5-methoxy-derivatives respectively[144].

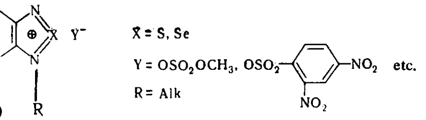
Friedel—Crafts reaction. This accompanies chloromethylation conducted in the presence of aluminium chloride, but it often plays the main part. Chloromethyl derivatives of benzothiadiazole and benzoselenadiazole do not under the Friedel–Crafts reaction with the initial heterocycles. Unsubstituted 1,2,5-thiadiazole behaves similarly in the presence of aluminium chloride[60]. This is consistent with the fact that methyl- and acetamido-benzothiadiazoles do not undergo the Friedel–Crafts reaction[151]. The probable reason is the electron-acceptor influence of the heterocycle.

Raising the temperature in the reaction of benzothiadiazole with alkyl bromides and iodides merely results in decomposition of the alkyl halides.

A relatively smooth reaction is obtained with acetic anhydride, whose interaction with aluminium chloride is not so exothermic as that of alkyl and acyl halides. This enables the process to be conducted at 130–140°C without resinification. However, the Friedel–Crafts reaction is then extremely slow[151].

Benzothiadiazole derivatives are themselves able to act as electrophilic reagents in the Friedel–Crafts reaction: e.g. benzothiadiazole-4-carbonyl chloride reacts with benzene in the presence of aluminium chloride to give an almost quantitative yield of the 4-benzoyl derivative[151].

N-Alkylation. Hinsberg[1,4] did not succeed in obtaining quaternary salts of benzothiadiazole and benzoselenadiazole, nor their 5-methyl derivatives, even by heating them with alkyl iodides at 160°C. Recently Nunn and Ralph[155] have accomplished alkylation of the unsubstituted benzo-compounds in high yields by means of dialkyl sulphates and substituted benzenesulphonates. They established that the products consisted only of mono-quaternary ammonium salts of the type



(X)

The selenadiazole ring is more easily quaternised, and the resulting adduct is more stable (e.g. to hydrolysis), than with the thia-analogue.

All the quaternary salts obtained can be converted into halides, thiocyanates, perchlorates, and other salts by double decomposition.

Quaternary salts are obtained also by the reaction between *o*-aminodiphenylamine hydrochloride and selenous acid[156].

Alkylation and acylation of amino- and hydroxy-derivatives. Hydroxylated benzothiadiazoles and benzoselenadiazoles are stronger acids than the corresponding phenols and naphthols; the amines are weaker bases than the corresponding anilines and naphthylamines. Thus the pK_a of 4- and 5-hydroxybenzothiadiazoles are 7.86 and 8.16 respectively (the corresponding value for phenol is 9.99, and those for the naphthols 9.83 and 9.91); values of pK_b for 4- and 5-aminobenzothiadiazoles and aniline are respectively 11.3 and 9.4.[76,157,158] However, this has little effect on the reactivities of the hydroxy- and amino-derivatives of benzothiadiazole and benzoselenadiazole, which are close to those of naphthols and naphthylamines‡. They undergo all the reactions characteristic of the latter, in particular diazotisation, azo-coupling, alkylation, etc.

A detailed study of the hydroxyethylation of aminobenzothiadiazoles has been made in connection with the synthesis of compounds of presumed cytotoxic activity.

---

‡Polymorphism is observed in hydroxylated benzothiadiazoles[159].

Since the mechanism of the hydroxyethylation of amines involves addition of the amine to a carbonium ion, the basic strength of the amine plays an important part in the reaction. This is less vigorous with the 4- and 5-amines than with aniline, since they are less basic, as mentioned above[76,157,158]. On treatment with oxiran in acetic acid they form only the monohydroxyethylamino-derivatives[118].

Methyl substituents *ortho* and *para* to the amino-group promote high yields of the bishydroxyethylamino-derivatives. Interchanging methyl and amino between positions 4 and 5 has no significant influence on the reaction. With the 7-methyl-4-amine, on the other hand, bishydroxyethylation can be effected only in a considerable excess of methanol, owing to the stronger interaction of the substituents[118].

4-Amino-5-methylbenzoselenadiazole undergoes this reaction under the same conditions as its thia-analogue, with the formation of bishydroxyethylated products.

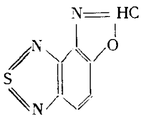
Hydroxyethylated benzothiadiazoles and benzoselenadiazoles can be converted by known methods into the corresponding chloroethylamino-derivatives. An interesting synthesis[160] is that of the thiadiazole analogue of the well known antitumorigenic preparations—*o*- and *p*-sarcolysin.

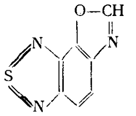
Alkylation of 4- and 5-aminobenzothiadiazoles with chloroacetic acid[161] yields the corresponding carboxymethylamino-derivatives.

On alkylation with alcohols in the presence of sulphuric acid, hydroxylated benzothiadiazoles behave like naphthols (phenols do not undergo this reaction), being converted into the corresponding alkoxy-derivatives[107], which are obtained also by alkylation with alkyl halides in the presence of alkoxides. Chloroacetic acid in the presence of alkali yields an *O*-carboxymethylated derivative. The alkylation of halogenated 4-hydroxy-derivatives with chloroacetic and with bromoacetic esters in the presence of sodium ethoxide gives 4-ethoxycarbonylmethoxy-derivatives containing halogen in the benzene ring[113,136,137].

Many studies have been made (e.g. Refs. 75, 76, 78, 79, 97, 98, 100, 101, 103, 105, 107, 108, 110, 115, 122, 134, and 162–164) of the acylation of amino- and hydroxybenzothia- and -selena-diazoles. The reactions are conducted under the usual conditions for aromatic amines and phenols, the heterocycles having no appreciable effect.

4-Amino-5-hydroxy- and 5-amino-4-hydroxy-benzothiadiazoles, like *o*-aminophenols, react with orthoformic ester to give oxazole derivatives[106,107]





.

Aminobenzothiazoles react with thiocyanic acid and with aryl isothiocyanates to form the corresponding thiourea derivatives[5,78,79,131].

Thus the substituent preferentially enters position 4(7) in electrophilic substitution of benzothiadiazoles and benzoselenadiazoles, as in the naphthalene series. The activating effect of substituents on the reactivity of position 5(6) increases regularly in the sequence—$CH_3 \ll OCH_3 < OH \leqslant NH_2$.[5] The influence of substituents on the reactivity of the benzene ring is qualitatively similar to analogous effects in the benzene series[5].

(*c*) Homolytic Substitution

Among homolytic substitutions in the benzo-1,2,5-thiadiazoles a detailed study has been made of bromination with *N*-bromosuccinimide. The latter does not act on (I) in boiling carbon tetrachloride, in dimethylformamide, or in the melt at 95–100°C.[5,161] Only aluminium chloride or 50% sulphuric acid catalyses this reaction, when the 4,7-dibromo-derivative is the main product[5,161]. On chlorination with chlorosuccinimide under similar conditions the process can be restricted to monosubstitution by using a threefold excess of benzothiadiazole (yield up to 20%[112]).

Benzene, too, is brominated by *N*-bromosuccinimide only in the presence of a Lewis acid. On the other hand, naphthalene, anthracene, and phenanthrene are brominated in carbon-tetrachloride solution in the absence of a catalyst. These comparisons indicate that benzothiadiazole is strongly aromatic in comparison with, for example, naphthalene. The isomeric 4- and 5-methylbenzothiadiazoles, like 1- and 2-methylnaphthalenes, are brominated by *N*-bromosuccinimide (in carbon tetrachloride, without a catalyst) in the side-chain[109,113,165]. Toluene is not brominated under these conditions. Chlorine in the benzene ring of (I) has no significant effect on the reaction. Under similar conditions to the above, 4,6-dichloro-7-methylbenzothiadiazole gives after 24 h 85% of the 7-bromomethylated compound[113].

The presence of a nitro-group in the benzene ring prevents homolytic bromination, which in the case of e.g. the 4-methyl-7-nitro-compound occurs only in the presence of benzoyl peroxide and under ultraviolet irradiation[109]. The isomeric 5-methyl-4-nitro-derivative is difficult to brominate under the same conditions; the presence of a brominated product has been detected only by thin-layer chromatography[166].

N-Bromosuccinimide (in carbon tetrachloride with benzoyl peroxide) smoothly brominates 4- and 5-carboxyethylbenzothiadiazoles[166] in the β-position with respect to the carboxyl, the yields being respectively 94% and 79%. The 4-chloromethyl-5-methyl compound is brominated under the same conditions as the corresponding carboxyethyl derivative, bromine entering the unsubstituted methyl group[145,151].

Bromine present in alkyl derivatives of benzothiadiazole readily undergoes nucleophilic substitution, which enables various derivatives to be obtained which are of interest for biological testing, in particular amino-acids and their *NN*-bis-2-chloroethyl derivatives[109,113,160,165,167–169].

(*d*) Nucleophilic Substitution

The thiadiazole ring, which has a weakly electron-acceptor character, favours nucleophilic substitution in a benzene ring fused to it. Nitro-derivatives of benzo-1,2,5-thiadiazole containing *ortho*- and *para*-halogen are easily substituted on treatment with nucleophilic reagents (alkoxides, amines, etc.[108,113,116,168–170]).

It is noteworthy that *o*- and *p*-halogenonitrobenzenes and 2,4-dibromonitrobenzene do not react with potassium thiocyanate under analogous conditions. This confirms the activating effect of the heterocycle in (I). The reactions of benzothiadiazole derivatives with other weak nucleophiles—ammonia, diethyl thiophosphate salts—reveal similar effects of the heterocycle[171,172].

An apparent anomaly is evident in the reaction of 4,6-dichloro-7-nitrobenzothiadiazole with ammonia in boiling ethylene glycol or in molten phenol, when only one chlorine atom is replaced by an amino-group (at position 6, *ortho* to the nitro-group). This shows the relatively weak influence of the heterocycle, which is insufficient to activate two positions in the benzene ring. For this purpose, however, it is sufficient to introduce a second nitro-group: the action of ammonia on the 4,6-dichloro-5,7-dinitro-compound yields the 4,6-diamino-derivative.

As is to be expected, the nature of the halogen which is replaced has no significant influence on the course of nucleophilic substitution in the benzo-1,2,5-thiadiazoles. No departures from the above rules are observed in the reactions of the halogeno-nitro-derivatives with other amines and hydrazines[118].

The activating effect of the heterocycle on the mobility of chlorine atoms is clearly revealed[173] by the example of 4- and 5-chlorobenzo-oxa(thia, selena)diazoles, which react with sodium methoxide in methanol at 130°C with quantitative formation of the corresponding methoxy-derivatives. The nucleophilic substitution of chlorine is a second-order reaction, the rate for the 5-chloro-derivatives increasing in the sequence—$O \gg Se > S$—and for the 4-chloro-derivatives in the sequence—$O > Se \gg S$.[173]

The thia- and selena-diazole rings have an activating influence and make the halogen mobile also in the fused pyrimido-systems[174]. Shealy and his coworkers[42-45,81] report enhanced mobility of substituents in position 7 of pyrimidothiadiazoles. An unsuccessful attempt has been reported[175] to prepare hydroxybenzothiadiazoles by alkaline fusion.

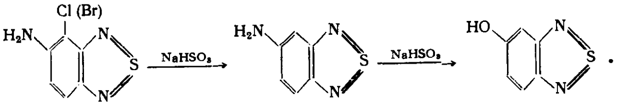
The similarity of benzothiadiazole and benzoselenadiazole to naphthalene, which is evident in several reactions, is clearly shown in the direct amination of the nitro-derivatives by hydroxylamine in alkaline medium[116,176,177]. Nitronaphthalenes undergo a similar reaction. 4- and 5-Nitrobenzo-thiadiazoles and -selenadiazoles yield the 5-amino-4-nitro- and 4-amino-5-nitro-derivatives respectively. Nitrobenzene is not aminated under these conditions, which clearly indicates the electron-acceptor character of the heterocycle. Dinitrobenzothiadiazole and also the isomeric methyl-nitro-compounds in which the position *ortho* to the nitro-group is unsubstituted undergo this reaction, but unsubstituted benzothiadiazole and benzoselenadiazole do not. The latter two compounds can be directly aminated by hydroxylamine sulphate in concentrated sulphuric acid[178].

Wen[179] found that 5-formylbenzothiadiazole reacts with nitromethane (in alkaline-alcoholic medium with subsequent acidification) to produce the 5-(1-hydroxy-2-nitro)-ethyl derivative.

(*e*) Amino- and Hydroxy-benzothiadiazoles in the Bucherer Reaction

Sodium hydrogen sulphite solution acts on 4- and 5-aminobenzothiadiazoles to form the corresponding hydroxy-derivatives in yields of 62.5% and 50% respectively. The presence of a methyl group in the benzene ring considerably diminishes the yields of hydroxy-derivatives[175,180].

Monohalogenated amino-derivatives behave differently under the conditions of the Bucherer reaction. Thus 5-amino-4-chloro(or bromo)benzothiadiazole eliminates halogen, perhaps[175] owing to its reduction:



The reverse conversion of hydroxy- into amino-compounds has been accomplished in the case of the 4- and 5-hydroxy-derivatives[124,127].

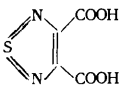
A mechanism has been suggested for the Bucherer reaction in the benzo-1,2,5-thiadiazoles which is analogous to that for naphthalene derivatives. It has been confirmed by the isolation, from the products of the reaction of isomeric hydroxy-nitroso-derivatives with sodium hydrogen sulphite, of the corresponding tetrahydro-oxonaphthalenesulphonic acids[124]. It has been stated[96] that 5-hydroxy-4-nitrosobenzothiadiazole does not react with sodium hydrogen sulphite, and hence does not undergo the Bucherer reaction.

(*f*) Oxidation of Benzothiadiazoles and Benzoselenadiazoles

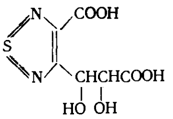
Hinsberg[1] observed that benzothiadiazole is slowly oxidised by acid potassium permanganate, but he did not isolate the oxidation products. Later he noted[67] that this heterocycle is not oxidised by 30% hydrogen peroxide in acetic acid at 100°C. It has been shown recently[113] that under these conditions the 4,6-dichloro-7-ethylthio- and -7-*p*-chlorophenylthio-derivatives are converted into 27% yields of the corresponding sulphones, the heterocycle being unaffected. Nor is benzoselenadiazole oxidised by 30% hydrogen peroxide[97] under the above[67] conditions.

Perbenzoic acid in chloroform does not oxidise benzothiadiazole. Peracetic acid completely decomposes the organic part of the molecule. This occurs also in the oxidation of the 5-methyl-, 5-chloro-, and 4,7-dichloro-derivatives, ammonium sulphate and glycollaldehyde being detected among the reaction products[33,34]. Ammonium sulphate has been isolated also from the action of hydrogen peroxide on 1,2,5-thiadiazole[9].

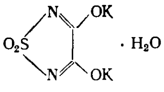
Ozonisation of benzothiadiazole yields the dialdehyde of thiadiazole, 1,2,5-thiadiazole-3,4-dicarboxylic acid (XI),[33,34] and glyoxal (analogy with naphthalene).



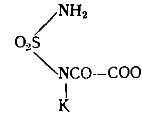
(XI)



(XII)



(XIII)



(XIV)

Among the products isolated from the oxidation of benzothiadiazole by aqueous potassium permanganate at 50–60°C were the acids (XI) and (XII) and also a compound of the presumed structure (XIII).[10,36] According to Wen[21] this compound (XIII) has the structure (XIV). His arguments suggest that this is probably closer to the truth. However, the experimental (synthetic) and spectral data which he cites are not inconsistent with the structure (XIII). The acid (XI) has been obtained also by the oxidation of 5-methyl-[37] and 4-nitro-benzothiadiazole[9] by aqueous potassium permanganate. The 4,7-dichloro-derivative is quite stable under these conditions, but is oxidised by alkaline potassium permanganate[33,34].

Benzothiadiazole and benzoselenadiazole are unaffected by a chromic mixture at 100°C. Resistance to oxidation is weakened by the presence of donor substituents in the ring. Under certain conditions it is possible to oxidise several benzothiadiazole derivatives and preserve the structure of the heterocycle. For example, the 4-amino-7-hydroxy-6-methyl and 4,7-diamino-5-methyl compounds are oxidised by a chromic mixture to the 5-methyl-4,7-dioxo-derivative of benzothiadiazole[108], which is a heterocyclic analogue of vitamin K_3.

The dibasic acid (XI) can be obtained in good yield by heating benzothiadiazole with chromium trioxide in sulphuric acid; under the same conditions benzoselenadiazole is completely decomposed[38-40]. A lower yield of

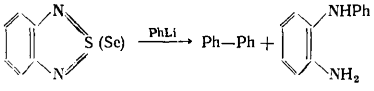
(XI) is formed by the oxidation of mono- and di-methyl derivatives of (I) under the same conditions. The oxidation of 5-bromobenzothiadiazole gives the 4,5-dibromo-derivative as well as the acid (XI). The 5-chloro-, 4,7-dichloro-, 4,7-dibromo-, 4-nitro-, and 5-nitro-derivatives are almost completely resistant to oxidation under these conditions.

The stability towards oxidising agents of benzothiadiazoles containing electron-acceptor substituents has enabled several carboxylated derivatives to be obtained[142].

Comparison of the behaviour of benzo-1,2,5-thiadiazoles and naphthalene on oxidation by chromic acid indicates that the benzene ring in the former is more stable than one of the naphthalene rings, whereas the tendency of derivatives of the latter to be oxidised to quinones is not so characteristic of compounds of the benzothiadiazole series.

(*g*) Reduction

The thiadiazole ring is extremely unstable towards reducing agents. Lane and Williams[181,182] established that phenyl-lithium reduces benzothiadiazole and benzoselenadiazole with fission of the heterocycle:



Several workers have shown[10,19,23,25,26,60] that the stability of the thiadiazole ring to the action of sodium in alcohol and also of various metal hydrides depends on the nature of the substituents in the ring. Shealy and his coworkers[42-45,81] studied the reactions of pyrimido-1,2,5-thiadiazoles, and found that both lithium tetrahydroaluminate and hydrogen sulphide reduce the heterocycle with the formation of *o*-diamines of the pyrimidine series.

The reductive cleavage of the thiadiazole ring by the action of zinc or tin in acids with the formation of aromatic or heterocyclic *o*-diamines provides a convenient method for preparing many of them, including those which are difficultly accessible by other methods[183-188].

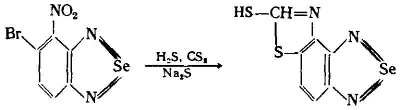
It has been established also that, in the reductive cleavage of fused thiadiazoles, the stability of the heterocycle is increased by the accumulation of chlorine atoms in the benzene ring[189]: 5 chloro- and 4,7-dichloro-benzothiadiazoles are quite stable towards sodium in boiling alcohol, whereas the unsubstituted compound and its methyl derivatives are cleaved under the same conditions[190]. Other workers have also reported that the behaviour of the heterocycle under these conditions depends on the nature of substituents in the benzene ring[19,23,25,26].

The thiadiazole ring in benzothiadiazol-5-ylacetic acid and its phenylisopropylamide[161,188] and also in chloromethylbenzothiadiazole[144] is stable to the action of sodium in alcohol and to Raney nickel.

The great stability of the thiadiazole ring to reducing conditions—in the presence of iron in 2% acetic acid, sodium dithionite, sodium hydrogen sulphide, sodium sulphide or disulphide, sodium sulphite, zinc in calcium chloride solution, ammoniacal hydrogen sulphide, hydrogen sulphide dissolved in sodium sulphide solution, alkaline iron(II) sulphate solution— has made it possible to reduce nitro-, nitroso-, and azo-derivatives of benzothiadiazole to the corresponding amino-compounds, and also to study the effects of other substituents and of the position of the reducible group on the reduction of the above derivatives[98,100,101,105,106,108,111,125,171,190,191].

The selenadiazole ring is still less resistant to reduction. Benzoselenadiazole derivatives are converted into *o*-diamines even by hydriodic acid or by sodium dithionite[10,123,192], which makes it possible to prepare many compounds of interest in connection with their biological activity, in particular derivatives of β-phenyl-α-alanine[193]. According to Elvidge et al.[123] the reduction of 4-nitro- and 4,6-dinitro-benzoselenadiazoles with hydriodic acid involves degradation of the heterocycle while the nitro-groups remain in the resulting phenylenediamines.

As with the thia-analogue, the sensitivity of the selenadiazole ring to reduction depends on the nature of substituents in the benzene ring. Thus hydrogen sulphide cleaves 4-amino-5-nitrobenzoselenadiazole to 1,2,3-triamino-4-nitrobenzene[116], whereas the 5-bromo-4-nitro-derivative in converted, without any destruction of the heterocycle, into selenadiazolobenzothiazole[194]:



The isomeric 4- and 5-nitrobenzoselenadiazoles behave differently towards iron in 2% acetic acid: the former is reduced to the 4-amino-derivative in 50% yield, whereas the 5-nitro-compound resinifies[115]. Under the same conditions 5-nitrobenzothiadiazole is reduced to the 5-amine[78]. This is evidence of the enhanced stability of benzoselenadiazole to reductive cleavage when a 4-nitro-group is present in the benzene ring.

Benzothiadiazoles and benzoselenadiazoles can be reduced either with potassium or cathodically to form radical-anions. These can be obtained also by reaction of the initial compounds with the dipotassium salt of the dianion of cyclo-octatetraene[195] or with the anions of propiophenone and 9,10-dihydroanthracene[196]. Electron transfer from the dipotassium salt is incomplete, the process being reversible[195]. Under similar conditions the reaction with 4- and 5-nitrobenzothiadiazole gives a quantitative yield of cyclo-octatetraene: electron transfer is complete, and no equilibrium is observed[197]. Thus the reduction of benzothiadiazole and benzoselenadiazole either with potassium or cathodically resembles that of naphthalene.

The ease of polarographic reduction increases from benzothiadiazole to benzoselenadiazole in conformity with the fall in electronegativity of the key heteroatoms and with the decrease in the dipole moment of the diazole. The final reduction product is *o*-phenylenediamine, which requires six electrons[198]. The overall process is irreversible and is regarded[199] as involving the intermediate formation of *o*-benzoquinonedi-imine.

In aprotic solvents the reduction of these compounds involves a reversible intermediate one-electron transfer with formation of the corresponding radical-anions[199-201]. The latter are stable at 20°C, and in the absence of oxygen are capable of one-electron oxidation to the original substances[196,199]. They are π-electron radicals.

(*h*) Complex formation

Several investigations have revealed the ability of benzothiadiazoles and benzoselenadiazoles to form complexes. Lane and Williams showed[202] that they are able to form molecular compounds with tetrahydroquinoxaline derivatives.

Bertini[30] noted that 1,2,5-selenadiazole and its methyl derivatives are able to form complexes with cadmium chloride. Benzoselenadiazole forms a 1 : 1 compound with palladium chloride, whose use has been suggested for the detection of palladium in the presence of platinum(IV), cobalt, nickel, and lead[203]. With a methanolic solution of benzoselenadiazole aqueous solutions of cadmium salts form insoluble complexes $Cd(III)_2X_2$, where X = Cl, Br, I, SCN, SeCN, NCO, N_3. On thermal decomposition these complexes split off one or two molecules of (III) in stages[204].

Benzothiadiazole and its 5-methyl derivative form 1 : 1 complexes with tin(IV) chloride[145,148,153]. A similar complex is formed with mercury(II) chloride under similar conditions[35]. Benzoselenadiazole derivatives under the same conditions form 2 : 1 complexes with aluminium chloride[153].

Apparently the formation of high yields of hydroxylated benzothiadiazoles and benzoselenadiazoles when the corresponding alkoxy-derivatives are heated with anhydrous aluminium chloride is also preceded by intermediate complex formation[158,164,173,205]. σ-Complexes of benzothiadiazole and its chloromethyl derivatives with aluminium chloride have been isolated in the presence of hydrogen chloride, and examined spectroscopically[5,151].

3. Relation between Structure and Reactivity of Benzothiadiazoles and Benzoselenadiazoles

There is no generally accepted structure for benzothiadiazole and benzoselenadiazole. On the one hand it has been shown[5,206] that these heterocyclic systems reproduce the most important properties of naphthalene, being fully comparable in aromatic character, and in this sense are its heterocyclic analogues. Examination of chemical, spectroscopic, and structural results for 1,2,5-thiadiazole, benzothiadiazole, benzoselenadiazole, and their derivatives indicates that the quinoid structure reported[76,96,115,122,126,207,208] for these systems is incorrect. On the contrary, all the experimental results indicate that the actual state of the benzothiadiazole and benzoselenadiazole molecules corresponds to a structure containing quadrivalent sulphur (or selenium), which forms two π-bonds by means of *pd*-hybrid orbitals.

From the similarity in the properties of 1,2,5-thiadiazole and pyrazine, and of benzothiadiazole and quinoxaline, an analogy was noticed[5,206] between the syntheses of benzothiadiazole and quinoxaline. A similar analogy has been shown[10,11,16,30-32] in the formation of derivatives of 1,2,5-thia(and selena)diazole and pyrazine. The ready conversion of aliphatic compounds into 1,2,5-thia(selena)-diazoles[10,12-32] also indicates the aromatic structure of benzothiadiazole and benzoselenadiazole.

Recently published spectroscopic and physicochemical investigations are also consistent with the above view. Strom and Russell[196] studied the electron spin resonance spectra of radical-anions of benzothiadiazole and benzoselenadiazole, and found that the acceptance of unpaired electrons by the key heteroatoms increases from sulphur to selenium. They calculated the distribution of spin density in the anion of benzothiadiazole by the LCAO-MO method to the Hückel approximation for a *d*-model (taking into account the *d*-orbitals of sulphur) and for a *p*-model. They obtained identical results in good agreement with the experimental data. A similar result has been obtained by other workers[209].

The e.s.r. spectra of the radical-anions from benzothiadiazole, benzoselenadiazole, naphtho[1,2-*c*]-[1,2,5]-thiadiazole, naphtho[2,3-*c*]-[1,2,5]-thiadiazole, and naphtho[1,8-*cd*]-[1,2,6]-thiadiazine have been interpreted[201] by the LCAO-MO method to the Hückel approximation. The experimental results agree satisfactorily with the *p*-orbital model, which also correlates adequately with the polarographic reduction of these compounds. However, the authors note that the e.s.r. spectra of the radical-anions containing conjugated sulphur are insufficient by themselves to decide the character of the nitrogen–sulphur bond in these compounds, which requires more extensive experimental data covering many other properties.

Solodovnikov and Todres[209] compared an analysis of the e.s.r. spectra of radical-anions from benzothiadiazole and benzoselenadiazole with calculations of the distribution of spin density in these anions. They concluded that the key heteroatoms in the molecules are in some way involved in conjugation. They based this conclusion also on an analysis of the electronic absorption spectra. Other workers[210] have reached the same conclusion. Comparison of the e.s.r. spectra of radical-anions of benzothiadiazole, benzoselenadiazole, and their 4- and 5-chloro-derivatives shows that the maximum density of the unpaired electron in the radical-anion of (I) is located on the α-carbon atom. Similar results have been obtained by other workers[196,211]. Thus the radical-anions of benzothiadiazole and of naphthalene are characterised by spin density distributions of the same type.

The unpaired electron densities on the $C_{(4)}$ and $C_{(5)}$ atoms are different in the anions from benzoxadiazole and from benzothiadiazole but the same in the anion from benzoselenadiazole[209]. The proton hyperfine splitting constants at positions 4 and 5 are equal in the radical-anion from benzoselenadiazole, but different in those from benzoxadiazole and benzothiadiazole[210]. These results agree well with those of chemical investigations[5,206].

Delocalisation of electrons in the benzothiadiazole and benzoselenadiazole molecules is confirmed also by the proton magnetic resonance spectra of these systems, which closely resemble one another and that of naphthalene: the heterocyclic compounds exhibit "naphthalenelike" spectra[212]. All three systems possess similar spin–spin splitting constants. The effects of substituents in the benzene ring of (I) and (III) (nitro, chloro, methyl, and amino in positions 4 and 5) on the chemical shifts are qualitatively identical with (and quantitatively closely similar to) analogous effects in the benzene series[212-214].

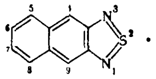
"Aromaticity" in the sense of the intensity of the ring current increases from sulphur to selenium[212].

These conclusions coincide with results of chemical experiments on the reactivity of benzothiadiazole and benzoselenadiazole[5,206]. Direct measurements of the magnetic susceptibility of these heterocyclic systems have confirmed the considerable levelling out of bonds in the heterocycle, i.e. the participation of the key atoms—sulphur and selenium—in forming the ring system of delocalised electrons[212].

It is interesting that the proton chemical shifts τ of 1,2,5-selenadiazole and 1,2,5-thiadiazole increase[32,212] from selenium (0.76) to sulphur (1.43),[29] i.e. in the opposite sequence to that following from the electronegativities of the key atoms. According to these results the selenadiazole is the most electrophilic.

Brown and Bladon[215] regard their results for the proton magnetic resonance spectra of benzothiadiazole and benzoselenadiazole as indicating that the six-membered rings are in some measure quinoid.

Ray and Narasimhan[211] have used the LCAO-MO method to calculate bond orders and lengths for 1,2,5-thiadiazole, benzothiadiazole, and naphtho[2,3-*c*]-[1,2,5]-thiadiazole (XV)



(XV)

They also calculated the π-electron density, the frontier electron density, and the localisation energy of the cation for positions 4 and 5 in (I) and positions 4–6 in (XV). Values of the spin density were computed for the radical-anion from (XV) as respectively 0.1130, 0.0413, and 0.0253 for positions 4–6 (experimental values not obtained). These workers[211] regard the calculated values as showing good agreement with corresponding experimental data where available, and also with experimental results for the reactivities and stabilities of these compounds.

The order of the N–S bond and the length of the C–N bond increase in the sequence—1,2,5-thiadiazole < (I) < (XV)—while the length of the N–S bond decreases in this sequence. These results are consistent with Cava and Schlessinger's view[216] that in the compound (XV) the sulphur is present in the quadrivalent state.

On the assumption that the sulphur is conjugated by means of *p*-orbitals Markov and Skancke[217] used the Pariser–Parr–Pople SCF MO method to calculate for the isomeric 1,2,5- and 1,3,4-thiadiazoles bond orders and lengths and π-electron charges on the sulphur, nitrogen, and carbon atoms. These workers[217] regard the calculated values as agreeing satisfactorily with certain experimental results. It must be noted that interatomic distances were not calculated for N–S, while the calculated C–C bond length diverges considerably from the observed values. Satisfactory agreement is found only for the C–N bond.

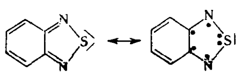
Soptrajanov[218] has shown that the enthalpy, entropy, and heat capacity increase in the sequence—1,3,4-thiadiazole, 1,2,5-thiadiazole, its deutero-analogue, and thiophen.

Calculated and experimental data relating to a quantitative estimate of the electronic structure of certain thiazoles and isomeric 1,2,5- and 1,3,4-oxa- and -thia-diazoles have been given[219], but no definite conclusions on the structure of the thiadiazoles.

Zahradnik and Koutecky[220] applied the LCAO-MO method to a comparative study of four isomeric thiadiazoles using the Longuet-Higgins model and a model which disregarded the participation of *d*-orbitals. They concluded that the limited experimental data can be interpreted better by the Longuet-Higgins model.

Kataev and Plemenkov[221] used the LCAO-MO method to the Hückel approximation to calculate the benzothiadiazole and benzoselenadiazole molecules, both with and without taking *pd*-hybridisation into account. They calculated the ionisation potentials, the $\pi-\pi^*$ transition energies, the π-moments of the molecules, the bond lengths, and the reactivity indices for both models. Comparison of calculated with experimental results showed that the actual state of these molecules corresponds to models involving *pd*-hybridisation.

The clearly defined aromaticity of (I) and (III) and the inability of their key atoms to increase their valency (to be oxidised) are consistent with another structure on the assumption that the sulphur (selenium) is involved in conjugation by the lone pair of electrons:



In this case aromaticity is achieved by the formation of a closed π*p*-electron system. In the benzenoid structure the closed system of electrons has the character $\pi(p-pd)$.[5,221]

With regard to which of these two structures represents the actual state of the molecule, the similarity of the chemical properties of benzothiadiazole and benzoselenadiazole to those of naphthalene, the similarity in the electronic spectra of benzothiadiazole and its derivatives to the typical spectra of fused aromatic compounds, the clearly defined aromatic character of benzothiadiazole and its derivatives revealed by their infrared spectra, the similarity of the proton magnetic resonance spectra of benzothiadiazole and of naphthalene, and the similarity in method of synthesis and in ultraviolet spectra between benzothiadiazole and quinoxaline, thiadiazole and pyrazine, and the similarity in the e.s.r. spectra of radical-anions from benzothiadiazole and from naphthalene—all these facts agree well with an aromatic, benzenoid structure for benzo-1,2,5-thiadiazole and benzo-1,2,5-selenadiazole.

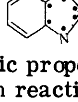
This conclusion is further confirmed by comparing benzothiadiazole and benzoselenadiazole with their oxygen analogue—the little studied benzofurazan. On nitration the nitro-group enters position 4, but the reaction occurs with considerably greater difficulty than in the (I) and (III) series. Benzofurazan readily adds four bromine atoms under normal conditions, is considerably less stable to oxidants, acids, and alkalis, and is more stable to reduction than are the thia- and selena-analogues. The reductive cleavage of benzofurazan by phenyl-lithium also takes place differently from that of (I) and (III).[181,182]

The ultraviolet spectrum of benzofurazan differs markedly from that of benzothiadiazole § and is displaced 30 nm to shorter wavelengths[10]. The dipole moments increase in conformity with the electronegativity of the key atoms in the sequence[223]

O > S > Se
D 4.37 1.73 0.94 .

The few experimental data give no adequate concept of the reactivity of benzofurazan. However, comparison of the properties which have been described with the corresponding properties of benzothiadiazole indicates that benzofurazan is weakly aromatic. On the whole the properties of the benzochalcogenadiazoles indicate that the sequence of increasing aromaticity (and hence diminishing "unsaturation") is—oxa < thia < selena.

Oxygen, in contrast to sulphur, is unable to expand its valency shell to ten electrons by means of *d*-orbitals. The weak aromatic properties of benzofurazan can be explained by the possibility of formation, in the planar[223–225] furazan ring, of a closed π*p*-system comprising six electrons. The structure of benzofurazan can therefore be represented by the formula



which reflects its aromatic properties.

Hence the difference in reactivity between benzofurazan and benzothiadiazole is explained by the different structures of these compounds. Since the above structure for benzofurazan is unique, it must be assumed that in benzothiadiazole and benzoselenadiazole the key heteroatom forms with the nitrogen atoms two π-bonds involving *pd*-hybrid orbitals[5,206,221].

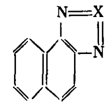
---

§The ultraviolet spectrum of furazan[222] also differs markedly from that of 1,2,5-thiadiazole.

IV. OTHER FUSED 1,2,5-THIADIAZOLES AND 1,2,5-SELENADIAZOLES

Naphtho[1,2-*c*]-[1,2,5]-thiadiazole (IV) and the corresponding napthoselenadiazole (XVI)

(IV, X=S)
(XVI, X=Se)



which were first obtained by Hinsberg[1,4], had not been investigated until recent years. These systems are stable towards acids, alkalis, oxidants, and heat, but are unstable towards reducing agents, which cleave the heterocycle.

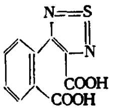
Naphthothiadiazole is nitrated as readily as is benzothiadiazole, forming predominantly the two isomeric 6- and 9-nitro-products[226,227], which can be reduced to the amino-derivatives by the action of iron in 2% acetic acid. The amines form readily hydrolysable salts, are acylated, are converted by means of the diazo-reaction into halogeno- and hydroxy-derivatives, and undergo the Bucherer reaction[226,227].

When naphthothiadiazole is chlorinated in acetic acid, either a dichloro-derivative or predominantly the 5-chloro-compound is formed, depending on the experimental conditions. The latter is obtained also by the action of sulphuryl chloride on the naphthothiadiazole. In formic acid or in the melt (in the presence of iron) chlorination occurs at position 5, and also a trichloro-derivative is formed identical with that obtained by chlorinating the 5-chloro-compound. Chlorination of molten naphthothiadiazole in the absence of iron yields an adduct—the 4,5-dichloro-4,5-dihydro-derivative[228].

Bromine acts on molten naphthothiadiazole to yield mainly the dibromo-derivative, whether in the absence or in the presence of iron[226,228]. In acetic acid the main product is the 4-bromo-compound.

Depending on the conditions and the concentration of oleum, sulphonation gives either the 4-sulphonic acid or (mainly) the corresponding disulphonic acid. Similarly, chlorosulphonation with chlorosulphuric acid gives either the 4-sulphonyl chloride or mainly the disulphonyl chloride, depending on the conditions[226,227].

The thiadiazole ring in the naphtho-compound resists oxidation by a chromic mixture: fission occurs at the $C_{(4)}-C_{(5)}$ bond, with formation of the dicarboxylic acid



The presence of electron-acceptor substituents, e.g. the nitro-group, enhances the stability of the system to oxidation. A chromic mixture or chromium trioxide in concentrated sulphuric acid produces no appreciable change in 6-nitronaphthothiadiazole: this compound is cleaved oxidatively only by an alkaline solution of potassium permanganate[226,227].

The spectrum of the radical-anion of the naphthothiadiazole has been studied[201].

Sulpho-derivatives of naphthoselenadiazole, obtained by Hinsberg's reaction, have been described[229-231].

Naphthoselenadiazole itself can, like naphthalene, be reduced by potassium or cathodically to form a radical-anion[209]. The latter is obtained also by reaction with the dipotassium salt of the dianion of cyclo-octatetraene[195] (difference from naphthalene—evidence of the electron-acceptor character of the heterocycle).

Comparison of the e.s.r. spectra of the anions of naphthoselenadiazole and benzoselenadiazole led to the conclusion that the distribution of spin density in the heterocycle probably changes little from benzologues to naphthologues[209].

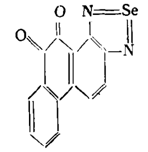
The linear naphtho[2,3-*c*]-[1,2,5]-thiadiazole (XV), which is isomeric with the above angular system (IV), was first obtained by Cava and Schlessinger[216], who showed that this compound undergoes diene synthesis with maleic anhydride and phenylmaleimide to form the corresponding adducts.

Oxidation of the linear naphthothiadiazole (XV) with potassium dichromate in acetic acid yields a heterocyclic analogue of anthraquinone, which can be reduced to a quinol of the linear naphthothiadiazole. The quinone is obtained also by cyclisation of 2,3-diamino-1,4-naphthaquinone with thionyl chloride[232,233].

Quantum-mechanical investigations of the linear naphthothiadiazole and its radical-anion have been reported[201,211].

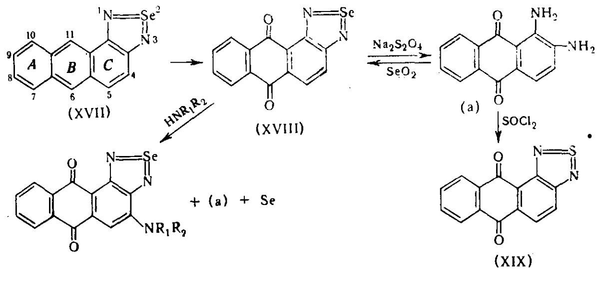
Depending on the conditions, chlorine and bromine act on the linear naphthothiadiazole to form either the 4,9-dihalogeno- or the 4,9-dihalogeno-4,9-dihydro-derivative. Chlorination with sulphuryl chloride gives a 41% yield of the 4,9-dichloro-derivative[234].

Among derivatives of phenanthrene only 10,11-dihydro-10,11-dioxophenanthro[1,2-*c*]-[1,2,5]-selenadiazole



obtained by Hinsberg's reaction, is known[235].

The same method has been used to obtain anthraselenadiazole and anthrathiadiazole, which have been subjected to several reactions[192,236-239]. Anthraselenadiazole (XVII) is oxidised by chromic acid to a quinone, which is reduced with the separation of selenium and the formation of 1,2-diaminoanthraquinone (a);[192] the latter can be converted either back into the quinone (XVIII) or into its thia-analogue (XIX):



Amines act on (XVIII) to produce partial amination of the benzene ring fused to the selenadiazole ring, the reaction being accompanied by formation of an *o*-diamine and separation of selenium[236,238].

Hydrogen or chlorine at position 4 in (XVIII) and (XIX) can be replaced by amino[237,238,240], arylthio, alkylthio, arylsulphonyl, and sulpho[239,241]. If chlorine is present at position 5, hydrogen at position 4 can also be replaced.

Chlorine at position 5 cannot undergo similar substitution. Several other reactions have been studied[241].

The above reductive opening of the selenadiazole ring has been considered[238] to involve initial addition of the amine at positions 4 and 5 of the dihydrodioxoanthraselenadiazole, after which the adduct is oxidised by the initial quinone, which is thus reduced mainly to 1,2-diaminoanthraquinone and selenium.

Nitration of the quinone (XIX) with a nitrating mixture at 50°C gives an 85% yield of a mixture of the 7- and 10-mononitro-derivatives in the proportions 1.5 : 1, which can be reduced with sodium hydrogen sulphide to the corresponding amines. Caustic soda acts on the nitro-derivatives to open the thiadiazole ring; the resulting 1,2-diaminoanthraquinones can be reduced to 1,2,5- and 1,2,8-triaminoanthraquinones[239].

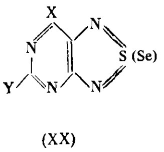
The fact that the nitro-groups enter the "outer" benzene ring A—not ring C—is explained[239] by deactivation of the latter by the thiadiazole ring, which is protonated in sulphuric acid.

A sulphurous diamide can be isolated[84] from the products of the action of alkali on the quinone (XIX) at 20°C. Both dihydrodioxoanthraselenadiazole (XVIII) and dihydrodioxophenanthroselenadiazole are equally readily cleaved by alkali to form the corresponding *o*-diamines. Fission of the selena- and thia-diazole rings by the action of alkalis on the quinone-diazoles is a convenient method for obtaining difficultly accessible derivatives of 1,2-diaminoanthraquinone[242,243].

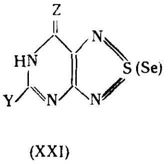
6,11-Dihydro-6,11-dioxoanthra[1,2-*c*]-[1,2,5]-thia(and selena)diazoles are chlorinated in acetic acid at position 4, but in sulphuric acid or oleum at positions 7 and 10, with the formation of 7,10-dichloro-derivatives[244].

Products in which the 1,2,5-thiadiazole and 1,2,5-selenadiazole rings have been fused with many cyclic systems—carbazoles, dibenzothiophens, dibenzoselenoles, benzothiazoles, benzoxazoles, quinoxalines, benzimidazoles, quinoline (by the Skraup synthesis from aminobenzothiadiazole)¶, pyridines, pyrimidines, pyridazine, benzo-1,2,5-thiadiazoles, and benzo-1,2,5-selenadiazoles—have now been investigated[41-45,78,79,81,88,106-108,131,174,176,245-260]. These complicated heterocyclic systems have been obtained mainly by reaction of the corresponding *o*-diamines with thionyl chloride, sulphinylaniline, or selenium dioxide. Systems containing a selenadiazole ring have been obtained also from amino- or acylamino-benzothiadiazoles and -benzoselenadiazoles by known methods[249,257,259].

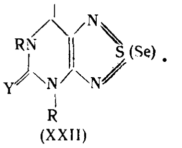
Especial interest attaches to investigations by Shealy and his coworkers[41-45,81] of several reactions of the pyrimidothiadiazole and pyrimidoselenadiazole derivatives



(XX)

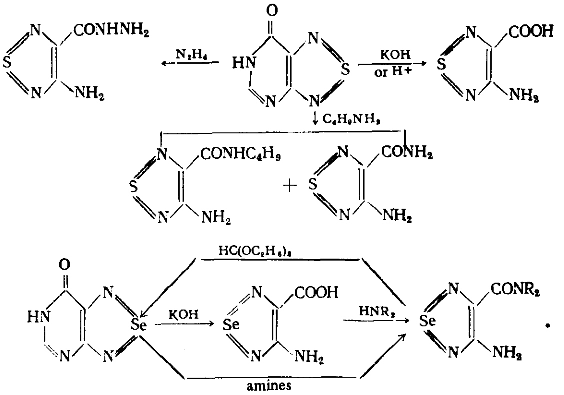


(XXI)



(XXII)

The substituents X = Cl, SH, $SCH_2C_6H_5$ in the compound (XX : Y = H) are shown to be highly mobile, and readily undergo substitution on reaction with aniline. The thiadiazole ring in (XX) is cleaved by lithium tetrahydroaluminate or by hydrogen sulphide to the corresponding *o*-diamines. Basic and acidic reagents under mild conditions open the pyrimidine ring:



V. SPECTROSCOPIC PROPERTIES OF 1,2,5-THIADIAZOLES AND 1,2,5-SELENADIAZOLES

Many workers have studied the spectroscopic characteristics of 1,2,5-thiadiazoles, 1,2,5-selenadiazoles, and their fused systems in both the ultraviolet and the infrared for the purposes both of identification and of comparison with the corresponding data for typical aromatic and heteroaromatic compounds[5,9,12,21,24,32,35,59,96,97,102,114-116,122,126,144,151,157,205,207,216,234,245-248,260-273]. The Raman spectra of the monocyclic and fused heterocycles have also been studied[264,267-269,271,272].

The ultraviolet spectra revealed a constant bathochromic shift in the absorption maximum on passing from thiadiazole and benzothiadiazole derivatives to their selenium analogues. Similarity in the character of the absorption and in the distribution of the maxima was observed in the ultraviolet spectra of benzothiadiazole and quinoxaline, and of 1,2,5-thiadiazoles and pyrazines[5,9,206]. Sawicki[248] explains the similarity of the ultraviolet spectra of several benzothiadiazole and benzoselenadiazole derivatives to those of the corresponding *o*-aminonitrobenzenes—the initial compounds for the synthesis of these heterocycles—by regarding the heterocyclic derivatives as *ortho*-substituted.

Bird and Cheeseman[270] compared the infrared spectra of benzoselenadiazole and twenty-five of its mono- and di-substituted derivatives with those of di-, tri-, and tetra-substituted benzenes. They felt that the results did not permit any conclusions to be drawn on the distribution of electron density or the fine structure of the benzoselenadiazole derivatives.

Soptrajanov and Ewing[267] made a comprehensive investigation of the vibrational spectra of 1,2,5-thiadiazole and its dideuterated derivative[267]. They gave a complete interpretation of the infrared spectra of liquid and gaseous specimens and of the Raman spectra of liquid 1,2,5-thiadiazole.

Benedetti and Bertini[271] studied the infrared spectrum over the range 4000–400 cm^{-1} of 1,2,5-selenadiazole in solid, liquid, and gaseous states and dissolved in carbon disulphide. The Raman spectrum was recorded for liquid selenadiazole. The molecule of this compound was shown to be planar, the key atoms—sulphur and selenium—being conjugated.

A satisfactory correlation has been demonstrated[200,273] between the positions of the maxima in the ultraviolet

---

¶4- and 5-Aminobenzothiadiazoles also undergo the Herz reaction[252], as well as with aryl isothiocyanates[261].

absorption spectra of 4- and 5-substituted benzoselenadiazoles and benzothiadiazoles and the Hammett σ_m and σ_p constants.

A study has been made of the infrared, ultraviolet, and proton magnetic resonance spectra of two isomeric pyrido-1,2,5-selenadiazoles[260]. The proton magnetic resonance spectra were regarded[260] as indicating considerable fixation of C–C bonds in the pyridine ring.

Study of the mass spectra of benzoselenadiazole, its 5-methyl and 4,5,6-trimethyl derivatives, and phenanthro-[1,2-*c*]-[1,2,5]-selenadiazole showed[274] that, in spite of the great stability of their molecular ions M^+, the two carbon-nitrogen bonds undergo rupture on electron bombardment with the formation of ions of dehydrobenzene or its analogues. It has also been shown[275] that benzoselenadiazole is less stable to electron bombardment than is phenazine or the above phenanthraselenadiazole (it splits off hydrogen cyanide more easily).

The mass spectra of 1,2,5-thia- and -selena-diazoles have been studied also by Marquardt[35] and Weinstock et al.[29] The stability of these heterocycles towards electron bombardment is evidence of their aromatic character.

From investigation of the infrared and ultraviolet spectra of benzothiadiazole and some of its derivatives the conclusion is drawn that it represents a typical heteroaromatic system[5,206,262-265] and there are no grounds for supposing that benzothiadiazole and benzoselenadiazole have a quinoid structure.

VI. APPLICATION OF DERIVATIVES OF 1,2,5-THIADIAZOLES AND 1,2,5-SELENADIAZOLES

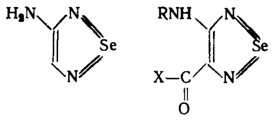
1,2,5-Thiadiazole and its benzo- and pyrimido-systems are in their way analogues respectively of pyrazine, quinoxaline, and pteridine, present in many biologically active compounds. There are indications that several derivatives of benzothiadiazole possess low toxicity[8].

The biological properties of acid derivatives of 1,2,5-thiadiazole have been investigated in detail. Hydrazides of the 3-carboxylic acid are active against *Escherichia coli*,[9] and also inhibit the action of monoamino-oxidase[276]. The *N*-phenylisopropylammonium salt of this acid has a strong stimulating action on the central nervous system and on respiration[277]. Sulphanilamides of the thiadiazole and selenadiazole series possess bactericidal activity[59,61,278-280]: thus 3-sulphanilamido-1,2,5-thiadiazole has been recommended[61,62,280] for the treatment of coccidiosis in poultry.

Several halogenated and hydroxylated 1,2,5-thiadiazoles have been found to have a bactericidal effect[12,14]. Among the above heterocyclic compounds substances have also been detected which possess insecticidal[162,163], fungicidal, herbicidal[55,56,64,65,280], antihelminthic[281-283], nematocidal[64,65], and diuretic[143] action.

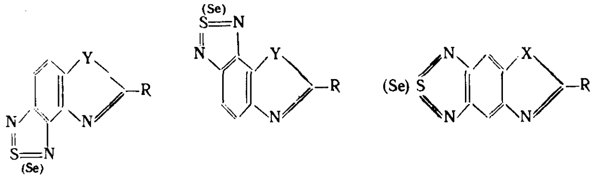
Daams, Koopman, and their coworkers have recently compared[112,113,283-285] the structure with the herbicidal and fungicidal action of chlorinated benzothiadiazoles. According to their observations the strongest herbicide is the 4,5,7-trichloro-derivative, and also the 5,7-dichloro-4-methyl compound. The latter, as well as several dichloronitrobenzothiadiazoles, exhibits high fungicidal activity. 4,5,7-Trichlorobenzothiadiazole has been proposed[286] in particular for the fight against harmful members of the fish fauna.

Several thia- and selena-diazole derivatives possess antitumorigenic activity. Shealy and his coworkers have reported[41,287] a new class of cytotoxic agents, the selenadiazoles, among which the most effective have been found to be



where R = H, Alk and X = OH, N<. Such activity is possessed also by several pyrimido-1,2,5-selenadiazoles[255,256] and their thia-analogues[249 288-290] containing hydroxy- and amino-groups in the pyrimidine ring. *NN*-Bischloroethylamino-derivatives of benzothiadiazole[5,160], including analogues of *o*- and *p*-sarcolysin, are of interest in this connection.

As mentioned above, fused thia- and selena-diazoles can be coupled with diazonium salts to form azo-dyes. Several of them show promise for industrial synthesis[205,291]. Cyanine dyes containing thia- and selena-diazole rings have been synthesised by Soviet[246,247] and Italian[245,292] chemists on the basis of the systems



(where X = S, NR; Y = O, S, Se, CH:CH, NR; and R = H, CH_3) and other fused heterocycles containing reactive methyl groups.

3-Chloro-1,2,5-thiadiazole has been claimed to possess good solvent power for certain polymers[18,61]. It is said[52] to be possible to obtain synthetic condensation resins from 1,2,5-thiadiazoline 1,1-dioxide and dialdehydes[52].

The analytical usefulness of the ability of thia- and selena-diazole derivatives to form complexes can be judged in particular from the possibility of detecting palladium in the presence of platinum(IV), nickel, cobalt, and lead by means of benzoselenadiazole[203]. It has been suggested that the ability of coloured solutions of certain derivatives of this compound, e.g. 5-(3,4-diaminophenyl)-benzoselenazole, to absorb in a certain range of the ultraviolet spectrum, should be used for analytical purposes[291,293,294]. This will permit a quantitative determination of the selenium content of benzoselenadiazole derivatives

The formation of certain derivatives—e.g. 4,5-dichlorobenzoselenadiazole, 5,5′-bibenzoselenadiazolyl—from the corresponding *o*-diamines can be used for the spectrophotometric determination of Se^{IV}.[273,295]

Dihydrodioxoanthra-thia- and -selena-diazoles can be used to obtain daylight-fluorescent colorants which show promise for practical application[296].

Structural and Steric Factors Determining the Rate of Autoxidation of α-Methylene Groups in Alkylarenes and Alkenes

V.V.Voronenkov, A.N.Vinogradov, and V.A.Belyaev

Data on structural and steric effects in the autoxidation of alkylarenes and alkenes are summarised. Special attention is paid to the effect of steric hindrance on the rate of oxidation of an α-CH bond in various hydrocarbons—alkylbenzenes, alkylnaphthalenes, alkenes, alkylindanes, and tetrahydronaphthalenes—and data are given on the relation between their refractions, ultraviolet spectra, and rate of oxidation. The role of the molecular conformation of the hydrocarbons in the conjugation of single bonds is demonstrated, together with the effect of this conjugation on the rate of autoxidation of the α-CH bond. A list of 91 references is included.

CONTENTS

1. Introduction

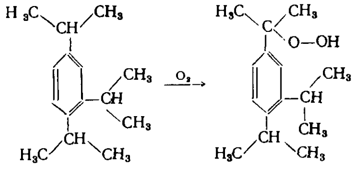
Oxidation with molecular oxygen (autoxidation) provides the basis for the large scale production of several synthetic organic products. Hence the publication of a number of reviews and monographs[1-4] on the autoxidation of hydrocarbons is not accidental. However, these works make no detailed examination of the influence of structural and steric factors on the rate of autoxidation. Yet recent investigations prove fairly convincingly[5-8] that the rate of autoxidation is determined in considerable measure by the chemical and three-dimensional structure of the molecules and by the presence of steric hindrance. Investigation of these effects is of value in understanding the mechanism of the oxidation of hydrocarbons.

2. Alkylbenzenes

The early experimental papers, which contained information on the influence of steric factors on the rate of autoxidation of alkylated aromatic compounds and their derivatives, reported investigations by Remsen[9-13] and by Ciamician and Silber[14]. Remsen noted that the ease of oxidation of a methyl group attached to an aromatic ring depends on the space occupied by the adjacent substituent. The latter workers studied the autoxidation of the isomeric xylenes, and concluded that *o*-xylene is the most resistant to oxidation, and the *para*-isomer the most unstable (the *meta*-isomer occupies an intermediate position). Mowry obtained similar results for the oxidation of the diethylbenzenes[15]. Erofeev and Chirco[16] found that the rate of autoxidation of the α-methylidyne group in *o*-cymene is half that in the *para*-isomer. Eventova and Mashkina[17] studied the oxidation of the di-isopropylbenzenes, and found that the tendency to oxidation increased in the sequence *ortho*–*meta*–*para*. The same order occurs with the cyclohexyltoluenes[18].

The spatial proximity of the adjacent alkyl groups in *o*-dialkylbenzenes is responsible not only for a decrease in the rate of oxidation of the α-methylene groups but also the formation of new oxygen-containing derivatives—α-lactones—during oxidation. Volkov and his coworkers[19-21] found that phthalans (0.2–0.3%) are formed in the earliest stages of the oxidation of *o*-alkyltoluenes and their homologues.

Thus the diminished rate of autoxidation of *o*-dialkylbenzenes and the accompanying formation of α-lactones are due to *ortho*-substitution (the "*ortho*-effect"). This effect determines the path and the rate of oxidation of other polyalkylbenzenes. Thus in the liquid-phase oxidation of 1,2,4-tri-isopropylbenzene[19,20] only the isolated isopropyl group undergoes oxidation, while the other two groups (located side by side) remain almost unoxidised:



.

The use of chromatographic methods of analysis made it possible to refine quantitatively the laws of the autoxidation of polyalkylbenzenes. For example, the relative rates of reaction of isopropylbenzene, 1-isopropyl-3,4-dimethylbenzene, 1-isopropyl-2,5-dimethylbenzene, and 1-isopropyl-2,3-dimethylbenzene with tertiary peroxy-radicals were 1, 2.1, 0.92, and 0.91[21]. It is interesting that even in the early work Weissberger[22,23], who investigated the autoxidation of benzoin and its homologues, noted that the reaction velocity is greatly dependent on the nature and position of substituents in the benzene ring (Table 1).

In this case steric hindrance due to *ortho*-substitution is shown in a marked decrease in the rate of oxidation, as in the *o*-dialkylbenzenes. Here the *ortho*-effect could be assessed numerically, because, according to Weissberger[23], the autoxidation rate coefficients which would be expected in the absence of an *ortho*-effect could be calculated.

The diminished rate of autoxidation in *ortho*-substituted alkylbenzenes was explained solely by mechanical factors—repulsion of substituents or shielding of the α-carbon atom by adjacent alkyl groups[24]. This interpretation of the influence of substituents does not indicate why the *meta*-isomer, in which there is no shielding of the α-carbon atom, is oxidised just as slowly as the *ortho*-isomer. An alternative explanation was based on the mechanism of autoxidation and the geometry of the transition state for hydrocarbons[5].

Table 1. Rates of autoxidation of substituted benzoins.

$Ar^1-\overset{O}{\overset{\Vert}{C}}-CH(OH)-Ar^2$	$10k_{20}$, observed
$Ar^1 = Ar^2 =$ *o*-diethoxyphenyl	7.32
$Ar^1 = Ar^2 =$ *p*-diethoxyphenyl	29.4
$Ar^1 = Ar^2 =$ *o*-dimethoxyphenyl	20.4
$Ar^1 = Ar^2 =$ *p*-dimethoxyphenyl	36.6
$Ar^1 =$ phenyl; $Ar^2 =$ *o*-tolyl	260.0
$Ar^1 =$ *o*-tolyl; $Ar^2 =$ phenyl	29.4
$Ar^1 = Ar^2 =$ *o*-chlorophenyl	725.0
$Ar^1 = Ar^2 =$ *p*-chlorophenyl	900.0

The liquid-phase autoxidation of alkylated aromatic hydrocarbons takes place by a free-radical chain mechanism, the attack usually occurring at hydrogen attached to a carbon atom in the α-position with respect to the aromatic ring. This is explained by the relative inactivity of the peroxy-radical $ROO^{\bullet}$ in the main chain-propagation reaction.

$$ROO^{\bullet} + R'H \rightarrow ROOH + R^{\bullet} \tag{I}$$

so that it acts fairly selectively: it attacks preferentially highly reactive bonds—homolytically conjugated C–H bonds of the α-carbon atom[25,26]. The rate of homolytic detachment of hydrogen in reaction (I) is determined by the strength of the α-C–H bond and the stability of the resulting radical. The strength of the bond under attack depends substantially on its σπ-conjugation with the aromatic ring. Thus, for example, the energy of rupture of a C–H bond in methane, where there is no σπ-conjugation, is 23–24 kcal $mole^{-1}$ greater than that for a similar bond in toluene, a compound with well defined σπ-conjugation[27].

Thus decreased σπ-conjugation between the benzene ring and the α-C–H bond under attack in the alkyl group should lead to a corresponding increase in its energy, and hence to an increase in the activation energy and a decrease in the rate of oxidation[28]. The diminished reactivity of the C–H bond in *o*-dialkylbenzenes indicates weakening of its conjugation with the benzene ring and diminished polarisability of molecules of this type. This conclusion is supported by the lower molar refraction MR_D of *o*-dialkylbenzenes compared with the *para*-isomers (Table 2).

Since molar refraction is proportional to the volume of the atoms, its dimunution in *o*-dialkylbenzenes indicates that their atoms are more compactly arranged than in the molecules of the *para*-isomers[29]. This is supported by the fact that the former isomers have higher densities, refractive indices, and boiling points[30].

The compaction of the alkyl groups in *o*-dialkylbenzenes (in *o*-cymene, for example, the methyl group forces the adjacent isopropyl group out of the plane of the benzene ring) destroys the σπ-conjugation of the α-C–H bond with the benzene ring. This is apparent in a decreased polarisability, and hence a decrease in the electron mobility of *o*-dialkylbenzenes compared with the *para*-isomers[31–38]. For the same reasons changes occur in electronic (ultraviolet) absorption spectra in dialkylbenzenes[39–43].

Table 2. Molar refraction of dialkylbenzenes.

Hydrocarbon	MR_D	ΔMR_D
p-Xylene	36.02	0.25
o-Xylene	35.77	—
p-Cymene	45.34	—
o-Cymene	45.04	0.30
p-Diethylbenzene	48.82	—
o-Diethylbenzene	48.53	0.29
p-Di-isopropylbenzene	54.65	—
o-Di-isopropylbenzene	54.35	0.30

The changes occurring in the electronic spectra of benzenes as a result of introducing an alkyl group into the ring are due to displacement of the electrons of the α-C–H bonds towards the ring, i.e. to σπ-conjugation. The presence of steric hindrance in the molecule weakens the conjugation of the alkyl group with the benzene ring to a greater or lesser extent. This weakening results in a shift of the electronic spectra to shorter wavelengths accompanied by a diminution in the intensity of absorption. On the other hand, displacement to longer wavelengths with increase in intensity indicates an increase in the conjugation of the system. Such spectra are distinguished by a steep rise to high extinctions with fine structure (Fig. 1).

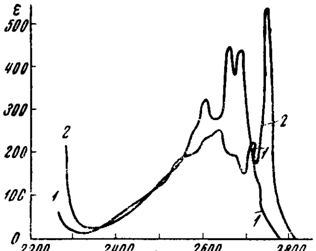


Figure 1. Ultraviolet absorption spectra of: 1) *o*-cymene; 2) *p*-cymene.

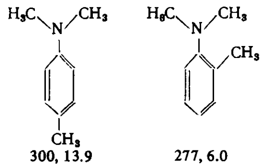
For dialkylbenzenes containing hydrogen atoms attached to the α-carbon atom the shift to longer wavelengths accompanied by increased strength of absorption occurs in the sequence—*ortho*, *meta*, *para*—as is clearly evident from Table 3. The same applies to the isomeric *NN*-dimethyl-*o*- and -*p*-toluidines[44]



300, 13.9 277, 6.0

(λ_{max} in μm, $10^{-3}\varepsilon$).

It has been remarked earlier that the dialkylbenzenes form the sequence—*ortho–meta–para*—according to their tendency to liquid-phase autoxidation. The absorption coefficients of the electronic spectra and also the exaltation of molar refraction—constants which characterise the mobility of the electrons in the dialkylbenzene molecules—increase in the same sequence. Thus there is a direct connection between the oxidisability of a C–H bond involving an α-carbon atom and its capacity for $\sigma\pi$-conjugation (electronic delocalisation): a high degree of $\sigma\pi$-conjugation between the bond and the benzene ring leads to greater oxidisability of the bond.

Table 3. Ultraviolet spectra of *o*- and *p*-dialkylbenzenes [39]*.

Compound	λ_{max}	ϵ_{max}
p-Xylene	2740	600
o-Xylene	2630	275
p-Diethylbenzene	2730	420
o-Diethylbenzene	2635	245
p-Cymene	2735	530
o-Cymene	2630	250
p-Di-isopropylbenzene	2715	370
o-Di-isopropylbenzene	2635	245

* The values of λ_{max} and ϵ_{max} for *m*-dialkylbenzenes are very close to the corresponding values for *o*-dialkylbenzenes.

This is confirmed by the kinetics of the autoxidation of dialkylbenzenes. Fig. 2 gives rate curves for the absorption of oxygen during the autoxidation of *o*- and *p*-cymenes [5], which show appreciable differences in the rates, *p*-cymene being oxidised considerably more rapidly than the *ortho*-isomer. A similar difference in rates of autoxidation is observed with a mixture of *o*- and *p*-dialkylbenzenes [45,46] and a mixture of isomeric alkylchlorobenzenes (Fig. 3). In particular the relative rate constants for the oxidation of the chloroisopropylbenzenes [6] are $k_p : k_m : k_o = 10 : 7 : 1$.

The hindrance to conjugation in *o*-diaklylbenzenes exists not only in the initial molecule but also in the transition state and in the radical. The geometry of the transition state in the autoxidation of hydrocarbons, e.g. cumene, can be represented by the scheme in Fig. 4. This shows that, during attack by the radical ROO• on the C–H bond, all three angles of the σ-bonds at the α-carbon atom change from 109° (the tetrahedral angle) to 120° in the radical, in which the three valences of the α-carbon atom are coplanar with the benzene ring. In this case maximum delocalisation of the unpaired *p*-electron is accomplished, with creation of a single "through" conjugated system covering the whole radical. A stable radical, capable of continuing the oxidation chain, is thereby formed. However, formation of a planar radical becomes difficult if *ortho*-substituents are present in the aromatic ring. Fig. 5 shows that coplanarity of the radical is impeded by overlapping of the van der Waals spheres [47,48] of the methyl and *o*-isopropyl groups, which are not directly bound to one another. In this case there is no gain in energy due to conjugation, which might have partly balanced (diminished) the energy required to break a C–H bond involving the α-carbon atom of the alkyl. For the same reason a stable radical capable of continuing the oxidation chain is not obtained.

Thus the steric hindrance ("*ortho*-effect") in the autoxidation of alkylated aromatic hydrocarbons consists essentially in destruction of the coplanarity of the system, which results in breakdown in the $\sigma\pi$-conjugation of the α-C–H bond with the benzene ring ("steric inhibition of mesomerism").

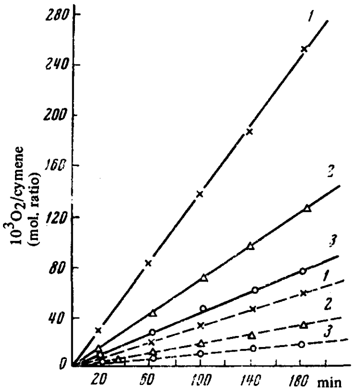


Figure 2. Rate curves for the absorption of oxygen in the presence of 4 wt. % of isopropylbenzene hydroperoxide at (°C): 1) 120; 2) 110; 3) 100. Full lines represent *p*-cymene; broken lines represent *o*-cymene.

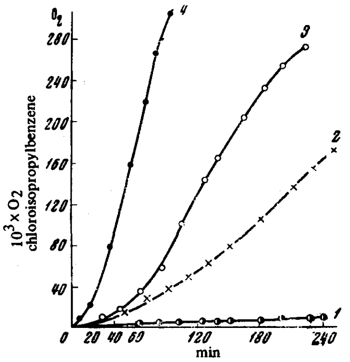

Figure 3. Effect, on rate of oxidation of chloroisopropylbenzene (with 0.6 wt. % of Na stearate + 4 wt. % of CaO at 120°C), of isomeric composition (wt. %): 1) 83 *o* + 13 *p*; 2) 34.3 *o* + 19.8 *m* + 45 *p*; 3) 23.55 *o* + 7.25 *m* + 69.2 *p*; 4) 7.42 *o* + 4.13 *m* + 88.5 *p*.

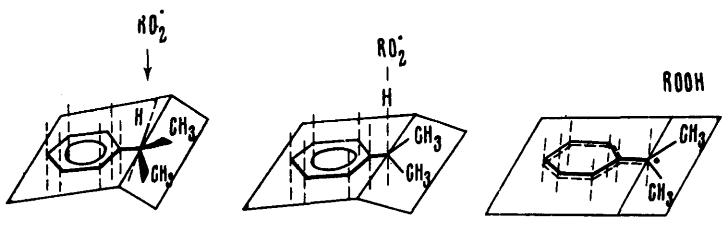
Similar conclusions were reached by Kooyman and Strang [49–51] in a study of the reactivity of α-methylene [and methylidyne (Ed. of Translation)] groups in various hydrocarbons towards the •CCl_3 radical. They found that the reactivity of the α-hydrogen atoms was greatly dependent on the coplanarity of the benzene ring and the α-carbon atom in the transition state. A quite close correlation was observed in the relative activities of •CCl_3 and ROO• radicals towards the same α-hydrogen atoms (Table 4).



initial state transition state final state—radical

Figure 4. Graphical representation of transition state in the oxidation of cumene.

The rate of autoxidation of an α-C–H bond is, of course, governed not only by the position but also by the nature of alkyl groups present in the benzene ring. Thus Russell[52], who studied the autoxidation of hydrocarbons in the presence of an initiator at 90°C, showed that (*a*) the relative rates of oxidation of cumene, ethylbenzene, and toluene were respectively 1 : 0.59 : 0.075; and (*b*) electron-donor substituents, e.g. methyl, accelerate autoxidation, whereas electron-acceptor substituents (COOH, NO_2, Cl, Br, etc.) slow it down.

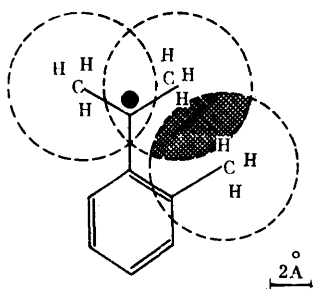


Figure 5. Effect of steric hindrance in the radical of *o*-cymene.

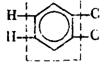
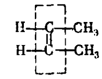
Similar results were obtained by Ingold[53], who found that the rates of autoxidation of *p*-nitrocumene, cumene, and *p*-cymene were approximately in the proportions 1 : 2 : 4. He also gave interesting data on the relative reactivities of the α-C–H bond in several alkylated aromatic hydrocarbons towards various radicals (Table 5). It is seen that the rate of abstraction of hydrogen from the α-carbon atom increases from toluene to cumene for all radicals other than ROO•. Although this radical removes hydrogen attached to the tertiary carbon atom in cumene, the rate of oxidation is lower than in ethylbenzene. A probable explanation is that the peroxy-radical formed from ethylbenzene is more active than that formed from cumene.

The autoxidation of alkylbenzenes is sensitive not only to the steric hindrance of $\sigma\pi$-conjugation in the molecule but also to such a delicate electronic effect in hydrocarbon molecules as the "alternation effect". This was shown by the work of Eventova and her coworkers[54] on the oxidation of the diphenylalkanes $C_6H_5[CH_2]_nC_6H_6$, the rates of which alternate with increase in *n*: i.e. the rate increases with an even number of carbon atoms in the polymethylene chain, but then decreases with an odd number (Table 6); this suggests that the chain is conjugated.

3. Alkenes

From the point of view of molecular symmetry *o*-dialkylbenzenes (I) correspond to the analogous *cis*-ethylene (I*a*)[55-60], and *para*-substituted benzenes (II) to the analogous *trans*-compounds (II*a*):





(Ia)

(II)

(IIa)

.

Table 4. Relative reactivity of hydrogen atoms in hydrocarbons towards radicals.

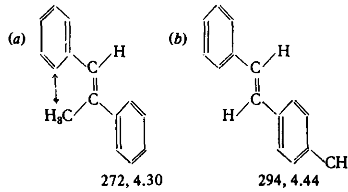
Hydrocarbon	$\cdot CCl_3$ [49,51]	ROO· [5,51]
Toluene	1	1
Isopropylbenzene	12.5	13.3
o-Cymene	1.1	1.3
p-Cymene	5.6	4.0

Table 5. Relative reactivities of hydrocarbons towards radicals.

Radical	Ethylbenzene	Cumene
$(CH_3)_3CO\cdot$	3.2	6.8
$C_6H_5\cdot$	4.6	9.7
ROO·	8.1	2.3
Br·	17.0	37.0
$Cl_3C\cdot$	50.0	260.0

In fact, the alkyl groups in *cis*-alkenes, like those in *o*-dialkylbenzenes, are squeezed together as a consequence of their proximity (Fig. 6). This results in increases in density and refractive index, rise in boiling point[30], and decrease in molar refraction in comparison with *trans*-alkenes (Table 7).

The relation between the ultraviolet spectra of *cis*- and *trans*-alkenes is similar to that between those of *o*- and *p*-dialkylbenzenes. For example, the absorption maximum of methyl-*trans*-stilbene (*a*), which exhibits "*cis*-packing" between methyl and phenyl, lies at a shorter wavelength than that of the *para*-isomer (*b*):



(λ_{max} in μm, log ε). In general *cis*-isomers have their maximum absorption at rather shorter wavelengths, and the absorption coefficient is in all cases considerably smaller than for the *trans*-forms[43].

Table 6.

No. of C atoms n = 1	2	3	4	5	6
Oxidation, % = 11.8	21.5	17.0	26.0	23.0	42.0

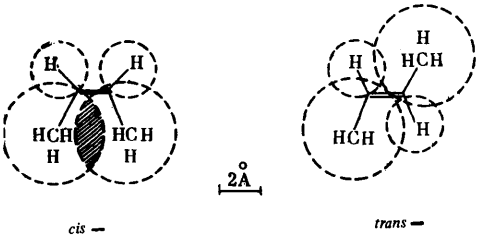


Figure 6. Interaction of atomic groupings, not directly combined together, in *cis*- and *trans*-but-2-ene.

Thus the "packing" in the *cis*-alkene molecule, like that in the *o*-dialkylbenzene molecule, destroys the coplanarity of the double bond with the trigonal α-carbon atom, thereby diminishing the degree of σπ-conjugation of the α-C—H bond. This leads to an increase in the energy of rupture of this bond compared with that of a C—H bond in *trans*-alkenes. This was shown initially in homolytic chlorination, which, like liquid-phase oxidation, has a radical-chain mechanism. Walling and Thaler[61] found that the homolytic chlorination of *trans*-but-2-ene with t-butyl hypochlorite yields 83% of *trans*-1-chlorobut-2-ene, whereas that of *cis*-but-2-ene under comparable conditions gives 65% of *cis*-1-chlorobut-2-ene. A similar difference in reactivity is apparent in the liquid-phase oxidation of isomeric *cis*- and *trans*-alkenes. The oxidation of a mixture of *cis*- and *trans*-4-methylpent-2-ene by oxygen shows[62] that the oxidisability of an α-C—H bond is considerably greater in the *trans*-alkene than in the *cis*-isomer (Figs. 7 and 8). The oxidation rate constants at 70°C were respectively 0.00385 and 0.0086 M min^{-1} for *trans*- and *cis*-forms.

Comparison of data obtained by various workers[63-67] on the autoxidation of branched alkenes clearly reveals that the oxidisability of α-methylene groups, e.g. in methylpentenes, diminishes in the sequence

$$\underset{\displaystyle CH_3}{CH_3—\overset{|}{C}}=CH—CH_2—CH_3 > CH_3—CH=\underset{\displaystyle CH_3}{\overset{|}{C}}—CH_2—CH_3 > CH_2=\underset{\displaystyle CH_3}{\overset{|}{C}}—CH_2—CH_2—CH_3 .$$

The molar refraction and the exaltation decrease in the same sequence. Nevertheless, it is evident that enhanced oxidisability of α-methylene groups is observed where the methyl and the oxidisable α-methylene group are in the *trans*-position (parallel).

Table 7. Molar refraction of *cis*- and *trans*-alkenes.

Hydrocarbon	MR_D	ΔMR_D
trans-Pent-2-ene	25.61	0.25
cis-Pent-2-ene	25.38	
trans-Hex-2-ene	25.59	0.24
cis-Hex-2-ene	29.34	
trans-Hex-3-ene	29.61	0.21
cis-Hex-3-ene	29.40	
trans-3-Methylpent-2-ene	29.96	0.25
cis-3-Methylpent-2-ene	29.71	
trans-4-Methylpent-2-ene	29.75	0.24
cis-4-Methylpent-2-ene	29.51	
p-Xylene (*trans*)	36.02	0.25
o-Xylene (*cis*)	35.77	

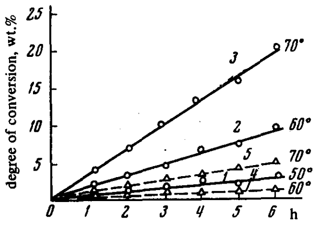

Figure 7. Variation in degree of conversion (with 0.5 mole % of 2-methylpent-2-ene hydroperoxide at 50—70°C):
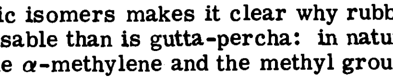
1)—3) *trans*-4-methylpent-2-ene; 4, 5) *cis*-4-methylpent-2-ene.

These results, which support Nesmeyanov's conclusion[68] that the single bonds are more highly conjugated in *trans*-alkenes, make it possible to estimate the oxidisability of certain polymeric hydrocarbons, e.g. rubber and gutta-percha



Comparison of the three-dimensional structures of these two polymeric isomers makes it clear why rubber is more readily oxidisable than is gutta-percha: in natural rubber the oxidisable α-methylene and the methyl groups are in the *trans*-position, in which steric hindrance is absent; in gutta-percha, however, these two groups are in the *cis*-position, causing steric hindrance to conjugation, and hence a decrease in the reactivity of the α-methylene group.

4. Monoalkylnaphthalenes

Isomeric 1- and 2-alkylnaphthalenes differ in physical properties in the same way as *o*- and *p*-dialkylbenzenes. This is shown by their boiling points, specific gravities, refractive indices, and molecular refraction[69]. Comparison of the latter shows that the 1-isomer possess a lower refraction than their 2-analogues. Table 8 gives these data for the liquid hydrocarbons and their solutions[29].

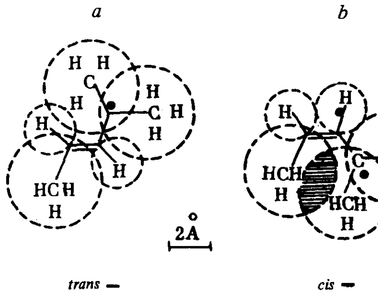


Figure 8. Radicals obtained by autoxidation of: *a*) *trans*-4-methylpent-2-ene; *b*) *cis*-methylpent-2-ene.

The diminished refraction of 1-alkylated naphthalenes in liquid and dissolved states supports the view that intramolecular factors—interaction between adjacent alkyl groups which are not directly bound to one another—are responsible for the regular variation in refraction, as in the case of *o*- and *p*-dialkylbenzenes and *cis*- and *trans*-alkenes. Fig. 9 illustrates such interaction for 1- and 2-monoalkylnaphthalenes.

Table 8. Molar refraction of 1- and 2-monoalkylated naphthalenes.

Substituent	Liquids		Solutions	
	MR_D	ΔMR_D	MR_D	ΔMR_D
2-Methyl	49.24	0.42	49.42	0.40
1-Methyl	48.82		49.02	
2-Ethyl	53.88	0.42	53.86	0.41
1-Ethyl	53.46		53.45	
2-Isopropyl	58.89	0.41	—	—
1-Isopropyl	58.48		—	
2-Butyl	63.31	0.43	—	—
1-Butyl	62.88		—	
2-Iodo	57.88	1.34	57.65	1.14
1-Iodo	56.54		56.51	

1-Alkylnaphthalenes have a lower optical exaltation as well as a lower refraction than the 2-isomers. This is all because the packing of the "*peri*-hydrogen" in 1-alkylnaphthalenes forces the adjacent $C_{Ar}-C_{Alk}$ bond out of the plane of the naphthalene ring, with a resultant breakdown in σπ-conjugation of the ring with an α-C–H bond in the alkyl group[70,71]. Thus steric hindrance to σπ-conjugation arises not only from the influence of bulky *ortho*-substituents but also from that of hydrogen in the *peri*-position with respect to the substituent in the 1-position of naphthalene. The occurrence of steric hindrance to σπ-conjugation in 1-alkylnaphthalenes is indicated also by the fact that the electronic absorption spectra of 2-alkylnaphthalenes, like those of *p*-dialkylbenzenes, possess a more intense long-wavelength maximum than do the 1-isomers.

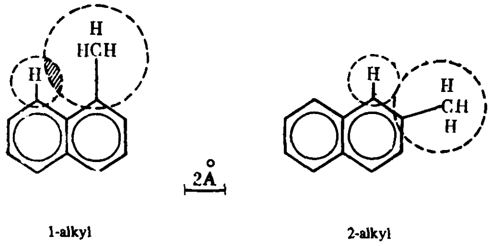

Figure 9. Interaction of unlinked groups in monoalkylnaphthalenes.

For the same reason the degree of conjugation of the unpaired *p*-electron of a new 1-alkylnaphthalene radical is lower and its stabilisation diminished, so that the radical is unable to continue the oxidation chain. This conclusion is supported by the oxidation rate curves for 1- and 2-monoalkylnaphthalenes illustrated in Fig. 10.

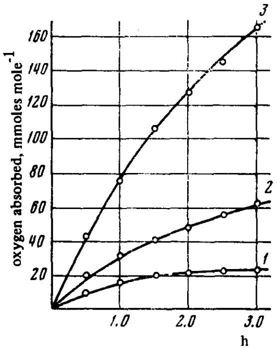

Figure 10. Variation in rate of oxidation of isopropylnaphthalene (with 0.01 wt.% of manganese resinate at 110°C) with amount (wt.%) of 1-isopropyl compound mixed with the 2-isomer: 1) 70; 2) 55; 3) 12.

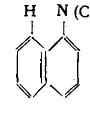
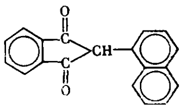
It is interesting that analogous hindrance to conjugation[72] arises also in compounds of the type



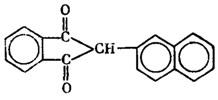
.

The above concepts can obviously explain also the difference in oxidisability of the tetrahydro-5(and 6)-isopropylnaphthalenes[73] and between 2-naphth-1′-ylindane-1,3-dione (*a*) and the corresponding 2-naphth-2′-yl derivative (*b*)[74].

(*a*)



(*b*)



Whereas 1-alkylnaphthalenes are less reactive in reactions involving autoxidation of an α-C–H bond in the alkyl, they are more reactive in the radical polymerisation of 1-vinylnaphthalenes. For example, 1-vinylnaphthalene polymerises about 2.5 times as fast as styrene[75]. It is interesting that the increase in reactivity in this case coincides with the increase in dissociation (the Gomberg series) of hexa-arylethanes[76] as a function of these substituents—phenyl < 2-naphthyl < 1-naphthyl—which means the alkyls having a greater steric effect on the α-carbon atom also show a greater degree of dissociation. This conclusion is supported not only by the Gomberg series but also by Theilacker and Ewald's data[77] on the dissociation of substituted hexa-arylethanes in benzene solution at 25°C (Table 9).

Table 9.

Hexa-arylethane	Degree of dissociation, %
Hexaphenylethane	2.5
Tetraphenyl-1,2-di-*o*-tolylethane	25.2
Hexa-*o*-tolylethane	90.8

The above cases of the effect of steric hindrance on rate of autoxidation in alkylated aromatic compounds and in alkenes constitute some of the most important specific examples of interaction between atoms which are not directly attached to one another in the molecule, a problem which was first formulated by Butlerov[78] and developed by Markovnikov.

The existence of such interaction is indicated by a mechanical model of the molecule. This was stated as early as 1904 by Chugaev[79]: "Chemical molecules represent a mechanism involving a known store of energy. In order to understand the action of these mechanisms, it is equally necessary to know their internal structure and the distribution of energy in them... We are indebted to organic chemistry for the first information on the nature of these mechanisms. Perhaps it is destined to make a further step and show how these mechanisms act, indicating the relation between them and the rate of chemical reactions. Is not this possibility evident in the cases of stereochemical hindrance, a large number of which are known in organic chemistry?". The above correlating data on the autoxidation of hydrocarbons confirm the validity of the ideas expressed by this remarkable Russian chemist.

5. Homologues of Indane and Tetreahydronaphthalene—Role of Molecular Conformation of Hydrocarbons in Conjugation of Single Bonds

The oxidation of homologues of indane and tetrahydronaphthalene has been studied in detail by Volkov and his coworkers[80], who have shown in particular that alkylindanes and alkyltetrahydronaphthalenes react far more readily than do the corresponding alkylbenzenes with a peroxy-radical ROO•. The difference between the rates of oxidation of these hydrocarbons is easily explained by the influence of rotational isomerism on the degree of coplanarity of the α-carbon atom with the benzene ring. In fact, the trigonal α-carbon atom lies in the plane of the ring in both the transition state and the radical of the oxidisable hydrocarbon (Fig. 4). The oxidisable α-C–H bond is then perpendicular to the plane of the ring: i.e. this bond has an axial orientation, which corresponds to the maximum degree of $\sigma\pi$-overlapping of the orbitals[81]. If this or a closely similar conformation is already present in the hydrocarbon molecule, conjugation (delocalisation of electrons) is readily accomplished, without the consumption of energy. This leads to an increase in the reactivity of the compound. Indane and its alkyl derivatives possess such a favourable conformation owing to the "rigid" fixation of the atoms of the alicyclic ring. The conformation of tetrahydronaphthalene is closely similar to that of indane. On the other hand, with e.g. di-isopropylbenzene the favourable conformation constitutes a small proportion among other conformations. In order to detach hydrogen from an α-carbon atom in di-isopropylbenzene, therefore, additional energy must be expended to bring the molecule into a coplanar condition in the transition state and in the radical (Fig. 4). Hence it follows that the autoxidation of alkylated aromatic hydrocarbons should have a higher activation energy, and hence a lower rate, than that of alkyl derivatives of indane and tetrahydronaphthalene.

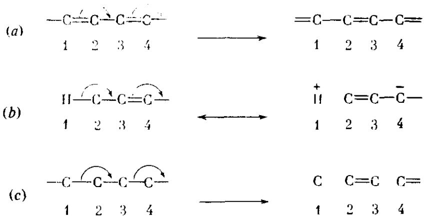
Thus Webster[82] found that the relative rates of oxidation of *m*-di-isopropylbenzene, tetrahydro-1,4-dimethylnaphthalene, and 1,1,3-trimethylindane—compounds having the same hindrance and forming tertiary radicals of similar structure—were 2 : 9 : 10. Hence indane derivatives show the highest rate of oxidation. It is interesting that the same sequence applies to the long-wavelength shift of the absorption maximum in the electronic spectra of these hydrocarbons. Since electronic spectra characterise the degree of delocalisation of electrons, it is obvious that the greatest delocalisation occurs in indane compounds.

The above oxidation results show that alkylindanes are rather more reactive than are alkyltetrahydronaphthalenes. The explanation is that the alicyclic ring of tetrahydronaphthalene is not so flat as that of indane because of its slight conformational distortion (the former has the "half chair" shape[83]), and therefore requires a definite though small additional energy to produce a favourable conformation. It is interesting to note a similar regularity in reactions involving heterolytic rupture of an α-C–H bond[84].

Numerous facts accumulated from the study of the autoxidation of alkenes and alkylarenes confirm the suggestion that conformation plays an important part in the conjugation of single bonds[85–87]. As early as 1950 Nesmeyanov[25] showed for the first time the possibility of such conjugation. He put forward the following principles for heterolytic conjugation: "The complete conjugation of two single bonds requires that they should be parallel (or nearly parallel) to one another. However, this condition is insufficient. ... It is also necessary (at least in heterolytic conjugation phenomena) that one of the conjugating σ-bonds should be of donor character and the other of acceptor character, and that they should be located *trans* to one another". This quotation shows that the first requirement for conjugation is a favourable conformation.

The same stereochemical laws apply to the homologous as to the heterolytic development of conjugation[25]. An actual case of the former is σπ-conjugation, on the stereochemistry of which several papers have been published by Nesmeyanov[88] and also by Shorygin[89,90] and their coworkers. This work shows that, whereas two single bonds are conjugated when mutually parallel, conjugation occurs between a single and a multiple bond when they are perpendicular. This clearly opposite character of the stereochemistry of the two types of conjugation obviously has the same origin: the most favourable conformation is produced, in which delocalisation of electrons can be achieved with minimum energy.

This principle of the role of a favourable conformation can be justified by fairly simple theoretical arguments. The interaction of single and multiple bonds involved in conjugation in saturated and unsaturated compounds can be represented as the displacement of electron density along a chain of atoms:



A common feature here is the formation of a new double bond 2–3. In the first case this change in electronic structure should not result in a change in the molecular conformation. In the second and third cases changes would occur in the configuration of the molecule. In particular, formation of the double bond 2–3 requires that substituents in this portion of the molecule should have a planar (or nearly planar) arrangement. If such conformation is already present, as in the dienes (*a*), electron transfer occurs freely. On the other hand, where a favourable conformation (*b*) and (*c*) must be created, additional energy is obviously needed.

In alicyclic hydrocarbon molecules the atoms may be rigidly fixed. Conjugation is therefore more clearly developed here, as is confirmed by the increased tendency of alicyclic compounds, e.g. indane and tetrahydronaphthalene, compared with alkylated aromatic compounds, e.g. isopropylbenzene, to undergo autoxidation. Data on the autoxidation of hydrocarbons indicate that the conjugation of single bonds is similar in character to that of double bonds and is due to a quantum-mechanical effect[91].

Organosilicon Derivatives of Aminoalcohols

E.Lukevics, L.Liberts, and M.G.Voronkov

The literature data and the present authors' investigations in the field of organosilicon derivatives of aminoalcohols are reviewed. The methods for the preparation, the chemical and biological properties, and the practical applications of organosilicon derivatives of aminoalcohols, in which the silicon atom is linked directly to the aminoalcohol heteroatom or via a carbon chain, are discussed.
The bibliography includes 204 references.

CONTENTS

I. INTRODUCTION

The increase of interest in the study of the properties and reactions of aminoalcohols and their derivatives is due to at least two causes: the specific biological properties and high reactivity associated with the presence of more than one functional group and the presence of competing reactive centres in their molecules. It is sufficient to mention that many aminoalcohols and their derivatives are biogenic amines playing an extremely important role in the vital processes of organisms (choline and acetylcholine). On the other hand, numerous widely employed medicinal preparations have been prepared on the basis of aminoalcohols (ephedrine, Pentaphen, Dimedrol, Novocaine, Dicaine, Spasmolytin, adrenaline, Ustimon, and others). Moreover, aminoalcohols are effective complex-forming agents and are used to remove from solutions various metal ions. Aminoalcohol complexes can be employed as models of oxidases and in all probability (after a detailed study of their biological properties) will find application in medicine.

The studies on the physical, chemical, and biological properties of organosilicon derivatives of aminoalcohols have provided valuable information about the influence of the amino-group on the strength and reactivity of the Si–O bond in aminoalkoxysilanes, about the degree of intramolecular interaction between the nitrogen atom of the aminoalkoxy-group and the silicon atom leading to the formation of a strong donor-acceptor Si ← N bond in cyclic organosilicon derivatives of triethanolamine (silatranes), and about the relation between the structure and biological activity of organosilicon derivatives of aminoalcohols, among which extremely toxic compounds have been discovered (1-arylsilatranes). The application or organosilicon derivatives of aminoalcohols as water repelling agents, hardening agents for epoxy-resins, dispersing agents, and intermediates for the synthesis of special polymers are no less important.

The results of studies in this interesting and extremely promising field of the chemistry of organosilicon compounds published up to May 1969 are reviewed in the present article.

II. ORGANOSILICON DERIVATIVES OF AMINOALCOHOLS IN WHICH THE SILICON ATOM IS LINKED DIRECTLY TO THE HETEROATOM OF THE AMINOALCOHOL

A. METHODS OF PREPARATION OF AMINOALKOXYSILANES

1. Reactions of Chlorosilanes with Aminoalcohols

When chlorosilanes and silicon tetrachloride react with ethanolamine and its *N*-substituted derivatives in the presence of hydrogen chloride acceptors, the first step is the silylation of the hydroxy-group of the aminoalcohol with formation of aminoalkoxysilanes [1-14]:

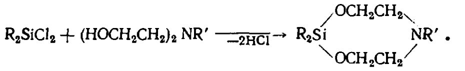
$$\geqslant\text{SiCl} + \text{HOCH}_2\text{CH}_2\text{NR}_2 \xrightarrow{+\text{B}} \geqslant\text{SiOCH}_2\text{CH}_2\text{NR}_2 + \text{B}\cdot\text{HCl}\,.$$

The reaction is carried out in chloroform [5,15], ethyl ether [5,8,9], petroleum ether [11], and benzene [13,14]. The hydrogen chloride acceptors employed are ammonia [8,15], triethylamine [5,9,10], pyridine [14], or an excess of the aminoalcohol itself [5,11,13]. Organosilicon derivatives of ethanolamine [5,8,13] and its *N*-substituted derivatives [1,9-11], 3-(α-pyridyl)propanol [10], and aminobutanols [14] have been obtained in this way.

When the reactant ratio is equimolar, the hydrogen chloride formed is bound by the aminoalkoxysilane itself, which is converted into the hydrochloride [5,7,16-20]:

$$\geqslant\text{SiCl} + \text{HOCH}_2\text{CH}_2\text{NR}_2 \rightarrow \geqslant\text{SiOCH}_2\text{CH}_2\text{NR}_2\cdot\text{HCl}\,.$$

The reaction of trialkylchlorosilanes with diethanolamine takes place similarly to the reaction with monoethanolamine: in the first step both hydroxy-groups are silylated and only then also the amino-group, in the presence of an excess of the trialkylchlorosilane [5,7]. It has been noted in patents [16,19,20] that the hydrochlorides of 2-[(2′-hydroxyethyl)amino]ethoxysilanes are formed in the reactions of alkyltrichlorosilanes with diethanolamine, while the products of the reaction of silicon tetrachloride with di- and tri-ethanolamines in the presence of ammonia are polymers[15]. A cyclic compound was obtained by the reaction of dichlorodimethylsilane with *N*-ethyldiethanolamine in the presence of triethylamine[21]:



It has been pointed out[22] that a deposit is formed in the exothermic reaction of silicon tetrachloride with diethanolamine. This was attributed to complex formation via the free electron pair of the nitrogen atom and the vacant 3*d* orbitals of the silicon atom. It is surprising that the author completely fails to take into account the possibility of a substitution reaction with participation of hydroxy-groups.

2. Alcoholysis of Alkoxysilanes and Acyloxysilanes by Aminoalcohols

When alkoxysilanes are heated with ethanolamine and its *N*-derivatives with simultaneous distillation of the alcohol evolved, the corresponding aminoalkoxysilanes are formed:

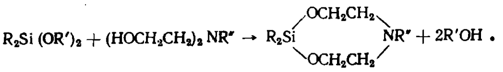
The reaction is carried out in the presence of catalytic amounts of potassium hydroxide[9], sodium methoxide[13,29], sodium aminoalkoxide[1,3,6,24], tetra-alkoxytitanium[25,26], or in the absence of catalysts[1,6,13,27-37].

For the synthesis of aminoalkoxysilanes, ethoxysilanes are most frequently employed[1-3,6,13,23-25,27-42] but methoxy-[1,9,26], n-propoxy-[33,40], isopropoxy-[33], and butoxysilanes[34,43] can also be used. Among alkoxysilanes, alkoxysilanes with three further organic substituents[3], dialkoxysilanes with two further organic substituents[1,9,23-27,31,32,37], trialkoxysilanes with one additional organic substituent[1,27,28,31,32], tetra-alkoxysilanes[13,29-31,33-36], and polyalkoxysilanes[34,38-42,44] have also been used in the reaction with ethanolamine and its *N*-substituted derivatives. In all cases all the alkoxy-groups at the silicon atom are replaced by aminoalkoxy-groups with formation of the corresponding di-, tri-, and tetra-(aminoalkoxy)-silanes. The attempts to isolate the mixed ethers from the products of the transetherification of tetraethoxysilane or tetraisopropoxysilane with ethanolamine, with the molar ratio of the reactants ranging from 1 : 1 to 1 : 3, were unsuccessful[33]. Nevertheless the reaction of tetraethoxysilane with 2-(diethylamino)ethanol (molar ratio 5 : 2) gave diethoxydi-[2-(diethylamino)ethoxy]silane[13]. Mixed aminoethoxyfurfuryloxysilanes containing between one and three furfuryloxy-groups have been obtained by the transetherification of tetraethoxysilane with a mixture of ethanolamine and furfuryl alcohol[29].

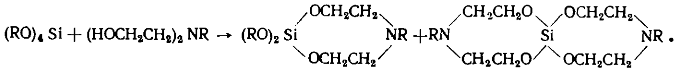
Two and three triethylsilyl groups can be introduced into the diethanolamine and triethanolamine molecules respectively by transetherification[3,6,7]:

$$n\,\mathrm{R_3SiOR} + (\mathrm{HOCH_2CH_2})_n\,\mathrm{NH}_{3-n} \rightleftarrows (\mathrm{R_3SiOCH_2CH_2})_n\,\mathrm{NH}_{3-n} + n\,\mathrm{ROH}\,. \quad n = 1\text{—}3,$$

Readily polymerised cyclic products have been obtained by the reaction of dialkoxysilanes containing two additional organic substituents with diethanolamine and its *N*-substituted derivatives[21,27,43,45-47]:



Usually ethoxysilanes are introduced into the reaction and the latter is carried out in the absence of a catalyst. However, best yields (80–86%) are achieved when dialkyldibutoxysilanes are employed in the presence of a catalytic amount of the corresponding sodium aminoalkoxide[43]. Polymers are obtained by the reaction of trialkoxysilanes containing an additional organic substituent with diethanolamine[48]. The reaction of tetra-alkoxy silanes with diethanolamine also leads to the formation of polymers[34,49]. However, in some cases it proved possible to isolate low-molecular-weight cyclic compounds[47]:



It is very probable that the intermediate acyclic compounds cyclise on distillation[13,47]:

$$\mathrm{(RO)_4\,Si + 2\,(HOCH_2CH_2)_2\,NH \xrightarrow[-2ROH]{} (RO)_2\,Si\,(OCH_2CH_2NHCH_2CH_2OH)_2}\,.$$

The reaction of trialkoxysilanes containing a further organic substituent[47,50-53] and tetra-alkoxysilanes[47,50,51,53-56] with triethanolamine (1 : 1 molar ratio) does not lead to the formation of polymers but to monomeric chelate cyclic compounds—silatranes†, stabilised as a result of the presence in the molecule of the transannular coordinate bond Si ← N:

$$\mathrm{RSi\,(OR')_3 + (HOCH_2CH_2)_3\,N \rightarrow RSi\,(OCH_2CH_2)_3\,N + 3R'OH}\,.$$

When the reaction of tetraethoxysilane with triethanolamine is carried out in the presence of phenols[50,61] or carboxylic acids[50,62], the products are the corresponding 1-aryloxy- and 1-acyloxy-silatranes:

$$\mathrm{(R'O)_4\,Si + ROH + (HOCH_2CH_2)_3\,N \rightarrow ROSi\,(OCH_2CH_2)_3\,N + 4R'OH}\,.$$

In some cases the formation of acyclic[37], spirocyclic[51], and also polymeric transetherification products[51] was observed in the reaction of tetra-alkoxysilanes with triethanolamine (for other reactant ratios).

The reaction of acyloxysilanes with aminoalcohols has not been investigated at all. In only one patent[63] is there a mention of the possibility of preparing 2-aminoethoxysiloxanes from acetoxysiloxanes and ethanolamine in the presence of tetraisopropoxytitanium. Another patent[64] describes the synthesis of a polymer from diheptadecyloxydimethylsilane (partially acylated by stearic acid) and triethanolamine.

3. Reactions of Siloxanes and Siloxanols with Aminoalcohols

When a solution or a hydrogel of silicic acid is heated with ethanolamine[65-68] or 2-(diethylamino)ethanol[67], the hydroxy-groups are partially substituted by aminoalkoxy-groups, which leads to the formation of modified silica gels. The same type of exchange of hydroxy-groups for aminoalkoxy-groups can occur in the reaction of aminoalcohols with polysiloxanols having a number of other organic substituents[69]. The siloxane bond is probably not involved in these reactions. The reaction of polysesquisiloxanes $(\mathrm{RSiO_{1.5}})_x$ and polysiloxanols $[\mathrm{RSiO_{1.5-y}(OH)_{2y}}]_x$, both containing a number of other organic substituents, with aminoalcohols in the presence of potassium hydroxide on heating in an inert solvent with azeotropic distillation of water is of quite a different type. It involves the cleavage of the Si–O–Si bonds with formation of tri-[2-(dialkylamino)ethoxy]silanes having one

---

†For details of the synthesis and properties of silatranes, see the appropriate reviews[50,57-60].

further organic substituent in the case of 2-dialkylaminoethanols[1] and silatranes with one organic substituent in the 1-position in the case of triethanolamine[50,57–60,70–72]:

$$2/x\,(\mathrm{RSiO_{1.5}})_x + 6\,\mathrm{HOCH_2CH_2NR'_2} \rightarrow 2\,\mathrm{RSi(OCH_2CH_2NR'_2)_3} + 3\,\mathrm{H_2O}\ ,$$

$$1/x\,[\mathrm{RSiO_{1.5-y}(OH)_{2y}}]_x + \mathrm{(HOCH_2CH_2)_3N} \rightarrow \mathrm{RSi(OCH_2CH_2)_3N} + (1.5+y)\,\mathrm{H_2O}\ .$$

The rate of reaction increases with the degree of condensation of the initial siloxanes and also on passing from alkyl- to aryl- and vinylpolysiloxanols. Polyhydrosiloxanes substituted by a number of organic groups $(\mathrm{RSiHO})_x$ can also be employed in this reaction. Then dehydrocondensation with evolution of hydrogen takes place in the absence of the catalyst, but the addition of alkali is necessary for the cleavage of the siloxane bond[1,71].

4. Reactions of Aminosilanes with Aminoalcohols

When diaminodi-t-butoxysilane is heated with ethanolamine at 150–200°C, ammonia is evolved and di-(2-aminoethoxy)di-t-butoxysilane is formed[73]:

$$\mathrm{(RO)_2Si(NH_2)_2} + 2\,\mathrm{HOCH_2CH_2NH_2} \xrightarrow[-2\mathrm{NH_3}]{} \mathrm{(RO)_2Si(OCH_2CH_2NH_2)_2}\ .$$

The reaction of diaminodi-t-butoxysilane with *N*-alkyl- and *NN*-dialkylethanolamines and propanolamine derivatives takes place similarly. In the case of 2-diethylaminoethanol the product formed by the substitution of the 1-amino-group by a 2-diethylaminoethoxy-group was also isolated. t-Butoxytri(2-ethylaminoethoxy)silane was detected in addition to di-t-butoxydi-(2-ethylaminoethoxy)-silane in the products of the reaction of 2-ethylaminoethanol[73].

The possibility of employing triethylaminosilane for the silylation of ephedrine is mentioned (without indicating the experimental conditions) in a brief communication[74].

Diethylaminotrimethylsilane readily silylates the hydroxy-groups in mono-, di-, and tri-ethanolamines[4,6,7,75]:

$$n\,\mathrm{R_3SiNR'_2} + \mathrm{(HOCH_2CH_2)}_n\mathrm{NH}_{3-n} \xrightarrow[-n\,\mathrm{R'_2NH}]{} \mathrm{(R_3SiOCH_2CH_2)}_n\mathrm{NH}_{3-n}\ ,$$

where $n = 1$–3.

With di- and tri-ethanolamines, it is possible to achieve the successive substitution of all the hydroxy-groups by trimethylsiloxy-groups. When diethylaminosilanes $\mathrm{R}_{4-n}\mathrm{Si(NR'_2)}_n$ containing between one and three diethylamino-groups are employed in this reaction, it is possible to obtain aminoethoxysilanes containing between one and three 2-aminoethoxy- or 2-dialkylaminoethoxy-groups[5,75,76]. When $n = 2$, the reaction with diethanolamine leads to monomeric cyclic compounds (as in the reaction with dialkoxysilanes), while the reaction with triethanolamine leads to polymers. On the other hand, when $n = 3$, diethanolamine gives a polymer, and a cyclic compound (a silatrane with an organic substituent in the 1-position) is formed in the reaction with triethanolamine[75]:

$$\mathrm{RSi(NR'_2)_3} + \mathrm{(HOCH_2CH_2)_3N} \xrightarrow[-3\mathrm{R'_2NH}]{} \mathrm{RSi(OCH_2CH_2)_3N}\ .$$

5. Reactions of Silazanes with Aminoalcohols

Hexamethyldisilazane silylates the hydroxy-groups of ethanolamine[6,8,77,78] and its *N*-substituted derivatives[74,79,80], diethanolamine[77,81], triethanolamine[77], and heterocyclic aminoalcohols[79,82]. The silylation involves both trimethylsilyl groups:

$$n\,\mathrm{(R_3Si)_2NH} + 2\,\mathrm{(HOCH_2CH_2)}_n\mathrm{NR'}_{3-n} \xrightarrow[-n\,\mathrm{NH_3}]{} 2\,\mathrm{(R_3SiOCH_2CH_2)}_n\mathrm{NR'}_{3-n}\ .$$

When 1,3-dialkoxy-1,1,3,3-tetramethyldisilazanes are heated with ethanolamine, the silazane group is cleaved and ammonia is evolved. The subsequent heating of the reaction mixture with simultaneous distillation of the corresponding alkanol leads to the formation of di-(2-aminoethoxy)dimethylsilane[77]:

$$\mathrm{(R_2R'OSi)_2NH} + 4\,\mathrm{HOCH_2CH_2NH_2} \xrightarrow[-\mathrm{NH_3}]{} 2\,\mathrm{R_2Si(OCH_2CH_2NH_2)_2} + 2\mathrm{R'OH}\ .$$

The reaction of hexamethylcyclotrisilazane and octamethylcyclotetrasilazane with ethanolamine, 2-dialkylaminoethanols, derivatives of isomeric propanolamines, and 4-amino-1-butanol leads to the formation of the corresponding di(aminoalkoxy)dimethylsilanes[6,77,79,83]:

$$\mathrm{(R_2SiNH)}_n + 2n\,\mathrm{HOCHR'(CH_2)}_m\mathrm{NR''_2} \xrightarrow[-n\mathrm{NH_3}]{} n\,\mathrm{R_2Si[OCHR'(CH_2)}_m\mathrm{NR''_2]_2},$$

where $\mathrm{R = CH_3}$, $\mathrm{R' = H}$ or $\mathrm{CH_3}$, $\mathrm{R'' = H, CH_3, C_2H_5, C_4H_9}$, or $\mathrm{(CH_2)_5}$, $n = 34$, and $m = 1$–3.

6. Dehydrocondensation of Hydrosilanes and Hydrosiloxanes with Aminoalcohols

Trialkylsilanes undergo dehydrocondensation with ethanolamine, its *N*-substituted derivatives, and 2-piperidinoethanol in the presence of sodium aminoalkoxides with formation of the corresponding aminoalkoxysilanes[1,3,6,74,84]:

$$\mathrm{{>}SiH} + \mathrm{HOCH_2CH_2NR_2} \rightarrow \mathrm{{>}SiOCH_2CH_2NR_2} + \mathrm{H_2}\ .$$

Polyalkylhydrosiloxanes $(\mathrm{RSiHO})_n$ react vigorously with ethanolamine in the absence of catalysts[1,85–89]. When cyclotetrasiloxanes ($n = 4$) and cyclopentasiloxanes ($n = 5$) are employed, the reaction products are gels to which the structure $[\mathrm{CH_3Si(OCH_2CH_2NH_2)O}]_n$ is attributed and which are insoluble in benzene, toluene, xylene, and dioxan[88]. With higher oligomers ($n \simeq 13$–16) in which $\mathrm{R = CH_3}$, the products of the reaction with ethanolamine are also gels, which rapidly become insoluble on storage. When $\mathrm{R = C_2H_5}$ (GKZh-94), the exothermic reaction with ethanolamine involves a stage in which a rubberlike gel is formed (at 60–65°C), but on attainment of 140°C the reaction mass becomes liquid again and completely transparent. The liquid product is soluble in aromatic hydrocarbons, ether, and dioxan[87].

7. Other Methods

A number of other methods which have as yet not acquired general importance have been employed for the synthesis of individual examples of aminoalkoxysilanes with different structures. The reaction of substituted oxirans with trimethyl(diorganyl)silanes at 80°C takes place with the opening of the oxygen-containing ring by the mechanism[90]

$$\mathrm{(CH_3)_3SiNR_2} + \mathrm{R'CHCH_2O} \rightarrow \mathrm{(CH_3)_3SiOCHR'CH_2NR_2}\ .$$

This apparently very simple and promising reaction cannot be used as a general method for the synthesis of aminoalkoxysilanes, since it can only be achieved when powerful electron-accepting substituents are present in the group R′ of the substituted oxiran. For example, whereas in the reaction of trimethylpiperidinosilane with trichloromethyloxiran the yield of (1-trichloromethyl-2-piperidinoethoxy)-trimethylsilane is 89% after only 1.3 h, in the reaction with chloromethyloxiran the yield does not exceed 45% even after heating for 22 h. Methyloxiran does not react at all with trimethylpiperidinosilane in a sealed tube at 80°C.[90] The rate of this reaction decreases also on passing from piperidinosilanes to diethyl- and dimethyl-aminosilanes, which is consistent with the sequence of decreasing basicity of the above amines[90].

The reaction of oxiranylmethoxysilanes with amines can also lead to the formation of aminoalkoxysilanes. In the only known example of such a reaction described in a patent[91], diethylenetriamine was employed as the amine, which led to the formation of infusible, insoluble resins.

Aminoalkoxysilanes can also be synthesised by substituting halogen atoms in halogenoalkoxysilanes by amino-groups[18]:

$$\equiv Si-O-(C)_n-X + HNR_2 \xrightarrow[-HX]{} \equiv Si-O-(C)_n-NR_2 .$$

1-Hydrosilatranes, which are very difficult to obtain by the reaction of triethoxysilane with trialkanolamines (because of the substitution at the Si–H bond), have been synthesised by the transetherification of triethoxysilane with boratranes[50,92,93]:

$$HSi(OC_2H_5)_3 + B(OCHRCH_2)_3N \rightarrow HSi(OCHRCH_2)_3N + B(OC_2H_5)_3 .$$

1-(triorganylsiloxy)titanatranes are obtained by the general method for the formation of the group Si–O–Ti.[94]

B. METHODS FOR THE PREPARATION OF ORGANOSILICON DERIVATIVES OF AMINOALCOHOLS CONTAINING THE Si–N BOND

The dehydrocondensation of substituted silanes $RSiH_3$ with ethanolamine and diethanolamine takes place vigorously with evolution of heat[95]. The structure of 2-hydroxyethylaminosilanes containing the Si–N bond, for example $RSi(NHCH_2CH_2OH)_3$, is attributed to the reaction products[95-99]. However, bearing in mind the comparative ease of the cleavage of the Si–N bond by alcohols[100,101] (including ethanolamine[7,75]) with formation of the Si–O bond, the structure proposed for the products of the reaction of substituted silanes with ethanolamine is very doubtful.

Also doubtful is the structure $RCH[(CH_2OH)NHSi(CH_3)_3]$ allegedly formed when di(trimethylsilyl) derivatives of the corresponding aminoacids $RCH[NHSi(CH_3)_3]COOSi(CH_3)_3$ are reduced with lithium aluminium hydride[102]. On hydrolysis of the reaction mixture with moist ether, the Si–N bond in these compounds is hardly likely to be retained. The final hydrolysis product might be formed with equal success from the *O*-derivative $RCHNH_2CH_2OSi(CH_3)_3$.

Organosilicon derivatives of aminoalcohols in which the presence of the Si–N bond has been unquestionably demonstrated have so far been synthesised from aminoethers not containing a free hydroxy-group. They have been synthesised by the reaction of aminoethers with trialkyldiethylaminosilanes[103], trialkyl-t-butylaminosilanes[103], hexamethyldisilazane[80], and substituted chlorosilanes in the presence of triethylamine[103]:

$$\equiv Si-X + H_2NCH_2CH_2OR \xrightarrow[-HX]{} \equiv SiNHCH_2CH_2OR .$$

C. METHODS FOR THE PREPARATION OF ORGANOSILICON DERIVATIVES OF AMINOALCOHOLS CONTAINING BOTH Si–O AND Si–N BONDS

Organosilicon derivatives of aminoalcohols containing both Si–O and Si–N bonds are synthesised by a number of reactions used for the preparation of aminoalkoxysilanes: by the reaction of aminoalcohols with chlorosilanes[1,5,6], dialkylaminosilanes[6,75,104], and hexamethyldisilazane[77]. The application of an excess of these organosilicon reagents leads to the formation of di- and tri-organylsilyl derivatives containing both the Si–O and the Si–N bonds. However, in many cases best results in the synthesis of these compounds are obtained on further silylation of the amino-group in individual aminoalkoxysilanes[4-7,75,77]:

$$R_3SiOCH_2CH_2NH_2 + XSiR'_3 \xrightarrow[-HX]{} R_3SiOCH_2CH_2NHSiR'_3 ,$$

$$(R_3SiOCH_2CH_2)_2NH + XSiR'_3 \xrightarrow[-HX]{} (R_3SiOCH_2CH_2)_2NSiR'_3 ,$$

where X = Cl, $(C_2H_5)_2N$, $(CH_3)_3SiNH$, or H.

It proved possible to introduce three trimethylsilyl groups into the ethanolamine molecule by allowing diethylaminotrimethylsilane[6,75] and hexamethyldisilazane[77] to react with its di(trimethylsilyl) derivative in the presence of ammonium sulphate:

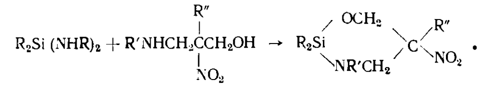
$$R_3SiOCH_2CH_2NHSiR_3 + XSiR_3 \xrightarrow[-HX]{} R_3SiOCH_2CH_2N(SiR_3)_2 .$$

Another reaction involving the formation of *N*-[2-(trisubstituted-siloxy)ethyl]hexamethyldisilazanes (yield 65%) takes place by the mechanism[105,106]

$$[(CH_3)_3Si]_2NNa + RCHCH_2O \xrightarrow[-NaCl]{+R'_3SiCl} R'_3SiOCHRCH_2N[Si(CH_3)_3]_2 .$$

In all probability it proceeds via the cleavage of the oxiran ring by hexamethyldisilazylsodium with subsequent silylation of the intermediate alkoxide by trisubstituted chlorosilane. It is very surprising that, in contrast to trialkylchlorosilanes, chlorodimethylsilane forms in this reaction dimethylsilyldi(trimethylsilyl)amine instead of the aminoalcohol derivative[105,106].

When dimethyldi(diorganylamino)silanes react with 2-alkyl-3-alkylamino-2-nitro-1-propanol (in molar proportions of 1 : 1) in the presence of ammonium chloride, the reaction involves both the hydroxy- and the amino-group with evolution of two equivalents of the primary amine and the formation of a cyclic product[107]:



It is asserted[86,88] that the products of the reaction of polyalkyl hydrosiloxanes with ethanolamine are siloxanes containing alternating $SiOCH_2CH_2NH_2$ and $SiNHCH_2CH_2OH$ groups. This has been confirmed by the reaction with hydrogen chloride in which only half the amino-groups were bound into salts. However, bearing in mind the possibility of the reaction of compounds containing Si–N bonds with alcohols to form Si–O bonds and also the possibility of the cleavage on the Si–N bond by hydrogen chloride, more reliable evidence is required to confirm the proposed structure of the reaction products.

D. PHYSICAL PROPERTIES

The infrared[52,108] and ^1H NMR[60,109] spectra and the dipole moments[110] of silatranes have been investigated and their crystallographic parameters have been determined[111-113]. Silatranes have high dipole moments (5.3–7.1 D), greatly exceeding (by 4.6–5.8 D) the values calculated for the structure without taking into account the donor–acceptor interaction between the nitrogen and silicon atoms[110]. This demonstrates convincingly the presence in silatrane molecules $RSi(OCH_2CH_2)_3N$ of an N → Si coordinate bond the length of which in 1-phenylsilatrane is 2.193 Å.[113] The presence of the same coordinate bond was attributed without any proof to the cyclic organosilicon derivatives of diethanolamine $R_2Si(OCH_2CH_2)_2NH$.[46,47] The study of their dipole moments did not confirm this hypothesis[45].

The ^1H NMR spectra of 2-aminoethoxysilanes indicate a lowering in these compounds (compared with ethoxysilanes) of the extent of $p\pi - d\pi$ interaction between the oxygen and silicon atoms[114].

E. CHEMICAL PROPERTIES

1. Hydrolysis

The hydrolysis of aminoalkoxysilanes has been little investigated. Some of them are readily hydrolysed by water[6,7,33,52]. At the same time it has been stated that compounds of the type $Si(OCH_2CH_2NR_2)_4$, where $R = C_2H_5$ or C_4H_9, are relatively stable in aqueous solution[33]. Silatranes are even more resistant to moisture and are hydrolysed with greater difficulty than the corresponding substituted triethoxysilanes[50,115]. The hydrolysis of silatranes in an aqueous medium is kinetically of first order with respect to the silatrane. The logarithms of the rate constants are linearly correlated with the σ^* constants of the substituents at the silicon atom[59].

Compounds of the type $R_3SiOCH_2CH_2NHR'$ are hydrolysed quantitatively by a 30% solution of alkali[8,116]. In contrast, *N*-[2-(trialkylsiloxy)ethyl] hexamethyldisilazanes are not hydrolysed even on refluxing with a solution of alkali, but are readily cleaved by dilute hydrochloric acid[104].

2. Alcoholysis

The alcoholysis of aminoalkoxysilanes takes place when they are heated with alcohols and the lower-boiling component of the equilibrium system is distilled off[6,7,31,33,34]:

$$(R_3SiOCH_2CH_2)_2NH + 2\,HOCH_2CH_2NH_2 \rightleftarrows R_3SiOCH_2CH_2NH_2 + (HOCH_2CH_2)_2NH\ .$$

The organosilicon derivatives of ethanolamine and diethanolamine containing both Si–O and Si–N bonds can be selectively desilylated by alkanols[5-7,117]:

$$(R_3SiOCH_2CH_2)_n\,NH_{2-n}SiR'_3 + HOR'' \rightarrow (R_3SiOCH_2CH_2)_n\,NH_{3-n} + R'_3SiOR'',$$

where $n = 1$ or 2.

The cleavage of the Si–N bond by alkanols in compounds of the silazane type takes place in the presence of a catalytic amount of ammonium phosphate[6,7,118] or traces of hydrochloric acid[105,106]. If one uses C_2H_5OD for desilylation under these conditions, an *N*-deuterated derivative is formed[6,7]:

$$R_3SiOCH_2CH_2N(SiR_3)_2 + 2R'OM \rightarrow R_3SiOCH_2CH_2NM_2 + 2R_3SiOR',$$

where M = H or D.

3. Reactions with Acids and Their Anhydrides

Aminoalkoxysilanes are fairly strong bases and can be titrated with hydrochloric acid in the presence of Methyl Red.[75] The formation of salts of aminoalkoxysilanes with inorganic[16,18-20,86,119-121] and carboxylic acids[13,16,121-123] has been noted in a number of patents. However, in only two cases[5,11] were the corresponding hydrochlorides isolated in a pure form and adequately characterised. The difficulty of obtaining the hydrochlorides of aminoalkoxysilanes can be accounted for by the ready cleavage of the Si–O bond in these compounds by hydrogen chloride[6,7,90,107]:

$$(R_3SiOCH_2CH_2)_n\,NH_{3-n} + (n+1)\,HCl \rightarrow n\,R_3SiCl + (HOCH_2CH_2)_n\,NH_{3-n}\cdot HCl,$$

where $n = 1$–3.

The cleavage of these compounds by acetic acid[6,7,90] and also acetic anhydride[107] and *p*-nitrobenzoyl chloride[105,106] takes place similarly. The reaction of disubstituted di-(2-aminoethoxy)silanes with the dianhydride of pyromellitic acid[26,63] and di-isocyanates[27] leads to the formation of polymers.

4. Reactions with Organosilicon Compounds

The silylation of the amino-group in aminoalkoxysilanes by chlorosilanes, aminosilanes, and silazanes was discussed in Section B, 3. Aminoalkoxysilanes are silylated by chloroalkylsilanes[5,8,116]:

In a study of the rate of reaction of various amines with (chloromethyl)dimethylethoxysilane in ethanol solution, the following series of decreasing reactivities was obtained[124]:

$$HOCH_2CH_2NH_2 > (CH_3)_3SiOCH_2CH_2NH_2 > C_3H_5NH_2 > (C_2H_5)_2NH\ .$$

The study of the products of this reaction showed that in the presence of triethylamine intramolecular cyclisation with elimination of ethoxytrimethylsilane takes place in addition to the silylation of the amino-group[9,125]:

5. Other Reactions

Aminoalkoxysilanes with an unsubstituted amino-group are readily hydroxyalkylated by oxiran and substituted oxirans[5,27,33,34,42,126]. The reaction of aminoalkoxysilanes with alkyl iodides yielded the corresponding ammonium salts[24,75,76]. The basic properties of the nitrogen atom in silatranes are reduced so much owing to the formation of the N → Si donor–acceptor bond that they do not react with methyl iodide[50,71].

1-Hydrosilatranes undergo dehydrocondensation with alcohols and phenols in the presence of alkali metal alkoxides (phenoxides) or zinc chloride[127] and with carboxylic acids in the presence of zinc chloride[50]:

$$N(CH_2CH_2O)_3SiH + HOR \rightarrow N(CH_2CH_2O)_3SiOR + H_2\ .$$

It proved impossible to carry out the dehydrocondensation of 1-hydrosilatranes with alcohols[127] and also to use them for the hydrosilylation of olefins (cyclohexene and styrene)[93] in the presence of $H_2PtCl_6.6H_2O$.

The reaction of 1-substituted silatranes with SbF_3 involves an exchange reaction by the mechanism[128]

$$N(CH_2CH_2O)_3SiR + SbF_3 \rightarrow RSiF_3 + N(CH_2CH_2O)_3Sb\ .$$

1-Vinylsilatrane reacts with silver nitrate in aqueous solution in the presence of fluoride ions, giving a characteristic blue colour, which rapidly becomes black. It is suggested that the reaction takes place with elimination of the vinyl group from the silicon atom by silver fluoride with subsequent decomposition of the vinylsilver formed initially[128,129].

F. BIOLOGICAL PROPERTIES

Like the corresponding aminoalcohols, the majority of aminoalkoxysilanes have a depressant effect on the central nervous system. After their administration, an inhibition of respiration and motor activity and convulsions are observed. However, triethyl-[2-(diethylamino)ethoxy]-silane and tri-[2-(diethylamino)ethoxy]phenylsilane have a stimulating effect.

2-(Diethylamino)ethoxytrimethylsilane and di(diethylaminoethoxy)dimethylsilane reduce the motor activity of mice and impair the coordination of motion in doses much lower than the median lethal dose (by a factor of 12.6 and 11.3 respectively).

Derivatives of ethanolamine in the series $R_{4-n}Si(OCH_2CH_2NH_2)_n$ with $n = 1-3$ are 2–9 times more toxic than ethanolamine itself. On the other hand, derivatives of 2-dialkylaminoethanols are less toxic than the corresponding aminoalcohol $HOCH_2CH_2NR_2$ (particularly for $R = CH_3$ or C_4H_9) or their toxicity is of the same order of magnitude (for $R = C_2H_5$). The toxicity of compounds in the series $(R_3SiOCH_2CH_2)_nNH_{3-n}$, where $R = CH_3$ or C_2H_5 and $n = 1-3$, decreases markedly with increase of n. On the whole, the toxicity of organosilicon esters of aminoalkanols is low and varies in the range from 120 mg kg^{-1} for di-(2-aminoethoxy)diethylsilane to 4000 mg kg^{-1} for tri-[2-(triethylsiloxy)ethyl]amine [7,130]. 1-Alkyl- and 1-alkoxysilatranes have a low toxicity [50,57–60,131–134].

In contrast, 1-arylsilatranes are highly toxic [135]. The median lethal dose of 1-phenylsilatrane in experiments on white mice administered intraabdominally is 0.43 mg kg^{-1} [132] (0.33 mg kg^{-1} according to Voronkov [59]). Even in doses of 0.2–0.25 mg kg^{-1} 1-phenylsilatrane causes marked motor excitation of the animal accompanied by a change in the position of the tail (the Straub symptom). 1-Tolylsilatrane is even more toxic (LD_{50} = 0.20 mg kg^{-1}). [59] In contrast to warm blooded animals, 1-phenylsilatrane has completely no effect on frogs in doses up to 30–40 mg kg^{-1}. [50,132]

[2-(Dimethylamino)ethoxy]trimethylsilane methiodide exhibited a H-cholinolytic activity in experiments on the smooth muscle of the stomach ($EC_{50} = 4.5 \times 10^{-4}$). [76]

G. PRACTICAL APPLICATIONS

Aminoalkoxysilanes are used to make water repellent fabrics [15,32,53,64,136,137], leather [64], glass [16,120], paper [64], and building materials [31]. Coatings with improved adhesion to metals [27,121], coatings with satisfactory dielectric and thermal properties [26,63,64,126], and also coatings for casting moulds [38] have been obtained on their basis.

Polyaminoalkoxysiloxanes are used as surface-active substances [42] and binders for refractory materials [34,39,40,138,139].

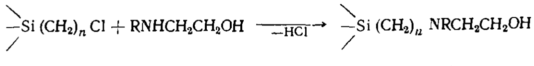
Aminoalkoxysilanes, their carboxylic acid salts, and products of their interaction with oxirans have been proposed as hardening agents for epoxy-resins [35,46,51,126], dispersing agents [13,37,119,122,123,140], viscosity-reducing agents in non-aqueous systems [13], vulcanisers [13], plasticisers [25], binders for fibre glass [53,141], and intermediates in the synthesis of polymers [26,27,53,63,126].

2,3-Di(difluoroamino)propoxysilanes can be employed as rocket fuel and as binders for solid rocket fuel [25].

III. ORGANOSILICON DERIVATIVES OF AMINOALCOHOLS IN WHICH THE SILICON ATOM IS LINKED TO THE AMINOALCOHOL HETEROATOM VIA A CARBON CHAIN

A. METHODS OF SYNTHESIS

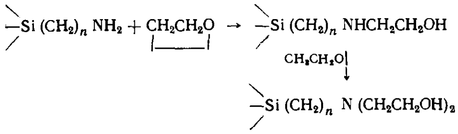
Trialkylchloroalkylsilanes silylate the amino-group of ethanolamine [2,142], 2-alkylaminoethanols [142–144], and diethanolamine [145], forming organosilicon aminoalcohols:



$$\geq Si(CH_2)_nCl + RNHCH_2CH_2OH \xrightarrow[-HCl]{} \geq Si(CH_2)_nNRCH_2CH_2OH\ .$$

The reactions of chloroalkylsiloxanes with β-(2-hydroxyethylamino)ethylamine take place similarly [146,147].

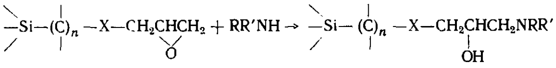
The highest yields of organosilicon aminoalcohols have been achieved in the hydroxyalkylation of organosilicon amines by oxirans [142,145,147]:



$$\geq Si(CH_2)_nNH_2 + \underbrace{CH_2CH_2O} \rightarrow \geq Si(CH_2)_nNHCH_2CH_2OH \xrightarrow{CH_2CH_2O} \geq Si(CH_2)_nN(CH_2CH_2OH)_2\ .$$

The hydroxyethylation of organosilicon anilines [149] and aminoalkylsiloxanes [150,151] is carried out similarly. Diglycidyl ether is also employed instead of oxiran [151,152]. Aminoalkylsilanes have been hydroxyethylated by ethylene chlorohydrin [144,148] and 2-chloroethyl vinyl ether [148,153].

Silicon-containing aminoalcohols are readily obtained by the reaction of silylated oxirans with ammonia [154,155] or amines [154,156–169]. Not only (oxiranylalkyl)silanes but also (oxiranylalkoxyalkyl)silanes [156,157,159,161,165,168–173] and (oxiranylalkylaminoalkyl)silanes [156,160,162] have been introduced into the reaction



$$\geq Si-(\overset{|}{\underset{|}{C}})_n-X-CH_2\underset{O}{CHCH_2} + RR'NH \rightarrow \geq Si-(\overset{|}{\underset{|}{C}})_n-X-CH_2\underset{OH}{\underset{|}{C}}HCH_2NRR'\ ,$$

where $X = CH_2$, O, or NR″.

The opening of the oxiran ring of trialkyl-[β-(1-methyloxiran-1-yl]ethynyl] silanes by aliphatic amines takes place at the carbon atom directly attached to the triple bond, which leads to the formation, in contrast to (oxiranylalkyl)silanes, of primary silylated acetylenic aminoalcohols [174].

Silylated ethers of aminoalcohols have also been synthesised by the hydrosilylation of alkylene ethers of aminoalcohols by hydrosilanes and hydrosiloxanes in the presence of $H_2PtCl_6.6H_2O$: [175,176]

$$\geq SiH + CH_2{=}CHCH_2OCH_2CH_2NR_2 \rightarrow \geq Si(CH_2)_3OCH_2CH_2NR_2\ ,$$

by the reaction of (chloroalkyl)silanes with sodium aminoalkoxides in toluene solution [177,178]:

$$\geq Si(CH_2)_nCl + NaOCH_2CH_2NR_2 \xrightarrow[-NaCl]{} \geq Si(CH_2)_nOCH_2CH_2NR_2\ ,$$

and also by the catalytic reduction of the products of the cyanoethylation of silylated alcohols in the presence of Raney nickel [179]:

$$\geq Si(CH_2)_nOCH_2CH_2CN + 2H_2 \rightarrow \geq Si(CH_2)_nOCH_2CH_2CH_2NH_2\ .$$

Among other reactions involving the formation of silylated aminoalcohols and their ethers, mention may be made of the reduction of silylated aminoacids [180] and esters of cyanoacids [181] by lithium aluminium hydride [180] or sodium borohydride[181], the reaction of silylated diazoketones with ethanolamine[182,183], the acylation of aminoalcohols by the chlorides of trisubstituted silylbenzoic acids[184], and finally organolithium synthesis by the mechanism[185]

$$LiC_6H_4N(CH_2CH_2OLi)_2 + 3R_3SiCl \xrightarrow[-3LiCl \atop -2R_3SiOH]{+2H_2O} R_3SiC_6H_4N(CH_2CH_2OH)_2 .$$

B. CHEMICAL PROPERTIES

Silylated aminoalcohols and their ethers enter into a number of reactions common to aminoalcohols: the formation of hydrochlorides[116,142,173] and quaternary ammonium salts[143,173,175,176], esters[76,143,145], oxazolidines by reaction with aldehydes[144], oxides of aminoethers[175,176], substitution of the hydroxy-group by chlorine when acted upon by thionyl chloride[142,143], silylation by dialkylaminosilanes[5], and also coupling with diazonium salts in the case of *N*-(triorganylsilylaryl) derivatives[185].

C. BIOLOGICAL ACTIVITY AND PRACTICAL APPLICATIONS

Salts of trialkyl(aminoalkyl)silyl benzoates with organic acids and their quaternary ammonium salts have an analgesic and local anesthetic effect[184]. Many hydrochlorides of the type $[R_3SiC_6H_4COOCH_2NHR_2']Cl$ have an antibacterial activity against *S. haemolyticus* and *M. avium*.[184]

Dialkylaminoethyl esters of trimethylsilylphenylhydroxypropionic acid exhibit anticholinergic activity and some of them have a protective effect on poisoning with organophosphorus compounds[186].

The methiodides of trimethyl-[*N*-methyl-*N*-(2-acetoxyethyl)aminomethyl]silane and trimethyl-[*N*-methyl-*N*-(2-benzoyloxyethyl)aminomethyl]silane exhibit H-cholinolytic [*N*-cholinolytic ? (Ed. of Translation)], ganglion blocking, and hypotensive activity[76].

Polysiloxanes containing hydroxyethylaminoalkyl or dialkylaminoalkoxy-groups, their salts, and oxides can be used as emulsifying agents[147,175,176], surface-active substances[147], coatings for fibre glass[146,152], anticorrosion coatings for metals[150], and also for the preparation of foam plastics[187].

Polysiloxanes of the type $[CH_3Si(O)(CH_2)_4N(CH_2CH_2OH)_2]_n$ are used for the flocculation of aqueous suspensions of clays and for the binding of copper and iron ions[151].

IV. ORGANOSILICON DERIVATIVES OF AMINOALCOHOLS CONTAINING BOTH Si-O-C AND Si-Cn-N GROUPS

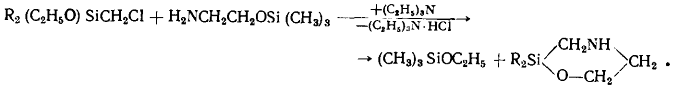
A. METHODS OF PREPARATION

Acyclic organosilicon derivatives of aminoalcohols of the type $\geqslant SiOCH_2CH_2NRCH_2Si\leqslant$, containing both Si-O-C and $Si-C_n-N$ groups have been obtained by the silylation of organosilicon aminoalcohols with trisubstituted dialkylaminosilanes[5,7] and by the silylation of trialkyl(2-aminoethoxy)silanes with chloroalkylsilanes[5,8,116]:

$$R_3SiCH_2NHCH_2CH_2OH + R_3SiNR_2' \xrightarrow[-R_2'NH]{} R_3SiCH_2NHCH_2CH_2OSiR_3 ,$$

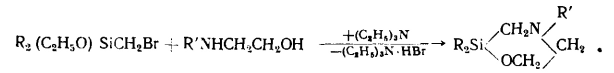
$$R_3SiOCH_2CH_2NH_2 + ClCH_2SiR_3' \xrightarrow[-HCl]{} R_3SiOCH_2CH_2NHCH_2SiR_3' .$$

If instead of trialkylchloromethylsilanes one employs alkyl(chloromethyl)alkoxysilanes of the type $(R'O)_{3-n}R_nSiCH_2Cl$, then after substitution in the amino-group intramolecular cyclisation also takes place on heating, with elimination of alkoxytrimethylsilane[9,125]‡. For example, when $n = 2$, the reaction takes place via the mechanism



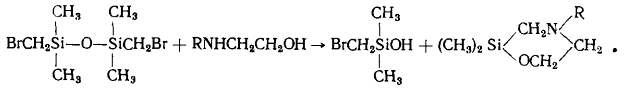
With di-(2-aminoethoxy)dimethylsilane, cyclic compounds having a similar structure are formed. Moreover, the $Si-CH_2Cl$ bond is cleaved in the initial (chloroalkyl)-silanes with further methylation of the N-H bond in the cyclic compounds formed.

When dialkyl(bromomethyl)ethoxysilanes react with 2-(*N*-organylamino)ethanols in the presence of triethylamine, substitution in the amino-group and intramolecular condensation with liberation of ethanol takes place, which also leads to the formation of 2-silamorpholine derivatives[189,192]:

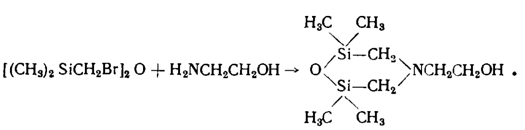


Instead of dialkyl(bromomethyl)ethoxysilanes, one may employ in this reaction also dialkyl(bromomethyl)chlorosilanes, but the yield of 2-silamorpholine derivatives is then reduced (from 62 to 37%).[192] When R′ = H, a cyclic derivative of ethanolamine could be obtained only when dimethyl(bromomethyl)chlorosilane was employed in the alkylation. On the other hand, when dimethyl(bromomethyl)ethoxysilane is used, the reaction product is the corresponding derivative of 2-(*N*-methylamino)ethanol, the formation of which has been explained by the cleavage of the $Si-CH_2Br$ bond by ethanol and the methylation of ethanolamine by the methylbromide liberated in this process[193].

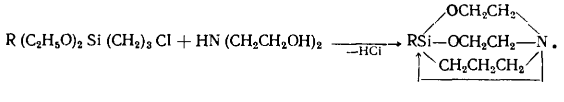
The reaction of 1,3-di(bromomethyl)-1,1,3,3-tetramethyldisiloxane with 2-(*N*-alkylamino)ethanols takes place with the cleavage of the siloxane bond[192-194]:



With ethanolamine, the product of the substitution of the amino-group, formed without the cleavage of the siloxane bond, was obtained[192,193,195,196]:



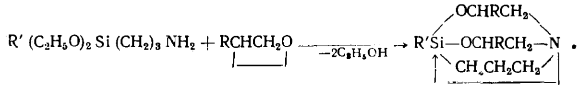
The reaction of substituted (3-chloropropyl)diethoxysilanes with diethanolamine in the presence of triethylamine leads to the silylation of the amino-group followed by intramolecular transetherification with liberation of ethanol and the formation of cyclic compounds (1-organyl-2-carbasilatranes):[4,197,198]



---

‡According to patent data[188], an acyclic substitution product was also obtained in this reaction.

Similar compounds are formed also in the reaction of alkyl-(3-aminopropyl)diethoxysilanes and of (3-aminopropyl)triethoxysilane with oxirans[198,199]:



$$R'(C_2H_5O)_2Si(CH_2)_3NH_2 + RCHCH_2O \xrightarrow[-2C_2H_5OH]{} R'Si{-}OCHRCH_2{-}N\ .$$

It has been stated that cyclisation takes place also in the case of 4-aminobutyl derivatives[199]. Other examples of this type of reaction for the synthesis of products employed in the treatment of fibre glass and for the preparation of adhesives have been described in a number of papers and patents. However, an acyclic structure is attributed to the reaction products and the possibility of cyclisation is not discussed[200-204].

B. PHYSICAL, CHEMICAL, AND BIOLOGICAL PROPERTIES

The comparatively high experimental dipole moments of 2-carbasilatranes (4.2–4.9 D), greatly exceeding the dipole moments calculated without taking into account the presence of the N → Si bond (0.2–0.8 D), indicate the presence in their molecules of a stable transannular coordinate bond N → Si.[4,7,45,198] Accordingly, they are not titrated by hydrochloric acid at room temperature and do not react with methyl iodide even on prolonged heating[198].

Intra-abdominal administration of 1-phenyl-2-carbasilatrane to white mice causes pronounced motor excitation accompanied by the Straub symptom, indicating the excitation of the spinal nervous system. When administered in doses close to the median lethal dose ($LD_{50} = 8$ mg kg^{-1}), this compound gives rise to clonicotonic convulsions[198].

Insect Chemosterilants

M.A.Bulyginskaya and M.D.Vronskikh

The review covers the literature data on the application of chemosterilants in the fight against harmful insects. The chemosterilants have been classified on the basis of their structural characteristics.
The bibliography includes 174 references.

CONTENTS

I. INTRODUCTION

The constantly rising requirement for food products to support the rapidly growing population of the earth necessitates an intensive application of chemical agents for the protection of plants in order to increase crop yields. However, large-scale application of chemical poisons has clearly shown both advantages and disadvantages of the chemical methods of combating pests. Without dealing with the undoubted advantages of this method, we shall only mention some of the problems which have arisen in consequence of the intensive application of pesticides. These include in the first place the accumulation of residual chemical poisons and their metabolites in the soil and plant, animal, and human tissues.

A progressive development of resistance to chemical poisons (in particular organic chloro-derivatives) has been noted in an increasing number of harmful species of insects and ticks (mites). The use of stable preparations with a wide spectrum of action upsets biocenotic equilibria, leads to the destruction of useful insects and ticks (mites), and gives rise to explosive multiplication of various pests.

These undesirable consequences of the large scale and intensive application of chemical poisons led to an increase of interest in many countries (particularly in the post-war years) in the biological methods of combating pests. There has been a sharp increase in publications on this question: 308 in 1955 [1] and 578 in 1958.[2] For example, in 1955 66% of all investigations in the USA were devoted to the application of insecticides and in 1967 only 21%, while the percentages of the studes dealing with biological and other specific methods were 17 and 42%.[3]

There has been a greater expansion of investigations into the ecology, biology, and dynamics of the populations of pests and entomophages and their biocenotic interactions, genetics and cytogenetics of insects, large scale cultivation of entomophages on artificial media, etc. However, it is as yet impossible to abandon the chemical methods of combating pests and employ only ecological and biological procedures. The most promising technique appears to involve a planned combination of all methods of combating pests with the maximum limitation of the use of highly toxic and stable pesticides. Such a system has been called the integral method (or the integrated system) of plant protection. Apart from taking into account the structure of agrobiocenoses, this includes the introduction of types of cultivated plants resistant to pests and disease, the prediction of the number of harmful species, and the use of selective chemical poisons, biological preparations, antibiotics, and herbicides. This programme should also incorporate the application of attractants, repellants, and chemical sexual sterilising agents, and also the breeding of entomophagous insects (or phytophagous insects in the fight against weeds) and sterile insects. The ultimate aim of integrated plant protection is the arrest or sharp reduction of the rate of "biological reconstruction", i.e. the invasion of cultivated areas by weeds, disease, and pests[4]. As regards harmful insects, this result can be achieved by methods in the following two groups: (a) by acting on the insects and the environment (destruction, modification of behaviour, destruction of natural resources); (b) by acting on hereditary properties (sexual sterilisation, introduction of harmful genes into the population)[5].

This review deals with methods of combating pests based on chemical sexual sterilisation.

Sexual sterilisation is so far the only method developed up to the stage of practical application in which the fight against pests involves influencing the hereditary properties of the species, Treatment of the population by an insecticide may be effective only when the increase of "standard mortality" is much greater than the "level of the standard birthrate". However, in accordance with the feedback principle, the temporary increase in the "rate of mortality" is countered by the insects by an increase of the "standard birthrate" and the initial population density is restored[6]. Moreover, the effectiveness of pesticides falls with decreasing population density of the pests. The fight against pests by the sterilisation method is based on another principle. The level of the "rate of mortality" remains temporarily unchanged, while the "birth rate" in the population is reduced because a definite percentage of its members are sterile—the population density will continue to decrease.

The increased interest of entomologists in the sexual sterilisation of insects can also be explained by the fact that this method introduces fundamentally new possibilities into the practice employed in combating harmful insects. Firstly, there is the high effectiveness of the method. Knipling[7] calculated the relative effectiveness of chemical methods of combating pests and of chemical sexual sterilisation. In the version where insecticides were employed (technical efficiency 95%) the insects surviving after treatment (5% of the initial population) multiplied and, possessing a biotic potential increased by a factor of five, restored towards the third generation the initial population density. In the version where a chemical sterilising agent was employed, all the insects survived but 95% became sterile.

These, by mating with one another and also with the remaining fertile individuals, deprived the latter of the possibility of multiplying. Since the sterile insects predominate in the population (19 : 1), then evidently only 5% of the cases of mating will be between fertile insects, while in all remaining cases (95%) one of the partners will be sterile. Thus only 0.25% of the individuals in the initial population will multiply. Therefore the number of insects in the succeeding generations falls sharply and towards the third is already virtually zero.

The calculations described are based on data obtained in the treatment of populations under natural conditions. Similar results are obtained when insects which have been trapped or bred under laboratory conditions are released among the natural population after treatment with the chemosterilant. It is then only necessary to maintain the required ratio between the sterile and natural insects.

Such high effectiveness permits the expectation that the population of many pests will be rapidly reduced and, in the case of some species residing in isolated centres, will be completely eradicated.

The second factor is the high specificity of the method. When the procedure involving the release of sterile insects or the application of chemosterilants in combination with sexual attractants is employed, the operation of the method is restricted to the species against which the fight is directed. The use of sexual sterilisation in combination with light traps or food attractants (or agents stimulating egg laying) reduces somewhat the specificity to group specificity but nevertheless it is still quite high and useful species of the biocenosis are not involved. The direct application of chemosterilants under natural conditions requires the utilisation of selective preparations of low toxicity, since the treatment of a natural population with chemosterilants available hitherto approaches the chemical method in the selectivity of action on the biocenosis.

Thirdly, the use of chemosterilants permits the solution of the problem of the resistance of insects to insecticides. Under laboratory conditions no difference was observed in the sensitivity to a chemosterilant of strains of the house fly resistant and susceptible to organophosphorus insecticides[8]. A similar situation was observed for spider mites[9]. Insects resistant to organic chloro-insecticides are highly susceptible to chlorine-containing chemosterilants[10]. However, experiments have shown the possibility of the development of resistance to chemosterilants also[11]. The degree of acquired resistance is relatively low and exceeds the resistance by the population sensitive to the sterilising agent by a factor of 4–5 only, while the resistance to organic chloro-insecticides increases very markedly (by a factor of hundreds and thousands)[12]. Moreover, the development of resistance in insects is accompanied by the accumulation of "small recessive genetic defects", which leads to an increase of sensitivity to the preparation after 4–5 generations[13] and the initial situation is thus restored. It is noteworthy that, when the method involving the release of sterile insects is employed, the problem of resistance to chemosterilants does not arise at all.

Fourthly, the effectiveness of the method of sexual sterilisation increases as the population density of the pest is reduced, while the effectiveness of insecticides and the majority of entomophages falls under these conditions.

Moreover, it is noteworthy that the application of this method of combating harmful insects solves the problem of the inaccessibility of the individuals for treatment, which is particularly important for certain species with a secretive mode of living. Sterile males driven by the sexual instinct seek their partners everywhere including secluded microscopic sites normally inaccessible to treatment by insecticides.

An essential condition which must be met in the method of sexual sterilisation is the retention of the normal sexual activity and normal behavioural responses in sterilised insects, which enables them to seek normal females under natural conditions and impregnate them.

In the initial experiments sexual sterilisation was achieved by irradiating insects with ultraviolet light and X-, α-, β-, and γ-rays. The success of this programme of eradication of the important pest *Cochliomyia hominivorax* Coq. in 1958–1959 over an extensive territory[14] stimulated research into methods for combating harmful species based on the release of sterile insects among natural populations. The studies carried out to discover more convenient and economical methods of sexual sterilisation of insects showed that certain chemicals give rise to phenomena in the insect organism similar in their final result to radiation-induced sterilisation, i.e. sexual sterility.

The sexual sterility of insect males can be caused by dominant lethal mutation in the sperm, aspermia, or the inactivation of the sperm. On the other hand, in females sterility may result from the suppression of ovogenesis or lethal mutations in egg cells.

The first experiments on the chemical sterilisation of insects were carried out in 1946–1947.[15-17] However, the ability of certain biologically active substances to cause hereditary changes (mutations) when acting upon organisms was noted in even earlier studies by Sakharov, Lobashev, and Smirnov in 1932–1933.[18]

Large scale research on chemosterilants was begun in 1960 in the USA and in 1961 several compounds with sterilising activity were discovered. During the next three years, more than 3000 compounds were tested, of which only about 100 preparations proved to be effective as sexual chemosterilants[19,20]. Up to the present time, the number of tested preparations has increased greatly: one laboratory in Gainsville (Florida, USA) alone tests annually 500–700 compounds in order to elucidate their sterilising activity, and Bořkovec's compilation[6] gives a list of 483 effective preparations tested on 75 insects species and 7 tick species.

The number of publications on chemical sterilisation alone increases annually in a geometrical progression and in 1967 amounted to 400 papers[21]. At present the bibliography on this subject includes more than 600 items. Several reviews of the literature on the problems of chemical sterilisation have been published: by Rukavishnikov[12,22-25], Bořkovec[6,19,26], Smith[27,28], Bertram[29], Kilgore[30], a group of authors under the editorship of La Brecque and Smith[21], and Proverbs[31].

The essential feature of the method of chemosterilants consists in the treatment of specially bred or trapped insects with specific chemical mutagenic agents (chemosterilants), followed by the release of the insects among the natural population or alternatively the natural insect population is treated at sites where it is concentrated.

However, later a distinction was drawn between chemical mutagenic and chemosterilants[32]. Many chemical mutagenic agents are sexual sterilising agents at the same time but not all chemosterilants can cause inheritable mutations or cytogenetic changes.

Chemosterilants may be defined as compounds which reduce or completely eliminate the capacity of animals for reproduction. There exist several groups of substances capable of affecting the reproductive functions of the species. The most thoroughly investigated are substances which inhibit the ovogenetic and spermatogenetic processes, destroying ripe egg cells and sperm[33,34] or causing dominant lethal mutations in the chromosomal apparatus of the sexual cells. Under these conditions, the egg cells survive and the sperm remain mobile, but the zygote dies in the early stages of development. These substances can be defined as chemosterilants in a narrow sense of the word.

In addition, there exists a group of substances which prevent mating by frightening the males away from the females or acting in a somewhat different way on the copulation process[12]. Certain compounds are capable of either eliminating or masking the odour of sexual attractans, which among insects serves as a guide in the search for a mate[12]. It may be expected that some of the substances will act on the insect organism in at least two ways. Data have been published showing that females of the codling moth treated with chemosterilants belonging to the first group or irradiated attracted males less then the untreated specimens[35,36]. Possibly, in addition to the expected effect (sexual sterilisation), chemosterilants and radiation suppressed the activity of the glands secreting the sexual attractant. Studies on these lines would be very timely, since they might provide a basis for the development of yet another method in the biological fight against harmful insects.

The inhibition of the multiplication of insects by certain chemical poisons[37] and also interference with metamorphisis and the sterility of individuals treated by the analogues of certain hormones[38,39] have been observed. However, compounds belonging to the above group (with the exception of the first) can be classified as chemosterilants, only in an extremely arbitrary sense and therefore will not be discussed in detail in the present review.

Frequently attempts at classification of chemosterilants have encountered difficulty in combining a wide variety of compounds into systems based on the similarity of differences in their structures, reactivities, or biochemical effects. In the first experiments on chemical sterilisation compounds employed in the treatment of cancer were applied[19,41-44].

An empirical relation between mitotic agents influencing the process of cell division (mitosis) and compounds with antineoplastic (antitumour) activities was established in the period between 1950 and 1960.[40] At the same time a relation was discovered between cytostatic activity and the effectiveness of these substances as chemosterilants. Although a direct correlation was not always evident, nevertheless compounds with high antineoplastic activities (TEM†. tepa, thiotepa, apholate, tretamine, and others) proved to be promising sexual sterilising agents for insects, and served as a starting point for the selection of possible chemosterilants.

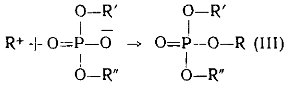
Up to 1964, in fact all the compounds effective as sterilising agents for insects were either anticancer substances or chemically related compounds[19]. Therefore we adopted (with small changes) the system employed in studies on anticancer agents for the classification of chemosterilants. Initially five categories were considered: alkylating substances, antimetabolites, radiomimetic compounds, mitotic poisons, and mixed agents[45]. This classification was partly chemical and partly biological. In addition, some overlapping of categories was noted. Later[6] the system was greatly simplifed and included only three categories: alkylating agents, antimetabolites, and compounds of a mixed type. Radiomimetic and mitotic poisons have been included in one of the above three categories.

II. ALKYLATING CHEMOSTERILANTS

Alkylation, which usually takes place when chemosterilants react with cell elements *in vivo* may be defined as the substitution of a hydrogen atom in the molecule by an alkyl group [see reaction (I)],[46,47] as the direct addition of such a group to a tertiary nitrogen atom with formation of a quaternary ammonium ion [reaction (II)], and finally as its addition to an anion, which leads to the formation of esters [reaction (III)]:[18,46]

$$R^+ + R'SH \rightarrow R'S{-}R + H^+ \quad (I)$$

$$R^+ + NR'_3 \rightarrow R'_3\overset{+}{N}{-}R \quad (II)$$



$$R^+ + O{=}\underset{\substack{|\\ O-R''}}{\overset{\substack{O-R'\\ |}}{P}}{-}\bar{O} \rightarrow O{=}\underset{\substack{|\\ O-R''}}{\overset{\substack{O-R'\\ |}}{P}}{-}O{-}R \quad (III)$$

The alkylating group R can be a hydrocarbon residue, for example the ethyl group $-CH_2CH_3$, or can contain a functional substituent, for example $-CH_2COCH_3$, $-CH_2CH_2NH_2$ (aminoalkyl), or $-CH_2CH_2COOH$.

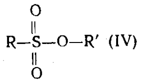
The aminoethylation reactions of nucleoprotein structures responsible for the hereditary properties of the cell (organism) in fact determine the mutagenic activity of alkylating agents[18].

Tests on compounds belonging to the following main groups of alkylating agents (Ross's classification[46]) have been described in the literature: sulphonic acid esters, dichloroethylamines (nitrogenous analogues of yperites), aziridines, halogenoalkyl ester of sulphuric acid, phosphoric acid esters, chloromethyl ethers, sulphonium and ammonium derivatives, 2-chloroethyl sulphides, ethoxides, β-lactones, diazoalkanes, and also activated derivatives of ethylene, halogenomethyl derivatives of ketones and ethers, olefins, and alcohols. The last two groups of substances (olefins and alcohols) alkylate only at a high temperature or in the presence of specific catalysts and do not operate in the living cells of the organism[6].

Sulphonic acid esters, dichloroethylamines, and ethyleneamines proved to be the most promising among alkylating chemosterilants (more than 50% of all the effective preparations belong to these groups) and they will be examined in detail. Examples of the remaining groups have been tested as sterilants on the screw-worm fly *Cochliomyia hominivorax* Coq., but largely negative results were obtained and therefore they will not be considered further.

Sulphonic Acid Esters

The alkylating activity of alkanesulphonic acid esters depends on the strength of the O–R′ bond. Alkane- and substituted alkylmethane-sulphonates (IV)



$$R{-}\underset{\substack{\|\\ O}}{\overset{\substack{O\\ \|}}{S}}{-}O{-}R' \quad (IV)$$

where $R' = CH_3$, are powerful anticancer agents[6]. The data on these compounds as chemosterilants are so far

---

† Significance of abbreviation uncertain (Ed. of Translation).

few but some of them, for example bisulphan (V) and its dimethyl derivative (VI),

$CH_3SO_2O-(CH_2)_4-OSO_2CH_3$ (V)

$CH_3SO_2O-\underset{CH_3}{CH}(CH_2)_2\underset{CH_3}{CH}-OSO_2CH_3$ (VI)

proved to be highly effective sexual sterilants for certain insect species, in particular beetles[6], and their toxicity is low. Certain sulphonic acid esters are effective chemosterilants for the Callitroga [screw-worm] fly. Diesters proved to be more active than monoesters as sterilants, but their toxicity is also higher[48].

Dichloroethylamines

In studies concerned with the treatment of cancer these compounds occupy a special place. A review of alkylating agents[49] tested as anticancer chemotherapeutic agents gives a list containing more than 20 000 compounds[49]. Chloroethylamines are structurally similar to yperite in which the sulphur atom has been replaced by nitrogen (VII):

$CH_3-N(CH_2CH_2Cl)_2$ (VII) .

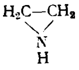
Compounds containing one 2-chloroethylamino-group ($=NCH_2CH_2Cl$) belong to single-chain yperites; compounds with a di-(2-chloroethyl)amino-group [$-N(CH_2CH_2Cl)_2$] are two-chain yperites. The presence of a number of functional groups in biological alkylating agents is regarded as an imporant property which promotes the cross-linking of chromosomes or other physiologically important cellular formations[46,50]. However, although cross-linking can sometimes account for the disproportionately high activity of polyfunctional compounds, the mechanism of the action of chloroethylamines is much more complex. Interference with metabolism (in particular of phosphorus[51]) and the inhibition of enzymes involved in the nucleic acid metabolism and also of glycolytic enzymes have been noted. This leads to the inhibition of cell division and gives rise to morphological changes in dividing chromosomes: fragmentation, mutual adhesion, the formation of bridges between chromosomes in the anaphase, and others[52].

Historically yperite derivatives have been some of the first chemical mutagenic agents discovered[15,16]. A large number of compounds of this series have already been tested as chemosterilants but only some of them showed a high effectiveness.

Nitrogenous yperite and its derivatives are effective sexual sterilants for the males of mice[53], the house fly[43], the Mexican fruit fly[54,55], and the Callitroga fly[56].

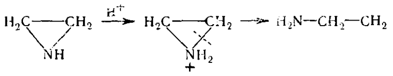
Derivatives of Aziridine

This is the most "promising" group of alkylating compounds. More than one third of the effective chemosterilants quoted in Bořkovec's compilation[6] are aziridine (ethylene imine) derivatives (VIII):



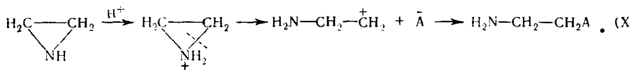
(VIII) .

The aziridine ring is responsible for the reactivity of aziridines in relation to nucleophilic agents. A characteristic property of the ring is the ease of addition of a proton to the nitrogen atom, the high reactivity of the carbon atoms, and the ease with which the ring is opened to form a chain (IX):



(IX)

The overall mechanism of the alkylation of a nucleophilic centre A by aziridine can be represented as follows [reaction (X)]:



(X)

Sulphur, nitrogen, and oxygen atoms, which usually form part of the genetic complex [see reactions (I), (II), and (III)] are most often alkylated in biological systems (S > N > O). In addition, their nucleophilic properties depend on the relative polarisability of the atom. Sulphur and nitrogen atoms, which have a high atomic weight, are more readily polarised and the compounds incorporating these elements in their molecules are powerful nucleophilic agents.

The high reactivity of alkylating compounds suggests that they can react with the majority of the substances present in each cell and containing nucleophilic groups. Such groups may be the carboxy-, phosphoryl, sulphydryl, and also amino-groups[57].

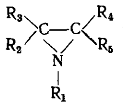
Hydroxy- and carboxy-groups of the protein complex and of aminoacids[58] and also reactive amino-groups and sulphydryl groups [see reaction (I)] should be included among biological centres capable of undergoing alkylation under mild physiological conditions (as aziridine penetrates the cell).

Carbohydrates are not as a rule alkylated, since their polar hydroxy-groups are present in an undissociated form at the physiological pH.

In contrast to glycerol esters, free aliphatic acids can be esterified on alkylation. A number of vitamins (B_1, B_6, biotin, and folic and p-aminobenzoic acids) each contain several centres undergoing alkylation. Such centres are nitrogen atoms in rings, and amino- or carboxy-groups. This accounts for the finding that not only the protein complex but also the prosthetic groups in enzymes may constitute centres sensitive to alkylation[18].

The study of a number of reactions of alkylating agents with highly purified native DNA and its components[59-61] and also with the transforming factor under mild physiological conditions[59,60] revealed the presence in DNA of several highly reactive nucleophilic centres.

The mole of an aziridine derivative consists of an active part (one or several aziridine rings) and a "carrier"—the residual component of the molecule, and can be represented schematically by formula (XI):



(XI) .

Among the aziridine derivatives investigated are compounds containing 1, 2, 3, 4, 6, and 8 alkylating rings. The increase of the sterilising activity of ethyleneimine derivatives is as a rule directly proportional to the number of aziridine rings. In investigations much attention is devoted to the problem of whether one or several aziridine groups are required for an effective chemosterilant[15,45,62,63]. Experimental data show that monofunctional derivatives are relatively ineffective as chemosterilants. Nevertheless the number of aziridine groups cannot be directly linked to the activity of the compound. For example tepa (with three aziridine groups) injected into male house flies proved to be more effective than apholate, which has six aziridine groups[64]. Moreover, the difference between the activities of difunctional and trifunctional aziridines may be much less than the difference between the monofunctional and difunctional compounds[6]. Certain diaziridines proved to be more effective than triaziridines with a similar structure[63,65,66].

The higher effectiveness of polyfunctional derivatives compared with monofunctional derivatives served as a basis for the hypothesis that polyethyleneimines can link DNA molecules in pairs and thereby bind pairs of chromosomes in the metaphase[67,68].

Examination under the microscope of the sexual cells of animals sterilised by polyfunctional compounds indeed reveals bridges between chromosomes. This is the reason for incorrect division of chromosomes among the daughter cells, which leads to genetic abnormalities and the non-viability of the daughter cells.

However, this hypothesis does not account for the mechanism of the mutagenic effect of monofunctional aziridines on mammals[50], although there is no doubt about the higher activity of polyfunctional compounds.

The sterilising activity of aziridine derivatives depends not only on the number of functional groups but also on the substitution at the carbon and nitrogen atoms of the ethyleneimine ring. The substitution of one hydrogen at a carbon atom of the aziridine ring sharply lowered the sterilising activity and the substitution of two hydrogen atoms resulted in its complete loss. Numerous reports lead to the conclusion that any substitution of hydrogen at the carbon atoms in the rings of aziridine compounds leads to a decrease of their sterilising activity on insects[19,28,45,56,63,65,69,70]. At the same time methylation is usually accompanied by a sharp lowering of the toxicity of the preparation. Substitution of one hydrogen atom lowers the toxicity of aziridine homologues by a factor of twelve in relation to rats and substitution of two atoms lowers the toxicity by a factor of twenty compared with unsubstituted aziridine[57]. This property of ethyleneimine derivatives leads to the possibility of seeking compounds whose toxicity for insects and warm blooded animals is low but which are still sufficiently effective for the purpose of sterilisation.

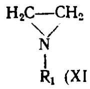
Substitution of the hydrogen atom at the nitrogen atom of the aziridine ring leads to analogous phenomena. Substitution of the hydrogen atom by aliphatic radicals lowers the toxicity of aziridine homologues in relation to rats by a factor of 10–20, substitution by aromatic groups lowers the toxicity by a factor of 40, and substitution by aliphatic-aromatic groups lowers it by a factor of 20–100 compared with unsubstituted aziridine[57]. Unfortunately, there are still insufficient data in the available literature for the analysis of the sterilising activity of such aziridine derivatives. On the other hand, acylation of aziridine (i.e. addition of an acid group to the nitrogen atom in the ring) increases the sterilising activity of the compound as well as its toxicity[28].

Moreover, the sterilising activity depends not only on the effective component but also on the nature of the "carrier component" of the molecule. For example, a decrease of the electronegativity of the central atom to which the aziridine groups are joined as a result of the replacement of oxygen by sulphur also lowers the sterilising activity of the compound. It must be emphasised that the substitution of hydrogen at a nitrogen atom in the "carrier component" of the molecule lowers primarily the toxicity, but has much less effect on the sterilising activity. In addition, some workers believe that the toxicity of chemosterilants is in general a function of the "carrier component" and is not closely linked to the number of aziridine groups in the molecule[48].

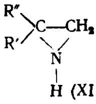
The most effective chemosterilants will probably be compounds in which aminoacids, peptides, nitrogen bases, etc. are linked to the "active component" of the molecule (aziridine ring), since natural groups apparently more readily transmit alkyl groups to cellular systems important in the vital processes of the cell and ensure their blocking. This approach has already been used in relation to compounds employed in the chemotherapy of malignant neoplasms[71].

All the aziridine derivatives already investigated can be divided (according to their chemical structure) into several groups.

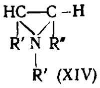
C- and N-substituted derivatives of the type



(XII)



(XIII)



(XIV) .

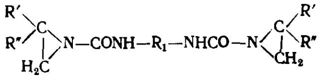
The simplest compound of this series is aziridine itself (ethyleneimine, dimethyleneimine, azacyclohexane). Experiments on the antiblastic effect of aziridines reveals its high toxicity (LD_{100} = 5 mg kg^{-1} for rats when administered intravenously). It has been established that the inhibition of the growth of tumours is achieved only on introduction of toxic (4 mg kg^{-1}) or the maximum tolerated (2.5 mg kg^{-1}) doses.

Aziridine and its homologues and also aliphatic derivatives in doses less than the maximum tolerated amounts stimulated the growth of tumours. Aromatic and aliphatic-aromatic compounds did not show this effect when administered in such doses, but some of them caused a weak inhibition of the growth of tumours. Aliphatic-aromatic ketones proved to be quite inactive in relation to sarcoma[57].

Unsubstituted aziridine showed the greatest mutagenic activity. A sharp reduction of mutagenic activity is observed in all cases of *C*- and *N*-substitution[72]. However, mutagenic activity cannot be fully identified with the sterilising activity of the compound, which involves a more complex process. Although chemosterilants without mutagenic activity exist, the majority of compounds sterilising insect males are as a rule mutagenic also.

Unsubstituted aziridine has been used to sterilise the Callitroga fly[56]. Compounds of this series are probably not very promising as chemosterilants, partly in view of their fairly high toxicity and partly because of their monofunctional nature.

Aziridine derivatives of urea (XV):



(XV) .

It has been noted that the toxicity of compounds of this type and also their antiblastic (and probably sterilising) activity falls with increase in the number of methyl groups at the carbon atoms of the aziridine ring, which constitutes yet another proof in support of the general rule (see above).

Moreover, the toxicity of many compounds with $R_1 = (CH_2)_n$ falls as the number of methylene groups is reduced. Among derivatives of this series the following chemosterilants of the house fly have been noted:

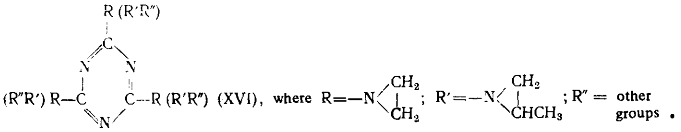
NN'-octamethylenebis(aziridine-1-carboxamide)[6],
NN'-octamethylenebis(aziridine-1-acetamide)[73],
NN'-heptamethylenebis(aziridine-1-carboxamide)[74],
NN'-pentamethylenebis(aziridine-1-carboxamide)[74],
NN'-phenylenebis(aziridine-1-carboxamide)[74],

and also chemosterilants of the Callitroga fly:

NN'-bis(aziridine-1-carboxamide)[75],
NN'-tetramethylenebis(aziridine-1-carboxamide)

and homologous compounds with 4–8 and 10 methylene groups[76]. However, aziridine derivatives have not found wide application as chemosterilants.

Aziridine derivatives of triazine (XVI):



(XVI), where R = ; R' = ; R'' = other groups .

Different derivatives may contain different combinations of the R, R', and R'' groups but an obligatory condition for these compounds is the presence of at least one aziridine group.

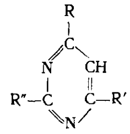
Compounds containing only one aziridine group are as a rule less toxic (LD_{100} for rats is higher by a factor of 20–100 compared with aziridine and its homologues). The presence of two aziridine groups leads to an increase of the toxicity of the preparation compared with monofunctional compounds (LD_{100} higher by a factor of only 1.5–6 compared with aziridine). Derivatives with three aziridine rings proved to be the most toxic (LD_{100} = 0.7 mg kg^{-1}).[57] The presence of various substituents instead of one or two aziridine groups (alkyl, alkoxy-, halogeno-, and others) and also of substituents at the carbon atoms of the aziridine ring likewise affects the toxicity of the compound, although the effect of these [latter? (Ed. of Translation)] substituents is much weaker than the substitution of the entire ethyleneimine group.

The cytostatic activity of aziridine derivatives as well as their toxicity depends to a considerable degree on the number of aziridine rings. It is highest for triethyleneaziridines, tretamine (TET), and methyltretamine (MeTET) and decreases progressively as the number of aziridine groups in the molecule is reduced. However, a direct correlation between toxicity and cytostatic activity is not always observed. For example, 6-benzyloxy-2,4-di-(1-aziridinyl)-*s*-triazine, which has a toxicity smaller by a factor of 20–40 than that of tretamine, is not inferior to the latter in its cytostatic activity[57].

In the series of 1-aziridinyl derivatives with amino-acid residues, the most toxic are derivatives with valine and lysine residues and the least toxic are those with glycine and alanine residues and among the latter the least toxic are compounds containing the residue of the ethyl ester of α-alanine. The introduction of an aromatic substituent into the molecule of the ethyl ester of α-alanine results in a further decrease of toxicity by a factor of two. The cytostatic activity of these compounds is less pronounced than that of tretamine and 1-aziridinyltriazines with alkyl, alkoxy, and aryl substituents[57].

Tretamine and methyltretamine are most widely used as chemosterilants[56,77-84].

Aziridine derivatives of pyrimidine (XVII):



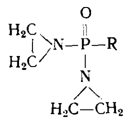
(XVII) ,

where R' and R'' are aziridine groups and R is another substituent. The nature of the R substituent has a marked influence on the toxicity of the compounds. For example, the replacement of chlorine by a methoxy-group reduces the toxicity of the preparation by a factor greater than 6.[57]

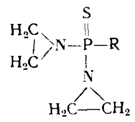
1-Aziridinyl derivatives of pyrimidine proved to be highly active. The introduction of the minimal toxic dose leads to complete disappearance of tumour tissue from male mice[57].

These compounds are of considerable interest for the purpose of sterilisation. Several preparations have been tested as chemosterilants: (a) 2,4-di-(1-aziridinyl)-6-methyl-5-nitropyrimidine (tested on *Diptera*[85,86]); (b) 4,8-di-(1-aziridinyl)pyrimido[5,4-*d*]pyrimidine[70,74]; 1-methyl-4-methylamino-1-pyrazolo[3,4-*d*]pyrimidine[56]; (d) phosphazine[*PP*-di-(1-aziridinyl)-*N*-2-pyrimidinylphosphinic amide][76,80,87]; (e) morphimide and pyrimide‡ [*PP*-di-(1-aziridinyl-*N*-6-piperidino-4-pyrimidinyl phosphinic amide and *PP*-di-(1-aziridinyl)-*N*-6-morpholino-4-pyrimidinylphosphinothioic amide], which show a high activity in tests on certain insect species and only moderate activity in tests on others[88-91].

1-Aziridinylphosphine oxides (XVIII) and sulphides (XIX):



(XVIII)



(XIX) .

This group of compounds has attracted most attention by both physicians and entomologists. The tri-(1-aziridinyl) derivatives of phosphine oxide and sulphide (tepa and thiotepa) proved to be valuable medicinal preparations and have been successfully used in the treatment of malignant tumours and a number of chemoblastoses[92].

Di-(1-aziridinyl) derivatives of phosphine oxide with aryl substituents at the phosphorus atom are as a rule less toxic than the tri-(1-aziridinyl) derivatives (tepa). However, this cannot be explained solely by the replacement of the aziridine ring, since compounds with three and four [one and two? (Ed. of Translation)] aziridine groups proved to be no less toxic than tepa. In the first case the aziridine ring is attached to the phenyl ring via a keto-group and in the second is present as the phosphoric acid diethyleneimide residue [di-(1-aziridinyl)phosphine oxide derivative (Ed. of Translation)]. This is further proof of the effect of the "carrier component" of the molecule on the properties of aziridine derivatives§.

Compounds of this group exhibit a wide variety of cytostatic effects. In their action on malignant tumours the most active compounds approach the effect of tepa, but

---

‡ These are transciptions of Russian names which transliterate as morfimid and pirimid. The order of the systematic names should probably be reversed (Ed. of Translation).

§ The test in this paragraph is confused possibly owing to the omission of one or more sentences from the Russian original (Ed. of Translation).

some are much inferior and others do not show any activity at all.[57]

Di-(1-aziridinyl)phosphine oxides containing aminoacid ester residues have a low toxicity. The relations noted for the analogous derivatives of the triazine series are also shown by this group of preparations. The least toxic proved to be a compound with a glutamic ester residue (LD_{100} for mice is more than ten times higher than LD_{100} of tepa). Compounds of this series proved to be relatively inactive as antitumour agents. We were unable to find any data in the literature on the sterilising activity of preparations of this group.

Di-(1-aziridinylphosphine oxides and sulphides with heterocyclic substituents at the phosphorus atom are as a rule less toxic than tepa (approximately by a factor of 3–10) but exhibit a high antiblastic activity. For example, Dipin has become widely known in the chemotherapeutic treatment of cancer. Certain compounds of this group are known as highly effective chemosterilants, for example Phophazine and compounds with a pyrimidine ring (these were discussed above; see the aziridine derivatives of pyrimidine), Dipin (1,4-piperazinediylbis[di-(1-aziridinyl)]-phosphine oxide);[81,87] derivatives with furan and toluene rings were tested without special success[70,93,94].

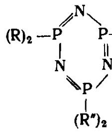
Tri-(1-aziridinyl)phosphine oxide and sulphide. As already mentioned tepa and thiotepa are most widely used in the chemotherapy of cancer. Their toxicity is fairly high but lower by a factor of 6–8 than that of unsubstituted aziridine. In entomology these compounds are known as highly active chemosterilants for a number of insects and tick species.

Tepa [aphoxide, tris-(1-aziridinyl)phosphine oxide] proved to be a highly effective chemosterilant for more than 25 insect species[10,56,69,83,86,95–114]. The methyl analogue of tepa (methaphoxide, metepa) is a preparation with a somewhat reduced effectiveness compared with tepa, but its toxicity is much lower; it was tested on more than fifteen insect species[56,69,94,98,101,103,106,109,111–123]. Tri-(1-aziridinyl)phosphine sulphide (thiotepa) is less toxic than tepa but its sterilising activity is weaker. It has also proved to be an effective chemosterilant for a large number of insect species[56,77–84,87–89,94,106,124–130]. The methyl analogue of thiotepa (methiotepa) has both a lower toxicity and a lower activity than the initial compound[56,85,97,106,131].

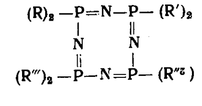
It is striking that the introduction into the metepa and methiotepa molecules of a further methyl group in place of hydrogen at a carbon atom of the aziridine ring leads to complete loss of sterilising activity[19,45,132].

The *PP*-di-(1-aziridinyl) derivatives of phosphinic and phosphinothioic amides and methyl phosphinothiolate are related to this group. These compounds have a low toxicity but nevertheless sterilise insects fairly actively even at low concentrations. *PP*-di-(1-aziridinyl)phosphinic amide proved to be a highly effective preparation for the codling moth[133]. *PP*-di-(1-aziridinyl)phosphinothioic amide is less active in relation to this insect[133]. Methyl di-(1-aziridinyl)phosphinothiolate is a highly active chemosterilant for the house fly[134].

Aziridine derivatives of the trimer (XX) and tetramer (XXI) of phosphonitrilic chloride:



(XX)



(XXI)

.

The initial compounds of this series of derivatives (the trimer and tetramer of phosphonitrilic chloride) have a low toxicity. The substitution of 4, 6, and 8 chlorine atoms by 1-aziridinyl groups leads to an increase of toxicity but it still remains of the same order of magnitude as that of tepa and thiotepa and is lower by a factor of 10–20 than the toxicity of tetramine. The introduction into the molecule of piperidine, morpholine, or glycine residues in place of chlorine atoms leads to an appreciable reduction of the toxicity of the preparations[57]. Compounds with not less than four 1-aziridinyl groups exhibit a high cytostatic activity. Their reduction to two or complete replacement of 1-aziridinyl groups fully eliminates the antiblastic activity.

Several compounds of this series have been tested as insect chemosterilants: LS-152 (monomorpholinotetra-(1-aziridinyl)chlorotriphosphonitrile)[89], methylapholate[56], and apholate. The last compound proved to be highly effective and is most widely used[9,10,48,56,69,77,78,81,82,84,85,87,91,94,96,98,100,102–105,107,109,111–114,119,121,123,126,135–143]. It showed a high sterilising activity on almost 40 species of insects and ticks[21].

III. ANTIMETABOLITES

Antimetabolites are structural analogues of metabolites, i.e. substances necessary for the existence and vital activity of organisms in consequence of their decisive role in metabolic reactions (for example, vitamins, hormones, aminoacids, etc.). However, structural analogy with natural metabolites is not the only characteristic of antimetabolites.

Another important requirement which must be met by antimetabolites is metabolic antagonism[6]. Antimetabolites are interesting also because they can give rise in organisms (or in individual biological systems) to an insufficiency of the metabolite to which they are structurally related and the biological effect observed under these conditions can be removed in almost all cases or reduced by a simple increase of the concentration (dose) of the metabolite.

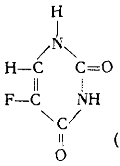
By virtue of the steric analogy, the antimetabolite competes with the metabolite and, participating together with the latter in biochemical reactions, displaces it from metabolic processes. The cell having employed antimetabolites cannot biosynthesise normal compounds (proteins, nucleic acids, and others).

Yet another characteristic of antimetabolites is their capacity to act on females alone, particularly when administered to adult insects. The synthesis of nucleic acids in adult females is usually a prolonged process: after the emergence from the pupa, the ovaries are as a rule only partially developed, but even after the attainment of sexual maturity and mating the production of eggs continues throughout the life of the female. Since the gonads are the principal site of mitotic activity in adult insects, their specific interaction with the antimetabolite is facilitated. Immediately after the emergence from the pupa, the male has as a rule a complete set of mature spermatozoa where the formation of nucleic acids has already been completed and therefore they are more resistant to the action of antimetabolites. However, it has not been determined exactly whether antimetabolites can arrest the spermatogenesis in the males belonging to species where this process is also prolonged[19,144]. The minimum sterilising dose of the antimetabolite is low and usually smaller by a factor of 100 than that of aziridine derivatives. The toxicity of these compounds is as a rule very low and their antiblastic activity is fairly high. Moreover, it is noteworthy that the vast majority of antimetabolites are active only when administered via the intestine and only exceptionally certain preparations exhibit contact activity.

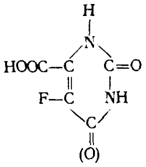
Analogues of Purine and Pyrimidine

Compounds of this series can act upon the normal cell metabolism in three ways: they can compete with a normal nucleotides for enzymes and thus prevent the regular combination of the nucleotides with nucleic acids, they can control by a feedback effect the synthesis of new nucleotides and hence nucleic acids, and finally they can be incorporated directly into newly formed nucleic acids and the latter, by losing their functional purpose, can give rise to pronounced metabolic disorders[19].

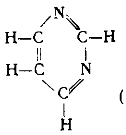
Although many analogues of purine and pyrimidine (XXIV) have already been tested, a detailed study has been made of only a few of them: 5-fluorouracil (XXII) and 5-fluoro-orotic acid (XXIII):



(XXII)



(XXIII)



(XXIV)

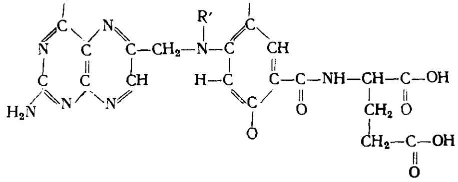
They were tested mainly on flies and mosquitoes. These compounds sterilise only the female insects[145]. 5-Fluorouracil replaces almost 50% of uracil in bacterial RNA [136] and 28–48% in TMV RNA [146] and stops their reproduction. 6-Methyluracil behaves similarly. A direct correlation has been observed between the content of 5-fluorouracil in the RNA in the eggs of the house fly and the loss of their viability[136]. It is noteworthy that in all cases the sterility was temporary and after 3–5 days was gradually eliminated[116]. 5-Fluorouracil is known as a sterilant for more than ten insect species.

5-Fluoro-orotic acid administered via the intestine proved to be effective[56,147] and the sterility was more stable—the treated females did not lay eggs. Moreover, 5-fluoro-orotic acid sterilised also males[14].

4-Amino-1-*H*-pyrazolo[3,4-*a*]pyrimidinium sulphate, which is a purine antagonist, is effective only at high concentrations[43].

Analogues of Folic Acid

Compounds of this series have a wide variety of structures and properties. More than 50 derivatives of *p*-aminobenzenesulphonamide and other sulphonamides have been tested as chemosterilants without much success[19], but the compounds bear only a very remote relation to the structure of folic acid[6] (XXV, R = OH, R′ = H):



(XXV)

On the other hand, antagonists of folic acid such as aminopterine (XXV, R = NH_2, R′ = H) and methotrexate (XXV, R = NH_2, R′ = CH_3) are highly acid sterilants for the females of numerous insect species[6,19,38,67,131,148]. It is noteworthy that the sterility caused by methotrexate is more stable—the ovaries remain undeveloped and the females do not lay eggs throughout their life[19]. Aminopterine and its sodium salt have a similar but weaker effect[10,42,148]. It is striking that the sterilising activity of these compounds can be inhibited by the introduction of an excess of folic acid[140,148].

It has been shown experimentally that aminopterin is a radiomimetic poison; it reduces the number of mitoses. Folic acid antagonists strongly inhibit the enzymes involved in the formation of folic acid and act on the synthesis of nucleic acids by inhibiting the conversion of folic acid into folinic acid and by interfering with the assimilation of the latter in the process of synthesis[26], impair cell division, and damage chromosomes[149].

Other Antimetabolites

Tests on numerous analogues of aminoacids, carbohydrates, steroids, and also aliphatic acids and hydroquinone derivatives showed that most of them are not very promising. Derivatives of hydroquinone[150], which have a low toxicity for insects and warm blooded animals, deserve mention. Among dimethylhydroquinones, 2,6-dimethylhydroquinone is the least toxic isomer. When tested, it proved to be a highly active chemosterilant for the females and males of the house fly[93].

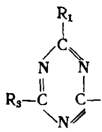
The addition of cyclopropene aliphatic acids and also of sterculic and malvalic acids to the feed lowers the egg laying capacity of chickens and the fertility of house fly females. A valuable property of these acids is their extremely low toxicity, which led some investigators[151] to suggest their inclusion as additives with certain toxic chemosterilants.

IV. COMPOUNDS OF MIXED TYPE

In recent years an increasing number of chemosterilants have appeared which are neither alkylating agents nor antimetabolite analogues. Such compounds sometimes have a structural analogy with certain of the previously described chemosterilants, but this feature alone cannot serve as a basis for their inclusion in the corresponding groups of preparations. Although the mechanism of the action of compounds of this type has as yet been little investigated, the available data suggest the existence of fundamental differences, specific for each individual group. In this section we shall consider only certain groups of the chemosterilants.

s-Triazines

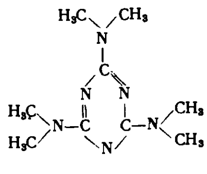
Derivatives of *s*-triazine (XXVI, R_1, R_2, R_3 = H) are not alkylating agents:



(XXVI)

The substitution of any of the three hydrogen atoms in *s*-triazine by an alkyl group leads to the formation of alkyl derivatives of triazine, some of which are well known chemosterilants (see the 1-aziridinyl derivatives of triazine) and mutagenic and antiblastic agents.

Historically, the first non-alkylating *s*-triazine chemosterilants are hemel (XXVII), hexamethylmelamine (HMM), and tri-(2,4,6-dimethylamino)-*s*-triazine [XXVII, R_1, R_2, $R_3 = N(CH_3)_2$], [66] which is a structural analogue of tretamine (TET):



(XXVII)

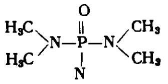
In view of the absence of aziridine rings, this compound has no alkylating properties, but it has retained the capacity to sterilise insects [66]. There exists the view that hemel is converted in animal organisms into effective chemosterilants (possibly into alkylating substances). For example, demethylation of hemel leads to the formation of formaldehyde [66]. Hemel is fairly rapidly eliminated from the insect's organism in the form of metabolities: about 50% after 5 h and about 98% after 18 h. [152]

In the last few years more than 800 derivatives of *s*-triazine were tested. Methyl-substituted melamines [XXVI, R_1, R_2, $R_3 = N(CH_3)_2$] proved to be most active chemosterilants. In this sense hemel (XXVII) may be regarded as hexasubstituted melamine. The activity of the compound increases with the number of methyl groups [131]. The substitution of one of two hydrogen atoms in the methyl groups of even penta- and hexa-methyl-substituted and *N*-propyl- and butyl-melamines leads to the loss of sterilising activity, while on their substitution by ethyl or isopropyl groups a high activity is retained by the compound. That this rule is not restricted solely to alkyl substituents, is shown by the high activity of monoacetylmelamine (XXVI, R_1, $R_2 = NH_2$, $R_3 = NHCOCH_3$), while the 2-hydroxyethyl derivative (XXVI, R_1, $R_2 = NH_2$, $R_3 = NHCH_2.CH_2OH$) and the 2-aminoethyl derivative (XXVI, R_1, $R_2 = NH_2$, $R_3 = NHCH_2CH_2NH_2$) proved to be inactive. The sterilising activity of mono-, di-, and tri-substituted derivatives is inversely proportional to the size of the substituting group. However, this rule does not apply to cyclic substituents [6,153]. Diamino-*s*-triazines with halogeno-, hydroxy-, alkoxy-, sulphydryl, and aryl groups show only a weak sterilising activity or none at all.

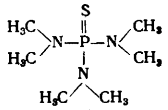
A characteristic feature of *s*-triazine derivatives is the specificity of their action: certain compounds, in particular hemel, are more effective on males than on females [62,63,66,70], but the majority of others are sterilants only in relation to females. Moreover, some of the compounds exhibit species specificity: for example, 2,4-diamino-6-(2-furyl)-*s*-triazine (XXVI, R_1, $R_2 = NH_2$, $R_3 = C_3H_3CO$) is a highly active chemosterilant of the house fly but does not have a significant influence on mosquitoes, the Mexican fruit fly, the Callitroga fly, and many other insects [6]. Possibly this compound will prove to be the first of a series of specific sexual sterilants which will be synthesised in the future for other insect species as well.

Phosphoramide Derivatives

Among these compounds, mention should be made in the first place of hexamethylphosphoramide [HMPA, hempa, tris(dimethylamino)phosphine oxide] (XXVIII), which may be regarded as a structural analogue of tepa:



(XXVIII)



(XXIX)

Hexamethylphosphoramide is the first highly effective chemosterilant in the series of numerous similar compounds which have been tested [13,40,63,66,88,89,154,155]. The majority of its derivatives are inactive and only some of them showed moderate sterilising activity.

Phosphorothioic hexamethyltriamide [thiohempa, tris-(dimethylamino)phosphine sulphide] (XXIX) may be regarded as a structural analogue of thiotepa. In its sterilising activity on certain insect species, it approaches hexamethylphosphoramide [6,155,156].

The substitution of larger alkyl or aryl groups or hetercyclic groups for hydrogen at a carbon atom leads to a lowering or loss of sterilising activity by compounds of this series.

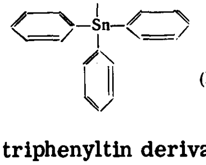
The activity of hexamethylphosphoramide in relation to certain insect species is very variable. The initial success is sometimes not repeated in subsequent tests (or in the experiments of some investigators hexamethylphosphoramide proved to be inactive in relation to insect species for which it had been claimed to be highly active in other experiments). The reason for this conflicting nature of the results is not as yet clear.

Although hexamethylphosphoramide and phosphorothioic hexamethyltriamide do not exhibit alkylating properties, their well defined physiological and cytotoxic properties give rise to changes in the cell, which resemble the phenomena occurring under the influence of alkylating agents [157]. This is consistent with the hypothesis that, like hemel, hexamethylphosphoramide is demethylated in the insect organism (in particular in the house fly) with formation of an effective alkylating agent—formaldehyde [66]. However, the latest studies [158] do not confirm these data.

The structural similarity of these compounds to aziridine derivatives and the relative simplicity of their molecules make them extremely valuable for the elucidation of the mechanism of sexual sterilisation.

Triphenyltin Derivatives

Preliminary tests on several trialkyl- and triphenyl-tin derivatives (previously employed as fungicides and insecticides) in 1960–1962 showed that they are either highly toxic or exhibit a moderate sterilising activity. After 1964 a series of studies were made on compounds of this type [74,113,159,160] exhibiting sterilising activity in very low doses. High activity is shown only by triphenyltin derivatives (XXX, R = halogen, hydroxyl, alkyl, ether group, etc.) but certain other derivatives can also show a limited activity:



(XXX)

The properties of triphenyltin derivatives indicate an activity of the antimetabolite type. They are active exclusively on insect females and the sterility which they cause is as a rule temporary. Moreover, they are effective only when administered via the intestine. Triphenyltin derivatives are highly toxic, which may be an obstacle to the sterilisation of many insect species.

Other Agents of the Mixed Type

The rapid growth of the range of substances tested as insect chemosterilants led to the discovery of sterilising activity in many compounds. Some of these deserve at least a brief mention.

In the last few years more than 100 derivatives of urea and thiourea were tested. Urea and thiourea show variable results[84,141,142,148], which can be accounted for by their toxicity for insects. The most active are cyclic derivatives of urea and thiourea[139], but they too act only on the females of certain species. Urea derivatives containing alkylating groups and known as cytostatic agents in the chemotherapy of cancer and also as effective chemosterilants were discussed above (see the 1-aziridinyl derivatives of urea).

To so called "natural products" constitute another category of compounds[6]. In the first place mention should be made of pyrrolizidine alkaloids[161,162]. However, their effectiveness is extremely limited: among the species tested, only the males of the house fly proved to be susceptible to monocrotaline. The products of the hydrolytic decomposition of monocrotaline did not exhibit a sterilising activity.

Hydroquinone derivatives were discussed above as antagonists of progesterone derivatives and will not be considered further here. Certain antibiotics should also be mentioned (streptomycin, biotin, and others)[163,164].

Colchicine was described as one of the first chemosterilants of Drosophila females as early as 1947.[165] Unfortunately its toxicity for many species and its specific effect of females alone greatly reduces the scope of its applications[85,94,166].

Compounds capable of acting selectively on the hormonal control of reproductive functions are of considerable interest. Here undesirable effect on other functions of the organism can be greatly limited. Only the first step has been taken on these lines[38,39,167-170], but they open up vast prospects for this method of influencing the populations of harmful species.

Many organic and inorganic insecticides[37,38,41,43,171-173] in sublethal doses suppress to a greater or less extent the reproduction of insects. These compounds are probably not of great interest as sterilising agents because the sterility in such cases may be a consequence of the general debilitating effect of the sublethal doses. On the other hand, cases of an increase in the fertility of insects under the influence of insecticides are well known. However, any effect of insecticides, inhibiting or stimulating reproduction, may be important in the assessment of the long term consequences of their application.

Recent studies led to the discovery of sterilising activity in certain groups of compounds which were neither mutagenic agents, nor antimetabolities, nor insecticides. For example, various organic and inorganic boron compounds proved to be chemosterilants for *Cochliomyia hominivorax* Coq. Here the sterilising activity is directly proportional to the amount of boric acid produced in the hydrolysis of the test compound[174].

---o0o---

In conclusion it is necessary to consider certain requirements which must be met by compounds tested as chemosterilants. High sterilising activity depends to a considerable degree on the chemical nature of the compounds, on the steric positions of its atoms, and also on the physical properties (solubility, capacity for migration, and others). A low solubility of the preparation gives rise to difficulties not only in the technique of its application, but also to a considerable degree determines its capacity for migration within the organism.

The toxicity of the compound for insects, warm-blooded animals, and man is also an important criterion of its usefulness as a chemosterilant. Preparations which are highly toxic for insects can appreciably lower their viability apart from sterilisation (reduction of the life-span of the treated individuals, lowering of the competitive capacity of males or the competitive capacity of spermatozoa, etc.). This can appreciably reduce the effectiveness of the method of sexual sterilisation. It should be noted that all compounds with sterilising activity are more or less toxic for insects. A criterion of the effectiveness of the preparation may be the ratio LD_{50}/ED_{50} or LD_{100}/ED_{100}, which has come to be called the "safety factor", where LD_{50} and LD_{100} are lethal doses for 50% and 100% of the individuals and ED_{50} and ED_{100} are the corresponding doses causing sterility; the chemosterilant may be regarded as more effective the higher is the ratio. A "safety factor" (SF_1) of 5 and above is regarded as satisfactory for the majority of chemosterilants[26]. However, it is not constant for all values of LD and ED and therefore, for a complete characterisation of the sterilant, it is necessary to determine a further two safety factors (SF_2 and SF_3).[65,66,140] The "safety factor" SF_2 may be defined by the formula

$$SF_2 = \frac{LD_{0.01} - ED_{99.99}}{ED_{99.99}} .$$

The third "safety factor" SF_3 is similar to SF_2:

$$SF_3 = \frac{LD_{0.01}}{ED_{99.99}},$$

where $LD_{0.01}$ is the maximum dose tolerated (or the dose resulting in the death of 0.01% of the individuals) and $ED_{9.99}$ is the minimum dose, sterilising 99.99% of the individuals. Compounds for which SF_2 is equal to or greater than zero and SF_3 is equal to or greater than unity can sterilise all insects without killing them. Preparations with negative SF_2 and SF_3 greater than -1 may be used to sterilise insects but then some of the treated individuals are destroyed. The degree of risk for man and warm-blooded animals is various for different groups of chemosterilants. The most dangerous and toxic are the derivatives of chloroethylamine and aziridine, which prevents their large scale practical application.

The phytotoxicity of sexual sterilants has been less investigated. Only apholate is an exception in this respect. Plants tolerate spraying with 1–2.5% solutions of the preparation without harm and only spraying six times in succession moderately retards the growth of plants, causes the dying off of leaves etc.[22] Naturally, even moderate phytotoxicity can limit the application of the chemosterilant in the treatment of populations under natural conditions.

The stability of the compounds can also be of great importance. Aziridine derivatives readily polymerise, are unstable in an acid medium, but are usually stable in an alkaline medium. The instability of the preparations makes their application difficult. The volatility of the compounds is also undesirable since it increases the danger from the preparation and can give rise to additional technical difficulties. On the other hand, it eliminates the problem of stable residues of chemosterilants. The high rate of metabolism of chemosterilants in warm-blooded animals and man, which, however, depends on the reactivity of the compound, somewhat reduces the potential danger of these substances.

The universality of the action of chemosterilants has a marked influence also on their effectiveness. The most effective preparations are active when administered both via the intestine and on contact. When the preparation administered in a particular way is inactive, it gives rise in the first place to technical difficulties in its application, but its effectiveness is only indirectly influenced. However, some chemosterilants are capable of sterilising only members of one sex. This property is directly reflected in their effectiveness. A preparation having a 95% activity and sterilising both males and females is twenty times more effective than a preparation capable of sterilising only members of one sex[12]. Moreover, the separations of the released insects in accordance with their sex is not always technically feasible.

Another requirement which must be met by chemosterilants is specificity of their action. The majority of the existing sterilants act not only on insect species but also on other invertebrate and warm-blooded animals. When sterilisation procedures based on the treatment of the pest population under natural conditions are employed, the specificity of the method is ultimately determined by the specificity of the action of the chemosterilant employed. Naturally, compounds exhibiting not only group specificity (i.e. acting on representatives of the same order, family, and genus) but also species specificity are necessary. However, difficulties then arise in the determination of the sterilising activity of the preparation, since tests are carried out a limited number of objects (the house fly, meat flies, etc.). When sexual sterilisation involving the release of sterile insects is employed, the problem of the specificity of the action of the preparations is not quite so acute, but this procedure is more laborious and expensive, since it necessitates the preliminary mass breeding of an enormous number of insects.

Improvement of Resistance of Glass-reinforced Plastics to Water by Means of Hydrophobic Adhesive Compounds

A.I.Mikhal'skii

Hydrophobic adhesives have been widely used to improve the resistance of glass-reinforced plastics to water. They are either applied to the surface of the glass filler, or introduced into the plasticiser or the polymeric binder.
Various mechanisms are discussed and compared, by means of which hydrophobic adhesives influence the properties of glass-filled polymers. The enhancement of the water resistance of the glass-reinforced plastics could result from improved mechanical adhesion between the polymer matrix and the glass, from a more uniform distribution of internal stresses in the boundary layer, from greater cohesive strength of the polymer film on the filler surface, and from increased adhesion between polymer and filler, which is due to the formation of stronger adsorption bonds between them. Special attention is paid to the possible formation of a chemical bond between the hydrophobic adhesive and the glass and silica surface.
A list of 114 references is included.

CONTENTS

I. Introduction

The main method for producing high-strength materials in modern technology is the reinforcement of polymers with fillers. The working characteristics of the material are determined by the combination of properties of the components and their interaction. Hence the improvement in the physical and mechanical properties of the reinforced polymer is not a consequence solely of the introduction of a high-strength filler into the system. The strengthening effect of the filler depends on a series of mechanical, physical, and chemical phenomena related to the structure of the polymer and the surface properties of the filler. The complex of phenomena occurring in the polymer–filler boundary layer is especially important. Rebinder[1] suggested that the reinforcing action of the filler is due to the transition of the polymer at its interface into a strengthened oriented state. Burov and Andreevskaya[2] discussing the mechanism of the strengthening action of glass fibre in glass-reinforced plastics, considered that the binder, while of low strength in the mass, became considerably stronger in thin films on the filler surface. The founding of Kargin's school of the theory of polymer structure was followed by considerable development of these views. Papers in recent years have extended these concepts to take into account the influence of the filler on the supermolecular structure of the polymer.

Lipatov, who observed the elevation of the glass point of a series of polymers as a function of the filler content[3] and the nature of the solvent for the polymer[4], suggested that reinforcement could be discussed in terms of adsorption. The nature of the solvent, the surface geometry of the filler, and adsorption interaction between the polymer and this surface affect primarily the number of possible conformations of the polymer molecule in the vicinity of the surface. Since this number is considerably diminished under the influence of adsorption forces, polymer molecules in adjacent layers are more loosely packed, while their flexibility is restricted. The glass point is determined by the mobility not only of the chain segments but also of the supermolecular structures. Thus the effect noticed by Lipatov is associated with a sharp limitation on the mobility not of single polymer chains on the filler surface but of the supermolecular structures which they form. Investigation of the dielectric relaxation of filled polymers[5] also shows that interaction with the surface restricts principally the mobility of supermolecular structures, whereas that of the chain segments changes little.

With polyhexanoamide as example Solomoko et al.[6] showed that the presence of a filler improves the mechanical properties of polymer films by changing the size of the spherulites. It is interesting that this process can be controlled in the required direction by surface modification of the filler. For example, two types of Aerosil—the original and an aminated sample—were used in this work[6]. In the former case the polyhexanoamide spherulites decreased in size from 30 to 26 μm on the introduction of 0.1% of the filler, and to 14 μm with 5%. In the latter case a greater decrease in size of the spherulites—to 19 μm—was found at a filler concentration of 0.1%; further increase in concentration did not affect their size. The aminated Aerosil surface shows a greater tendency to interact with the polymer, which leads to a substantial change in the mobility of the macromolecules, and hence in the conditions of formation of the spherulites. It is noteworthy that the mechanical properties of the films are improved only at low filler concentrations (0.1%), i.e. when the strength is influenced only by the morphology of the polymer. At high filler concentrations the mechanical properties of the polymer film deteriorate owing to the appearance of defects in the system.

The strength of a filled polymer is determined in considerable measure by the internal stresses. Lipatov[5,7,8] emphasises in particular that, with increase in the rigidity and the interaction energy of the polymer chain with the filler surface, the system departs further from equilibrium during hardening of the polymeric binder. This decreases the number of points of contact between the polymer chain and the filler surface, which lowers their adhesive interaction and also causes the appearance of internal stresses, these being especially large in systems having a large surface, e.g. glass-reinforced plastics. Under certain conditions of mechanical constraint the stresses produced in the material during its forming later supplement those caused by its use. For example, the action on a filled polymer of various agents, among which moisture is the most typical under the working conditions of glass-reinforced plastics, will lead to an appreciable deterioration in properties†. This is the more important in that water, because of its high polarity, possesses great competitive power for interactions at the polymer – filler boundary.

Thus a paramount requirement in the production of high-strength polymeric materials which are reliable during operation is to create conditions at the polymer – filler interface which will ensure maximum adaptability of the macromolecular chains to the geometry of the filler surface, an adequate number of points of contact with the latter, and strengthening of adhesion bonds.

II. Principles of Matching Hydrophobic Adhesives to Polymer Systems

A procedure which has proved its value during recent years has been to use hydrophobic adhesives in glass-reinforced plastics filled with thermoplastics and elastomers. Alkylalkoxysilanes containing various functional groups in the organic radical have been most widely used in this connection.

A fairly wide range of such compounds have now been prepared and tested. Many workers[9-21], on examining their efficiency as a function of composition, have shown that the choice of hydrophobic adhesives as modifiers for polymeric materials reinforced with glass fibre must be based on the potentiality for chemical interaction between functional groups of modifier and polymer. General recommendations, supported by practical results, are in effect to use derivatives of vinyl- or methacryloyl-alkoxysilanes for polyester resins and derivatives of amino- or epoxy-alkoxysilanes for epoxide and phenolic resins.

Jellinek and Hanson showed[22] that the primary amino-group in 3-aminopropyltriethoxysilane (A-1100) is involved in cross-linking the epoxy-resin into a network structure. Vanderbilt and Clayton[23] noted the efficiency of unsaturated silanes with elastomers vulcanised in the presence of peroxides, the degree of cross-linking having been raised by the additional use of dienes containing conjugated double bonds. According to these workers the latter were able to bond the organosilicon product on the surface of the glass fibre and the elastomer.

Somewhat different criteria are used to select modifiers for thermoplastic materials reinforced with glass fibre. In the opinion of Plueddemann the decisive factor for the efficiency of a modifier is its compatibility with the polymer[24]. Since chemical interaction of the components is improbable, compatibility is ensured by similarity in polarity. More strongly polar properties of the modifier should have improved the adhesion of polymer to glass. However, Plueddemann showed[24] the presence of a maximum, the strength of the material reaching a limit and then falling with increased polarity of the modifier. An important part is obviously played by the orientation of the organic radicals in the modifier on the surface of the glass, which diminishes the effective polarity of the modifier when deposited on glass.

Plueddemann's hypothesis is supported by the work of Lee[25], who studied the wetting of polysiloxane finishing films on a glass surface, for which he determined the critical surface tension γ_{cr}. The latter was a measure of the polarity of glass surfaces which had been treated with various compounds. It was highest for 3-glycidyloxypropyltrimethoxysilane, and lowest for vinyltrimethoxysilane (42.5 and 25 dyn cm^{-1} respectively). From an examination of a fairly wide range of finishes Lee concluded that the functional groups of the finish are arranged horizontally on the surface. Hence the conformation of the molecules of the finish in the boundary layer are such that its polarity is not determined solely by the type of functional group, since the latter may occupy different positions relative to the surface of the glass.

Sterman and Marsden[26], however, do not exclude chemical interaction between hydrophobic adhesives and thermoplastic materials at the end-groups of the polymer or at free radicals formed by degradation of individual polymer chains during forming. On this hypothesis it is obviously difficult to make a practical recommendation for the choice of modifier. These workers therefore combined the components empirically, after examining a fairly wide range of compounds and assessing them from the change in mechanical and electrical properties of the filled thermoplastic materials produced by the action of water.

III. Procedures for Modifying Glass-filled Polymers with Hydrophobic Adhesives

In the present-day manufacture of glass-reinforced plastics hydrophobic adhesives are applied in three ways— deposition of the modifier from dilute solution on the filler (finishing), incorporation in the lubricant for the glass fibre, and finally direct incorporation in the polymeric binder. Since hydrophobic adhesives were first used as finished, many papers have been published on this technique. They cover optimum recipes for the finishes, temperature schedules for fixing them on the glass surface[27], and the effect of various physicochemical factors on the properties of the resulting materials.

It has been noted above that the choice of modifier is specific to each kind of binder. This has been illustrated[9-15] by actual examples of the use of finishes in glass-reinforced plastics, the properties of the latter being assessed after subjection to moisture. Losev, Aslanova, et al.[13] have examined the effect of ten aminoethoxysilane finishes, with various substituents attached to the nitrogen atom, on the mechanical properties of a glass-reinforced epoxy-resin, and shown that the water resistance is lowered by replacing an amino-hydrogen atom by e.g. a butyl radical. However, introduction of a second amino-group into an aminoalkylethoxysilane (AGM-3), although it improves the properties of phenol – formaldehyde plastics, has an adverse effect on the properties of the epoxy-resins. This is explained by the greater reactivity of the latter. It probably affects formation of the polymeric structure on the filler surface, which is too active towards the given polymer and hence intensifies the disequilibrium of the system during setting[7].

---

† The above is not the only reason for the adverse effect of moisture.

The properties of glass-reinforced plastics can be improved, not only by a specific choice of finish, but also by using a mixture of finishes of the same class. Voitsekhovich et al.[14] note that more monolithic glass-reinforced plastics are obtained by using a mixture of di- and tri-ethoxyaminosilanes (ADE-2 and ADE-3). Grinevich[15] showed that a mixture of methyl and vinyl siliconates (GKZh-11 and GKZh-12) is an effective finish for an unsaturated polyester resin, whereas a mixture of vinyl and allyl siliconates (GKZh-12 and GKZh-18) is required for a polyester–polyacrylate resin. The latter improves the mechanical properties of a thermosetting glass-reinforced plastic in the initial state, and reduces the loss in strength after treatment with boiling water to 11%, whereas when vinyltriethoxysilane is used the loss in strength is 32%. After air hardening of the same resin a smaller change in strength is observed on finishing with vinyltriethoxysilane, although the efficiency of a mixture of GKZh-12 and GKZh-18 is maintained because the initial strength is increased. Thus the action of a finish is governed not only by the class of compound to which it belongs but also by peculiarities in its molecular structure and by the composition of the polymeric binder.

Nevertheless, a correct choice of finish based on the above principles still does not ensure that it will be efficiently used. Finishing is a technical process, for which conditions must be determined and maintained. Thus the properties of a glass-reinforced plastic will depend on the quantity of finish applied, the conditions of hydrolysis, the pH of the working solution, the temperature at which the finish is fixed on the glass fibre, the duration of this process, and several other factors. Biefeld and Phillips[27] give the temperatures at which finishes are fixed on glass depending on their functionality and the nature of the groups which are likely to interact with the surface. However, technical schedules developed for one finish can by no means always be used for treatment with other finishes[28] even belonging to the same class.

The second method of modification—the use of active lubricants—eliminates several adverse technical factors in the thermochemical treatment of fillers[39-42]. A finish incorporated into the lubricant comes into contact with a clean glass surface, which is freshly formed and therefore more active. The treatment of individual glass fibres avoids the effect of capillary flow of the finish and enables a more uniform film of the alkylalkoxysilane to be obtained on the filler. Furthermore, the introduction into the lubricant of an elastomer or a plasticiser, e.g. dibutyl sebacate, lowers the internal stresses in the surface layer of the binder during setting[23]. The above peculiarities were probably a consequence of the less sharply defined dependence of the strength of the glass-reinforced epoxy–phenolic plastic on the period of immersion in water when an active lubricant containing AGM-3 was used than in the case of thermochemical treatment with AGM-3 finish[29]. It is noteworthy that neither short-period nor long-term tests in air reveal differences in the method of applying AGM-3.

It was shown[29] that the third method of modification—the incorporation of an epoxyalkylalkoxysilane (ES) into the resin—did not have the proper effect: the strength of the glass-reinforced plastic depended quite markedly on the time it was immersed in water. Obviously, no analogy can be drawn here between the first two and the last method of modification with the aim of comparing their efficiency, since the last case involved a finish of a quite different class, containing epoxy-groups instead of amino-groups.

A systematic study of methods for modifying glass-reinforced plastics with hydrophobic adhesives was made by Kiselev and Bodrova[16]. They used a series of binders—phenol–furaldehyde–formaldehyde (FN), resol (BSL), phenol–formaldehyde (VFT), this third resin modified with viniflex, and butyral–phenol (BF-2)—to examine the effect of aminoethoxysilanes (A-1100, AM-2) and an ethoxysilane containing hydroxyl in the organic radical (MR-1), incorporated into the resin, on the stability of glass-reinforced plastics after treatment with water and a highly humid environment. With the optimum content of active additive in the binder glass-reinforced textolites retain 65–90% of their strength after subjection to boiling water for 2 h, whereas the usual value for an unmodified plastic is ~30%. The dielectric characteristics of the glass-reinforced textolites were used to assess the method of modification with aminoethoxysilanes; they showed that the stabilisation effect is most completely developed when the additive is introduced into the resin.

Other papers[17-21] also indicate an improvement in the properties of glass-reinforced plastics when ethoxysilanes are used as modifiers for the binder. The advantages of this method over finishing are firstly that the binder comes into contact with a more uniform surface, which possesses better wetting properties than a surface treated with a finish[34]. The tendency of the molecules of the finish to aggregate[34], especially when applied from aqueous solutions, aggravates the impairment of wetting.

Zisman[35] considers that, even with a small contact angle, individual cavities on the rough surface of a finished glass fibre remain unfilled with resin because of its high viscosity and rapid polymerisation. On the application of a load or of water to the plastic, stress concentrations will arise around each of the cavities, which will impair its properties. Bascom and Romans[36] examined the influence of such microdefects on the strength of a glass-reinforced epoxide plastic and found that, in order to reduce their number, it was necessary to make the wetting angle smaller and improve the technique of impregnation, e.g. by using a variable tension in the filament passing through the impregnating solution.

Further, the distribution of hydrophobic adhesive in the resin–filler system probably has a certain effect on the properties of the glass-reinforced plastic. Thus Kenyon[37] has shown that, in spite of the greater adhesion interaction of an epoxy-resin with glass finished with the product A-1100, the use as finish of 3-glycidyloxypropyltrimethoxysilane (A-187) produces a greater improvement in the mechanical strength of the plastic (Table 1 and diagram). He ascribes this inconsistency to the differing abilities of the finishes to diffuse inside the resin adjacent to the filler surface. This changes the depth of the modified binder near the surface of the filler, which in the present case probably determines the strength of the glass-reinforced plastic.

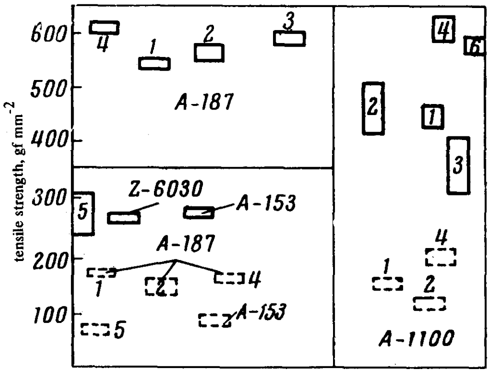
We shall attempt to compare the processes undergone by the binder in a glass-reinforced plastic modified by a hydrophobic adhesive, using Lipatov's views[5,7,8] on the mechanism of the reinforcing effect of fillers in polymers. Application of a finish to the filler surface increases its tendency to interact with the polymer, since the finish contains groups capable of interacting with the binder. Hence the rate of setting of the resin will be far higher on the finished surface than in bulk. The polymer molecules, having combined with it through the appropriate functional groups, lose their mobility, and are unable to pass into the equilibrium state. The formation of chemical bonds on the surface is then a favourable factor, whereas the strain in the polymer molecules is undoubtedly an adverse factor. Incorporation of a hydrophobic adhesive into the binder does not influence to such an extent formation of the polymer structure near the filler, so that the system will be closer to equilibrium.

Table 1. Strength of adhesion between Epon 815 resin and glass[37] (in conformity with ASTM D 1344-57).

Surface modifier		Breaking load, kg
brand	chemical name	
—		110
A-153	phenyltriethoxysilane	160
Z-6030	3-methacryloylpropyltrimethoxysilane	200
A-187	3-glycidyloxypropyltrimethoxysilane	297
A-1100	3-aminopropyltriethoxysilane	414
"Inner-layer" modifier + A-1100	—	502

New problems inevitably arise in the modification of binders with active additives[16-20]. Sterman and Marsden[19] studied the effect of several additives on the properties of polyester, epoxide, and phenolic resins containing various powdered fillers (glass, quartz, kaolin, calcium carbonate, etc.). From a comparison of the effect of hydrophobic adhesives when used as finishes and when introduced into the binders (0.5–2%) these workers concluded that the active additive migrates from the bulk of the resin to the surface of the filler, thereby enhancing the stability of the glass-reinforced plastic to the same extent as does the finish. Migration is confirmed by the improved stabilising effect of the additive on the properties of the material when the filled composition is kept until it sets. Immediate setting, for example, will not give the effect observed for some time (19 h). These workers show further that the action of the additive is connected with the presence of the filler (the strength of pure resin mouldings is unaffected by silanes) and depends on its nature. Addition of an active product has no effect on the strength of a composition filled with calcium carbonate, but considerably improves the properties of systems filled with glass, quartz, etc. A necessary condition for an alkoxysilane to be effective is that it should be hydrolysed on the filler surface. Preheating kaolin at 120°C removes most of the water from its surface, so that the mechanical properties of a filled resin become worse. This does not apply to fillers to whose surface water is more firmly bound (glass, quartz). Finally, assessing the influence of the technique of hardening on the properties of plastics modified by addition of a silane, these workers note that the condensation of a finish and its adhesion to the surface are not complete without further heating, continued for a definite time until gelling occurs.

Vanderbilt and Jaruzelsky[18] studied the mechanical properties of butadiene–styrene, polyester, and epoxide resins containing similar fillers, and paid special attention to the choice of optimum quantities of the additives A-1100 and A-172 (vinyltris-2-methoxyethoxysilane) introduced into the resin. The content of these did not exceed 2% on that of the filler, 4.6% based on the binder. These workers showed that, when quartz was used as filler, the optimum content of the silane was 0.5–1% on the filler. The additive has different effects on the properties of different resins: the strength of butadiene–styrene mouldings, which are weak in the original state, is increased several times; whereas the increase for epoxy-mouldings, which possess greater strength, is small. It is considered[18],[38] that the epoxy-resin contains functional groups which tend to interact with the original surface of the filler to form stable bonds, and these ensure quite good mechanical properties for the plastic independently of the presence of a silane. The butadiene–styrene resin is unable to form such bonds, and therefore the action of an added hydrophobic adhesive, which promotes interaction of the resin with the filler surface, is shown in a sharp increase in strength.



Strength of Epon 815 resin filled with finished glass microspheres: —) in the dry state; --) after immersion in boiling water for 24 h. Finishing process: 1) finish dissolved in hexane; 2) finish dissolved in acetone; 3) finish dissolved in CCl_4; 4) "inner-layer" modifier applied before finishing[37]; 5) finish absent; 6) filler absent.

A different situation is found after filled mouldings have been subjected to boiling water for 7 days: the strength indices of the unmodified butadiene–styrene resin remain at the same level, whereas those of the epoxy-resin are substantially diminished. The presence of a hydrophobic adhesive then produces an increase in strength: as a result of modification the strength of a specimen after the treatment with water has increased several times. This was explained by the different amounts of water absorbed by the resins—3% for the expoxy-resin, 0.3% for the butadiene–styrene resin.

The above workers[18] confirm for calcium carbonate other data[19] showing that a filler containing on the surface neither water nor groups capable of hydrolysing an ethoxysilane produces no change in strength of mouldings as a result of their modification. No effect is produced by adding to the resin–calcium carbonate system the product A-172 which has previously been hydrolysed with water. Noting the necessity for at least partial hydrolysis of the additive introduced into the binder for a glass-reinforced plastic, Vanderbilt and Jaruzelsky consider that the amount of water needed is present in actual resins: even the "driest" butadiene–styrene resin contains 0.04% of water.

The interaction of moisture in the binder FN with the added aminoethoxysilane AM-2 was studied by Kiselev and Bodrova[16] using the Karl Fischer method. With not more than 2% of additive the moisture content decreases, after which it increases somewhat owing to the accumulation of water formed presumably by the condensation of silanols, which are products of the hydrolysis of AM-2. The additive content corresponding to the minimum on the curve is the optimum content for the given resin, but it will vary somewhat on passing to other batches. Apart from correct choice of the concentration of the hydrophobic adhesive in the resin, the possibility that it may affect the setting of the binder must be taken into account; this aspect is ignored in most papers.

In conclusion it must be noted that there are several practical reasons, in addition to the above considerations, for the greater efficiency of the use of additives rather than finishes. Elimination of a finishing stage, requiring special equipment, from the industrial production of glass-reinforced plastics simplifies the process and makes it far more economic. Furthermore, glass cloth containing a finish or an active lubricant on the surface is unsuitable for prolonged storage after impregnation with the binder, since premature setting of the resin takes place as a consequence of the high surface concentration of modifier on the cloth. Impregnation of glass cloth with a modified binder does not have such a great effect on its viability.

In view of the above facts the incorporation of hydrophobic adhesives in the polymeric binder is the most economical prodedure for modifying glass-reinforced plastics to improve their resistance to water.

IV. Mechanisms by which Alkylalkoxysilanes Influence the Properties of Glass-reinforced Plastics

It has been noted above that the incorporation of hydrophobic adhesives into the binder involves their migration on the filler surface, just as finishing involves diffusion of the finish into the bulk of the resin. Thus some common phenomena are observed in glass – resin – alkyloxysilane systems, independently of the method of introducing this last component. We have noted individual differences above. Now let us examine possible mechanisms by which the finish influences the properties of glass-reinforced plastics, assuming to a first approximation that they are applicable to any of the modification procedures.

The properties of filled systems are not determined solely by those of their separate components—polymer and filler. Processes occurring at the interface between the two phases acquire great importance[1-8], especially with systems having a large surface (glass-reinforced plastics). It is here that the greatest effect of modification by a hydrophobic adhesive must be expected. Several authors discuss the role of the finish in terms of mechanical "swaging" of the fibre by the binder and the friction arising between them. In fact, the coefficient of linear expansion α_t of polymeric binders is more than ten times that of glass fibre‡, so that after the material has set and cooled the glass fibres are firmly held in the polymer matrix. In this case physical contact—pressure and friction—governs interaction of the components. Landsman and Klunder[39] consider that water, penetrating into a glass-reinforced polyester plastic, has a lubricating effect on the contact surface between resin and glass, and diminishes the friction between the components. They support their conclusion by the fact that the strength of the plastic, although dropping greatly under the influence of water, is almost completely restored after drying. Vašta and Zvonař[40] and also Skupin[41], while sharing this view, consider that the role of the finish is to restrict access of water to the surface of the fibres, so that the friction between the components varies to a less extent.

In effect these workers[40,41] consider only one of the properties of the finish, which is rendering the glass surface hydrophobic. However, as shown above, the choice of finish is not entirely determined by this property. In particular, Clark and Plueddemann[21], by treating glass cloth initially with chlorosilane and then with Z-6030 finish (3-trimethoxysilylpropyl methacrylate), obtained from a polyester resin a plastic possessing high water-repellency but low strength in both dry and wet states. Application of the finish Z-6030 to the surface of the original glass cloth considerably improved the mechanical properties of the glass-reinforced plastic. Replacement of the active additives AM-2 and MR-1 in the binder FN by methyltriethoxysilane[16] resulted in a deterioration in the properties of the glass-reinforced plastic, although methyltriethoxysilane tends to make the glass more water-repellent.

There is no doubt about the mechanical adhesion between filler and binder in a glass-reinforced plastic[40-42]. However, the behaviour of the system is determined probably not so much by its magnitude as by the uniformity of distribution of the stresses which arise. The part played by the finish must evidently be appraised on these lines, with the effect of the mechanical "swaging" of the fibres on the properties of the glass-reinforced plastics taken into account. It is obviously for this reason that some authors regard the finish as an interlayer, which diminishes the internal stresses in the plastic. This opinion is held in particular by Hooper[43], who considers that the presence of the finish lowers the interfacial tension during forming of the system. Erickson et al.[44] assume that the finish changes the adsorptive power of the glass surface, leading e.g. to preferential adsorption of the hardener in the surface layer. As a result of this, thin polymer films adjacent to the glass surface acquire a different structure and different properties. These workers[44] consider that their elasticity increases, so that the stresses in the boundary layer become smaller.

The above views[43,44], however, have not found practical confirmation by other investigators, and to some extent even contradict the latter. Hooper[43], when discussing the decrease in internal stresses in a filled plastic due to the deformability of the layer of finish, does not consider the effect of modifying the surface on the formation of adjacent polymeric structures, which according to Lipatov[7] will be less in equilibrium and more strained on interaction with the filler surface. The views of Erickson et al.[44] also contradict the position of Lipatov, who, considering the effect of the interface on the structure of three-dimensional polymers[45], has shown that a filler increases the effective density of the polymer network as a result of the appearance of additional branch points on interaction with the surface.

Thus great caution must be exercised in speaking of an increase in the elasticity of a hardened polymer in the

---

‡ For example, glass E has $\alpha_t = 4.8 \times 10^{-6}$ deg^{-1}, while the corresponding value for polyester resins is $(80-150) \times 10^{-6}$ deg^{-1}.

boundary layer. It is not in vain that Kenyon[37] has used, together with finishes, the so called "inner-layer modifier"§, which was applied to finished glass particles. This artefact on the surface of the filler in a polymer film possesses enhanced elasticity and improves the strength characteristics of the glass-reinforced plastic in dry and wet states (Table 1). Furthermore, the presence of the "inner-layer modifier" led to an increase in the strength of the plastic with increase in the bulk content of filler, which was not observed in its absence. These facts indicate efficient plasticisation of the binder directly adjacent to the filler surface, and show that the layer of finish on the glass most probably does not produce a relaxation of internal stresses which are due to the effect of the filler surface on the formation of polymeric structures. For the same reason plasticising additives have an appreciable effect in active lubricants[33].

Trostyanskaya and Poimanov[46-48] take a different view of the decrease in internal stresses under the influence of a finish in a glass-reinforced plastic. They consider that the hydrate sheath of the glass, while inhibiting hardening (e.g. in the case of phenol–formaldehyde resins), changes the density of the hardenable resin as the distance from the interface increases, which intensifies the internal stresses in the plastic. Treatment of the glass fibre with finishes (MR-1, AM-2, etc.) eliminates the action of the hydrate sheath of the glass and results in a more uniform setting of the binder, which improves the properties of the glass-reinforced plastic.

The possibility has been discussed above that adhesion between glass fibre and binder may be accomplished by mechanical "swaging". This is only one of the factors determining the strength of a reinforced plastic. Another factor, which in the opinion of most investigators is more important, is the formation of strong adhesive bonds between polymer and filler. The action of finishes has been discussed in detail from this point of view by Andreevskaya and her coworkers[49-51], and also by several other authors[52-55]. The presence of a finish on the surface of the glass fibre was shown to strengthen adhesion between the hardened resin and the glass. The investigations were made[49-55] on models representing the interaction of the components in actual glass-reinforced plastics, and in several cases the laws deduced were confirmed by the results of mechanical tests on such a plastic[49]. The increase in adhesion interaction between binder and finished glass surface was explained[49-56] by formation of a chemical bond between finish and resin during hardening of the latter.

Spectroscopic analysis has in fact shown changes in the structural constitution of the compositions studied. Thus Nikonova[52,53] has observed a decrease in intensity of the 1600 cm^{-1} band, corresponding to vibrations of the vinyl group in the finish, during the setting of a polyester resin in the presence of vinylalkoxysilane (GVS-9). Wende and Gähde[57,58] examined the infrared spectra of glass cloth treated with vinyltrichlorosilane, followed by methyl methacrylate in the presence of benzoyl peroxide. From the variation in intensity of the 3060-cm^{-1} band, which is also associated with vibrations of the vinyl group, they showed that ~67% of surface vinyl groups are involved in copolymerisation with methyl methacrylate. Other methods of investigation also indicate reaction between the polymer resin and the finish. Consideration of the thermal deformation and the elastic properties of phenol–formaldehyde and urea–formaldehyde resins reveals[17,55,56] that the introduction of alkylalkoxysilanes—AM-2 and MR-1 [17,56], AGM-9 and ES [55] —leads to the formation of a denser network in the hardened polymer. This was regarded as due to chemical interaction between resin and finish.

Thus it can be accepted on the basis of a number of investigations[53-59] that the increase in strength of adhesion between polymeric resins and a finished glass surface is due to the formation of a chemical bond between the binder and the layer of finish. Hence it is not fortuitous that different finishes have different effects on the adhesion of the binder to a glass fibre. For example, AGM-9 and ES increase the strength of adhesion between a glass fibre and a urea resin[54] to about 130 kgf cm^{-2}, whereas AGM-3 increases it to 56 kgf cm^{-2} (compared with 29 kgf cm^{-2} for the original glass fibre). In tests on aluminium borosilicate and basalt fibres[50] finish AM-2 increases the strength of adhesion by 30% in the case of an epoxy–phenol binder (480 instead of 366 kgf cm^{-2}), and by 20% with a butyral–phenolic binder (e.g. 260 instead of 216 kgf cm^{-2}).

Besides the chemical composition of the binder and the character of the glass surface, internal stresses at the polymer–filler interface influence the adhesive strength, these arising from defects in the glass surface and from the shrinkage of the binder when it sets. The contribution made by these stresses to the adhesive strength is especially great with large shrinkages of the binder, and can be diminished with a uniform distribution of stress over the interface. The lubricant (a paraffin emulsion) has a characteristic effect on the adhesion of glass fibre to various resins[50]. The presence of a lubricant lowers the surface energy of the glass and also avoids the formation of any specific bonds with the binder. Thus application of a lubricant would be expected to be accompanied by a decrease in adhesive strength, as has been observed[50] for an epoxy-resin (258 instead of 303 kgf cm^{-2}), the shrinkage of which does not exceed 3%. With modifications of a polyester resin having larger shrinkages (5.8–8.5%) the presence of a lubricant on the glass increased the adhesive strength from 110 to 134 kgf cm^{-2}. The ability of a plastic paraffin layer to "resorb" surface tensions makes a larger contribution to the change in adhesive strength than does change in the nature of the glass surface. This suggests that surface tensions in the polymer–filler system influence its properties. The action of a finish was not assessed from this point of view[50]. However, the results obtained have something in common wtth data[33,37] showing that a plasticiser in an active lubricant has a favourable effect on the properties of glass-reinforced plastics.

The properties of reinforced materials depend not only on the forces of adhesion between binder and glass fibre—mechanical or physicochemical in character—but also on the cohesive strength of the components. Tikhomirov[60], in particular, regards this as the decisive factor. He employed in his discussions the concept of a critical contact surface, at which the "aggregate" strength of the adhesive bonds between each individual fibre and the polymer matrix is equivalent to the tensile strength of the fibre. The ratio of the breaking load of the glass fibre to its strength of adhesion to the polyester resin gives a value of 0.025 mm^2 for the critical contact surface, which corresponds to a fibre length of ~0.5 mm. Thus accord-

---

§ The "inner-layer modifier" was the same epoxy-resin from which the glass-reinforced plastic had been obtained, but it contained a polyester plasticiser. As a result the modulus of elasticity of the resin on the surface of the finished glass could be lowered by a factor of 8.

ing to Tikhomirov it is sufficient to ensure in a glass-reinforced plastic complete contact between binder and fibre for a length of 0.5 mm in order that fracture of the material will be determined by the strength of the fibres. Further increase in adhesive strength will bring no advantage. Since the fibres normally used are longer than 30 mm, efforts to increase adhesion are not justified in all cases[60]. Discussing problems of the surface modification of the filler, this worker considers it incorrect to explain the strengthening of materials[49-55] by increase in the adhesion interaction with the polymer, which is not the cause of the improvement in strength but merely accompanies it. He refers[60] to Rebinder's work[1], and explains reinforcement as an increase in the cohesive strength of the binder in thin films on the modified glass surface. In fact the finish, by reacting chemically with the resin[52,53,55-58] and also raising the interaction energy of the latter with the filler, changes the properties of the binder in the glass-reinforced plastic in conformity with the views of Lipatov[7]. However, the question posed by Tikhomirov of the unjustified increase in adhesion interaction in glass-reinforced plastics must be regarded as debatable.

In connection with Tikhomirov's concept[60] of increasing the cohesive strength of the filler to strengthen the polymeric material we must consider several papers[61-64] which report an increase in the strength of glass produced by applying an organosilicon film to its surface. Removal of adsorbed water from the surface will obviously be of no little importance here, since it affects the surface tension, and the strength will increase in conformity with Griffiths' equation

$$\sigma^2 = \frac{2\gamma E}{\pi a}$$

where σ is the tensile strength of the glass, γ its surface tension, E the Young's modulus, and a the depth of the cracks.

Outwater and Ozaltin[61] showed that treatment with the finishes A-1100 and A-172 increases the initial strength of glass by about 18%, and boiling diminishes it by a smaller amount. Thus a finish can have a favourable effect on the cohesive strength of both polymer and filler. For the present it is difficult to say whether this is decisive.

V. Reasons for Improvement of Water Resistance of Glass-reinforced Plastics

Hydrophobic adhesives have found application in glass-reinforced plastics not so much because they improve the properties of the latter in the initial state as because of the high stability conferred to the action of moisture. The question arises as to how finishes, by increasing the strength of adhesion between resin and glass, are able to maintain it at a high level after the plastic has been kept in water. Being highly polar, water is able to destroy adsorption bonds at the resin–glass interface—both weak dispersion bonds (of energy not exceeding 1–2 kcal mole^{-1}) and polarisation bonds—and then the still stronger hydrogen bonds (5–10 kcal mole^{-1}). Furthermore, water is able to break down chemical bonds which are unstable to hydrolysis. For example, an epoxy-resin is capable of forming a chemical bond with a glass surface[38]:

(I)

However, the resulting C–O–Si bond is hydrolytically unstable.

Zisman[35] examined the specific effects of finishes on the susceptibility of glass-reinforced plastics to the action of water, and discussed two possible causes—change in the ability of water to penetrate the plastic when a finish was used, and the formation of hydrolytically stable chemical bonds at the resin–glass boundary.

Three molecular diffusion processes—through the mass of polymer, along the glass–polymer interface, and finally through any protective film on the glass at sites not covered by the resin—underlie the mechanism of the penetration of water into a glass-reinforced plastic. The permeability of the glass-reinforced plastic to water changes with modification of the properties of the polymer and the glass surface. Intermolecular (cohesive) interaction of the polymer plays some part in this: increase in such interaction impedes diffusion of water between the macromolecules. Thus the cohesive strength of various films on glass, including those formed by the polymer or the finish, determines the rate of the diffusion process, which will also depend on the hydrophilic character of the surface. In this respect the action of the finish is in effect to produce on the glass a highly cohesive layer which is not readily wetted by water. Zisman remarks, however, that on this basis finishing will have a large effect when the whole surface of the glass fibres is made water-repellent and the angle of wetting is ~90°, since only then does the ability of water to penetrate the system by capillarity become insignificant.

With regard to the role of chemical bonds Zisman notes that intermolecular physical forces are sufficient to obtain a high-strength glass-reinforced plastic; these develop with good wetting and filling of the cracks in the glass by the binder, i.e. with a sufficient area of contact. This is consistent with Tikhomirov's views[60]. However, Zisman[35] and Dean[38] consider that formation of a chemical bond between resin and glass is desirable in cases in which the stability of the plastic to the action of a corrosive medium must be raised. Dean[38] states that, among all the forces acting between an ionic solid (glass) and a resin, only covalent bonds (50–100 kcal mole^{-1}) are not weakened by the action of water. A large number of chemical bonds is not required to strengthen the material; moreover, it is undesirable, since according to Dean their purpose at the interface is to ensure the simultaneous operation of the far weaker van der Waals forces. For steric reasons chemical bonds possess low mobility, and the presence a large number of them lead to strain in the surface layer of polymer.

Furthermore, the decrease in strength of glass-reinforced plastics after being kept in water is in some measure due to plasticisation of the binder. Whereas Zisman and Dean completely ignore this aspect, Pohl[65] assigns paramount importance to it. He determined the dynamic bending modulus of elasticity of a glass-reinforced plastic and the torsional modulus of rigidity, and attributed[65] variation in the former to destruction of adhesion bonds between resin and filler and change in the latter to plasticisation of the binder.

The investigation was made on a glass-reinforced polyester plastic with vinyltrichlorosilane and the product A-172 as finishes. Pohl showed that keeping the plastic in boiling water produced a more marked change in the dynamic modulus of rigidity than in the modulus of elasticity. The stabilising effect of the finish shows far more clearly in shear tests. Thus he assumes that the action of water on a glass-reinforced plastic is determined primarily by its plasticising ability, and he draws an analogy between water and acetone, towards the action of the latter of which the finish was also useful. This investigation[65] was made essentially on a single material (a glass-reinforced polyester plastic), and it is therefore difficult to transfer the author's confidently expressed point of view to other systems, the action of water on which may develop differently, e.g. as a consequence of a change in the chemical composition of the resins and of their specific properties in general.

Clark and Plueddemann[21] and also Vanderbilt[66] assume that a layer of finish, chemically combined with the resin, reacts with the glass by means of bonds which readily tend to recombine, as a result of which the finish moves, as it were, along the surface of the glass, relieving local stresses. Hydrogen bonds and single siloxane bonds are considered[21] as possibilities, the latter formed by interaction of surface hydroxysilyl groups of the glass with alkoxyl or hydroxysilyl groups of the finish. The authors assume that single –Si–O–Si– bonds are capable of recombination, while hydrogen bonds prevent removal of the finish by water. Although the latter statement cannot be accepted[35,38], the contribution of hydrogen bonds to strengthening at the resin–finish–glass boundary is not open to doubt. The view[21] that local stresses are "relieved" by a layer of finish has much in common with Hooper's ideas[43], which we have already discussed.

Thus the question arises of the nature of the bonds between glass and finish. Arguments are given[53,57,58] in support of a chemical (siloxane) bond formed by interaction of alkoxy- and hydroxy-groups of the finish with surface hydroxyls of the glass or silica. If this mechanism is accepted, it is easy to explain the improved resistance to water of glass-reinforced plastics modified with hydrophobic adhesives, since the –Si–O–Si– bond is stable to hydrolysis.

VI. Interaction of Silicate Surfaces with Simple Analogues of Alkylalkoxysilanes

Before analysing this work let us consider, as the closest model to glass, the chemistry of a silica surface and its interaction with certain silanes. The hydroxyl coating on silica includes[67,68] various types of hydroxy-groups—isolated or free, 5.2–5.4 Å or at least 3.1 Å apart; paired hydroxyls linked by a hydrogen bond, the distance between them being 2.52–2.60 Å; and groups of three or four hydrogen-bonded hydroxyls—and is accompanied by a polymolecular film of water the main adsorption centres of which are either bound hydroxyls and coordinatively unsaturated silicon atoms (sites with groups of three or four bound hydroxyls)[68–71] or free hydroxy-groups[72,73]. It has been estimated[67] that on an Aerosil surface containing no adsorbed water the concentration of free hydroxyls per 100 $Å^2$ is 2.6, and that of bound hydroxyls 2.2.

Formation of a hydrogen bond between hydroxy-groups on a silica surface affects their properties. Firstly, they show far less tendency to any kind of interaction—specific adsorption or chemisorption—with organic compounds[67,72]; secondly, they are more liable to removal from the silica surface on heat-treatment[71,74], as a result of which some of the bound hydroxyls become free hydroxyls.

In the infrared absorption spectra of SiO_2 (silica, Aerosil, porous glass) vibrations of the O–H bond in free hydroxyls are represented by a narrow band at 3750–3745 cm^{-1} [67,69,71], and those in bound hydroxyls by a broad band in the range 3750–3000 cm^{-1} [67], after which O–H vibrations of adsorbed water molecules occupy the range 3750–2800 cm^{-1} in the case of silica[72]. In glasses undergoing crystallisation all the above bands are displaced to lower frequencies[75,76]: e.g. a band at 3500–3640 cm^{-1} corresponds to vibrations of free hydroxyls. Furthermore, new bands may appear[75] owing to formation of the strongest hydrogen bonds between hydroxyls in glasses having a low silica content (e.g. below 62%).

The mechanism of the interaction between certain substances and a silica surface can be assessed from the change in intensity of the vibrational bands corresponding to the different types of hydroxy-groups. In particular Kiselev and his coworkers[67,72,77] have shown that the adsorption of aromatic compounds (benzene, toluene, etc.) and of alcohols (methanol, ethanol) produces a sharp drop in intensity of the absorption band due to free hydroxyls. Furthermore, removal of the latter from the surface diminishes its ability to adsorb such compounds. The intensity of the 3750-cm^{-1} band decreases even at low surface coverage with alcohol molecules, whereas the intensity of the band due to bound hydroxyls does not change at all[72]. Hence only free surface hydroxyls are involved in the specific adsorption of alcohols. Sidorov[71] considers that bound hydroxyls are involved in this process at or above 550°C. However, this temperature is so high that in practice all bound hydroxy-groups are removed, the surface being enriched with free hydroxyls[67,74,78].

The weakening and complete disappearance of the band due to free hydroxyls when the Aerosil is treated with alcohols indicates[72] the occurrence of alkoxylation on the silica surface, i.e. the formation of surface Si–O–C bonds. Ease of alkoxylation of silica with alcohols was probably one of the reasons for the concept of chemical reaction between a silica surface and complicated hydroxy- and alkoxy-derivatives, including finishes.

A number of papers have been published on the interaction of Aerosil[67,79–83], silica gel[78,84], glass fibre[57,58,85], and microporous glass[86] with alkylchlorosilanes. Davydov et al.[67] showed that treatment of Aerosil with trimethylchlorosilane results in disappearance of the band due to free hydroxyls (3750 cm^{-1}) but leaves that due to bound hydroxyls unchanged. This phenomenon was explained by two causes—firstly energetic (a certain amount of energy is required to rupture the hydrogen bond of surface hydroxyls, but the heat of reaction with trimethylchlorosilane is only 11 kcal $mole^{-1}$), and secondly steric hindrance (the areas occupied by one trimethylsilyl group and one free hydroxyl together with one bound hydroxyl are roughly equal: i.e. the remaining chlorosilane molecules are unable to approach the bound hydroxyls after the more active free hydroxyls have reacted).

From the appearance, in the infrared spectra of silica modifications treated with trimethylchlorosilane[85,86], of bands in the region of C–H-stretching vibrations (2970 cm^{-1}) and their preservation after the solvent has been washed off and the sample subjected to prolonged vacuum treatment, it was concluded that the chemical reaction

$$-O-Si(O-)_2-OH + ClSi(CH_3)_3 \xrightarrow{-HCl} -O-Si(O-)_2-O-Si(CH_3)_3 . \qquad (II)$$

took place on the silica surface. This is the only possible reaction involving an alkylated monochlorosilane on the silica surface which will yield an alkylated silyl coating. A side-reaction is hydrolysis of the trimethylchlorosilane followed by condensation to a dimer, but the resulting hexamethyldisiloxane is easily removed by vacuum treatment. An equally unambiguous interpretation can be given to the treatment of Aerosil with dimethyl chlorosilane[83], which contains only one functional group (chloro) capable of chemical reaction.

The properties of a trimethylsilyl coating on silica have been studied by adsorption[79-81,84], chromatographic[78,84], and mass-spectrometric[87] methods. Borisenko, Kiselev, et al.[84] showed that the most uniform trimethylsilyl surface coating is formed by treating silica gel with trimethylchlorosilane in the absence of traces of water (dry silica gel and the silane were sealed in an ampoule) at a high temperature. The defects in the coating permit only the small molecules of acetone to penetrate to the residual surface hydroxyls. These defects are inaccessible to the larger benzene molecules, which tend to interact specifically with a silica surface[77]. The decrease in the retention volumes of benzene on the surface by a factor of 50 and the lowering of the heat of adsorption from 11 to 6 kcal mole^{-1} as a result of its trimethylsilylation[84] suggest that the actual nature of the adsorption process has changed: whereas specific adsorption of benzene is observed on hydroxylated silica, the adsorption on a trimethylsilylated surface is non-specific. The results indicate not only a fundamental change in the surface properties of the silica but also complete shielding of the residual hydroxyls by the trimethylsilyl coating (under the given conditions of treatment), which excludes any interaction whatever with substances whose molecules are not smaller than those of benzene. This is confirmed by comparing the areas occupied by a trimethylsilyl group, a free hydroxyl, and a bound hydroxy-group[67].

Different results were obtained[84] when silica gel was treated with dimethyldichlorosilane: the retention volume of benzene changed roughly tenfold in comparison with the original surface. However, this ratio was poorly reproducible because the dimethyldichlorosilane formed a polymer, polydimethylsiloxane. This was considered[84] to impair the uniformity of the alkylsilyl coating. The great influence of secondary processes on the character and degree of modification of the silica surface becomes still more evident when it is remembered that dimethyldichlorosilane interacts with two types of surface hydroxyls: besides the free hydroxy-groups some of the bound hydroxyls react with the chlorine atoms[67], so that the silica surface should have undergone more profound changes than on treatment with trimethylchlorosilane. However, this does not occur[84], for the reaction analogous to (II) is not the sole reaction.

Burushkina, Chuiko, et al.[82] have used methylvinyldichlorosilane to make a detailed study of the interaction of a dichlorosilane with an Aerosil surface. Treatment of the Aerosil with the vapour at various temperatures (20–400°C) was assessed from the change in intensity of a series of bands in the infrared spectrum of the modified Aerosil. The effects of temperature, duration of treatment, and preliminary dehydration of the Aerosil were noted. Thus evacuating the Aerosil at 200°C before treatment increased the number of silyl groups grafted to the surface. Their number successively decreased on passing to the higher temperatures of 400° and 500°C. The increase was attributed to the freeing of hydroxysilyl groups perturbed by a hydrogen bond. This obviously implies the rupture of hydrogen bonds between surface hydroxyls and adsorbed water molecules. The decrease was caused by loss of a proportion of the surface hydroxysilyl groups and hence a decrease in the active centres. Since only bound hydroxyls are removed at 400–500°C [67,71,74], not only free but also bound hydroxyls are involved in the reaction of methylvinyldichlorosilane with the silica surface. The rate curves[82] enable this process to be interpreted as chemisorption, with hydroxysilyl groups regarded as reactive centres. The experimental conditions excluded formation of the polysiloxane polymer, so that systematic examination of chemical interaction on the surface was possible.

VII. Interaction of Glass and Silica Surface with Actual Finishes

Methods of studying the reactions of simple organic silanes have been used to investigate the interaction of actual finishes with a silica surface[53,57,58,88-91]. The infrared spectrum of a finished glass fibre contains new bands[53,57,58] belonging to the finish—stretching vibrations of C–H in the range 3000–2800 cm^{-1} [53] and vibrations of the vinyl group at 3070–3055 cm^{-1} [57,58]—which are not appreciably affected by prolonged (at least 30 h) rinsing of the glass fibre with the solvent, subsequent vacuum treatment (0.001 mmHg at 200°C for 2 h), and boiling in a weak alkali (0.5% ammonia solution for 2 h) [53]. The stability of the grafted groups is regarded[53,57,58] as proof of the formation of a chemical bond between finish and glass, since no other bonds are able to retain the layer of finish on the surface under such severe conditions. The most probable reaction in these systems will occur between halogeno-, hydroxy-, and alkoxy-groups in the finish and hydroxysilyl groups in the glass. On the basis of this scheme the authors conclude that a siloxane bond may be formed at the finish–glass boundary.

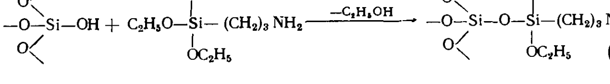
This conclusion was fully substantiated by a study of the interaction between trimethylchlorosilane and a silica surface[86]. The compounds used in the above researches[53,57,58]—finish GVS-9, vinyltrichlorosilane, vinyltriethoxysilane in its original state and partly hydrolysed—are multifunctiona: GVS-9 contains three ethoxyethoxy-groups attached to the silicon atom, and the others contain three halogeno-, ethoxy-, or hydroxy-groups. The experimental method, which ultimately simulated the behaviour of a finish on the surface of an actual filler, in no way excluded any additional reactions due to hydrolysis and condensation of the compounds used. Since all the finishes[53,57,58] were terfunctional, they might give rise to network polysiloxanes.

Wende and Gähde[57,58] showed that treating glass cloth with a chlorinated vinylsilane results in the formation of a grafted compound which is stable in a vacuum at 300°C (for 1 h). Treatment with an ethoxy-derivative gives no band at 3060 cm^{-1} in the infrared spectrum of the glass cloth which had been subsequently heated at 100°C. However, partial hydrolysis of the vinyltriethoxysilane results in the appearance of a band due to vinyl groups, although it is far weaker than for treatment with vinyltrichlorosilane. The authors interpret their observations in terms of the different abilities of chloro-, hydroxy-, and ethoxy-groups to form a chemical bond with the glass surface. They do not dwell on the complete consistency of this pattern with the ability of the compounds to polymerise: chloro-substituents are easily hydrolysed even in the air, whereas particular conditions are needed with alkoxy-groups, so that hydrolysis of the ethoxysilane was necessary before application to the glass surface. This process is accelerated in alkaline medium, and it is probably for this reason that Nikonova[53] finds that finishes graft to an alkaline glass fibre to a greater extent than to an alkali-free glass fibre. Conversion of even the small proportion of finish molecules into a network polysiloxane and adsorption of the latter on the glass fibre will result in the formation on the glass surface of a polymer which firstly is insoluble, since it has a network structure, and secondly is thermostable, like all polysiloxanes. The structural groups which the authors observed in the infrared spectra are present both in the initial finish and in the polymer formed from it. Thus their results[53,57,58] leave no doubt as to the formation on the glass surface of grafted compounds which are stable to various agencies, but these results in no way determine the nature of the compounds or the character of the interaction with the surface. In our view the unequivocal conclusion that an Si−O−Si bond is formed between finish and glass is unjustified with the given experimental method.

More thorough spectroscopic investigations have been made[88-91] at the Pisarzhevskii Institute of Physical Chemistry of the Ukrainian SSR Academy of Sciences. The experimental conditions simulated less closely the finishing of a glass filler, but permitted a deeper insight into its mechanism. The test materials were 3-aminopropyltriethoxysilane and Aerosil, the former is widely employed as a finish, and the latter is a convenient form of silica for spectroscopic investigations. Conditions of treatment were varied widely: Aerosil was modified with the 3-aminopropyltriethoxysilane both as the vapour (at 20−150°C) and as dilute solutions in benzene (at 20−80°C). Determinations were made of the statistical exchange capacity (SEC) to characterise the concentration of groups grafted to the surface. Besides the C−H-stretching vibrations (3000−2800 cm^{-1}), the antisymmetric (3367 cm^{-1}) and symmetric (3288 cm^{-1}) N−H vibrations of the primary amino-group[88,89] and the O−H vibrations of the surface hydroxyls were examined in the infrared spectra of the modified Aerosils.

The main conclusions on the mechanism by which a finish adds to a silica surface were based on the insolubility and great thermal stability of the grafted compound in a vacuum (300°C at 10^{-4} mmHg), the weakening and complete disappearance of the band due to free surface hydroxyls (3750 cm^{-1}) with increase in the statistical exchange capacity of the specimens[88,89], and finally the decrease in the concentration of ethoxy-groups in the surface compound[90]. In the last case the calculation was made from determinations of carbon in the specimens: the concentration of ethoxy-groups was found by subtracting the carbon in propyl groups from the total carbon content, the number of propyl groups having been calculated from the concentration of amino-groups.

Results are presented[90] showing that increase in the statistical exchange capacity of the specimens is accompanied by a change in the ratio of amino-groups to ethoxyl from 1 : 2 to 1 : 1. Since the theoretical ratio for the initial substance in 1 : 3, it is obvious that the molecules of the finish lose some of their ethoxy-groups during transformation on the surface. On the basis of the observations[88,89] the surface reaction is given as



(III)

Thus, although additional information has been obtained on the nature of structural groups on the Aerosil surface, the same conclusion is reached as before[53,57,58] on the formation of a siloxane bond. The fundamental possibility of the formation of a cross-linked polysiloxane from 3-aminopropyltriethoxysilane is not considered, nor is its tendency to hydrolysis under the treatment conditions discussed.

Nevertheless, this process is of interest if only because it leads to a decrease in the ethoxyl content of the grafted layer, and hence should be considered in interpreting the results[90]. Furthermore, the absence of the 3750-cm^{-1} band in the spectra of the modified Aerosil is not unequivocal evidence that free surface hydroxyls are involved in reaction (III), since other O−H vibrational bands were observed, e.g. at 3690 cm^{-1} [89]. This band is due to bound hydroxyls[67], and its presence may imply conversion of free into bound hydroxyls as a consequence of specific adsorption of the compound on the surface. It was obviously in this connection that the hydroxyl concentration of the Aerosil was determined[90] by deuterium exchange and mass spectrometry, and compared with the content of amino-groups on the Aerosil surface. This revealed that increase in the statistical exchange capacity to a particular value was accompanied by a decrease in the content of hydroxy-groups. Further increase in the concentration of amino-groups by a factor of 2.5 produces almost no change in the hydroxyl content of the surface (Table 2). Thus the question arises of incomplete realisation of the proposed reaction mechanism (III).

Table 2. Mass-spectrometric analysis of aminoalkylated Aerosils after deuterium exchange[90].

Conditioning temp., °C	SEC after conditioning (15 h), mmole g^{-1}	Duration of exchange, h	Total exchangeable centres on surface, mmoles g^{-1}	Quantity of centres, mmoles g^{-1} for the groups	
				NH_2	OH
200	0.14	2	1.49	0.28	1.21
200	0.39	2	1.51	0.78	0.73
200	0.57	2	1.52	1.14	0.38
200	0.93	3	2.20	1.86	0.34
200	1.41	3	3.18	2.82	0.36

How is it possible to graft 2.82 millimoles of amino-group per gramme to the silica surface if, after a concentration of 1.14 mole NH_2 g^{-1} has been reached, surface hydroxyls are not involved in the process? An obvious answer is to postulate that molecules of the finish can undergo independent transformation with the formation of polymeric derivatives on the Aerosil surface, but it is difficult to assess the relative proportions of these processes. It is hardly possible to check them from the variation in the ethoxyl content, since transformation of the finish—whether etherification on the surface (scheme III) or the cocondensation of molecules—involves the liberation of ethanol, which interacts readily with a silica surface[79-81]. After treatment of Aerosil with 3-aminopropyltriethoxysilane vapour at 150°C a band appeared in the infrared spectrum[90] at 2985 cm^{-1}, which corresponds to antisymmetric vibrations of the methyl group in the presence of a C_2H_5-O bond. Thus, an additional possibility is ethoxylation of the surface, which probably accompanies[90] the main processes, and under favourable conditions will become increasingly dominant. The absence of the 2985-cm^{-1} band with the other Aerosil modifications may not be complete proof of the absence of ethoxylation, since the concentration of grafted ethoxy-groups is probably small, and a strong band due to C–H-stretching vibrations (2935 cm^{-1}) is superimposed on their characteristic band (2985 cm^{-1}).

Consequently interaction between the silica surface and ethanol, which is a product of the hydrolysis and the condensation of the ethoxysilane, should lead both to a decrease in the concentration of surface hydroxyls and to a change (decrease) in the ratio of amino- to ethoxy-groups in the grafted compound. The experimental results, including those in Table 2, are interpreted[90] solely as a consequence of condensation of the ethoxy-groups of the silane with hydroxysilyl groups of the silica. In our view, however, all the observed phenomena may be due also to other processes—firstly hydrolysis and condensation of the terfunctional finish into a cross-linked polymer adsorbed on the silica surface, and secondly ethoxylation of the Aerosil surface by ethanol liberated in the first process. The unequivocal conclusion that a chemical bond is formed between finish and silica surface is open to doubt, since the phenomena observed by these workers can be explained by other processes.

An interesting investigation was made by Tertykh, Chuiko, et al.[91] on the part played by amino-groups in the reaction between 3-aminopropyltriethoxysilane and an Aerosil surface. This group was characterised by two absorption bands—at 3380 and 3305 cm^{-1}—which were displaced to shorter wavelengths by vacuum treatment at 450°C, their frequencies becoming respectively 3500 and 3425 cm^{-1}. This substantial shift in the bands was explained by breakdown of the hydrogen bond between the primary amino-groups in the finish and the free hydroxyls on the silica. This bond is quite stable, since it is destroyed only after vacuum treatment at 450°C, when the hydroxyls hydrogen-bonded to amino-groups were split off, i.e. when "removal of one of the components of the hydrogen-bonded complex" takes place. As long as the complex does not break down, the aminoalkylated Aerosil is not involved in specific adsorption interaction with methanol and acetone. After destruction of the complex these compounds are adsorbed on the surface, which results in broadening of the 3425-cm^{-1} band.

The results[91] show that the amino-group of the finish is able to interact with the silica surface with formation of a fairly stable bond. At present, of course, this conclusion applies only to 3-aminopropyltriethoxysilane, for other amino-alkoxysilanes have not been studied from this point of view. An analogous investigation would enable us not only to establish the possibility of interaction between finishes and a silica surface through the amino-groups but also to ascertain the effect of substituents attached to the nitrogen atom on its tendency to surface reaction.

It has been shown[92] that analogues of real finishes—aminoalkylethoxysilanes containing one ethoxy-group—do in fact react chemically with a silica surface. This is proved by the preservation of bands due to CH-stretching vibrations in the spectrum of the Aerosil after extraction and high-temperature vacuum treatment. Formation of any thermostable derivatives of the aminoalkylsilane not grafted to the surface was excluded by the monofunctionality of the agent. The use of model compounds led to the conclusion[92] that chemical reaction is possible between an ethoxy-group in the aminoalkylsilane and the surface hydroxyls of Aerosil.

It is difficult to say to what extent this process occurs with finishes containing two or three ethoxy-groups and showing a tendency to more complicated reactions. Since these compounds have proved effective for practical application, it would be of great interest to examine their tendency to polymerisation in contact with a glass surface and determine the contribution of this process to the general pattern of transformation of the finish on the surface.

---o0o---

The above review was written at the beginning of 1969. While it was being prepared for publication a considerable number of papers appeared on improvements to the application of hydrophobic adhesives in polymeric materials and on extensions to their field of use[93-97]. It has been proposed[93,94] that finishes and active additives should be employed not only in glass-reinforced plastics but also in glues, sizes, coatings, and moulding compositions. New modifiers have appeared which improve adhesion in filled polymers, e.g. finishes based on modified epoxy-resins[98] and novel organosilicon compounds containing nitrogen[99].

Hydrophobic adhesives find application in the most recent and promising types of composite materials, e.g. in a glass-reinforced plastic based on a thermostable polyimide resin[100] and in carbon-reinforced plastics[101]. The properties have been described[100] of glass-reinforced plastics based on a polyimide binder obtained from the dianhydride of benzophenone-3,3′,4,4′-tetracarboxylic acid and *m*-phenylenediamine. Glass cloth S-994 was used as filler, with its surface modified three ways: it was subjected to heat-treatment; it was finished with product A-1100 after heat-treatment; and it was treated with product HTS during stretching of the glass fibres. The presence of the modifier on the glass cloth produced a sharp increase in the water resistance of the material: 90–99% of its bending strength was maintained after immersion in boiling water for 2 h, whereas a glass-reinforced plastic based on the heat-treated glass cloth retained only 45% of the initial strength. A second, no less important point is the sharp increase in the initial strength of the glass-reinforced polyimide plastic resulting from modification of the filler with products A-1100 and HTS: the bending strength of the material in the dry state was changed from 2140 to 3060–3670 kg cm^{-2}. Thus there is no doubt about the prospects for modifying glass-reinforced polyimide plastics with a finish to raise their initial strength and their resistance to water. However, the problem arises of preserving the strength of the material at high temperatures, since thermal stability remains a primary requirement of such plastics. Finishing a glass cloth with product A-1100 has an adverse effect on the strength of the material during its thermal aging at 316°C, while the use of product HTS leads to a sharp deterioration in the strength indices after aging at this temperature for 300 h. Research workers will probably direct their efforts towards developing methods for stabilising glass-reinforced polyimide plastics which will enable the heat resistance of the material to be maintained while its water resistance is improved.

Alkylalkoxysilanes have hitherto been used in polymeric materials filled with glass, silica, quartz, etc. However, Harris et al.[101] have found an effective method of applying hydrophobic adhesives in carbon-reinforced plastics. They have been able to strengthen a carbon-reinforced polyester plastic considerably by applying alkoxysilanes containing epoxy-groups in the organic radical (A-186 and

A-187) to the surface of carbon fibre previously immersed in boiling 70% nitric acid for 2 h. The strength of the plastic is already increased by the use of oxidised fibres, but their finishing leads to further increases in tensile strength (from 56.6 to 63.7 kgf mm^{-2}), bending strength (47.5 to 53.0 kgf mm^{-2}), and shearing strength (2.52 to 2.77 kgf mm^{-2}). The shear tests indicate that the strengthening of the material due to oxidation and finishing of the carbon fibres is 35% (2.77 compared with 2.06 kgf mm^{-2}). In order to achieve the same improvement solely by oxidising the carbon fibres in boiling nitric acid, the time of immersion would have to be increased from 2 to 24 h. Preliminary oxidation of carbon fibres in aqueous medium is regarded as yielding surface hydroxyls, and the interaction with the silane finish occurs by a mechanism analogous to that observed with glass-reinforced plastics. On studying the fracture of specimens by scanning electronic stereoscopy, however, peculiarities were noted[101] in the detachment of the finished carbon-fibre surface from the mass of the binder. A layer of finish or binder usually remains on the finished glass surface[37]. The surface of a carbon fibre torn from a polymer matrix, however, contained no trace of finish and was entirely similar to an unfinished surface. The explanation given[101] is that the finish bonds more strongly to the binder than to the carbon fibre.

Thus hydrophobic adhesives are beginning to be used, not only in new types of resins, but also in combination with new forms of filler. Hence the interest of research workers in the chemistry of the interaction between these modifiers and various kinds of surfaces is not accidental. Broun, Korolev, et al.[102] used the infrared spectra to estimate the content of grafted groups on the surface of titanium dioxide (anatase, rutile), and showed[103] that, unlike silica, the same number of trimethylsilyl groups are grafted on independently of whether the surface is treated with trimethylchlorosilane or trimethylethoxysilane. Furthermore, these workers observed the formation of carboxylates on a titanium dioxide surface treated with trimethylchloro- and trimethylacetoxysilanes.

Information on the interaction of simple alkylalkoxysilanes with a silica surface has been extended. The relative activities of trimethyl-ethoxy-, -acetoxy-, and -chloro-silanes and their firmness of retention on silica have been characterised[103] by the surface concentrations of grafted trimethylsilyl groups. In the spectrum of Aerosil treated with dimethoxydimethylsilane vapour[104] the band due to C–H vibrations in the trimethylsilyl group (at 2965 cm^{-1}) was accompanied by a band at 2953 cm^{-1}, both of which remained after vacuum treatment of the specimen at 450°C. The appearance of a band at 2853 cm^{-1} is explained[104] by the grafting of methoxy-groups to the silica surface. In fact the spectrum of Aerosil which has been treated with methanol contains a band at 2857 cm^{-1}. Thus this work[104] has shown that the main reaction between dimethoxydimethylsilane and silica—analogous to scheme (III)—is accompanied by a secondary reaction, in which the methanol liberated reacts with surface hydroxyls. The possibility of such interaction has been discussed above (Section VII), and this paper[104] supplies experimental confirmation.

Johanson et al.[105],[106] labelled organosilanes with carbon-14 to examine their interaction with silica and alkali free glass surfaces. They found that trimethylchlorosilane was adsorbed on the glass than on silica, On immersion of the glass in boiling water or on exchange with unlabelled trimethylchlorosilane molecules, however, the number of primarily adsorbed molecules greatly diminished. This suggested that the interaction of trimethylchlorosilane with glass is not confined to chemical reaction with surface hydroxyls, but includes adsorption interaction of additional molecules of the substance with surface metal ions. In contrast to trimethylchlorosilane, trimethylsilanol is easily removed from a silica surface. From this it is assumed that trimethylsilanol adds to a silica surface by means of hydrogen bonds between its own hydroxyl and those of the silica. By using ammonia as catalyst for the silanol condensation, however, these workers were able to prevent the adsorbed trimethylsilanol molecules from exchanging with those in the solution. After desorption the silica retained 90% of the grafted molecules, instead of the 20% observed in the absence of ammonia. Thus a transition from a hydrogen bond to a chemical bond between the compound and the silica surface was accomplished.

It has been shown[105], with hexamethyldisilazane as example, that adsorbed water has a vigorous effect on the transformation of organosiloxanes in contact with a glass surface. For this purpose the water adsorbed on glass was replaced by ^3H_2O, and the variation in its amount during reaction with hexamethyldisilazane was followed. It was established that water causes conversion into trimethylsilanol, which in the presence of the ammonia liberated forms a chemical bond with the glass.

Daley and Rodriguez[107] pay great attention to the hydrolysis of finishes on a glass surface. In their opinion this process precedes interaction of actual finishes with the surface, and its extent affects the properties of glass-reinforced plastics. They checked the hydrolysis of vinyltriethoxysilane (A-151), hydroxypropyltrimethoxysilane (A-174), and pentyltrimethoxysilane (Y-2815) from the variation in intensity of the chromatographic peak of the unhydrolysed finish on contact with glass. Hydrolysis of the finishes was catalysed by alkali-metal ions in the glass, which had an especially marked effect on A-151, whose relatively small molecules most easily approached the surface ions[107]. Glass was finished with the product A-151 under various conditions: (i) particles of glass were merely introduced into a solution of the finish; (ii) acetic acid was added initially, and then the glass; and (iii) the glass was added, and only then was the solution acidified. Hydrolysis of the finish occurred to the greatest extent in case (ii), its completeness being shown in the mechanical properties of polystyrene filled with the finished glass. The polymer had its highest bending strength (510 kgf cm^{-2}) when it contained glass particles finished in the absence of acid, i.e. when hydrolysis of the finish was insufficiently advanced. When hydrolysis was most complete, the strength of the filled polymer had its minimum value (440 kgf cm^{-2}). The explanation given[107] is that the finish, hydrolysed by acetic acid, is deposited on the glass surface only after some delay. This probably involves formation on the glass of a layer of finish, which results in less effective interaction between polymer and filler.

Recent papers[108–110] have examined the adsorption of water on silica, and its effect on the wetting and adhesion of silicate surfaces[111]; others have assessed the destructive effect of water on glass-reinforced plastics and the possibility of diminishing it by means of hydrophobic adhesives[112–114]. The opinion is expressed[112] that water breaks the bonds at the boundary between polyester resin and glass by leaching substances of low molecular weight out of the resin, so that the binder shrinks. Eakins assumes[113] that in general the action of water on glass-reinforced plastics consists in penetrating the material and increasing the rigidity of the layer of resin on the surface of the glass. This diminishes the ability of the surface layer of polymer to relieve the stresses arising on the formation of cracks and their extension to the filler surface. Furthermore water, by rupturing hydrolytically unstable bonds between glass and resin, disturbs the closeness of packing of binder macromolecules in the surface layer, which permits access of water to the rest of the material. It is considered[112,113] that the use of finishes diminishes the destructive action of water on glass-filled polymers.

Garanina, Semenova, et al.[114] have shown that the properties of a glass-reinforced plastic, in both dry and wet states, can be improved by slightly drying the glass cloth at 80°C for 1.5 h before production of the material. Such removal of water from the filler surface lowers the number and size of microdefects (pores) in the material. These observations are especially significant when it is remembered that the application to glass cloth of most finishes, e.g. aminoalkylethoxysilanes[114], considerably increases the amount of water adsorbed on the glass surface.

Ionisation Potentials of Aromatic and Heterocyclic Compounds

V.K.Potapov

The relation between the ionisation potentials of aromatic and heterocyclic compounds and their electronic structures is considered. The nature of the orbitals in the ground states of molecules of different structures is examined on the basis of an analysis of the ionisation potentials. It has been shown how substituents affect the positions of the electronic levels of aromatic compounds.
The bibliography includes 57 references.

CONTENTS

I. INTRODUCTION

During recent years, there has been an increase in the number of studies on the photoionisation of organic compounds in the gas phase, dealing with the investigation of the electronic structure of molecules and the mechanism of their decomposition on ionisation. The advances achieved in this field are due to the successful development of the technique of the accurate determination of adiabatic ionisation potentials (i.p.) by the photoionisation method.

At the present time this method has been developed and used to determine ionisation potentials by Soviet and non-Soviet investigators[1-9]. Valuable information about the upper ionisation potentials of aromatic compounds was obtained by photoelectronic spectroscopy[10-12].

The ionisation potentials of a large number of aromatic and heterocyclic compounds containing $>$N–, $>$C=O, –O–, and –S– groups in different positions are now known. However, this information has not been arranged systematically, which makes it difficult to discover the characteristic properties of the structures of organic compounds.

From the standpoint of electronic structures and the influence of chromophoric groups and substituents on the π-electron system, aromatic compounds can be usefully divided in three main groups.

1. Aromatic-hydrocarbons with an upper π-electron level in the ground state.
2. Aromatic compounds in which the heteroatoms supply a lone pair of p electrons to the π-electron system: (a) compounds with a chromophoric group outside the ring (aniline, phenol, and others); (b) heterocyclic compounds containing the –N$<$, –O–, and –S– groups (pyrrole, furan, and others).
3. Aromatic compounds in which each heteroatom supplies one p electron to the π-electron system: (a) nitrogen-containing heterocyclic compounds (pyridine and others); (b) aromatic compounds with a carbonyl group (quinones).

This classification of aromatic and heterocyclic compounds, based on an analysis of their ionisation potentials, provides information about the energies and the nature of their molecular and atomic orbitals.

This review deals with studies on the electronic structure of aromatic compounds of the above type on the basis of ionisation potentials, corresponding to the removal of electrons from different orbitals in the ground state, and the influence of substituents and heteroatoms on the nature and positions of π-orbitals.

II. IONISATION POTENTIALS OF AROMATIC HYDROCARBONS

The electronic structure of polycyclic aromatic hydrocarbons is characterised by a stable π-electron system ensuring a high energy stability of molecules of this type in photochemical and radiation-chemical reactions. Thus the mass spectra of benzene and naphthalene show a relatively low yield of fragment ions formed as a result of the disruption of the ring. The reactivity of aromatic polycyclic compounds in photochemical reactions is determined by the nature of their excited electronic states ($\pi\pi^*$). As a result of the delocalisation of electrons in the π orbitals of both the ground and excited electronic states, the valencies produced are common to the molecule as a whole, which determines the relative passivity of the ($\pi\pi^*$) states with respect to intermolecular interactions and the low photochemical activity of polycyclic hydrocarbons[13].

Accurate values of the first ionisation potentials for hydrocarbons were obtained by the photoionisation method mainly during the last few years (Table 1). The upper ionisation potentials corresponding to the energies of removal of electrons from various filled inner orbitals have been determined from the photoelectronic spectra of the molecules (Table 2).

The first ionisation potentials of polycyclic hydrocarbons (benzene, naphthalene, anthracene) decrease with the number of π electrons in the molecule, which is due to the decrease of the energy of the upper filled π orbital in consequence of the increase of the conjugation energy. It follows from the molecular orbital theory that the energy of the upper filled π orbital is linearly related to the first ionisation potential of the given molecule[1,14]. Accordingly, the first ionisation potential may be represented as follows:

$$I_p = -(\alpha + m_i\beta),$$

where α is the Coulombic integral, β the resonance integral, and m_i the coefficient of the energy of the ith molecular orbital. This equation has the specific form $I_p = 5.78 + 3.75\, m_i$ and holds satisfactorily for polycyclic hydrocarbons.

It has been shown[15] that the upper ionisation potentials of aromatic hydrocarbons and the energies of the filled π orbitals in the ground state are also correlated in the zeroth Hückel approximation.

Table 1. First ionisation potentials of aromatic hydrocarbons.

Compound	Ionisation potential, eV									
	photoionisation	Refs.	spectroscopy	Refs.	photoelectronic spectroscopy	Refs.	electron impact	Refs.	calc.	Refs.
Benzene	9.246±0.005	9	9.247	16	9.24	11				
o-Xylene	8.56±0.01	7	—	—	—	—	—	—	—	—
m-Xylene	8.57±0.01	7	—	—	—	—	—	—	—	—
p-Xylene	8.44±0.01	7								
Naphthalene	8.12±0.01 8.14±0.02	7 18	8.13	19.20	8.12	15	—	—	8.12	21
α-Methylnaphthalene	7.96±0.01	7	—	—	—	—	—	—	8.28	22
β-Methylnaphthalene	7.96±0.01	7	—	—	—	—	—	—	—	—
Anthracene	7.38±0.03	28								
	7.41	18	7.41	18	—	—	—	—	7.38	22
	7.3	23	—	—	—	—	—	—	7.3	24
Phenanthrene	7.75	18	7.69	18					7.96	25
									8.02	21
Azulene	7.41±0.01	18,26	7.41	18	7.42	15				
Indene			—	—	8.13	15	—	—	—	
Biphenylene			—	—	—	—	7.95±0.3	15	—	—
Biphenyl	8.27±0.01	7	—	—	—	—	—		—	—
p-Terphenyl			7.7	18						
Toluene	8.82±0.01	6	—	—	—	—	9.10	27	—	—
Diphenylmethane	—	—	—	—	—	—	8.95	27	—	—
Triphenylmethane	—	—	—	—	—	—	8.80	27	—	—
Naphthacene	6.88±0.03	28	—	—	—	—	—	—	—	—

Thus the following relation holds for the ionisation potentials and the π-orbital energies of benzene, indene, azulene, and biphenylene:

$$I_p^j = 6.22 + (2.77 \pm 0.15)\,m_j,\ \text{eV},$$

where m_j is the coefficient of the energy of the jth π orbital in the ground state of the given molecule.

Table 2. The first and upper ionisation potentials of aromatic compounds.

Compound	Ionisation potential, eV				References
Benzene	9.24	11.48	14.0	16.83	11
Naphthalene	8.12	8.90	10.0	10.85	15
Indene	8.13	8.95	10.29	11.58	15
Azulene	7.42	8.49	9.91	10.85	15
Anthracene	7.41	9.25			18
Phenanthrene	7.75	9.35			18
Biphenyl	8.20	9.08	9.70	11.02	15

The resonance integral $\beta = 2.77 \pm 0.15$ eV is consistent with the estimate obtained from the ionisation potentials. This equation was used to estimate the ionisation potentials of the compounds investigated and showed good agreement with the experimental data in Table 2. Naturally, such an examination is important for the determination of the sequence and nature of the upper and lower π orbitals in the ground state of the given molecule.

The ionisation potentials of benzene were determined by El Sayed et al. from the ultraviolet absorption spectra on the basis of the convergence limits of the Rydberg series[16]. The first and second ionisation potentials, which are 9.247 and 11.489 eV, were attributed to the removal of electrons from π orbitals. The Rydberg series converging to 16.84 eV and representing a vibrational progression with a frequency of 900 cm^{-1} was attributed to the removal of an electron from the σ_{CC} orbital. The ionisation potentials of benzene determined from high-resolution photoelectronic spectra[11] agreed to a high degree of accuracy with the corresponding spectroscopic values (Fig. 1 and Table 2).

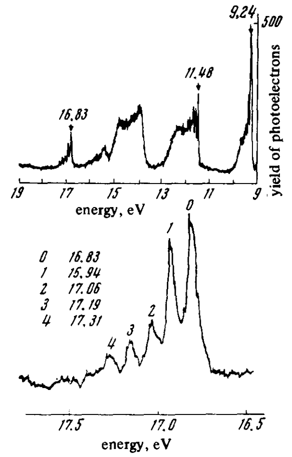

Figure 1. High-resolution photoelectronic spectrum of benzene.

The structure of the vibrational levels converging to the third ionisation potential also consists of a progression: 17.31, 17.19, 17.06, 16.94, and 16.83 eV. The results of these two investigations and also new studies on the photoionisation of benzene[4,5] (Fig. 2) established that the first and second ionisation potentials of benzene, 9.246 and 11.489 eV respectively, correspond to the energies of the removal of an electron from the π orbitals of the ground state and the ionisation potential of 16.83 eV corresponds to the removal of an electron from the σ_{CC} orbital. The photoionisation threshold at 14 eV (see the photoelectronic spectrum in Fig. 1) is probably also associated with the removal of an electron from the σ orbital, since according to the photoionisation data for benzene $C_6H_5^+$ fragment ions are formed at an energy of 13.8 eV.[5]

It should be noted that the calculation by the self-consistent field molecular orbital (SCF-MO) method for the benzene molecule[29] yielded unduly high energies for the upper σ_{1g} orbital. This is the reason for the incorrect assignment of the ionisation threshold associated with the removal of electrons from this σ orbital in a series of experimental studies on the ionisation potentials of benzene before the studies on the photoionisation[4,5] and photoelectronic spectra[11].

In the vicinity of the first ionisation potential the photoionisation curve for benzene shows breaks at energies of 9.33 ± 0.01 and 9.42 ± 0.01 eV, associated with the vibrational excitation of the second overtone of the ν_{18} symmetrical vibrations (670–690 cm^{-1}) of the molecular ion in the

Rydberg series converging to the first ionisation potential[5,30].

The ionisation potentials of anthracene and phenanthrene were determined from the electronic absorption spectra[18] on the basis of the convergence limits of the Rydberg series. The same workers determined by the photoionisation method the first ionisation potentials of naphthalene, anthracene, phenanthrene, and azulene, which agreed with the spectroscopic values. The photoionisation curves for anthracene and phenanthrene in Fig. 3 show that the vibrational excitation levels of the molecular ions observed in the vicinity of the first ionisation potentials are diffuse, which makes their assignment difficult.

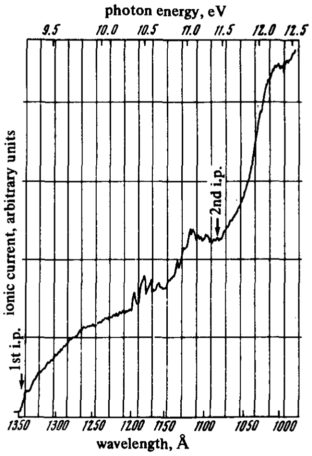

Figure 2. Photoionisation curve for benzene recorded on an MKh-1311 mass-spectrometer.

Absorption bands converging to the second ionisation potential have been observed on photoionisation curves between the first and second ionisation potentials of polycyclic hydrocarbons. The structure of the maxima is shown most distinctly for benzene in the energy range 10.4–11.2 eV (Fig. 2) (the first four maxima constitute a vibrational progression with a frequency of 0.09 eV), which can be accounted for by pre-ionisation from Rydberg molecular states, converging to the second ionisation potential of benzene corresponding to the removal of an electron from the π orbital $1b_1$ (a_{2u} level)[5]. The vibrational structure of the pre-ionisation bands of toluene is not resolved. The position of the first toluene band agrees with that of the first absorption band of toluene vapour due to the excitation of electrons from the lower π_1 orbital.

Pre-ionisation bands at energies of 9.1 and 9.0 eV converging to the second ionisation potentials of 9.25 and 9.35 eV have been observed for anthracene and phenanthrene[18]. It is noteworthy that the pre-ionisation levels of phenanthrene and azulene are of a pre-dissociation type.

The ionisation potentials of benzene, biphenyl, and *p*-terphenyl, corresponding to the removal of an electron from the upper π orbitals of these molecules, decrease with the number of phenyl rings in the chain, which is probably associated with the decrease of the energy of the upper filled π orbitals of this series of compounds in consequence of the conjugation between the π electrons of the phenyl groups. This conclusion is confirmed by the fact that the ($\pi\pi^*$) electronic transition band is displaced towards long wavelengths by 2200 cm^{-1} on addition of the phenyl group[32].

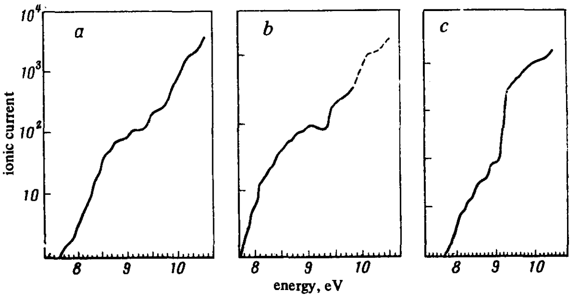

Figure 3. Photoionisation curves: *a*) anthracene; *b*) phenanthrene; *c*) phenothiazine.

A characteristic feature of the electronic structures of the phenyl derivatives of methane (toluene, diphenylmethane, and triphenylmethane) is that the ionisation potentials of these molecules differ little[27]. The insignificant decrease in this series of the energy of removal of electrons from upper filled π orbitals is evidence of only a weak interaction between the π electrons in the phenyl rings in consequence of their non-coplanarity. This feature of the electronic structure is shown also in the decomposition of the phenyl derivatives of methane. For example, the decomposition of triphenylmethane on ionisation takes place with a change in the initial tetrahedral configuration of the molecule and the formation of the stable $(C_6H_5)_3C^+$ ion having a planar configuration.

III. IONISATION POTENTIALS OF AROMATIC COMPOUNDS WITH HETEROATOMS

1. Benzene Derivatives

The substitution of a hydrogen atom in benzene by chromophoric groups may lead to a change in the nature and positions of the upper electronic levels of the ground state of the molecule. The incorporation of the unshared electron pair of the heteroatom in an electron-donating substituent into the π electron system in benzene leads to the removal of the degeneracy of the upper e_{1g} level and the splitting of the energies of the π_3 and π_2 orbitals. The π_3 orbital (B_1 symmetry) corresponds to the maximum electron density at the carbon atom and the π_2 orbital (A_2 symmetry) corresponds to a node. Analysis of the photoelectronic spectra of mono- and *p*-substituted benzene derivatives quoted by Baker et al.[11] shows that the band at 9.40 eV, corresponding to the first vertical ionisation potential of benzene, broadens or splits when the hydrogen atom is substituted (Table 3).

For toluene, diffuse bands corresponding to the first ionisation potential are observed. The splitting of the energies of the π_3 and π_2 levels is probably fairly small and cannot be determined from the photoelectronic spectrum. The same conclusion follows also from the analysis of the initial section of the photoionisation curve for toluene[5].

Table 3. Vertical ionisation potentials of benzene derivatives according to Turner[11].

In aromatic ethers C_6H_5OR, where the unshared electron pair of oxygen is conjugated with the π electrons of the phenyl group, the π_3 and π_2 orbitals of phenol are split—to the extent of 0.70 and 0.83 eV in the case of anisole. In *p*-butoxybenzene $C_6H_5OC(CH_3)_3$ the splitting is less. It follows from the photoelectronic spectra of alkyl phenyl ethers (Fig. 4 and Table 3) that the second ionisation potential hardly changes but the first decreases on substitution. This finding leads to the conclusion that the substitution of hydrogen by alkyl groups leads to a decrease of the energy of the π_3 orbital with B_1 symmetry, while the energy of the π_2 orbital with A_2 symmetry hardly changes under these conditions. For this reason, the first ionisation potentials of alkyl phenyl ethers (Table 4) correspond to the removal of electrons from the upper π_3 orbitals of type B_1 and decrease in the series phenol, anisole, and phenetole, and the second ionisation potentials correspond to the removal of an electron from the π_2 orbital of type A_2. On passing to benzyl methyl ether, where the conjugation between the unshared pair of the oxygen *p* electrons and the π electrons of the phenyl group is weakened, the first ionisation potential is higher compared with those of alkyl phenyl ethers.

The photoelectronic spectra of trifluoromethyl phenyl ether and pentafluoroethyl phenyl ether do not show a splitting of the first ionisation band due to the breakdown of conjugation between the unshared electron pair of oxygen and the π electrons of the phenyl group. This may be attributed to the powerful inductive effect of the fluorine atoms, which leads to a change in the nature of the unshared electron pair of oxygen and an increase of the energy of the upper π level.

The above characteristics of the electronic structures of alkyl phenyl ethers are well illustrated by the position of the upper π-electron levels in the ground state shown in Fig. 5.

For *p*-substituted benzenes containing –OR groups, the splitting of the energies of the π_3 and π_2 orbitals is fairly large (1.0–1.2 eV), but their investigation requires a more detailed examination of the photoelectronic spectra and the photoionisation potentials of the molecules.

The ionisation potentials of aniline and its derivatives in Table 4 were first determined by Viletov and coworkers[17,37,38] and assigned to the removal of electrons from π orbitals. These investigations also showed that in the vicinity of the threshold the photoionisation curves are diffuse and the probability of the formation of molecular ions in the vibrational ground state is low.

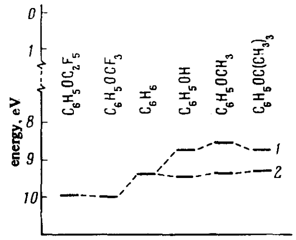

Figure 5. Positions of the upper π-electron levels in the ground state of alkyl phenyl ethers: *1*) π_3 (symmetry B_1); *2*) π_2 (symmetry A_2).

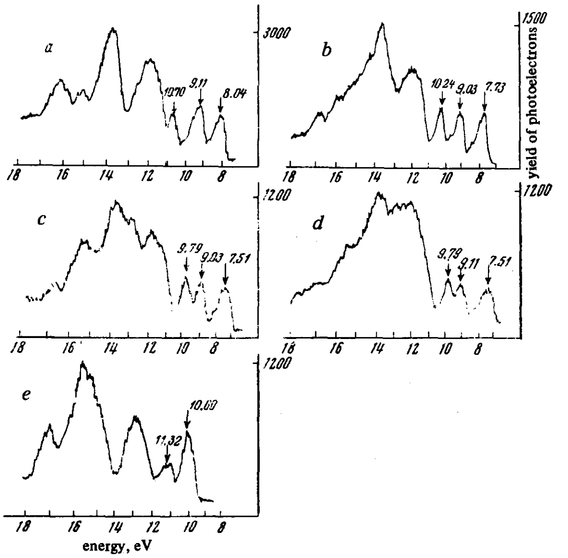

Figure 6. Photoelectronic spectra: *a*) aniline; *b*) *N*-methylaniline; *c*) *NN*-dimethylaniline; *d*) *NN*-diethylaniline; *e*) $C_6H_5N(CF_3)_2$.

The substitution of a hydrogen atom by an amino-group leads to an appreciable separation of the π_3 and π_2 orbitals, mainly due to the decrease of π_3 orbitals of type B_2 which correspond to maximum electron density at the point of substitution. For aniline, this splitting is 1.07 eV and, on consecutive substitution of hydrogen atoms in the amino-group by CH_3 groups, amounts to 1.3 eV for *N*-methylaniline and 1.52 eV for *NN*-dimethylaniline (Table 3 and Fig. 6).

The second ionisation potentials of aniline and its derivatives, associated with the removal of electrons from π_2 orbitals of type A_2 with an electron density node at the point of substitution, remain virtually constant.

The substitution of hydrogen atoms in the alkyl groups by fluorine atoms [$C_6H_5N(CF_3)_2$] leads to the breakdown of conjugation between the unshared electron pair of nitrogen and the π electrons of the phenyl group and the displacement of the first ionisation band towards higher energies. The absence of conjugation between the unshared electron pair of nitrogen and the π electrons of the phenyl group in benzylamine also leads to an increase of the first ionisation potential compared with aniline and its derivatives. It is interesting to note that decomposition processes with abstraction of a hydrogen atom from the methylene group, associated with ionisation as a result of the removal of an electron from the orbital of the unshared pair in the amino-group, are observed for benzylamine at a photon energy exceeding 9.5 eV.[37]

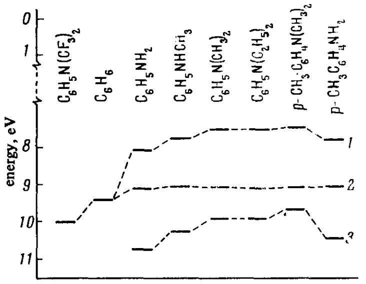

Figure 7. Positions of the upper π-electron levels of aniline and its derivatives: *1*) π_3 (B_1 symmetry); *2*) π_2 (A_2 symmetry); *3*) $\pi 2p_z$ ($-N\langle$).

The photoelectronic spectrum of aniline in Fig. 6 also shows that the third ionisation potential (vertical) of 10.70 eV corresponds to the removal of an electron from the π orbitals with maximum electron density at the nitrogen atom. The third adiabatic ionisation potential of aniline determined from the photoionisation curve is 10.2 eV.[37] It is interesting to compare the change in the third vertical ionisation potential of aniline, as hydrogen atoms in the amino-group are substituted, with the first ionisation potentials of aliphatic amines:

NH_3	CH_3NH_2	$(CH_3)_2NH$	$C_6H_5NH_2$	$C_6H_5NHCH_3$	$C_6H_5N(CH_3)_2$
10.16 eV	9.18 eV	8.36 eV	10.70 eV	10.24 eV	9.79 eV

Fig. 7 shows the positions of the upper filled electronic levels of aniline and its derivatives showing that the separation between the π_3 and π_2 orbitals decreases as the hydrogen atoms in the amino-group are substituted by alkyl groups, owing to the decrease of the energy of the π_3 orbital with B_1 symmetry. Under these conditions, the energy of the π_2 orbital with A_2 symmetry remains virtually unchanged for all aniline derivatives. The nature of the change in the energy of the $\pi(2p_z)$ orbital associated with the unshared $2p_z$ electron pair of nitrogen is the same as for the π_3 orbital.

Analysis of the photoelectronic spectra of $C_6H_5CF_3$, C_5H_5CN, C_6H_5NO, and $C_6H_5NO_2$ shows that the first ionisation band is not split but is displaced towards higher energies (the ionisation potentials of these molecules exceed that of benzene). This may be attributed to the transfer of charge from the benzene ring to the substituents owing to the inductive effect (CF_3) and the negative mesomeric effect ($-CN$, $-NO_2$).

The ionisation potentials of mono- and *p*-substituted benzenes corresponding to the removal of an electron from the lower π_1 orbital, analogous to the $\pi_1(a_{2u})$ orbital of benzene, as a rule exceed the second ionisation potential of benzene (11.49 eV).[11] This is shown more clearly by halogeno-derivatives of benzene and the rule of addivity holds most satisfactorily when substituents are introduced into the 1- and 4-positions (Table 3).

The change in ionisation potentials associated with the removal of an electron from the σ_{CC} orbitals can also be followed in halogeno-derivatives of benzene. Thus the ionisation potential corresponding to the removal of an electron from the σ_{CC} orbital changes on substitution of hydrogen by fluorine from 16.83 to 17.4 eV and on substitution by chlorine and bromine the changes are to 16.7 and 17.0 eV respectively.

The above analysis of the electronic structure of benzene derivatives based on the photoionisation potentials is confirmed also by theoretical calculations. The calculation by the Pariser–Parr–Pople method showed[39] that in aniline the non-bonding electrons of nitrogen are conjugated with the π-electrons of the phenyl ring. The upper filled $3b_1$ and $1a_2$ aniline π orbitals have electronic configurations similar to those of the corresponding upper $2b_1$ and $1a_2$ benzene π orbitals and the lower $1b_1$ aniline π orbital corresponds to the lower $1b_1$ benzene π orbital. The $2b_1$ aniline π orbital, which is located between the $1a_2$ and $1b_1$ orbitals, has the maximum electron density at the nitrogen atom.

The substitution of hydrogen atoms in the amino-group of aniline by phenyl groups leads to a lowering of the first ionisation potential to 7.25 eV (diphenylamine) and 6.68 eV (triphenylamine)[35]. This finding may be attributed to a decrease of the energies of the upper π orbitals in consequence of the conjugation between the phenyl rings via the unshared pair of nitrogen. Calculations by the LCAO-MO method showed that compounds such as diphenylamine have a single π-electron system[40]. The conjugation between the unshared pair of nitrogen and the π-electron system of the aromatic group in α-naphthylamine and β-naphthylamine also leads to a decrease of the energies of the upper π orbitals and hence the ionisation potentials.

2. Nitrogen-containing Heterocyclic Compounds

The ionisation potentials of azines were investigated in studies on photoionisation[7,41] and photoelectronic spectroscopy[9,15,42,43] (Tables 5 and 6).

Information about the nature and energies of the π and *n* orbitals from which electrons are abstracted on ionisation may be obtained by comparing the experimental ionisation potentials with the calculations of the wave functions and the energies of azabenzenes and azanaphthalenes[42,44,45].

It has been shown[42] that the energies of the upper π orbitals in the ground states of benzene, pyridine, and pyrazine are the same, while those for pyrimidine and pyridazine are higher by 0.4 eV. The energy of the *n* orbital of the unshared pair of nitrogen does not change in the series pyridine, pyrazine, and pyrimidine, but decreases for pyridazine in consequence of the powerful Coulombic interaction between the electrons of the two unshared pairs of nitrogen. On this basis, the first adiabatic ionisation potentials of pyridine and pyrazine, 9.31 and 9.36 eV respectively (Table 5), were assigned to the removal of an electron from the π orbital and the first ionisation potentials of pyrimidine and pyridazine were attributed to the removal of an electron from the *n* orbital of the unshared pair of nitrogen.

Table 5. First adiabatic ionisation potentials of nitrogen-containing heterocyclic compounds.

Calculation of the energies of the filled orbitals of pyridine, pyrazine, and pyrimidine by the more accurate SCF MO method[42] confirmed the assignment of the first ionisation potentials of the azabenzenes and also showed that the energies of the *n* orbitals of nitrogen in pyridine and pyrazine slightly exceed (by 0.01–0.1 eV) the energies of the upper π orbitals. This permits the assignment of the second ionisation potentials of pyridine and pyrazine, each of which is 9.51 eV, to the removal of an electron from the orbital of the unshared pair of nitrogen. Analysis of the ionisation potentials of azabenzenes also permits an interpretation of the upper ionisation potentials of pyridine on the basis of the calculation of the orbital energies by the SCF MO method. Thus the ionisation threshold at 10.45 eV may be attributed to the removal of an electron from the $2b_1$ π orbital or the upper σ orbital. Such assignment of the ionisation potentials of pyridine was not made in earlier studies on photoelectronic spectroscopy[10] and Rydberg absorption spectra[16], because the second ionisation potential at 9.51 eV had not been observed.

Information about the nature of the π and *n* orbitals in the ground state of pyridine and pyrazine was obtained by calculating all the wave functions for the molecules by the SCF MO method[44,45], based on the derivation of special Gauss functions.

It was shown that the upper $1a_2$ pyridine π orbital has a node at the nitrogen atom and an equal charge distribution at the carbon atoms. This property of the upper $1a_2$ π orbital is clearly reflected in the similarity of the first adiabatic ionisation potentials of pyridine and benzene and also in the fact that the substitution of hydrogen atoms by methyl groups in pyridine in different positions leads to a decrease of the first ionisation potential by virtually the same amount. For example, the ionisation potentials of methylpyridines are in the range 9.02–9.04 eV. Finally, it should be noted that there is a linear relation between the first ionisation potentials of pyridine derivatives and those of the corresponding benzene derivatives[10]. This correlation constitutes yet another proof that the first ionisation potential of pyridine corresponds to the removal of an electron from the upper π orbital with A_2 symmetry. The substitution of hydrogen atoms by alkyl groups leads to a decrease of the π-orbital energies owing to the inductive effect.

Data have also been obtained[44,45] on the nature of the orbitals of the unshared pairs of the nitrogen atoms in pyridine and pyrazine. The $11a_1$ orbital of the unshared pair of the nitrogen atom in pyridine is partially delocalised (to the extent of 0.6 charge units) over the carbon and hydrogen atoms. The unshared pairs of the nitrogen atoms in pyrazine are non-equivalent both in type and as regards energy. The upper $11a$ pyrazine n orbital is delocalised, as in pyridine, while the lower $10a_1$ orbital is only slightly delocalised. The determination of the relative energy of this orbital requires a further detailed examination of the photoelectronic spectrum and the photoionisation curve of pyrazine.

The interpretation of the ionisation potentials of azanaphthalenes was achieved on the basis of the first-order perturbation theory by an empirical selection of corrections to the orbital energies derived from the first ionisation potentials of naphthalene, quinoline, and isoquinoline, obtained from the photoelectronic structures of these compounds[42]. It was shown that the first ionisation potentials of quinoline, isoquinoline, quinoxaline, and quinazine correspond to the removal of an electron from the upper π orbital and the first ionisation potentials of phthalazine and cinnoline correspond to the removal of an electron from the upper n orbital of the unshared pair of the nitrogen atom. This conclusion is consistent with data on the photoionisation of quinoline, isoquinoline, quinoxaline, phthalazine, and cinnoline[41].

Gencha and El-Sayed[41] observed on the photoionisation curves of pyrazine and pyridine a vibrational level structure in the vicinity of the first ionisation potential and attributed it to the planar vibrations of the molecular ion (by analogy with the corresponding vibrations of these molecules in the ground state)[46,47]. However, these data require revision, since the first and second ionisation potentials of azabenzenes corresponding to the removal of an electron from the π and n orbitals are similar.

The ionisation potentials of acridine and phenazine, associated with the removal of an electron from the π and n orbitals, were obtained from the electronic absorption spectra of their complexes with iodine and chloranil[23,24,48]. Acridine and phenazine are n donors in relation to iodine and π donors in relation to chloranil. The ionisation potentials calculated from the absorption spectra and corresponding to the removal of an electron from the upper filled π orbital are 7.9 and 8.4 eV respectively.

It is interesting to note that the ionisation potentials of pyridine, quinoline, and acridine on the one hand and the energies of the π,π^* and n,π^* triplet levels are correlated. For example the energy of the excited n,π^* triplet level of pyridine exceeds by 0.3 eV the energy of the lower π,π^* triplet level[49,50] and the second ionisation potential of pyridine, corresponding to the removal of an electron from the n orbital of nitrogen, exceeds by 0.2 eV the first ionisation potential corresponding to the removal of an electron from the upper $1a_2$ π orbital. However, there is no such correlation between the ionisation potentials and the excitation energies of the singlet levels of azines of this type, because the energy of the n,π^* level is even lower than the energy of the π,π^* level. This discrepancy between the ionisation and excitation energies is due to the fact that the energy of the π,π^* level exceeds that of the n,π^* level by only 0.45 eV, while the singlet–triplet splitting of the π,π^* level of pyridine is 1.1 eV, exceeding the singlet–triplet splitting of the n,π^* level by 0.75 eV.

3. Compounds with a Carbonyl Group

The first ionisation potentials of aromatic compounds containing a carbonyl group were determined in a number of studies[7,12,28,51] (Table 7).

Table 7. First photoionisation potentials of aromatic compounds containing the groups $>N-$, $-O-$, $-S-$, and $>C=O$.

It has been shown[51] that the first ionisation potential of 9,10-anthraquinone (9.55 eV) corresponds to the removal of an electron from the orbital of the unshared pair of oxygen and the second ionisation potential (10.24 eV) corresponds to the removal of an electron from the π orbital. The energy of the singlet π,π^* level of anthraquinone is higher than the energy of the n,π^* level by an amount close to the difference between the second and first ionisation potentials. There is a similar correlation also between the ionisation potentials of 9,10-anthraquinone and the energies of the triplet n,π^* and π,π^* levels[52]. This assignment of the ionisation potentials is consistent with the calculation for the 9,10-anthraquinone molecules by the Pariser–Parr–Pople method[53]. It has also been shown[53] that the first ionisation potentials of *p*-benzoquinone (9.95 eV) and benzaldehyde (9.55 eV) corresponds to the removal of an electron from the orbital of the unshared electron pair of the oxygen atom in the carbonyl group. This interpretation of the ionisation potentials agrees with the positions of the lower electronic singlet and triplet levels of *p*-benzoquinone and benzaldehyde[54].

4. Heterocyclic Compounds containing the Groups $>$N–, –O, and –S–

The unshared electron pair of the heteroatom (nitrogen, oxygen, and sulphur) in compounds of this type may be incorporated in the π-electron system of the molecule, and leads to a change of the nature of the π orbitals in the ground state and an appreciable splitting of the upper π levels of the molecules.

The question of the nature and relative positions of the electronic levels of pyrrole, furan, and thiophen remained unresolved for a long time until the studies on photoionisation and photoelectronic spectroscopy[10].

The first ionisation potentials of pyrrole, furan, and thiophen (Table 7) were determined by the photoionisation method and attributed to the removal of electrons from the π orbitals[7]. The upper ionisation potentials of pyrrole and furan have also been investigated by Turner[10] (Table 6).

The interaction of the unshared electron pair of the nitrogen atom with π electrons in the pyrrole molecule is fairly pronounced, which leads to the removal of the degeneracy of the π_3 and π_2 orbitals and the separation of their energies by 0.8 eV (Table 2). On this basis, one may assume that the π-electron system of pyrrole consists of three filled $1a_2$, $2b_1$, and $1b_1$ π orbitals. The first and second ionisation potentials of pyrrole (8.22 and 9.03 eV) correspond to the removal of electrons from the $1a_2$ and $2b_1$ orbitals.

Information on the nature of the π orbitals of pyrrole from which electrons are removed on ionisation and about the distribution of electron density at the carbon, hydrogen, and nitrogen atoms was obtained from the calculation of all the wave functions of pyrrole by the SCF MO method[55]:

Distribution of π electron density in pyrrole.

Atom in five-membered ring	$1a_2\pi$ orbital	$2b_1\pi$ orbital	$1b_1\pi$ orbital
N $(2p_z)$	—	0.76	0.9
$C_2(2p_z) \pm C_5(2p_z)$	1.40	0.03	0.72
$C_3(2p_z) \pm C_4(2p_z)$	0.60	1.21	0.38

The upper $1a_2$ π orbital, the energy of which corresponds to the first ionisation potential, has an electron density node at the nitrogen atom and a maximum at the adjacent carbon atoms (1.40). The second, $1b_1$ π orbital has an electron density node between the nitrogen atom and the centre of the molecule, a maximum at the carbon atoms not linked to the nitrogen atom, and a minimum at the nitrogen atom. The lower $1b_1$ π orbital of pyrrole embraces the entire molecular skeleton and has an electron density maximum at the nitrogen atom. Analysis of the wave functions also shows that the nitrogen atom in pyrrole "loses" 0.34 charge units to the π orbital and "acquires" 0.75 charge units from the σ orbital. Trigonal hybridisation in pyrrole is appreciably modified for nitrogen ($s^{1.37}p^{2.38}$) but for carbon remains virtually unchanged ($s^{1.06}p^{2.10}$).

It is interesting to compare data on the distribution of electron density in pyrrole with the changes in the first ionisation potential corresponding to the removal of an electron from the $1a_2$ orbital on substitution of a hydrogen atom by a methyl group in various positions, determined by the present author and Yuzhakova[56]. Table 7 shows that the maximum decrease of the first ionisation potential (by 0.42 eV compared with the first ionisation potential of pyrrole) is observed for 2-methylpyrrole, i.e. on substitution of the hydrogen atom by a methyl group at the carbon atom adjoining the nitrogen atom; at this carbon atom the $1a_2$ π orbital has a maximum electron density. The minimum change of the first ionisation potential is observed on substitution of the hydrogen atom by a methyl group at the nitrogen atom, where the $1a_2$ π orbital has an electron density node (*N*-methylpyrrole). Naturally, the replacement of a hydrogen atom by an n-butyl group does not lead to an appreciable decrease of the first ionisation potential (*N*-n-butylpyrrole).

In furan the separation of the energies of the π_3 and π_2 orbitals is even greater than in pyrrole (1.44 eV) (Table 6). The energy of the unshared pair of oxygen, which does not participate in the conjugation with the π electron system, exceeds the energies of the upper π orbitals[10].

Earlier it was noted that a characteristic feature of the electronic structure of anthraquinone is that the upper level of the ground state is populated by the unshared electron pair of the oxygen atom in the carbonyl group[51]. However, the nature and relative positions of the *n* and π electronic levels in the ground state change significantly on introduction of an amino-group into the conjugated system, which happens in acridone and its derivatives. The electronic spectra of acridone and its derivatives show that the first long-wavelength absorption band in their spectra corresponds to the ($\pi\pi^*$) electron transition and that the unshared electron pair of the amino-group participates in the exchange interaction with the electrons in the π orbitals[57].

The first ionisation potentials of acridone, *N*-methylacridone, *N*-ethylacridone, and *N*-phenylacridone (Table 7) are in the range of energies 7.6–7.46 eV and correspond to the energies of the removal of electrons from the upper π orbitals. Indeed the exchange interaction of the unshared electron pair of nitrogen with the π electrons of the molecule leads to an appreciable (compared with anthraquinone) rise of the upper π level of acridone and its derivatives, i.e. a decrease of the ionisation potential. It is necessary to remember that the energy of the nonbonding orbital of the oxygen atom in the carbonyl group changes little when the dimensions and the nature of the π-electron system are altered.

The insignificant change in the first ionisation potentials in this series is evidence that the position of the upper π level alters little under these conditions. The fact that the ionisation potential of *N*-phenylacridone is close to those of [other] acridone derivatives suggests in turn that the phenyl group is located outside the plane of the molecule.

The removal of an electron from the upper π orbital of 9,10-dihydroacridine, where there is no carbonyl group, requires a somewhat lower energy (0.2–0.3 eV) compared with *N*-alkyl derivatives of acridone. The closeness of the ionisation potentials of 9,10-dihydroacridine and diphenylamine[35] is evidence that the π-electron systems of these molecules are isoelectronic.

Phenothiazine, the first ionisation potential of which is also associated with the removal of an electron from the upper π orbital[11], should be included in this type of heterocyclic compounds, where the heteroatom supplies two nonbonding electrons to the π-electron system. A characteristic feature of the photoionisation curve of phenothiazine at higher energies is a steep rise in the region of 9.15 eV, corresponding to the second ionisation potential of the molecule.

---o0o---

Thus the above analysis of the ionisation potentials of aromatic compounds permits definite conclusions concerning the nature and positions of the electronic levels of the molecules from which electrons are removed on ionisation.

The electronic structure of aromatic compounds containing heteroatoms outside the ring, the unshared electron pair of which is incorporated in the π-electron system (aniline and its derivatives, alkyl phenyl ethers), is characterised by the presence of four π orbitals. The energies of the upper π_3 and π_2 orbitals of compounds of this type are separated (compared with benzene), mainly due to the decrease of the energy of the π_3 orbital with B_1 symmetry (Figs. 6 and 7). The mass spectra of these compounds reveal their relative stability on ionisation. However, in those cases where the conjugation between the unshared electron pair of the heteroatom and the π electrons of the phenyl group is weak (for example in benzylamine), the stability of the molecules decreases owing to their decomposition into ions and radicals.

A characteristic of the structure of heterocyclic compounds, the π-electron system of which includes an unshared electron pair (pyrrole, furan) is that the upper electronic level in the ground state of molecules of this type corresponds to the π orbital with A_2 symmetry, which has an electron density node at the heteroatom. This type of upper π orbitals is clearly revealed by the different first ionisation potentials of pyrrole and its derivatives.

The ionisation potentials of nitrogen-containing heterocyclic compounds (azines), in which each heteroatom supplies one p-electron to the π-electron system, correspond to the removal of an electron from the upper π orbitals. Pyrimidine, pyridazine, phthalazine, and cinnoline, the first ionisation potentials of which correspond to the removal of an electron from the orbitals of the unshared electron pair of the nitrogen atom, are an exception.

Metal† Hydrogen Fluorides

A.A.Opalovskii and T.D.Fedotova

The review deals with the available information on metal hydrogen fluorides. The methods of synthesis of hydrogen fluorides and their physical and chemical properties are examined and studies on the hydrogen bonds in hydrogen fluorides and their structures are discussed. The principal trends in the research in this field have been outlined on the basis of these data.

The bibliography includes 190 references.

CONTENTS

I. INTRODUCTION

Fluorine is a very reactive element and forms compounds with all other elements. Its high electronegativity and small ionic radius are largely responsible for the wide variety of the properties of fluorine-containing compounds and their large number. Among fluorine compounds one may mention interesting classes of substances such as halogen compounds of fluorine[1-4] and noble gas fluorides[5-7], the development of the studies of which is related to the general advances in the chemistry of inorganic fluorides achieved in the last decades.

Since fluorine is known to form numerous complex compounds in which it behaves as the ligand[8,9], it is interesting to examine the interaction of inorganic fluorides with fluorine-containing solvents. Among these mention should be made in the first place of hydrogen fluoride, the specific properties of which are the reason for the increasing interest in it as a solvent[9].

The high dielectric constant and low viscosity of hydrogen fluoride make it a good ionising solvent. It is an associated liquid and its self-ionisation takes place via the mechanism[10]

$$(HF_m)\xrightarrow[+]{F^-}(HF)_n\rightleftarrows H_mF^+_{m-1}+H_nF^-_{n+1}\,.$$

The equilibrium constant for this process at 0°C [9] is 2.07×10^{-11}.

Reactions in anhydrous hydrogen fluoride normally involve the participation of the solvent itself. The unusual properties of hydrogen fluoride are responsible for the wide variety of compounds formed when fluorides react with hydrogen fluoride and its solutions[11].

A characteristic feature of the reaction of many fluorides with anhydrous hydrogen fluoride is their solvation by HF molecules. This process is not characteristic solely of hydrogen fluoride but occurs also with halogen compounds of fluorine, for example. Thus it is known

---

† Including ammonium hydrogen fluorides (Ed. of Translation).

that these compounds undergo self-ionisation in the liquid state[12-15]:

$$2XF_n \rightleftarrows XF^+_{n-1} + XF^-_{n+1}$$

and numerous studies in recent years have shown that their interaction with many inorganic fluorides is due to the presence of the above ions in solution and the formation of the fluorohalogenates MXF_{n+1} ($MF.XF_n$) can itself be regarded as the solvation of fluorides by the halogen fluoride[16,17].

The solvating capacity of hydrogen fluoride is well illustrated by the data of Jache and Cady[18], who established that highly soluble fluorides exhibit a greater capacity for combining with hydrogen fluoride. However, they quote only the approximate composition of the solid phase in the saturated solutions of fluorides in hydrogen fluoride after centrifugation and therefore their results cannot be regarded as final proof of the existence of definite solvates as individual compounds.

The most complete information about processes involving the solvation of inorganic fluorides by hydrogen fluoride was obtained by the physicochemical analysis of binary and ternary systems containing hydrogen fluoride and metal fluorides. The results of studies on fusion diagrams for $HF-MF_m$ systems and on isothermal solubility in $HF-MF_m-H_2O$ systems indicate the formation in such systems of individual compounds with the composition $MF_m.nHF$, which are called the acid fluorides or hydrogen fluorides of the corresponding elements.

The formation of metal hydrogen fluorides in anhydrous hydrogen fluoride may be explained as follows. Hydrogen fluoride is an extremely active acidic solvent and ionic fluorides are strong bases in relation to HF, since they dissociate in it with formation of fluoride ions[19]. This leads to a displacement of the self-ionisation equilibrium of hydrogen fluoride towards the formation of the polymeric anions $H_nF^-_{n+1}$, which combine with metal cations to form metal hydrogen fluorides. It is noteworthy that the high tendency of hydrogen fluoride to solvate the F^- anion is due to the fact that the fluorides of many metals are dissociated in hydrogen fluoride to a greater extent than their hydroxides in water, although the dielectric constants of the two solvents are similar[20]. From this point of view, it becomes understandable why metal hydrogen fluorides are formed primarily by univalent and divalent metals, the dissociation of the fluorides of which in hydrogen fluoride differs from that of the fluorides of polyvalent elements, which exhibit molecular solubility in hydrogen fluoride[21,22] or have acidic properties in this solvent, i.e. behave as acceptors of fluoride ions[23,24].

The formation of metal hydrogen fluorides is also possible in aqueous solutions of hydrogen fluoride since here there is a possibility of an autocomplex-formation process:

$$H_2O + (n+1)\ HF \rightleftarrows H_3O^+ + H_nF^-_{n+1}\ .$$

The number of HF molecules added to the metal hydrogen fluorides formed increases as the concentration of water in the solution falls.

It is interesting to note that solvation by hydrogen fluoride is observed not only for simple fluorides but is also characteristic of certain complex fluorides, provided that they are stable in anhydrous hydrogen fluoride and its highly complicated solutions. Thus in a study of ternary systems of the type $HF-H_2MF_6-H_2O$ (M = Ge or Sn) it was established that rubidium, caesium, and ammonium hexafluorogermanates and rubidium and caesium hexafluorostannates form the solid solvates $H_2MF_6.nHF$. [25-27]

The first studies on metal hydrogen fluorides were undertaken primarily in connection with their practical applications. The most important application of these compounds is in the preparation of fluorine by electrolysis. This method, used in 1886 by Moissan[28]. was subsequently developed and improved and is now the main industrial procedure for the manufacture of elemental fluorine, since it yields this important chemical industrial product in a fairly pure form and in a high yield[29-31]. Among other examples of the application of metal hydrogen fluorides, mention should be made of the use of potassium hydrogen difluoride for the preparation of pure anhydrous hydrogen fluoride[32-34]. Sodium hydrogen difluoride has found extensive application for the synthesis of anhydrous hydrogen fluoride from aqueous solutions[35] and for the elimination of hydrogen fluoride from fluorine in the industrial process[29,30].

The studies on metal hydrogen fluorides are of interest from the standpoint of the development of our knowledge of fluorine chemistry, since they are associated with important theoretical problems concerning the mechanism of the solvation of fluorides by fluorine-containing solvents, the structure of metal hydrogen fluorides, and the nature of their chemical bonds.

However, so far the only reviews of studies on metal hydrogen fluorides are restricted to chapters in monographs by Simons[36] and Ryss[8]. The publications which have appeared in the last 10–15 years on this problem and also the general progress in the development of the chemistry of inorganic fluorides make it possible in many cases to reassess the value of the earlier investigations and to draw new conclusions and generalisations. This review deals with the data available at present on the methods for the synthesis of metal hydrogen fluorides and their physical and chemical properties, structure, and the nature of their chemical bonds and the prospects of further research in this field of chemistry are discussed. The problems of the industrial utilisation of metal hydrogen fluorides are not considered, since they are dealt with in the specialist literature.

II. SYNTHESIS OF METAL HYDROGEN FLUORIDES

The first communication on the synthesis of alkali metal hydrogen fluorides was by Berzelius[37], who obtained lithium, sodium, and potassium hydrogen difluorides by dissolving the corresponding fluorides in hydrofluoric acid, and ammonium hydrogen difluoride by heating an aqueous solution of the fluoride. Later potassium hydrogen difluoride was synthesised by Fremy[38] from potassium carbonate and a hydrofluoric acid solution and became known as the Fremy salt. Borodin obtained NaF.HF and KF.HF by evaporating solutions of the fluorides in organic acids[39].

Moissan[40] synthesised compounds with the composition KF.2HF and KF.3HF from a solution of potassium hydrogen difluoride in anhydrous hydrogen fluoride. An attempt was made to obtain potassium hydrogen fluoride with the formula $KF.nHF$ by evaporating KF.HF solutions in hydrofluoric acid, but this yielded only KF.2HF contaminated with K_2SiF_6. [41]

The synthesis of the rubidium hydrogen fluorides RbF.HF and RbF.2HF mixed with RbF.3HF was first reported by Eggeling and Meyer[42]. However, subsequent investigations[43,44] showed that the compounds obtained by

Eggeling and Meyer[42] are in fact rubidium hexafluorosilicates; Eggeling and Meyer[42] described the synthesis of RbF.2HF containing a small admixture of Rb_2SiF_6 from a solution of rubidium carbonate in 40% hydrofluoric acid. Webb and Prideaux[41] described the synthesis of the hydrogen fluorides RbF.HF and RbF.2HF from a solution of rubidium fluoride in hydrofluoric acid and of RbF.3HF from anhydrous hydrogen fluoride.

The following acid salts have been reported for caesium fluoride: CsF.HF,[45] CsF.1.5HF, and CsF.2HF (approximate composition)[46], which were synthesised from anhydrous hydrogen fluoride.

According to a number of communications, silver(I) fluoride also forms acid salts. Thus Guntz[47] described the preparation of AgF.HF from a solution of AgF in hydrofluoric acid. A silver hydrogen fluoride with the composition AgF.3HF is formed in hydrofluoric acid solution and also when gaseous hydrogen fluoride acts upon dry silver fluoride at 13°C. [21,48]

In addition to the hydrogen difluoride[49], the acid fluorides with the composition TlF.2HF [50] and $TlF.2HF.0.5H_2O$ [51] were obtained for thallium(I), but subsequently it was shown that the latter compound is a hexafluorosilicate[52].

All the investigations enumerated above were concerned with the synthesis of the hydrogen fluorides of univalant metals, the fluorides of which are readily soluble in hydrogen fluoride and its solutions.

Until recently the acid salts of the fluorides of other metals, much less soluble in hydrogen fluoride, were almost unknown. Only barium hydrogen fluoride $BaF_2.HF$ was obtained[53] and the existence of the compound $PbF_2.2.5HF$ on the basis of vapour pressure data[54] for the $HF-PbF_2$ system was suggested. The reports of the existence of the acid fluorides $CaF_2.2HF.6H_2O$ [55] and $MF_2.5HF.6H_2O$ (M = Cu, Ni, Co, or Mn) [56] proved to be erroneous; the substances obtained were in fact hexafluorosilicates[57,58]. The earlier report of the synthesis of zinc hydrogen fluoride from a solution of the fluoride in hydrofluoric acid is also doubtful[59].

Although the existence of compounds with the composition $MF_m.n HF$ has been known for a long time and the publications quoted above include reports of their synthesis, it should be noted that a considerable proportion of these data are doubtful. This is mainly due to the fact that the experimental technique available at the time did not allow the early investigators to obtain the hydrogen fluorides in a pure state. As admitted by the authors themselves, the majority of the compounds synthesised contained an admixture of hexafluorosilicates or metal hydrogen fluorides of another composition. Moreover, the individuality of the hydrogen fluorides obtained was established in most cases only on the basis of chemical analysis, which gives rise to particular doubts concerning the composition of the compounds quoted, since most metal hydrogen fluorides are unstable even at room temperature and lose the combined HF molecules. This may also be reflected by the finding that certain physical constants of metal hydrogen fluorides of the same composition differ in various investigations.

The application of the methods of physicochemical analysis to the study of the interaction of metal fluorides with hydrogen fluoride and its solutions yielded accurate information about the composition and conditions of synthesis of metal hydrogen fluorides.

The first studies in this field were those of the fusion diagrams by Ruff and Staub[60] for the system $HF-NH_3$ and by Cady[61] for the system HF–KF. Later the corresponding binary systems with rubidium and caesium fluorides were investigated[62,63]. The results obtained indicate the formation in the HF–MF system of the following individual hydrogen fluorides: KF.nHF (n = 1, 2, 2.5, 3, or 4), RbF.nHF (n = 2, 3, 3.5, or 4.5), CsF.nHF (n = 1, 2, 3, or 6), and $NH_4F.n HF$ (n = 1, 2, 3, or 5). Subsequently the data on the $HF-NH_3$ system were significantly revised by Euler and Westrum[64], who reject the existence of the compound $NH_4F.2HF$.

Tananaev's studies[65–67] by isothermal solubility of the ternary systems $HF-MF-H_2O$ (M = Li, Na, or K) were an important stage in the investigation of methods for the synthesis of metal hydrogen fluorides. The value of his results consists in the fact that the possibility of synthesising a whole series of sodium and potassium hydrogen fluorides, NaF.nHF (n = 1, 2, 3, or 4) and KF.nHF (n = 1, 2, 2.5, 3, or 4) from aqueous hydrogen fluoride solutions was demonstrated, which has undoubted advantages compared with the use of anhydrous hydrogen fluoride. The formation of the hydrogen difluoride LiF.HF in the $HF-LiF-H_2O$ system (investigated up to 75% HF) was established, but, because of the slowness of the reaction LiF → LiF.HF in the solid phase, it was recommended that lithium hydrogen difluoride be obtained by crystallisation from a saturated solution of LiF in hydrofluoric acid[65].

In a subsequent reinvestigation of the $HF-NaF-H_2O$ system[68] and part of the HF–NaF system[69], metal hydrogen fluorides were obtained whose composition was similar to that established previously[66].

Further investigations of systems of the type $HF-MF-H_2O$ were undertaken by the authors of this review. In a study of the highly concentrated region of the $HF-LiF-H_2O$ system, including anhydrous hydrogen fluoride, we did not observe any phase transformations of lithium hydrogen difluoride, although its solubility increased appreciably[70]. The results of the study of the $HF-RbF-H_2O$ and $HF-CsF-H_2O$ systems over the entire range of HF concentrations showed that the interaction in these systems leads to the formation of metal hydrogen fluorides with the composition RbF.nHF (n = 1, 2, 3, or 3.5) and CsF.nHF (n = 1, 2, or 3) [71]. In the $HF-CsF-H_2O$ system we did not observe compounds with compositions intermediate between CsF.HF and CsF.2HF, as in the HF–CsF system[63]. Evidently the report of the synthesis of the caesium hydrogen fluoride with the composition CsF.1.5HF is erroneous and Mathers and Stroup[46] must have obtained a mixture.

In a study of the $HF-NH_4F-H_2O$ system, hydrogen fluorides with the compositions $NH_4F.HF$ and $NH_4F.3HF$ were found as the solid phases[72]. The acid salts 3AgF.2HF, AgF.HF, AgF.2HF, AgF.3HF, and AgF.5HF as well as a compound with the somewhat unexpected composition $6AgF.7HF.2H_2O$ were obtained for silver fluoride in the ternary system[23].

The results of studies on binary and ternary systems containing alkali fluorides and hydrogen fluoride reveal certain general features of the solvation of these fluorides by HF molecules and the formation of metal hydrogen fluorides. The solubility of alkali metal fluorides and their capacity for solvation in hydrogen fluoride increase with the ionic radius of the cation, which is evidently due to the decrease of their crystal lattice energy on passing from LiF to CsF. The maximum number of HF molecules added to caesium fluoride is six, while for lithium only the hydrogen difluoride LiF.HF is known. The solubility of ammonium fluoride in hydrogen fluoride also obeys the above relation. The formation by NH_4F of hydrogen fluorides with a larger number of combined HF molecules than in the case of rubidium fluoride can probably be accounted for by its capacity to form hydrogen bonds of two types: F–H... F and N–H... F.

Bearing in mind the ionic radius of Ag^+, silver(I) fluoride should occupy in the above series a position intermediate between the fluorides of sodium and potassium, but this is not observed, which may be due to different electronic structures of alkali metal and silver cations.

A marked tendency towards solvation would be expected for thallium fluoride, which has the highest solubility in hydrogen fluoride among univalent fluorides. However, the corresponding systems with thallium fluoride have not been investigated and therefore the problem remains unelucidated; at the present time hydrogen fluorides other than TlF.HF and TlF.2HF are unknown.

The possibility of synthesising alkaline earth metal hydrogen fluorides from aqueous hydrofluoric acid solutions was previously considered unlikely[8], although the data of Jache and Cady[18] indicated a tendency by these fluorides to combine with HF. In a study of the $HF-MF_2-H_2O$ systems (M = Ca, Sr, or Ba), Nikolaev and Ikrami[11] obtained metal hydrogen fluorides with the following compositions: $CaF_2.2HF$, $SrF_2.nHF$ (n = 1, 2, or 2.5), and $BaF_2.nHF$ (n = 1, 3, or 4.5). Lead(II) fluoride behaves in hydrogen fluoride and its solutions similarly to alkaline earth metal fluorides, the formation of $PbF_2.2.5HF$ having been established in the $HF-PbF_2-H_2O$ system[74].

The interaction of alkaline earth metal and lead fluorides with hydrogen fluoride obeys the same relation as a function of the ionic radius of the cations as for alkali metal fluorides, the only exception being the anomalously high solubility of strontium fluoride in anhydrous hydrogen fluoride. Comparison of the results of the studies on the $HF-MF_2-H_2O$ (M = Ca, Sr, Ba, or Pb) systems shows that the formation in them of the metal hydrogen fluoride begins as a rule at a higher HF concentration in solution than for univalent metal fluorides, evidently because of the greater stability of the MF_2 crystal lattice.

Recent studies on the $HF-MF_2-H_2O$ (M = Cu, Zn, Cd) systems[75,76] showed that, despite their very low solubility in anhydrous hydrogen fluoride and its concentrated solutions, the fluorides of copper, zinc, and cadmium also form the hydrogen fluorides $CuF_2.3HF$, $ZnF_2.2HF$, and $CdF_2.HF$. This suggests that the hydrogen fluorides of other divalent metals whose fluorides are sparingly soluble in hydrogen fluoride, such as HgF_2, MnF_2, etc., may also be obtained.

We may note that the studies on the systems $HF-UF_4-H_2O$ [77] and $HF-ThF_4-H_2O$ [78], where the fluorides are sparingly soluble over the entire range of concentrations of hydrogen fluoride, established the formation in the solid phase of compounds with the composition $UF_4.4HF$, $ThF_4.HF.H_2O$, and $ThF_4.4HF$, but the properties of these compounds were not investigated and their nature has not been elucidated.

In conclusion of the discussion of the methods for the synthesis of metal hydrogen fluorides, we may note that they reduce to the reaction between the fluorides and a solution of hydrofluoric acid (the conditions of synthesis are determined by the $HF-MF_m-H_2O$ solubility isotherm) or anhydrous hydrogen fluoride (the conditions are determined by the $HF-MF_m$ fusion diagram). One may also point out the possibility of the synthesis of these compounds by the thermal decomposition of metal hydrogen fluorides with a higher HF content. The principal data at present available on the solvation of fluorides by hydrogen fluoride are compiled in Table 1.

Table 1. Solvation of uni- and divalent-metal fluorides by hydrogen fluoride.

Hitherto it has not proved possible to obtain hydrogen fluorides containing two different metals as the cations. In principle their existence might be established by studying the corresponding binary or ternary systems.

The study of isothermal solubility in systems of the type HF–MF–M′F (M and M′ are alkali metals)[70] showed that they contain as solid phases the hydrogen fluorides of the same composition as in the HF–M(M′)F systems, the compound less soluble in hydrogen fluoride occupying a wide crystallisation field. Solid solutions and binary compounds are not formed in the systems. The type of interaction in them is determined primarily by the difference between the solubilities of the fluorides in HF and their different capacities for solvation.

III. PROPERTIES OF METAL HYDROGEN FLUORIDES

Metal hydrogen fluorides are white crystalline substances. The pyknometric densities of alkali metal hydrogen difluorides[79] and alkaline earth metal hydrogen fluorides[80] have been determined (Table 2).

The solutions of all metal hydrogen fluorides in water are acidic. The hydrogen difluorides of all alkali metals (except LiF.HF) and ammonium and also KF.2HF (at 40°C), RbF.2HF, CsF.2HF, and RbF.3HF are congruently soluble in water, which follows from the results of an investigation of the isothermal solubilities in the systems[65-67,68,71]. The solubilities of sodium, potassium, and ammonium hydrogen difluorides in water increase with temperature[66,67,81-83]. Hydrogen difluorides are insoluble in ethanol[84]. The isotherms for the ternary systems $H_2O-KCl-KHF_2$,[85] $H_2O-NH_4Cl-NH_4HF_2$,[86] and $H_2O-NH_4F-NH_4HF_2$ [87] are of a eutonic type.

The enthalpies of solution of alkali metal and ammonium hydrogen fluorides in water were determined for the first time by Peterson[88], Guntz[89], and de Forcrand[90], the data being revised subsequently[91,92] (Table 3). The standard entropy of the HF_2^- ion (16 cal mole^{-1} deg^{-1}) found by Cox and Harrop[91] differs from the value calculated previously (26 cal mole^{-1} deg^{-1}) [93]. The enthalpies of solution of the hydrogen fluorides $NH_4F.HF$ and $NH_4F.3HF$ in anhydrous hydrogen fluoride have also been determined (−5.76 and −3.35 kcal mole^{-1} respectively[94]).

The thermal properties of hydrogen fluorides are of interest primarily in connection with their practical applications; they have been most thoroughly investigated for alkali metal and ammonium hydrogen fluorides.

Table 2. Pyknometric densities of metal hydrogen fluorides.

SrF_2·HF	3.999±0.004	BaF_2·4.5HF	2.947±0.004

The melting points of alkali metal fluorides determined in the early studies are in most cases erroneous, owing to the presence of impurities in the test compounds and the deviation of their compositions from stoichiometry. Thus the following melting points were found initially: 227°C [95], 215−225°C [96], and 217°C [97] for potassium hydrogen difluoride, 142°C [46] for caesium hydrogen difluoride, and 105°C [40] and 70°C [98] for KF.2HF. Later the melting points of the hydrogen fluorides were determined with greater accuracy from a study of the fusion diagrams[61−64]. Comparison of these values (Table 4) shows that the melting points of alkali metal hydrogen fluorides decrease from sodium to caesium and with increase in the number of HF molecules combined.

Table 3. Enthalpies of solution of hydrogen fluorides in water (298.16°K).

Compound	LiF·HF	NaF·HF	KF·HF	RbF·HF	CsF·HF	NH_4F·HF	AgF·HF	KF·2HF	KF·3HF
$-\Delta H°$, kcal mole^{-1}	18.60	6.2	6.0	5.31	3.73	4.85	2.0	8.0	8.6

The sodium hydrogen fluoride NaF.3HF melts incongruently[69]. According to Cady's data[61], all the potassium hydrogen fluorides melt congruently. However, in a recent paper[99] it is claimed, on the basis of a thermodynamic calculation for the decomposition reactions of the hydrogen fluorides formed as individual compounds in the HF−KF system[61], that compounds with the composition KF . 2.5HF and KF.3HF exist only in the solid state and on fusion decompose according to the mechanisms

$$2K_2H_5E_7 \rightarrow 3KH_2F_3 + KH_4F_5; \quad 2KH_3F_4 \rightarrow KH_4F_5 + KH_2F_3 .$$

The enthalpies and entropies of fusion of potassium hydrogen difluoride have been determined as 1.582 ± 0.003 kcal mole^{-1} and 3.09 ± 0.01 cal mole^{-1} deg^{-1} respectively[100,101]. The properties of potassium hydrogen fluoride melts have been investigated by a number of workers in connection with their use in the manufacture of elemental fluorine. It has been established that the addition to the hydrogen fluorides KF.HF and KF.2HF of lithium and sodium fluorides appreciably lowers the melting points despite their low solubility in the melts[61,102,103]. The viscosities and densities of KF−HF melts and the effect of the addition of lithium fluorides on them have been investigated[104].

Table 4. Melting points of hydrogen fluorides.

Compound	M.p., °C	Compound	M.p., °C

RbF·HF	204—205	CsF·3HF	32.6
RbF·2HF	51.7	CsF·6HF	−42.3
RbF·3HF	45.0		

On the basis of a study of the densities and viscosities of HF−NH_4F melts, Semerikova and Alabyshev[104] suggested that the electrolytic dissociation of ammonium hydrogen fluorides takes place differently from metal hydrogen fluorides: ammonium hydrogen fluorides are dissociated to only a slight extent, they merely promote the dissociation of hydrogen fluoride. Sudarikov et al.[105], who investigated the $NH_4F-NH_4HF_2$ and $NH_4HF_2-KHF_2$ systems and determined the enthalpies of fusion of NH_4HF_2, disagree with this view on the mechanism of the dissociation of $NH_4F.nHF$. They believe that ammonium hydrogen difluoride dissociates in the melt according to the mechanism $NH_4HF_2 \rightleftharpoons HF_2^- + NH_4^+$, i.e. in the same way as metal hydrogen difluorides, and that the mechanism put forward by Semerikova and Alabyshev[104] is incorrect. The enthalpy of fusion of ammonium hydrogen difluoride is 15.68 kcal mole^{-1} [106]. The entropy of fusion of the hydrogen fluoride $NH_4F.3HF$ has been determined as 16 cal mole^{-1} deg^{-1}.[64]

The studies on the thermal stability of metal hydrogen fluorides are concerned mainly with alkali metal hydrogen difluorides. Wartenberg and Bosse[107] quote the following temperatures of the rapid decomposition of hydrogen difluorides:

LiF · HF	NaF · HF	KF · HF	RbF · HF	CsF · HF
210°	270°	310—440°	500—600°	550—670° .

The following decomposition temperatures have been indicated for lithium hydrogen difluoride: 105°C [108] and 27°C [65]. A more accurate value of the decomposition temperature of LiF.HF (129.5°C) was determined by measuring the temperature variation of the vapour pressure of HF over LiF.HF (36−118°C) [79]. According to Cox and Harrop[91], at 25°C the vapour pressure of HF over LiF.HF is 1.89 mmHg. The thermodynamic functions for the dissociation of LiF.HF were determined also in the last two studies (Table 5).

The vapour pressure of HF over sodium hydrogen difluoride has been investigated by numerous workers by various methods in connection with the use of sodium fluoride as an absorber of hydrogen fluoride in many technological processes. Equations have been obtained for the temperature variation of the vapour pressure of HF and the enthalpy of decomposition of sodium hydrogen difluoride has been determined[109-113]. ΔH_{decomp} for NaF.HF was also calculated from the results of calorimetric measurements[113,114] (Table 6). The decomposition temperature of sodium hydrogen difluoride is 278°C [111]. The entropy change in the decomposition of NaF.HF is 26.35 cal mole^{-1} deg^{-1}.[110] Fisher[113] obtained the following equation for the free energy of dissociation of NaF.HF:

$$\Delta F^0 = 16.11 \cdot 10^3 - 30.17T \; (157\text{—}269°) .$$

The enthalpy of decomposition of the hydrogen fluoride NaF.2HF has been found to be 10.3 kcal mole^{-1} [115] and 9.0 kcal mole^{-1}.[64]

The vapour pressure of HF over potassium hydrogen difluoride was investigated in connection with the problem of the preparation of fluorine with a minimal HF impurity and the use of KF.HF for the preparation of anhydrous hydrogen fluoride. This problem was investigated by Morgen and Hildebrand[116] in the temperature range 230.5–347.5°C. Fredenhagen and Cadenbach[96] found that KF.HF begins to decompose at 400°C and the final elimination of HF terminates at 504°C. They also noted the effect of traces of water in KF.HF on its thermal decomposition. The non-equilibrium nature of the thermal decomposition of potassium hydrogen difluoride has also been pointed out by Yatlov et al.[117], who established that the temperature of the rapid decomposition of potassium hydrogen difluoride is 600–620°C. When sodium fluoride is added to a melt of KF.HF, the vapour pressure of HF initially decreases somewhat and, when the NaF content is in excess of 5%, it increases[118].

Westrum and Pitzer[100] obtained the following relation for the dissociation pressure of KF.HF in the temperature range 196–238.8°C:

$$\lg p\,(\text{mmHg}) = 8.57 - 4000/T$$

and determined the thermodynamic functions for the dissociation process (Table 5).

The vapour pressure of hydrogen fluoride over HF–KF melts of various compositions was studied by Cady[61], who showed that the values of p_{HF} over KF.HF and KF.3HF found previously at 100° and 150°C [119] were erroneous. Cady's data were used subsequently by Sudarikov et al.[99] to establish a relation between the equilibrium hydrogen fluoride vapour pressure and the composition of the HF–KF melt. The enthalpies of decomposition of the hydrogen fluorides were determined:

$$KHF_2 \rightarrow KF + HF \qquad \Delta H = 21.1 \text{ kcal mole}^{-1} ,$$
$$KH_2F_3 \rightarrow KHF_2 + HF \qquad \Delta H = 14.3 \text{ kcal mole}^{-1} ,$$
$$KH_4F_5 \rightarrow KH_2F_3 + 2HF \qquad \Delta H = 19.3 \text{ kcal mole}^{-1} ,$$

The dissociation pressures of rubidium and caesium hydrogen difluorides have not been investigated. The standard enthalpies of decomposition of RbF.HF and CsF.HF were obtained from calorimetric measurements as 21.8 and 25.0 kcal mole^{-1} [114].

Table 6. Thermal stabilities of sodium hydrogen difluorides.

Temperature range, °C	Temperature variation of HF vapour pressure	ΔH_{decomp}, kcal mole^{-1}	References

		17.9	114

The vapour pressure of ammonium hydrogen difluoride was measured in the temperature ranges 70–110°C [94] and 130–237°C [106]. The enthalpy of the reaction NH_4HF_2(solid) → NH_4F(solid) + HF(gas) is 51.9 kcal mole^{-1} (thermochemical data[115]) or 51.1 kcal mole^{-1} (vapour pressure data[94]). The enthalpies of sublimation (17.05 kcal mole^{-1}) and evaporation (1.2 kcal mole^{-1}) of ammonium hydrogen difluoride have been calculated and its enthalpy of decomposition in the vapour phase has been found to be 33.85 kcal mole^{-1}.[106]

Measurements of the vapour pressure of NH_4F.3HF yielded the relation[64]

$$P\,(\text{mmHg}) = -5288/T + 20.97 \; (-10 \text{ to} + 23.4°) .$$

The enthalpy of the decomposition reaction NH_4F.3HF(solid) → NH_4HF_2(solid) + 2HF(gas) was found to be 17.6 kcal mole^{-1} [115] and 17.1 kcal mole^{-1} [94].

There exist only isolated purely qualitative data on the thermal stabilities of other alkali metal hydrogen fluorides. Thus the hydrogen fluorides NaF.3HF and NaF.4HF are known to be converted at room temperature in air into the hydrogen difluoride[66]. Under these conditions, potassium hydrogen fluorides decompose to KF.2HF, which is converted into potassium hydrogen difluoride at 150°C [67]. RbF.2HF, which is stable at room temperature, begins to split off hydrogen fluoride at 100–110°C [42] and is converted into RbF.HF after prolonged heating at 150–190°C [44].

The thermal stability of the entire series of alkaline earth metal hydrogen fluorides was investigated thermogravimetrically by the authors of this review[120]. The mechanisms of the decomposition reactions of the hydrogen fluorides were established and the intermediates in the reactions, which proceed stepwise, were determined. The existence of the previously unknown compound BaF_2.2HF was discovered in the decomposition of barium hydrogen fluoride. The kinetics of the decomposition of the hydrogen fluorides were investigated and the kinetic parameters for individual reaction stages were determined (Table 7).

According to the HF vapour pressure data for the HF–PbF_2 system, p_{HF} = 0.016 atm and ΔH_{decomp} = 4.5 kcal $mole^{-1}$ for $PbF_2.2.5HF$ at 0°C [54].

Table 7. Kinetic parameters of the decomposition reactions of alkaline earth metal hydrogen fluorides.

Decomposition mechanism	Temp. of maximum extent of reaction, °C	Reaction order *n*	Activation energy, kcal $mole^{-1}$	Frequency factor, $mole^{1-n} \times min^{-1}$
$BaF_2 \cdot 4.5HF \xrightarrow{-2.5HF} BaF_2 \cdot 2HF$	95	0.50	32.1±0.6	$9 \cdot 10^{18}$
$BaF_2 \cdot 2HF \xrightarrow{-HF} BaF_2 \cdot HF$	100	0.30	12.0±0.5	$3 \cdot 10^{6}$
$BaF_2 \cdot HF \xrightarrow{-HF} BaF_2$	224	0.35	16.7±0.6	$7 \cdot 10^{6}$
$SrF_2 \cdot 2.5HF \xrightarrow{-0.5HF} SrF_2 \cdot 2HF$	82	0.18	12.1±0.4	$8 \cdot 10^{6}$
$SrF_2 \cdot 2HF \xrightarrow{-2HF} SrF_2$	145	0,35	24.7±0.5	$4 \cdot 10^{12}$
$CaF_2 \cdot 2HF \xrightarrow{-2HF} CaF_2$	130	0.34	27.3±0.5	$3 \cdot 10^{14}$

Analysis of the available data on the thermal stabilities of alkali and alkaline earth metal hydrogen fluorides shows that their stability decreases with increase in the number of combined HF molecules and also with decrease of the ionic radius of the cation and increase of its polarising capacity.

Westrum and coworkers [79,98,100,114] carried out a series of studies on the thermodynamic properties of univalent metal and ammonium hydrogen fluorides. Measurements were made of the heat capacities of LiF.HF and NaF.HF (10–298.16°K), KF.HF (20–500°K), RbF.HF, CsF.HF, and TlF.HF (7–305°K), and $NH_4F.3HF$ (200–320°K). Anomalies were discovered in the temperature variation of the heat capacities of NaF.HF and $NH_4F.3HF$. The heat capacity of liquid potassium hydrogen difluoride was determined as 25 cal $mole^{-1}$ deg^{-1}. The thermodynamic functions of the hydrogen difluorides, the standard values of which are listed in Table 8, were calculated from the results of these investigations.

The following equations relating the thermodynamic functions to temperature were obtained for potassium hydrogen difluoride (the α- and β-phases):

at 330–469.2°K:

$$H_T^\circ - H^\circ = 11.353T + 11.56 \cdot 10^{-3} T^2 758 \text{ cal mole}^{-1},$$

$$C_p^\circ = 11{,}353 + 23.12 \cdot 10^{-3} T \text{ cal mole}^{-1} \text{ deg}^{-1},$$

$$S^\circ = 26.141 \lg T + 23.12 \cdot 10^{-3} T - 46.65 \text{ cal mole}^{-1} \text{ deg}^{-1};$$

at 469.2–500°K:

$$H_T^\circ - H^\circ = 23.96T - 1469 \text{ cal mole}^{-1},$$

$$C_p^\circ = 23.96 \text{ cal mole}^{-1} \text{ deg}^{-1},$$

$$S_0^\circ = 55.17 \lg T - 107.68 \text{ cal mole}^{-1} \text{ deg}^{-1},$$

$$S_{500}^\circ = 41.22 \pm 0{,}1 \text{ cal mole}^{-1} \text{ deg}^{-1}.$$

There is an appreciable regularity in the temperature variation of the heat capacities and entropies of the hydrogen difluorides MF.HF. Davis and Westrum [101] attempted to correlate the entropies and, using the relation thus obtained between the entropy and the logarithm of the atomic weight of the cation, determined $S^\circ_{298.16}$ for silver hydrogen difluoride as 30.5 cal $mole^{-1}$ deg^{-1}.

IV. THE STRUCTURE OF METAL HYDROGEN FLUORIDES AND THEIR HYDROGEN BONDS

A detailed study has been made of the structures of alkali metal, ammonium, and thallium hydrogen difluorides, which consist of M^+ cations and the linear anion $[F-H-F]^-$ formed by hydrogen bonding (Table 9).

Table 9. Structural data for alkaline earth metal, ammonium, and thallium hydrogen difluorides.

Lithium [121] and sodium [122–124] hydrogen difluorides crystallise in the rhombohedral system. NaF.HF was found to undergo a polymorphic transformation into a phase with rhombohedral symmetry at a pressure of 8.5 kbar [125]. Potassium, rubidium, and caesium hydrogen difluorides have the same structures and have two polymorphic modifications [61,63,126]. The low-temperature modification crystallises in the tetragonal system[126-128] and the high-temperature modification in the cubic system[126]. The structure of ammonium hydrogen difluoride includes additional N–H... F hydrogen bonds and the substance crystallises in the rhombohedral system[129,130]. At room temperature the crystal structure of thallium hydrogen difluoride has the highest symmetry among the hydrogen difluorides: TlF.HF crystallises in the cubic system and does not undergo a phase transformation even on cooling to the temperature of liquid helium[131].

The phase transition from the tetragonal to the cubic modification of potassium hydrogen difluoride is accompanied by appreciable heat (2.671 kcal mole^{-1}) and entropy (5.69 cal mole^{-1} deg^{-1}) change, the latter exceeding by a factor of almost two the entropy of fusion[99-101]. The study of the structure of the β-phase of potassium, rubidium, and caesium hydrogen difluorides showed an appreciable entropy of phase transition associated with the fact that the HF_2^- ions can occupy with equal probability each of the four sites on the diagonal of the cubic unit cell[126]. The volume of the β-phase also increases appreciably. The coefficients of thermal expansion of α- and β-KHF_2 and the volume change in the $\alpha \rightarrow \beta$ transition have been determined dilatometrically[132].

$$(\partial V/\partial T)_p^0 = 0.0047 \pm 0,0005 \text{ cm}^3 \text{ deg}^{-1} \text{ mole}^{-1} \, (20\text{—}135°) \ ,$$

$$(\partial V/\partial T)_p^0 = 0.015 \pm 0,004 \text{ cm}^3 \text{ deg}^{-1} \text{ mole}^{-1} \, (196\text{—}259°) \ ,$$

$$\Delta V^0_{\alpha \rightarrow \beta} = 4.2 \pm 0.1 \text{ cm}^2 \text{ mole}^{-1} .$$

The phase transition of potassium hydrogen difluoride also leads to a sharp change in its electrical conductivity[101,133]. Davis and Westrum[101] obtained the following equation for the electrical conductivity of β-KHF_2:

$$\lambda = 1.15 \cdot 10^5 \exp(-1.05 \cdot 10^4/T), \ E_{\text{act}} = 20.9 \text{ kcal mole}^{-1} .$$

Later studies on the electrical conductivity of KF.HF and KF.DF suggested that the mechanism of conduction in the crystals is associated with the migration of interstitial protons or proton defects, the formation of which involves the following activation energies[133]:

	KF · HF	KF · DF	
E_{act}, kcal mole^{-1}	21.7	23.5	α-phase
	19.8	20.9	β-phase .

The F – F interatomic distances in the HF_2^- ion in the structure of the hydrogen difluorides MF.HF provide information about the strength of the hydrogen bonds in these compounds, but the values found for them initially were determined with a large error and had to be corrected in subsequent studies.

The initial values of r_{F-F} found for sodium hydrogen difluoride (2.50 Å [122] and 2.38 Å [123]) were clearly too high. This interatomic distance was found more accurately in a neutron diffraction study of NaF.HF (Table 9) [124].

Initially the F – F distance in potassium hydrogen difluoride was found to be 2.25 Å [131] and was then corrected to 2.26 Å [128]. The latter value was adopted in all subsequent studies on KHF_2. However, in a neutron diffraction study a somewhat higher value was obtained[134] (Table 9). The studies of the crystal structures of rubidium and caesium hydrogen difluorides[126] led to the conclusion that the F – F interatomic distances in these compounds are the same as in KHF_2 (according to the data of Helmholz and Rogers[128]).

In the ammonium hydrogen difluoride structure the F – F distance was initially found to be 2.37 Å [129]. The theoretical F – F distance for the symmetrical linear HF_2 ion in NH_4HF_2 is 2.32 Å according to Pauling's data[135]. Later it was established that these values are too high and the structure of ammonium hydrogen difluoride contains hydrogen difluoride ions with two different F – F distances[130] (Table 9).

Isotope substitution of the proton in sodium and potassium hydrogen difluorides increases slightly the F – F distance in the crystal[124,136].

Using the available structural data for potassium, rubidium, and caesium hydrogen difluorides (Table 9), Waddington[137] calculated the energies of their crystal lattices as –33.0, –29.6, and –24.7 kcal mole^{-1} respectively. The enthalpy of the process $HF_2^-(\text{gas}) \rightarrow HF(\text{gas}) + F^-(\text{gas})$ which he calculated (58 kcal mole^{-1}) and also the F – F distances in the HF_2^- ion in alkali metal hydrogen difluorides obtained from structural studies (Table 9), which are much smaller than in solid hydrogen fluoride (r_{F-F} = 2.49 Å) [138], indicate the presence of a strong hydrogen bond in the hydrogen difluoride ion.

The nature of the hydrogen bond in the hydrogen difluoride ion and in the first place the position of the proton between the fluorine atoms are of interest. The latter may be assymetric as in the O–H... O bond or symmetrical, and for the symmetrical model there are two possibilities: (a) the proton is located at equal distances from the two fluorine atoms; (b) the F–H distances are unequal but the proton oscillates between two positions[139]. To solve the problem of the position of the proton in the HF_2^- ion, many different research techniques were resorted to and in most cases potassium hydrogen difluoride was investigated.

Ketelaar[140] observed in the KHF_2 infrared spectrum absorption frequencies at 1222 and 1450 cm^{-1}, which he assigned to the HF_2^- assymmetric stretching vibration doublet and explained the doublet splitting by the presence of a double potential energy minimum in this ion. However, the results of subsequent studies on KHF_2 were not consistent with this model of the hydrogen difluoride ion.

Polder[141] measured the dielectric constant of KHF_2 and observed a weak temperature variation: $d\epsilon/dT = 2 \times 10^{-4}$ (80–300°K), whereas in the case of a double minimum in the HF_2^- ion the presence of free electric dipoles should give rise to a large temperature coefficient of the dielectric constant. Analogous results were obtained by Pitzer and Westrum[142] in the measurements of ϵ for KHF_2. On the basis of the heat capacity data for potassium hydrogen difluoride at low temperatures, they also calculated its entropy in the vicinity of the absolute zero, the value obtained (26.17 cal mole^{-1} deg^{-1}) agreeing well with 26.05 cal mole^{-1} deg^{-1} found from direct calorimetric measurements. This indicates the absence of residual entropy, which should be present in the case of a double minimum, as, for example, for the hydrogen bond in ice. Moreover, the experimental dissociation pressures of potassium hydrogen difluoride fall on the line calculated theoretically without taking into account the double minimum[98].

All the above data required a new interpretation of the infrared spectrum of potassium hydrogen difluoride. Halverson[143] explained the presence in the spectrum of the 1222 and 1450 cm^{-1} absorption bands by the splitting of the 1300 cm^{-1} band owing to perturbations of the crystal lattice, but this was not confirmed by subsequent experiments. A more correct explanation was suggested by Westrum and Pitzer[100], who assigned the 1222 cm^{-1} frequency to the deformation vibrations of the HF_2^- ion (ν_2) and the 1450 cm^{-1} frequency to the asymmetric stretching vibration (ν_3), but agreed with Ketelaar[140] that the

5090 cm^{-1} band is due to the $3\nu_3$ overtone, having postulated that there is a marked negative anharmonicity of the levels associated with the ν_3 vibration in the symmetrical hydrogen difluoride ion.

Later investigations of Ketelaar and Vedder[144] of the infrared absorption and reflection spectra of KHF_2 in polarised light and of the low-temperature infrared spectra obtained by Cote and Thompson[145] agree with this frequency assignment. There is a difference in the assignment of the frequencies associated with the overtones in the work of Newman and Badger[146], who suggested a slight positive anharmonicity of the levels in the hydrogen difluoride ion.

Ibers[147] studied the potential function in the region of the stretching vibrations of potassium hydrogen difluoride. Neglecting the interaction between the HF_2^- ions and the lattice vibrations and the interaction between deformation and stretching vibrations, he calculated the force constants and absorption frequencies $[\nu_1, \nu_3(H, D), 3\nu_3(H, D)]$ and the isotope effects on bond lengths. The satisfactory agreement of these quantities with experiment is evidence of a symmetrical linear configuration of HF_2^-.

The Raman spectrum of potassium hydrogen difluoride revealed absorption bands at 595 and 604 cm^{-1}, the positions of which virtually coincided with those predicted by Ketelaar[140] for the symmetrical stretching vibrations of HF_2^-. Initially the appearance of the doublet was accounted for by resonance between two configurations of the HF_2^- ion with a double minimum[148]. However, analysis of the band intensities led the investigators to the conclusion that the splitting is caused by the interaction of individual HF_2^- ions in the crystal[149]. The infrared spectrum of KHF_2 does not show an absorption in the region of 600 cm^{-1}, which can be explained by the selection rules for the linear symmetrical configuration $[F-H-F]^-$ [145]. Thus the results of the infrared spectroscopic studies on potassium hydrogen difluoride support a symmetrical model of the HF_2^- ion.

Peterson and Levy[150] investigated the hydrogen bond in potassium hydrogen difluoride by neutron diffraction and concluded that the proton in the HF_2^- ion occupies a symmetrical position between the fluorine atoms. Later these results were subjected to critical analysis and it was shown that the use of the neutron diffraction method alone does not allow an unambiguous choice between the two models, although the difference between the mean square vibration amplitudes of the hydrogen and fluorine atoms calculated from the spectroscopic data and obtained by the neutron diffraction method is the same, which probably confirms the symmetry and linearity of the hydrogen difluoride ion[134].

An NMR study of potassium hydrogen difluoride yielded best agreement between the experimental resonance absorption line and the line calculated theoretically[151] on the assumption of the symmetrical model for HF_2^-.

However, having analysed numerous investigations of the hydrogen bond in potassium hydrogen difluoride, Blinc[152] believes that some of them are not inconsistent with the model of the HF_2^- ion having a structure intermediate between those of symmetrical and asymmetric ions, i.e. one may suppose that there is a potential barrier between two minima, but it is small.

As mentioned earlier, the energy of the hydrogen bond in the HF_2^- ion is large but the separate contributions to it of the electrostatic interaction and covalent energies are unknown. The energy 47.3 kcal mole^{-1} obtained by Davies[153] for a purely electrostatic interaction is evidently too high. The necessity to take into account the covalent component of the hydrogen bond, which is probably associated with the participation of the excited orbitals of the hydrogen atom, has been emphasised by a number of investigators[154,155]. In an NMR study of deuterated potassium hydrogen difluoride[156] the chemical shift and the screening constant for the ^{19}F NMR signal were determined: the filling coefficient for the *p*-shells of the fluorine atoms and the effective atomic charges were determined on the basis of the theory of Carplus and Das[157]. The estimates obtained agree with the assertion that, in the case of powerful interactions such as those in the HF_2^- ion, all three atoms should make significant contributions to the molecular orbital and the two electron pairs should be delocalised among the three atoms[158].

Apart from the experimental studies on the hydrogen bond in the hydrogen difluoride ion, a number of theoretical calculations of the electronic structure of the HF_2^- ion have been made by quantum-mechanical methods[159-164].

As stated above, the hydrogen bond in potassium hydrogen difluoride was investigated in greatest detail. The studies of the hydrogen bond in the entire series of univalent metal hydrogen difluorides by various physical methods (NMR, infrared spectroscopy, refractometry) were a further development of these investigations.

The NMR spectra of the hydrogen difluorides of alkali metals (except LiF.HF) [151,156,165] and ammonium[165,166] are similar in form with the spectra calculated theoretically for the hydrogen difluoride ion with a linear symmetrical configuration[151] and the absorption lines have similar second moments. This is due to the similarity of the structure of the HF_2^- ion in these compounds. The symmetrical position of the proton in sodium hydrogen difluoride has also been demonstrated by neutron diffraction studies[167]. The NMR data for lithium[156,164] and silver[167] hydrogen difluorides show that the structures of these compounds contain HF_2^- ions with a weaker hydrogen bond than in other hydrogen difluorides. This weakening of the hydrogen bond is also accompanied by a shift of the equilibrium position of the proton from the mid-point between the fluorine atoms.

Table 10. Principal absorption bands in the infrared spectra of hydrogen fluorides.

Compound	ν_1, cm^{-1}	ν_2, cm^{-1}	ν_3, cm^{-1}	Compound	ν_1, cm^{-1}	ν_2, cm^{-1}	ν_3, cm^{-1}

* Raman spectrum.

The first data on the infrared spectra of $NaHF_2$ and NH_4HF_2 were quoted in Refs. 168–171. Ketelaar et al.[170] were the first to point out the differences in the positions of the absorption bands in the infrared spectra of sodium, potassium, and ammonium hydrogen difluorides as a function of the method of preparation of the specimens for the recording of the spectra.

In a systematic infrared spectroscopic study of the entire series of alkali metal hydrogen difluorides

MF.HF (M = Cs, Rb, K, Na, and Li) and their deuterated derivatives, we investigated[172,173] the effect of various methods of preparation of the specimens on the quality of the spectrum and established optimum conditions for the recording of the spectra. The absorption frequencies associated with the deformation (ν_2) and asymmetric stretching (ν_3) vibrations of HF_2^- in the spectra of alkali metal hydrogen difluorides (Table 10) show the presence in these compounds of a strong hydrogen bond, which becomes weaker on passing along the series from caesium to lithium. In silver hydrogen difluoride the hydrogen bond is approximately as strong as in $LiHF_2$, in agreement with the NMR data[155,165,168].

In a study of the infrared spectra of sodium and potassium hydrogen difluorides at low frequencies, it was established that the absorption frequencies corresponding to the translational vibrations of the crystal lattice are not altered when the hydrogen difluorides are deuterated[174,175].

Table 11. Refractometric data for hydrogen fluorides.

Compound	Refractive indices				R_D, cm^3	$R_{H\text{-bond}}$, cm^3
	n_g	n_m	n_p	n_{av}		
$CsF \cdot HF$	—	1.414	1.410	1.413	11.06	0.73
$RbF \cdot HF$	—	1.373	1.357	1.368	8.57	0.98
$KF \cdot HF$	—	1.352	1.327	1.344	7.01	0.96

$BaF_2 \cdot 4.5HF$	—	1.360	—	1.360	19.8	0.40

The strength of the hydrogen bond in alkali metal and ammonium hydrogen difluorides can be estimated quantitatively with the aid of the refractometric method[176]. The first data were obtained for potassium and ammonium hydrogen difluorides[177]. Later this method was employed to study the hydrogen bonds in the entire series of hydrogen difluorides[178]. Comparison of the refraction of the hydrogen bonds (Table 11) shows that the strongest hydrogen bonds are characteristic of rubidium and potassium hydrogen difluorides, while in sodium and lithium hydrogen difluorides they are much weaker. An anomalously low refraction of the hydrogen bond was obtained for $CsHF_2$ compared with $RbHF_2$ and KHF_2, while according to the data derived by other methods the hydrogen bonds in these compounds are approximately of equal strength. This can be accounted for by the steric effect of the Cs^+ ion, which has a large ionic radius, or by its deformation[178]. The weakening of the hydrogen bond in the HF_2^- ion in ammonium hydrogen difluoride is caused by the presence in its structure of hydrogen bonds of the type N–H... F.[177]

The problems concerning the structures of alkali metal hydrogen fluorides with the composition MF.*n*HF ($n > 1$) have been investigated much less completely than for hydrogen difluorides.

There has been only one X-ray diffraction study of these compounds, in which the structure of KF.2HF was considered[179]. This hydrogen difluoride crystallises in the orthorhombic system with the unit cell constants $a = 8.52$ Å, $b = 4.09$ Å, and $c = 6.69$ Å and its density is 2.06 g cm^{-3}. The KF.2HF lattice consists of K^+ ions and the polymeric $H_2F_3^-$ anions formed by hydrogen bonding in which the F–F distance is 2.33 Å and the angles formed by the fluorine atoms are 133° and 139°. It proved possible to determine the F–H distances in $H_2F_3^-$ ions by the NMR method as 1.065 and 1.265 Å [180]. The NMR data for RbF.2HF [156,165] suggest that this compound also contains the polymeric $H_2F_3^-$ anions with the same structure. We may note that potassium and rubidium hydrogen difluorides have similar structures too.

NMR studies of RbF.3HF and CsF.3HF led to the hypothesis that their structures include the polymeric $H_3F_4^-$ anions with an asymmetric hydrogen bond[160,165]. The existence of two modifications has been established for the hydrogen fluoride NaF.3HF (transition temperature 43.1 °C), but their structures are unknown[69].

Further increase of the number of combined HF molecules in the hydrogen fluorides MF.*n*HF probably also leads to the formation of the polymeric ions $H_nF^-_{n+1}$ by hydrogen bonding, the structure of which approaches the infinite zig zag chains with asymmetric hydrogen bonds in the structure of solid hydrogen fluoride[138]. The presence of such anions has also been suggested for silver hydrogen fluorides with the composition AgF.*n*HF ($n > 1$) [168].

The low-frequency molecular vibrations in the hydrogen fluorides NaF.2HF and KF.2HF were investigated by a method based on the non-elastic scattering of slow neutrons[181]. An infrared spectroscopic study of the hydrogen fluorides MF.2HF (M = Rb or K) was undertaken for the first time by the present authors[172,173] and it was found that there is a significant difference between the infrared spectra of the MF.HF and MF.2HF compounds, owing to the presence in the structure of the latter of $H_2F_3^-$ ions.

The asymmetric stretching vibrations of the $H_2F_3^-$ ion are shown in the region of 1780 cm^{-1}, while deformation vibrations give rise to a broad band with a maximum at 1025–1100 cm^{-1}. The appearance in the MF.2HF spectrum of an absorption band with a frequency of 480 cm^{-1}, which was assigned to the symmetrical stretching vibration of $H_2F_3^-$, can be explained by the fact that for the $H_2F_3^-$ ion with an asymmetric hydrogen bond this vibration is not forbidden in the infrared spectrum.

Later data[182] on the infrared spectra of KF.2HF and KF.2DF agreed fully with the above absorption frequencies of the $H_2F_3^-$ ion and their assignment. The force constants of $H_2F_3^-$ were also estimated in the above investigation, the results indicating an asymmetric position of the proton in this ion.

Comparison of the infrared spectra of the hydrogen fluorides MF.HF and MF.2HF reveals a weakening of the hydrogen bond with increase in the number of combined HF molecules (Table 10). Comparison of the vibration frequencies in the infrared spectra of KF.HF, KF.2HF, and solid hydrogen fluoride[183] with the F–F and F–H distances in these compounds shows that they vary in parallel.

In a refractometric study of the hydrogen fluoride KF.2HF, the refractions of the $H_2F_3^-$ ion (6.93 cm^3) and its hydrogen bond (0.61 cm^3) were calculated[178]. These values agree well with the regular change in the strength of the hydrogen bond in the hydrogen fluorides with increase in the number of combined HF molecules (Table 11).

Thus the study of the structure of alkali metal hydrogen fluorides by physical methods established the presence in them of complex anions with the composition $H_nF^-_{n+1}$, in which the strength of the hydrogen bond increases with increase in the ionic radius of the cation and with decrease of the number of combined HF molecules.

Ikrami, Ruchkin, and Nikolaev[80,184] and the present authors[156,185] investigated the structure of alkaline earth metal hydrogen fluorides. Using the NMR method, it proved possible to deduce the structures of these compounds. Analysis of the adsorption line form and the second moments of the NMR spectra of the hydrogen fluorides $MF_2.HF$ established that they contain the anions HF_2^- and F^-. An increase in the number of combined HF molecules leads to the formation of two hydrogen difluoride ions in compounds with the composition $MF_2.2HF$. In the hydrogen fluorides $MF_2.3HF$ the additional HF molecule adds to the HF_2^- ion, forming $H_2F_3^-$. Thus the addition of HF to alkaline earth metal fluorides is somewhat different from the addition to the fluorides of univalent elements, since here there is an equal possibility of the formation of a hydrogen bond with each fluoride ion in MF_2. Evidently, solvation takes place with formation of the most symmetrical structures, identical anions being formed when the number of combined hydrogen fluoride molecules is even[156,185]. The structures of the hydrogen fluorides of other divalent metals (lead, copper, zinc, and cadmium[74-76]) may be represented similarly.

The ^{19}F NMR and ^1H NMR spectra of alkaline earth metal hydrogen fluorides indicate some asymmetry in the position of the proton in the hydrogen difluoride ion in their structure, which is quite reasonable, since, although accurate values of the interatomic distances in the $MF_2.nHF$ lattices are unknown, an estimate of r_{F-H} in the HF_2^- ion based on NMR data indicates the presence in them of a much weaker hydrogen bond than in potassium and sodium hydrogen difluorides[156,185].

The first results of studies on alkaline earth metal hydrogen fluorides by infrared spectroscopic[184] and refractometric[80] methods led the investigators to the conclusion that the hydrogen bond in these compounds is much stronger than in hydrogen fluoride but weaker than in potassium hydrogen difluoride and also to the hypothesis that the polymeric ions $H_nF_{n+1}^-$ are formed in metal hydrogen fluorides with the composition $MF_2.nHF$ ($n > 1$). In a reinvestigation of the infrared spectra of calcium, strontium, and barium hydrogen fluorides, we concluded[173] that the spectra of hydrogen fluorides with the compositions $CaF_2.2HF$ and $SrF_2.2.5HF$ may be interpreted in terms of a structure with two hydrogen difluoride ions. On the other hand, the absorption bands in the region 740–750 cm^{-1}, which were assigned[184] to the polymeric ions $H_nF_{n+1}^-$, were found to be due to the decomposition products of the hydrogen fluorides. The characteristic absorption frequencies of the HF_2^- ions in the infrared spectra of $MF_2.nHF$ indicate a steady weakening of the hydrogen bond in alkaline earth metal hydrogen fluorides with decrease of the ionic radius of the cation, as in the case of alkali metal hydrogen fluorides (Table 10).

Thus alkali and alkaline earth metal hydrogen fluorides are formed via hydrogen bonds of the type $F-H...F$, which lead to the formation of the ions $H_nF_{n+1}^-$. However, in alkaline earth metal hydrogen fluorides the hydrogen bond is on the whole weaker and their structures may include several types of anions.

The hydrogen bond in hydrogen fluoride solutions has not so far been investigated. Studies have been made on aqueous solutions of alkali metal hydrogen difluorides by the NMR method[186-188] in which the concentration dependence of the ^{19}F signal and the chemical shift of the HF_2^- ion were determined. Infrared spectroscopic studies on potassium hydrogen difluoride solutions in water established that the hydrogen bond in the hydrogen difluoride ion is somewhat stronger in solution than in the crystalline state[189]. It was not possible to obtain the Raman spectrum and a KHF_2 solution, which has been explained[190] by the markedly ionic character of the bond in the hydrogen difluoride ion.

---o0o---

The above data show that until recently the study of metal hydrogen fluorides was restricted to those of alkali metals and among them only the hydrogen difluorides were largely investigated in greater detail. The advances in the chemistry of inorganic fluorides in the last decades, the development of synthetic chemistry, and the advances in experimental techniques greatly expanded our knowledge in this field of fluorine chemistry, which is of theoretical and practical importance. The difficulties in experiments with metal hydrogen fluorides—substances which are frequently extremely unstable and hygroscopic, liberating on decomposition the corrosive hydrogen fluoride—have now been overcome in the majority of cases, ensuring that the experiments are carried out with fairly pure substances of the required composition. In addition, the present level of development of physical research methods undoubtedly promotes a further expansion of comprehensive studies on metal hydrogen fluorides. A characteristic feature of the investigations in recent years is an increasing interest in higher alkali metal hydrogen fluorides $MF.nHF$ ($n > 1$) and divalent metal hydrogen fluorides.

Analysis of the data at present available on metal hydrogen fluorides permits an outline of the principal trends in the development of investigations in this field.

1. Physicochemical study of systems containing hydrogen fluoride and metal fluorides with the aim of synthesising new metal hydrogen fluorides.
2. The study of the physical and chemical properties of metal hydrogen fluorides and their solutions.
3. The study of the thermal stability of metal hydrogen fluorides and the determination of its quantitative characteristics.
4. Thermodynamic study of metal hydrogen fluorides.
5. The study of the crystal structures of metal hydrogen fluorides and their hydrogen bonds by various physical methods.

The development of investigations in the field of metal hydrogen fluorides along the lines indicated above will lead to the preparation of many new compounds of this class and will expand our knowledge of the properties of metal hydrogen fluorides. Moreover, further study of metal hydrogen fluorides will evidently lead to new types of their applications in science and engineering.

Stereochemistry of Certain Catalytic Reactions of Cyclic Hydrocarbons in the Presence of Group VIII Noble Metals

O.V.Bragin and A.L.Liberman

The mechanisms of certain catalytic reactions in the presence of solid catalysts—mainly Group VIII noble metals—are discussed in the review. Attention has been concentrated on the stereochemistry of the reactions. It has been shown that the modern conformational hypotheses may be successfully employed to investigate the detailed mechanisms of a number of heterogeneous-catalytic reactions, in particular certain stereochemical reactions of cyclic hydrocarbons. The most widely adopted mechanisms of the hydrogenation of dialkylcyclo-olefins and also di- and poly-alkylbenzenes have been examined and discussed. Both types of reactions are genetically related and the proportions of the stereoisomers obtained serve in many cases as a definite criterion for the selection of a particular reaction mechanism. The configurational isomerisation of di- and poly-cycloalkanes—a reaction involving direct interconversion of the isomers—has been examined in detail. The direct involvement of hydrogen in this reaction, which at first sight appears to be unimolecular but is in fact bimolecular, has been demonstrated.
The bibliography includes 125 references.

CONTENTS

I. INTRODUCTION

This review is devoted to the mechanisms of certain catalytic reactions where stereochemical-factors play a very significant role. By combining and mutually supplementing the usual catalytic and stereochemical concepts, in particular those of conformational analysis, hypotheses of great promise for the understanding of the detailed mechanisms of heterogeneous catalytic reactions are obtained. This view is confirmed by certain studies quoted in a number of reviews[1-8], where the above approach is employed in some form.

The general concept of reaction mechanism is nowadays understood to involve collisions of reacting species, redistribution of electron density in the species, and other elementary stages, taking into account in each individual step in as great detail as possible the stereochemistry of the conversion of the reactants into products. This presupposes the knowledge of the so called activated complex or transition state, which entails not only the enumeration of the molecules or species involved in it but also geometrical factors (interatomic distances and angles). Therefore the problem of determining the mechanism of a particular reaction has become unusually complex. Bond and Wells[4] believe that the mechanism has been elucidated when sufficient information has been obtained on the following three questions: (a) the nature of all the species participating in the reaction; (b) the qualitative types of their interactions making a major contribution to the overall reaction; (c) the quantitative aspects of these interactions—relative rather than absolute. This view is probably correct.

Whereas in homogeneous reactions this problem is frequently simplified by the fact that the mechanisms of many such reactions are identical and their transition states are very similar, in heterogeneous catalytic reactions there arises a new specific factor, which is very difficult to take into account—the compound adsorbed on the surface. Indeed, the principal difficulty in the interpretation of the mechanism of a heterogeneous catalytic reaction consists in the fact that the surface itself is actively involved in the reaction and is essentially one of the reactants. The problem is complicated by the fact that it is virtually impossible to determine the concentration of the active surface at the instant of the reaction step. Nevertheless the information about the geometry of the distribution of the surface catalyst atoms, i.e. about the type of crystal lattice and its defects and also about the steric distribution of the reactants and products, is all the more important. The sum total of such knowledge may promote the understanding of the stereochemistry of the complex adsorbed on the surface, i.e. may provide certain more detailed hypotheses concerning the mechanism of heterogeneous catalytic reaction.

In the light of the considerations set out above, certain stereochemical reactions of cyclic hydrocarbons are discussed in this review. The first part reviews the studies on the hydrogenation of di- and poly-alkylcyclo-olefins, and the second deals with the stereochemistry of the hydrogenation of the benzene ring with two or three alkyl groups. The hydrogenation of dialkylcyclo-olefins and also di- and poly-alkylbenzenes results in the formation of stereoisomeric (in relation to the plane of the ring) cycloalkanes. The proportions of the steric isomers depend on the structures of the starting materials and on the hydrogenation conditions (pressure, temperature, catalyst, medium, etc.) and may serve as a definite criterion for the validity of a particular hypothetical reaction mechanism. Finally the last section is devoted to the direct interconversion of stereoisomeric di- and poly-alkylcycloalkanes. This reaction, which we have called configurational isomerisation, is, by virtue of its relative simplicity, a good model for the elucidation of the details of the structure of the activated complex adsorbed on the catalyst surface.

In this review, particular attention has been devoted to configurational isomerism also because there is virtually no review in the literature where it is discussed in any detail, although we believe that, because of a number of important characteristics discussed below, it merits special consideration.

II. HYDROGENATION OF CYCLO-OLEFINS

There is a fairly large literature on the hydrogenation of cyclo-olefins in the presence of Group VIII metals. The fundamental finding is that the hydrogenation of dialkylcyclo-olefins in the presence of heterogeneous catalysts leads not only to *cis*- but also to *trans*-isomers. Probably *cis*- addition of hydrogen is accompanied by *trans*-hydrogenation over various catalysts under different conditions.

The relative amounts of the *cis*- and *trans*-isomers depend on the structure and positions (relative to one another and the double bond) of the alkyl groups, on the nature of the catalyst, on hydrogen pressure, and, if the hydrogenation is carried out in a liquid phase, on the solvent and the pH. The formation of *trans*-products under these conditions is very important for the understanding of the hydrogenation mechanism. This reaction is one of the most typical examples of the use of stereochemistry for a more detailed investigation of the mechanism of heterogeneous catalytic reactions.

Before considering specific studies on the hydrogenation of substituted cyclo-olefins and the conclusions which follow from them, it is necessary to consider briefly various types of steric forms of substituted five- or six-membered cycloalkanes in order to comprehend better the possibilities in their interconversions and the nature of the energy barriers overcome in these processes.

Classical stereochemistry, which deals with the positions of atoms in space, takes into account only interatomic distances and valence angles. This already made it possible to understand many characteristics of the behaviour of cyclic molecules. However, a new enormous advance in this respect was made in modern stereochemistry after the introduction of conformational concepts.

The modern conformational concepts are based on the fact that the steric relations between neutral atoms not linked directly to one another are not determined by volumes depending on atomic radii but on effective or van der Waal's volumes. These volumes, which in recent years have come to be called conformational volumes, are much larger than the atomic volumes (for example the atomic radius of the hydrogen atom is 0.30 Å and its conformational radius is 1.2 Å) and these in fact determine the relative positions in space of the individual components of molecules, provided that their interrelations are not influenced by some other more powerful interactions. In particular, the steric distribution of atoms in alkane and cycloalkane molecules is largely determined by the conformational volumes of neighbouring, but not linked directly, hydrogen atoms. When these atoms approach one another to distances slightly exceeding the sum of their van der Waals radii, repulsion forces arise between them. When the distance between non-bonded atoms are equal to this sum, the repulsion forces increase sharply. Further mutual approach or overlapping of the van der Waals radii may lead to the instability or even the breakdown of the molecule. Under the influence of these forces, all the hydrogen atoms in the molecule tend to take up positions as far away from one another as possible.

In any organic molecule, except the simplest, there is a possibility of a multiplicity of relative positions of all its components (atoms or groups) with different distances between non-bonded atoms. If there is a possibility of interconversion of such distributions merely as a result of rotation about particular bonds without their dissociation, the states corresponding to each distribution are called conformations (conformations of molecules or groups).

Each conformation is characterised by its own set of distances between non-bonded atoms and consequently by its own sum of non-bonding interactions (repulsion of non-bonded atoms). Thus different conformations of any organic molecule are usually energetically non-equivalent even if none of the bond lengths and valence angles deviate from the normal values.

The molecule can pass from one conformation to another by internal rotation (for reasons which will become clear subsequently, this rotation can no longer be referred to as free). Certain conformations have an energy minimum in the sense that, whatever the direction of the internal rotation, the sum of the energies of non-bonding interactions increases, i.e. the potential energy of the molecule as a whole also increases. All conformations of this type have a certain stability, but the energy minima in different conformations of a single molecule may have unequal depths; for this reason, their stabilities also differ. The most favourable of these conformations of a molecule is frequently referred to as the usual conformation or simply as the conformation of the given molecule. On the other hand, other conformations are distinguished by energy maxima, i.e. internal rotation can only decrease their energy. Naturally, such conformations are unstable. Since the transitions from one favourable conformation to another by internal rotation necessarily proceed via conformations with maximum energies, such unfavourable conformations are frequently called rotational barriers. Thus one may say that the ease of transition from one favourable conformation to another is determined by the height of the barrier separating them. On rotation of one part of the molecule relative to another about a bond, a series of rotational barriers are overcome in succession. Therefore it would be incorrect to call such rotations free.

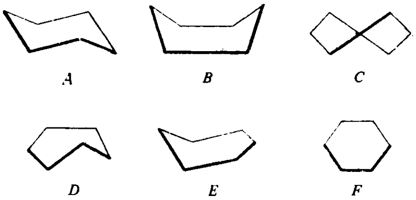

Figure 1. Conformations of cyclohexane: *A*) chair form; *B*) boat form; *C*) twist form; *D*) half-chair form; *E*) envelope form; *F*) planar form.

All that has been said above must be taken into account in one way or another in an experimental study and discussion of the stereochemistry of catalytic reactions. In particular, according to the concepts of classical stereochemistry, cyclohexane can exist in two states free from angular strain—the chair and boat forms (Figs. 1*A* and 1*B*). However, Raman[9] and infrared[10] spectra, electron diffraction[11], and other physical methods have shown that in fact it exists in virtually only one state. This finding was explained by conformational concepts.

It was found that cyclohexane can exist in six conformations (Figs. 1*A*–1*F*), which are energetically non-equivalent. In form *F* the conformational strain is greatest owing to the particular proximity of all six adjacent hydrogen atoms on either side of the ring. In addition there is in this case also a considerable Baeyer strain. Hydrogen atoms assume the most favourable positions in form *A* and it is least strained. It is followed, as regards the amount of strain, by form *C* and then form *B*. All these factors can be traced on special Stuart–Briegleb models taking into account the conformational volumes of the atoms. The difference between the energies of forms *A* and *C* is 5–6 kcal mole^{-1} which is sufficiently large for the concentration of form *C* in real cyclohexane to be much less than 1%. Therefore cyclohexane normally consists of molecules in the chair form. The energy relations of the most interesting transitions between the three conformations of cyclohexane are presented in Fig. 2.

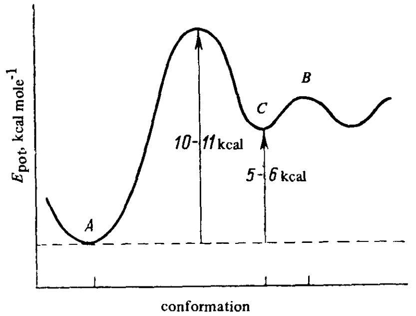

Figure 2. Potential curves for the interconversions of cyclohexane conformers (*A*, *B*, and *C*)—see Fig. 1.

When one of the hydrogen atoms in the cyclohexane molecule is replaced by a CH_3 group, the latter can be either in an equatorial (*e*) or an axial (*a*) position. However, in the *a*-form the non-bonding interactions between the methyl group and the hydrogen atoms in the 3- and 5-positions (the so called 1,3-interactions) prove to be fairly appreciable. On the other hand, in the *e*-form the CH_3 group is relatively remote from the ring and such interactions do not occur. The difference is 1.6–1.8 kcal mole^{-1}.[12] Thus methylcyclohexane is predominantly in the *e*-form. Thermodynamic calculations[12] and also electron diffraction data[11] confirm this conclusion. It has been shown experimentally[13] that at 25°C equilibrium is rapidly established between the *e*- and *a*-forms in which about 95% of the molecules are in the *e*-form and only 5% in the *a*-form. This does not of course mean that methylcyclohexane must react only in the *e*-form, since the energy barrier between the two conformations is lower than the activation energy for the majority of reactions.

When two hydrogen atoms in the cyclohexane molecule are replaced by substituents, for example in dimethylcyclohexane, a new type of stereoisomerism arises—the *cis–trans* isomerism of di- and poly-substituted cycloalkanes. According to conformational analysis, *cis*-1,2-, *trans*-1,3-, and *cis*-1,4-dimethyl-cyclohexanes each have one axial and one equatorial group. Only one conformation is possible for them, since ring inversion yields an identical structure, i.e. $ea \rightleftharpoons ae$. On the other hand, *trans*-1,2-, *cis*-1,3-, and *trans*-1,4-dimethylcyclohexanes might each consist of two forms—*ee* and *aa*. However, the powerful non-bonding 1,3-interaction of two axial CH_3 groups in dimethylcyclohexane and hydrogen atoms gives rise to an additional strain in the molecule. It is so great that the concentration of the diaxial form in the equilibrium mixture proved to be negligible.

It must be specially emphasised that conformational isomers, for example the diequatorial and diaxial forms of *trans*-1,2-dimethylcyclohexane, can be converted into one another as a result of rotation about single C–C bonds. This is a usual case of rotational isomerism and therefore on conversion of one chair-form into another the configuration of dialkylcyclohexane does not change. On the other hand, *cis*- and *trans*-dialkylcycloalkanes are configurational isomers, i.e. they differ by the steric distribution of groups about one of the asymmetric carbon atoms. Consequently the interconversion of the *cis*- and *trans*-isomers requires a rearrangement, i.e. a "jump" by the substituents at this asymmetric carbon atom from one position to another, which necessarily involves the dissociation of the old and the formation of a new bond and consequently a considerable energy expenditure.

Many of the points discussed above refer to a greater or lesser degree also to cyclopentane hydrocarbons. The stereochemistry of this class of hydrocarbons has now been investigated in fair detail.

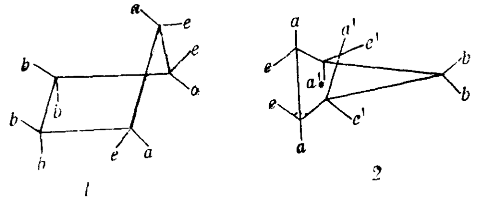

Figure 3. Conformations of cyclopentane: *1*) envelope form; *2*) half-chair form; (*a* and *a'*—axial and quasiaxial bonds respectively; *e* and *e'*—equatorial and quasiequatorial bonds; *b*—bisectional bonds).

Experimental measurements of the entropy of gaseous cyclopentane[14,15] and calculated data[12] show that the cyclopentane ring is not coplanar. According to conformational considerations analogous to those for cyclohexane, the planar conformation of cyclopentane is highly strained. Therefore the ring bends in space owing to the internal strain and some distortion of the valence angles. In this process two conformations are produced: the envelope and half-chair forms (Fig. 3), similar to the corresponding conformations of cyclohexane. Their Baeyer strain is greater than in the planar form but this is compensated by an energy gain owing to the decrease of the conformational strain. The envelope form is slightly more favourable than the half-chair form. As in cyclohexane, the side bonds in cyclopentane are not identical. In the envelope form there are equatorial (*e*) and axial (*a*) bonds (Fig. 3), fully analogous to the corresponding positions in cyclohexane. In the half-chair form there exist also quasiequatorial (*e'*) and quasiaxial (*a'*) bonds with slightly different directions relative to the "plane of the ring" compared with the *e* and *a* bonds. In addition in both forms there exists also a special bisectional (*b*) bond position which is energetically intermediate between the *e*- and *a*-bonds. The energy differences between the *e*- and *a*-positions in cyclopentane are smaller than in cyclohexane: for the methyl group, the energy difference is 0.75–0.9 kcal mole^{-1}.[16–18]

In cyclopentane the site where the ring atom is displaced from the plane is not fixed; the system undergoes simultaneously vibrations about the most stable position and pseudohomogeneous rotation in which the site of the bend rotates about the ring.

Like cyclohexane hydrocarbons, di- and poly-alkylcyclopentanes exist in the form of *cis*- and *trans*-isomers. *Trans*-1,2-dimethylcyclopentane is thermodynamically more stable, like *trans*-1,2-dimethylcyclohexane. For the same reason, *cis*-1,3-dimethylcyclopentane is more stable than the *trans*-isomer.

Proceeding now to the discussion of specific studies on catalytic hydrogenation, account must be taken of the characteristics of the steric structures of the starting materials and the final products. In many cases this approach leads to new possibilities for the elucidation of reaction mechanisms.

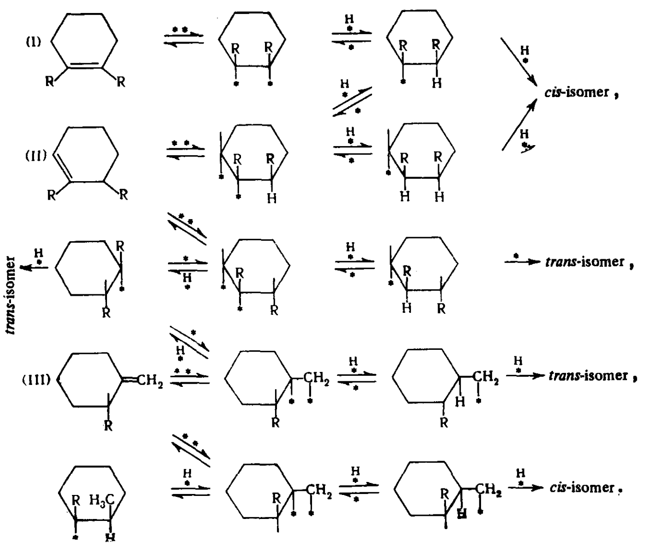

Figure 4. Mechanism of the hydrogenation of dialkylcyclo-olefins according to Siegel and Smith[20] (*—adsorption centre).

In a series of studies of Siegel and coworkers[2,7,19-22] and also in those of Burwell[1,23,24] and Sauvage and coworkers[25,26] certain definite generalisations have been made and certain considerations have been put forward concerning the mechanism of the hydrogenation of disubstituted cyclo-olefins in the presence of metal catalysts. However, one must not overestimate the information obtained in these studies, as there exist processes (for example the migration of the double bond in the ring) which must be taken into account for the concepts about the reaction mechanism to be adequately rigorous. For example, it is known that on a platinum catalyst there are differences in the rates and stereoselectivity of the hydrogenation of 1,2-dimethylcyclohexene and its 2,3-isomer. The structure of the first gives rise to its adsorption in the form of a π-complex or a σ-1,2-diadsorbed state, in which both CH_3 groups assume the *cis*-configuration on hydrogenation. On the other hand, in 2,3-dimethylcyclohexene the two sides of the ring are not identical. Therefore, when a substituent in the 3-position is directed away from the surface of the catalyst in the adsorption process, σ-1,2-diadsorbed *cis*-2,3-dimethylcyclohexane is formed as an intermediate, which is then desorbed as the *cis*-form. On the other hand, when the CH_3 group in the 3-position is directed towards the surface in the adsorption process, *trans*-1,2-dimethylcyclohexane is formed. To account for the observations made in the hydrogenation of cyclo-olefins, Siegel and Smith[20] proposed the mechanism shown schematically in Fig. 4.

The mechanism takes into account two important factors: (a) the simultaneous hydrogenation and migration of the double bond in the ring and (b) the effect of hydrogen on the hydrogenation and the relative rates of formation of the *cis*- and *trans*-isomers of 1,2-dimethylcyclohexanes.

Indeed it has been shown experimentally[20] that an increase of hydrogen pressure at 25°C over the initial 1,2-dimethylcyclohexene in acetic acid results in an increase of the amount of the *cis*-isomers of 1,2-dimethylcyclohexane in the catalytic reaction mixture (82% at atmospheric pressure and 93.5% at 150 atm H_2; see also Fig. 5).

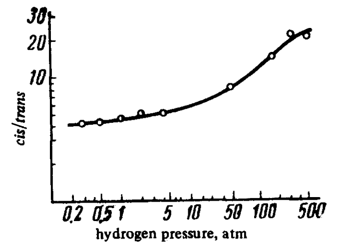

Figure 5. Variation of the stereoselectivity of the hydrogenation of 1,2-dimethylcyclohexene with hydrogen pressure[20].

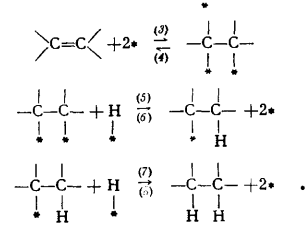
According to Siegel and coworkers[7,20,21], the above mechanism of the hydrogenation of cyclo-olefins is consistent with the Horiuti–Polanyi mechanism[27] of the hydrogenation of unsaturated hydrocarbons:



$$H_2 + 2* \underset{(2)}{\overset{(1)}{\rightleftarrows}} 2\underset{\substack{|\\ *}}{H}$$

$$>C=C< + 2* \underset{(4)}{\overset{(3)}{\rightleftarrows}} -\underset{\substack{|\\ *}}{\overset{|}{C}}-\underset{\substack{|\\ *}}{\overset{|}{C}}-$$

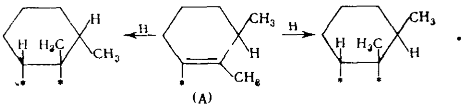
$$-\underset{\substack{|\\ *}}{\overset{|}{C}}-\underset{\substack{|\\ *}}{\overset{|}{C}}- + \underset{\substack{|\\ *}}{H} \underset{(6)}{\overset{(5)}{\rightleftarrows}} -\underset{\substack{|\\ *}}{\overset{|}{C}}-\underset{\substack{|\\ H}}{\overset{|}{C}}- + 2*$$

$$-\underset{\substack{|\\ *}}{\overset{|}{C}}-\underset{\substack{|\\ H}}{\overset{|}{C}}- + \underset{\substack{|\\ *}}{H} \underset{(8)}{\overset{(7)}{\rightleftarrows}} -\underset{\substack{|\\ H}}{\overset{|}{C}}-\underset{\substack{|\\ H}}{\overset{|}{C}}- + 2* \quad .$$

In their explanation of the increase of the concentration of *cis*-1,2-dimethylcyclohexane with increasing hydrogen pressure, the authors suggest that at sufficiently high hydrogen pressures the overall course of the reaction is determined by the formation of an αβ-diadsorbed state [reaction (3)]. On the other hand, at low hydrogen pressures the rate-limiting stage is the formation of the semihydrogenated state [reaction (5)]. According to Siegel[7], examination of the individual stages shows that the rate of reaction (3) is independent of hydrogen pressure†, while the rates of reactions (5) and (7) are functions of the surface concentration of hydrogen and consequently its pressure. Then the rate of stage (7) depends in the first place on the concentration of the semihydrogenated state, which is itself a function of hydrogen pressure, and in the second place it depends directly on the concentration of adsorbed hydrogen. Therefore stage (7) should be accelerated by increasing hydrogen pressure to a greater extent than all others. The increase of the yield of *cis*-1,2-dimethylcyclohexane with increasing hydrogen pressure is probably associated with this factor (Fig. 5). It is specially noted that the structures of the species adsorbed on the catalyst and produced by reactions (3) and (5) are significantly different: the diadsorbed species largely retains the geometry of the olefin, while the semihydrogenated state has essentially a saturated structure.

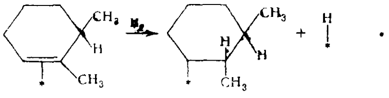
It is noteworthy that, although the mechanism proposed by Siegel and coworkers[20] (Fig. 4) is in fact consistent with the experimental data, it is by no means unique and has been criticised. Thus Bond and Wells[4] note that the reaction with such a mechanism should proceed towards the thermodynamically less stable cyclo-olefin—2,3-dimethylcyclohexene. Moreover, it appears unlikely that the latter would be desorbed to a sufficient extent.

Smith and Burwell[28] and also Sauvage and coworkers[25,26] proposed a different pathway for the formation of stereoisomeric cycloalkanes. These workers suggest that the intermediate stage in the hydrogenation may be the radical A disadsorbed by a dissociative mechanism, which then reacts with formation of both the *cis*- and *trans*-isomers:



(A)

Yet another interpretation of the appearance of *trans*-isomers in the hydrogenation of cyclo-olefins is that of Gault et al.,[29] who suggest the possibility of a direct addition of hydrogen from the bulk phase to the π-complex adsorbed on the catalyst surface:



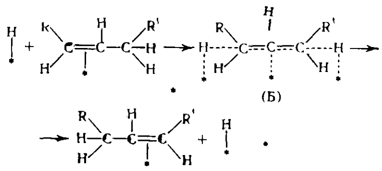
In this mechanism of hydrogenation the stage involving isomerisation to the corresponding 2,3-cyclo-olefins becomes obligatory for the formation of the *trans*-isomers from 1,2-dimethylcyclopentene and 1,2-dimethylcyclohexene. However, this as well as the preceding mechanism (in contrast to Siegel's work[7,20]) do not explain the experimental results obtained when the hydrogen pressure is altered (Fig. 5).

It is also necessary to note that in recent years the concept of intermediate adsorbed compounds of the π-allyl type has been successfully employed to explain the mechanism of hydrogenation, deuterium exchange, and other reactions of hydrocarbons[30-40]. A π-allyl complex of one metal atom and three carbon atoms with a common electron cloud, produced as a result of the loss of one hydrogen atom by the initial olefin, is then considered as the intermediate surface compound:

$$RCH{=}CHCH_2R' \xrightarrow[-H]{*} RCH{-}CH{-}CHR .$$

It is postulated that the adsorbed π-allyl compound has a structure similar to those of the known π-allyl complexes of palladium[41]. In this connection the finding[20] that the migration of the double bond in the hydrogenation of substituted cyclo-olefins takes place only in the presence of hydrogen is of undoubted interest. This phenomenon has features in common with the analogous relation in the case of open-chain olefinic hydrocarbons[42-44] and also the relations which we discovered[45] in a study of the configurational isomerisation of di-alkylcycloalkanes, described in Section IV.

In a discussion of the stereochemistry of the hydrogenation of disubstituted cyclopentanes in the presence of many Group VIII noble metals, we proposed an associative version of double bond migration in olefins, in particular in cyclo-olefins, with participation of activated hydrogen. The double bond migrates via a transition state of the π-allyl type (B), which subsequently decomposes into the isomeric cyclo-olefin and adsorbed hydrogen:



Within certain limits, this transition state (B) resembles the π-allyl complex described above, although in principle it differs from it by the fact that it is not a kinetically independent species and does not exist for any appreciable time on the catalyst surface. This last mechanism has the advantage, compared with the dissociative mechanism, in that it does not require the assumption of a complete dissociation of the C–H bond in the first reaction stage, which is known to require a considerable energy expenditure. Different versions of the adsorption of cyclo-olefins on the surface of various catalysts have been examined[46] and it has been concluded that the rate of migration of the double bond depends significantly on the geometry of the transition complex, determined by the nature of the catalyst.

Tables 1–3 present data on the stereoselectivity of the hydrogenation of various cyclo-olefinic hydrocarbons over platinum, palladium, and other Group VIII metal catalysts.

Examination of Table 1 reveals a considerable scope for the analysis and comparison of the data for the hydrogenation of cyclo-olefins of a very wide variety of structures and permits additional conclusions concerning the mechanism of this reaction. Table 1 shows that a definite relation obtains between the structures of the initial cyclo-olefins and the stereoselectivity of their hydrogenation on the same catalyst. For example, on PtO_2 the amount of the *cis*-isomer formed in the hydrogenation of the cyclo-olefins under consideration decreases in the sequence shown in Fig. 6.

---

† Strictly speaking, the rate of reaction (3) depends on hydrogen pressure, since the number of free active centres on the catalyst surface on which the olefin may be adsorbed with formation of αβ-diadsorbed species depends on the amount of hydrogen in the system. When this factor is taken into account, Siegel's conclusion[7] becomes even more convincing, since at high pressures of H_2 an increase in its amount in the system lowers the rate of formation of αβ-diadsorbed species even more [reactions (3) and (6)].

a) The initial hydrocarbon contained 20% of the corresponding 2,3-dialkylcyclopentene.
b) In acetic acid solution[21].

For example row *a* shows the most favourable positions of the double bond in the six-membered cyclo-olefin for the *cis*-addition of hydrogen. On the other hand, the identical proportions of the *cis*- and *trans*-isomers obtained in the hydrogenation of 1,2- and 2,3-dimethylcyclopentenes (row *g*) suggest that, under the chosen conditions, the interconversion of these isomers is significantly faster than their hydrogenation. Row *c* shows that the length and bulk of the group located directly at the double bond do not in fact affect the stereoselectivity of the hydrogenation of cyclohexenes. This conclusion should probably still be regarded as preliminary, since the hydrocarbons investigated do not include 1-t-butyl-4-methylcyclohexene. The bulky substituent at the double bond can screen it to a certain extent, altering the stereoselectivity of the hydrogenation. At the same time examination of row *b* indicates a definite influence of the bulk of the substituent in the 4-position relative to the double bond: in the hydrogenation of 4-t-butyl-1-methylcyclohexene the amount of the *cis*-isomer formed is much less than in the case of 1,4-dimethylcyclohexene. Naturally, the above relations may be modified by altering the experimental conditions, in particular the catalyst, pressure, etc.

It follows from Table 1 that platinum and palladium catalysts exhibit different stereoselectivities in the hydrogenation of cyclohexenes. On a platinum catalyst in acetic acid solutions, the hydrogenation products are mainly the *cis*-isomers, while on a palladium catalyst the products are the *trans*-isomers. According to the view of Gault et al.,[29] these facts can be accounted for by the different capacities of these metals for the formation of intermediate π-allyl complexes. While on palladium π-allyl complexes predominate, on platinum the reaction proceeds to a considerable degree also with participation of a σ-bonded intermediate compound.

Table 3. Stereoselectivity of the hydrogenation of certain dialkylcyclopentenes in the presence of PtO_2 at 25°C in acetic acid[21] and under other conditions[48-50] (unless otherwise stated the figures refer to Ref. 21).

Table 1 shows that the stereospecificity of rhodium in the hydrogenation of cyclohexenes is very similar to that of platinum. The different stereoselectivities of various Group VIII noble metals in hydrogenation have been demonstrated by Bragin et al.,[46] for 1,2-dialkylcyclopentenes (Table 2). It was found (Fig. 7) that in a neutral n-hexane medium rhodium and particularly iridium catalysts form preferentially *cis*-dialkylcyclopentanes, while platinum and palladium catalysts give rise mainly to the *trans*-isomers.

Table 3 presents data on the hydrogenation of a number of dialkylcyclopentenes in the presence of various platinum catalysts. The specific effect of various catalysts (platinum, palladium, and rhodium) is also shown in the hydrogenation of octalins:

9,10-octalin

1,9-octalin

It might have been expected that 9,10-octalin would tend to undergo only *cis*-addition under the conditions of heterogeneous hydrogenation. However, as for 1,2-dimethylcyclopentene and 1,2-dimethylcyclohexene, the hydrogenation of 9,10-octalin on various catalysts results in the formation of both *cis*- and *trans*-decalins. The results are presented in Table 4.

It would appear that the relations obtained might be accounted for by the above considerations concerning the mechanism of the hydrogenation of 1,2-dimethylcyclohexene. However, it has been observed that the hydrogenation of 1,9-octalin catalysed by palladium yields more *cis*-decalin than the hydrogenation of 9,10-octalin. Therefore in this case the formation of *trans*-decalin from 9,10-octalin cannot be a result of the isomerisation of the latter to 1,9-octalin. The data in Table 4 as well as the results given previously show that, among the three metals discussed, the rhodium catalyst favours most the *cis*-addition of hydrogen.

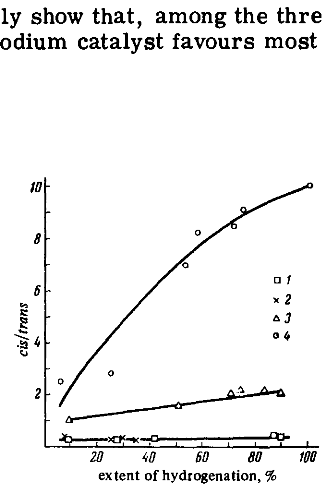

Figure 7. Stereoselectivity of the hydrogenation of 1,2-dimethylcyclopentene on Group VIII metals[46]: *1*) Pt/C; *2*) Pd/C; *3*) Rh/C; *4*) Ir/C.

The solvent and in particular the pH have a great influence on the stereoselectivity of liquid-phase hydrogenation. Thus Skita[53] and Auwers[54] showed that the hydrogenation of cyclo-olefins in an acid medium takes place mainly with formation of *cis*-isomers and in a neutral medium with formation of *trans*-isomers. Later this was also noted by Kazanskii and coworkers[55,56].

a) In ethyl alcohol. b) In ether.

The stereoselectivity of the hydrogenation of a triple bond in a cyclic hydrocarbon is also of definite interest. Partial hydrogenation of a cyclononyne, cyclodecyne, and cycloundecyne over various palladium catalysts results as a rule in the formation of a *cis*-olefin, i.e. *cis*-addition of hydrogen takes place[57-62]. Table 5 presents the conditions and results of the hydrogenation of the above cyclic acetylenic hydrocarbons in the presence of various palladium catalysts.

Turner and Meador[63] obtained data on the heat of hydrogenation of the *cis*- and *trans*-isomers of cyclo-octene, cyclononene, and cyclodecene and found that in acetic acid solution in the presence of PtO_2 the heat of hydrogenation of the *trans*-isomers is greater than that of the corresponding *cis*-isomers.

Examination of the above versions of the hydrogenation mechanism leads to the conclusion that none of them can account for all the experimental data available. Probably there is as yet no general mechanism for the hydrogenation of cyclo-olefins. It may be that, as the system (initial hydrocarbon, catalyst, and solvent) and the hydrogenation conditions are altered, there is also an appreciable change also in the reaction mechanism. Whereas under conditions of liquid-phase hydrogenation at room temperature and atmospheric pressure π-complexes and compounds of the π-allyl type may predominate as intermediates, under more severe conditions the reaction may proceed also via some other mechanism. Then in many cases factors such as the nature of the catalyst, the geometry of the active surface, the polarity of the medium, the structure of the initial cyclo-olefin, etc., play a decisive role. A significant role must be attributed in this case also to intramolecular isomerisation—the migration of the double bond in the ring. This process is undoubtedly fairly significant in all the reactions examined above and itself depends greatly on the nature of the primary adsorption of the initial compounds on the surface of the catalyst.

According to the literature[34-36], the hydrogenation of cyclohexenes may be regarded to some extent as one of the stages of the hydrogenation of aromatic hydrocarbons. Therefore the data in the present section constitute to an appreciable degree an introduction to the next. Both sections are related and supplement one another.

III. HYDROGENATION OF AROMATIC HYDROCARBONS

The study of the stereoselectivity of the hydrogenation of di- and poly-substituted aromatic hydrocarbons can greatly expand the existing concepts concerning the mechanism of the hydrogenation of benzene and its derivatives. The conclusions arrived at in many studies are largely the same as those obtained in the hydrogenation of di- and poly-substituted cyclohexenes, although in many cases the specific characteristics of the initial substances hydrogenated are shown to some extent.

The hydrogenation of aromatic hydrocarbons has been investigated by many workers on different catalysts under different conditions (solvent, temperature, pressure). However, the stereochemical aspect of this reaction has as yet been inadequately examined, since the majority of studies have been of a purely preparative type. In the main the hydrogenation of di- and poly-alkyl benzenes has been studied on platinum and nickel catalysts. It was found that on both catalysts a certain amount of *trans*-isomers was formed as well as the *cis*-isomers. Nevertheless it would appear that simple addition of six hydrogen atoms to the aromatic ring when the latter undergoes planar adsorption should lead exclusively to the *cis*-form. Therefore here the following questions are mainly of interest: in what way are the *trans*-isomers of the cyclohexane series formed and via what intermediate stages, and whether these intermediate compounds are desorbed (at least partially) with subsequent readsorption on the catalysts or do all stages take place directly in the adsorption layer? The amount of *trans*-isomer formed depends on the nature of the catalyst and the hydrogenation conditions. Table 6 demonstrates the most typical results for

the stereoselectivity of the hydrogenation of *o*-, *m*-, and *p*-xylenes and also certain other di- and tri-alkylbenzenes over various heterogeneous catalysts.

Analysis of Table 6 leads to the isolation of a number of relations.

1. Under mild hydrogenation conditions, a mixture of the *cis*- and *trans*-isomers is obtained, but the former as a rule predominates.

2. In the hydrogenation of 1,2- and 1,4-dialkylbenzenes, the relative amount of the *trans*-isomer increases and becomes dominant as the temperature is raised from 25° to 180°C. In the hydrogenation of *m*-xylene in the same temperature range, constant preferential formation of the *cis*-isomer is observed. One should remember that in the 1,2- and 1,4-series the *trans*-isomers are energetically more favoured (*ee*-substituents) than the *cis*-isomers (*ae*-substituents), while in the 1,3-series the *cis*-isomers are diequatorial and therefore energetically more favoured.

3. The relative amounts of the *cis*- and *trans*-isomers obtained in the hydrogenation of each of the three xylenes are related to the relative positions of the substituents. In the hydrogenation of xylenes under similar conditions the content of the *cis*-isomer in the reaction product diminishes in the sequence *ortho* > *meta* > *para* (for example in the hydrogenation over PtO_2 at 25°C in acetic acid or over Rh/C and Ru/C at 100°C).

4. Tetralin and naphthalene‡ behave under similar hydrogenation conditions like 1,2-dialkylbenzenes and 1,3,5-trialkylbenzenes behave like 1,3-dialkylbenzenes. Not only the nature of the metal employed but also its relative content in the catalyst has a considerable influence on the stereoselectivity of the hydrogenation. It has been found that in the hydrogenation of *o*- and *p*-xylenes on Rh/C the content of the *trans*-form of the corresponding dimethylcyclohexane increases with the concentration of the metal in the catalyst; on the other hand, in the hydrogenation of *m*-xylene the content of the *trans*-form of 1,3-dimethylcyclohexane diminishes somewhat. The relevant data are presented in Table 7.

The study of the effect of the carrier is very important in an examination of the stereoselectivity of the hydrogenation of the aromatic ring. Table 8 presents the results of the hydrogenation of all three xylenes on 5% rhodium, and ruthenium catalysts deposited on different carriers. It has been shown that, among the six carriers investigated, activated charcoal leads to preferential *cis*-addition of hydrogen; moreover, it has been discovered that as a rule more *cis*-isomers are formed on the ruthenium catalyst than on rhodium.

The mechanism of the hydrogenation of aromatic hydrocarbons has been discussed by many investigators, but the problem is very complex and there is as yet no generally accepted view on this subject. According to the multiplet theory, the hydrogenation of aromatic compounds on the surface of metal catalysts takes place with planar adsorption of the aromatic ring on the metal surface (platinum, nickel, cobalt, copper, ruthenium, iridium, palladium, rhodium, osmium, and rhenium). This mechanism has been discussed in a number of papers by Balandin[73] and many Soviet and non-Soviet investigators have shown that the above metals, which have a face-centred cubic or hexagonal lattice with interatomic distances in the range up to 2.49 Å for nickel and 2.77 Å for platinum, are indeed hydrogenation–dehydrogenation catalysts. According to the multiplet theory, when an aromatic ring undergoes planar adsorption, it does not leave the active centre until six hydrogen atoms have added either in succession or all at once. The problem of the formation of *trans*-substituted cyclohexanes remains open.

* All the experiments were carried out at 100°C and an initial pressure of 70 atm H_2.

In their discussion of the mechanism of the hydrogenation of benzene, Farkas and Farkas[74] suggested that the rate-limiting stage of this reaction is the interaction of the adsorbed benzene with two adsorbed hydrogen atoms:

$$C_6H_6(\text{ads.}) + 2H(\text{ads.}) \xrightarrow[\text{slow}]{} C_6H_8(\text{ads.}) \xrightarrow[\text{fast}]{2H_2} C_6H_{12} + \text{catalyst (Ct)}\,.$$

* All the experiments were carried out at 20°C and an initial pressure of 3.5 atm H_2; all the catalysts contained 5 wt.% of the metal.

At the same time according to these authors, deuterium exchange involving benzene takes place via a dissociative mechanism:

$$C_6H_6 + \text{Ct} \rightarrow C_6H_5(\text{ads.}) + H(\text{ads.})$$

and further

$$C_6H_5(\text{ads.}) + D(\text{ads.}) \rightarrow C_6H_5D + \text{Ct}\,.$$

---

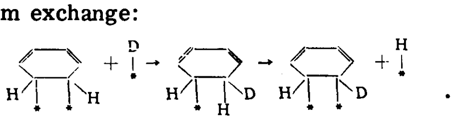
‡ The stereochemistry of the hydrogenation of these hydrocarbons and their homologues in the presence of metal catalysts has been described in detail in a recently published review by Weitkamp[8].

According to Horiuti and Polanyi[27], both reactions (hydrogenation and deuterium exchange) involve an associative mechanism and in the first case the two hydrogen atoms are added consecutively:

Hydrogenation:

$$C_6H_6(ads.) + 2H(ads.) \rightarrow C_6H_7(ads.) + H(ads.) \xrightarrow[slow]{} C_6H_8(ads.) \xrightarrow[fast]{2H_2} C_6H_{12} + Ct.$$

Deuterium exchange:



Later Greenhalgh and Polanyi[75] showed that, if in deuterium exchange via the dissociative mechanisms the rate-determining stage is the interaction of the adsorbed phenyl radicals with a deuterium atom, then both mechanisms (dissociative and associative) are described by the same kinetic equation.

In a number of studies[76-78] of the hydrogenation of benzene on a nickel catalyst and of xylenes on ruthenium, rhodium, nickel, and PtO_2 catalysts, the formation of a small amount of the corresponding cyclo-olefins was observed. Thus in the hydrogenation of *p*-xylene[77] the formation of 1,4-dimethylcyclohexene was discovered and in the hydrogenation of *m*-xylene that of 1,3- and 2,4-dimethylcyclohexenes, although the rates of hydrogenation of cyclo-olefins are significantly higher than those of the corresponding aromatic hydrocarbons[79]. On this basis, Siegel and coworkers[78] suggest that the hydrogenation of aromatic hydrocarbons in the presence of heterogeneous catalysts proceeds via the intermediate formation of cyclo-olefins, which are then very rapidly hydrogenated further in accordance with the mechanism described previously (Fig. 4).

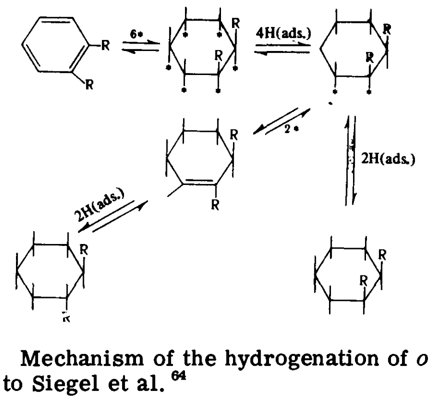


Figure 8. Mechanism of the hydrogenation of *o*-xylene according to Siegel et al.[64]

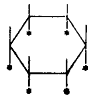
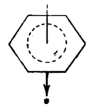
The mechanism proposed by Siegel and coworkers[64] is presented below in Figs. 8, which shows the possible pathways in the formation of the *cis*- and *trans*-isomers of 1,2-dimethylcyclohexane from *o*-xylene. In the same study the authors investigated the relative amounts of the *cis*- and *trans*-isomers as a function of hydrogen pressure. It was found that for aromatic hydrocarbons, as for cyclo-olefins, this ratio increases with hydrogen pressure. However, it follows from the work of Siegel and coworkers[19,20,64] that the hydrogenation of xylenes gives an appreciably greater amount of the *cis*-isomers than the hydrogenation of the corresponding cyclo-olefins. Therefore the considerations adduced above concerning the hydrogenation mechanism do not appear very convincing.

The most widely held view, which has been reflected in a number of investigations[34,35,64] in recent years, is that the hydrogenation reactions of aromatic hydrocarbons and cyclo-olefins have a number of stages in common. Therefore both can involve common partially hydrogenated intermediates adsorbed on the surface of the catalyst. One can easily imagine two versions of the adsorption of the aromatic ring on the catalyst: (I) the formation of six new σ bonds[64] and (II) the formation of a π complex of benzene with the catalyst[35]:



(I)



(II)

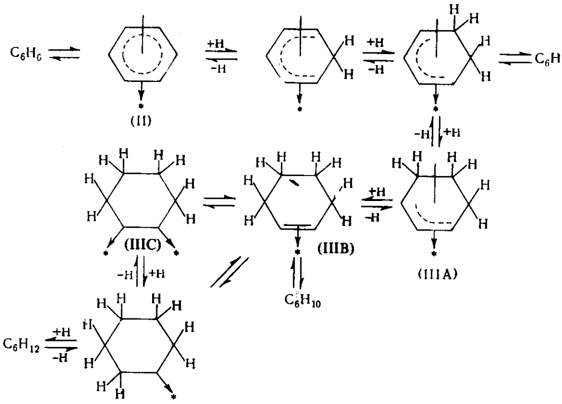


Figure 9. Mechanism of the hydrogenation of benzene according to Rooney[35].

We believe that model (II) is energetically more favoured and hence more probable. Rooney[35] represents the hydrogenation of benzene as a process involving the transformation of (II) via a series of intermediates into cyclohexene and further into cyclohexane. Then the cyclohexene adsorbed on the catalyst surface is represented either as a π-allyl adsorbed structure (IIIA) or as a π-complex (IIIB) (see the mechanism in Fig. 9). Probably the stereoselectivity of the hydrogenation of dialkylbenzenes depends primarily on the last step in the transformation of structure (IIIA) or (IIIB) [or their σ-diadsorbed analogue (IIIC)] into the corresponding dialkylcyclohexane. In turn, the similarity (or the difference) in the stereoselectivity of the hydrogenation of disubstituted aromatic compounds and the corresponding cyclohexenes can serve as a criterion of the similarity of the mechanisms of the hydrogenation of the hydrocarbons in these classes. It is noteworthy that, according to Rooney, the structures (IIIA) and (IIIB) represented in the above mechanism may be hydrogenated not only by adsorbed hydrogen but also by the hydrogen in the bulk phase. Thus, these concepts may account for the formation of *cis*- and *trans*-cyclohexanes in the hydrogenation of aromatic compounds.

In conclusion of this section it must be emphasised that, under mild hydrogenation conditions (Table 6), *cis*-addition of hydrogen with the formation of the *cis*-isomer predominates. Under more severe conditions, the situation changes: as mentioned above, with increase of temperature, the amount of the *trans*-isomer rises appreciably. We believe that this phenomenon is largely caused by the configurational isomerisation of the *cis*-isomer formed in the hydrogenation process. Indeed, it has now been shown that in the presence of many Group VIII metals the *cis*- and *trans*-isomers of di- and poly-alkylcycloalkanes are interconverted at a high rate (see Section IV). However, in none of the studies quoted above is the possibility of such direct interconversions of stereoisomers under severe hydrogenation conditions of aromatic hydrocarbons in any way discussed. Nevertheless, as shown in the next section, such possibility must be taken into account. At the same time, it should be specially noted that under mild conditions (particularly at room temperature), configurational isomerisation does not take place. Therefore, it cannot be used to explain the formation of *trans*-isomers under these conditions. Indeed, at room temperature the mixture of the stereoisomeric 1,3-dimethylcyclohexanes in thermodynamic equilibrium should contain, according to calculation, only about 5% of the *trans*-isomers, but in the hydrogenation of *m*-xylene under these conditions 14–23% of *trans*-1,3-dimethylcyclohexane is formed (Table 6). Thus, in order to explain the formation of the *trans*-isomers in the hydrogenation of aromatic compounds, it is necessary to resort to a special mechanism. In this sense, Rooney's mechanism[35] is supported by insufficient evidence.

IV. CONFIGURATIONAL ISOMERISATION OF STEREOISOMERIC DI- AND POLY-ALKYLCYCLOALKANES

As already mentioned in the preceding section, until recently the mechanism and characteristics of the direct interconversion of the stereoisomeric di- and poly-alkylcycloalkanes were hardly discussed in the literature. However, these reactions have a direct bearing on the composition of the reaction products formed as a result of the hydrogenation of both cyclo-olefins and aromatic hydrocarbons. The mechanism below (Fig. 10) represents the reversible interconversion of the *cis*- and *trans*-forms of di-alkylcycloalkanes, which takes place readily in the presence of many Group VIII metals. In this process there is at least formally no addition of atoms to or their abstraction from the initial molecule, the molecular skeleton remaining unchanged, and only one of the alkyl groups migrates from one side of the ring to the other, i.e. the configuration of one of the ring carbon atoms changes. In this connection the reaction discussed received a special name—configurational isomerisation[80]. Below it will be shown why the term *cis–trans* isomerisation encountered in the literature should not be employed in this case. These interesting and at first sight simple reactions constitute a convenient model which may yield important information about the detailed mechanism of heterogeneous catalysis and about the intermediate activated complex, the formation and decomposition of which govern the course of this reaction.

Configurational isomerism was described for the first time by Zelinskii and Margolis[67] in 1932 for the stereoisomeric 1,2- and 1,4-dimethylcyclohexanes. These workers observed that the *cis*-forms of the above hydrocarbons are converted into the corresponding *trans*-forms under the influence of a nickel catalyst. Subsequent investigation showed that these reactions do not result in the formation of the individual stereoisomers but their mixtures, the composition of which approaches to some extent the composition of mixtures at thermodynamic equilibrium.

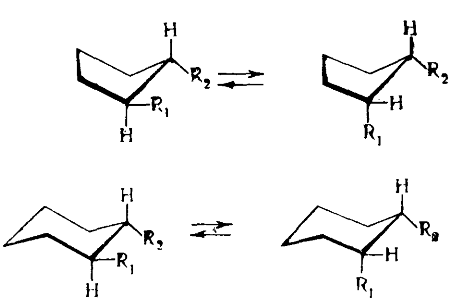

Figure 10. Configurational isomerisation of stereoisomeric 1,2-dialkylcycloalkanes.

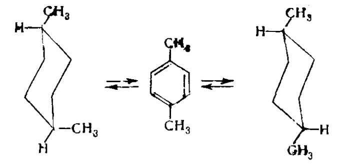
Whereas in the series of cyclohexane homologues the mechanism of the interconversion of the stereoisomeric forms could be readily represented in terms of the intermediate formation of aromatic hydrocarbons,



,

for other ring compounds (in particular cyclopentane homologues) such possibility is excluded. Therefore the work of Kazanskii et al.,[81] in which they observed for the first time configurational isomerism in the cyclopentane series, is extremely unexpected and interesting. It was shown that the hydrogenolysis of stereoisomeric 1,2,3-trimethylcyclopentane on a platinum catalyst is accompanied by configurational isomerisation. For any initial stereoisomer, the thermodynamically most stable $1^c,2^t,3^c$-form predominates in the catalytic reaction mixture, the amount of the $1^c,2^c,3^t$-isomer is significantly less, and the $1^c,2^c,3^c$-stereoisomer is present in an altogether negligible amount.

After this first publication on the configurational isomerisation of stereoisomeric trimethylcyclopentanes, this reaction was not discussed in the literature for about 15 years. Only at the beginning of the 1960's, after the work of Gault et al.[29] and the first publications by the present authors[82,83], configurational isomerisation of cyclopentane homologues became the subject of discussion by a number of Soviet and non-Soviet investigators. We showed[82] that in the presence of platinised charcoal stereoisomeric 1,2-dimethylcyclopentanes are readily interconverted over a wide temperature range (150–280°C). The configurational isomerisation takes place at a significantly higher rate than the accompanying hydrogenolysis of the five-numbered ring. Later we showed[83] that, together with platinum, rhodium, osmium, iridium, and palladium are also active catalysts promoting configurational isomerisation. Subsequently this range of catalysts was extended to include ruthenium[80] and cobalt[84].

Deuterium exchange in polymethylcyclopentanes on the surface of metallic films (platinum, palladium, nickel, and rhodium) was investigated[29]. Together with D–H exchange, a study was made of the configurational isomerisation of the *cis*- and *trans*-forms of 1,1,3,4-tetramethylcyclopentane and also *cis*-1,2-dimethylcyclopentane. Having investigated the kinetics of deuterium exchange and configurational isomerisation, Gault and coworkers concluded that the rates of both reactions are described by an equation for a first-order process and can be expressed as follows:

deuterium exchange:

$$-d(d_0)/dt = k_H[(d_0) - (d_0)_\infty]/[100 - (d_0)_\infty]\ ; \qquad (I)$$

configurational isomerisation:

$$-dx/dt = k_I(x - x_\infty)/(100 - x_\infty)\ , \qquad (II)$$

where k_H and k_I are the rate constants for reactions (I) and (II) respectively, d_0 is the concentration of the initial hydrocarbon not containing deuterium at time t, $(d_0)_\infty$ the equilibrium concentration of the initial hydrocarbon not containing deuterium, x the concentration of the initial *cis*- or *trans*-isomer at time t, and x_∞ the equilibrium concentration of the initial *cis*- or *trans*-isomer.

After simple rearrangement, these equations can be put in the form

$$\lg\frac{x - x_\infty}{x_0 - x_\infty} = \frac{k_I}{k_H}\,\frac{100}{100 - x_\infty}\,\lg\frac{(d_0)}{100} \qquad (III)$$

where x_0 is the concentration of the initial *cis*- or *trans*-isomer at time $t = 0$.

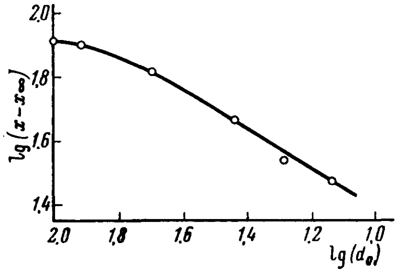


Figure 11. Relation between the configurational isomerisation and deuterium exchange of *cis*-1,1,3,4-tetramethylcyclopentane on a palladium catalyst[29].

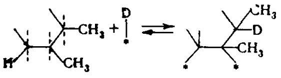
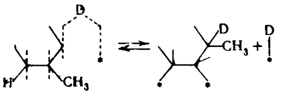
It follows from Eqn. (III) that the relation between $\lg(x - x_\infty)$ and $\lg(d_0)$ should be linear, which the authors indeed observed (Fig. 11) for the configurational isomerisation and deuterium exchange of *cis*-1,1,3,4-tetramethylcyclopentane on a palladium catalyst at 65°C in the above range of values of $\lg(d_0)$.

These data show that both reactions are definitely related: the greater the extent of deuterium exchange the more far-reaching is the configurational isomerisation. The authors explain certain deviations of the experimental points from the straight line by the fact that the reactions investigated do not obey the equation for a first-order process altogether rigorously over the entire range of concentrations of the initial hydrocarbon.

The slope of the straight line (0.51) shows that the rate of deuterium exchange is approximately twice as high as that of configurational isomerisation. Probably the ratio of the rates of these two reactions depends primarily on the nature of the catalyst and not on the experimental temperature, since the results obtained in the presence of the same palladium catalyst at 87° and 146°C are very close to those at 65°C described above. In the presence of other catalysts investigated the rate of deuterium exchange predominates over that of configurational isomerisation to an even greater extent. On the basis of the data obtained, the authors conclude that these two reactions have a common mechanism and that they both take place with formation on the surface of the catalyst of transition complexes of the π-allyl type. They believe that the first reaction stage consists in the formation of this type of adsorption complex, located in a single plane which also contains all the methyl groups of the initial molecule. The second stage is the interaction of the adsorbed π-complex with the atom or molecule of hydrogen (deuterium) adsorbed on the catalyst surface. For 1,2-dimethylcyclopentane, the addition of hydrogen or deuterium to this type of adsorbed π-complex can be represented by the following two reversible processes:



, (A)



. (B)

They show that the adsorbed π-complex arises in the reaction of the catalyst with the p orbital of the carbon atom, which is shown by dashed lines. In mechanism (A) the adsorbed deuterium atom attacks the ring from below, adding to the p orbital of the carbon atom bound to the methyl group. In mechanism (B) deuterium adds to the p orbital of the carbon atom after attacking the ring from above. After the addition of deuterium or hydrogen to the adsorbed π-complex and after the desorption of 1,2-dimethylcyclopentane, the sp^3 hybridisation of carbon atoms in the latter is restored with formation of *cis*-1,2-dimethylcyclopentane [mechanism (A)] or the *trans*-form [mechanism (B)] respectively. The authors of this mechanism suggest that the first stage—the step involving the dissociative chemisorption of the initial hydrocarbon with formation of an adsorbed π-complex of the allyl type—is rate-determining. Thus in their analysis of studies on the configurational isomerisation of dialkylcycloalkanes, Bragin et al. noted that in previous investigations this reaction was always accompanied by other processes (hydrogenolysis, deuterium exchange, dehydrogenation). After a large-scale study of the conditions under which configurational isomerisation takes place, we demonstrated[84] the possibility of a smoother course of this reaction, without any side and secondary processes. It was found that the configurational isomerisation of 1,2-dimethylcyclopentane on platinum and palladium catalysts below 200°C at space velocities of 1.4–21.6 h^{-1} takes place quite successfully without being complicated by side processes. At the same time on other Group VIII noble metals (osmium, ruthenium, rhodium, and iridium) at 200°C hydrogenolysis products were formed (particularly vigorously on the Ru/C catalyst). However, at 150°C and below there were virtually no side reactions on these metals either and the rate of configurational isomerisation remained appreciable. Comparison of the relative activities of the metals enumerated above, deposited on activated charcoal, showed that their catalytic activities are extremely varied. In all cases Pt/C and Rh/C showed the greatest activity and the remaining four catalysts were significantly less active. Comparative data on the configurational isomerisation of *trans*-1,2-dimethyl- and *trans*-2-ethyl-1-methyl-cyclopentanes, obtained on six of the above catalysts, are presented in Fig. 12. The results for the corresponding *cis*-isomers of the cyclopentane and the stereoisomeric cyclohexane hydrocarbons were similar.

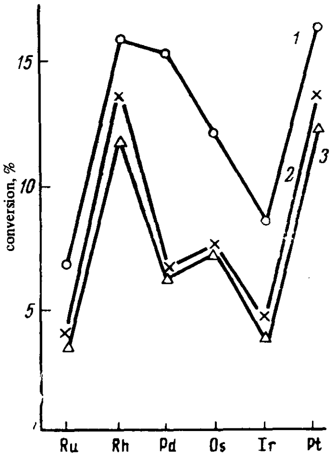


Figure 12. Relative activities of Group VIII metals in configurational isomerisation[84]: *1*) and *2*) *trans*-1,2-dimethylcyclopentane at 300° and 200° respectively; *3*) *trans*-2-ethyl-1-methylcyclopentane at 200°C.

In a study of the kinetics of the configurational isomerisation of stereoisomeric 1,2-dialkylcyclopentanes we showed[80,85] that, under the conditions investigated, this reaction is of zero (or nearly zero) order with respect to the hydrocarbons. The conversion of the energetically more stable *trans*-forms of 1,2-dimethyl-, 2-ethyl-1-methyl-, and 1-methyl-2-n-propyl-cyclopentanes into the *cis*-isomers requires a somewhat greater activation energy than the reverse process. The activation energies found on platinum, rhodium, and cobalt catalysts are similar and are listed in Table 9.

Kalechits and coworkers[86] carried out the configurational isomerisation of 1,3-dialkylcyclopentanes. The conversion of *cis*-1,3-dimethylcyclopentane into the *trans*-form over an iron–platinum catalyst takes place up to concentrations close to equilibrium; the reverse transformation occurs to a relatively low extent.

In the studies of Petrov and coworkers[87] the configurational isomerisation of stereoisomeric di- and poly-alkylcyclopentanes was employed to establish thermodynamic equilibrium between them and to calculate a number of thermodynamic functions.

In all the studies on configurational isomerisation quoted above hydrogen or deuterium was always present to some extent in the reaction zone. In one of our early investigations[83] we suggested that hydrogen chemisorbed on the surface of the catalyst may enter into the composition of the transition complex and thereby may play a significant role in the reaction. Subsequently this hypothesis was tested and confirmed experimentally. Thus in one of our investigations[45] we considered a number of possible mechanisms of configurational isomerisation, the essential feature of which consists in the application to this reaction of various modifications of the dissociative and associative modes of adsorption of the initial hydrocarbon. The adsorption of the latter by a dissociative mechanism can lead to the formation of either ions or radicals. In this case the formation of carbonium ions can probably be excluded, since it would have to be accompanied by a more profound skeletal isomerisation (the formation of a six-membered ring), which was not observed either in experiments in a flow system or under pulse conditions. The second possibility is the intermediate formation of radicals adsorbed on the surface of the catalyst. This process should take place in at least two stages: (a) chemisorption of the hydrocarbon with formation of radicals (monomolecular reaction) and (b) addition of hydrogen to these radicals from the side opposite to that from which it had been abstracted (bimolecular reaction). In the second stage the attack of hydrogen on the mono- or di-adsorbed (chemisorbed) complex, results in the formation of the hydrocarbon stereoisomeric with the initial compound and the free catalyst. For instance, the two stages can be represented schematically in the following way:

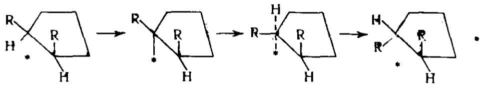

Table 9. Activation energies for the configurational isomerisation of stereoisomeric 1,2-dialkylcyclopentanes[80,85].

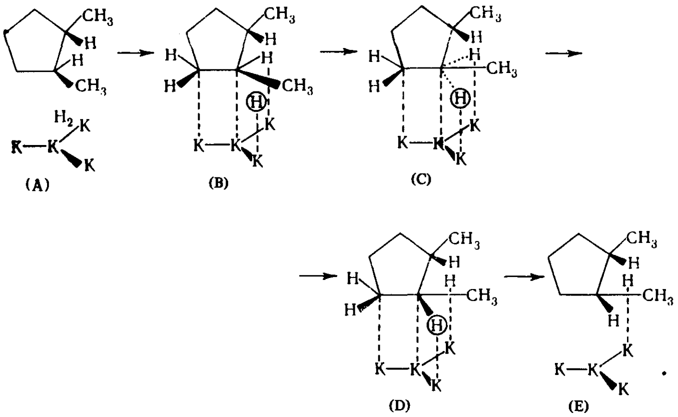
Initial hydrocarbon	Activation energy Q, kcal mole^{-1}		Initial hydrocarbon	Activation energy Q, kcal mole^{-1}	
	Pt/C	Rh/C		Pt/C	Rh/C
trans-1,2-Dimethylcyclopentane	12	14.5	*trans*-1-Methyl-2-n-propylcyclopentane	9	—
cis-1,2-Dimethylcyclopentane	10	9.5	*cis*-1-Methyl-2-n-propylcyclopentane*	5	—
trans-2-Ethyl-1-methylcyclopentane	16.5	—			
cis-2-Ethyl-1-methylcyclopentane	7.5	—			

* In the presence of 18% Co/C, the activation energy for the conversion of *cis*-1-methyl-2-n-propylcyclopentane into the *trans*-form was 7.5 kcal mole^{-1}.

In this version the rate of reaction is determined by either the first or the second stage. Further studies excluded the first stage—the formation of the adsorbed complex—from the rate-limiting steps.

Nevertheless, we believe it likely that the intermediate transition complex is formed by an associative mechanism. The data quoted below on the participation of hydrogen as a second reactant in configurational isomerisation, the absence of dehydrogenation and skeletal isomerisation products under mild reaction conditions, and also kinetic results are consistent with this view. The kinetic results demonstrate a comparatively low activation energy for configurational isomerisation, whereas the dissociation of the C–H bond (the first stage in the formation of the transition complex by the dissociative mechanism) requires a significantly greater energy expenditure. The transition complex formed by the associative mechanism probably includes the reacting hydrocarbon molecule, the active catalyst surface, and a hydrogen species. The formation and breakdown of this activated complex proceed by a mechanism identical or formally similar to the S_N2 Walden inversion:



The mechanism presents the stages in the conversion of *trans*-1,2-dimethylcyclopentane into the *cis*-form. The initial *trans*-1,2-dimethylcyclopentane (A) is adsorbed via two carbon atoms and one hydrogen atom on three adsorption centres of the catalyst with formation of (B). The hydrogen atom adsorbed in an adjacent position attacks the hydrocarbon molecule and the transition complex (C) is formed. The latter then breaks down with incorporation of the attacking hydrogen atoms in the hydrocarbon molecule and with simultaneous loss by the molecule of another hydrogen atom [stage (D)]. This results in the formation of *cis*-1,2-dimethylcyclopentane adsorbed on the catalyst surface, which is then desorbed [stage (E)].

It should be noted that the available data do not as yet provide sufficient grounds to decide whether the mechanism proposed is truly of S_N2 type or only bears a formal resemblance to it. A reaction involving an S_N2 mechanism requires attack by either an anion or a negatively polarised group. In the case discussed this could be a negatively polarised hydrogen atom, the hydride ion, or an H_2^- ion. The existence of the last two species on films of a number of Group VIII metals was demonstrated by Krasil'shchikov and Antonova[88]. However, there is as yet no direct evidence for the presence of such species under the conditions of configurational isomerisation. Nevertheless, it is noteworthy that a number of studies have shown[88,94] that hydrogen may be chemisorbed on the surface of certain metals (including platinum) in the form of species other than neutral atoms. In the adsorption layer hydrogen atoms may be polarised by the conductivity electrons of the metal, forming with the atoms of the latter dipoles, the properties of which resemble those of hydride ions.

The above considerations demonstrate the important role which hydrogen plays in configurational isomerisation. For this reason, special series of experiments were performed in which the effects of the concentration and the space velocity of hydrogen on the rate of configurational isomerisation were elucidated.

In experiments where stereoisomeric 1,2-dimethylcyclopentanes mixed with inert gases (helium, argon, and nitrogen) and also with methane were passed over a platinum catalyst, we discovered that under these conditions the reaction does not take place at all. However, when the carrier gas contains quite a low concentration of hydrogen (about 3%), the reaction begins at an appreciable rate; on further increase of the hydrogen concentration in the gas, the rate of reaction rises and, beyond a certain hydrogen concentration, reaches a constant value and no longer alters (Fig. 13).

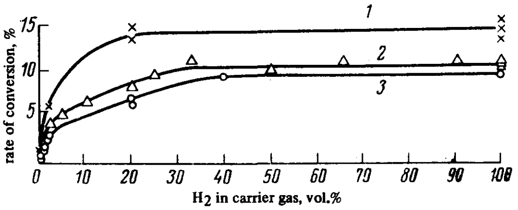


Figure 13. Variation of the rate of the configurational isomerisation of *cis*- and *trans*-1-2-dimethylcyclopentanes on Pt/C with the ratio of H_2 and N_2 (or He) in the carrier gas[45]: *1*) *cis*-isomer at 110°C (H_2 + N_2); *2*) and *3*) *trans*-isomer at 220°C (H_2 + He) and 150°C (H_2 + N_2) respectively.

The study of the effect of the space velocity of hydrogen on the rate of configurational isomerisation led to similar results. This is shown in Fig. 14, where the ascending sections of the curves are indeed similar to the corresponding sections in Fig. 13. They show that at low hydrogen flow rates, i.e. at low hydrogen concentrations in the mixtures of hydrocarbons, the rate of reaction depends significantly on the hydrogen concentration and tends to zero when the latter is reduced. The subsequent decrease of the rate of reaction (the descending sections in Fig. 14) can be explained by the fact that, at a certain instant, the increase of the rate of supply of hydrogen leads to an appreciable decrease of the duration of contact of the mixture as a whole. In the experiments presented in Fig. 13 this phenomenon was not observed, since, whatever the mixture composition, the duration of contact was kept constant from the beginning to the end of the experiment.

The above relations are very similar to those observed for bimolecular reactions and suggest that in the presence of platinum hydrogen does not behave as a simple carrier gas but as a second reactant in configurational isomerisation. The principal relations remain the same on other Group VIII metals[45]. In an atmosphere of hydrogen these metals activate configurational isomerisation, while in the absence of hydrogen the isomerisation does not occur. However, a more detailed study revealed certain specific features of particular metals, but the decisive role of hydrogen, demonstrated previously on platinum, was found to apply also to palladium, rhodium, ruthenium, osmium, and iridium.

Thus we believe that the associative mechanism of configurational isomerisation[45], of the S_N2 Walden inversion type, may be extended also to the other Group VIII metals investigated.

The mechanisms discussed above emphasise the fundamental role of hydrogen in configurational isomerisation. The relations obtained are not exceptional and have a number of analogies in other reactions. Thus it was noted earlier that the *cis–trans* isomerisation of olefins on Group VIII metals also takes only in the presence of hydrogen or deuterium[42–44]. In this connection, the work of Siegel and coworkers[20,21] quoted above, in which it was noted that the hydrogenation of cyclo-olefins on platinum and palladium catalysts is accompanied by isomerisation with migration of the double bond in the ring while in the absence of hydrogen the isomerisation does not occur, is of definite interest. Probably the mode of action of these catalysts has certain features in common in the above reactions, although their specific mechanisms may in fact be different.

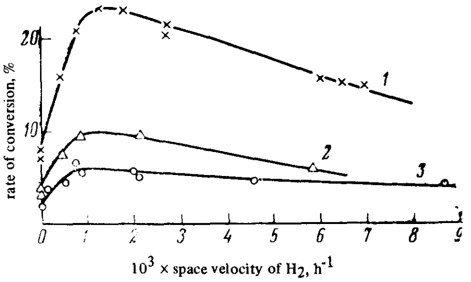

Figure 14. Variation of the rate of the configurational isomerisation of *cis*- and *trans*-1,2-dimethylcyclopentanes on Pt/C with the space velocity of hydrogen[45]: *1*) *cis*-isomer at 110°C; *2*) and *3*) *trans*-isomer at 150° and 130°C respectively.

Almost all the papers quoted above, in which the configurational isomerisation is discussed, refer to hydrocarbons of the cyclopentane series. However, there are indications in the literature that configurational isomerisation takes place also in other cyclic systems. Thus Gault, Maire, and coworkers[39,95,96] investigated the simultaneous hydrogenolysis, deuterium exchange, and configurational isomerisation of stereoisomeric 1,2-dimethylcyclobutanes on platinum, palladium, rhodium, and nickel catalysts. According to these authors, the above reactions of cyclobutane homologues have identical or similar mechanisms with formation of intermediate complexes of the π-allyl type.

Allinger and coworkers widely employed configurational isomerisation for the attainment of thermodynamic equilibrium between stereoisomers and for the calculation of the thermodynamic functions of stereoisomeric 1,3-dimethylcyclo-octanes[97], decalins[98], bicyclo[5,2,0]nonanes[99] and bicyclo[5,3,0]decanes[100].

The reaction has been widely investigated in the cyclohexane series, but not in quite such detail as for cyclopentane hydrocarbons. This is probably due to the complications which arise due to the accompanying dehydrogenation reaction and possibly also the somewhat lower rate of the configurational isomerisation of cyclohexane homologues compared with cyclopentanes[84]. The rate of attainment of thermodynamic equilibrium in the series of cyclohexane homologues depends on the nature and activity of the catalyst employed, the experimental conditions, and the properties of the initial isomers. Thus Waterman and coworkers[101] showed that, in the presence of a nickel/kieselguhr catalyst at 170–180°C and a hydrogen pressure of 7–8 atm, *cis*- and *trans*-1,3- and 1,4-dimethylcyclohexanes reached thermodynamic equilibrium more rapidly than 1,2-dimethylcyclohexanes. Under the influence of Raney nickel, *trans*-1,2-dimethylcyclohexane attains equilibrium faster than the corresponding *cis*-isomer. Allinger and coworkers[102–107] carried out a series of studies on the conformational analysis of the stereoisomeric cyclohexane homologues, which in the presence of a palladium catalyst can be reversibly interconverted by configurational isomerisation. The composition of the thermodynamic equilibrium mixtures formed in this process enabled the authors to calculate the equilibrium constants, a number of thermodynamic functions, and also the energies of the interconversion of a number of conformers.

Petrov, Zakharenko, and coworkers[108,109] also determined the equilibrium ratios of stereoisomeric di- and poly-alkylcyclohexanes with the aid of configurational isomerisation. The work of Eliel[110–112], who investigated the configurational isomerisation of stereoisomeric mono- and di-alkylcyclohexanols, is of interest too. These studies yielded information about the relative rates of interconversion, esterification, and oxidation of stereoisomeric alkylcyclohexanols and also yielded the conformational energies of various axial alkyl groups in stereoisomeric 1,3- and 1,4-dialkylcyclohexanols.

In these and certain other studies the term epimerisation (and correspondingly the terms epimerisation conditions and rate of epimerisation) is applied to configurational isomerisation but, from our point of view, it is non-rigorous and may lead to an incorrect understanding of the essential features of the reaction. Indeed, the term epimerisation is usually applied to a racemisation process involving one asymmetric centre (of the several present) in the molecule of an optically active substance. For example, the conversion of D-*trans*-1,2-dimethylcyclopentane, which has two asymmetric centres, into the L-*trans*-stereoisomer can be legitimately called epimerisation, but the conversion of the *trans*-form into the *cis*-form is a completely different reaction. In configurational isomerisation stereoisomeric dialkylcycloalkanes are not as a rule optically active and, for example, the interconversion of *cis*-1,2-dimethylcyclohexane and its *trans*-form is the interconversion of two racemates. We believe that the mechanism of the interconversions of stereoisomeric dialkylcycloalkanes is fundamentally different also from the mechanism of the *cis–trans* isomerisation of olefins and this is why we propose a special name for the former reaction, i.e. configurational isomerisation.

Shopov and Andreev[113] showed that the rate of dehydrogenation of stereoisomeric dialkylcyclohexanes depends on the nature of the catalyst. Thus on a platinum catalyst the *cis*- and *trans*-forms of 1,2-dimethylcyclohexane are dehydrogenated to xylene at the same rate, while on palladium and nickel the *trans*-form is dehydrogenated at an appreciably lower rate. This is probably associated in some way with the different relative rates of the configurational isomerisation of the *cis*- and *trans*-isomers of dimethylcyclohexane in the presence of various catalysts. Indeed, in the configurational isomerisation of the *cis*- and *trans*-isomers of 1,3-dimethylcyclohexane we found that[84] platinum and rhodium catalysts are more active than other Group VIII noble metals.

Our finding[45] that on all Group VIII noble metals the configurational isomerisation of cyclohexane homologues takes place only in the presence of hydrogen§, as in the cyclopentane series, is extremely important. The study of the kinetics of the configurational isomerisation of *cis*-1,2- and *trans*-1,3-dimethylcyclohexane showed[115] that the activation energies for the conversion of these hydrocarbons into the corresponding stereoisomers are 7.5 and 6 kcal mole^{-1}. These and other facts obtained in the study of the configurational isomerisation of cyclohexane hydrocarbons indicate a number of similar features of these reactions in the cyclopentane and cyclohexane series. In the first place these include the direct participation of hydrogen in the reaction, the absence of cyclo-olefins and aromatic hydrocarbons under mild conditions of configurational isomerisation, fairly close activation energies, etc. All these findings suggest that the configurational isomerisation of cyclohexane homologues takes place by an S_N2 mechanism identical with or similar to the mechanism described above for stereoisomeric dialkylcyclopentanes.

It may be supposed that such an S_N2 mechanism plays a role not only in the reactions of the classes of compounds discussed above, but also in many others. This hypothesis is based on the exo ⇌ endo isomerisation of alkyl substituents in the series of bridged bicyclic hydrocarbons described by Plate and coworkers[116,117].

In conclusion, it should be noted that at the present time the stereochemical approach to certain catalytic reactions, in particular hydrogenation or hydrogenolysis, is comparatively widely employed. The studies of the hydrogenolysis of optically active compounds began by Bonner[118] and continued by Japanese investigators[119-122] are very promising in this connection. The structure of the initial compounds, the nature of the metal, its concentration in the catalyst, and sometimes the carrier employed influence the mechanism of hydrogenolysis, which, depending on these factors, can proceed via S_N1, S_N2, or S_i mechanisms. These studies have been analysed in Klabunovskii's review[5]. In this connection, the series of investigations by Balandin, Klabunovskii, and coworkers[123-125] of the structure of the active catalyst surface by the hydrogenation of molecules with a rigid steric configuration are also of undoubted interest.

The study of model reactions in which the starting materials undergo minimal changes (ortho–para conversion of hydrogen, configurational isomerisation, etc.) and the use for investigation of optically active and labelled compounds in combination with the latest physical techniques for the study of the catalyst itself constitutes new and promising approaches to the elucidation of the fine details of reactions on the surface of the catalyst.

Advances in Asymmetric Hydrogenation. Catalytic Synthesis of Optically Active Hydroxy- and Amino-acids

E.I.Klabunovskii and E.S.Levitina

In the present review an attempt is made to follow the general relations in the formation of optical isomers and to elucidate the optimum conditions for the reactions on the basis of an analysis of the available literature data on the catalytic synthesis of aminoacids with reference to data on the hydrogenation of C=C and C=O bonds in optically active compounds. The extremely interesting and promising field of asymmetric hydrogenation using dissymmetrical heterogeneous catalysts, which requires special treatment, has been dealt with in the review only in connection with the synthesis of aminoacids.
The bibliography includes 87 references.

CONTENTS

I. INTRODUCTION

Asymmetric hydrogenation has always attracted the attention of investigators as one of the methods for the preparation of optically active compounds by the addition of hydrogen to the multiple bonds C=C, C=O, and C=N, in the presence of an asymmetrising agent (an optically active group in the molecule, a dissymmetric catalyst). Recently there has been a particular growth of interest in asymmetric hydrogenation in connection with the application of new methods for the synthesis of optically active α-aminoacids.

The advances in asymmetric hydrogenation have not yet been reflected in an adequate compilation of the relevant studies. There are only a few obsolete reviews [1,2] in Japanese.

Asymmetric catalysis is based on the concept of the *cis*-addition of hydrogen from the catalyst surface, which has been expressed quantitatively in Balandin's multiplet theory of catalysis and theory of hydrogenation. According to the multiplet theory, the addition of hydrogen to the molecule of an unsaturated compound takes place in a reaction sphere of minimum volume without the desorption of the intermediate semihydrogenated species from the catalyst surface. The presence of the heterogeneous catalyst surface gives rise to additional steric hindrance in this process and promotes its stereospecificity.

The formation of optically active compounds in asymmetric heterogeneous catalytic hydrogenation confirms the mechanism of *cis*-addition, since otherwise, in *trans*-addition or for desorption of the semihydrogenated species, the racemate would be formed in the bulk phase. At the same time these data show that, under the conditions investigated, the impact hydrogenation mechanism is unlikely and it must be assumed, in accordance with the multiplet theory, that the reaction takes place in direct contact with the catalyst. According to Balandin's hydrogenation theory [3], the activation of the compound hydrogenated B and hydrogen H takes place at different centres K' and K respectively, and the centre K may be subdivided further into centres A which are responsible for the separate adsorption of hydrogen atoms. Then the stages in the attainment of adsorption equilibrium at the two types of centre are represented by mechanisms (1) and (2) and the rate-limiting stage of the process is represented by mechanism (3):

$$B + K' \rightarrow BK';\ H_2 + K' \rightarrow H_2K';\ C + K' \rightarrow CK', \qquad (1)$$

$$B + K \rightarrow BK;\ H_2 + K \rightarrow H_2K \rightarrow 2\,(H \cdot A);\ C + K \rightarrow CK, \qquad (2)$$

$$BK' + HA \rightarrow XK'A;\ XK'A + HA \rightarrow CK' + K, \qquad (3)$$

where C is the reaction product and X the semihydrogenated species, which is not released into the bulk phase from the catalyst surface and which undergoes all transformations on the surface. The adsorption of compound B (to be hydrogenated) at centres K' [mechanism (1)] and the rate-limiting stage [mechanism (3)] must take place on the sterically least hindered side of the molecule, which determines the stereochemistry of the product.

The occurrence of asymmetric synthesis is due to the difference between the rates of formation of the optical isomers of the product C from the initial compound B:

$$\begin{tikzcd} B \arrow[r, "k_d"] \arrow[dr, "k_l"'] & (+)\,C \\ & (-)\,C \end{tikzcd},$$

which is determined by the difference between the free energies of activation $\Delta F^{\neq}$ for the diastereoisomeric transition states. According to the transition state theory, the specific rate of formation of one of the optical isomers, for example, the (+)-isomer, is defined as follows:

$$k_d = \frac{kT}{h} e^{-\frac{\Delta F_d^{\neq}}{RT}} .$$

For two competing reactions involving the formation of the (+)- or (−)-isomers, we have, $k_d/k_l = C_d/C_l$ and for a transmission coefficient close to unity the ratio of the rate constants for the formation of the (+)- and (−)-isomers is

$$\ln\frac{k_d}{k_l} = \ln\frac{C_d}{C_l} = \left(\frac{\Delta S_d^{\neq}}{R} - \frac{\Delta H_d^{\neq}}{RT}\right) - \left(\frac{\Delta S_l^{\neq}}{R} - \frac{\Delta H_l^{\neq}}{RT}\right) =$$
$$= \left(\frac{\Delta S_d^{\neq}}{R} - \frac{\Delta S_l^{\neq}}{R}\right) - \left(\frac{\Delta H_d^{\neq}}{RT} - \frac{\Delta H_l^{\neq}}{RT}\right) = \frac{\Delta\Delta S_{d-l}^{\neq}}{R} - \frac{\Delta\Delta H_{d-l}^{\neq}}{RT} ,$$

where the enthalpy of activation $\Delta H^{\neq}$ is related to the experimentally determined activation energy E by the equation

$$\Delta H^{\neq} = E - RT .$$

Low values of $\Delta\Delta S^{\neq}$ indicate a similarity of the structures of the diastereoisomeric transition states.

The specific rotation of the product is determined from the expression

$$\alpha_{D}^{t} = \alpha_{obs} \times 100/lC,$$

where α_{obs} is the observed optical rotation in a layer of length l (in decimeters) at a concentration C (1 g per 100 ml solution). The molecular rotation $[M]_{\lambda}^{t}$ is defined thus:

$$[M]_{\lambda}^{t} = [\alpha]_{\lambda}^{t} \frac{M}{100} .$$

The optical purity (P, %), also called the optical yield or the asymmetric yield, is defined by the ratio of $[\alpha]_{D\,found}$ for the product to the maximum specific rotation quoted in the literature $[\alpha]_{D(lit.)}$ for the optically pure compound:

$$p = \frac{[\alpha]_{D(found)}}{[\alpha]_{D(lit)}} \cdot 100 = \frac{[M]_{D(found)}}{[M]_{D(lit)}} \cdot 100 .$$

The specificity Sp_{+}, or the ratio of the fraction of one optical isomer to the other in a given compound, determined from the expression

$$Sp_{+} = \frac{[(+)\text{-isomer}]}{[(-)\text{-isomer}]} = \frac{100+p}{100-p} ,$$

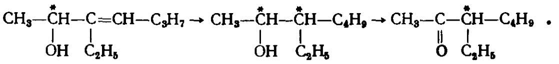
varies in the range $\infty \geqslant Sp \geqslant 1$.

Two methods are employed at present for the determination of the optical purity of the compound. The first requires the separation of the optical isomers in a pure form or in the form of their diastereoisomers. This procedure includes, apart from the classical method of the isolation of usually one optical isomer by the recrystallisation of the diastereoisomers, the method of isotope dilution[4], a kinetic method[5], and an enzymatic method. In the second procedure it is sufficient to determine analytically the ratio of the diastereoisomers, for example by gas-liquid chromatography (Weygand[6], Belikov and coworkers[7]) or by NMR (Raban and Mislow[8,9]).

The stereochemistry of the asymmetric hydrogenation of C=C and C=O bonds, on which extensive data have accumulated recently, provides valuable information for the understanding of the catalytic synthesis of optically active aminoacids.

II. HYDROGENATION OF OPTICALLY ACTIVE UNSATURATED AND CARBONYL COMPOUNDS

Arcus and coworkers[10-12] made a detailed study of the stereochemistry of the hydrogenation of optically active compounds on nickel using as an example optically active 3-ethylhept-3-en-2-ol[10] and 3-methyl-4-phenylbut-3-en-2-ol[11]. The initial asymmetric centre in the molecules is destroyed by oxidising the hydrogenation product to the corresponding ketone by the mechanism



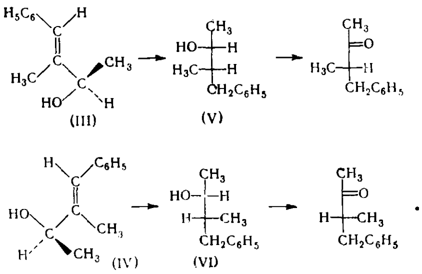
$$\mathrm{CH_3-\underset{OH}{\overset{*}{C}H}-\underset{C_2H_5}{C}=CH-C_3H_7 \rightarrow CH_3-\underset{OH}{\overset{*}{C}H}-\underset{C_2H_5}{\overset{*}{C}H}-C_4H_9 \rightarrow CH_3-\underset{O}{\overset{}{C}}-\underset{C_2H_5}{\overset{*}{C}H}-C_4H_9} .$$

The experimental results showed that in the hydrogenation of (–)- and (+)-3-ethylhept-3-en-2-ol there is partial asymmetric synthesis with an optical yield of 76 and 36% of the (+)- and (–)-ketones respectively. The authors explained this finding by postulating that the substrate molecule is oriented with respect to the catalyst surface predominantly in the sterically least hindered conformation. The stereochemistry of the transition state has been examined in the hydrogenation of (–)-3-methyl-4-phenylbut-3-en-2-ol[11]. In this case the product is (+)-3-methyl-4-phenylbutan-2-ol and, after oxidation of the alcoholic group with chromium trioxide, (–)-3-methyl-4-phenylbutan-2-one:

$$\mathrm{C_6H_5-CH=\underset{CH_3}{C}-\underset{OH}{\overset{*}{C}H}-CH_3 \rightarrow C_6H_5CH_2-\underset{CH_3}{\overset{*}{C}H}-\underset{OH}{\overset{*}{C}H}-CH_3 \rightarrow C_6H_5CH_2\underset{CH_3}{\overset{*}{C}H}-\underset{O}{C}-CH_3} .$$

(I) (II)

We shall consider the structure of the transition state on the surface of the catalyst. The molecule of *trans*-3-methyl-4-phenylbut-3-en-2-ol can be adsorbed in conformations (III) or (IV) (the plane of the figure corresponds to the catalyst surface):

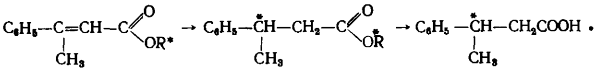


In the hydrogenation of (III) and (IV) hydrogen approaches from behind the plane of the figure with formation of the diastereoisomers (V) and (VI). It is postulated that the adsorption of the molecule in conformation (III) is the most probable, since in conformation (IV) the two bulky methyl groups are located too close to one another. Since the specific rotation of the pure diastereoisomers (I) and the ketones (II) was unknown, the degree of asymmetric synthesis (more precisely "dissymmetric synthesis") was estimated by quantitative gas-chromatographic analysis of the diastereoisomeric alcohols and, in two experiments, from the hydrogenation of (–)-3-methyl-4-phenylbut-3-en-2-ol and was found to be 22 and 17%.

The hydrogenation of racemic *trans*-4-phenylpent-3-en-2-ol[12] in conformations corresponding to (III) and (IV) gives a mixture of the four possible diastereoisomers, which consist of two pairs of optical isomers. The degree of dissymmetric synthesis in the two experiments proved to be 50 and 57% respectively. The proposed method, based on the chromatography of diastereoisomers, is extremely promising in the study of the stereochemistry of the reactions of various compounds, since there is no need to determine the optical activity of the product and it is possible to employ racemic compounds.

It was noted long ago that the stereochemistry of the activating optically active group determines to a considerable degree the effectiveness of asymmetric catalysis.

In the hydrogenation of optically active esters of β-methylcinnamic acid on platinum black, Vavon and Yakubovicz[13] obtained, after hydrolysing the hydrogenation products, optically active β-phenylbutyric acid with different degrees of optical purity:

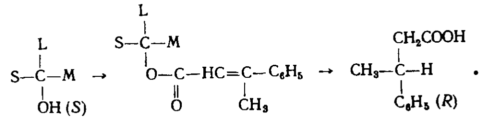


$$\mathrm{C_6H_5-\underset{CH_3}{C}=CH-C{\overset{O}{\underset{OR^*}{\lessgtr}}} \rightarrow C_6H_5-\underset{CH_3}{\overset{*}{C}H}-CH_2-C{\overset{O}{\underset{O\overset{*}{R}}{\lessgtr}}} \rightarrow C_6H_5-\underset{CH_3}{\overset{*}{C}H}-CH_2COOH} .$$

Menthol, neomenthol, *cis*- and *trans*-carvomenthols, and 3α- and 3β-cholestanols were employed as the optically active alcohols. The highest optical yield (20%) of β-phenylbutyric acid was obtained when menthol was employed.

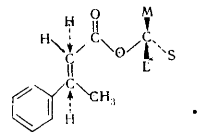
Hydrogenation of hydrocinchoninium salts of β-methyl and β-(α'-naphthyl)cinnamic acids on platinum oxide gave β-phenylbutyric acid with $[\alpha]_{546} = +4.5°$ and an optical yield of 9% and β-(α′-naphthyl)-β-phenylpropionic acid with $[\alpha]_{546} = -0.5°$. The stereochemistry of the catalytic hydrogenation of β-methylcinnamic acids was examined in detailed by Prelog[14,15].

The stereochemistry of asymmetric hydrogenation is determined by the difference between the sizes of the substituents at the asymmetric carbon atom in the activating alcohol. An increase of the difference between these sizes leads to an increase of the optical yield of the reaction. If L, M, and S are respectively large, medium, and small substituents at the asymmetric carbon atom, then the configurations of the optically active alcohol and the optical isomer of β-phenylbutyric acid obtained in excess are related as shown in the scheme below [i.e. under the conditions investigated, the (S)-configuration of the alcohol promotes the formation of the (R)-configuration of the acid]:

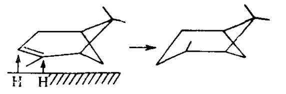


$$\text{S—C(L)(M)—OH}\ (S) \rightarrow \text{S—C(L)(M)—O—C(=O)—HC=C(CH}_3\text{)—C}_6\text{H}_5 \rightarrow \text{CH}_3\text{—C(CH}_2\text{COOH)(H)—C}_6\text{H}_5\ (R).$$

Examination of the conformation of the molecule of β-methylcinnamic acid shows that all the atoms, except the substituents L, M, and S, lie in the same plane. Hydrogen attacks the double bond from the sterically least hindered side, i.e. from the side of the small substituent S:



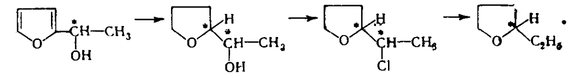
This should result in the formation of (−)-(R)-β-phenylbutyric acid. Table 1 shows that this mechanism, based on Prelog's rule, does indeed hold in the hydrogenation of the menthyl and bornyl esters of β-methylcinnamic acid. However, in the hydrogenation of neocarvomenthyl and 3α-cholestanyl esters Prelog's rule does not hold. It may be supposed that the rigid configuration of the molecule, which hinders the catalytic process, has an effect in this case. This is clearly shown, for example, in the hydrogenation of bicyclic compounds with bridged systems. Thus the hydrogenation of (+)-α-pinene on Raney nickel (W-3) in ether at 107°C and 100 atm results in the formation of almost exclusively *cis*-pinane, because α-pinene is adsorbed on the catalyst in such a way that the isopropylidene bridge is directed away from the catalyst[12]:



Prelog and coworkers[15] showed that the asymmetric yield of β-phenylbutyric acid depends also on the experimental conditions. Thus, in the hydrogenation of the ester of β-methylcinnamic acid and t-butylmethylmethanol on Raney nickel, Pd/C, and PtO_2 in acetic acid, the optical yield was greatest in the last case.

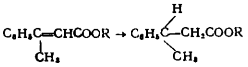
The degree of asymmetric synthesis is also influenced by the location of the dissymmetric centre in the molecule. The greatest asymmetrising effect of this centre may be expected when it is adjacent to the reacting group. Vavon[13] explained the low degree of asymmetric synthesis in the hydrogenation of optically active β-methylcinnamic esters by the remoteness of the optically active group from the group of reacting atoms.

The remoteness of the asymmetric centre in the ester precludes racemisation, whereas the racemisation at the α-asymmetric carbon atom proceeds extremely readily. This can account for the failure of the attempt at asymmetric synthesis in the preparation of a furan derivative by the hydrogenation on nickel of optically active furylmethylmethanol, which was undertaken by Duveen and Kenyon[16] on the basis of the mechanism



The product obtained after the removal of the initial asymmetric centre proved to be optically inactive. It is also possible that the choice of reaction conditions was inappropriate.

Table 1. Asymmetric hydrogenation of β-methylcinnamic acid esters.



$$C_6H_5C(CH_3)=CHCOOR \rightarrow C_6H_5C(H)(CH_3)-CH_2COOR$$

R	Optical rotation of product		Optical yield of acid, %
	established in Ref.13, deg	sign of rotation predicted by Prelog's rule	
S-(+)- 	− 4.7	(−)	8.5
S (−) 	− 2.5	(−)	4.5
S (−) 	− 4.2	(−)	7.5
R (+) 	+ 7.5	(+)	13
R (+) 	+15.5	(+)	27

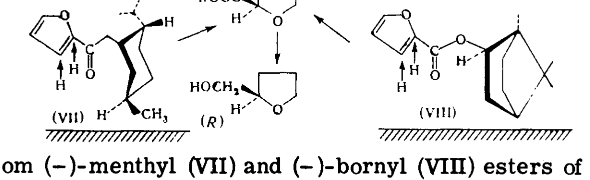
3-α-cholestanol	− 3	(+)	5.2
3-β-cholestanol	− 2.3		4.0

Asymmetric hydrogenation of the furan ring was achieved by Godunova, Klabunovskii et al.[17] by the mechanism



from (−)-menthyl (VII) and (−)-bornyl (VIII) esters of furancarboxylic acid. On the $Pd(OH)_2/C$ catalyst, the hydrogenation (150 atm, 20°C) takes place stereospecifically with formation of about 20% of an excess of the (*R*)-isomer. The ester of tetrahydrofurancarboxylic acid is reduced by $LiAlH_4$ to an alcohol, which is characterised by a positive optical rotatory dispersion curve. Examination of the stereochemistry of the transition states (VII) and (VIII) in accordance with Prelog's rule shows that (−)-(*R*)-menthol and (−)-(*R*)-borneol lead to tetrahydrofuryl alcohol with the same (*R*)-configuration as the product.

The stereochemical concepts based on Prelog's rule have been increasingly adopted in catalysis in recent times but one must consider the following important factor, which makes it necessary to employ this rule with caution. As stated above, asymmetric catalysis is due to the differences between the free energies of activation for diastereoisomeric transition states. When the difference between these quantities for the (+)- and (−)-products is large, a sharp difference may be expected between the curves relating the optical yields of the two optical isomers to reaction temperature.

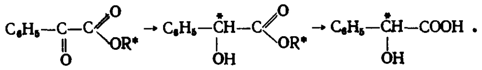
Pracejus[18] showed experimentally that the asymmetric yield of methyl β-phenylpropionate in the reaction of methylphenylketen with methanol promoted by acetylquinine as a dissymmetric catalyst increases sharply when the reaction temperature is reduced and that at −111° it reaches 74%, which corresponds to $Sp = 6.6$. The (−)-(*R*)-ester is formed almost 7 times faster than the (+)-(*S*)-isomer with $\Delta\Delta H^{\neq}_{R-S} \simeq -2.8$ kcal mole^{-1} and $\Delta\Delta S^{\neq}_{R-S} = -13$ cal mole^{-1} deg^{-1}. Hence it follows that $\Delta H^{\neq}_{S}$ of the sterically more hindered reaction leading to the formation of the (+)-(*S*)-isomer is higher by about 2.8 kcal mole^{-1} than for the reaction with formation of the (−)-(*R*)-isomer and the entropy of activation $\Delta S^{\neq}_{S}$ for the (+)-(*S*)-isomer exceeds by 13 e.u. $\Delta S^{\neq}_{R}$ for the (−)-(*R*)-isomer.

These data confirm the theoretical postulates and show that stereospecific catalysis, in which the entropy factor plays an important role, takes place above the isokinetic temperature[19] where a compensation effect [simultaneous increase (or decrease) of $\Delta H^{\neq}$ and $\Delta S^{\neq}$] is observed.

The above data show at the same time the importance of studying the temperature variation of the asymmetric reaction, since the change in the sign of the optical rotation and of the optical yield of the product at an arbitrary temperature (such as, for example, the temperature at which the Grignard reaction was carried out in Prelog's experiments) may lead to incorrect conclusions concerning the configurational relations. Therefore Prelog's method for the determination of such relations is applicable only for high differences between the free energies of activation for the diastereoisomers investigated and for fairly high optical yields. These limiting conditions still await experimental confirmation.

In the catalytic synthesis of optically active compounds and in the determination of the configuration, the stereochemical relations are complicated still more by the effect of the nature of the catalyst and of adsorption on its surface. This is seen from the hydrogenation of keto-compounds as an example.

The catalytic hydrogenation of α-ketoacids esterified by certain optically active alcohols was investigated by Mitsui and coworkers[20-25]. They chose for investigation benzoylformic acid, the asymmetric reduction of which by aluminium amalgam and other agents had been studied previously. The heterogeneous catalytic hydrogenation of optically active esters of benzoylformic acid was carried out on metallic catalysts (Raney nickel, PtO_2, Pd/C, $Pd/CaCO_3$, and $Pd/BaSO_4$). The experimental results showed (Table 2) that the hydrogenation of (−)-menthyl[20] and (+)-bornyl[21] esters with subsequent hydrolysis yield optically active mandelic acid:



$$C_6H_5-\underset{\underset{O}{\|}}{C}-C\overset{O}{\underset{OR^*}{\swarrow}} \rightarrow C_6H_5-\underset{\underset{OH}{|}}{\overset{*}{C}H}-C\overset{O}{\underset{OR^*}{\swarrow}} \rightarrow C_6H_5-\underset{\underset{OH}{|}}{\overset{*}{C}H}-COOH\ .$$

However, it was found that the sign of the rotation of the product is almost independent of the nature of the catalyst employed and is wholly determined by the presence on the catalyst surface of traces of acid or alkali, which may be inferred from the procedure employed in the preparation of the catalyst.

When catalysts containing traces of a base (B), such as PtO_2, Raney nickel, and Pd/C–B were used, (−)-menthyl (−)-mandelate and (+)-bornyl (+)-mandelate were obtained respectively; after hydrolysis they yielded (−)- and (+)-mandelic acids. On the other hand, the hydrogenation of the above esters under the same conditions on "acidic" catalysts (A) gave (+)- and (−)-mandelic acids. The reduction of cholesteryl esters of benzoyl formic acids on "acidic" and "alkaline" catalysts leads to racemic mandelic acid[21]. In the hydrogenation of (−)-α-phenylethyl ester of benzoylformic acid[22] the sign of the rotation of mandelic acid depends on the nature of the surface of the catalyst employed[22]; namely on "alkaline" and "acidic" catalysts the (+)- and (−)-mandelic acids were obtained (Table 2). However, the reduction of the (−)-α-phenylethylamide of benzoylformic acid was unaffected by the nature of the catalyst surface; the laevorotatory hydroxyacid was obtained in both cases[22].

To elucidate the influence of substituents in the ester molecule on the mechanism of the asymmetric reduction of α-ketoacids under the conditions of heterogeneous catalysis, a study was made of the hydrogenation of (−)-menthyl esters of certain other α-ketoacids: pyruvic, t-butylglyoxylic[23], and α-naphthylglyoxylic[24,25]. It was found that the ester of α-naphthylglyoxylic acid behaves in this reaction like the ester of benzoylformic acid, i.e. on "acidic" (platinum with added hydrochloric acid etc.) and "alkaline" catalysts, the (+)- and (−)-α-naphthylglyoxylic acids were obtained[24]. On the other hand, the sign of the rotation of the lactic and t-butylglyoxylic acids was independent of the nature of the catalyst surface[23]. In the reduction of (−)-menthyl esters of the corresponding α-ketoacids, the (+)-hydroxyacids were always obtained (Table 2).

The interpretation of the results from the standpoint of Prelog's rule showed that the hydrogenation of (−)-menthyl benzoylformate on "alkaline" catalysts presupposes the *trans*-conformation (IXa) of the group $-\overset{\overset{O}{\|}}{C}-\underset{\underset{O}{\|}}{C}-$, while on "acidic" catalysts it is necessary to postulate the *cis*-conformation (IXb):

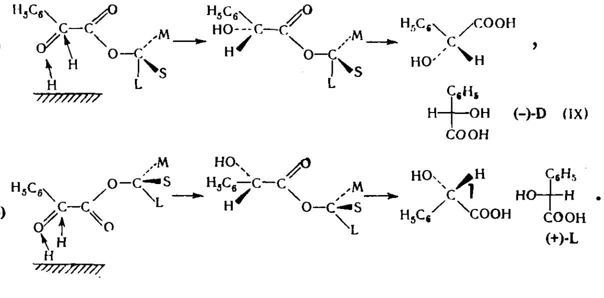


Table 2. Dependence of the configuration of the hydrogenation product on the nature of the catalyst[20–25,27].

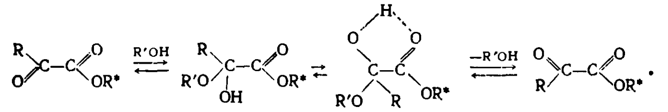
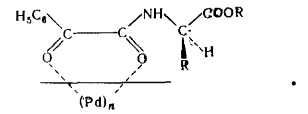
Substrate	Reaction product: hydroxyacid formed	Reaction product: configuration, sign of rotation, optical yield (%), and most effective catalyst: "acidic"	"alkaline"
 where R*:	mandelic acid		
(a) (-)-(R)-menthyl 	ditto	(+)-L; 16.8% 5% Pd/C—B+ +HCl	(-)-D; 21.7% PtO_2
(b) (+)-(S)-bornyl 	»	(-)-D; 7.2% 5 %Pd/C+ +HCl	(+)-L; 22.9% PtO_2
(c) cholesteryl	»	0 %	0 %
(d) (-)-D-α-phenylethyl 	»	(-)-D; 2.4% Pd/C—A	(+)-L; 3.6%, Ni
(e) sugar derivatives 	»	(+)-L; 24.1 5% Pd/C—A	(-)-D; 44.6% Raney Ni
	»	(+)-L; 20.3% 5% Pd/C—A	(-)-D; 36.7% Raney Ni
	»	(+)-L; 9.4% 5% Pd/C—A	(-)-D; 19.9% Raney Ni
	»	(+)-L; 12.8% 5% Pd/C—A	(-)-D; 14.0 Raney Ni
	mandelic acid	(-)-D; 10.8% Pd black	(-)-D; 25.0 Ni
	(+)-L-lactic acid	(+)-L; 22% Pd/C—A	(-)-L; 33% PtO_2
	(+)-t-butyl glycolic acid	(+); 17% Pd/C—A	(+); 41% PtO_2
	naphthylglycolic acid	(+)-D; 16.5% Pd, $Pd(OH)_2/C$	(-)-L; 54.6% PtO_2

The formation of this energetically less favourable *cis*-conformation can be accounted for by the presence of a hydrogen bond between the carbonyl groups:



In the reduction of the (−)-α-phenylethylamide of benzoylformic acid the configuration of the reaction product is independent of the nature of the catalyst; the laevorotatory mandelic acid was always obtained. Consequently the optically active acid amide reacts preferentially in the *cis*-conformation (IXb) in the presence of both "acidic" and "alkaline" catalysts. Harada and Matsumoto[26], who investigated the hydrogenation on Pd/C of the amide derivatives of benzoylformic acid with the general formula  $C_6H_5-\underset{O}{\underset{\|}{C}}-\underset{O}{\underset{\|}{C}}NH-CH\begin{smallmatrix}R\\COOR\end{smallmatrix}$, confirmed the hypotheses of Mitsui and coworkers[22]. According to the authors' postulate, the *cis*-conformation of the molecule is stabilised by the formation of a five-membered cyclic complex with the catalyst:



On the other hand, the (−)-menthyl esters of pyruvic and t-butylglyoxylic acids probably react predominantly in the transoid conformation (IXa)

Kawana and Emoto[27] used certain monosaccharide derivatives as asymmetrising agents. The hydrogenation of the corresponding esters of benzoylformic acid on Pd/C−A, Pd/C−B and Raney nickel gave the optically active hydroxyacids after hydrolysis. Under the conditions of "alkaline" catalysts (Pd/C−B, Raney nickel), (−)-D-mandelic acid is the product, while the use of an "acidic" catalyst Pd/C−A gives (+)-L-mandelic acid. These and other results discussed above are compiled in Table 2, which shows that the configuration of the hydroxyacid formed depends on the nature of the surface of the catalyst employed and on the conformation in which the substrate is preferentially adsorbed on the catalyst surface.

The optical purity of the product is influenced by other factors, such as, for example, the chemical nature of the catalyst employed, the solvent, the duration of hydrogenation, and the time during which the solution is kept before hydrogenation. The use of a series of different catalysts showed that the most effective of the "acidic" catalysts is 5% Pd/C−A with added hydrochloric acid—the optical yield then reaches $p = 24\%$, while with "alkaline" catalysts the maximum asymmetric yield was obtained on the PtO_2 catalyst: $p = 54.6\%$, which exceeds by a factor of 8−10 the asymmetric yield found in the presence of homogeneous catalysts of this reaction. Since the addition of acid or alkali to the catalyst leads to a change of the optical purity of the isomer formed in excess, it would be extremely important to investigate the effect of the pH of the medium on the stereospecificity of the process.

An interesting variation of the asymmetric yield with the solvent employed has been noted (Table 3).

If the solution tested is kept for several hours before hydrogenation, the optically active acid obtained is more laevorotatory than the acid formed by the hydrogenation of the solution without preliminary standing. These results can be accounted by the mutarotation of the benzoylformic acid esters. Indeed Glazer and Turner[28], who investigated the mutarotation of the above esters, showed that the equilibrium optical rotation of the esters decreases with decrease of the dielectric constant of the solvent empolyed (Table 4).

Table 3. Optical rotation of mandelic acid obtained in the hydrogenation of (−)-menthyl benzoylformate in various solvents.

Catalyst	Solvent					
	methanol	ethanol	1-propanol	2-propanol	ether	benzene
Alkaline PtO_2	−18.8	−4.3	−45.4	−42.5	−37.0	−47.2
Acidic 5% Pd/C-A	+ 8.3	+4.2	+17.0	+ 8.3	+ 5.6	+ 6.0

Evidently the observed sequence (with certain exceptions) is the reverse of that presented in Table 3. This indicates a possible relation between the effectiveness of the catalytic asymmetric synthesis of mandelic acid and the degree of mutarotation of menthyl phenylglyoxylate in the corresponding solvent; the greater the degree of mutarotation, the lower the purity of the product. Consequently, an increase of the polarity of the solvent lowers in this case the effectiveness of the asymmetric synthesis.

Table 4. Variation of the specific rotation of (−)-menthyl benzoylformate with the solvent[28].

$[\alpha]_{5461}^{25}$	Solvent			
	methanol	ethanol	1-propanol	2-propanol
Initial	−54	−54	−54	−52
Equilibrium	−75	−60	−61	−52
Δ	21	8	7	0

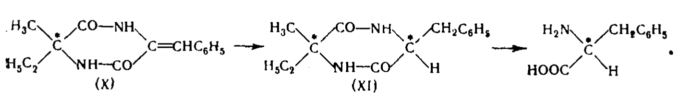
The same relation in the synthesis of aminoacids was observed by Harada and Matsumoto[29] (for a more detailed description, see p. 1044). So far the results presented in Table 2 do not allow definite conclusions concerning the correlation between the configurations of the asymmetric alcohol and the hydroxyacid formed. The results require further revision and in particular a study of the dependence of asymmetric yield on temperature, pH, and the solvent.

III. CATALYTIC ASYMMETRIC SYNTHESIS OF α-AMINOACIDS

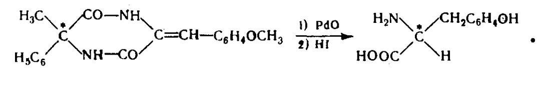
1. Hydrogenation of C=C Bonds in Optically Active Compounds

Optically active α-aminoacids may be obtained by the catalytic reduction of the C=C bond in dehydro-α-aminoacids in the presence of an asymmetrising agent. The number of examples of such asymmetric syntheses in the literature is fairly large[30-35].

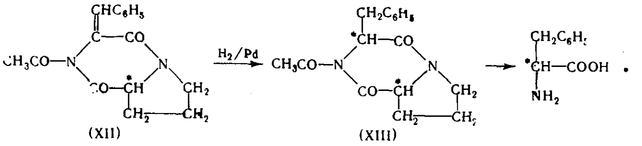
Akabori and coworkers[30,31] obtained L-phenylalanine with $[\alpha]_D^{21} = -34.0°$ by the hydrogenation over platinum oxide of the mixed anhydride of dehydrophenylalanine and L-isovaline (X). The asymmetrising agent (L-isovaline) was then eliminated in the hydrolysis of the diastereoisomer (XI) formed:



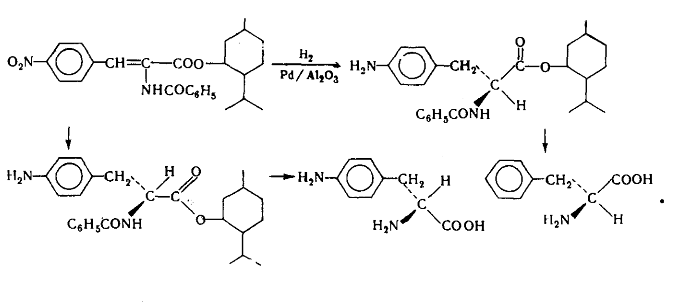
Maeda[32], who employed (+)-D-α-amino-α-phenylpropionic acid instead of isovaline, carried out a similar asymmetric synthesis and obtained L-tyrosine in 35% optical yield:



Bergman and Tietzmann[33] reduced the optically active dioxopiperazine formed by N-acetyldehydrophenylalanyl-L-proline (XII) over palladium black and obtained a 50% yield of the cyclic dimer of N-acetyl-L-phenylalanyl-L-proline (XIII) with $[\alpha]_D^{22} = +202.6°$ and after its hydrolysis L-phenylalanine with $[\alpha]_D^{27} = -33.9°$:

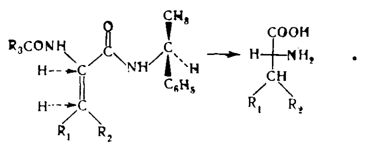


Pedrazzolli[34] achieved an asymmetric synthesis involving the catalytic dehydrogenation of the C=C bond over Pd/Al_2O_3 by reducing the (−)-menthyl ester of α-benzamido-p-nitrocinnamic acid and obtained a mixture of diastereoisomers. The separation of the latter showed that the (SR)-diastereoisomer is present in excess, with (SR) : (RR) = 68 : 32. After the hydrolysis of the hydrogenation products to p-aminophenylalanine, it was found that the degree of asymmetric synthesis is p = 34%. When the bornyl ester was employed, the final product proved to be optically inactive:



Sheehan and Chandler[35] carried out the asymmetric synthesis of valine and phenylalanine by the catalytic hydrogenation on Raney nickel of the optically active alkylamides of α-acetamido-β-methylcrotonic and α-benzamidocinnamic acids. Optically active α-phenylethylamine was employed as an asymmetrising agent. In accordance with Prelog's rule, when (−)-phenylethylamine is employed [provided one adopts for the (−)-amine the configuration indicated in the scheme], the products are

(–)-D-valine and (+)-D-phenylalanine, while the use of (+)-phenylethylamine leads to their optical isomers:



1) $R_1 = CH_3$, $R_2 = CH_3$, $R_3 = C_6H_5$; (–)-D; $p = 18\%$

2) $R_1 = CH_3$, $R_2 = CH_3$, $R_3 = CH_3$; (–)-D; $p = 39\%$

3) $R_1 = C_6H_5$, $R_2 = H$, $R_3 = C_6H_5$; (+)-D; $p = 6\%$

The first data on the asymmetric reduction of β-methylcinnamic acid by hydrogen transfer were quoted by Lipkin and Stewart[36,37]; the use of Raney nickel in the presence of D-glucose led to β-phenylbutyric acid with $\alpha_D = 0.42°$ ($p = 5\%$):

$$C_6H_5\underset{\displaystyle CH_3}{C}{=}CHCOOH \rightarrow C_6H_5\underset{\displaystyle CH_3}{\overset{*}{C}H}{-}CH_2COOH\ .$$

By reducing acetamido- and benzamido-cinnamic acids on Raney nickel in the presence of glucose, Nakazaki[38] obtained phenylalanine in a very low optical yield (Table 5):

$$C_6H_5CH{=}\underset{\displaystyle NHR}{C}{-}COOR' \rightarrow C_6H_5CH_2{-}\underset{\displaystyle NHR}{CH}{-}COOR'\ .$$

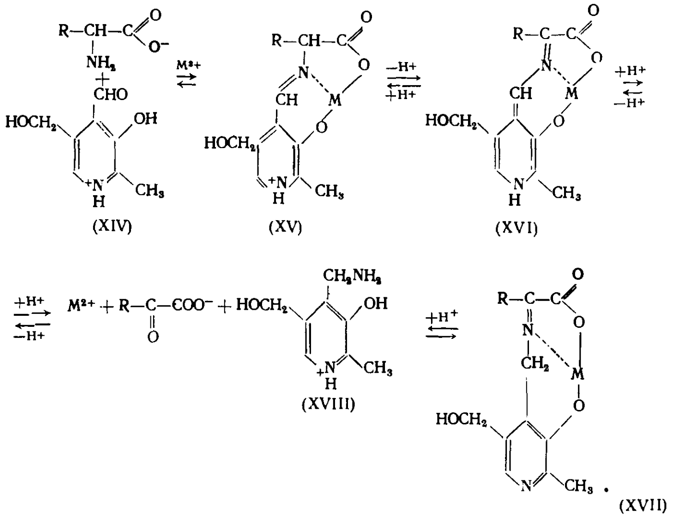
Table 5. Reduction of acylaminocinnamic acids on nickel in the presence of glucose.

R	Acid, g	Glucose, g	Ni, g	Reaction temp., °C	Phenylalanine	
					α_D, l2	$[\alpha]_D$
CH_3CO	4.1	7.9	0.8	30	–0.02	–2.22
CH_3CO	3.9	7.7	1.0	24	+0.03	+3.26
C_6H_5CO	4.0	5.9	1.0	28	+0.02	+1.96

The author interpreted the results as asymmetric reduction with hydrogen transfer, in which glucose is a hydrogen donor and the nickel catalyst an activator and hydrogen-transferring agent. However, the reliability of the data obtained is extremely doubtful, since the observed rotations are within the limits of the error of the measurement.

2. Preparation of Aminoacids by the Reduction of the C=N Bond

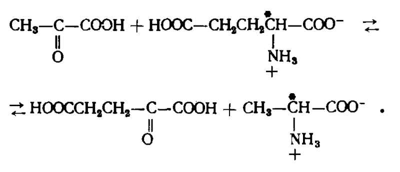
A large number of facts indicate a significant role of the C=N bond in biochemical processes. Although many details of enzymatic reactions are still not clear, certain simplest enzyme systems with a C=N group have been thoroughly investigated. Snell and coworkers[39] proposed a fairly simple mechanism for the transfer of the amino-group from an aminoacid to a ketoacid catalysed by pyridoxal in the presence of certain complex-forming metals:



The reverse transfer by the reaction of pyridoxamine (XVIII) with the ketoacid is possible via the intermediate states (XVII) → (XVI) → (XV); as a result pyridoxal (XIV) is regenerated.

The catalytic methods for the synthesis of optically active aminoacids by the hydrogenation of compounds containing the azomethine group C=N can be divided into three types: (1) enzyme-catalysed transamination of optically inactive aminoacids and ketoacids; (2) transamination of ketoacids and optically active aminoacids; (3) reductive transamination of ketoacids in the presence of optically active amines.

In reactions of the first type the enzyme plays the role of an asymmetrising agent, which probably forms intermediate complexes analogous to (XV) ⇌ (XVI) ⇌ (XVII). For example, L-alanine and α-oxoglutaric acid react in the presence of muscle tissue enzymes, forming pyruvic and L-glutamic acids[40,41]. The reaction between pyruvic and L-glutamic acid catalysed by pyridoxal phosphate and an enzyme leads to the formation of L-alanine[42]:

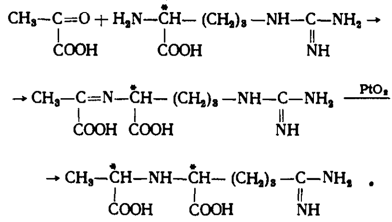


$$CH_3{-}\underset{\displaystyle O}{\overset{\|}{C}}{-}COOH + HOOC{-}CH_2CH_2\underset{\displaystyle \overset{+}{N}H_3}{\overset{*}{C}H}{-}COO^- \rightleftarrows$$
$$\rightleftarrows HOOCCH_2CH_2{-}\underset{\displaystyle O}{\overset{\|}{C}}{-}COOH + CH_3{-}\underset{\displaystyle \overset{+}{N}H_3}{\overset{*}{C}H}{-}COO^-\ .$$

An aminoacid in an optically active form can have a similar asymmetrising effect in the reaction; however, the degree of asymmetric activation is usually low. Thus the reaction of L-alanine or L-phenylalanine with α-oxoglutaric acid catalysed by copper-pyridoxal phosphate gives rise to glutamic acid[43] in which the ratio of the L- and D-isomers is 55 : 45. In this case the asymmetric synthesis takes place as a result of the formation of dissymmetric intermediate chelates, which may be protonated stereospecifically.

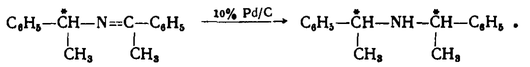
The third type of asymmetric synthesis of aminoacids is achieved when an optically active aminoacid or amine is employed as the asymmetrising agent. Thus the hydrogenation on PtO_2 of a mixture of L-arginine and pyruvic acid in aqueous solution gives octopine $\{[\alpha]_D^{20} = +22.3°\}$.[44,45]

It is suggested that the mechanism of this reaction consists in the reduction of an intermediate Schiff base[46]:



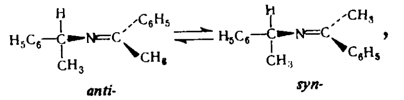
$$CH_3-\underset{COOH}{C}=O + H_2N-\underset{COOH}{\overset{*}{C}H}-(CH_2)_3-NH-\underset{NH}{\underset{\|}{C}}-NH_2 \rightarrow$$
$$\rightarrow CH_3-\underset{COOH}{C}=N-\underset{COOH}{\overset{*}{C}H}-(CH_2)_3-NH-\underset{NH}{\underset{\|}{C}}-NH_2 \xrightarrow{PtO_2}$$
$$\rightarrow CH_3-\underset{COOH}{\overset{*}{C}H}-NH-\underset{COOH}{\overset{*}{C}H}-(CH_2)_3-\underset{NH}{\underset{\|}{C}}-NH_2 .$$

The hydrogenation on Pd/C of the Schiff base obtained from acetophenone and α-phenylethylamine $\{[\alpha]^{25}_{D} = -40.5°\}$ results in the formation of an almost pure optically active product (p = 97.5%) and not a mixture of the optical isomer and the meso-form[47]:



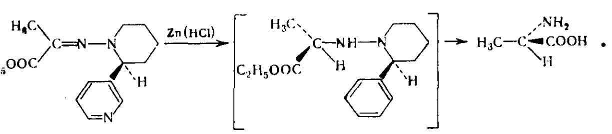
$$C_6H_5-\underset{CH_3}{\overset{*}{C}H}-N=\underset{CH_3}{C}-C_6H_5 \xrightarrow{10\%\ Pd/C} C_6H_5-\underset{CH_3}{\overset{*}{C}H}-NH-\underset{CH_3}{\overset{*}{C}H}-C_6H_5 .$$

This result can be explained by the fact that in the initial compound, which is an equilibrium mixture of two *syn*- and *anti*-isomers,

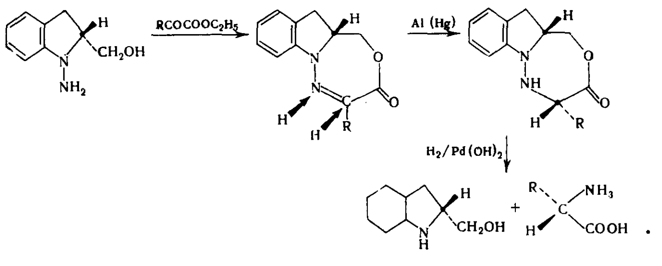


the less stable *syn*-isomer is hydrogenated at a higher rate, which leads to the optically active amine.

A method based on the reduction of the azomethine bond in the system C=N–N– with subsequent dissociation of the N–N bond was employed by Akabori[48,49] and Kost et al.[50] When α-ethoxycarbonylethylidene-N-aminoanabasine (formed from pyruvic acid and N-aminoanabasine) is reduced with zinc in alcoholic hydrochloric acid, D-alanine is formed in an optical yield of 40%:



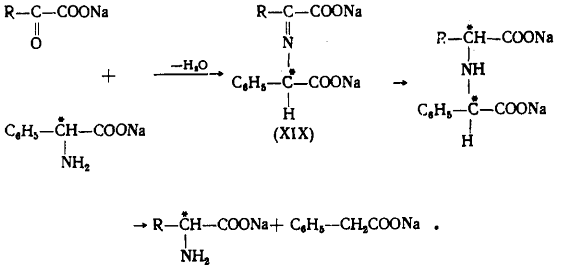
An exceptionally high optical yield was obtained by McCaully[51], who achieved a new synthesis from an optically active hydrazone-lactone (obtained from optically active 1-amino-2-hydroxymethylindoline and a ketoacid), the hydrolysis of which gives alanine (R = CH_3; p = 82%) and α-aminobutyric acid (R = C_2H_5, p = 98%), the initial 1-amino-2-hydroxymethylindoline being regenerated:



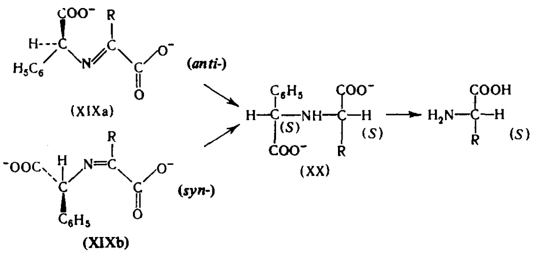
The high stereospecificity of the reaction in the stage involving the reduction by aluminium amalgam can be explained[52] by the *cis*-disposition of the five- and seven-membered rings in the molecule, which forces hydrogen to approach predominantly from one side.

Harada[53,54] employed as an asymmetrising agent optically active phenylglycine, the sodium salt of which was found to undergo readily hydrogenolysis on Pd/C at the C–N bond, giving ammonia and phenylacetic acid.

On the basis of this property, it proved possible to synthesise optically active alanine and α-aminobutyric, glutamic, and aspartic acids from the corresponding ketoacids and optically active phenylglycine according to the mechanism

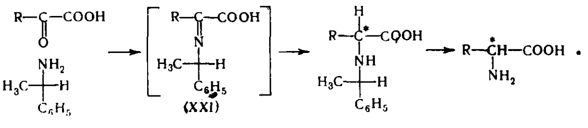


The asymmetric yield of α-aminoacids reaches 40 to 60%. To avoid an alteration of the optical yield during the isolation and purification of the product, measurements were made of the optical activities of the corresponding 2,4-dinitrophenyl derivatives of the aminoacids, which were separated chromatographically on Celite[55]. The mechanism proposed for this reaction consists in the asymmetric reduction of the intermediate Schiff base (XIX). Examination of the conformations of compound (XIX) led to the conclusion[53] that the hydrogenation of both possible isomers [the *syn*-isomer (XIXb) and the *anti*-isomer (XIXa)] leads to the same configuration of compound (XX):



According to this mechanism, the use of (S)-phenyl glycinate as the asymmetrising agent should give the aminoacid with the (S)-configuration and the use of (R)-phenylglycinate should give the corresponding (R)-amino acid. The results showed that these hypotheses are quite valid. It is interesting that the asymmetric yield changes little with increase in the size of the alkyl group at the α-carbon atom of ketoacids.

Hiskey and Northrop[56] obtained optically active aminoacids by hydrogenating the azomethine derivatives of α-ketoacids and (−)- and (+)-α-phenylethylamine on Pd/C, PtO_2, and $Pd(OH)_2/C$ catalysts according to the mechanism



Compound (XXI) (a Schiff base) was not isolated or identified, being immediately subjected to catalytic hydrogenation and hydrogenolysis with formation of the aminoacid. The results of these experiments are presented in Table 6, which shows that the configuration of the aminoacid formed depends on that of the α-phenylethylamine employed: the (+)-amine promotes the formation of the D-aminoacid. The optical yield of the aminoacid varies with the hydrogenation catalyst employed. The maximum optical yield was observed on 10% Pd/C. The addition of acid or alkali does not influence the course and the degree of asymmetric synthesis, in contrast to the asymmetric hydrogenation of ketoacids[22-24]. The size of the alkyl group in the α-ketoacid has a powerful influence on the degree of asymmetric synthesis. Thus, whereas the optical yield of D-alanine (R = CH_3) was 85%, under the same conditions phenylalanine (R = $C_6H_5CH_2$) was obtained with an optical yield of 56% and the optical yield of leucine [R = $(CH_3)_2CHCH_2$] was zero.

Table 6. Asymmetric yield of aminoacids obtained by the transamination of α-ketoacids RCOCOOH with optically active α-phenylethylamine.

α-ketoacid, R	Catalyst	Configuration of amine	Yield of aminoacid, %	Configuration, sign of rotation, optical yield of aminoacid, %
CH_3	10% Pd/C	(+)	47.9	*D*, (—); 85.2
CH_3	10% Pd/C	(—)	43.1	*L*, (+); 90.7
CH_3CH_2	10% Pd/C	(—)	84.9	*L*, (+); 81.4
CH_3CH_2	$Pd(OH)_2/C$	(+)	71.7	*D*, (—); 71.7
CH_3CH_2	PtO_2	(+)	59.2	*D*, (—); 56.3
$(CH_3)_2CH$	10% Pd/C	(+)	15.7	*D*, (—); 64.2
$(CH_3)_3$	$Pd(OH)_2/C$	(+)	0.0	—

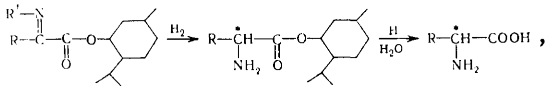
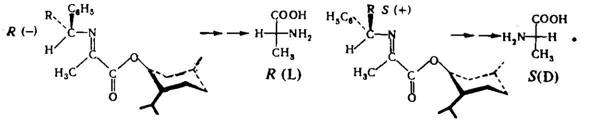
$C_6H_5CH_2$	10% Pd/C	(—)	65.0	*L*, (—); 56.0

The asymmetric synthesis of aminoacids by the hydrogenation of the C=N bond was also investigated by Harada and Matsumoto[26,58]. The oximes of the (–)-menthyl esters of pyruvic, α-oxobutyric, and phenylglyoxylic acids and also the Schiff bases of these esters with benzylamine and optically active α-ethyl-α-methylbenzylamines were employed as the starting materials:

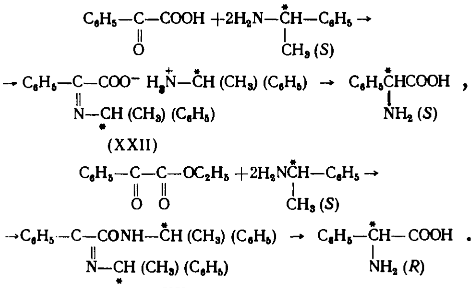


where R = CH_3, C_2H_5, or C_6H_5 and R′ = OH, $C_6H_5CH_2$, $C_6H_5CH(CH_3)$, or $C_6H_5CH(C_2H_5)$.

Table 7 shows that (–)-D-aminoacids are formed with a higher asymmetric yield in the hydrogenation of the oximes than in the hydrogenation of the corresponding Schiff bases with benzylamine. The stereochemistry of the reaction is consistent with Prelog's rule. On the other hand, the hydrogenation of Schiff bases with optically active amines showed that the asymmetric atom of the amine has a more marked influence on the stereospecific addition of hydrogen, namely when the (–)-(*R*)-amine was employed, the product was the (+)-L-aminoacid with a 19–24% optical yield. But when the steric effects of both asymmetric atoms are concerted, the yield of the aminoacid increases sharply and reaches 60%. Table 7 also shows that an increase in the size of the alkyl group at the asymmetric atom of the amine lowers the optical purity of the aminoacid formed. To account for these results, the following stereochemical reaction pathway was suggested[26,58]:



Kanai and Mitsui[59], who applied the method of Hiskey and Northrop[56,57], obtained optically active phenylglycine by the hydrogenation of benzoylformic acid and its ethyl ester in the presence of optically active (*S*)-phenylethylamine on various catalysts [PtO_2, Raney nickel, Pd/Cb, Pd/Ca, $Pd(OH)_2/C$]. It was established that the hydrogenation of ethyl benzoylformate on all the catalysts gives (*R*)-phenylglycine, while the hydrogenation of the acid itself under the same conditions leads to (*S*)-phenylglycine:



$$C_6H_5-\underset{\underset{O}{\|}}{C}-COOH+2H_2N-\underset{\underset{CH_3\,(S)}{|}}{\overset{*}{C}}H-C_6H_5\rightarrow$$

$$\rightarrow C_6H_5-\underset{\underset{N-\underset{*}{C}H\,(CH_3)\,(C_6H_5)}{\|}}{C}-COO^-\;H_3\overset{+}{N}-\overset{*}{C}H\,(CH_3)\,(C_6H_5)\rightarrow C_6H_5\underset{\underset{NH_2\,(S)}{|}}{\overset{*}{C}}HCOOH\ ,$$

(XXII)

$$C_6H_5-\underset{\underset{O}{\|}}{C}-\underset{\underset{O}{\|}}{C}-OC_2H_5+2H_2N\underset{\underset{CH_3\,(S)}{|}}{\overset{*}{C}}H-C_6H_5\rightarrow$$

$$\rightarrow C_6H_5-\underset{\underset{N-\underset{*}{C}H\,(CH_3)\,(C_6H_5)}{\|}}{C}-CONH-\overset{*}{C}H\,(CH_3)\,(C_6H_5)\rightarrow C_6H_5-\underset{\underset{NH_2\,(R)}{|}}{\overset{*}{C}}H-COOH\ .$$

(XXIII)

Table 7. Asymmetric synthesis of aminoacids by the hydrogenation of oximes and Schiff bases of (–)-menthyl esters of ketoacids.

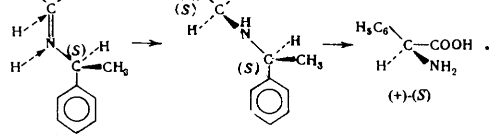
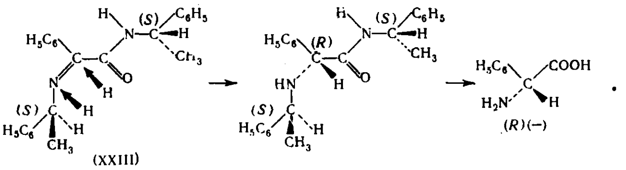
*DNP-aminoacid = dinitrophenyl derivative of aminoacid (Ed. of Translation).

The optical yield of phenylglycine did not exceed 2–3% with the exception of the hydrogenation of compound (XXII) on the highly stereospecific catalyst $Pd(OH)_2$, where the optical yield reached 73%. The authors suggested the following mechanism for the hydrogenation of compound (XXII):



(XXII)

To account for the experimental data, it is necessary to postulate that compound (XXIII) reacts preferentially in the conformation where the imino- and amido-groups are in the *trans*-positions:



(XXIII)

An attempt was made[26] to investigate the mechanism of the asymmetric synthesis of α-aminoacids by the hydrogenation of the C=N bond. The hydrogenation was carried out on a $Pd(OH)_2/C$ catalyst at room temperature. Three types of reactions were investigated: (1) hydrogenation of the Schiff bases of α-ketoacids with (−)-(*S*)- and (+)-(*R*)-α-methylbenzylamines and (−)-(*S*)- and (+)-(*R*)-α-ethylbenzylamines; (2) hydrogenation of the oximes of (−)-(*S*)-*N*- and (+)-(*R*)-α-methylbenzylbenzoylformamide and (−)-(*S*)-*N*- and (+)-(*R*)-*N*-α-ethylbenzylbenzoylformamide; (3) hydrogenation of the Schiff bases of (−)-menthyl pyruvate with (−)-(*S*)- and (+)-(*R*)-α-methylbenzylamines and (−)-(*S*)- and (+)-(*R*)-α-ethylbenzylamines (Table 8); (4) hydrogenation of the Schiff bases of the isobutyl ester of pyruvoyl-(+)-(*S*)-alanine and the isobutyl esters of pyruvoyl-(+)-(*S*)- and -(−)-(*R*)-valines with benzylamine (Table 12).

Table 8. Hydrogenation of the Schiff bases of α-ketoacids and optically active α-methyl- and α-ethylbenzylamines.

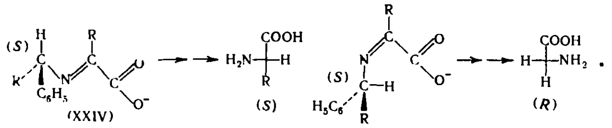
	C_2H_5 (+)	71	*R*, (+)	5	11
CH_2CH_2COOH	CH_3 (−)	74	*S*, (+)	13	12
	C_2H_5 (−)	75	*S*, (+)	2	6

The reaction of type 1 was investigated to test the mechanism proposed by Kanai and Mitsui[59]. Table 8 shows that the optical purity of the aminoacids formed depends on the bulk of the alkyl group in the α-ketoacid; namely the optical purity falls in the series $CH_3 > C_2H_5 > C_6H_5 > CH_2C_6H_5 > CH_2CH_2COOH$. The use of α-methylbenzylamine leads in all cases to a higher optical purity than is obtained with α-ethylbenzylamine. The data quoted contradict the mechanism proposed by Kanai and Mitsui[59]. If the conformations of molecules (XXII) and (XXIII) which they proposed are correct, the optical purity of the aminoacids should be independent of the size of the alkyl group and the optical yield should be higher when α-ethylbenzylamine is employed. Therefore it is necessary to put forward another mechanism for reactions of type 1:



(XXIV)

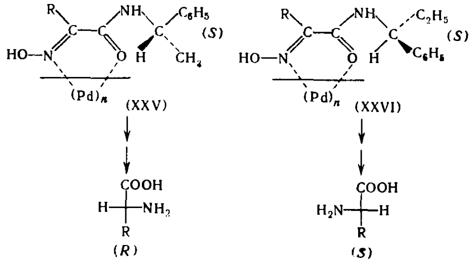
According to the experimental data, the structure (XXIV) is tentative but the increase in the size of the alkyl substituents both in the ketoacid and in the amine hinders the approach of hydrogen to the molecule, which lowers the optical purity of the product. This mechanism accounts satisfactorily for the experimental results and is consistent with the mechanism proposed by Hiskey and Northrop[56].

In reactions of type 2 optically active phenylglycine is obtained by the hydrogenation of the corresponding oxime. The results are given in Table 9.

Table 9. Hydrogenation of the oximes of optically active α-methyl- and α-ethyl-benzylbenzoylformamides.

Configuration of amine	Aminoacid			DNP-aminoacid
	yield, %	configuration, sign of rotation	Optical purity, %	Optical purity, %
CH_3, (-)-(*S*)	56	*R*, (−)	1.5	5.5
C_2H_5, (-)-(*S*)	52	*S*, (+)	1.4	8.8
CH_3, (+)-(*R*)	53	*S*, (+)	0.8	4.9
C_2H_5, (+)-(*R*)	48	*R*, (−)	2.1	10.0

When (*S*)- or (*R*)-α-methylbenzylamines were employed, the products were (*R*)- and (*S*)-phenylglycines respectively, in agreement with Prelog's rule. However, the use of (*S*)- and (*R*)-α-ethylbenzylamines yielded (*S*)- and (*R*)-phenylglycines. To account for these results, it is necessary to postulate that both structures (XXV) and (XXVI) react in the cisoid conformation, as shown in the scheme below:



However, when the methyl group of the optically active amine is replaced by the ethyl group, the molecule should probably react more readily in conformation (XXVI) and give rise to the (*S*)-aminoacid. The carbonyl and azomethine groups can interact with the catalyst (Pd/C) forming coordinate bonds and giving rise to a five-membered cyclic complex. This stabilises the *cis*-conformation of the substrate molecule. The possibility of the formation of such complexes for compounds with C=O and C=N bonds was discussed by Hartung and coworkers[60].

The study of the hydrogenation of optically active azomethine derivatives in various solvents showed that an increase in the polarity of the solvent leads to a decrease of the optical density of the aminoacid formed (alanine, phenylalanine, phenylglycine) and even to a change in the sign of the rotation (glutamic acid) (Table 10)[29].

Table 10. Effect of solvents on the configuration and optical yields of aminoacids.

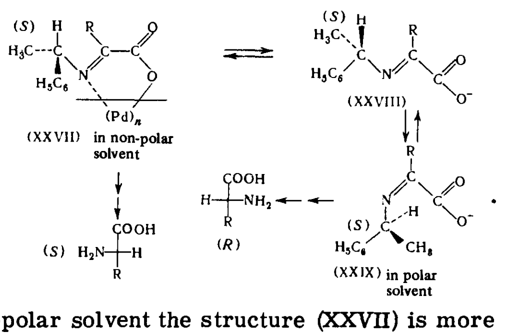
*The optical purity was calculated from the optical rotation of the dinitrophenyl derivatives of the aminoacids.
**The reaction mixture was not homogeneous.

The results suggest that the reactive conformation of the molecule changes under the influence of the solvent according to the mechanism



In a non-polar solvent the structure (XXVII) is more favourable, since the electrostatic attraction between the catalyst and the substrate is greater than under conditions where polar solvents are employed; the weak solvation of the substrate molecules in non-polar solvents promotes a more ready formation of the intermediate complex with the catalyst. In polar solvents the non-chelate structure (XXIX), which can be converted into the non-chelate structure (XXVIII) with decrease of the polarity of the medium, is more likely.

A study of the hydrogenation of oxaloacetic acid in the presence of various amines was undertaken to obtain optically active aspartic acid[61]. It was found that, depending on the amine and the solvent employed, either a mixture of alanine and aspartic acid or alanine alone are obtained (Table 11). The hydrogenation of the Schiff base with benzylamine in alcoholic solution gives racemic alanine. A similar result is also obtained with optically active α-methyl- and α-ethyl-benzylamines. On the other hand, when (+)-(*S*)- and (−)-(*R*)-phenylglycines were used, mixtures of (+)-(*S*)-alanine and (+)-(*S*)-aspartic acid and of (−)-(*R*)-alanine and (−)-(*R*)-aspartic acid were obtained:

The above reaction mechanism presupposes that the Schiff base of oxaloacetic acid formed can be readily decarboxylated with formation of the corresponding Schiff base of pyruvic acid, the hydrogenation and subsequent hydrogenolysis of which give alanine.

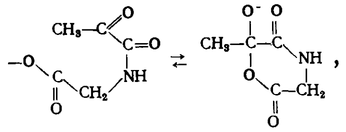
The mechanism of the asymmetric hydrogenation of azomethine derivatives of α-ketoacids proposed above[26] consists in the formation of an intermediate complex (XXV, XXVI) of the compound with the Pd catalyst and the subsequent adsorption of the substrate molecule on the catalyst surface and the addition of hydrogen to the C=N bond. This mechanism is proved by the results of an investigation of similar reactions in media of different polarity[29] and also the study of asymmetric hydrogenation of compounds with a peptide bond[57,62]. Hiskey and Northrop[57] achieved the asymmetric synthesis of peptides in the following experiments:

(a) reduction of *N*-pyruvoylglycine with optically active α-methylbenzylamine;

(b) reduction of *N*-pyruvoyl-L-alanine with optically active α-methylbenzylamine;

(c) reduction of *N*-pyruvoyl-L-alanine with benzylamine.

The experimental results showed that in the hydrogenation of the Schiff bases of pyruvoylglycine with (−)- and (+)-α-methylbenzylamines the optical yield of alanylglycine (30–60%) is lower than in the reduction of pyruvic acid under the same conditions (cf. Table 6). This can be accounted for by the unfavourable interaction between the keto- and carboxy-groups,

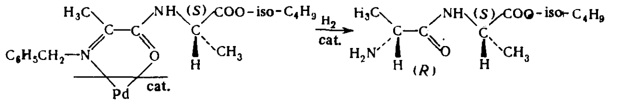


and also by an increase of steric hindrance due to the bulky substituent (glycine) at the carboxy-group of the ketoacid. Steric correlations in accordance with Prelog's rule hold in the reaction: when the (−)-amine is employed, the L-peptide is obtained and the (+)-amine gives rise to the D-peptide. The hydrogenation of *N*-pyruvoyl-L-alanine under the same conditions showed that the asymmetric atom of L-alanine does not play the main role in the formation of the new asymmetric centre: when the D-amine was employed, the product contained an excess of the D-L-isomer of the dipeptide, while in the presence of the L-amine, the L-L-isomer was obtained in excess. The hydrogenation of *N*-pyruvoyl-L-alanine in the presence of optically inactive benzylamine was carried out to elucidate the asymmetrising effect of the L-alanyl part of the molecule. Contrary to expectation, the D-L-dipeptide was found to be in an excess, although Prelog's rule predicts the formation of the L-L-dipeptide.

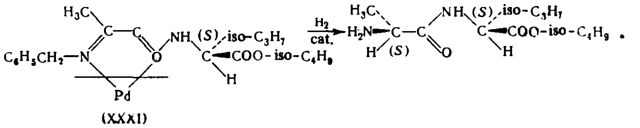
It is noteworthy that the dipeptides were obtained in these reactions in low yields (up to 30%). Possibly this is because *N*-pyruvoylalanine is reduced to lactic acid at a higher rate than that of the formation of the Schiff base; indeed lactic acid was found in the reaction mixture in a yield greater than 80%.

Harada and Matsumoto[62] achieved similarly the asymmetric synthesis of certain alanyl dipeptides and found that, in the hydrogenation of the Schiff bases of the isobutyl and methyl esters of *N*-pyruvoyl-(*S*)-alanine with benzylamine, the newly formed asymmetric atom has the (*R*)-configuration, i.e. the results are consistent with those of Hiskey and Northrop[57]. But, when the esters of optically active valine, leucine, phenylalanine, phenylglycine, and aspartic and α-aminobutyric acids were employed as the asymmetrising agents, the (*S*,*S*)-alanyl dipeptide was formed preferentially.

The authors proposed the following stereochemical mechanism for the reaction:



(XXX)



(XXXI)

When the alkyl substituent at the asymmetric carbon atom is R = CH_3, the substrate molecule reacts preferentially in conformation (XXX), but when the R group is larger than methyl, in all other reactions hydrogenation takes place preferentially with the substrate in conformation (XXXI). In both conformation (XXX) and (XXXI) the C=N and C=O groups are in the *cis*-positions stabilised by the formation of a complex with the catalyst. If the asymmetrising agent has the (*S*)-configuration, the hydrogenation of the molecule in conformation (XXX) leads to the formation of (*R*)-alanine, while conformation (XXXI) induces the formation of (*S*)-alanine. The hydrogenation of the Schiff bases and oximes of α-oxobutyric acid activated by various optically active aminoacids showed that in this case the reaction takes place preferentially in conformation (XXXI) (Table 13).

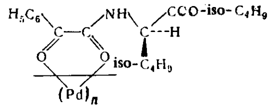
That the reaction proceeds via the formation of a complex of the substrate with the catalyst is proved to some extent by the study of the asymmetric synthesis of mandelic acid[62] (Table 14). Assuming that the molecule (for example in the synthesis of mandelic acid) forms with the catalyst a complex via two C=O bonds,



the authors concluded that the steric hindrance in the adsorption of keto-compounds is lower than for the azomethine derivatives (oximes and Schiff bases). The substituent at the C=N bond in the azomethines (OH or $CH_2C_6H_5$) increases the steric hindrance between the substrate and the catalyst and therefore the use of (*S*)-alanine alone (R = CH_3) leads to the (*R*)-configuration of the new asymmetric atom, i.e. the molecule reacts in conformation (XXX). In the hydrogenation of the keto-group the use of esters of (*S*)-alanine (R = CH_3) and (*S*)-leucine [R = $(CH_3)_2CHCH_2$] yields (*R*)-mandelic acid and only the use of (*S*)-valine [R = $(CH_3)_2CH$] gives rise to (*S*)-mandelic acid. Consequently in the first two reactions the substrate molecule reacts in conformation (XXX) and in the last case the preferred conformation is (XXXI).

The numerous examples quoted above demonstrate a significant effect of the substituent at the reacting bond on the effectiveness of asymmetric catalysis. Formally this phenomenon may be described by the correlation equation derived by Ugi[63] for asymmetric hydrogenation, which is of the form

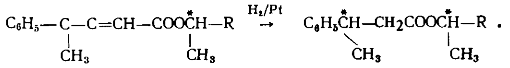
$$\lg Sp = \lg\frac{p}{100-p} = \varkappa\tau\delta_p,$$

where $\varkappa$ is the "chirality parameter" determined from $\varkappa = (\lambda_1 - \lambda_2)(\lambda_2 - \lambda_3)(\lambda_3 - \lambda_1)$ (λ_1, λ_2, and λ_3 are constants characterising the groups linked to the asymmetric atom in the ligands) and τ and δ_p are empirical constants.

Table 15. Calculation of the stereospecificities *Sp* from Ugi's equation for the hydrogenation of β-methylcinnamic acid esters.

R	$\varkappa$	δ_p	*Sp* (for τ = 0.110) calc.	*Sp* (for τ = 0.110) found	λ_R constant for group R
$(CH_3)_3C$	—0.730	—1	54.6	54.3	1.49
C_6H_5	—0.283	—1	52.0	52.3	1.23
2,4,6-$(CH_3)_3C_6H_2$	0.918	1	55.8	56.5	1.58
1-$C_{10}H_7$	—0.375	—1	52.5	53.8	1.29
2,4,6-$(C_6H_{11})_3C_6H_2$	2.303	1	64.3	63.5	2.10

For the hydrogenation of a number of optically active esters of β-methylcinnamic acid in acetic acid on platinum at 20°C, the calculated values of *Sp* agree well with experiment (Table 15).

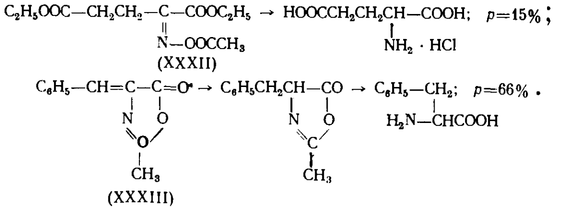


$$C_6H_5{-}C(CH_3){=}CH{-}COO\overset{*}{C}H(CH_3){-}R \xrightarrow{H_2/Pt} C_6H_5\overset{*}{C}H(CH_3){-}CH_2COO\overset{*}{C}H(CH_3){-}R\,.$$

IV. CATALYTIC SYNTHESIS OF OPTICALLY ACTIVE AMINOACIDS ON DISSYMMETRIC CATALYSTS

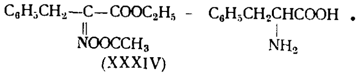
The first unsuccessful attempts at the asymmetric hydrogenation of acetophenone on nickel in the presence of cholic acid or sodium deoxychelate may be regarded as attempts at modifying the catalyst surface by adding an optically active compound to produce a dissymmetric catalyst[64]. Thus the asymmetric reduction by hydrogen transfer[36–38] could also be interpreted as involving interaction to some extent between the hydrogen donor (glucose) and the surface of the metal catalyst whereby the latter is specifically modified.

Isoda and coworkers[65] showed for the first time that the catalyst obtained by the reduction of the Pd–L-tyrosine complex is capable of promoting the asymmetric hydrogenation of compounds (XXXII) and (XXXIII) with formation of (–)-D-glutamic acid and (+)-D-phenylalanine:



Partial optical activation of the aminoacids formed is observed also in the hydrogenation of compounds (XXXII) and (XXXIII) on Raney nickel treated with (–)-tyrosine, (–)-leucine, (–)-phenylalanine, or (–)-arginine. Treatment with (–)-methionine does not lead to optically active products. At the same time modification of the Pd/C catalyst with methionine can be achieved and the hydrogenation of α-acetamidocinnamic acid (XXXIV) on such a catalyst leads to the formation of L-phenylalanine[66].

Isoda and coworkers[65] were guided by the statements of Akabori and coworkers[67–99], who obtained a dissymmetric catalyst by reducing $PdCl_2$ (33 wt. %) deposited on silk fibres at 50°C and 80 atm. In their first communications, Akabori and coworkers stated that such a catalyst is capable of promoting the asymmetric synthesis of aminoacids by the hydrogenation of (XXXII), (XXXIII), and (XXXIV) with an appreciable asymmetric yield—39, 38, and 26% respectively:



$$C_6H_5CH_2{-}C({=}NOOCCH_3){-}COOC_2H_5 \rightarrow C_6H_5CH_2CH(NH_2)COOH\,.$$

(XXXIV)

However, it is difficult to reproduce these results[70,71]. The studies of the effect of disymmetric nickel catalysts modified by optically active compounds were developed further in a number of investigations by Izumi, Akabori, and coworkers[70–73], mainly in the hydrogenation of the carbonyl group on the catalyst modified with (+)-tartaric acid[74] and aminoacids.

Klabunovskii and Petrov[75,76] extended the study of modified nickel catalysts to the hydrogenation of the C=N bond. Thus the hydrogenation of acetophenoxime takes place asymmetrically (*p* = 2.6%), which suggests that there is a possibility of the application of these catalysts in the synthesis of optically active aminoacids. This method has an undoubted advantage over others, since there is no need to introduce an asymmetrising group into the initial molecule.

There are so far few data on the mechanism of the asymmetrising effect of modified catalysts but already certain conclusions may be made[75,77]. Probably asymmetric hydrogenation takes place only with formation of a fairly stable intermediate complex via the mechanism

where S is the substrate, M the optically active modifying agent, and K the catalyst.

The formation of such a complex fixes the conformation of the reacting molecule in a particular way. The M–K, K–S, and S–M interactions in the complex may be examined in succession.

The M–K bond is responsible for the modification of the catalyst and the formation of a surface nickel complex with the modifying substance (hydroxy- or amino-compound). Such complexes are centres for asymmetric hydrogenation and the maximum asymmetric effect will be observed for the optimum stability of the complex. Approximate data on the stability of the M–K bond may be obtained from the stability constants K_S of nickel complexes of hydroxy- or amino-acids. Comparison of the literature data for the stability constants of the nickel complexes of certain aminoacids and the stereospecificities Sp shows that Sp passes through a maximum as K_S increases, i.e. an unduly high stability of the complex has an unfavourable effect on asymmetric catalysis—a situation analogous to the energy correspondence (the equality of the adsorption potential of the optimum catalyst to half the sum of the energies of the reacting bonds in the molecule) considered in the multiplet theory of catalysis. Klabunovskii showed[77] that there is an approximately linear relation between the logarithm of the stereospecificity Sp and the change in the enthalpy ΔH of the catalyst modifying agent employed in the hydrogenation of methyl acetoacetate on nickel modified with tartaric, malic, and mandelic acids, alanine, and leucine:

$$RT \ln Sp \simeq \Delta H \ .$$

The K–S bond is altered under the influence of the modification of the catalyst and therefore the bonding energy Q between the atoms in the reacting molecule and the catalyst Q_{K-S} will differ from the value $Q_{K'-S}$ for the unmodified catalyst K′.

The experimental data[70–73,78–80] show that, since fairly stable complexes are formed on chemisorption of C=O, C–OH, and C=N groups in the reacting molecule, the asymmetrising property of the catalyst is shown only in relation to C=O and C=N but not C=C bonds.

It is so far difficult to make a quantitative assessment of the S–M bond and therefore the only measure of the interaction between the molecules of the substrate and the modifying agent is the stereospecificity of the reaction.

Qualitative data may be obtained about the nature of the K–S and K–M bonds by means of the energy calculations of the multiplet theory of catalysis. The energies of the bonds of nickel with oxygen and nitrogen (57.7 and 29.3 kcal) greatly exceed the values for palladium and platinum (44.1 and 25.1 kcal; 34.3 and 24.4 kcal) and therefore nickel is readily modified by compounds containing free amino- and hydroxy-groups and forms more readily reactive complexes with substrates containing C=O and C=N bonds. At the same time the energy of the bond with hydrogen decreases in the series $Q_{Pt-H} > > Q_{Pd-H} > Q_{Ni-H}$, which facilitates the adsorption of the reacting compound on nickel and the oriented adsorption of the substrate molecule becomes rate-limiting.

However, these theoretical concepts still require a detailed experimental and quantitative development.

The validity of the hypothesis that asymmetric catalysis takes place via the formation of intermediate complexes is apparently confirmed by the known cases of the asymmetric synthesis of aminoacids[81,82] and asymmetric reactions under the influence of disymmetric catalysts[83–87].

Acyl Phosphites

E.E.Nifant'ev and I.V.Fursenko

The review deals with an interesting new field among organophosphorus compounds—the chemistry of acyl phosphites. The possible ways of synthesising and the chemical properties of these highly reactive compounds have been examined together with the likely mechanisms of the reactions considered.

The bibliography includes 111 references.

CONTENTS

I. INTRODUCTION

One of the results of the rapid development of the chemistry of organophosphorus compounds has been the discovery and detailed study of new classes of substances. In particular, one of such classes is acyl phosphites. Like other mixed anhydrides of phosphorus and carboxylic acids, acyl phosphites readily enter into phosphorylation and acylation reactions with nucleophilic agents. They react also with electrophilic agents owing to the presence of the unshared electron pair in the outer shell of the phosphorus atom. This property of acyl phosphites is responsible for the very wide range of reagents which react with them and makes them interesting objects for theoretical studies as well as important key substances in organophosphorus synthesis.

The majority of investigations of acyl phosphites have been carried out very recently and therefore there are no relevant reviews. This and also the appearance in the chemistry of acyl phosphites of certain new trends, characteristic also of other classes of organic derivatives of phosphorus, made it desirable to write the present article. The review is not merely a compilation. Together with a description of the advances in this field of chemistry, the authors make a critical assessment of certain experimental studies and put forward a number of general considerations concerning this subject.

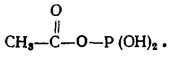
II. SYNTHESIS OF ACYL PHOSPHITES

1. The Reaction of Phosphorous Acid and Dialkyl Phosphites with Carboxylic Acid Anhydrides

In order to elucidate the structure of phosphorous acid, in 1866 Menshutkin allowed it to react with acetyl chloride and obtained a substance to which he attributed the following structure:

$$CH_3-\overset{\overset{O}{\|}}{C}-O-\overset{\overset{OH}{|}}{P}-O-P(OH)_2\,.$$

Somewhat later Vvedenskii achieved the reaction of phosphorous acid with acetic anhydride and isolated a crystalline product, which he believed to be monoacetyl phosphite:



$$CH_3-\overset{\overset{O}{\|}}{C}-O-P(OH)_2\,.$$

The same substance was obtained by Brooks[3] in a reaction of acetyl chloride with phosphorous acid under somewhat milder conditions than in Menshutkin's reaction. However, Cade[4] established on the basis of chemical and X-ray diffraction data that in fact the above workers did not obtain a mixed anhydride but acetylphosphonic acid: $CH_3C(O)PO(OH)_2$. Cade's conclusion concerning this reaction is consistent with the data of A. E. Arbuzov, who showed that sodium (and potassium) salts of dialkyl phosphites react with acetyl chloride to form 1-ketophosphonic acids[5]:

$$(RO)_2PONa + CH_3COCl \rightarrow (RO)_2\overset{\overset{O}{\|}}{P}-\overset{\overset{O}{\|}}{C}-CH_3 + NaCl\,.$$

Ketophosphonates are obtained similarly also in the reaction with benzoyl chloride[6].

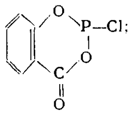
The reaction of carboxylic acid chlorides with dialkyl phosphites in the presence of tertiary amines has also been discussed in the literature. Here the products are not acyl phosphites, α-ketophosphonates and the corresponding enol carboxylates being isolated in a high yield[7]:

$$RCH_2-\overset{\overset{O}{\|}}{C}-Cl + H\overset{\overset{O}{\|}}{P}(OR')_2 \xrightarrow{+NR''_3} RCH_2-\overset{\overset{O}{\|}}{C}-\overset{\overset{O}{\|}}{P}(OR')_2 + R-CH=\overset{\overset{R-CH_2-CO-O}{|}}{C}-\overset{\overset{O}{\|}}{P}(OR')_2\,.$$

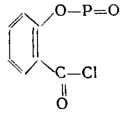
Thus so far it has not proved possible to find conditions under which phosphorous acid and salts of dialkylphosphorous acid react with carboxylic acid anhydrides to form $-\overset{\overset{O}{\|}}{C}-O-P\langle$ fragments and not $-\overset{\overset{O}{\|}}{C}-\overset{\overset{O}{\|}}{P}\langle$. However, in view of the limited number of publications on this question, one cannot state categorically that there is no possibility of developing methods for the synthesis of acyl phosphites on the basis of such reactions.

2. Reaction of Phosphorus(III) Acid Chlorides with Carboxylic Acids and Their Salts

Acyl phosphites were obtained for the first time by Anshutz and Emery[8] by the reaction of phosphorus trichloride with salicylic acid. They discussed two possible structures of the products:



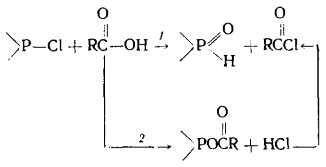
(IA)



(IB)

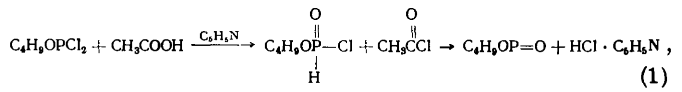
On the basis of preparative data for the reaction of carboxylic acids with phosphorous trichloride, which leads to acyl chlorides, the authors concluded that their compound has the structure (IB). This formula was attributed to compound (I) in the well known monograph of Kosolapoff[9]. Later Young[10] and Cade and Gerrard[11] established that the original conclusion was erroneous and the structure (IA) was assigned to the substance obtained by Anshutz and Emery. The data allowing this conclusion can be more usefully dealt with below in the section concerned with the reaction of amines with acyl phosphites (see p. 1059).

Further discussion of the preparation of acyl phosphites by the reaction of carboxylic acid with phosphorus(III) acid chlorides makes it necessary to consider the mechanism of this reaction. Cade and Gerrard[12] attempted to elucidate this problem. They attempted to discover whether there is a direct exchange of chlorine bound to the phosphorus atom for the hydroxy-group of the carboxylic acid (mechanism *1*) or whether chlorine is substituted by the acyloxy-group with formation of an acyl phosphite which reacts *in situ* with the hydrogen chloride liberated (mechanism *2*):



Bearing in mind that in the presence of pyridine acetyl chloride and acetic acid react to form acetic anhydride and pyridine hydrochloride[13] (this reaction takes place extremely rapidly even at −78°C), the authors carried out the reaction of dibutyl phosphorochloridite with two moles of acetic acid in the presence of one mole of pyridine. It was thought that, if the reaction proceeds via mechanism *1*, the acetyl chloride formed in the presence of pyridine should immediately react in the second stage with the residual mole of acid, forming acetic anhydride and pyridine hydrochloride. On the other hand, if the process proceeded via mechanism *2*, then the reaction products should contain acetyl dibutyl phosphite, pyridine hydrochloride, and one mole of unreacted acid.

Since Cade and Gerrard obtained a 92% yield of acetic anhydride, they considered it proved that the reaction of carboxylic acids with phosphorus(III) acid chlorides takes place via mechanism *1*. Attributing great importance to the formation of acetic anhydride in their experiments and failing to see another mechanism of its formation, these workers suggested that mechanism *1* obtains also when a carboxylic acid salt and pyridine are introduced into the reaction with phosphorochlorodites. In this connection the considerations they put forward concerning the mechanism of the reaction of butyl phosphorodichloridite with two moles of acetic acid and two moles of pyridine, which leads to the formation of diacetyl butyl phosphite[12], are noteworthy. They asserted that at the beginning there is "as usual" a direct exchange of one of the chlorine atoms of butyl phosphorodichloridite for a hydroxy-group with formation of acetyl chloride and butyl hydrogen phosphorochloridite, which decomposes into butyl metaphosphite and pyridine hydrochloride. Subsequently acetyl chloride reacts with another mole of acetic acid and forms acetic anhydride, which reacts with the metaphosphite to give diacetyl butyl phosphite:



$$C_4H_9OPCl_2 + CH_3COOH \xrightarrow{C_5H_5N} C_4H_9O\underset{H}{\overset{O}{\overset{\|}{P}}}{-}Cl + CH_3\overset{O}{\overset{\|}{C}}Cl \rightarrow C_4H_9OP{=}O + HCl\cdot C_5H_5N\,, \tag{1}$$

$$CH_3\overset{O}{\overset{\|}{C}}Cl + CH_3COOH \xrightarrow{C_5H_5N} (CH_3CO)_2O + HCl\cdot C_5H_5N\,, \tag{2}$$

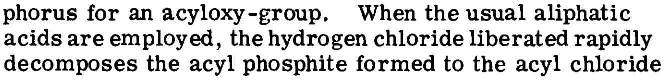
$$C_4H_9OP{=}O + (CH_3CO)_2O \rightarrow C_4H_9OP(OCOCH_3)_2\,. \tag{3}$$

Cade and Gerrard saw a confirmation of this mechanism in the fact that the metaphosphite formed by the controlled hydrolysis of butyl phosphorodichloridite indeed reacted with acetic anhydride to form diacetyl phosphites. Thus, having discovered a new way of synthesising acetyl phosphite (unfortunately they quote only one example, which precludes the consideration of this reaction in a separate section), the authors omitted from all their discussions another way in which the actual products may be formed: namely by the reaction of equimolar amounts of acyl phosphite and carboxylic acid to give dialkyl phosphite and acetic anhydride[14] (see p. 1056). Having disregarded this possibility, Cade and Gerrard could not find an alternative mechanism for the formation of acetic acid anhydride in their experiments and therefore arrived at an incorrect conclusion concerning the reaction of carboxylic acids and their salts with phosphorus(III) acid chlorides.

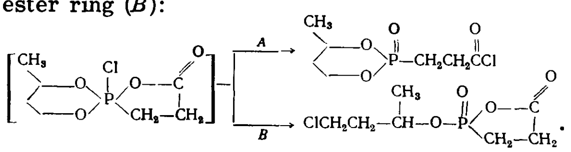
That the conclusion of Cade and Gerrard was incorrect was subsequently shown experimentally by Anderson and Young[15–17], who successfully employed dialkyl phosphorodichloridites in reactions with carboxylic acids in the presence of tertiary amines in order to obtain acyl phosphites.

The above analysis of the literature data shows that most probably the reaction of carboxylic acids and their salts with phosphorus(III) acid chlorides consist in a nucleophilic substitution of a chlorine atom bound to phosphorus for an acyloxy-group. When the usual aliphatic acids are employed, the hydrogen chloride liberated rapidly decomposes the acyl phosphite formed to the acyl chloride and acid phosphite and therefore mixed anhydrides cannot be obtained by this method. Cyclic acyl phosphites synthesised from acids having substituents with functional groups are more resistant to the action of hydrogen chloride. For example, salicylic acid reacts with phosphorus dichloride to form compound (IA) without a hydrogen chloride acceptor. Similarly mercaptoacetic acid gives a stable mixed anhydride[18,19]. Probably acyl phosphites based on other acids with specific structural factors can also be prepared in this way.

In a discussion of the general problem of the reaction of phosphorochloridites with carboxylic acids, it is necessary to consider in greater detail the studies on $\alpha\beta$-unsaturated acids carried out in recent years. A mechanism different from those analysed above has been proposed for this case. Acrylic and methacrylic acids react with cyclic glycol phosphorochloridites to form oligomeric products. The reaction proceeds readily and in some cases with liberation of heat. It is suggested that the mechanism of the process includes as the initial stage nucleophilic attack by the phosphorus atom on the β-carbon atom in the acid with subsequent cyclisation[20,21]:



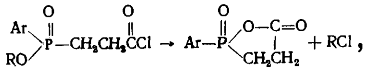
The authors believe that the cyclic product can isomerise in two ways: with opening of the anhydride ring (*A*) or the ester ring (*B*):



They assert[20,21] that the ester ring is opened since the infrared spectrum of the products has an intense band at 1720 cm^{-1}, which can only be due to the carbonyl group in the ester and not the acid chloride group; moreover the substance contains hardly any mobile chlorine. Thus, if the above mechanism is adopted, one may conclude that the quasiphosphonium chloride decomposes anomalously, since in such cases the chloride anion usually attacks the more electrophilic carbon of the carbonyl group (mechanism *A*). It is more likely that, if a bicyclic quasiphosphonium intermediate is in fact formed in this reaction, it decomposes via mechanism *A* with subsequent conversion into the product postulated in mechanism *B*. This hypothesis is consistent with the available data concerning the tendency of neutral phosphonates[22] and phosphates[23] to react with acetyl chloride:

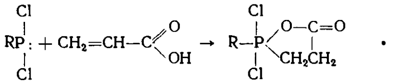
$$(RO){>}\overset{O}{\overset{\|}{P}}OR + CH_3\overset{O}{\overset{\|}{C}}Cl \rightarrow (RO){>}\overset{O}{\overset{\|}{P}}{-}O\overset{O}{\overset{\|}{C}}CH_3 + RCl\,.$$

Moreover, the above hypothesis is confirmed directly by the latest work of Pudovik and coworkers, who quote data on the reaction of ester chlorides of phosphonous acids with $\alpha\beta$-unsaturated acids. They succeeded in isolating the chlorides of phosphonocarboxylic acids and in showing that they are unstable and readily undergo cyclisation[24,25]:

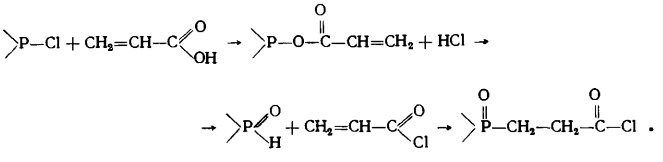


i.e. a reaction takes place, the possibility of which had not been taken into account in studies dealing with the reaction of alkylene phosphorochloridites with unsaturated acids[20,21].

In conclusion of the discussion of the reaction of phosphorus(III) acid chlorides with $\alpha\beta$-unsaturated acids, it is necessary to consider the results obtained in the investigation of the reaction of the unsaturated acids with dichlorophosphines. Here the only products isolated were the chloride anhydrides of phosphorylates carboxylic acids[26,27], the formation of which was explained by the mechanism already considered:



Thus one may say that, according to published data, the reaction of phosphorus(III) acid chlorides with $\alpha\beta$-unsaturated acids proceeds via a stage involving the formation of a cyclic compound. However, the formation of a cyclic adduct has been in no way proved. Moreover, the mechanism has not been confirmed by recent investigations either[28]. We believe that the formation of the final products can be accounted for by a simpler mechanism, which follows logically from the facts discussed above:



$$>P{-}Cl + CH_2{=}CH{-}C\begin{smallmatrix}\nearrow O\\ \searrow OH\end{smallmatrix} \rightarrow\ >P{-}O{-}\overset{O}{\overset{\|}{C}}{-}CH{=}CH_2 + HCl \rightarrow$$
$$\rightarrow\ >P\begin{smallmatrix}\nearrow O\\ \searrow H\end{smallmatrix} + CH_2{=}CH{-}C\begin{smallmatrix}\nearrow O\\ \searrow Cl\end{smallmatrix} \rightarrow\ >\overset{O}{\overset{\|}{P}}{-}CH_2{-}CH_2{-}\overset{O}{\overset{\|}{C}}{-}Cl\,.$$

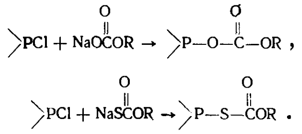
This course of the process explains why the reaction of phosphorochloridites with $\alpha\beta$-unsaturated acids of the type RCH=CHCOOH with substituents at the β-carbon atom takes place in an unusual way: thus crotonic and cinnamic acids do not form the above products and are only converted into their chlorides[29]. Probably in this case the reaction stops at an intermediate stage, since acid phosphites should add less readily to such chlorides owing to the steric and electrostatic effects of the hydrocarbon groups.

Summarising the discussion of the literature data on the reaction of phosphorus(III) acid chlorides with carboxylic acids, the following may be noted. At the present time there is no convincing proof for a particular mechanism of this reaction, but the known facts indirectly confirm that in all the syntheses which have been achieved the primary products are acyl phosphites. In some cases acyl phosphites were isolated in a pure form but usually they are decomposed by hydrogen chloride to acid phosphites and acyl chlorides.

For preparative purposes, acyl phosphites are best synthesised from phosphorus(III) acid chlorides and carboxylic acid salts. Optimum results are obtained when alkali metal salts are employed. Experimentally this method is distinguished by simplicity and ease of isolation of the required products. The reaction is of general importance. On the one hand, aliphatic and aromatic phosphorochloridites[30-34], phosphoramidochloridites[33], and phosphonous acid chlorides[33,35,36] and, on the other hand, salts of various aliphatic and aromatic acids enter into it.

The reaction of phosphorochloridites with formic acid salts is of considerable interest, since it is known that formic anhydrides constitute a little investigated group of compounds in organic chemistry. Unfortunately the formyl phosphites obtained proved to be unstable, decomposing with liberation of carbon monoxide. The second decomposition product is acid phosphite[33]. Since this decomposition is not accompanied by other side processes, formyl phosphites are promising reagents for the synthesis of certain acid phosphites.

Dialkyl phosphorochloridites react also with salts of alkylcarbonic[37] and alkylthiocarbonic[38,39] acids:



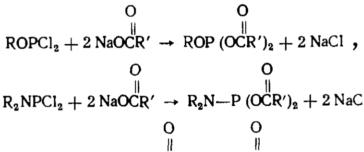
$$>PCl + NaO\overset{O}{\overset{\|}{C}}OR \rightarrow\ >P{-}O{-}\overset{O}{\overset{\|}{C}}{-}OR\,,$$
$$>PCl + NaS\overset{O}{\overset{\|}{C}}OR \rightarrow\ >P{-}S{-}\overset{O}{\overset{\|}{C}}OR\,.$$

Phosphite-carbonates are of interest for the synthesis of completely esterified phosphorus(III) acids and natural acidophilic alcohols, since phosphorylation by phosphite-carbonates should be accompanied by the liberation of monoalkyl carbonates, which, by virtue of their extreme instability, decompose into alcohols and carbon dioxide—substances which are inert with respect to neutral phosphites.

When dialkyl phosphorochloridites react with silver carbonate, a symmetrical phosphite-carbonate is formed, which is also unstable and is readily decarboxylated to pyrophosphite[40]:

$$2\,(RO)_2PCl + Ag_2CO_3 \rightarrow (RO)_2P{-}O{-}\overset{O}{\overset{\|}{C}}{-}O{-}P\,(OR)_2 \rightarrow CO_2 + (RO)_2P{-}O{-}P\,(OR)_2\,.$$

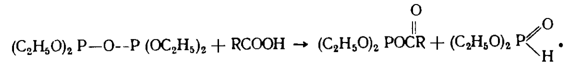
Apart from phosphorus(III) monochlorides, dichlorides[41] and also phosphorus trichloride[42] react with carboxylic acid salts, forming di- and tri-acyl phosphites, for example:



$$ROPCl_2 + 2\,NaO\overset{O}{\overset{\|}{C}}R' \rightarrow ROP\,(O\overset{O}{\overset{\|}{C}}R')_2 + 2\,NaCl\,,$$
$$R_2NPCl_2 + 2\,NaO\overset{O}{\overset{\|}{C}}R' \rightarrow R_2N{-}P\,(O\overset{O}{\overset{\|}{C}}R')_2 + 2\,NaCl\,,$$
$$PCl_3 + 3\,NaO\overset{O}{\overset{\|}{C}}R' \rightarrow P\,(O\overset{O}{\overset{\|}{C}}R)_3\,.$$

3. Reaction of Pyrophosphites with Carboxylic Acids

Acyl alkyl phosphites were obtained for the first time by the acidolysis of tetraethyl pyrophosphites using a method developed by A. E. Arbuzov and Alimov[43]. These investigators showed that pyrophosphite reacts with carboxylic acids with liberation of heat according to the following mechanism:

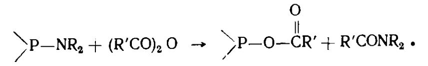


$$(C_2H_5O)_2P{-}O{-}P(OC_2H_5)_2 + RCOOH \rightarrow (C_2H_5O)_2PO\overset{O}{\overset{\|}{C}}R + (C_2H_5O)_2P\Big\langle^{O}_{H}\,.$$

Anderson et al.,[44] who employed tetraethyl pyrophosphite for the synthesis of peptides, also stated that acyl phosphites are formed as intermediates. Despite its ease, this method of synthesis has many disadvantages. Firstly, it is not universal, since frequently it is difficult to separate by distillation the anhydride and the side product (acid phosphite). Secondly only half of the phosphorus bound to the organic group is usefully employed in this method. Moreover, one must remember that the initial pyrophosphites are frequently difficult to obtain. These reasons probably explain why the above method of synthesis of acyl phosphites has not found preparative application.

4. Reaction of Phosphorus(III) Acid Amides with Carboxylic Acids and Their Anhydrides

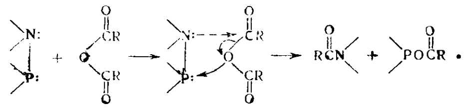
A novel synthesis of acyl phosphites distinguished by a high yield of the desired product is based on the reaction of the amides[45-49] and hydrazides[49] of phosphorus(III) acids with carboxylic acid anhydrides:



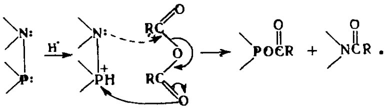
$$>P{-}NR_2 + (R'CO)_2O \rightarrow\ >P{-}O{-}\overset{O}{\overset{\|}{C}}R' + R'CONR_2\,.$$

A series of acyl phosphites and acyl phosphinites have been obtained in this way, but this method can hardly be recommended for preparative purposes, since the second reaction product (the acyl amide or acyl hydrazide) frequently has a boiling point close to that of the required product. In this case the separation of the products is extremely difficult. Moreover, in the reaction of triamide of phosphorous acid with 1, 2, or 3 moles of acetic anhydride, it was not possible to isolate acetyl phosphorodiamidite, diacetyl phosphoroamidite, or triacetyl phosphite respectively[46]. Formyl phosphites cannot be obtained by this method, since formic acid anhydride does not exist. It should also be noted that the amides and even more so the hydrazides of phosphorus(III) acids are in most cases more difficult to obtain than the chlorides (the latter are frequently employed as the starting materials for the synthesis of the amides). Thus the reaction of phosphorus(III) amides and hydrazides with mixed carboxylic acid anhydrides must be regarded as a new reaction of compounds with a phosphorus–nitrogen bond rather than as a preparative method for synthesising acyl phosphites.

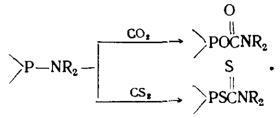
The study of the mechanisms of this process is of considerable interest. Recently the first mechanism was proposed, according to which the carbon in the carbonyl group is subjected to nucleophilic attack by the nitrogen atom with a free electron pair[46]:



This treatment of the mechanism is open to a number of objections. In particular, it contradicts the available data showing the greater nucleophilicity of the phosphorus(III) atom compared with the nitrogen atom in phosphorus(III) amides[50-52]. Bearing in mind what has been said above and also the observations according to which phosphoramidites frequently react in a protonated form[41,53], a different mechanism may be proposed for this reaction:



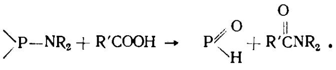
By the reaction of phosphoramidites with carbon dioxide and carbon disulphide, it proved possible to obtain mixed anhydrides of *NN*-substituted carbamic acids and phosphoramidous and phosphorodiamidous acids[54-56]:



However, the attempts to synthesise the trianhydrides of phosphorous and carbamic acids were unsuccessful.

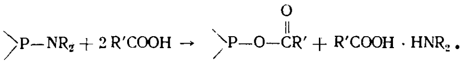
In a study of carbonylation it was established that the reaction takes place successfully only in the presence of proton donors, for example amine hydrochlorides[57]. Probably the mechanism of this process is the same as that considered above for carboxylic acid anhydrides.

One of the preparative methods for the synthesis of carboxylic acid amides is the reaction of phosphoramidites with carboxylic acids[58]:



$$>P{-}NR_2 + R'COOH \rightarrow P\Big\langle^{O}_{H} + R'\overset{O}{\overset{\|}{C}}NR_2\,.$$

A new application of this reaction, permitting the preparation of acyl phosphites, has been recently demonstrated[59]:



$$>P{-}NR_2 + 2\,R'COOH \rightarrow\ >P{-}O{-}\overset{O}{\overset{\|}{C}}R' + R'COOH\cdot HNR_2\,.$$

Probably this method will be of synthetic value in those cases where phosphorus(III) acid amides are more readily available than their chlorides.

5. Reaction of Acetyltrialkylsilanes with Phosphorous Acid Halides

In 1952 Anderson[60] reported that the exchange of a halogen linked to the phosphorus(III) atom for acyloxy-group takes place readily when trimethylsilyl α-monochloroacetate reacts with phosphorus tribromide:

$$2\,M_3SiCOOCH_2Cl + PBr_3 \rightarrow 3\,M_3SiBr + P(O\overset{O}{\overset{\|}{C}}CH_2Cl)_3\,.$$

Later Orlov and Kaufman[61], who investigated this reaction with phosphorus trichloride, found that triacetyl phosphite is not formed and the process takes place by the following mechanism:

$$3\,R_3SiOAc + PCl_3 \rightarrow Ac\overset{O}{\overset{\|}{P}}(OSiR_3)_2 + 2\,AcCl + R_3SiCl\,.$$

It appears that Anderson's report is incorrect.

---o0o---

Thus several types of reactions leading to mixed anhydrides of phosphorus(III) and carboxylic acids are known at present. We believe that in most cases the most promising method of synthesising acyl phosphites is based on the reaction of sodium (or potassium) salts of carboxylic acids with phosphorus(III) acid chlorides. The method is fairly general and experimentally simple, giving high yields of the desired products.

III. CHEMICAL PROPERTIES OF ACYL PHOSPHITES

All the reactions of acyl phosphites, which are probably heterolytic processes, can be divided into two large groups on the basis of the reagents employed—electrophilic and nucleophilic. Such subdivision of the available data is of course arbitrary and is used merely to facilitate description.

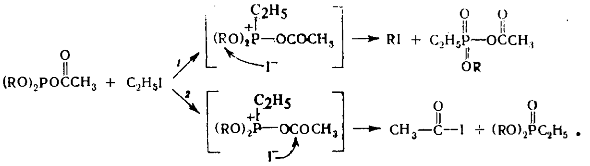
A. REACTIONS WITH ELECTROPHILIC AGENTS

1. Oxidation and Addition of Sulphur

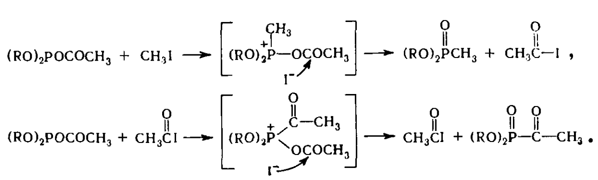
Like all compounds containing a phosphorus(III) atom, acyl phosphites are readily oxidised to acyl phosphates[30], combine with sulphur[43,45], and react with monohalogenocompounds of copper with liberation of heat, forming crystalline products[43,62]. As was to be expected, derivatives containing phosphorus-carbon bonds are very reactive in these processes.

2. The Arbuzov Reaction

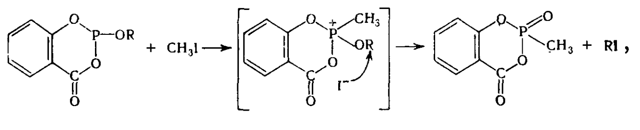
The fundamental process in the chemistry of organophosphorus compounds is the Arbuzov reaction. It has recently been applied to acyl phosphites. Since acyl phosphites contain both alkoxy- and acyloxy-groups at the phosphorus atom, it might have been expected that the process would involve the elimination of either an alkyl or an acyl halide:



In 1951 A. E. Arbuzov and Alimov reported[43] that the reaction of diethyl isovaleroyl phosphite with ethyl iodide gives a low yield of an isomerisation product via mechanism *1*. At the same time there is a high yield of a product the structure of which the authors did not establish. Later Pudovik and coworkers[63,64] showed that the intermediate complex decomposes predominantly via mechanism *2*, and the acid halide liberated reacts in turn with the acyl phosphite:

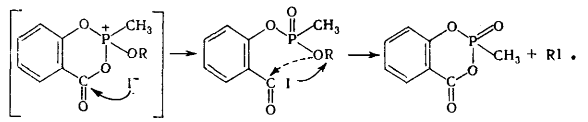


It is interesting that, when methyl iodide is introduced into the reaction, it remains almost completely unchanged. It is quite evident that in this case the process takes place via the Arbuzov mechanism and in the second stage of the reaction the iodide ions attack the more electrophilic centre—the carbon of the carbonyl and not the alkoxy-group. It is noteworthy that in the alkylation of salicylphosphorous acid esters by methyl iodide the overall situation changes. According to Nesterov and Sabirova[65], who achieved this reaction, the iodide ion attacks the carbon of the alkoxy-group which results in the formation of phosphonates in high yields:



where R = CH_3, C_2H_5, or iso-C_4H_9.

The authors of the above investigation believe that this mode of reaction is most likely, since "the C–O bond is polarised in the required direction in the alkoxy-group"[65]. This statement is not altogether clear. Another reaction mechanism, which does not contradict data showing a greater electrophilicity of the carbon atom in the carbonyl group compared with the carbon atom in the alkoxy-group, is more likely:

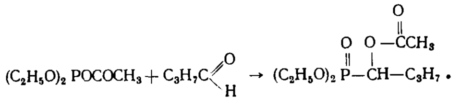


The studies confirming the possibility of the concluding stage of the reaction were discussed above (p. 1052).

Above we considered the interaction of acyl phosphites with acyl halides as an intermediate stage in certain reactions. Later this process was investigated also as an independent reaction, using as the acyl chlorides the chlorides of mono-, di-, and tri-chloroacetic acids[66].

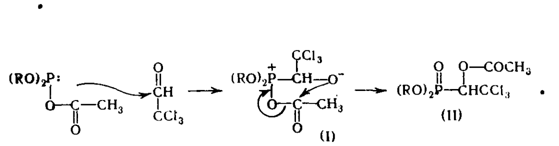
3. Reaction with Aldehydes and Ketones

In 1956 Alimov and Cheplanova reported that the reaction of acetyl diethyl phosphite and butyraldehyde results in the formation of α-acetoxybutyl diethyl phosphonate[67]:

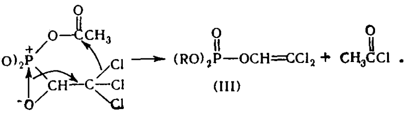


$$(C_2H_5O)_2POCOCH_3 + C_3H_7C\overset{O}{\underset{H}{\lt}} \rightarrow (C_2H_5O)_2\overset{O}{\overset{\|}{P}}-\overset{O-\overset{O}{\overset{\|}{C}}CH_3}{\overset{|}{C}H}-C_3H_7\,.$$

Subsequently other workers extended this reaction to new systems[34,68]. The reaction of α-halogenoaldehydes with acyl phosphites is similar to that of the simplest aldehydes[70,71]:

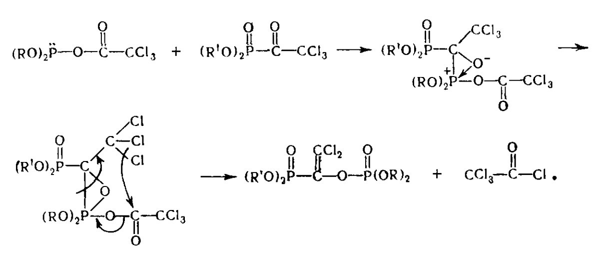


In this case the reaction takes place much more readily (with spontaneous liberation of heat). This was in fact to be expected, bearing in mind that the reaction begins with the nucleophilic attack by the phosphorus(III) atom on the carbon atom in the carbonyl group. The dipolar adduct (I) formed in the first stage of the process has two electrophilic centres: the phosphorus atom and the carbon atom of the carbonyl group. Consequently in the second stage of the reaction the attack by the negatively charged oxygen atom may be directed either to the carbonyl group, with formation of a product having the phosphonate structure (II), or to the phosphorus atom, whereupon the mechanism of the Perkow reaction[71] may obtain with formation of a product having the enol phosphate structure (III):



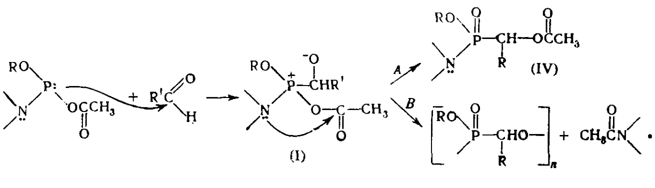
Indeed in some cases, for example in the reaction of acetyl di-isobutyl phosphite with chloral, ββ'-dichlorovinyl di-isobutyl phosphate was isolated together with α-acetoxyphosphonate[71]. It is noteworthy that in the reaction of chloral with dialkyl phosphites, enol phosphates are formed preferentially[72]. This difference in the behaviour of trialkyl phosphites and acyl dialkyl phosphites can probably be explained by the presence in the molecules of the latter of a carbonyl group, which in the second stage of the process may be attacked by the negatively charged oxygen atom in preference to the phosphorus atom.

Pudovik and Gazizov obtained very interesting results in a study of the reaction of acyl dialkyl phosphites with trichloroacetylphosphonic acid esters[66]:



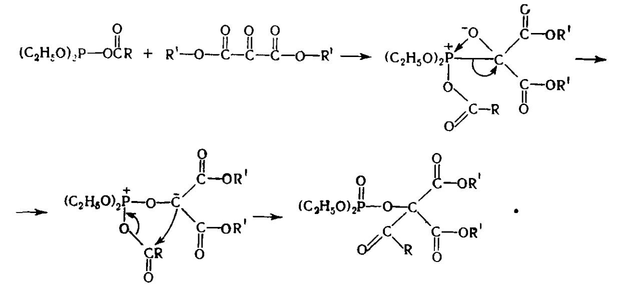
The mechanism of this reaction is different from that with chloral. Evidently the $(RO)_2P{=}O$ group, which replaces a hydrogen atom in chloral, increases the electrophilicity of the phosphonic acid centre. As a result, the attack by the anionic centre is directed to the phosphorus atom and not to the carbon atom in the carbonyl group, and the reaction proceeds via the Perkow mechanism. The occurrence of both competing reactions has been discovered when aldehydes were allowed to react with acetyl phosphoramidites[69].

Possibly in this case the reaction proceeds via a stage involving the formation of a dipolar ion of type (I), which either rearranges under the influence of the nucleophilic attack by the negatively charged oxygen atom on the carbon atom of the carbonyl group with formation of the phosphonate (IV) (mechanism *A*) or decomposes to acetamide and a phosphorus-containing polyester (mechanism *B*):



4. Reaction with α-Ketoacid Esters

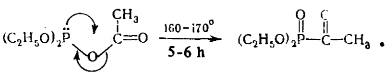
Acyl phosphites react with mesoxalic esters. Probably in this case the phosphorus(III) atom exhibits its nucleophilic properties[73]:



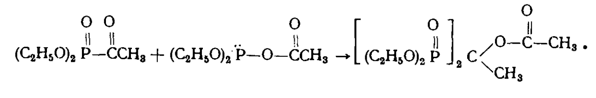
It must be emphasised that in this reaction the attack by the carbanionic centre of the intermediate compound is directed to the carbon atom of the carbonyl and not the alkoxy-group, as happens in the reaction of neutral phosphites with mesoxalic acid esters. Pyruvate and glyoxylate esters react with acyl phosphites similarly to mesoxalic acid esters[74].

5. Thermal Isomerisation

In contrast to acyl phosphates[32,75], acyl phosphites are not readily disproportionated on heating to pyrophosphites and carbon dioxide. However, they can undergo a rearrangement, the mechanism of which is as follows[32]:

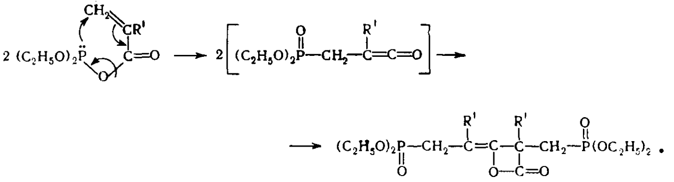


This rearrangement is a kind of intramolecular version of the Arbuzov reaction. The diethyl acetylphosphonate formed reacts further with another molecule of acetyl diethyl phosphite with formation of methylbis(diethylphosphono)methyl acetate:



$$(C_2H_5O)_2\overset{\overset{O}{\|}}{P}-\overset{\overset{O}{\|}}{C}CH_3+(C_2H_5O)_2\ddot{P}-O-\overset{\overset{O}{\|}}{C}CH_3\rightarrow\Big[(C_2H_5O)_2\overset{\overset{O}{\|}}{P}\Big]_2C\begin{smallmatrix}O-\overset{\overset{O}{\|}}{C}-CH_3\\ CH_3\end{smallmatrix}.$$

The isomerisation of acyl phosphites formed by αβ-unsaturated acids takes place in an unusual manner. In the first stage of the reaction a phosphorylated ketone is formed, which, being unstable, undergoes subsequent isomerisation[32]:

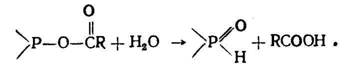


B. REACTIONS WITH NUCLEOPHILIC AGENTS

Acyl phosphites have two electrophilic reaction centres: the carbon atom in the carbonyl group and the phosphorus atom. This property of acyl phosphites leads to the expectation that two series of reaction products may be formed, the structure of which is determined by the mode of attack by the nucleophilic agent.

1. Hydrolysis

When water acts upon acyl phosphites, the latter decompose into the carboxylic and the corresponding phosphorous acids. The reaction is accompanied by the liberation of heat[43,62]:



$$\rangle P-O-\overset{O}{\overset{\|}{C}}R + H_2O \rightarrow \rangle P\overset{O}{\underset{H}{\lessdot}} + RCOOH\,.$$

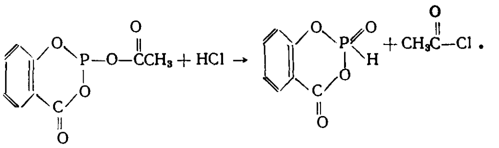
It is noteworthy that the formation of the final products may take place as a result of the attack by the hydroxy-group on both the phosphorus atom and the carbon atom in the carbonyl group. This problem still remains open.

2. Reaction with Acids

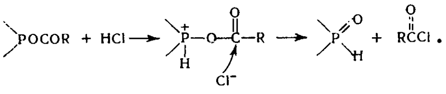
Data have been published on the reaction of certain acyl phosphites with hydrogen chloride. It has been established that salicyl phosphorochloridite hardly changes in the presence of hydrogen chloride. However, butyl salicyl phosphate is cleaved with formation of butyl phosphorodichloridite[76]. The hydrochlorination of diacetyl trifluoromethyl phosphonite, resulting in the formation of acetic acid and dichlorotrifluoromethylphosphine, is formally analogous to this process[35]:

$$CF_3P(OCOCH_3)_2 + HCl \rightarrow CF_3PCl_2 + 2\,CH_3COOH\,.$$

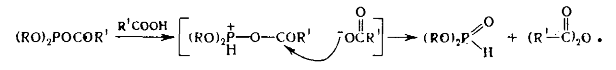
The mechanism of these reactions has not been investigated and the available data do not allow the appropriate analysis. However, we may conclude that the reactions considered are accompanied by the formation of phosphorus–chlorine bonds and are energetically favourable under the given conditions. Another result was obtained for reactions of hydrogen chloride with acetyl salicyl phosphite[77] and acetyl dialkyl phosphites[78]:



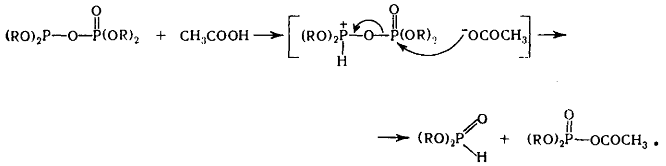
Evidently the latter syntheses proceed via a mechanism similar to that which was adopted for the alkylation of acyl phosphites:



This mechanism is also consistent with the results of the reaction of acyl phosphites with carboxylic[14,33,79]†, dialkylphosphoric[80], and dialkylphosphorodithioic[81] acids:



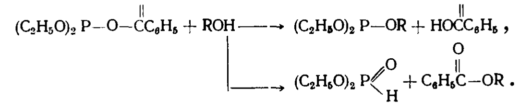
Probably the Arbuzov mechanism operates also in the reaction of neutral subphosphates with acetic acid[82]:



This process can be represented in a different way too: initially there is transacylation to acyl phosphite and dialkylphosphoric acid, which then react with one another to form the products isolated. However, ultimately these mechanisms do not differ significantly.

3. Reaction with Alcohols

One may expect that the alcoholysis of acyl phosphites will lead to the formation of either phosphorus(III) acid esters or carboxylic acid esters. A. E. Arbuzov and Alimov[43] showed that benzoyl diethyl phosphite reacts with alcohols to give a small yield of a phosphorylated product, i.e. of the possible modes of reaction the first actually occurs:



(1)

(2)

Subsequently certain additional data on this reaction were published[30,31,62,76,83,84]. They are mainly concerned with the fact that the reaction of acyl phosphites with alcohols yields both neutral phosphites and dialkyl phosphites. This result was explained by secondary dealkylation of the neutral phosphites formed initially[31,85].

The possibility, in principle, of this reaction at an elevated temperature has been demonstrated[86]. Therefore, in order to prevent the dealkylation side process, it is recommended that neutral phosphites be employed only in the presence of acid acceptors (triethylamine[31,85] or dialkyl phosphoramidites[83,85]). The authors of these hypotheses note themselves that the use of such procedures gives rise to considerable experimental difficulties in the isolation of the required products. Consequently this version of the method does not have fundamental advantages over the alcoholysis of phosphorochloridites, which also requires the application of an acceptor; moreover, phosphorochloridites are more readily available and are usually employed as the starting materials in the synthesis of acyl phosphites.

Thus the procedures for the phosphorylation of alcohols by acyl phosphites described in the early investigations are of no synthetic value.

Subsequently this reaction was studied in greater detail. In the first place the stability of the neutral phosphites with respect to carboxylic acids at room temperature was estimated. For this purpose, the most labile neutral esters (trimethyl phosphite and 1,3-butylene methyl phosphite) were kept at 20°C with acetic acid and the mixture was periodically analysed by gas chromatography. It was

---

† In a brief communication[47] it has been stated that acetyl ethylene phosphite reacts with benzoic acid to form benzoyl ethylene phosphite. The conditions of the synthesis and the yield and the constants of the product are not quoted. The reaction of acetyl diethyl phosphite with benzoic acid described in the same paper is striking. The authors assert that transacetylation also takes place in the first stage and subsequently diethyl phosphate and acetyl benzoate are formed. No factual data are given for this reaction either.

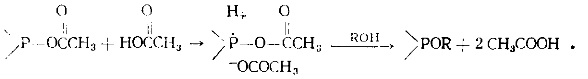
shown[79] that only after 48 h weak peaks due to methyl acetate appeared on the chromatogram. Consequently, under the phosphorylation conditions, acetic acid hardly reacts with neutral phosphites and the side process involving their dealkylation, which had been suggested previously, does not in fact occur.

On the basis of this experiment, it was concluded that acid phosphites are formed via another side process.

In the preceding section of this review, the reaction of carboxylic acids with acyl phosphites was discussed and it was concluded that such reaction takes place significantly more readily than the reaction of acids with neutral phosphites. This finding led to the conclusion[14,79] that in the earlier investigations of the alcoholysis of acyl phosphites the formation of hydrogen phosphites was not associated with the dealkylation of the neutral phosphites but with the deacylation of the phosphorylating agent. The carboxylic acid liberated by the reaction accumulates in the reaction medium and, when its concentration becomes equal to that of the alcohol, it can successfully compete with the latter for the phosphorylating agent. Evidently, in order to develop a preparative method for the synthesis of neutral phosphites, it is necessary to find conditions such that the alcohol reacts faster with the phosphorylating agent. Since acetyl dialkyl phosphites are deactivated by carboxylic acids at an appreciable rate only above 0°C while they react with alcohol also at lower temperatures, at 0°C the synthesis may be successfully employed to prepare neutral phosphites without the introduction of carboxylic acid acceptors. Experiments confirmed this hypothesis and the method thus developed has been used to prepare a series of neutral phosphites, the yield of which was in all cases higher than under conditions where acceptors are employed[33,79,87].

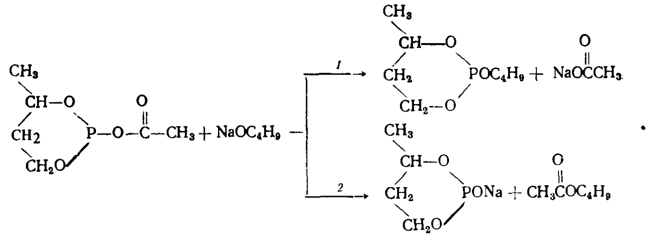
The mechanism of the alcoholysis of acyl phosphites is of considerable interest. In a study of this reaction it was concluded that, when the reactants are mixed, the process does not begin at once but only after an induction period and, once begun, the reaction proceeds exothermically. Hence it was suggested that the alcoholysis does not reduce merely to the reaction of the acyl phosphite and the alcohol but that the carboxylic acid also takes part[79].

We believe that the following mechanism of the alcoholysis is most likely. The process begins with the protonation of the mixed anhydride by the acid, probably due to the free electron pair of the phosphorus atom. The protonation is accompanied by the induction of a considerable positive charge at the phosphorus atom, which is subsequently subjected to nucleophilic attack by the alcohol, terminating with the formation of the neutral phosphite and carboxylic acid; the latter accumulates in the reaction medium and accelerates the process:



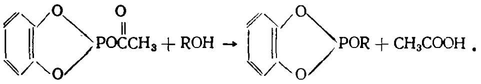
$$>P-O\overset{O}{\overset{\|}{C}}CH_3 + HO\overset{O}{\overset{\|}{C}}CH_3 \rightarrow >\overset{H_+}{\dot{P}}-O-\overset{O}{\overset{\|}{C}}CH_3 \;\; {}^{-}OCOCH_3 \xrightarrow{ROH} >POR + 2\,CH_3COOH\,.$$

This mechanism has been confirmed experimentally by comparing the rates of reaction of acetyl 1,3-butylene phosphite with 2-octanol in the absence and in the presence of triethylamine. It was established that in the first case the process is much faster than in the second[74]. Experiments, in which the effect of the acid on the phosphorylating capacity of acyl phosphites was excluded, indirectly confirm this mechanism. Thus the reaction of acetyl 1,3-butylene phosphite with sodium butoxide results in the formation of a mixture of both phosphorylation and acetylation products, i.e. butyl 1,3-butylene phosphite and butyl acetate were obtained[79]:



On the other hand, the acetate ester could not be isolated in the reaction between acetyl 1,3-butylene phosphite and butanol. Thus, in those cases where the reaction mixture contains an acid which is an effective protonating agent, the reaction proceeds virtually in one way, while in the absence of such acid there are two reaction mechanisms. If the reaction mixture contains an acid, it activates the phosphorylating centre and the reaction involves only that centre. If there is no acid, there is no activation either (or it takes place less effectively via the solvation of the reactant) and both phosphorylation and acylation, which previously took place to a lesser extent, occur.

The alcoholysis of acyl phosphites in the presence of acids is a convenient and effective method for the synthesis of a wide variety of neutral phosphite esters. Particularly satisfactory results were obtained when acetyl *o*-phenylene phosphite was employed[87]:

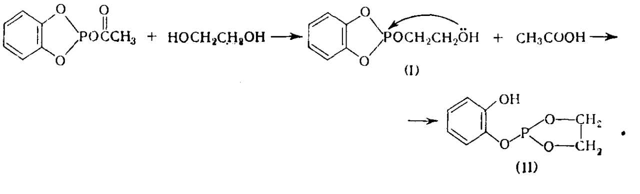


In this synthesis the yield of neutral phosphites reached 90%; this was explained by the enhanced stability (with respect to acetic acid) of the anhydride, which did not change on being kept for 24 h with an equimolar amount of the acid. Since *o*-phenylene phosphites are used industrially as stabilisers for certain materials[88,89], the explanation of the finding that they are formed readily and in high yields is very important. It should also be noted that the esters obtained in this way are purer than those synthesised by other procedures[89,90].

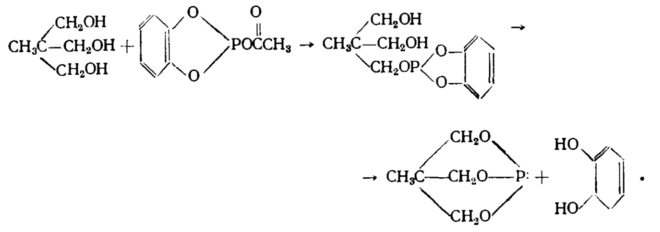
Like monohydric alcohols, glycols readily react with mixed anhydrides of dialkyl(aryl)phosphorous and carboxylic acids without the introduction of acceptors[87]. Diphosphites were obtained in this way in high yields. Esters containing a free hydroxy-group were synthesised in a low yield. This result can be accounted for by the disproportionation of the hydroxyalkyl phosphites (formed initially) under the conditions of their isolation:

$$2>PO(CH_2)_n OH \rightarrow >P-O-(CH_2)_n-O-P< + HO(CH_2)_n OH\,.$$

A similar transphosphorylation reaction was recently investigated for acid hydroxyalkyl phosphites[91]. When acetyl *o*-phenylene phosphite reacted with ethylene glycol in proportions of 1 : 1, ethylene *o*-hydroxyphenyl phosphite (II) was obtained instead of the expected hydroxyethyl *o*-phenylene phosphite (I)[87]:



Intramolecular transesterification takes place very readily also when 2-hydroxymethyl-2-methyl-1,3-propanediol is phosphorylated by acetyl *o*-phenylene phosphite:

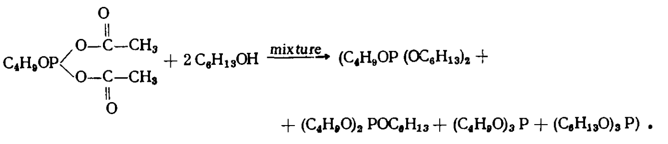


However, in the reaction with an excess of the anhydride the main product is the fully phosphorylated diol. Under analogous conditions, pentaerythritol is phosphorylated to give the tetraphosphite[87].

Acyl phosphites are highly effective in the phosphorylation of hydroxylated polymers. In this case the effect of acids on the process is particularly pronounced. Thus in the phosphorylation of hydroxylated macromolecular compounds [cellulose and poly(vinyl alcohol)] it was virtually impossible to obtain phosphorus-containing polymers when the experiments were carried out without added acid[92], whereas in similar syntheses with added acids such polymers are obtained readily and their phosphorus content reaches 14%.[93,94]

Di- and tri-acyl phosphites are also good phosphorylating agents for alcohols[41]. It might have been supposed that they would prove to be more promising for the synthesis of certain neutral phosphites than monoacetyl phosphites. This hypothesis was based on the following factors.

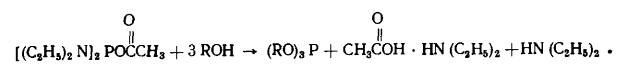
Firstly, the synthesis of di- and tri-acetyl phosphites takes place in one stage and experimentally does not differ from the synthesis of monoacyl phosphites. Secondly, the initial acid dichlorides and phosphorous trichlorides are more readily available than the monochlorides of dialkylphosphorous acid. Unfortunately only symmetrical phosphites could be obtained by this procedure in high yields. All the experiments undertaken to synthesise esters with different groups resulted in a mixture of neutral phosphites[41], for example:



$$C_4H_9OP\left<\begin{matrix}O-\overset{O}{\overset{\|}{C}}-CH_3\\ O-\underset{O}{\underset{\|}{C}}-CH_3\end{matrix}\right. + 2\,C_6H_{13}OH \xrightarrow{\text{mixture}} (C_4H_9OP\,(OC_6H_{13})_2 + (C_4H_9O)_2\,POC_6H_{13} + (C_4H_9O)_3\,P + (C_6H_{13}O)_3\,P)\,.$$

Many workers have concluded that asymmetric neutral phosphites disproportionate during their synthesis and suggested that the tendency towards "ester exchange" is a characteristic of the asymmetric neutral phosphites themselves. The reason for this phenomenon was never elucidated. The first step towards the determination of the mechanism of such disproportionation was taken by the present authors[41], who succeeded in establishing that the disproportionation of asymmetric phosphites takes place only in the presence of acid compounds or at least is sharply accelerated by them.

The results of the alcoholysis of acyl phosphoramidites merit special consideration. The reaction of acetyl *NNN'N'*-tetraethylphosphorodiamidite and alcohol in molar proportions of 1 : 3 at a temperature above 10°C gave a high yield of trialkyl phosphite[33]:

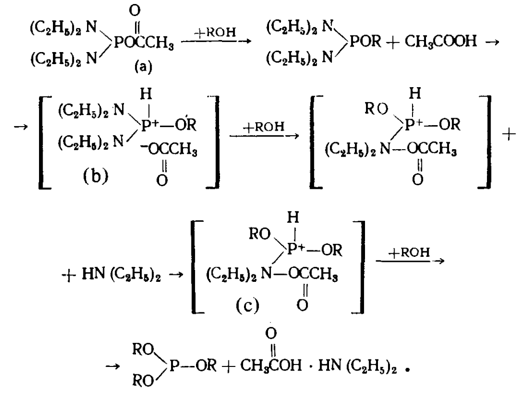


$$[(C_2H_5)_2\,N]_2\,PO\overset{O}{\overset{\|}{C}}CH_3 + 3\,ROH \rightarrow (RO)_3\,P + CH_3\overset{O}{\overset{\|}{C}}OH \cdot HN\,(C_2H_5)_2 + HN\,(C_2H_5)_2\,.$$

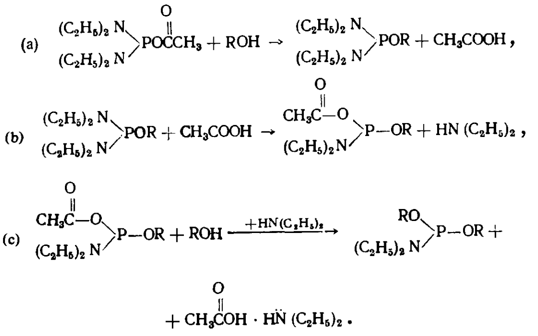
Fully esterified phosphorous acid is also formed under these conditions in the alcoholysis of diacetyl *NN*-diethylphosphoramidite[41]:

$$(C_2H_5)_2\,N{-}P\,(O\overset{O}{\overset{\|}{C}}CH_3)_2 + 3\,ROH \rightarrow (RO)_3\,P + CH_3\overset{O}{\overset{\|}{C}}OH \cdot HN\,(C_2H_5)_2 + CH_3COOH.$$

The reaction is exothermic and therefore, in order to avoid spontaneous heating, it is necessary to mix the reactants very cautiously with cooling. Such reaction conditions are consistent with the phosphorylation of alcohols by mixed anhydrides but not phosphorus(III) acid amides, which react with alcohols only on heating[95]. Consequently one may conclude that in the phosphorylation by amidoanhydrides, phosphoramidites and acetic acid are formed in the first stage and then interact with formation of new products, which are capable of readily phosphorylating alcohols. Probably these intermediates have the structure of quasiphosphonium salts:

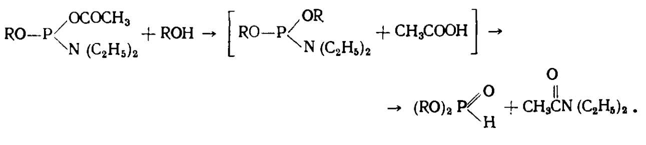


It is interesting that ammonium acetate is isolated only at the end of the reaction after the P–N bonds in the phosphoramidite have been fully replaced by P–O bonds. Probably this finding can be explained by the higher basicity of the phosphoramidite compared with the neutral phosphite, the quasiphosphonium complex of which with carboxylic acid is extremely unstable and readily decomposes into the initial compounds. In our cases the acid isolated is immediately converted into the salt by the diethylamine present in the reaction mixture. Probably the ready formation of neutral phosphites in the alcoholysis of acyl phosphoramidites cannot be represented by another mechanism, including the formation of acyl phosphite by the reaction of phosphoramidite and acetic acid produced in the first reaction stage (the possibility and scope of this reaction were demonstrated above—see Section II, 4):

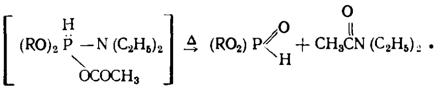


In this case the acetic acid bound in a salt with diethylamine can no longer participate in the formation of the next anhydride bond and the product must be *NN*-dialkylphosphoramidite and not the neutral phosphite, as is in fact observed experimentally. One should also remember that the amine is much more nucleophilic than the alcohol and therefore if the occurrence of stage (b) involving the formation of acyl phosphoramidite and diethylamine is postulated, the amine will react with the phosphoramidite faster than the alcohol.

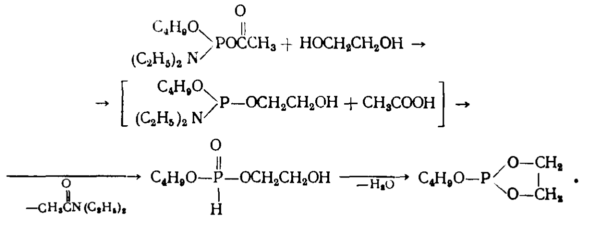
Yet another treatment of the mechanism of the alcoholysis of acetyl phosphoramidites[84] must be rejected. The authors conclude that the reaction of equimolar amounts of the phosphorus-containing reactant and alcohol yields dialkyl phosphite and *NN*-diethylacetamide via the following mechanism:



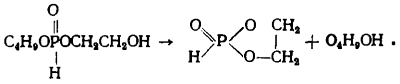
Probably in this case the phosphoramidite and acetic acid formed in the first stage are not produced in a pure form but are present as a quasiphosphonium compound. On heating, this adduct may decompose to acid phosphites and *NN*-diethylacetamide:



It was to be expected that, when the temperature of the process is controlled and a large amount of alcohol is employed, it should result in neutral and not acid phosphites‡. Unfortunately Evdakov et al.[84] did not arrive at this conclusion. Moreover, they carried out the reaction of acetyl butyl *NN*-diethylphosphoramidite with an equimolar amount of glycol (which corresponds to two moles of a monohydric alcohol in terms of the number of hydroxy-groups) and obtained butyl ethylene phosphite—a neutral ester of phosphorous acid. However, on the basis of their general mechanism of alcoholysis, including the formation of an acid phosphite as an obligatory stage, the authors put forward the following scheme for the process:

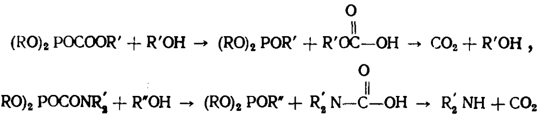


However, this postulate contradicts the logic of the chemistry of phosphites. It is known that diesters of phosphorous acid are not esterified by alcohols under the usual conditions[96,97] and in general the conversion of derivatives of phosphorous acid with a tetracoordinate phosphorus atom to derivatives with a tricoordinate phosphorus atom is extremely difficult. Moreover, the assertion that alkyl β-hydroxyethyl phosphites can be cyclised to alkyl alkylene phosphites contradicts also specific experimental data, since it has been shown that these compounds are cyclised by a transesterification and not a dehydration mechanism[91]:



Thus the inclusion in the mechanism of the alcoholysis of acyl phosphoramidites of a stage involving the formation of an acid phosphite is unjustified. Probably protonation products are always formed§ and, depending on the specific conditions, these are converted into various compounds in accordance with the factors described above.

The range of acyl phosphites employed was very recently extended in a study of the phosphorylation of alcohols. Apart from the mixed anhydrides of phosphorus(III) acids and carboxylic acids, the corresponding derivatives of alkylcarbonic[37] and carbamic[57] acids have begun to be employed. The results obtained are extremely interesting: the synthesis takes place under mild conditions and, what is most important, acid does not accumulate in the reaction mixture:

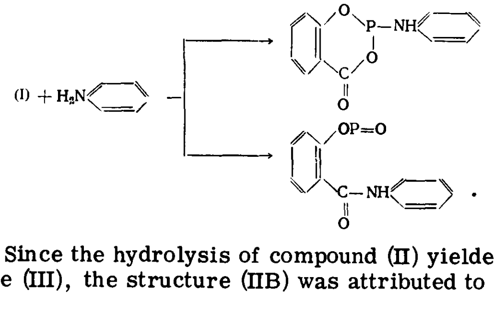


$$(RO)_2POCOOR' + R'OH \rightarrow (RO)_2POR' + R'O\overset{O}{\overset{\|}{C}}-OH \rightarrow CO_2 + R'OH\,,$$

$$(RO)_2POCONR'_2 + R''OH \rightarrow (RO)_2POR'' + R'_2N-\overset{O}{\overset{\|}{C}}-OH \rightarrow R'_2NH + CO_2\,.$$

4. Reactions with Amines and Phosphines

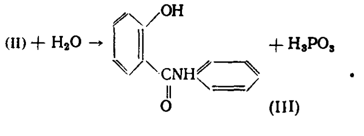
In Section II, 2 it was stated that the reaction of salicylic acid with phosphorus trichloride yields a product to which one of the two structures (IA) or (IB) (see p. 1051) could be attributed. The reaction of compound (I) with aniline led to the isolation of a product (II), the structure of which may also be represented by two formulae, corresponding to those of compound (I):



(IIA)

(IIB)

Since the hydrolysis of compound (II) yielded salicylanilide (III), the structure (IIB) was attributed to the product[8]:

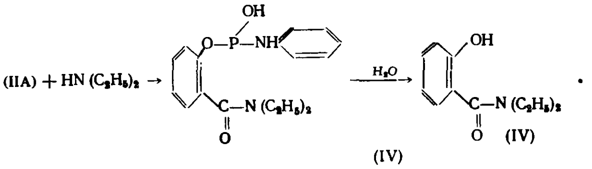


---

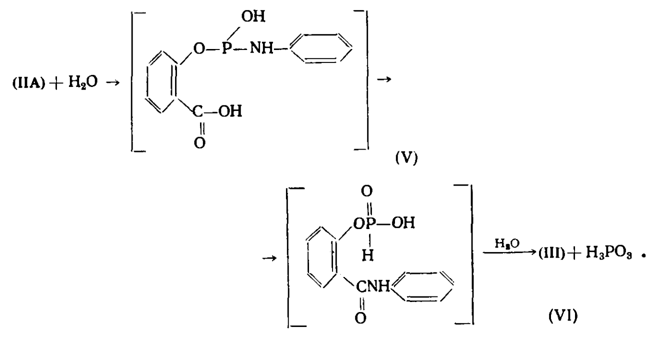
‡ Subsequently[41] acetyl butyl *NN*-diethylphosphoramidite was allowed to react with two moles of butanol at 0°C and tributyl phosphite was obtained in a high yield. The second reaction product is diethylammonium acetate and not *NN*-diethylacetamide.

§ Acid catalysis is probably of general importance in the reactions of phosphorus(III) acid derivatives with nucleophilic agents. Thus in the presence of acetic acid, triamides react with three moles of alcohol and are converted into trialkyl phosphites at 0°C[53], whereas previously, without the use of acid, this synthesis was carried out at a temperature frequently exceeding 100°C.

However, the reaction of (II) with diethylamine and subsequent hydrolysis of the intermediate led to the isolation of *NN*-diethylsalicylamide (IV)[10]. The formation of (IV) is probably possible only when compound (II) includes an anhydride ring, i.e. has the structure (IIA):

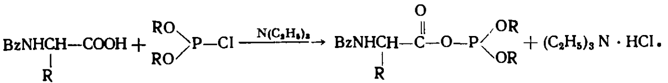


The isolation of salicylanilide in the hydrolysis of (II) is also consistent with the structure (IIA) and may be represented by the following mechanism:



Above we stated that the amides of phosphorus(III) acids react vigorously with carboxylic acids to form carboxamides[58]. Therefore the conversion of (V) into (VI) agrees with expectation. Thus the demonstration of the cyclic structure of compound (I) yields information about the reaction of acyl phosphites and amines.

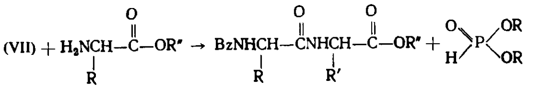
As we have seen above, the reaction of *N*-benzoylated α-aminoacids with phosphorus(III) chlorides leads to the formation of acyl phosphites:



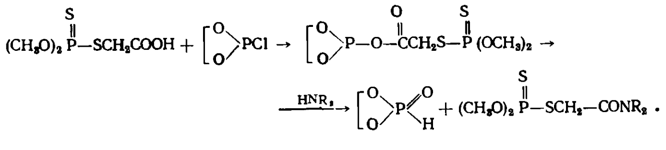
$$\underset{\mid\atop R}{BzNHCH}{-}COOH + (RO)_2P{-}Cl \xrightarrow{N(C_2H_5)_3} \underset{\mid\atop R}{BzNHCH}{-}\overset{O}{\overset{\|}{C}}{-}O{-}P(OR)_2 + (C_2H_5)_3N\cdot HCl.$$

(VII)

These compounds react further with α-aminoacids, forming peptides[16]:



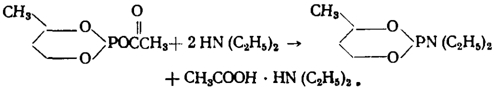
Amine acylation products were obtained in the synthesis of analogues of the insecticide Ragor[98]:



Thus the data quoted show that the ammonolysis of acyl phosphites gives high yields of acylation products and does not result in their phosphorylation. This finding is not trivial, since we know that acyl phosphites react with alcohols to form esters of phosphorous and carboxylic acids, i.e. act as phosphorylating agents.

It would be wrong to seek the cause of the difference between the reactions of acyl phosphites with alcohols and amines only in the different nature of the reactants employed and to use for this purpose one of the familiar concepts, for example those of Pearson[99], which have been recently resorted to in the interpretation of the results of the reactions of other phosphorus-containing mixed anhydrides with alcohols and amines[100].

The above considerations are based on the relevant experiments. An experiment was performed in which the mode of attack by the amine on the phosphorus atom in the acyl phosphite was definitely demonstrated. Indeed, at 0°C acyl phosphites react with twice the equimolar amount of diethylamine, so that one obtains a more than 50% yield of the phosphoramidite and the ammonium salt of the carboxylic acid[78,101], for example:

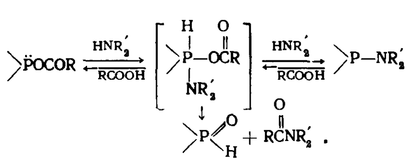


In a parallel experiment without temperature control the diethylamide of the carboxylic acid was obtained in high yield.

Probably the first stage of the reaction of acyl phosphites with amines involves an addition process similar to that which occurs when certain phosphorus(III) acid fluorides are treated with amines[102].

The addition product, which is essentially a quasiphosphonium salt, can undergo a nucleophilic substitution reaction if the reaction mixture contains an excess of the amine. In the absence of temperature control, the addition product decomposes with formation of the pure acid phosphite and the carboxylic acid amide.

The general scheme should be supplemented by the decomposition of the addition product on treatment with acid to the acyl phosphite and the ammonium salt. The overall process mechanism can be represented as follows:



It is interesting to add to the above that, in contrast to the amine, according to the data of Trippett and coworkers, diphenylphosphine forms with acyl phosphinate diphosphine and a carboxylic acid even when the reactants are present in stoichiometric proportions[36]:

$$(C_6H_5)_2P\overset{O}{\overset{\|}{O}}CR + H\ddot{P}(C_6H_5)_2 \rightarrow (C_6H_5)_2P{-}P(C_6H_5)_2 + HO\overset{O}{\overset{\|}{C}}R.$$

5. Reaction with Mercaptants

The reaction of acyl phosphites with mercaptants has been very little investigated despite the fact that it has a number of characteristic features compared with the alcoholysis of phosphonimidites. After the acyl phosphites had been treated for a long time with an equimolar amount of a mercaptan at 20°C under conditions excluding radical reactions, new products were not obtained[101,103]. When the reaction was carried out in the presence of triethylamine or sodium mercaptide was employed instead of the mercaptan, phosphorothioites were obtained[101].

Neutral phosphorodithioates were synthesised by treating acyl dialkyl phosphites with an excess of a mercaptan[104]:

$$(\text{RO})_2\text{POCOCH}_3 + 2\,\text{HSR}' \rightarrow (\text{RO})_2\overset{\text{S}}{\overset{\|}{\text{P}}}\text{—SR}' + \text{HO}\overset{\text{O}}{\overset{\|}{\text{C}}}\text{CH}_3 + \text{R}'\text{H}\,.$$

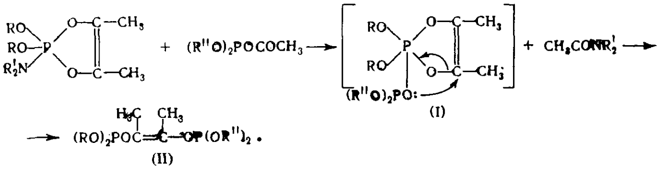
Probably in this case phosphorylation was accompanied by the desulphuration of the mercaptan, i.e. a process which is very familiar in the chemistry of phosphites[105,106]. The reaction of acyl phosphoramidites with mercaptans, which leads to neutral phosphorodithioites but not phosphorothioates, has also been described[104]:

$$\begin{matrix}\text{RO}\\ \text{R}'_2\text{N}\end{matrix}\!\!>\!\text{P—OCOCH}_3 + 2\,\text{HSR}'' \rightarrow \text{ROP(SR}'')_2\,.$$

The authors[104] did not analyse the causes of the difference in the mode of the two formally similar reactions.

6. Interaction with Aminophospholens

Aminophosphoranes with a phospholen ring are an interesting type of nucleophilic agent with several centres capable of undergoing attack by electrophilic agents. The reaction of aminophospholens with acyl phosphites has been described[107] and the following mechanism has been put forward:

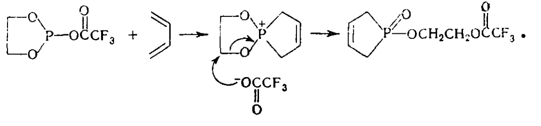


It is suggested that in the first stage the carbon atom of the carbonyl group undergoes nucleophilic attack with formation of acetamide and an intermediate pentacovalent compound(I), which undergoes further rearrangement to the final product (II). It is surprising that Mizrakh et al.[107] discussed the possibility of nucleophilic attack by nitrogen only and on only one electrophilic centre in acyl phosphites—the carbon atom of the carbonyl group. Nevertheless, having concluded that compound (II) is formed (yield 23%), the authors failed to prove rigorously its structure. For example, no data are quoted concerning the presence of a phosphorus(III) atom in the molecule. At the same time the absence of a phosphorus–carbon bond is not demonstrated either, although it is well known that it is always formed when dialkyl phosphite anions are alkylated by unsaturated compounds[108] (this in fact happens in the mechanism proposed). Moreover, it remains obscure why the dialkylphosphite anion attacks the carbon atom involved in the multiple bond and not the more electrophilic carbon atom of the alkoxy-group.

Thus at present it is impossible to include the reaction of acyl phosphites with aminophospholens among the known processes.

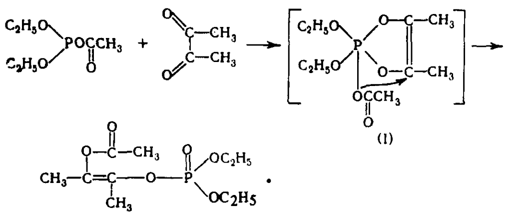
7. Reactions with Dienes

The reaction of acyl phosphites with conjugated dienes, the investigation of which began only very recently[109], can be considered in this section in a somewhat arbitrary fashion, for example:



It has been noted that mixed anhydrides containing a trifluoroacetic acid residue react with dienes more readily than the corresponding acetic acid derivatives.

When diacetyl is employed as the diene, the reaction takes place readily also with mixed anhydrides incorporating non-halogenated carboxylic acids[110]:



The intermediate (I), the structure of which had been demonstrated by ^{31}P NMR[110], proved to be unstable, undergoing, according to the authors of the investigation, a rearrangement via the mechanism of the second stage of the Arbuzov reaction. However, the cause of the attack by the anion of the carbon atom of the multiple bond is not explained. At the same time this factor must be investigated in detail, since phospholen, which has a similar structure and is formed in the reaction between diacetyl and dialkyl phosphorochloridite[111], decomposes with elimination of alkyl chloride and not with ring opening:

The Present State of the Chemistry of 1,4-Benzodiazepines

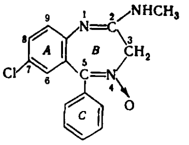
A.V.Bogatskii and S.A.Andronati

Derivatives of 1,4-benzodiazepines have found wide application as minor tranquilisers. Moreover, compounds of this class are of interest for the investigation of problems in stereochemistry, tautomerism, and mutual effects of atoms in heterocyclic systems and also for the determination of the relation between pharmacological activity and structure. This review deals with the methods of preparation and the chemical properties of 1,4-benzodiazepines and also their dihydro- and tetrahydro-derivatives and the stereochemistry and applications of these substances.
The bibliography includes 195 references.

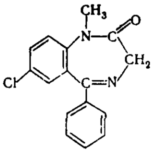
CONTENTS

I. INTRODUCTION

The chemistry of 1,4-benzodiazepines has been attracting increasing interest each year. The reason is that 7-chloro-2-methylamino-5-phenyl-3*H*-1,4-benzodiazepine 4-oxide [Chlordiazepoxide, Librium, Elenium†, and Thymosine† (I)],[1,2] 7-chloro-1-methyl-5-phenyl-1,3-dihydro-2*H*-1,4-benzodiazepin-2-one [Diazepan, Valium, or seduxene† (II)][3] and their derivatives have proved to be exceptionally effective tranquilisers of a new type[4]:



(I)



(II)

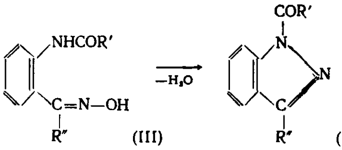
On the other hand, the chemical reactions of these systems and their stereochemistry and tautomerism proved to be unusual. The range of studies carried out so far includes systems resembling (I) and (II) with various substituents in the rings, A, B, and C, systems with non-benzene substituents in the 5-position, tetrahydro-derivatives, and also derivatives of 1,4-benzodiazepine with various functional groups. One review has been published on the chemistry of 1,4-benzodiazepines covering the literature up to 1963.[4] In the general reviews on diazepines[5] and benzodiazepines[6] a number of problems are not dealt with at all, for example the problem of the stereochemistry of 1,4-benzodiazepines and their tautomerism, and extensive new data have now accumulated which were not considered in previous reviews. Moreover, although the first derivative of 1,4-benzodiazepine, namely 4-(*N*-phenylacetamido)-3,4-dihydro-5*H*-1,4-benzodiazepine-3,5-dione was sythesised as early as 1904 by Gärtner[7], the chemistry of these structures has developed essentially only in the last ten years. The present review covers the bibliography up to 1969 inclusive.

II. METHODS OF SYNTHESIS OF 1,4-BENZODIAZEPINE SYSTEMS

1. 3*H*-1,4-benzodiazepines

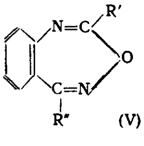
Fully unsaturated 1,4-benzodiazepines were synthesised for the first time in 1959 by Sternbach and coworkers, but the problem has had a fairly long previous history.

In 1891 Auwers and Meyenburg[8] reported that, in the reaction between oximes of *o*-carbamoylaceto- and *o*-carbamoylbenzophenones (III) and a Beckmann mixture, water is split off with formation of acylindazoles (IV). However, these "acylindazoles" were not hydrolysed to indazoles as might have been expected, but were reconverted on hydrolysis into acetamido-oximes, which threw doubt on the proposed structure (IV):



(III) (IV)

Three years later Bischler[9] proposed formula (V) for these substances, whereby they were assigned to the class of benzoxadiazepines. This formula was adopted by all investigators, including Auwers himself, although the latter believed that the proof of structure (V) was insufficiently vigorous[10].



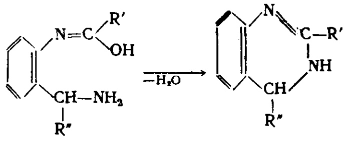
(V)

In 1954 Ried and Stahlhofen[11] observed that benzoxadiazepines combine with two molecules of hydrogen over Raney nickel and are converted into dihydroquinazolines.

---

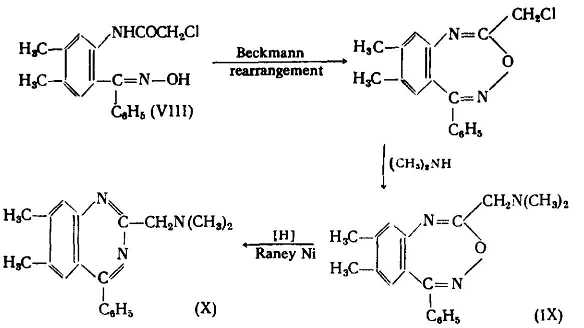
† Tentative spelling (not traced) (Ed. of Translation).

These investigators suggested that compound (V) is hydrogenated to product (VI), which eliminates water and is converted into dihydroquinazoline (VII):



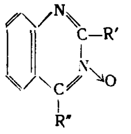
(VI) (VII)

Almost simultaneously Sternbach carried out the following synthesis in order to obtain structures of type (IX), i.e. benzoxadiazepines with basic substituents:



However, on reduction by the method of Ried and Stalhofen the product (IX) gave a high yield of the quinazoline (X) instead of the expected 3,4-dihydroquinazoline of type (VII).

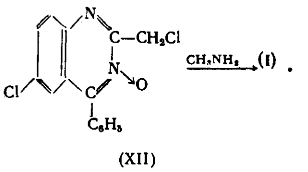
On the basis of the work of Schmitz[12], Katritzky[13], and others in the field of heterocyclic *N*-oxides, Sternbach established that the Auwers compounds have the structure of quinazoline *N*-oxides (XI):



(XI)

This was indicated by the presence of an intense absorption band in the region of 1318–1290 cm^{-1}, which is usually attributed to the N → O bond[14]. Soon structure (XI) was finally proved also chemically[15].

By allowing methylamine to react with 6-chloro-2-chloromethylquinazoline-3-oxide (XII), Sternbach obtained a compound isomeric with the expected 6-chloro-2-methylaminoquinazoline 3-oxide, but differing in its ultraviolet and infrared spectra. A more detailed study showed that this is the 4-oxide of 7-chloro-2-methylamino-5-phenyl-3*H*-1,4-benzodiazepine (I, trivial name—Chlordiazepoxide‡):

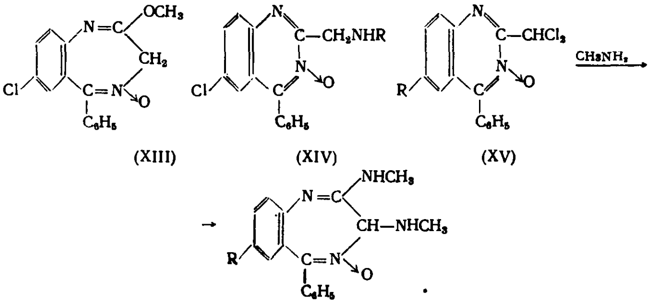


(XII)

According to Sternbach[4], the rearrangement occurring during the reaction of (XII) with methylamine takes place in three stages. The carbon atom in the 2-position of the quinazoline (XII) has a partial positive charge owing to the inductive effect of the N→O group. The first stage is the nucleophilic attack by methylamine on this carbon atom, the second stage includes the dissociation of the C–N bond between the 2-carbon atom and the *N*-oxide nitrogen, and the third stage is the formation of a new C–N bond between the amine oxide nitrogen and the methylene carbon atom with elimination of a chloride ion. The seven-membered ring is in fact formed in this third stage.

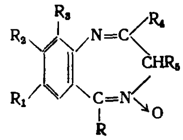
A similar rearrangement with ring expansion takes place when (XII) reacts with ammonia, primary aliphatic amines[2,16], hydrazine[17], and sodium methoxide[18]. In the latter case the product is 7-chloro-2-methoxy-5-phenyl-3*H*-1,4-benzodiazepine 4-oxide (XIII), which is obtained also when diazomethane reacts with compound (XXVIII).[18,19]

In some cases the reaction of (XII) with primary amines also gives 2-aminomethylquinazolines (XIV) as side products[20]. This type of reaction with secondary amines leads to aminoquinazolines. Only the normal substitution product is formed in the reaction of diethylamine and pyridine. The reaction of 2-dichloromethylquinazolines (XV) with methylamine leads to bismethylamino-derivatives of 1,4-benzodiazepines (XVI):[21]



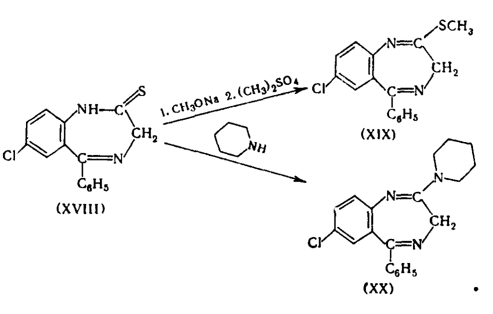
(XVI)

A necessary condition for the rearrangement is the presence of the *N*-oxide group. Without this group, quinazoline reacts with amines to form substitution products. Quinazolines with electron-donating substituents in the 6- and 8-positions also do not undergo the rearrangement. The method described permitted a synthesis of 3*H*-1,4-benzodiazepine *N*-oxides (XVII) with a large number of a wide variety of substituents[1,2,15-37]:



(XVII)

3*H*-1,4-Benzodiazepines without the *N*-oxide group can be obtained by the reduction of the corresponding *N*-oxides or by the reaction of 1,2-dihydro-3*H*-1,4-benzodiazepine-2-thiones with amines or alkylating agents[38]:



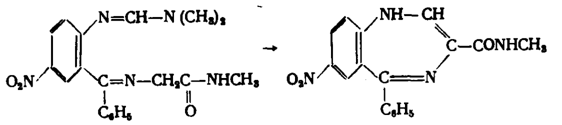
---

‡ The names Librium and Elenium were given to the hydrochloride of Chlordiazepoxide.

As already stated, 1,4-benzodiazepine derivatives are distinguished from the isomeric quinazolines by their infrared and ultraviolet spectra. In the infrared spectra of 1,4-benzodiazepine there is an intense absorption band in the region 1620–1605 cm^{-1} and a second intense band in the region 1590–1580 cm^{-1}, while quinazoline has only two weak bands in this region[2], at 1605 and 1550 cm^{-1}.

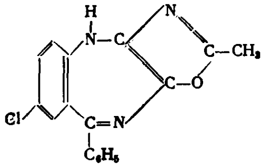
2. 1*H*-1,4-Benzodiazepines

Only two compounds of this series are known. One of these, compound (XXI), was obtained by the cyclisation of the corresponding di-imine (XXII):[39]



(XXII) (XXI)

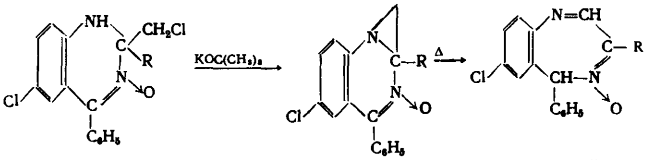
The second derivative (XXIII) is obtained as a side product in the acetylation of 2-amino-7-chloro-5-phenyl-3*H*-1,4-benzodiazepine 4-oxide:



(XXIII)

3. 5*H*-1,4-Benzodiazepines

When acted upon by potassium t-butoxide, the 3-oxides of dihydroquinazolines of type (XXIV) form the *N*-oxides of aziridinoquinazolines (XXV),[40,41] which readily isomerise on heating to derivatives of 5*H*-1,4-benzodiazepines (XXVI):

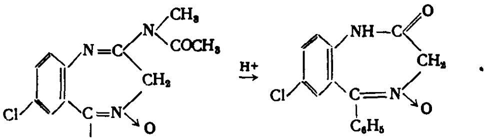


(XXIV) (XXV) (XXVI)

where R = H or CH_3.

4. 1,2-Dihydro-3*H*-1,4-Benzodiazepines

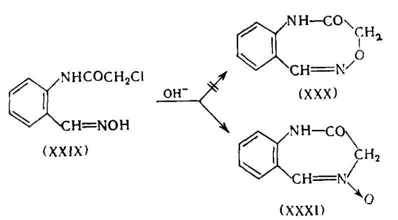
When an inorganic acid is allowed to react with an acetyl derivative of Chlordiazepoxide (XXVII) under mild conditions, the hydrolysis product (XXVIII) [22] is identical with the substance formed when a solution of the hydrochloride of compound (I) is allowed to stand in the cold for a long time§. Alkaline hydrolysis of the acetyl derivative yields the initial 1,4-benzodiazepine (I):



(XXVII) (XXVIII)

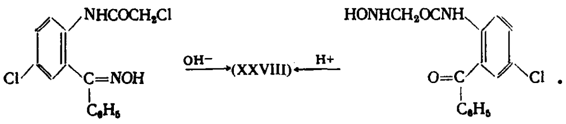
Similar compounds are readily obtained by the reaction of the 3-oxide of 6-chloro-2-chloromethyl-4-phenylquinazolines with alkali[44,45]. This process resembles the rearrangement (described above) which occurs in the course of the synthesis of compounds of type (I) from the corresponding quinazolines. Here the attacking nucleophilic agent is the hydroxide ion[45].

By treating 2-chloroacetamidobenzaldehyde β-oxime (XXIX) with alkali, Auwers[42] obtained a substance, to which he attributed the structure of benzoxadiazocine (XXX), but later it was shown that the substance is in fact the 4-oxide of 1,2-dihydro-3*H*-1,4-benzodiazepin-2-one (XXXI):[47]



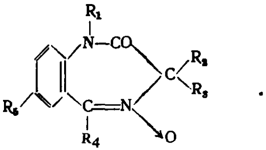
(XXIX) (XXX) (XXXI)

Under these conditions 5-chloro-2-chloracetamidobenzophenone β-oxime (XXXII) cyclises to the *N*-oxide (XXVIII),[42] which is also formed from the hydroxylamine derivative (XXXIII) in an acid medium[48-51]:



(XXXII) (XXXIII)

A number of homologues and analogues of compound (XXVIII) having the general formula (XXXIV) have been synthesised by these methods[22,44-53]:



(XXXIV)

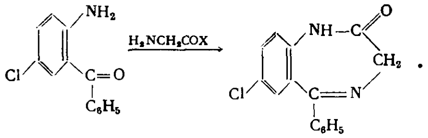
The reduction of the 4-oxide of 7-chloro-1-methyl-5-phenyl-1,2-dihydro-3*H*-1,4-benzodiazepin-2-one yielded compound (II), which also proved to be a tranquiliser and was given the trivial name Diazepam. The high activity of compounds of this kind stimulated the synthesis of analogues and homologues of compound (II).

Several methods are known for the preparation of 1,2-dihydro-3*H*-1,4-benzodiazepin-2-one from aromatic and

---

§ Like the 4-oxide of 2-amino-7-chloro-5-phenyl-3*H*-1,4-benzodiazepine, this compound is a product of the metabolism of Librium in the human and dog organisms[43].

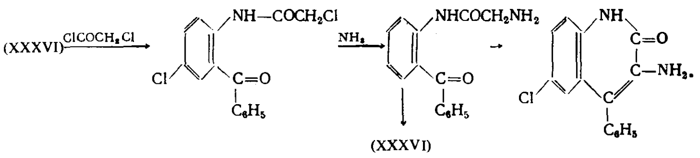
aliphatic-aromatic *o*-aminoketones. The simplest synthesis is based on the condensation of *o*-aminobenzophenones with glycine or its hydrochloride or the hydrochloride of the ethyl ester of glycine[3,54-56]:



(XXXV) (XXXVI)

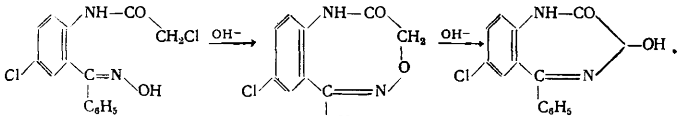
Sometimes the amino-group in glycine is protected by a benzyloxycarbonyl or phthaloyl group[44,57-60]. Syntheses have been described where one obtains initially halogenoacetamidobenzophenone (XXXVII), which is then converted into the amino-derivative (XXXVIII) and cyclised to (XXXVI).[3,23,44,61] Sometimes the dihydroquinolone (XXXIX) is then obtained as a side product.

3-Hydroxy-1,2-dihydro-3*H*-1,4-benzodiazepin-2-ones may be obtained by treating 2-chloroacetamidobenzophenone α-oximes (XL) with alkali, with the intermediate formation of the benzoxadiazocine (XLI), which is readily converted into benzodiazepine:



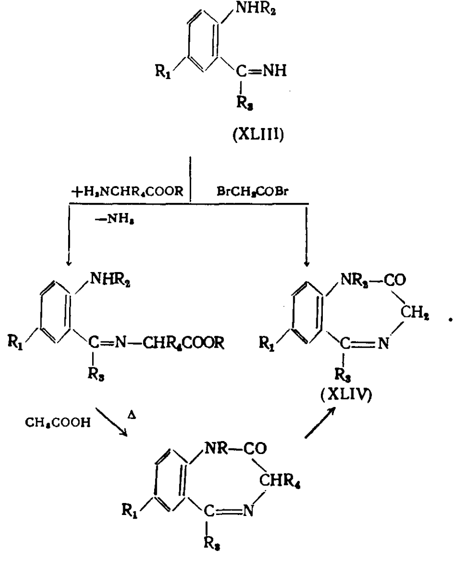
(XXXVI) (XXXVII) (XXXVIII) (XXXIX)

7-Chloro-3-hydroxy-5-phenyl-1,2-dihydro-3*H*-1,4-benzodiazepin-2-one (XLII) [the active principle of the medicinal preparation Oxazepam (or Adumbran)] was synthesised in this way[62]:

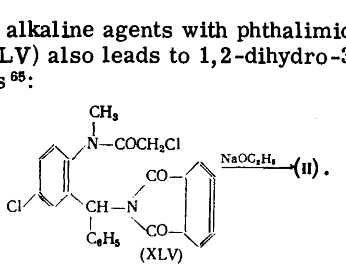


(XL) (XLI) (XLII)

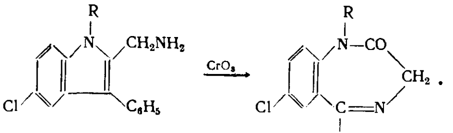
Together with *o*-aminophenones, *o*-aminoketimines (XLIII) may be employed as the starting materials for the synthesis of 1,2-dihydro-3*H*-1,4-benzodiazepin-2-ones.[63] Another way involves the reaction of the ketimines with bromoacetyl bromide, which leads directly to compounds of type (XLIV):[64]



The reaction of alkaline agents with phthalimido-derivatives of type (XLV) also leads to 1,2-dihydro-3*H*-1,4-benzodiazepin-2-ones[65]:



The 1,2-dihydro-3*H*-1,4-benzodiazepine system is formed on oxidation of aminoindoles (XLVI) with chromium trioxide[66]:

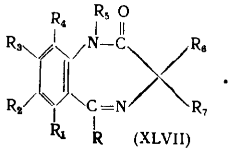


(XLVI)

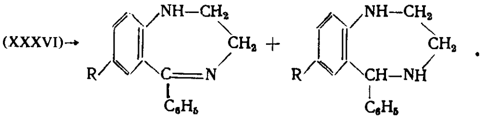
1,2-Dihydro-3*H*-1,4-benzodiazepin-2-ones can also be obtained by the reduction of *N*-oxides of type (XXVIII) or by oxidising tetrahydro-1,4-benzodiazepines or 1,2-dihydro-3*H*-1,4-benzodiazepines.

Substituents in the 1-position are usually introduced by alkylating the benzodiazepinone.

Recently many analogues and homologues of compound (II) having the general formula (XLVII) have been obtained[3,23-25,44,57-94]:



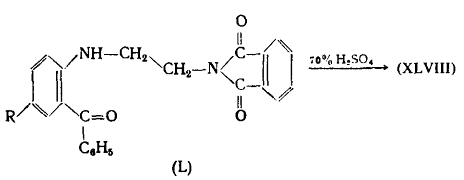
The conversion of the carbonyl group in 1,2-dihydro-3*H*-1,4-benzodiazepin-2-ones into a methylene group leads to 1,2-dihydro-3*H*-1,4-benzodiazepines[82,95-98]. However, when the initial lactams are reduced by lithium, aluminium hydride or hydrogen in the presence of a Raney nickel, tetrahydro-1,4-benzodiazepines (XLIX) are formed in addition to the dihydro-derivatives of type (XLVIII):



(XLVIII) (XLIX)

A more convenient method is the reduction over Raney nickel of the thiones (XVIII),[99,100] which are readily obtained from the corresponding carbonyl compounds.

1,2-Dihydro-3*H*-1,4-benzodiazepine (XLVIII, R = H) may be obtained by the cyclisation of phthalimidoethylaminobenzophenone (L):[95]

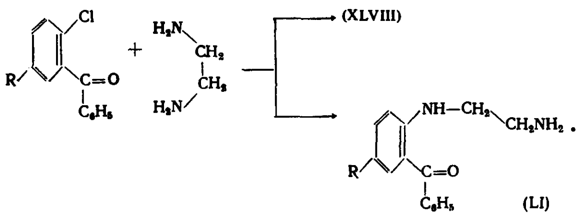


(L)

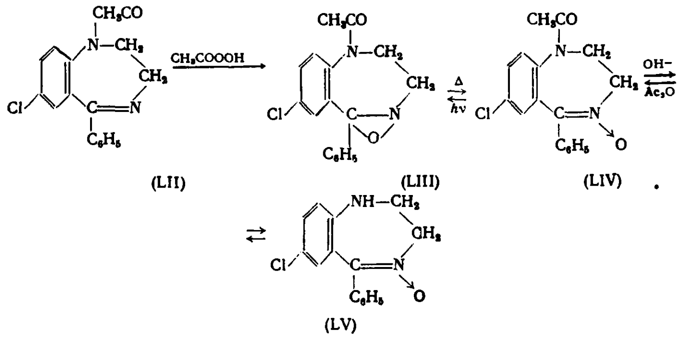
where R = H.

Another version of the reaction considered is the condensation of *o*-aminobenzophenones with aziridine in the presence of aluminium chloride. This reaction has a very low yield[95].

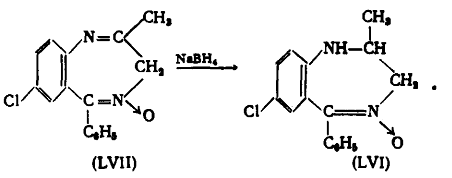
Finally, yet another procedure whereby compounds with a methylene group in the 2-position may be obtained is based on the reaction of *o*-chlorobenzophenones with diamines[101]. Then the yields of the dihydro-derivatives are higher when a nitro-group or CF_3 group is present in the *para*-position relative to the chlorine atom. With 2,5-dichlorobenzophenone, the yield is only 10%. The open-chain compounds (LI) may be formed in this reaction together with 1,4-benzodiazepines (XLVIII):



The 4-oxides of 1,2-dihydro-3*H*-1,4-benzodiazepines were synthesised from the 1-acetyl derivatives (XLVIII). Thus, when 1-acetyl-7-chloro-5-phenyl-1,2-dihydro-3*H*-1,4-benzodiazepine (LII) is treated with peracetic acid, an oxaziridine derivative (LIII) is obtained and then converted on heating into the isomeric *N*-oxide form (LIV). The acetyl group may be eliminated in an alkaline medium[102]:

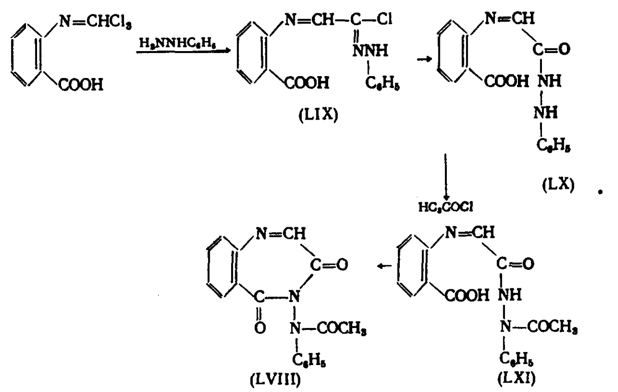


The formation of compound (LVI) on reduction of 7-chloro-2-methyl-5-phenyl-3*H*-1,4-benzodiazepine 4-oxide (LVII) with sodium borohydride has been described[41]:

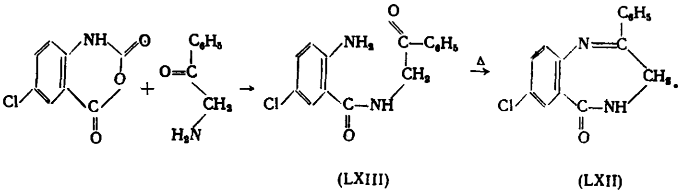


5. 3,4-Dihydro-5*H*-1,4-benzodiazepines

As stated above, the first 1,4-benzodiazepine synthesised was 4-(*N*-phenylacetamido)-3,4-dihydro-5*H*-1,4-benzodiazepine-3,5-dione (LVIII). Trichloroethylidene-anthranilic acid was converted into the phenylhydrazide (LIX) by condensation with phenylhydrazine and then by treatment with water into compound (LX), which reacted with acetyl chloride to give the acetyl derivative (LXI). Its vacuum distillation gave compound (LVIII):[7]



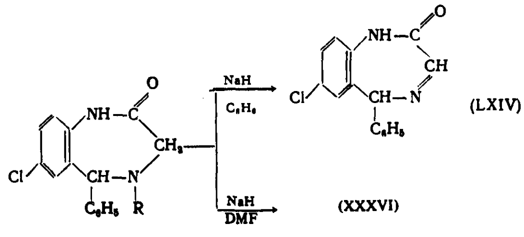
7-Chloro-5-phenyl-3,4-dihydro-5*H*-1,4-benzodiazepin-5-one (LXII) is formed by the cyclisation of compound (LXIII), obtained by the reaction of 5-chloroisatoic anhydride with aminoacetophenone[103,104]:



Similarly 2-(*o*-chlorophenyl)-3,4-dihydro-5*H*-1,4-benzodiazepin-5-one is obtained from ω-amino-*o*-chloroacetophenone and isatoic anhydride[105]. Another method for the preparation of 3,4-dihydro-5*H*-1,4-benzodiazepines consists in the reduction of the homologues and analogues of Chlordiazepoxide with lithium aluminium hydride.

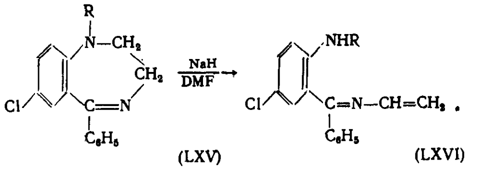
6. 1,2-Dihydro-5*H*-1,4-benzodiazepines

Representatives of this system are fairly unstable, i.e. they readily isomerise to 1,2-dihydro-3*H*-1,4-benzodiazepines. They are obtained by treating 4-tosyl(or methanesulphonyl)tetrahydro-1,4-benzodiazepin-2-ones with sodium hydride[106] or ethoxide[50] in an anhydrous non-polar solvent:



where R = *p*-tosyl, methanesulphonyl, or $OCOCH_3$. When the reaction is carried out in a polar solvent or aqueous solution, the more stable isomer (XXXVI) is formed.

When treated with sodium hydride in dimethylformamide, 1-tosyl(or methanesulphonyl)-1,2-dihydro-3*H*-1,4-benzodiazepines (LXV) form the vinylimines (LXVI) and not the 1,4-benzodiazepine derivatives:

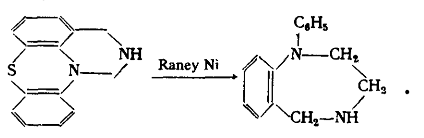


(LXV) (LXVI)

7. 1,2,3,4-Tetrahydro-5*H*-1,4-benzodiazepines

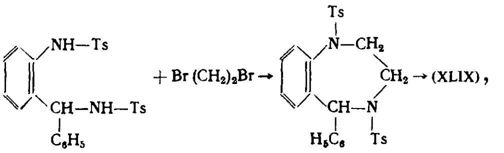
These compounds are largely obtained by the reduction of the corresponding carbonyl derivatives and *N*-oxides by complex metal hydrides or hydrogen in the presence of catalysts (palladium, nickel, and platinum).[95,98,103,107] When acted upon by $LiAlH_4$ and $NaBH_4$, the N→O group is converted into N–OH.

Diazepinophenothiazine (LXVII) undergoes reductive desulphuration on Raney nickel with formation of compound (LXVIII):[108]



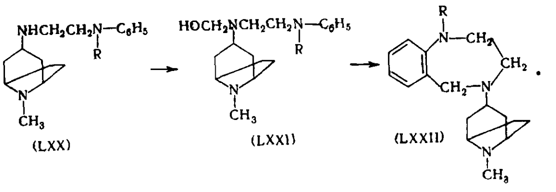
(LXVII) (LXVIII)

By allowing ethylene bromide to react with the diamide (LXIX), a ditosyl derivative was obtained, which on treatment with sulphuric acid was converted into (XLVIII, R = H).[109]



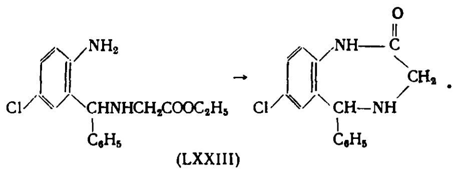
where R = H.

The reaction of formaldehyde and formic acid with tropanylethylenediamine (LXX) gave tropanyl derivatives of 1,4-benzodiazepine[110,111]. It is suggested that compound (LXXI) is formed as an intermediate, the intramolecular rearrangement of which gives tetrahydro-1,4-benzodiazepine (LXXII):



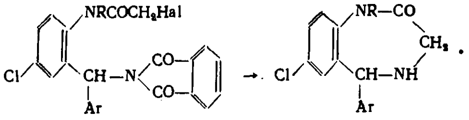
(LXX) (LXXI) (LXXII)

1,2,3,4-Tetrahydro-5*H*-1,4-benzodiazepin-2-ones are obtained from aminoesters of type (LXXIII), which are formed when [*o*-aminophenyl(phenyl)]methylamines are treated with bromoethyl acetate or *o*-aminobenzyl chlorides are treated with glycine ethyl ester[112-115]:



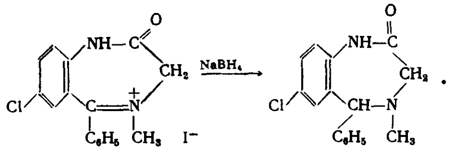
(LXXIII)

Derivatives of tetrahydro-1,4-benzodiazepin-2-one (LXXV) were synthesised by heating phthalimide derivatives of type (LXXIV) in aqueous potassium carbonate solution and subsequent treatment of the product with hydrobromic acid in acetic acid[116]:



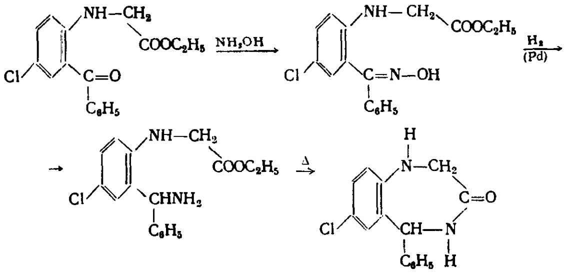
(LXXIV) (LXXV)

The reaction of $NaBH_4$ with the quaternary salt (LXXVI) leads to the selective reduction of the C=N bond (the carbonyl group is then retained)[44]:



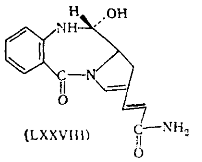
(LXXVI)

7-Chloro-1,2,3,4-tetrahydro-5*H*-1,4-benzodiazepin-3-one (LXXVII) [117] was synthesised from 5-chloro-2-ethoxycarbonylmethylaminobenzophenone according to the following mechanism:

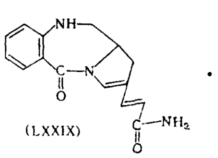


(LXXVII)

The 1,2,3,4-tetrahydro-5*H*-1,4-benzodiazepin-5-one system is a component of the structure of the cytotoxic antibiotic anthramycin (LXXVIII) and its simpler analogue (LXXIX):

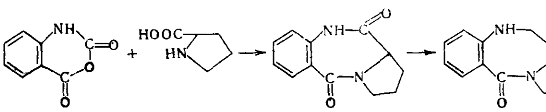


(LXXVIII)



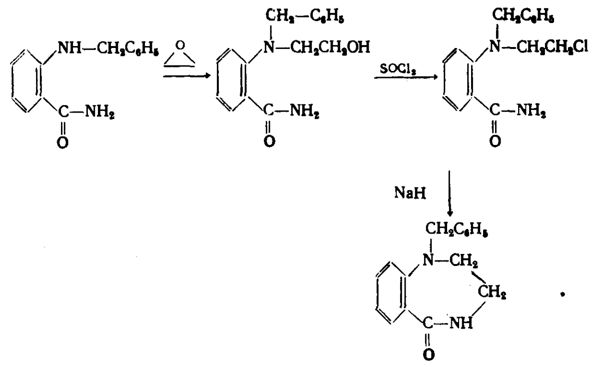
(LXXIX)

The structures of these compounds, their stereochemistry, and intramolecular transformations have been investigated in very great detail and described in a number of papers by Leimgruber and coworkers[118,119]. Compound (LXXX) was synthesised by these investigators as a model using the following procedure:



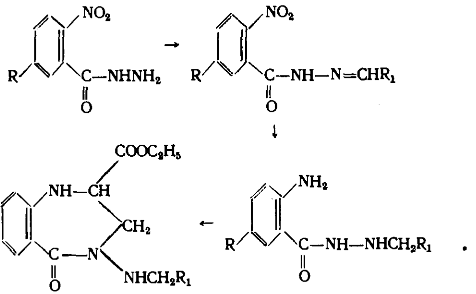
(LXXX)

The synthesis of a compound in the 1,2,3,4-tetrahydro-5*H*-1,4-benzodiazepin-5-one series was first described by Santilli and Osdene[103]. However, later it was established that the substance which they assumed to be 1-tosyl-1,2,3,-4-tetrahydro-5*H*-1,4-benzodiazepin-5-one has in fact the structure of the isomeric oxazoline[104,120]. The same investigators[121] achieved the synthesis of compound (LXXXI) from the amide of *N*-benzylanthranilic acid according to the mechanism



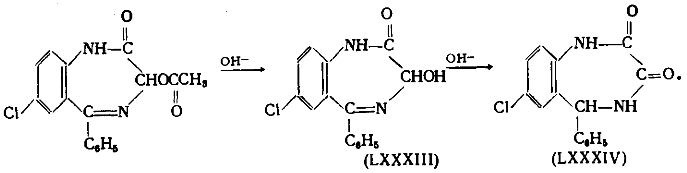
(LXXXI)

A number of various derivatives of 4-arylalkylamino-1,2,3,4-tetrahydro-5*H*-1,4-benzodiazepin-5-ones (LXXXII) were synthesised from *o*-nitrobenzoylhydrazines[122]:



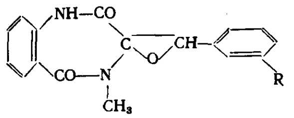
(LXXXII)

1,2,3,4-Tetrahydro-5*H*-1,4-benzodiazepin-2,3-diones are formed when 1,2,3,4-tetrahydro-5*H*-1,4-benzodiazepines and their 2-carbonyl derivatives are oxidised with CrO_3 and also on treatment with alkali of 3-acetoxy-1,2-dihydro-3*H*-1,4-benzodiazepin-2-one via the intermediate 3-hydroxy-derivative[123]:



(LXXXIII) (LXXXIV)

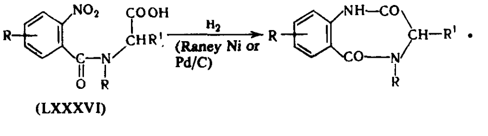
Cyclopenin (LXXXVa) and cyclopenol (LXXXVb), metabolites of the fungi *Penicillium cyclopium* Westling and *Penicillium viridicatum* Westling[124,125], are derivatives of 1,2,3,4-tetrahydro-5*H*-1,4-benzodiazepin-2,5-dione[126]. The structure of (LXXXVa) was confirmed by synthesis[127,128]:



(a—R=H; b—R=OH).

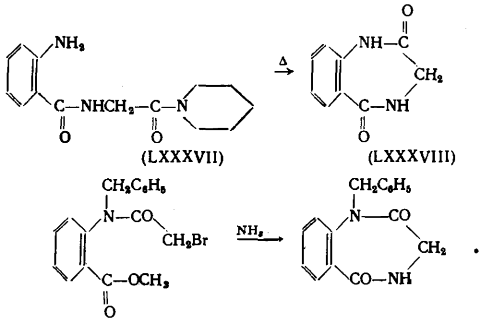
(LXXXV)

There are several synthetic procedures for the preparation of the 2,5-diones. One of these consists in the reductive cyclisation of *o*-nitrobenzamides of type (LXXXVI):[129–133]



(LXXXVI)

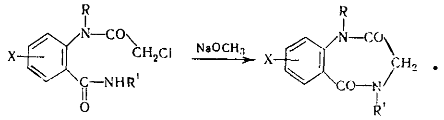
The amide of *o*-aminohippuric acid (LXXXVII) splits off piperidine on heating in acetic acid and is converted into the 2,5-dione (LXXXVIII). Its 1-benzyl derivative (XI) is obtained by treating with ammonia the methyl ester of *N*-benzyl-*N*-bromoacetylanthranilic acid (LXXXIX):[134,135]



(LXXXVII) (LXXXVIII)

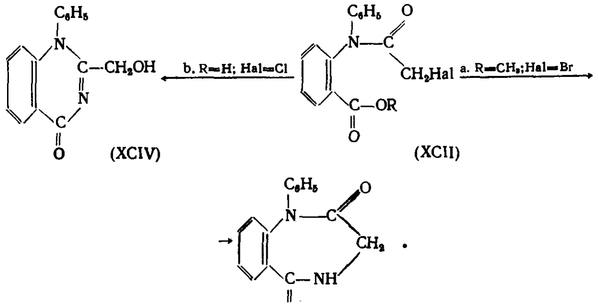
(LXXXIX) (XC)

A similar process takes place when *o*-chloroacetamidobenzamides (XCI) are treated with bases such as sodium methoxide and potassium carbonate[136–138]:



(XCI)

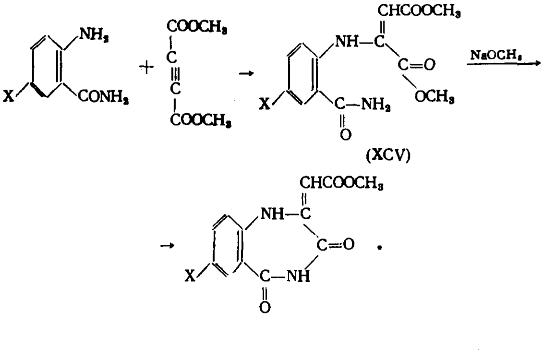
However, it has been observed[139,140] that in certain cases the reaction yields a quinazoline and not a benzodiazepine derivative. Thus, like compound (LXXXIX), the methyl ester (XCII, R = CH_3, Hal = Br), gives 1-phenyl-1,2,3,4-tetrahydro-5*H*-1,4-benzodiazepine-2,5-dione (XCIII), while *N*-acetyl-*N*-phenylanthranilic acid (XCII, R = H, Hal = Cl) cyclises to the isomeric quinazolinone (XCIV):



(XCIV) (XCII)

(XCIII)

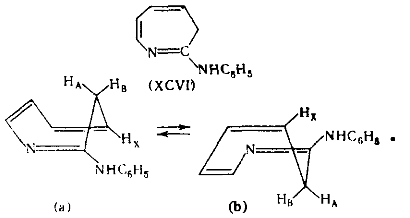
1,2,3,4-Tetrahydro-5*H*-1,4-benzodiazepin-3,5-diones were obtained by the Michael reaction from anthranilic acid amides and the dimethyl ester of acetylenedicarboxylic acid via the intermediate compound (XCV):[141,142]



(XCV)

III. STEREOCHEMISTRY OF 1,4-BENZODIAZEPINES

In 1967 Mannschreck et al.[143] investigated by NMR the intramolecular mobility of various azepines and diazepines, including 2-phenylamino-3*H*-1,4-azepine [Dibenzamil (XCVI) and similar compounds]. According to their data, in deuterated acetone compound (XCVI) (and similar substances) exist in the boat form, which undergoes inversion at a temperature as low as −55° ± 7°C between two conformations (a) and (b) 258 times per second. The free energy of activation for the process (a)⇌(b) proved to be 10.2 ± 0.4 kcal mole^{-1}. An approximately the same barrier (17 kcal mole^{-1}) was found also for 7-chloro-1-methyl-5-phenyl-1,3-dihydro-2*H*-1,4-benzodiazepin-2-one:



(XCVI)

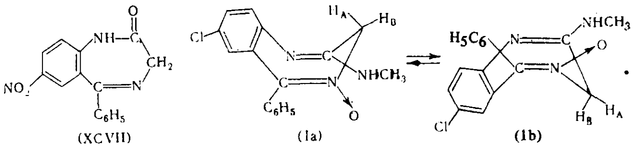
(a) (b)

Somewhat later Nuhn and Bley[144,145] found that at room temperature the methylene protons located near the 3-C atom of compound (II) gives rise in the spectrum to a typical AB-quartet with $\Delta\nu = 144$ Hz (spectrometer with $\nu_0 = 100$ MHz) and $J_{HH'} = 10.5$ Hz. At a temperature as low as 32°C the lines of the quartet begin to blur and at 127°C the protons of the methylene group contribute to a singlet peak.

Thus at room temperature the Diazepam (II) molecule exists in a conformation which does not undergo inversion and the conformational inversion of the system begins only at 32°C. The conformational stability of compounds (XCVII) and (I) is lower. The inversion of their conformations begins at −65° and −10° respectively.

The values of ΔH^* are respectively 15.9 ± 0.4 kcal mole^{-1} for (II), 10.9 ± 1.1 kcal mole^{-1} for (I), and 11.0 ± 0.3 kcal mole^{-1} for (XCVII), while the ΔS^* are 5.1 ± 1.0 kcal mole^{-1} deg^{-1} for (II), 3.4 ± 4.5 kcal mole^{-1} deg^{-1} for (I), and 13.3 ± 0.9 kcal mole^{-1} deg^{-1} for (XCVII).

The higher conformational stability of compound (II) compared with (XCVII) and (I) can be accounted for by an increase in the rigidity of the system on introduction of a methyl substituent in the 1-position of the benzodiazepine ring:

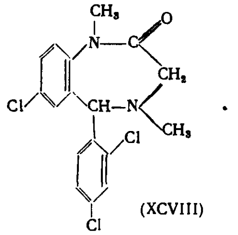


(XCVII) (Ia) (Ib)

It is also interesting that the lowest entropy of activation is observed for compound (I), which indicates a lower probability of the formation of a transition state in this case, probably because the nature of the transition state for substance (I) differs significantly from that of the transition state formed on conformational inversion of compounds(II) and (XCVII). It is not difficult to see that in the transition state formed by the inversion of conformation (I) considerable electrostatic repulsion may occur, which evidently effects the probability of the formation of such a system.

By comparing the spectra with Dreiding's models, Nuhn and Bley concluded that the most probable conformation of the above systems is the boat form¶. Consequently the above investigators arrived at the general conclusion that compounds (I), (II), and (XCVII) have a non-polar conformation, which is probably the boat form, and inversion of the type (Ia)⇌(Ib) is observed after definite temperature barriers have been overcome.

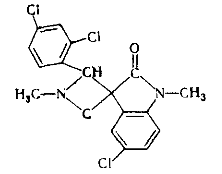
Karle and Karle[147] showed by X-ray diffraction that 7-chloro-5-(2,4-dichlorophenyl)-1,4-dimethyl-4,5-dihydro-3*H*-1,4-benzodiazepin-2-one (XCVIII) crystallises in the triclinic space group with two molecules in the unit cell, the dimensions of which are as follows: $a = 8.84$ Å; $b = 10.18$ Å; $c = 10.80$ Å; $\alpha = 93°51'$; $\beta = 112°31'$; $\gamma = 101°39'$.



(XCVIII)

The nitrogen atom in the 1-position is planar while that in the 4-position is pyramidal, which contributes to the difference between their basicities.

The $-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{\substack{\| \\ O}}{C}}-\underset{\substack{| \\ CH_3}}{N}-\overset{|}{\underset{|}{C}}-$ group is almost planar but is rotated by 50°C relative to the condensed benzene ring. On the basis of the above calculations of the bond lengths and valence angles in the molecule, the authors[147] assert that the configuration of the compound corresponds to a distorted "boat", the 5-phenyl and 4-methyl groups being in the *trans*-positions with respect to one another:



It follows from the above that only the first steps have been taken in the study of the stereochemistry of the systems under consideration. Despite the valuable information obtained recently, important problems such as the question of the preferred conformation of the ring and the factors influencing the stability of the conformation have still not been resolved unambiguously. Further study of the problem will help in the development of the chemistry of 1,4-benzodiazepines and will undoubtedly promote further development of modern stereochemistry.

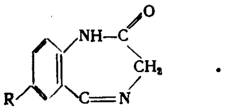
IV. PROPERTIES OF 1,4-BENZODIAZEPINES

1. Certain Characteristics of the Structure and Tautomerism of 1,4-benzodiazepine

The study of the infrared spectra of lactams of type (XCIX) leads to the conclusion that in the crystalline state and in concentrated solutions these compounds form association complexes via intermolecular hydrogen bonds.

¶ 7-Chloro-5-phenyl-1,3-dihydro-2*H*-1,4-benzodiazepin-2-one and its *N*-oxide exist in the same preferred conformation[146].

The interaction of (XCIX) with the molecules of polar solvents (chloroform, pyridine) also has a distinctive effect. The electronic influence of the substituent in the 7-position on the absorption frequency of the carbonyl group can be readily traced in the spectra of crystalline specimens of compound (XCIX).



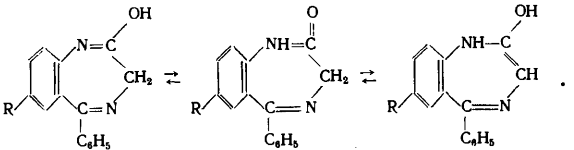
(XCIX)

The carbonyl band in the spectrum of the compound with R = NO_2 is displaced by 20 cm^{-1} towards higher wave numbers compared with the spectrum of the compound with R = CH_3 and by about 10 cm^{-1} compared with the spectrum of the compound where R = Cl.[148]

An electron-accepting substituent, for example a nitro-group, increases the polarisation of the carbonyl group and displaces the carbonyl absorption band towards higher wave numbers, as happens in other examples known from the chemistry of the aromatic series[149]. An electron-donating substituent causes the opposite shift of the absorption band, while substituents with $-J$ and $+C$ effects (halogens) have an intermediate influence. It has been found that the relative changes in the shift of the carbonyl absorption bands as a function of the substituent in the 7-position are satisfactorily correlated with Hammett's σ constants.

Usually investigators[2] regard the bands at 1620–1605 cm^{-1} and 1580–1590 cm^{-1} as characteristic of this system, but this assertion is so far insufficiently supported by evidence although empirically it is probably reliable.

Three tautomeric forms may be suggested for compounds of type (XCIX):



(a) (XCIX) (b)

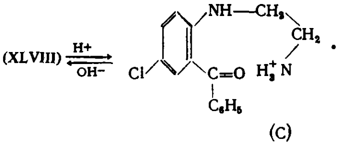
In the crystalline state and in acid and neutral solutions, (XCIX) exists in the lactam form, as shown by the infrared spectra and the chemical properties of the compound. In the presence of bases the lactim or enol forms may be produced, which has been demonstrated by ultraviolet spectroscopy at different pH of the medium. The changes in the position of the long-wavelength absorption band (λ_{max} = 320–370 nm) are of greatest interest. The bathochromic shift of this band in alkaline and acid media (to λ_{max} = 350–370 nm) compared with the neutral medium (λ_{max} = 320 nm) may be accounted for by an increase in the conjugation chain, which occurs as a result of the quaternisation of the fourth nitrogen atom (in an acid medium) and the formation of the lactim form (XCIXa) (in an alkaline medium).

The choice of structure (a) in preference to (b) was made on the basis of the finding that the ultraviolet spectra of 1-substituted and unsubstituted benzodiazepines are identical in neutral and alkaline media.

2. Hydrolysis of 1,4-Benzodiazepines

Acid hydrolysis under mild conditions of the *N*-oxides of 3*H*-1,4-benzodiazepines or their acetyl derivatives leads to the *N*-oxides of 1,2-dihydro-3*H*-1,4-benzodiazepin-2-ones.[22,150]. Under more severe conditions, 7-chloro-2-methylamino-5-phenyl-3*H*-1,4-benzodiazepine is hydrolysed to 2-amino-5-chlorobenzophenone, glycine, and methylamine[2].

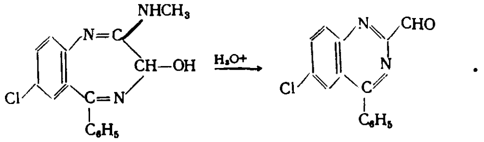
The acid hydrolysis of 1,2-dihydro-3*H*-1,4-benzodiazepines (XLVIII) takes place with the opening of the seven-membered ring and the formation of the salt (C), which on treatment with alkali cyclises to the initial compound[95]:



(C)

where R = Cl.

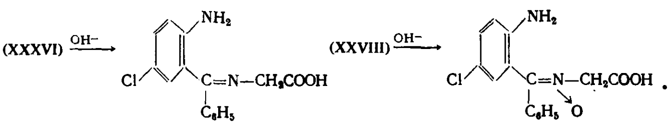
7-Chloro-3-hydroxy-2-methylamino-5-phenyl-3*H*-1,4-benzodiazepine (CI) is hydrolysed by acids to quinazoline-aldehyde (CII):[151]



(CI) (CII)

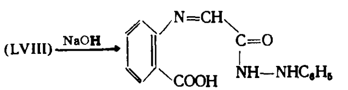
When treated with hot 75% sulphuric acid, the 2,5-dione (LXXXVIII) is converted into anthranilic acid[134].

Alkaline hydrolysis of 1,2-dihydro-3*H*-1,4-benzodiazepin-2-ones (XXXVI) and their 4-oxides (XXVIII) leads to the aminoacid salts (CIII) and (CIV) respectively, which, however, react differently with acids: compound (CIII) decomposes into *o*-aminobenzophenone and glycine and compound (CIV) cyclises to the initial product[22,44]:



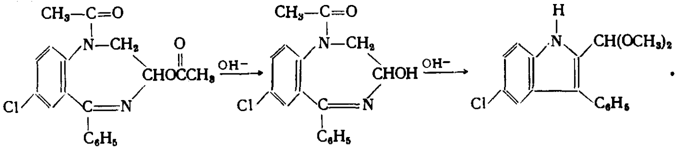
(CIII) (CIV)

1,2,3,4-Tetrahydro-5*H*-1,4-benzodiazepine-2,5-diones (LXXXVIII) are not decomposed by alkali, in contrast to the 3,5-dione (LVIII), which is readily cleaved by a hot sodium hydroxide solution to the phenylhydrazide (CV):[7,134]



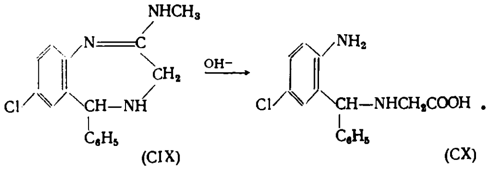
(CV)

The alkaline hydrolysis of 3-acetoxy-1-acetyl-1,4-benzodiazepine (CVI) gives the 3-hydroxy-derivative (CVII), while under more severe conditions it rearranges to the indole derivative (CVIII):[153]

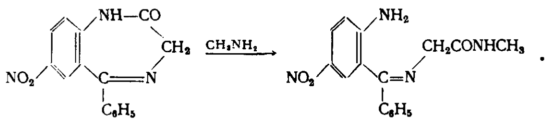


(CVI) (CVII) (CVIII)

When an aqueous alcoholic solution of compound (CIX) is refluxed with barium hydroxide, an aminoacid derivative (CX) is formed[2]:



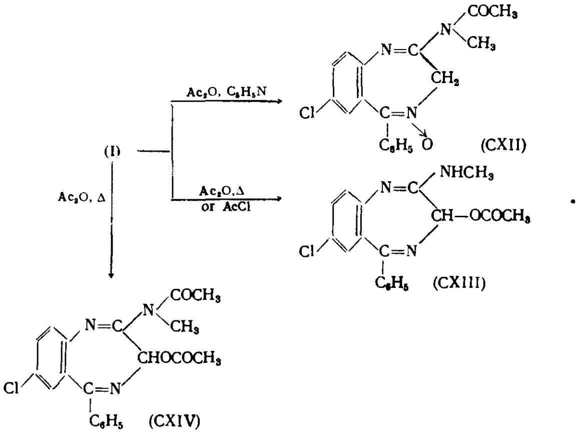
It has been shown for 7-nitro-5-phenyl-1,2-dihydro-$3H$-1,4-benzodiazepin-2-one (XCVII) that the seven-membered ring is opened when acted upon by methylamine[39]†:



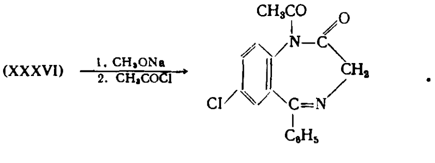
The heterocyclic ring in the 2,5-dione (LXXXVIII) is cleaved under the same conditions[134].

3. Acylation of 1,4-Benzodiazepines

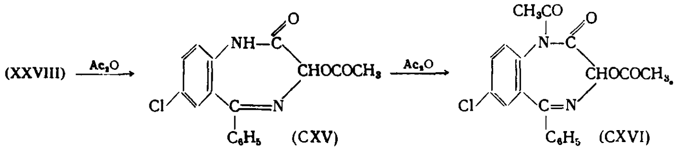
When benzodiazepines of the "Chlordiazepoxide" type are acetylated, various derivatives are obtained depending on the reaction conditions[151,154]. Thus the acetylation of compound (I) with acetic anhydride in pyridine at room temperature leads to the 2-acetyl derivative (CXII). When Chlordiazepoxide is treated with hot acetic anhydride or acetyl chloride in dimethylformamide, a rearrangement of the Polonovskii type takes places with formation of the 3-acetoxy-derivative (CXIII). Prolonged heating of compound (I) with acetic anhydride gives the 3-acetoxy-2-acetyl derivative (CXIV):



1,2-Dihydro-$3H$-1,4-benzodiazepin-2-ones are capable of being acetylated when their sodium salts are acted upon by acetyl chloride[155]:



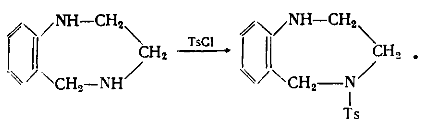
Like compound (I), on treatment with acetic anhydride the N-oxides of 1,2-dihydro-$3H$-1,4-benzodiazepin-2-ones (XXVIII) undergo a rearrangement in which the N-oxide oxygen atom migrates to the carbon atom in the 3-position forming 3-acetoxy-1,2-dihydro-$3H$-1,4-benzodiazepin-2-ones (CXV). Further reaction with acetic anhydride leads to compound (CXVI): [123,156]



When 1,2-dihydro-$3H$-1,4-benzodiazepin-2-ones (XXXVI) are treated wtih a mixture of acetic and peracetic acids and acetic anhydride, 3-acetoxy-derivatives (CXVI) are immediately obtained[157].

Other reactions of compounds of type (XXXVI) on treatment with acylating agents will be discussed below.

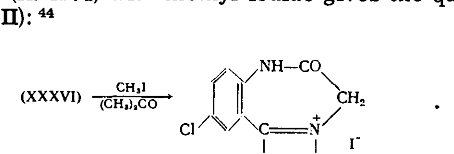
1,2-Dihydro-$3H$-1,4-benzodiazepines are acylated in the 1-position by acid anhydrides and chlorides[92,98,153]. It is interesting that the acylation of 1,2,3,4-tetrahydro-$5H$-1,4-benzodiazepine with p-toluenesulphonyl chloride in pyridine gives only the 4-tosyl derivative[105], which indicates a higher basicity of the nitrogen atom in the 4-position:



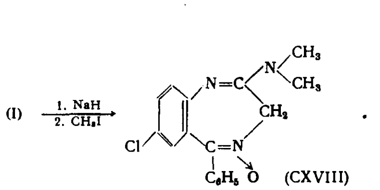
4. Alkylation and Alkoxylation of 1,4-Benzodiazepines

1,4-Benzodiazepines are alkylated preferentially in the 1- and 4-position when they or their sodio-derivatives are treated with the usual alkylating agents[3,22,44]. The methylation of the 2,5-dione (LXXXVIII) gives a mixture of the 1-methyl and 1,4-dimethyl derivatives[107].

Owing to the different basicities of the two nitrogen atoms in 1,2,3,4-tetrahydro-$5H$-1,4-benzodiazepin-2-ones, 1- or 4-alkyl or 1,4-dialkyl derivatives may be obtained depending on the reaction conditions[76]. The reaction of compound (XXXVI) with methyl iodide gives the quaternary salt (CXVII): [44]



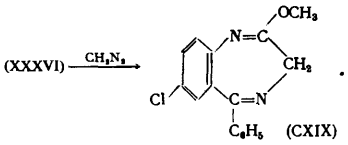
On treatment with methyl iodide in the presence of sodium hydride, Chlordiazepoxide (I) is converted into the 2-dimethylamino-derivative (CXVIII): [158]



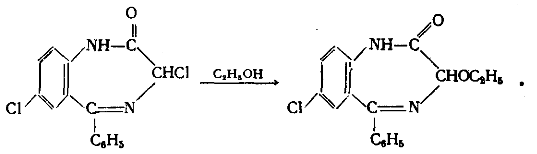
---

† The corresponding amidine is also formed as a side product in this reaction[152].

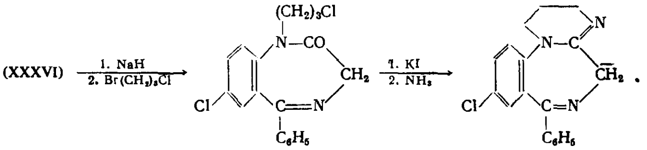
When compounds (XXVIII) and (XXXVI) react with diazomethane, the *O*-methyl derivatives of the 3*H*-1,4-benzodiazepine system (CXIX) are formed:[17,159]



3-Halogeno-derivatives of 1,4-benzodiazepines are converted into the 3-ethoxy-derivatives when acted upon by ethanol[45]:



By alkylating 1,2-dihydro-3*H*-1,4-benzodiazepin-2-ones unsubstituted in the 1-position, a large number of compounds of this series with various substituents at the N_1 atom‡ were obtained. In many cases this method is used to synthesise more complex condensed systems. For example dihydroimidazo- and tetrahydropyrimido-[1,2-*a*]-1,4-benzodiazepines were obtained in this way[161,162]:



5. Oxidation of 1,4-Benzodiazepines

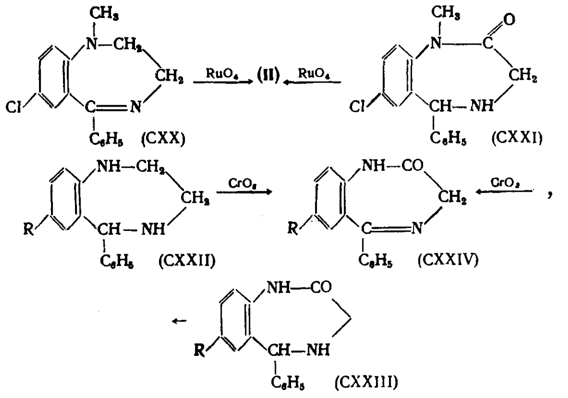
Several examples of the oxidation of these substances by peroxides have been described. 1,2-Dihydro-3*H*-1,4-benzodiazepin-2-ones may be converted into the 4-oxides by treatment with hydrogen peroxide[22]. 1,4-Benzodiazepin-2-ones unsubstituted in the 1-position (XXVI, CXIV) react with peracetic acid to form the 4-oxides.

Under these conditions, 1-acetyl-7-chloro-5-phenyl-1,2-dihydro-3*H*-1,4-benzodiazepine (LII) forms the oxaziridino derivative (LIII), which on heating is converted into the *N*-oxide (LIV).

2-Acetylmethylamino-3*H*-1,4-benzodiazepines are oxidised by peracetic acid to compounds of type (XXVIII).[150]

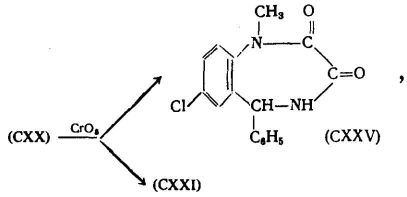
Mercury(II) oxidises 4,5-dihydro-3*H*-1,4-benzodiazepin-4-ols to *N*-oxides of type (I).[163]

When acted upon by RuO_4, CrO_3, SeO_2, or AgO, dihydro- and tetrahydro-1,4-benzodiazepines (CXX and CXXI) and tetrahydro-1,4-benzodiazepin-2-ones (CXXII and CXXIII) are converted into dihydro-1,4-benzodiazepinones (II) and compound (CXXIV) [112,164,165] respectively:



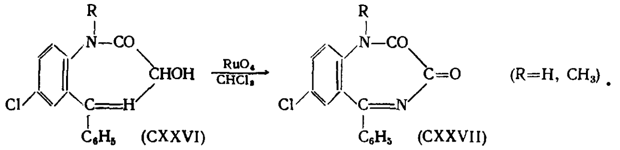
where R = H.

However, it should be noted that 1-alkyltetrahydro-1,4-benzodiazepines are oxidised to the dihydrobenzodiazepinones only by RuO_4, while CrO_3, SeO_2, and AgO oxidise compounds (CXX) to the monocarbonyl (CXXI) or dicarbonyl (CXXV) derivatives of tetrahydro-1,4-benzodiazepines:

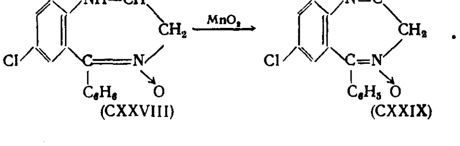


where R = CH_3.

3-Hydroxy-1,2-dihydro-3*H*-1,4-benzodiazepin-2-ones (CXXVI) are oxidised by ruthenium tetroxide to the unstable *α*-dicarbonyl derivatives (CXXVII):[165]



When 7-chloro-2-methyl-5-phenyl-1,2-dihydro-3*H*-1,4-benzodiazepine 4-oxide (CXXVIII) is oxidised with MnO_2, the 4-oxide of 7-chloro-2-methyl-5-phenyl-3*H*-1,4-benzodiazepine (CXXIX) is obtained:



6. Reduction of 1,4-Benzodiazepines

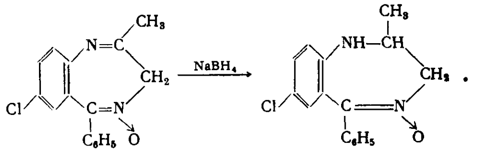
The *N*-oxides of 1,4-benzodiazepines are reduced to the corresponding deoxy-compounds by phosphorus trichloride or hydrogen in the presence of Raney nickel[2].

---

‡ It proved possible to synthesise in this way all the metabolites of 7-chloro-1-(diethylaminoethyl)-5-(2-fluorophenyl)1,2-dihydro-3*H*-1,4-benzodiazepin-2-one observed previously in the urine of patients receiving this preparation[160,161].

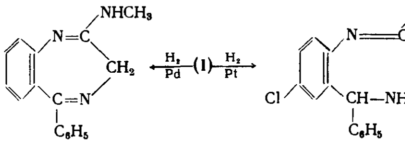
The *N*-oxide group is reduced to N–OH by complex hydrides [$LiAlH_4$, $NaBH_4$, $(CH_3)_4NBH_4$], hydrogen on a platinum catalyst and in the presence of Raney nickel, and also by Grignard reagents. Apart from the *N*-oxide group, the adjacent C=N double bonds are also reduced and in the case of *N*-oxides of 1,4-benzodiazepines $LiAlH_4$ reduces the carbonyl group to the methylene group[2,98,163].

The 4-oxides of 5*H*-1,4-benzodiazepines are reduced by complex hydrides to 1,2,3,4-tetrahydro-5*H*-1,4-benzodiazepines[41]. In contrast to other 1,4-benzodiazepine *N*-oxides, compound (CXXX) is reduced by sodium borohydride to (CXXXI), i.e. in this case a selective reduction of the C=N bond in the 1,2-position without involvement of the N→O group is observed[41]:



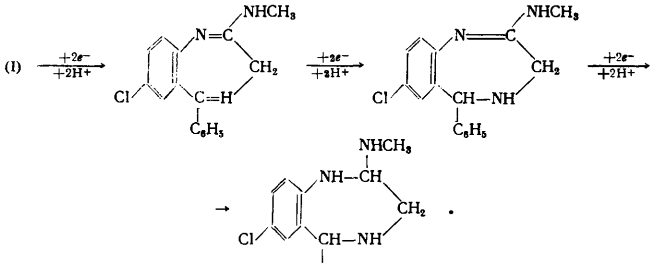
(CXXX) (CXXXI)

Chlordiazepoxide (I) is reduced in different ways by hydrogen on palladium and platinum catalysts: in the first case the reduction proceeds with elimination of chlorine from the 7-position and the oxygen from the N→O group, while in the second case the N→O group and the adjacent C= N bond are reduced[2]:



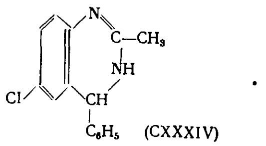
(CXXXII)

The attempts to reduce further compound (CXXXII) by hydrogen in the presence of platinum were unsuccessful. Compound (I) is reduced at a dropping mercury electrode in three stages, which corresponds to three polarographic waves[166]:



(CXXXIII)

In the first stage the *N*-oxide group is reduced, in the second stage the azomethine bond in the 4,5-position, and in the last case the double bond in the 1,2-position. However, it proved impossible to isolate compound (CXXXIII) by the preparative electrochemical reduction of (CXXXII) owing to its instability and ready conversion into the dihydroquinazoline (CXXXIV) with elimination of methylamine[167]:

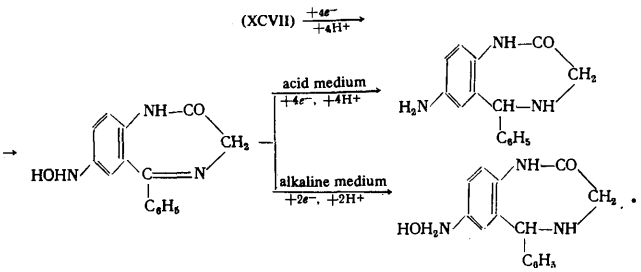


(CXXXIV)

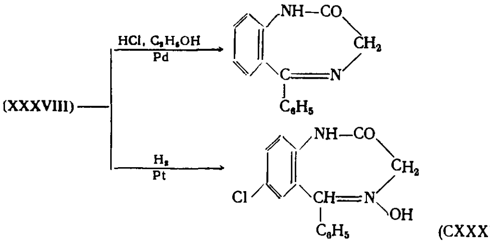
The azomethine group is reduced polarographically in 1,2-dihydro-3*H*-1,4-benzodiazepin-2-ones of type (II).[168-171]

The mechanism of the reduction of 7-nitro-5-phenyl-1,2-dihydro-3*H*-1,4-benzodiazepin-2-one (CXVII)§ is more complex, since this compound contains another polarographically active group (NO_2). In the first stage, corresponding to the first wave, the nitro-group is reduced to the hydroxyamino-group. In the second stage (second wave) in an acid medium the azomethine bond and the hydroxyamino groups are reduced, the latter to the amino-group.

In an alkaline medium only the azomethine bond is reduced in this stage[169,170]:

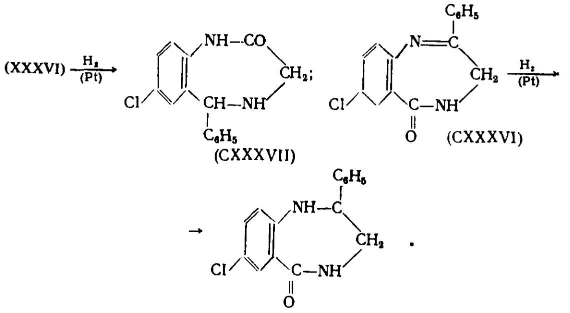


The benzodiazepinone (XXVIII) is also reduced on a palladium catalyst with elimination of chlorine and *N*-oxide oxygen atoms, whereas treatment with hydrogen in the presence of platinum results in the formation of compound (CXXXV):[22,44,172]



(CXXXV)

Compounds (XXXVI) and (CXXXVI) are reduced on a platinum catalyst to the 1,2,3,4-tetrahydro-5*H*-1,4-benzodiazepinones (CXXXVII) and (CXXXVIII) respectively[22,103]:



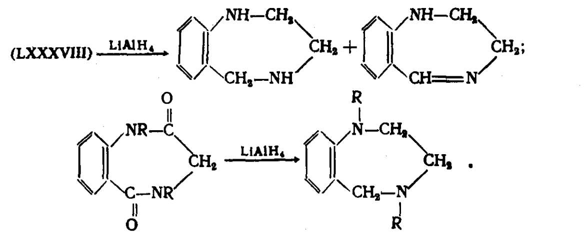
(CXXXVII) (CXXXVI) (CXXXVIII)

When compounds (XXXVI) and (LXXXVIII) are reduced with lithium aluminium hydrides, a mixture of dihydro- and

---

§ The active ingredient of the familiar sedative "Mogadon" ["Mogadan", "Nitrazepam", "Eunoctine" (tentative spelling—Ed. of Translation)].

tetrahydro-derivatives is formed, while 1,4-disubstituted diones give only the tetrahydro-derivatives (CXL): [95,107,134]



(CXXXIX) (CXL)

Dihydro-derivatives of 1,4-benzodiazepines of type (XLVIII) are reduced to tetrahydro-1,4-benzodiazepines by lithium aluminium hydride and hydrogen on platinum and palladium catalysts[95].

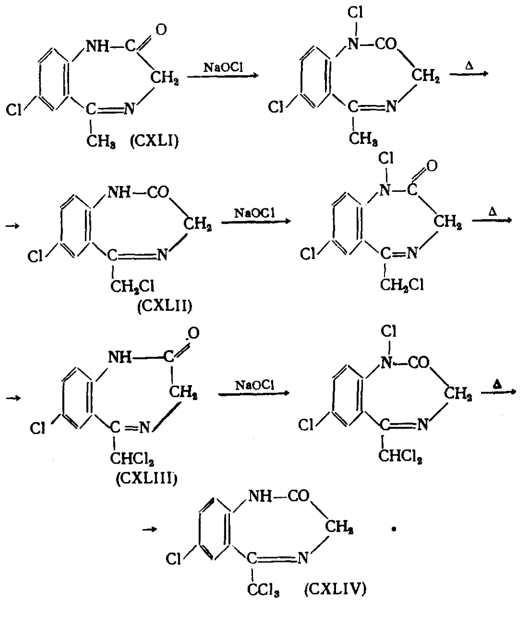
7. Nitration of 1,4-Benzodiazepines

Benzodiazepines unsubstituted in ring *A* are nitrated in the 7-position. When 7-substituted 5-phenyl-1,3-dihydro-2*H*-1,4-benzodiazepin-2-ones are nitrated, derivatives with the nitro-group in ring *C* occupying the *meta*-positions are obtained[173]. Consequently the 1,4-benzodiazepine system behaves as an electron acceptor in relation to the benzene ring. Further nitration leads to the substitution of hydrogen by a nitro-group in the 9-position[174] and in the nitration of tetrahydro-1,4-benzodiazepines substitution also takes place in ring *C*, but this time in both the *meta*- and *para*-positions and not the *meta*-position only.

8. Halogenation of 1,4-Benzodiazepines

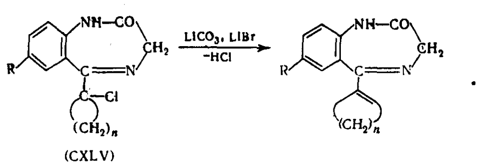
1,2-Dihydro-3*H*-1,4-benzodiazepin-2-ones with a very mobile chlorine atom in the 1-position can be obtained by the reaction of the lactams (CXLI) with organic or mineral hypochlorites[175].

The chlorine atom readily migrates to the carbon atom of the substituent in the α-position relative to the seven-membered ring provided that there is at least one hydrogen atom at this carbon atom. If there are two or three such hydrogen atoms, they are all successively substituted by chlorine atoms:



The chlorine atoms in compounds of type (CXLII), (CXLIII), and (CXLIV) can be readily replaced, by the usual procedures, by a CN group or amino-residues.

When chloro-derivatives of type (CXLV) in solution in dimethylformamide are refluxed with lithium carbonate or bromide, a molecule of HCl is split off with formation of a double bond in the αβ-position of the substituent at C_5:

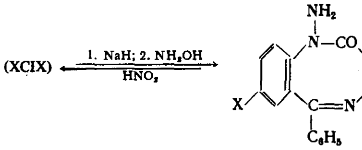


(CXLV)

There are data showing the successful halogenation of 1,2-dihydro-3*H*-1,4-benzodiazepin-2-ones by *N*-halogeno-compounds[176]. However, according to Bell's results[50], the bromination of compound (XXXVI) by *N*-bromosuccinimide does not give the required 3-bromo-derivative. The latter was obtained by the action of *N*-bromosuccinimide on an isomer of compound (XXXVI)—7-chloro-5-phenyl-1,2-dihydro-5*H*-1,4-benzodiazepin-2-one[50].

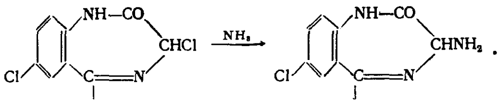
9. Amination of 1,4-Benzodiazepines

The sodium salts of lactams of type (XCIX) can react with chloramine to form 1-amino-derivatives (CXLVI), [177] which are readily deaminated by nitrous acid:



(CXLVI)

3-Amino-derivatives (CXLVIII) are obtained when solutions of 3-chloro-1,2-dihydro-3*H*-1,4-benzodiazepin-2-ones (CXLVII) are treated with ammonia:



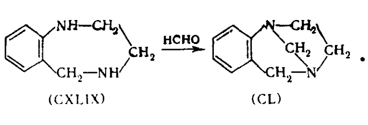
(CXLVII) (CXLVIII)

1,4-Benzodiazepines with an amino-group in the 7-position are obtained from the 7-nitro-derivatives by reduction with hydrogen in the presence of Raney nickel[25] and also by the Hofmann degradation of 7-carbamoyl-1,4-benzodiazepines. Aminobenzodiazepines may be converted into the corresponding hydroxy-, cyano-, and halogeno-derivatives via diazo-compounds.

10. Other Reactions

The reaction of 1,4-benzodiazepin-2-ones with P_2S_5 (in boiling pyridine) leads to the substitution of carbonyl oxygen by sulphur, i.e. to the formation of 1,4-benzodiazepine-thiones, from which methylthio-derivatives have been obtained by reaction with dimethyl sulphate[38,158].

Tetrahydro-1,4-benzodiazepine (CXLIX) undergoes condensation with formaldehyde, forming a bridge-type compound (CL): [110]

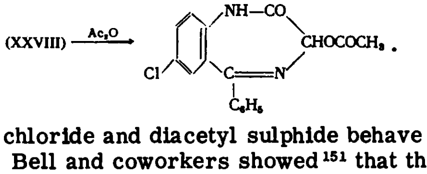


(CXLIX) (CL)

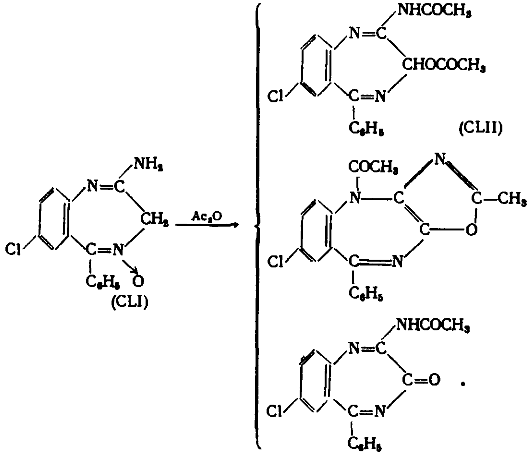
1,4-Benzodiazepines readily form coordination compounds with Lewis acids. Thus it has been observed that 1,2-dihydro-3*H*-1,4-benzodiazepin-2-ones react with SiF_4 to give 1 : 1 adducts. The SiF_4 molecule is probably coordinated to the 4-N atom[178].

11. Rearrangements and Isomerisation

The rearrangement of *N*-oxides of 1,4-benzodiazepines of the Polonovskii type¶ under the influence of acetic anhydride leads to the formation of derivatives with the acetoxy-group in the α-position relative to the nitrogen atom of the *N*-oxide group[123]:

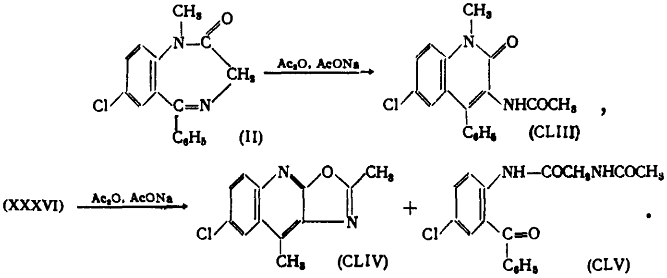


Benzoyl chloride and diacetyl sulphide behave analogously[181]. Bell and coworkers showed[151] that the 4-oxide of 2-amino-7-chloro-3*H*-1,4-benzodiazepine (CLI) forms three compounds on heating with acetic anhydride; the authors suggest that the last two are formed from the diacetyl derivative (CLII):



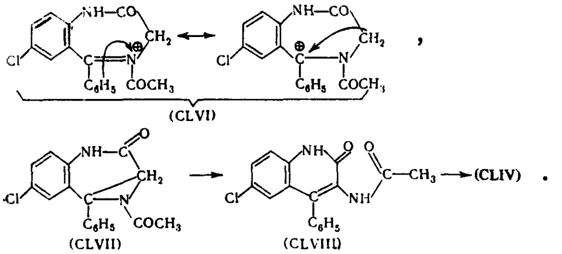
(CLI) (CLII)

The reaction of acetic anhydride with 7-chloro-1-methyl-5-phenyl-1,2-dihydro-3*H*-1,4-benzodiazepin-2-one (II) in the presence of sodium acetate leads to an intramolecular rearrangement with formation of 3-acetamido-6-chloro-1-methyl-4-phenyl-2-(1*H*)-quinolone (CLIII).[182] The corresponding 1,4-benzodiazepinone without the methyl group at the nitrogen atom rearranges under these conditions to the tricyclic compound (CLIV) and at the same time the seven-membered ring is cleaved with formation of compound (CLV):



(II) (CLIII) (CLIV) (CLV)

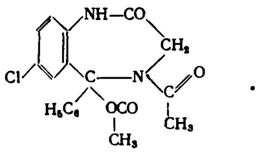
The formation of compound (CLIV) can be accounted for as follows. The mesomeric acetylated ion (CLVI), formed when acetic anhydride reacts with compound (XXXVI) via the unstable intermediate (CLVII), is converted into acetamidoquinolone (CLVIII), which is cyclodehydrated under the reaction conditions to compound (CLIV):



(CLVI)

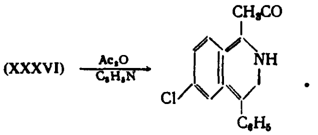
(CLVII) (CLVIII)

The formation of compound (CLIII) from (II) can be explained similarly. The second intermediate (CLIX) is postulated to account for the formation of compound (CLV) and the mesomeric acetylated ion (CLVI):



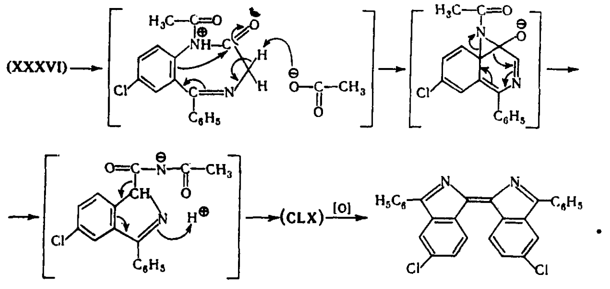
(CLIX)

When acted upon by acetic anhydride in the presence of pyridine, compounds of type (XXXVI) are converted into isoindole derivatives (CLX):[183]



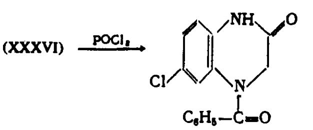
(CLX)

It is suggested that this reaction also proceeds via a stage involving the formation of an acetylated ion:



A certain amount of the "dimer" is formed as a result of the oxidative dimerisation of the isoindole.

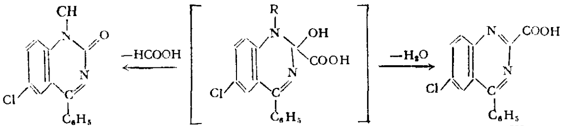
1-Alkyl-1,3-dihydro-2*H*-1,4-benzodiazepin-2-ones also rearranges to isoindoles when acted upon by bases in an anhydrous medium[184]. When compounds (XXVIII) are treated with phosphorus oxychloride or *p*-toluenesulphonyl chloride, a rearrangement of the Beckmann type takes place with formation of 4-benzoyl-6-chloro-3,4-dihydro-1*H*-quinoxalin-2-one:[185]



¶ The mechanism of the rearrangement has been discussed in a number of papers (see, for example, Refs. 179 and 180).

1,2-Dihydro-3*H*-1,4-benzodiazepine-2,3-diones rearrange to the quinozoline derivatives in the presence of acids[165].

It is suggested that the rearrangement of compound (CXXX) in the presence of acids takes place with participation of an intermediate (CLXI), which splits off formic acid (R = CH_3) or water (R = H) and gives 6-chloro-1-methyl-4-phenyl-1,2-dihydroquinazolin-2-one (CLXII) or 6-chloro-4-phenylquinazolinecarboxylic acid (CLXIII) respectively:

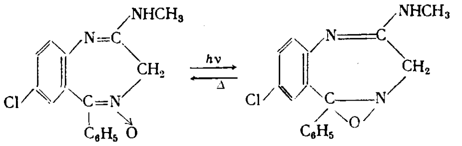


(CLXII) (CLXI) (CLXIII) ,

where R = CH_3 or H.

When 1,2-dihydro-5*H*-1,4-benzodiazepin-2-ones are acted upon by bases (alkalis, alkoxides, or triethylamine), they isomerise to 1,2-dihydro-3*H*-1,4-benzodiazepin-2-ones[50].

The photoisomerisation of 1,4-benzodiazepines has been described[186]. When a dilute solution of compound (I) in isopropyl alcohol is illuminated, the two absorption maxima in the ultraviolet spectra at λ_{max} = 245 and 265 nm characteristic of the substance disappear and are replaced by a band with a lower intensity at λ_{max} = 278 nm. It is suggested that this involves the formation of an epoxide, as happens in the conversion of nitrones into oxaziridines[187,188]:



.

V. APPLICATIONS OF 1,4-BENZODIAZEPINES

The development of the chemistry of 1,4-benzodiazepine systems is in many ways due to their practical applications. We may recall that the first studies by Sternbach of compounds of this class were undertaken to find substances acting on the central nervous system. The first preparation of this class—Chlordiazepoxide (Librium or Elenium) (I)—already proved to be an unusually effective tranquiliser[189]. Apart from this effect, compound (I) exhibits a muscle relaxing and anticonvulsive activity.

The tranquilising action of 1,4-benzodiazepines is not only accompanied by the inhibition of the central nervous system but there is at the same time a stimulating effect. All these factors led to the isolation of 1,4-benzodiazepines as a new important group of psychotropic preparations—minor tranquilisers.

All derivatives of the Chlordiazepoxide type, i.e. 4-oxides of 3*H*-1,4-benzodiazepine, and also 1,2-dihydro-3*H*-1,4-benzodiazepin-2-ones exhibit an effect on the central nervous system similar to that of Librium. The presence or absence of basic groups in the 2-position of the ring and also of the amine oxide group does not involve a loss of psychopharmacological activity[4].

Probably the 1,4-benzodiazepine ring itself and possibly also its conformation play the most significant role in physiological activity[190].

As effective tranquilisers, 1,4-benzodiazepines have found wide application in the treatment of epilepsy, alcoholism[191], various psychological disorders[4], and tetanus; their use before and after operations as sedatives has been indicated. Among the widely employed preparations enumerated above, Valium (Diazepam), which gives excellent results in 50% of psychotic and 80% of psychoneurotic cases[192] may be particularly recommended. The latest published data suggest that the above effects are not optimal, since the study of this series of physiologically active substances has only just begun[193].

Unfortunately so far other applications of these preparations have been little investigated, although, in view of the presence of an interesting conjugated system in their molecules, they are not without interest for the chemistry of dyes and possibly also in other practical fields. Certain data on this problem have been published recently[194]: a series of cyanine dyes derived from 1,4-thiazepines, diazepines, and selenazepines have been obtained.

Probably 1,4-benzodiazepine derivatives are capable of giving rise to new possibilities in both theory and practice, which will be discovered in further investigations of this interesting group of substances[195].

Synthesis and Chemical Reactions of Metal-containing Macromolecules

S.L.Davydova, N.A.Plate, and V.A.Kargin (deceased)

The synthesis of polymers containing "non-organic" elements has been discussed in the literature, the most exhaustive monographs being those of Andrianov[1], Nametkin and coworkers[2], Gefter[3], and others. There have also been a large number of publications concerning the problem of the synthesis of polymers containing alkali metals, alkaline earth metals, heavy metals, and transition metals.

The present review deals with the most important studies on the synthesis and chemical reactions of metal-containing polymers of various types. Metal-containing polymeric compounds are understood as organometallic polymers with organic principal chains containing a direct carbon-metal bond (regardless of the type of metal), saltlike compounds, in particular those with macromolecule-oxygen-metal bonds, and also complex polymeric compounds containing, for example, coordinated atoms of 3*d* transition metals.

Wherever possible the reactivities of metal-containing molecules and their low-molecular-weight analogues have been compared. The review mentions unsuccessful attempts to prepare metal-containing macromolecules and their reaction products[4]; the studies where the formation of these compounds was inferred only from the change in the colour of the reaction mixture[5] and also those where the possibility of metallation was admitted merely in principle[6] are not included.

In the preceding review on the synthesis of metal-containing polymers[7], the problems of their reactivity were hardly dealt with owing to the lack of sufficient factual data at the time.

The bibliography includes 111 references.

CONTENTS

I. INTRODUCTION

Metal-containing polymers as well as low-molecular-weight organometallic and complex compounds are interesting primarily from the standpoint of the reactivity of the bond formed by the metal. The bonds between the metal and the polymer chain may be of fundamentally different types. Covalent polymer–metal bonds are extremely reactive and this has been used in many chemical reactions involving macromolecules.

Coordinate bonds of the type $C-O-M \leftarrow O$, $C-O-M \leftarrow N$, etc. are particularly interesting, since they are formed in many of the most important biochemical systems. The nature of bonds of this kind changes significantly as a function of the metal and the ligand coordinated to it; the coordination centres are as a rule quasiaromatic systems.

The saltlike metal–polymer bond, for example $C-O-M$ or $CO-O-M$, is widely used in ion exchange; many publications have dealt with metal-containing polymers of this type[8] and therefore we shall not consider them in detail.

Dative polymer–metal π interaction is assumed, for example, for copper(I), silver(I), and gold(I) acetylides in which electrons are transferred from the bonding π_n acetylene orbitals to the *d* orbitals of the metal and from the latter to the unoccupied antibonding π_g orbitals of acetylene; a recent review by Sladkov and Ukhin[9] dealt with this problem.

Depending on the nature of the polymer–metal bond, various applications of metal-containing compounds are possible.

When a fairly stable bond (for example a saltlike bond) is formed by the metal with polymers, the latter may be used and have been used to detect and separate traces of metal ions and to separate ions quantitatively to achieve a high degree of purification of water and organic solvents. Here we have the entirely realistic problem of the application of salt forming polymers for medical and agricultural purposes associated with the introduction and elimination of metals from organisms.

When a reactive metal–polymer bond is formed, as happens in true organometallic compounds, the polymers may be used as catalytic systems for chemical reactions of different kinds. One of the most important fields in the modern physical chemistry of polymers is concerned with the search for macromolecular catalysts and the study of the mechanism of their action. The long-chain structure of the molecule containing in the chain active centres capable of interacting with one another, with the additional possibility of altering the shape of the molecule sorbing selectively particular reactants, makes polymer catalysis noteworthy not only from the theoretical (simulation of biocatalysis) but also from the practical standpoint of the achievement of particular oxidation–reduction, polymerisation, hydrolytic, etc. reactions. Effective catalysts of this type may be both organometallic polymers and complex polymeric compounds obtained by the coordination of variable-valence metal ions to polymeric ligands of a wide variety of types.

Recently polymeric substances have been employed with increasing frequency in medical practice and therefore increasing attention has been devoted to the problems of the synthesis and investigation of new polymeric systems with physiological activity and a set of properties necessary for their employment in medical practice (blood substitutes, oxygen-transferring agents, medicinal preparations, materials for artificial internal organs). In their theoretical aspect, the studies on macromolecular compounds are coming into increasingly close association with the investigation of biopolymers and the simulation of biological systems, where complex-forming polymers as model systems are already of particular interest.

II. ORGANOMETALLIC POLYMERS DERIVED FROM GROUP I, II, AND III METALS. THE USE OF LITHIUM-CONTAINING POLYMERS FOR THE INITIATION OF POLYMERISATION AND THE PREPARATION OF POLYFUNCTIONAL POLYMERS

Recently most attention has been devoted to the study of the chemical reactions of macromolecules of two types: containing alkali metals (mainly lithium) and heavy metals (mainly tin). This can be understood if one remembers the wide range of reactions of which low-molecular-weight organolithium compounds are capable, on the one hand, and also the great interest in low-molecular-weight organotin compounds as stabilisers for a wide range of polymers, antiseptics, etc., on the other.

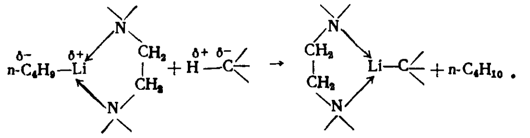
Among all the possible syntheses of organometallic polymers derived from Group I, II, and III metals, the following may be employed: (1) direct replacement of a hydrogen atom for a metal atom, for example by metallic lithium[10] ($RH + Li \rightarrow RLi + H$); (2) metallation consisting in the reaction of a metal, for example lithium, with a halogeno-derivative of the polymer[11] ($RX + 2Li \rightarrow RLi, LiX$); (3) metallation of polymeric hydrocarbons by lithium alkyls[12] ($RH + R'Li \rightarrow RLi + R'H$); (4) exchange reaction between a low-molecular-weight organolithium compound, for example $N\text{-}C_4H_9Li$, or C_6H_5Li, and a halogeno-derivative of the polymer[13] ($RX + R'Li \rightarrow RLi + R'X$); (5) addition of the metal hydride to a double bond of the polymeric hydrocarbon[5].

The first reaction has not been achieved for polyolefins owing to the lack of sufficiently reactive C–H bonds (the energies of the $-\overset{|}{\underset{|}{C}}-H$ bonds in polyethylene and in polypropylene are 128 and 80 kcal mole^{-1} respectively).

The use of the second reaction for the introduction of lithium into polyolefins is also difficult for the following reasons: judging from the literature data[14], an increase of the yield of the organolithium compound containing the metal at a saturated secondary carbon atom may be expected only when the reaction temperature is reduced and this involves the necessity to carry out the reaction under heterogeneous conditions, since both components (the polymer and metallic lithium) are insoluble in the reaction medium at low temperatures.

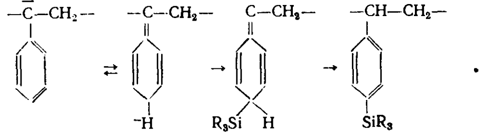
In order to introduce the metal into aryl-containing polymers by the third method, the authors of the review, Yampol'skaya, and Okhlobystin employed the reaction of the complex of butyl-lithium with *NNN'N'*-tetramethylethylenediamine, which is familiar in the chemistry of low-molecular-weight compounds; the starting materials employed in this reaction were acetic polystyrene and aryl-containing polyolefins–copolymers of α-methylstyrene and α-methyl-*p*(*m*)-methylstyrene and propene[15].

The high reactivity of the complex of n-butyl-lithium with *NNN'N'*-tetramethylethylenediamine can be accounted for by the increase in the ionic character of the C–M bond owing to the vigorous solvation of the lithium atom. The metallation of aryl-containing polymers by hydrogen–metal exchange takes place as a result of nucleophilic attack by the anion of the complex on the benzene hydrogen (in styrene polymers and copolymers of α-methylstyrene and propene) or on the methyl group attached to the arene ring [for poly-*p*-methylstyrene and copolymers of α-methyl-*p*(*m*)-methylstyrene and propene]:



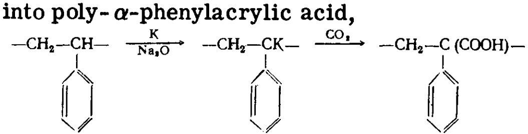
Although the formation of metal derivatives is in fact complicated by competing reactions, nevertheless the degree of metallation is quite sufficient for further reactions of such polymers with compounds containing the appropriate functional groups[16].

Chalk subsequently investigated the metallation of polystyrene by the butyl-lithium–*NNN'N'*-tetramethylethylenediamine complex[17] and compared it with the metallation of a low-molecular-weight model (toluene)[13] under the same conditions. With the aid of successive trimethylsilylation and treatment with dimethyl sulphate or D_2O, it was shown that, whereas toluene is substituted by lithium mainly in the side chain (up to 90.8%) and only slightly in the ring (the yields of derivatives substituted in the *meta-*, *para-*, and *ortho*-positions were 5.3, 1.8, and 2.0% respectively), polystyrene is substituted by lithium almost exclusively in the ring (20–25%) and only slightly in the chain (1–2%), regardless of the duration of the reaction; the substitution takes place to the extent of 80% in the *para*-position and to the extent of 20% in the ortho-position. The author proposes the following mechanism of such "anomalous" course of the reaction:



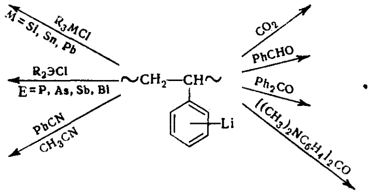
We believe that these results can be explained by the steric hindrance to the reaction in the benzyl-position of the polystyrene chain (see p. 1093).

Poly-α-potassiostyrene, which is subsequently converted into poly-α-phenylacrylic acid,



was obtained by Morton and Taylor[19] by the action of metallic potassium on polystyrene, but these data were not confirmed subsequently.

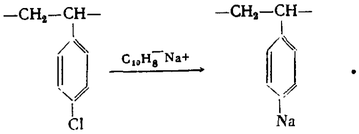
The fourth method has been most widely used for the metallation of polyhydrocarbons; here the principal investigations have been carried out by Braun and coworkers[7]. They discussed comprehensively the metallation of halogen-containing polymers in a number of publications[20–23]; they investigated a large number of reactions of polylithiostyrene:



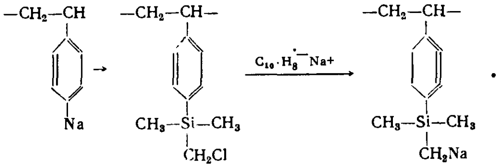
Apart from the reactions indicated in the above scheme, the reactions of poly-*p*-lithiostyrene with O_2, SO_2, nitroso- and nitro-compounds, phenyl isocyanate and thiocyanate, orthoformic ester, pyridine, dimethylformamide, etc. have been described. Braun also obtained an insoluble lithium-substituted polystyrene starting with a cross-linked (degree of cross-linking 2%) polymer of iodostyrene and styrene with a high content of the latter. Then he replaced lithium by residues of nicotine, comphor, camphorsulphonic acid, and other organic groups[21], as well as groups containing "non-organic" elements[22]; by allowing the copolymer to react with sulphur powder, he obtained mercaptopolystyrene[23]. Thus the chemical reactions of lithium-substituted polystyrene made it possible to introduce virtually any functional group into polystyrene. It has been noted that in the reaction of butyl-lithium with iodinated polystyrene, the order of addition of the reactants is very important (polymer to a solution of the organometallic compound and not vice versa) in order to prevent the cross-linking of the chains[21].

Lithium derivatives of polystyrene have also been obtained by Leavitt and Matternas[24] by the metallation of poly-*o*- or poly-*p*-bromostyrene; to suppress the Wurtz–Fittig reactions, the metallation was carried out at a high concentration of butyl-lithium and a low temperature (−35°); subsequently the lithium-substituted polystyrene was substituted by tin with the aid of R_3SnCl.

Greber and coworkers[5] carried out a series of studies on the metallation of halogen-containing polymers (for poly-*p*-chlorostyrene and its copolymer with styrene) by sodionaphthalene in tetrahydrofuran or dimethoxyethane:

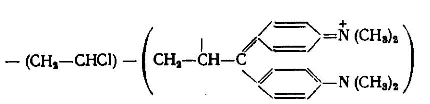


The authors employed the metallated polymers obtained as polymeric initiators of polymerisation or for the introduction of functional groups (for example the dimethylchloromethylsilyl group), which are in turn capable of undergoing further metallation:



By this type of metallation of poly(vinyl chloride), Greber prepared a polyhydrocarbon of unknown structure with a high content of cyclopropane groups. Fig. 1 shows that, in the metallation of poly-*p*-chlorostyrene, 2 g-atoms of sodium are consumed for each g-atom of chlorine; this implies that the Wurtz side reaction (interchain cross-linking) hardly occurs under these conditions[5].

Several attempts have been made to achieve the reaction of poly(vinyl chloride) or poly(vinyl bromide) with organometallic compounds such as diethylzinc[25], trityllithium and its analogues[26], and sodionaphthalene[26]. The reaction of poly(vinyl chloride) with butyl-lithium was investigated in greatest detail by Shiina and Minoura[6]. It leads to only partial metallation of the polymer, since in this case the competing reactions are as for halogenopolystyrenes, butylation and dehydrochlorination. The lithium-substituted fraction of poly(vinyl chloride) was employed in polymerisation initiated by CO_2, Michler's ketone, etc. For example the polymeric analogue of Malachite Green was obtained:



The authors note that the attempts to carry out the reaction of poly(vinyl chloride) with phenyl-lithium and sodionaphthalene were unsuccessful[6].

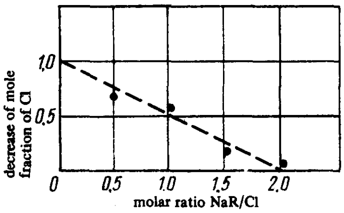


Figure 1. Metallation of poly-*p*-chlorostyrene (M = 78 000) with $NaC_{10}H_8$.

It has been found that the metallation of halogen-containing polymers, for example polychlorotrifluoroethylene, may be achieved by treatment with a solution of the given metal in liquid ammonia; lithium, sodium, calcium, barium, and magnesium have been used[27]. The introduction of sodium may be achieved also with the aid of a solution of sodionaphthalene in dimethoxyethane[28]. Examination under the electron microscope of a polymer film after its immersion for 2–3 s in the metallating solution shows that the metallating component penetrates to a depth of 10^{-4} cm. Metallation of this kind increases the adhesion of adhesives to films of the above type.

The exchange reaction between a low-molecular-weight compounds RLi, for example n-butyl lithium or phenyllithium, and polymers were carried out by the authors of the review and Yampol'skaya[29] for halogeno-derivatives of polyolefins:

$$-\underset{\displaystyle Hal}{CH_2C}(R)-CH_2-CH(R)- + R'Li \rightleftarrows -CH_2-\underset{\displaystyle Li}{C}(R)-CH_2-CH(R)- + R'Hal\,,$$

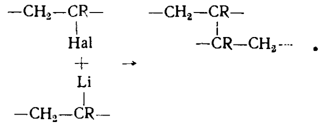
where R = H or CH_3 and R′ = n-C_4H_9 or C_6H_5.

Chlorinated and brominated polyethylene and chlorinated polypropylene were employed as halogen-containing polyolefins. The reaction involving the substitution of a halogen by lithium is reversible; its equilibrium position is determined by the relative stabilities of the corresponding carbanions. Therefore in the reaction of halogenopolyolefins with n-butyl- and phenyl-lithium one cannot expect a high yield of the metallated products: the stabilities of the butyl and polymeric anions are comparable and the phenyl anion is actually more stable than the polymeric anion. Indeed the amount of lithium in the polymeric molecule, determined by direct titration, proved to be low (lithium-substituted polyethylene containing 0.85% of lithium was obtained from chlorinated polyethylene containing 24.5% of chlorine, i.e. only 22% of the chlorine present was replaced by lithium). To increase the degree of metallation, it is necessary to employ an excess of the organolithium compound; moreover, the rate of reaction increases in the presence of highly solvating solvents, for example tetrahydrofuran (THF).

Being reversible, the reaction is complicated by the competing process involving the nucleophillic substitution of the halogen by the group R′ of the organolithium compound:

$$-CH_2-\underset{Hal}{CR}- + R'Li \rightarrow -CH_2-\underset{R'}{CR}- + LiHal\ .$$

The side condensation reaction can also lead to the formation of cross-linked products of the following type:



As a result of second side reaction, dehydrochlorination under the influence of the nucleophillic organometallic compound:

$$-CH_2-\underset{Hal}{CR}-CH_2-CHR- + RLi \rightarrow -CH=CR-CH_2-CHR-\ ,$$

double bonds appear in the chlorinated polyethylene. The degree of metallation of brominated polyethylene by n-butyl-lithium is very insignificant; dehydrobromination is the dominant reaction in this case.

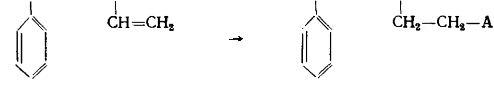
The reaction of chlorinated polypropylene is more unambiguous—when treated with phenyl- and n-butyl-lithium, it undergoes only condensation and dehydrochlorination reactions. This is in fact understandable, since an increase in the mobility of the chlorine atom at the tertiary carbon atom in the chlorinated polypropylene molecule leads to an increase of the proportion of dehydrohalogenation at the expense of metallation.

As mentioned previously (see, p. 1084), lithium-containing polymers react with various organic compounds such as dialkyl(aryl)chlorophosphines, trialkyl(aryl)chlorosilanes, trialkyl(aryl)chlorostannanes, carbonyl compounds, etc., with formation of the corresponding derivatives[30].

The high reactivity of metallated polyethylene and the copolymers of polyethylene and polypropylene with styrene permitted their application as polymeric initiators in the ananionic polymerisation of many monomers; methyl methacrylate, acrylonitrile, isoprene, and styrene. As a result of this reaction, copolymers with polyolefinic main chains and side chains comprising units of the grafted comonomers were obtained; the reaction is complicated by the homopolymerisation of the monomers by the excess n-butyl-lithium[31].

The hydrometallation of polyhydrocarbons and their derivatives was in fact achieved in the 1950's when Morton and coworkers[32] showed that alfin catalysts can cause, apart from the polymerisation of dienes, a side reaction involving the metallation of the macromolecule formed.

This method of metallation of polymers has been achieved by the addition of, for example, organoaluminium hydrides to unsaturated polymers, in particular a copolymer of styrene and butadiene[33]:



and enabled Greber and coworkers[33] to prepare a series of aluminium-containing polymers; the metallation kinetics (bromometry) are presented in Fig. 2.[33]

The same workers[34] demonstrated the intermediate formation also of another kind of metallated polymer—with a C=N–M bond, for example:

$$-CH_2-\underset{C\equiv N}{CH}- \xrightarrow{+RMgCl} -CH_2-\underset{RC=N-MgCl}{CH}-\ ,$$

by the reaction of lithium alkyls or alkyl(aryl)magnesium halides with copolymers containing nitrile groups (acrylonitrile-styrene).

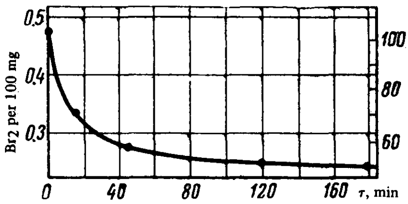


Figure 2. Decrease with time of the degree of unsaturation of the butadiene-styrene copolymer during metallation.

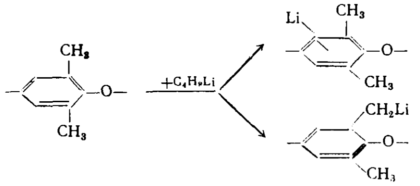
Greber employed metallated aluminium-containing polymers as macromolecular Ziegler catalysts (in a mixture with transition metal chlorides: $TiCl_4$, $TiCl_3$, $VOCl_2$, etc.).[35]

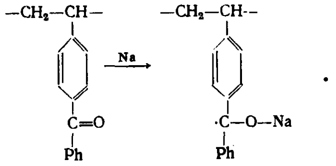
Hulot et al.[36], who repeated and revised Greber's data, investigated the interaction of unsaturated polymers (a styrene-butadiene copolymer and polyisopropene) with dibutylaluminium hydride and titanium tetrachloride as a function of the reaction conditions (effect of the order of addition and the relative amounts of the reactants and also temperature). They showed that a soluble and homogeneous polymeric catalyst of the Ziegler type is obtained only following the exhaustive metallation of the polyhydrocarbon by dialkylaluminium hydride at 130°C and subsequent reaction with titanium tetrachloride. The polymeric initiator thus obtained was used in the polymerisation of ethylene; graft copolymers containing 80% of the styrene-butadiene copolymer and 20% of the grafted monomer were also synthesised.

Chalk and Hay[37] achieved the metallation of polymers containing oxygen, namely substituted polyphenylene oxide; they employed poly-2,6-dimethyl-1,4-phenyl ether:



With the aid of butyl-lithium, both the ring (about 20%) and the alkyl group (about 80%) are metallated. The mode of metallation depends on the duration and temperature of the reaction. The authors believe that the use of potassio- and sodio-derivatives for this purpose leads to the preferential metallation of the alkyl substituents (demonstrated by trimethylsilylation). The authors believe that the initial stage of the process is ring-metallation, assuming that this stage is accompanied by the migration of the substituent to the benzyl position.

Other oxygen-containing metallated polymers (polymeric metal ketyls) were described by Braun and Löflund[38]. They were prepared by treating poly-*p*-vinylbenzophenone with sodium powder; the solutions of sodiopoly-*p*-vinylbenzophenone were employed as polymeric initiators of the radical polymerisation of vinyl monomers, for example acrylonitrile[38]:



The type of reaction between inorganic salts and polymeric epoxyethane is not entirely clear, although it can be classified as an interaction between a metal and an oxygen-containing polymer[39]. The proof of the occurrence of such interaction is the appreciable lowering of the degree of crystallinity of the polymer in the presence of 10–30% KI (the two substances being completely compatible) (Fig. 3) quoted by the authors.

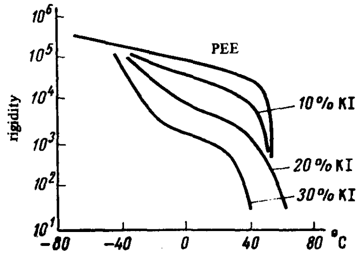


Figure 3. Dependence of the modulus of rigidity on KI content in polyepoxyethane (PEE).

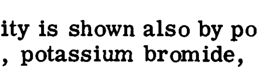
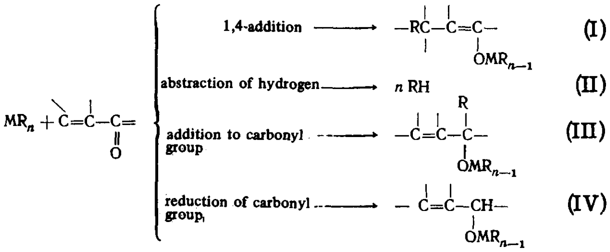
The finding that in the adduct investigated there is one salt molecule for nine polymer units suggests that ion-dipole interaction takes place but it is not clear which ion is directly linked to the chain:



$$-CH_2-CH_2-\underset{KI^-}{\overset{+}{O}}-CH_2-CH_2- \; .$$

A similar capacity is shown also by potassium fluoride, potassium chloride, potassium bromide, rubidium fluoride, and rubidium iodide, but not lithium chloride and lithium bromide; probably other polyethers, for example polyoxypropylene, are also capable of undergoing reactions of this kind[39].

An interesting mechanism for the reaction between organometallic compounds and ketones (at a low-molecular-weight level) has been put forward by Tsuruta and coworkers[40]. The reactions of a large number of organometallic compounds (RLi, RMgX, AlR_3, ZnR_2, $CaZnR_4$) with $\alpha\beta$-conjugated ketones such as phenyl vinyl (and also isopropenyl, β-styryl, isopropylidene, and benzylidene) ketone and methyl phenyl ketone have been investigated. It was found that, when $(C_4H_9)_2Zn$ and $(n\text{-}C_4H_9)_3Al$ are used, the principal stages are 1,4-addition and abstraction of hydrogen; other possible reactions (reduction of the carbonyl group, addition to the carbonyl group) take place to a lesser extent:



The contributions of the reactions (calculated from the amount of hydrocarbon produced by a particular mechanism) depend markedly on the nature of the organometallic compound:

Organometallic compound	Reaction (I)	Reaction (II)	Reaction (III)	Organometallic compound	Reaction (I)	Reaction (II)	Reaction (III)
RLi	1	1	1	ZnR_2	1	2	—
RMgX	1	1	1	$CaZnR_4$	1	2	—
AlR_3	1	3	—				

Metallation reactions of a similar type can undoubtedly be carried out also at a macromolecular level.

In conclusion of the section, we may point to another class of polymetallated oxygen-containing polymers, namely metal-containing derivatives of cellulose. Its alkoxides, not containing an excess of the alkali metal, are obtained by treatment with sodium in ammonia[41] or by an exchange reaction with sodium alkoxide[42]; however, the mechanism of the reaction of cellulose with metals leading to the formation of metal-containing derivatives in solutions of the complexes of these metals has not as yet been adequately elucidated. Cellulose metallated in this way is highly reactive in alkylation, etherification, and other reactions[42].

One may conclude that the reactivity of polymeric organometallic compounds is on the whole lower than that of their low-molecular-weight analogues. This is probably due to the great scope for the delocalisation of the charge in the polymeric cryptocarbanion (see p. 1092) and also the factors complicating the reactions and specific to polymers, which have been discussed on p. 1092.

III. ORGANOMETALLIC POLYMERS DERIVED FROM HEAVY METALS. METALLATED POLYMERS AND STABILISATION

The introduction of heavy metals such as mercury, thallium, tin, or lead into polymers has been mentioned in the literature from 1957†. The introduction of mercury into polymers was investigated in fair detail by Smirnov[43] and later by Traylor[44], who mercuated polystyrene with mercury(II) acetate; mercury-containing polymers have been obtained by the action of mercury(II) butyrate on polystyrene and poly-α-vinylthiophen[45]. The substitution of polystyrene and poly-α-vinylthiophen by thallium(III) isobutyrate takes place similarly to mercuration[46]. The substitution of cellulose derivatives by mercury and thallium has been investigated by Rogovin and coworkers[47];

---

†We shall not consider the phenomenon of association, which is well known in the chemistry of organometallic compounds of the type $[R_xM]_n$.

recently they obtained the corresponding tin and lead derivatives[48].

The sulphonated copolymers of styrene and divinylbenzene have been mercurated with mercury(II) perchlorate[49]. Polymers and copolymers of butadiene are oxymercurated by mercury(II) acetate at the double bond and also in the allyl position[50]. The reactivity of the mercurated specimens was investigated in acylation by acetyl chloride and benzenesulphonyl chloride.

In order to modify chlorinated polyethylene and poly(vinyl chloride), the authors of the review and Purinson[51] introduced organotin groups, having developed special methods for the synthesis of such tin-substituted polymers. Dimetallic mixed organic derivatives of lithium and tin, capable of reacting with chlorine atoms, for example triphenylstannyllithium or tributyl stannyllithium, were chosen for the introduction of R_3Sn groups into polymeric molecules:

$$-\mathrm{CH_2}-\underset{\mathrm{Cl}}{\mathrm{CH}}-\mathrm{CH_2}-\mathrm{CH_2X}- + \mathrm{R_3SnLi} \rightarrow -\mathrm{CH_2}-\underset{\mathrm{SnR_3}}{\mathrm{CH}}-\mathrm{CH_2}-\mathrm{CH_2}- + \mathrm{LiCl}, \qquad (\mathrm{I})$$

where X = H or Cl and R = C_6H_5 or n-C_4H_9.

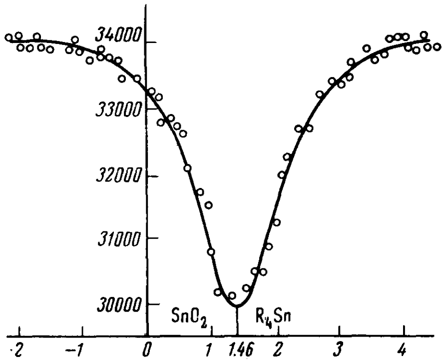


Figure 4. Mössbauer spectrum of triphenylstannated chloropolyethylene.

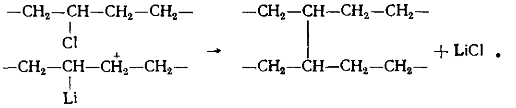
The structure of triphenylstannylated chloropolyethylene was confirmed by Mössbauer (gamma-resonance) absorption spectroscopy without recoil[52]. The isomeric shifts relative to SnO_4 in the Mössbauer spectra of the stannated polymers correspond to compounds of the type R_4Sn (Fig. 4). The stannation reaction via mechanism (I) is accompanied by a reaction in which lithium is introduced into chloropolyethylene by triphenylstannyllithium:

$$-\mathrm{CH_2}-\underset{\mathrm{Cl}}{\mathrm{CH}}-\mathrm{CH_2}-\mathrm{CH_2}- + \mathrm{LiSnPh_3} \rightarrow -\mathrm{CH_2}-\underset{\mathrm{Li}}{\mathrm{CH}}-\mathrm{CH_2}-\mathrm{CH_2}- + \mathrm{Ph_3SnCl}, \qquad (\mathrm{II})$$

which results in the formation of an insoluble fraction via the interaction of the lithium-substituted chloropolyethylene with the initial chloropolyethylene:



$$\begin{array}{c} -\mathrm{CH_2}-\underset{\mathrm{Cl}}{\mathrm{CH}}-\mathrm{CH_2}-\mathrm{CH_2}- \\ + \\ -\mathrm{CH_2}-\underset{\mathrm{Li}}{\mathrm{CH}}-\mathrm{CH_2}-\mathrm{CH_2}- \end{array} \rightarrow \begin{array}{c} -\mathrm{CH_2}-\mathrm{CH}-\mathrm{CH_2}-\mathrm{CH_2}- \\ | \\ -\mathrm{CH_2}-\mathrm{CH}-\mathrm{CH_2}-\mathrm{CH_2}- \end{array} + \mathrm{LiCl}\,. \qquad (\mathrm{III})$$

We may note that cross-linking can also occur via the formation of macroradicals without the intermediate formation of the lithium-containing polymer:

$$-\mathrm{CH_2}-\underset{\mathrm{Cl}}{\mathrm{CH}}- + \mathrm{Ph_3SnLi} \rightarrow -\mathrm{CH_2}-\dot{\mathrm{C}}\mathrm{H}- + (\mathrm{Ph_3Sn})_2 + \mathrm{LiCl}\,. \qquad (\mathrm{IV})$$

Reactions (II), (III), and (IV), which compete with the triphenylstannation reaction (I), take place to a considerable degree in heptane (for chloropolyethylene) or in tetrahydrofuran [for poly(vinyl chloride)]; in such cases fully soluble stannated polymers are formed[52].

Among all the possible chemical reactions of stannated poly(vinyl chloride), its interaction with hydrogen chloride, simulating the mechanism of the stabilisation of poly(vinyl chloride) by organotin compounds, is of greatest interest. The reaction of triphenylstannylated poly(vinyl chloride) in tetrahydrofuran with dry hydrogen chloride supplied at a constant rate was investigated. The kinetics of the dehydrochlorination of various specimens of triphenylstannylpoly(vinyl chloride) are presented in Fig. 5. The rate of dehydrochlorination was determined from the change in the amount of chloride ions bound by the polymer (curve *1*) and from the content of chloride ions in the gaseous reaction products absorbed by water (curve *2*). The dearylation of polymeric organotin compounds has also been investigated by the nuclear gamma-resonance method[30].

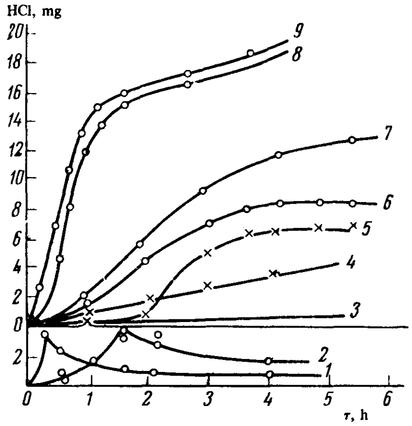


Figure 5. Kinetics of the dehydrochlorination of triphenylstannylpoly(vinyl chloride) (SPVC): 1) 0.05 g of SPVC, bound HCl; 2) 0.05 g of SPVC, free HCl; 3) mixture of 0.05 g of SPVC and 1 g of PVC, bound HCl; 4) mixture of 0.05 g SPVC and 1 g of PVC, free HCl; 5) 0.05 g of SPVC, total HCl; 6) 0.05 g of PVC, free HCl; 7) mixture of 0.05 g of SPVC and 1 g of PVC, total HCl (experimental); 8) 1 g of PVC, free HCl; 9) mixture of 0.05 g of SPVC and 1 g of PVC, total HCl (calculated).

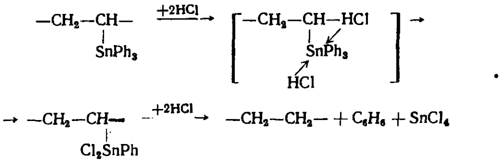
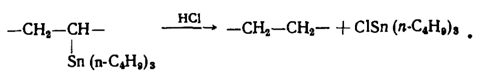
According to the mechanism adopted by the authors, substituents at the tin atom are not split off one by one but in pairs: initially the two phenyl groups and then the third phenyl group and the polymer chain together; the intermediate formation of a hexacoordinate complex with tin is postulated:



$$-CH_2-\underset{SnPh_3}{CH}- \xrightarrow{+2HCl} \left[\begin{array}{c}-CH_2-CH-HCl\\ SnPh_3\\ HCl\end{array}\right] \rightarrow -CH_2-\underset{Cl_2SnPh}{CH}- \xrightarrow{+2HCl} -CH_2-CH_2- + C_6H_6 + SnCl_4$$

However, the analogous reaction of tri-n-butylstannated poly(vinyl chloride) with dry hydrogen chloride takes place in virtually only one stage with formation of tri-n-butyltin chloride and polyethylene [52]:

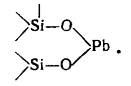


$$-CH_2-\underset{Sn(n\text{-}C_4H_9)_3}{CH}- \xrightarrow{HCl} -CH_2-CH_2- + ClSn(n\text{-}C_4H_9)_3 \,.$$

Since it is known that alkyl substituents are split off from the tin atom with greater difficulty than aryl substituents and the difficulty increases with increase in their chain length, it is understandable why phenyl groups are split off before the polymer chain, whereas in the case of butyl substituents such a sequence no longer holds. The overall study of the reactions of triphenyl and tri-n-butyltin derivatives of poly(vinyl chloride) with hydrogen chloride enabled the authors to make certain conclusions concerning the mechanism of the stabilisation of poly(vinyl chloride) by low-molecular-weight organotin compounds [30].

In conclusion of the section dealing with polymers metallated by heavy metals, the following point may be noted. There is no doubt that in the step involving the stabilisation of any polymer by compounds of heavy metals the latter are incorporated in the chain. Thus it was shown recently [53] that the basic lead sulphates $PbO.PbSO_4$, $3PbO.PbSO_4.H_2O$, and $4PbO.PbSO_4$ enter into complex formation reactions with the double bonds of poly(vinyl chloride), which appear in the latter on heating, and this leads to a weakening of the colour of the polymer owing to the breakdown of the double bond conjugation chain. It was noted that the introduction of various metal compounds into polymers, for example polyorganosiloxanes, significantly lowers the rate of their depolymerisation and decomposition. Therefore it was suggested that various metal compounds be introduced into polymer compositions; studies of this kind are listed in detail in a review by Balykova and Rode [54].

Thus Rafikov and coworkers [55] showed that the stabilising effects of titanium and iron acetylacetonates, alkoxyacetylacetonates, and also oxides on the thermal degradation of polydimethylsiloxane is due to their reaction with macromolecular chains, which leads to the formation of new high-molecular-weight compounds with metal atoms in the siloxane chain. Basic cerium acetylacetonate probably reacts with the terminal groups of the siloxane chains, forming new –Ce–O–Si– bonds [56]. The effect of many metals (metal oxides) on the thermal stability of polyalkylarylsiloxanes and their resistance to thermal oxidation has been demonstrated by Atkins et al. [57], who suggested that the treatment of the polymer with PbO leads to the formation of structures of the type



The interaction with salts, oxides, or alkoxides of metals of different Groups in the processing of polymers may be regarded as similar examples of the metallation of polymer chains: thus crystals, mainly of basic salts, insoluble in the rubber are formed in carboxylate rubbers obtained by the copolymerisation of butadiene with acrylic acids and in vulcanisation by divalent metal oxides or hydroxides [58]; the list of examples of this kind may be extended.

Whereas the polymeric derivatives of light metals can find application in the introduction into the chain of a wide variety of functional groups for the purpose of extensive chemical modification of polymers, polymeric derivatives of heavy metals are of course much less suitable for this. Therefore the number of studies on chemical reactions with participation of heavy metals is also significantly smaller. Almost all the investigations of polymer derivatives of heavy metals described in the literature deal mainly with problems of polymer stabilisation in one form or another.

IV. TRANSITION METAL COMPLEXES WITH MACROMOLECULAR LIGANDS

Two fundamentally different classes of macromolecular complexes are known [59]. Macromolecules the main chain of which contains the metal and fragments when the latter is eliminated may be obtained by the polycoordination of polyvalent ions to polydentate low-molecular-weight ligands. Regardless of the type of ligand, polymeric complexes of this kind are called polycoordination polymers; they have been extensively described by Marvell, Korshak, Vinogradova and coworkers, Baylar, Berlin, and others [60].

Macromolecules containing the metal in side chains can be prepared by the coordination of transition metal ions to macromolecular ligands already synthesised; in this case the metal can be readily removed or replaced by another without the breakdown of the main chain of the macromolecule. Polymeric complexes of this type, which will henceforth be referred to as complexes with macromolecular ligands, include in fact also the ion-exchange resins capable of the formation of chelates; the latter were investigated by Sansoni, Hering, and others [61].

In principle, all the complexes with macromolecular ligands discussed in the literature were obtained by the reaction of the complex-forming groups of the macromolecule with metal ions [59]. The few investigations in which a complex in the finished form, for example an acid metal-complex dye, are introduced into a poly(vinyl alcohol) [62] or Wofatit matrix [63], are an exception.

The reactivity of complexes with macromolecular ligands of various types is determined by the fact that both the metal–ligand bonds and the polymeric ligands can take part in chemical reactions.

1. Reactions with Participation of the Metal–Ligand Bond

The reactivity of the metal–macromolecular ligand coordinate bond is shown in the catalysis of a number of organic and inorganic reactions, in its participation in the so called ligand exchange reactions, and also redox reactions with participation of complexes having macromolecular ligands.

Usually the problem of the effect of the ligand on the reactivity of the M–L bond is treated as the effect of the coordination with the ligand on the catalytic activity of M^{n+}. The nature of the ligand is known to have a significant influence on the catalytic properties of the metal ions; a particularly marked influence is observed for enzymes and their models [64]. The nature of the ligand can influence not only the reactivity of the metal-containing catalyst but also the mode of the reaction catalysed[65]. An explanation of the causes of the effect of the ligand on the catalytic properties of the complexes, including polymeric complexes, should be sought in the effect of several factors. The nature of the M–L bonds affects the donor–acceptor properties of the metal ion: an increase in the amount of ionic character of this bond entails an increase in the electron-accepting and a decrease in the electron-donating capacity of the metal; the formation of dative $M \rightarrow L$ bonds increases the charge of M, increasing thereby its electron-accepting capacity. It may be that in some cases ligands participate in the catalytic process itself. Thus in oxidation–reduction reactions there is a possibility of electron transfer via a ligand bridge; in some cases the coordinated ligands may form hydrogen bonds with the solvent, influencing thereby the mutual orientation of the reactants[65].

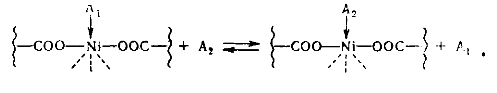
An attempt was made to employ complexes with ion exchangers (for example, resins based on polystyrene) containing iminodiacetic acid groups[66] as heterogeneous catalysts. The authors think that the advantages of using polymeric complexes for catalysis compared with low-molecular-weight complexes consist in the ease of separation of the catalyst from the reaction medium and, what is more important, in the fact that during the catalytic reaction very low but constant concentrations of metal ions in equilibrium with the polymeric complex are established:

$$\sim[fM] \rightleftarrows \sim[f^{n-}] + [M^{n+}]\ .$$

A review has already been devoted to the problem of using macromolecular complexes as heterogeneous catalysts for chemical reactions[67]. On the whole, one may conclude that, although certain macromolecular complexes do in fact show an enhanced catalytic activity compared with their low-molecular-weight analogues, nevertheless the employment of heterogeneous catalysts of this type is greatly impeded by diffusion phenomena, the inhomogeneity of the composition of the ligand, the non-uniform content of the metal, and similar factors complicating the study of the process.

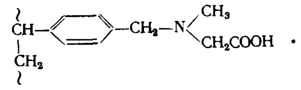
The capacity of such complexes to exchange ligands, which is based on the use of coordination vacancies in the transition metal incompletely saturated by the polymeric ligand, may be regarded as one of the effects of the reactivity of the metal–macromolecule coordinate bond.

Helfferich[68] was virtually the first to use for ligand exchange acidic cation exchangers in the nickel-form. Subsequently Latterel and Walton[69] showed that the nickel-forms of ion exchangers with carboxylic acid residues may be employed to separate many amines (A_1 and A_2):



Siegel and Degens[70] isolated aminoacids from their mixtures with the aid of sorption–desorption on the copper chelate complex of Chelex 100,[100] which consists of a polystyrene matrix with iminodiacetic acid groups. They also examined the reactivity of the Fe^{3+}-, Co^{2+}-, Ni^{2+}-, and Zn^{2+}-forms of Chelex 100 in relation to the sorption of amines, phenols, and also purine and pyrimidine bases, unsaturated hydrocarbons, sugars, peptides, humic acids, and other interesting natural compounds.

Hering and Heilmann[71] separated quantitatively glycine and β-alanine on poly-*N*-(*p*-vinylbenzyl)-*N*-methylaminoacetic acid in the nickel- and copper-forms (other metals were also employed):



Rogozhin and Davankov[72] obtained dissymetric complex forming ion-exchange sorbents of similar structure with optically active α-aminoacid groups. In many cases it proved possible to achieve a quantitative separation of the optical isomers by the chromatography of the ligands on these sorbents in the presence of complex-forming metal ions. Since their separation is based on stereoselective effects in the complex formation process, this method is an example of a new principle of the cleavage of racemates[72]. The sequence in which the ligands emerge from the chromatographic column is directly related to the stability of the complexes formed by them with participation of the stationary polymeric ligand. Therefore chromatography of the ligands may be employed in the study of the kinetics of labile mixed complexes[73].

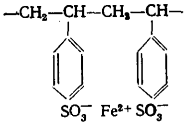
We shall consider in greater detail how the reactivity of complexes with macromolecular ligands is reflected in their redox properties. All metal-containing redox polymers are obtained by combining a polymeric matrix with specific substances capable of oxidation and reduction. Three main classes of such compounds are distinguished[61], the coupling of which to the matrix involves (1) the formation of covalent bonds and is thus essentially irreversible, (2) the coupling is to some extent reversible and can involve some form of complex formation, (3) the substance being an oxidising or a reducing agent is linked to the polymeric matrix by adsorption forces, via the formation of clathrate compounds, etc. Since in the last class of compounds the metal atoms are linked to the polymer chain by forces weaker than those of covalent or coordinate bonds, we shall consider only the first two classes of metal-containing redox polymers.

By combining ferrocene with diazotised poly-*p*-aminostyrene, Sansoni and Sigmund[74] obtained a polymer the apparent normal potential of which is 0.415 V and the redox capacity is 5.4 mequiv. g^{-1}. Fe^{II} and Fe^{III} polyvinylferrocenes have been reported[75]. Arimoto and Haven[76] oxidised the polymer (molecular weight of the order of 50 000) by suspending it in a solution of cerium sulphate, the polymer being gradually converted into a water-soluble pale blue Fe^{III} form, which can be reduced by any reducing agent to an insoluble yellow form containing iron(II). Partially sulphonated polyvinylferrocene is soluble in water and may be oxidised but the sulphonated molecule is unstable in the oxidised state and rapidly loses iron ions. Sansoni and Sigmund's ferrocene polymers[74] constitute essentially an example of the irreversible binding of a molecule with redox properties to a polymer already synthesised.

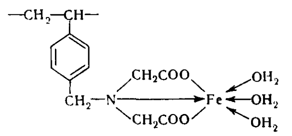
Examples of the formation of polycoordination compounds with the aim of synthesising redox polymers having reversible properties may be found in studies in which ion-exchange resins were saturated by inorganic cations. Thus Sansoni[74] also obtained oxidation–reduction cation exchangers by saturating Amberlite IR-120, Dowex-50, and Wofatit by the following redox systems: Fe^{2+}/Fe^{3+}, Sn^{2+}/Sn^{4+}, Ce^{3+}/Ce^{4+}, and Ti^{3+}/Ti^{4+}. Mills and Dickenson treated Duolite A-3 with a solution of copper sulphate until the resin became completely saturated and then with an excess of sodium hydrosulphite until the complete reduction of copper ions to the metal.

Similarly silver ions on Duolite A-2 resin were reduced by the same reagent to metallic silver; after such treatment the resin reacts with oxygen and eliminates it from liquid media[77].

M^n/M^{n+1} redox systems fixed in a suitable manner in a macromolecular matrix (the so called redoxites) or linked ionogenically to the ion-exchange resin (the so called redox ion exchangers) are of significant interest for preparative and analytical chemistry, since, when they are employed, the reduced (oxidised) substances are not contaminated by the reduction product of the reducing (oxidising) agent. The industrial application of systems of this kind was hindered for a long time by the fact that the usual reducing agents (Fe^{2+}, Sn^{2+}, and others) do not exhibit a high reducing capacity on ion-exchange resins. Hering[78] was the first to use for complex formation at a polymeric level the principle, familiar from inorganic chemistry, of a change in the redox potential of the metal ion following the addition of complex-forming agents or following a change in the pH (which in most cases is also explained by the formation of complexes with hydroxide ions). The formation of complexes of macromolecular ligands with metal ions can result in the formation of both reducing and oxidising agents, the reactivity of which greatly exceeds that of the free metal ions. We may quote a specific example of a change in the normal redox potential of the Fe^{2+}/Fe^{3+} system when it is combined with a resin containing iminodiacetic acid groups. According to Hering[78], the reducing capacity of Fe^{2+} increases markedly when the iron ions are not fixed on strongly acidic cation exchangers, which are capable of binding Fe^{2+} only in the ionic form, such as, for example,



but on resins of the type of Dowex-A-1 or Dowex-50W which are capable of complex formation:



The Fe^{2+}/Fe^{3+} oxidation–reduction system, the normal potential of which is +0.78 V, is known to be a weak oxidising agent. The normal potential of the Fe^{2+}/Fe^{3+} system on a resin containing iminodiacetic acid groupings may be calculated from the Nernst equation:

$$E = E_0 + RT/nF \lg C_{ox}/C_{red} = +0{,}78 + (0.058 \cdot \lg 10^{-11}/10^{-6}) = +0.49\text{v}.$$

It is evident from the data presented that, when a polymeric matrix is employed, the weakly oxidising Fe^{2+}/Fe^{3+} system becomes a powerful reducing agent. The fact that the reducing capacity of the Fe^{2+}-form of the iminodiacetic acid resin is sufficient to reduce the oxygen dissolved in water merits particular attention[78]. When Ag^+ ions form complexes with the same Dowex-A-1 resin, the normal oxidation–reduction potential of the Ag^0/Ag^+ system shifts to positive values; thus the Ag-form of Dowex-A-1 resin is a more powerful oxidising agent than the Ag^0/Ag^+ system.

2. Reactions of a Coordinated Macromolecule

Little information has been published about the reactions of a coordinated macromolecular ligand, but the reactivity of coordinated low-molecular-weight compounds has now been investigated fairly widely. Thus there is a large number of specific examples of the effect of coordination on the reactivity of molecules, for example bidentate singly-charged ligands such acetylacetone, acetoacetic ester, aminoacid esters, salicylaldimines, etc. have been quoted in a review by Jones and Connor[79].

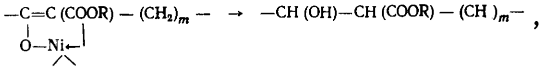
Since coordination leads to a redistribution of electron density in the ligand molecule and to a change of interatomic distances and valence angles, which entails a change in the polarity and strength of the bonds, it follows naturally that in the general case it cannot fail to influence the reactivity of the ligand. It is known that coordination usually, if not always, weakens the bonds (frequently those adjoining the coordinate bond) within the molecule and lowers the frequencies of the corresponding stretching vibrations. Such decrease of the frequency $\Delta\nu$ is determined by the acceptor capacity of the complex-forming cation, which is confirmed by the observed parallel variation of $\Delta\nu$ and the electron-accepting properties of cations, determined by an independent procedure[80]. During complex formation, coordination via the interaction of the unpaired electrons of the ligand and the free orbitals of the metals shifts the electron density of the ligand towards the metal, as a result of which the ligand becomes more electrophilic. The situation becomes more complicated when dative interaction with the reverse transfer of negative charge to the ligand contributes appreciably to the formation of the $M \rightarrow L$ bond; in the formation of such an $M \leftarrow L$ bond the effect of coordination extends to a large number of electrons and the antibonding orbitals of the ligand are involved in the binding, which entails a weakening of the bonds in the ligand.

Siling and Gel'bshtein[65] quote the following references concerning the reactivity of ligands in complexes: (a) data on the chemical reactions of coordinated organic molecules (see, for example, Jones and Connor[79]); (b) infrared spectroscopy (see, for example, Nakamoto[80]); (c) data on the acid dissociation constants of the complexes and free ligands (see, for example, Grinberg[81]); (d) data on catalytic activity in reactions with participation of coordinated organic molecules (see, for example, Langenbeck[82]) or macromolecules[67].

The first attempts at investigation of the reactions of a coordination macromolecular ligand dealt with transesterification and hydrogenation. A study of the transesterification kinetics of acetoacetic ester and its copper complex showed[83] that transesterification with butanol takes place in both polar and non-polar solvents; the rate constants for the reaction and the activation energies and entropies were determined. However, the polymeric ligand (I) and the copper complex obtained on its basis have very low reaction rates.

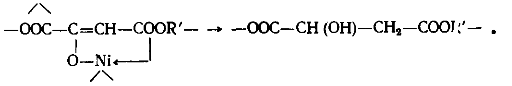
The hydrogenation of polymeric ketoesters on a Raney nickel catalyst may be quoted as an example of reactions of a coordinated macromolecule which take place more effectively.

It has been shown[85] that macromolecular ligands of the β-ketoester type (I and II) can undergo hydrogenation in the coordinated (Ni^{2+}) state, being converted into poly-β-hydroxyesters; the reaction takes place with liberation of Ni^{2+} ions, probably in consequence of the breakdown of the resonance in the quasiaromatic ring of the coordination centre:



(I)

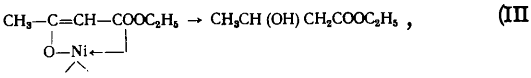
$$-C{=}C(COOR)-(CH_2)_m- \rightarrow -CH(OH)-CH(COOR)-(CH\,)_m- ,$$



(II)

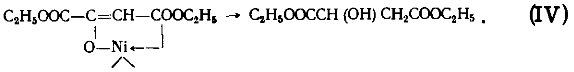
$$-OOC-C{=}CH-COOR'- \rightarrow -OOC-CH(OH)-CH_2-COOR'- .$$

Nickel complexes of acetoacetic ester [complex (III)] and oxaloacetic ester [complex (IV)], which may be regarded as low-molecular-weight analogues of the macromolecular complexes (I) and (II), also enter into the hydrogenation reaction with formation of β-hydroxybutyric and malic acid esters[86]:



(III)

$$CH_3-C{=}CH-COOC_2H_5 \rightarrow CH_3CH(OH)CH_2COOC_2H_5 ,$$



(IV)

$$C_2H_5OOC-C{=}CH-COOC_2H_5 \rightarrow C_2H_5OOCCH(OH)CH_2COOC_2H_5 .$$

It has been established that the hydrogenation of complexes (I)–(IV) under asymmetrising Akabori conditions (Raney nickel catalyst subjected to preliminary modification by an asymmetric compound) leads to optically active reaction products (Table).

Asymmetric hydrogenation of coordinated ligands of the ketoester type.

Initial ketoester and polyketoester complexes	Modifying agent (0.5 h, pH 5.1, 0°C)	Yield of hydroxy-ester or polyoxy-ester, %	$[\alpha]^{20}_{589}$
$(CH_3COCHCOOC_2H_5)_2Ni$	—	95	0.0
	L-glutamic or (+)-tartaric acid	92	—2.0
	—	100	0.0
$[-(CH_2)_m-COCH(COOC_2H_5)]_2Ni$	L-glutamic or (+)-tartaric acid	96	+1.2
	—	100	0.0
$(C_2H_5OOCCOCHCOOC_2H_5)_2Ni$	L-glutamic acid	98	—1.3
	—	100	0.0
$(-OOCCOCHCOOR')]_2Ni$	L-glutamic acid	92	+8.6

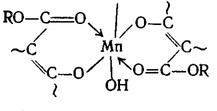
It may be supposed that in the hydrogenation of nickel complexes by hydrogen under pressure at an elevated temperature the initial complex breaks down with simultaneous (or subsequent) coordination of the substrate containing groups capable of chelation to the surface of the heterogeneous catalyst; this results in the formation of an intermediate mixed substrate–metal–modifying agent chelate. Such fixation of the conformation of the transition state and the steric limitation of the accessibility of unsaturated bonds to hydrogen lead to preferential formation of one of the optical isomers of polyoxyesters and hydroxyesters[87]. On the other hand, the hydrogenation of copper complexes of poly-β-ketoesters or acetoacetic ester does not lead to identified reaction products, only the decomposition of the complexes with liberation of the metal on the surface of the catalyst is observed[88]. The use of synthetic polymers as carriers for the active phase of the catalyst for non-stereospecific hydrogenation has been described by Sokol'skii and coworkers[89]. Thus palladium and platinum were deposited on poly(ethylene terephthalate) to be used subsequently in the hydrogenation of unsaturated alcohols (the reactivity of catalysts of this kind increased by a factor of 5–6 compared with palladium black). We attempted to employ the products of the asymmetric hydrogenation of (I) and (II) (above) as polymeric modifying agents in asymmetric induction from polymer to polymer[84]. It was shown that, like the Akabori catalyst[90], the metal-containing polymeric catalyst exhibits a definite stereospecific control in the hydrogenation of polymeric ketoesters.

In conclusion of the section on the synthesis of complexes with macromolecules and their chemical reactions, we may note that certain difficulties arise in the interpretation of these processes.

The steric factor plays an important role in the formation of complexes with macromolecules and their reactions. To calculate the energy of formation of low-molecular-weight complexes, formulae are employed in which account is taken of the radius of the complex-forming ion and the ligand[91] and it is assumed that the ligands approach closely the metal ion. On the other hand, in the formation of complexes with macromolecular ligands, the metal ions cannot in all cases approach the ligand owing to its large dimensions and the wide variety of its conformations. The so called critical ratios of the radii r_M/r_L or r_L/r_M make it possible to infer for low-molecular-weight compounds the highest coordination number n allowed by given steric factors[91], whereas for macromolecular ligands it is not always clear what value of r_L should be adopted.

A characteristic feature of a low-molecular-weight complex is a rigorous geometrical disposition of the functional groups of the ligand relative to the metal. On the other hand, for polymeric complexes the geometrical and stoichiometric relations may be significantly altered, which of course entails a change in the reactivity of both the coordinate metal–ligand bond and of the coordinated macromolecule. In polymeric complex compounds there is a possibility of the formation in the same macromolecule of coordination centres of various symmetries, frequently extremely strained, and, as shown by Tolmachev and coworkers[92], with various magnetic characteristics. Moreover, in complexes with bi- and poly-dentate macromolecular ligands part of the metal ions may be held by the usual Coloumbic forces without forming a coordinate bond and frequently retaining their counterions or forming 1 : 1 coordination centres (for example, instead of 1 : 2), such cases being quoted by Marinsky and coworkers[93] for the polymeric analogues of iminodiacetic acids.

A coordination number $n = 6$ is known to obtain usually for complex-forming metals. When 1 : 2 coordination centres are formed with macromolecular bidentate ligands, the residual vacancies in the complex-forming ion may be saturated, for example, by solvent molecules or by other ligands (the ligand exchange quoted above is based on this principle, p. 1089). As an example of the formation of a mixed macromolecule–metal–solvent complex, we may quote the coordination centre of the manganese complex of a poly-β-ketoester[59]:



Naturally the degree of coordination unsaturation of the centres cannot fail to influence significantly the reactivity of the given class of polymeric compounds.

Even these few examples show that the concepts adopted in the chemistry of low-molecular-weight complexes may be extended to macromolecular objects only when account is taken of the fine structure of the macromolecular ligand and the polymeric complex formed from it. Therefore one of the tasks at the present stage of the investigation of the synthesis and chemical reactions of complexes with macromolecules is the accumulation and systematic arrangement of factual data in order to discover the specific features of this field.

V. FACTORS DETERMINING THE PROPERTIES OF VARIOUS TYPES OF POLYMER–METAL BONDS

To estimate the reactivity of any type of compounds, the following procedures have been employed[94]: (a) examination of various charge densities, bond orders, bond polarisibilities, etc. (b) determination of the energies of the reactants and the transition state. Only the second procedure is valid, since any treatment without taking into account the transition state is not sufficiently precise. Nevertheless up to the present time the procedure involving a comparative semiquantitative estimation of the reactivities of various compounds is still mainly used in the chemistry of organometallic compounds.

In discussions of the problems of the reactivity of organometallic compounds attention is concentrated on the behaviour of the C–M bond. Although the understanding of the nature of this bond is in fact most important for the understanding of the properties of the organometallic compound, other factors also play a certain role. These include certain steric characteristics of the organic substituent, the possibility of intra- and inter-molecular coordination with participation of the metal, effect of the solvent employed, etc.[94] These factors of course play a significant role also for polymeric organometallic compounds in which the multiplicity of chain conformations, solvation of the macromolecules, and interchain coordination may actually become of decisive importance in a particular reaction. To assess the properties and reactivities of organometallic compounds, the concept of electronegativity is sometimes employed[95]; nowadays it is believed that this criterion is neither a qualitative nor a quantitative characteristic of the chemical bond[96].

The main common factors determining the reactivity of organometallic compounds with a metal–carbon σ-bond, including polymeric organometallic compounds, are the nature of the metal and the stability of the organic cryptocarbanion.

One of the procedures whereby the nature of the metal–carbon bond in organometallic compounds may be inferred consists in the determination of the effective charges of the linked atoms. The effective charges may be calculated from the X-ray absorption spectra and frequently dipole moments are adduced to assess the effective charges and the electronegativities; sometimes the effective charges are determined from the ratio of the bond moment to the product of the elementary charge and the bond length[96]

Various methods have been employed to elucidate the problem of the relative stabilities of the carbanions of saturated low-molecular-weight hydrocarbons[97]. Thus the equilibria $RX + R'M \rightleftharpoons RM + R'X$ or $RMg + R'Hg \rightleftharpoons RHg + R'Mg$ have been investigated; a polarographic scale has been proposed for the determination of the CH acidity from the equation $\alpha E_{1/2} = f(pK_a)$ and the equilibrium ionisation constant of the CH acid has been used to assess the relative stability of the corresponding carbanion[97]. On the whole, one may assume that the higher is the acidity of the hydrocarbon, the greater the concentration of the charge in the corresponding carbanion, and the lower the nucleophilicity of the corresponding organometallic compound.

Unfortunately no studies on the determination of the effective charges of metals in polymeric metal-containing compounds or on the determination of the stability of macromolecular carbanions are described in the literature.

In the general case there are two limiting possibilities in the formation of bonds in complex compounds[98]: (a) formation of covalent bonds by utilising the unshared pairs of, for example, an oxygen-containing ligand; when two electrons are delocalised to an equal extent between two atoms, for example O and M, a negative charge is transferred to the metal (so that its resultant charge may actually become negative) with formation of a positive charge at the oxygen atom; (b) the ligand molecules are held around the metal ion by ion–dipole interaction forces only.

The true position for both low-molecular-weight and macromolecular complexes is intermediate between these two limiting mechanisms and in molecules of complex compounds the metal–ligand bond is to some degree covalent with unequal sharing of the electrons.

It is known[98] that the majority of transition metal complexes are of the type ML_4 or ML_6; the first usually has a square or tetrahedral form and the complexes of the second type are almost always octahedral (in polymeric complexes these postulates may not in fact hold, see p. 1091).

When a non-transition metal forms an octahedral complex, for example SnR_4X_2 by the reaction of triphenylstannated poly(vinyl chloride) with hydrogen chloride (p. 1088), the metal (tin) utilises one *s*, three *p*, and two *d* orbitals of the valence shell from which six sp^3d^2 hybrid orbitals oriented along the three coordinate axes are formed. In the formation of an octahedral transition metal complex, a similar hybridisation takes place, but here the *d* orbitals of the inner shell are employed. Thus, in the transition metals of the First Period (iron, nickel cobalt, and manganese), d^2sp^3 hybridisation involves only two 3*d*, one 4*s*, and three 4*p* orbitals. Many characteristic features of transition metal complexes are due precisely to the fact that a metal atom still has residual 3*d* orbitals not participating in the hybridisation and formation of valence bonds.

One may assume that the reactivities of both organometallic and complex compounds, including macromolecular complexes, are determined by the same factors—the nature of the metal and the nature of the organic component of the molecule. Probably, the most striking feature of the properties of coordination compounds is the coordination unsaturation of the metal due to the 3*d* or 4*f* vacant orbitals, as already stated above.

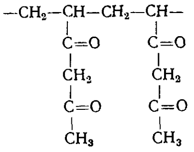
VI. CHARACTERISTICS OF THE CHEMICAL REACTIONS OF METAL-CONTAINING MACROMOLECULES DUE TO THEIR POLYMERIC NATURE

The field of chemical reactions in polymer chains is not at the present time simply the field of the synthesis of new macromolecular compounds which are difficult or even impossible to obtain by the polymerisation or polycondensation of low-molecular-weight substances. It is closely related to the problem of the reactivity of macromolecules and goes far beyond the framework of the concepts applied to it in the classical scheme of the individual branches of the chemistry of macromolecular compounds.

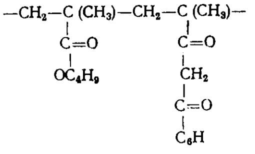
We shall examine the effect of the macromolecular nature of polymeric metal-containing compounds on their reactivity, following the classification of the characteristics of the reactions involving polymers proposed by one of the authors [99].

As already stated on p. 1085 the chemical modification of a polymer chain by substitution of lithium leads to the possibility of ionic grafting of a number of monomers on polylithiopolyethylene and polylithiostyrene. The study [100] of the kinetics of the anionic polymerisation of styrene and isoprene on these macromolecular initiators showed that in polar media the rate of polymerisation is higher than in the presence of the corresponding low-molecular-weight initiator (butyl-lithium): for the polymerisation of styrene on polylithiopolystyrene (PLPS), the ratio of the effective rate constants for chain propogation $k_{\mathrm{PLPS}}/k_{\mathrm{C_4H_9Li}}$ is 2.5 at 25°C and 3.9 at 10°C. The increase of the rate of polymerisation of styrene initiated by the macromolecular initiator ("live polystyrene") may be accounted for as due to the effect of the association of the growing polystyrene chains via intermolecular interaction between them, since they are formed in the immediate vicinity of one another owing to the presence of active centres in the same chain of the lithium-substituted polymer. In the microphase comprising such growing polymer chains the local concentration of the monomer may prove to be higher than its average concentration in the bulk phase (the concentration effect); the reaction takes place within such aggregate, which exhibits an enhanced selective permeability in relation to monomer molecules [16]. The effect of the polymeric nature of the system to be metallated influences the substitution of lithium in polystyrene compared with its low-molecular-weight analogue (toluene) [17] (p. 1083). In this case the so called chain effect is of decisive importance, namely the steric inaccessibility of the benzyl position in the polystyrene chain.

The formation of complexes between macromolecular ligands of the poly-β-diketone type with 3*d* transition metals is convenient for the demonstration of the change in the reactivity of a functional group owing to the chain effect. It was found that the effectiveness of the formation of coordination centres depends on the distribution of the complex-forming groups in the chain. Thus Fig. 6 shows the effectiveness of the binding of Ni^{2+} (expressed as a percentage) for two polymeric ligands: ligand (I) obtained by the polymerisation of methyl vinyl ketone with simultaneous acetylation and containing diketone groups in each unit and ligand (II) obtained by the ester condensation of poly(butyl methacrylate) with acetophenone and not necessarily containing diketone groups in each macromolecular unit:



$-CH_2-CH(COCH_2COCH_3)-CH_2-CH(COCH_2COCH_3)-$ (I)



$-CH_2-C(CH_3)(COOC_4H_9)-CH_2-C(CH_3)(COCH_2COC_6H)-$ (II)

In the polymeric ligand (I) only 45% of the functional groups are employed for the binding of Ni^{2+} and this proportion remains constant regardless of the excess of Ni^{2+} ions in the medium [99]. On the other hand, in the polymeric ligand (II) up to 70% of the complex-forming groups are employed; in the presence of a small excess of ions the effectiveness of complex formation is low but increases with the concentration of the metal in solution.

Examination of the Stuart–Briegleb models shows that in the given case the chain effect is shown by the steric hindrance to the complex-formation process; with low-molecular-weight analogues, all the functional groups of the ligand are of course employed in the formation of the complex.

The chain effect was shown fairly notably in a comparative study of the stabilities (β_2) of the poly-β-ketoester (I) and acetylacetonate (II) complexes of the same metals [101]:

$\lg\beta_2$ for (I)	$\lg\beta_2$ for (II)	$\lg\beta_2$ for (I)	$\lg\beta_2$ for (II)
Mn^{2+} 7.10	Mn^{2+} 10.50	Ni^{2+} 7.55	Ni^{2+} 13.50
Co^{2+} 7.35	Co^{2+} 12.60	Cu^{2+} 8.00	Cu^{2+} 18.40

The defectiveness of the coordination centres formed, the distortion of the geometry of the coordination centres, and mixed complex formation with participation of the solvent (p. 1091) all lead to a greater lability of the L–M bond compared with the stoichiometric and geometrically regular acetylacetone complexes. One cannot exclude the possibility that this property of macromolecular and manganese complexes in fact makes them active‡, for example in the polymerisation of butadiene [67]: the corresponding acetylacetonates exhibit only a slight activity under these conditions.

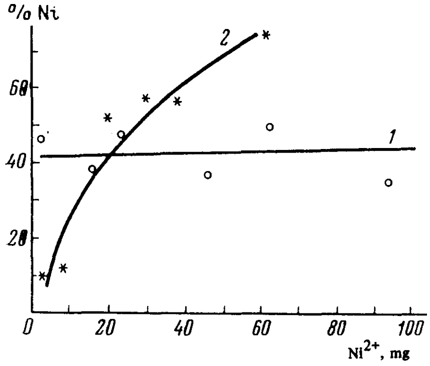


Figure 6. Effectiveness of the binding of Ni^{2+} (%) by polymeric ligands of types (I) (curve *1*) and (II) (curve *2*).

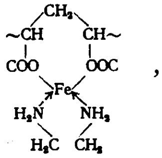
An interesting example of the influence of the concentration effect, which is a direct consequence of the presence of the polymer chain, on the catalytic activity of polymeric complexes in the decomposition of hydrogen peroxide was demonstrated by Kabanov et al. [102] They observed that, by virtue of the local concentration of H_2O_2

---

‡There is of course no direct relation between the thermodynamic stability constant of the complexes and their catalytic activity due to the homolytic splitting of the L–M bond; here it would be more correct to compare the thermal stabilities of the complexes and their activities; however, the K_{st} data presented may also be of definite interest.

in the vicinity of the coordination centres of the mixed iron(II) chelate with poly(acrylic acid) and ethylenediamine,



the catalase activity of the latter exceeds that of the low-molecular-weight analogue (Fe^{2+}, malonic acid, ethylenediamine) by several powers of 10.

The study of the interaction of copper(II) salts and polymethacryloyl-lysine by Moravetz et al.[103] showed that the polymer tends to form complexes even at a comparatively low pH, where the content of the complex in solutions of the monomeric analogue is low. This phenomenon may be understood if each spiral of the ligand macromolecule is regarded as a specific region of a concentrated solution of the polyaminoacid, which for this reason forms complexes effectively independently of the formation of 20-membered rings (the concentration effect). The concentration effect is shown in the fact that the macromolecular ligand behaves apparently as a more powerful complex-forming agent than its low-molecular-weight analogue.

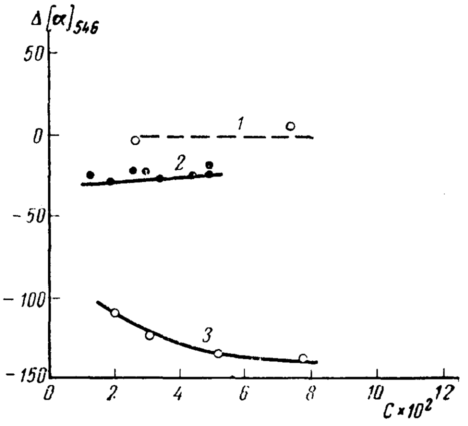


Figure 7. Dependence of the change $\Delta[\alpha]$ of a reaction mixture of triethylenediaminecobalt(III) and a polymeric anion on the concentration of the latter:
1) sodium acetate; 2) sodium polyacrylate;
3) sodium polymethacrylate.

Another consequence of the presence of the polymer chain is the conformation effect. Thus the study of optical rotatory dispersion in a system comprising a polymeric anion (polyacrylate, isotactic, syndiotactic, or atactic polymethacrylate, polyphosphate, polystyrenesulphonate) and an optically active cation $[Coen_3]^{3+}$ or $[Niphen_3]^{2+}$ showed that in such a system the nature of the polymeric ligand is more important. Fig. 7 shows that $\Delta[\alpha]$ falls with increasing polymethacrylate concentration but increases slightly as the concentration of polyacrylate rises, remaining unchanged in the presence of acetate. This is probably associated with different types of metal–polymeric ligand outer sphere interaction, which depends on the charge density along the chain and consequently on the chain–coil conformational transitions[104].

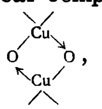
The configurational effect involving a change in the reactivity of the functional groups in the macromolecule compared with the low-molecular-weight ligands may be divided into several subtypes according to Plate's classification[99]. A striking example, where the presence of a group already involved in complex formation next to a free complex-forming group influences (unfavourably) the formation of the next coordination centre along the chain, is provided by the nickel complexes of polyacryloylacetone discussed above (p. 1093) (the so called "neighbour effect").

Another subtype of the configurational effect is shown in the influence of electrostatic interactions in the macromolecule on the rates of chemical reactions and on the equilibrium concentrations of the resulting complexes owing to the additional attraction (repulsion) of the reacting groups. The above example of the reaction of an optically active complex cation and a polyanion shows that not only the nature of the ionised groups but also the degree of their neutralisation is important[104].

Leyte and coworkers[105,106] observed the formation of mononuclear or dinuclear copper complexes in solutions of polymethacrylic acids as a function of the degree of neutralisation of the polymeric ligand; they expressed the binding of the Cu^{2+} by the polymeric acid in terms of the ratio

$$f = \frac{\text{equivalent concentration of ionised polymeric acid}}{\text{equivalent concentration of } Cu^{2+}}$$

When the charge of the polyelectrolyte was low ($f = 1.3$), the formation of the dinuclear complexes



in which, as in copper acetate, copper ions form a structure with D_{4h} symmetry having two polymeric ligands along the C_4 axis, was demonstrated with the aid of spectroscopic and static magnetic data.

With increase of the charge of the polyanion to $f = 3.3$, the dinuclear complexes dissociate into mononuclear species in which the central ion is surrounded in a distorted octahedron by polymeric ligands with negative charges. It is interesting that an analogous relation between the nature of complex formation with copper and the degree of neutralisation of a macromolecular ligand was observed by Japanese investigators[107] for polyglutamic acid.

The influence of different microstructures of the polymer chain on the rate of a chemical reaction with participation of the macromolecule, as happens in the formation of diastereoisomers in the chemistry of low-molecular-weight organic compounds, may be regarded as yet another consequence of the configurational effect.

The influence of the chain microstructure reduces in principle to the occurrence of a favourable (or unfavourable) disposition of neighbouring units in a transition state of known geometry. Complex-formation reactions with polymeric ligands of the acrylic and methacrylic types, for which there exist reliable methods whereby polymers microtactic to different degrees may be obtained, have been most thoroughly investigated. Moravetz et al.[103] were some of the first investigators to turn their attention to the dependence of the chelating capacity of polymethacrylic acid in relation to copper or magnesium ions on its stereoregularity. They started with the hypothesis that, if complex formation involves neighbouring sections of the chain, the steric configuration of the latter should influence the stability of the complexes formed; on the other hand, when complex formation involves remote COOH groups, the complex formation equilibrium should be relatively insensitive to the configuration of the microligand. It was found that, in relation to Cu^{2+}, the isotactic polymer is three times more reactive than the syndiotactic polymer, whereas in relation to Mg^{2+} the opposite relation obtains:

k_b (isotactic)	k_b (syndiotactic)
13.4—18.0 Cu^{2+} (degree of ionisation 0.5-0.9)	1.6—6.1 (degree of ionisation 0.3-0.9)
9—14 Mg^{2+} (degree of ionisation 0.25-0.75)	15—24 (degree of ionisation 0.25-0.75)

$$k_b = [M_b^{2+}]/[M_f^{2+}](CO\ddot{O})_p\ ,$$

where M_b and M_f are the concentrations of bound (b) and free (f) cations and $(COO)_p$ is the concentration of ionised carboxy-groups in the polymer.

This is in fact understandable since copper ions form complexes with a definite geometry of the coordination centre, which are particularly stable when the ligand is the isotactic polymer, whereas magnesium ions form relatively unstable complexes with a less well defined geometry of the coordination centre; in the latter case the complexes of the syndiotactic polymer are actually somewhat more stable than those with the isotactic polymer.

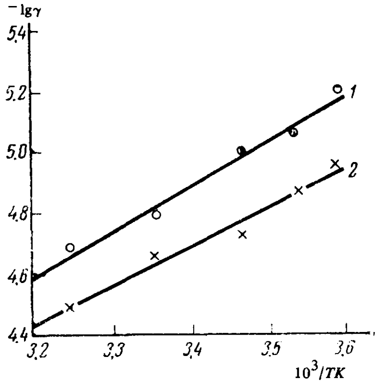


Figure 8. Kinetics of complex formation by isotactic (line *1*) and syndiotactic (line *2*) polymethacrylic acids with Cu^{2+}.

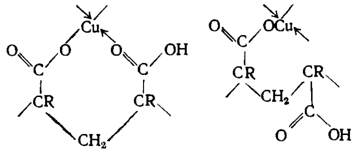
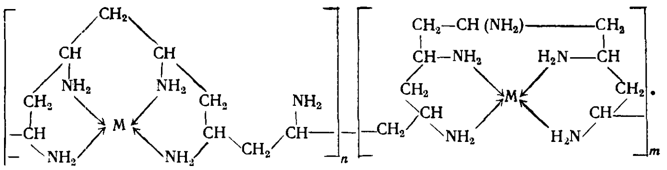
Geuskens et al.[108] re-examined the differences between the reactivities of polymethacrylic acid in relation to copper ions as a function of the microtactic character of the polymeric ligand chain:



Kinetic data show (Fig. 8) that in the temperature range 5–35°C isotactic polymethacrylic acid is more reactive than its syndiotactic isomer: the rate of complex formation involving the first-isomer is higher by a factor of 1.5 than for the second; the activation energies are 6 and 7 kcal $mole^{-1}$ respectively.

The polymeric nature of the macromolecular ligand is shown particularly clearly in the so called "synthetic muscle model"; in the chemistry of low-molecular-weight complexes there are simply no analogues. Teyssie et al.[109] investigated the formation of transition metal complexes of polyvinylamine and obtained complexes soluble in water over a wide range of pH and ionic strengths; with the aid of a wide variety of research techniques, they showed that the formation of complexes with Cu^{2+}, Ni^{2+}, Co^{2+}, and Zn^{2+} greatly influences the dimensions and shape of the polymeric ligand molecules:



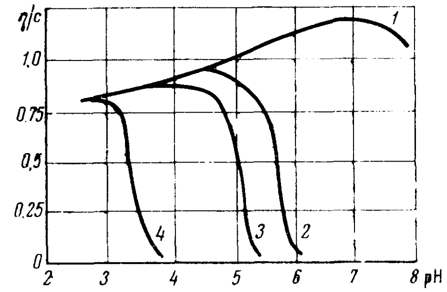


Figure 9. Variation of the viscosity of polyvinylamine solutions in complex formation with transition metal ions: 1) polyvinylamine; 2) Zn^{2+}; 3) Ni^{2+}; 4) Cu^{2+}.

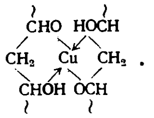
The three condensed cyclic structures produced by complex formation give rise to very powerful contraction of the macroligand molecule, which has been clearly demonstrated by a viscometric technique (Fig. 9). The authors explain the colossal decrease of the viscosity of polyvinylamine solutions in the presence of 3*d* transition metal ions by a change in chain conformation during the complex formation step.

The work of Kuhn et al.[110] provides a still more unusual example of the effect of the polymer chain on complex formation. Employing the principle of reversibly contracting fibres already known from biochemistry, they showed that a partially neutralised and cross-linked copolymer of poly(vinyl alcohol) and polyacrylic acid contracts under the influence of a number of salts (Ca^{2+}, Mg^{2+}, Cu^{2+}) and is reversibly extended in the presence of EDTA; the reversible shift of the system is determined by the presence of the competing ligands poly(vinyl alcohol) and EDTA. We may note here that DNA and RNA nucleoprotein filaments also contract when the above salts are added to the medium and become extended when a suitable complex-forming agent is introduced. The "contracting polymeric systems" of Kuhn[110] operating on the principle of complex formation and oxidation–reduction simultaneously are also extremely interesting. On treatment with Cu^{2+} ions, the gel of poly(vinyl alcohol) swollen in water (100% H_2O and 10% of the polymer) forms a coloured complex with simultaneous intense contraction of the gel fibres (recorded dynamometrically):



If the system is then acted upon by H_2/Pt, the central metal ion is reduced to Cu^+ and the coordination centre breaks down; the gel fibres are decolourised and resume their former dimensions. On the other hand, the effect of O_2/Pt leads to the oxidation of the metal ion to Cu^{2+}, complex formation, and the dyeing and contraction of the gel fibres (Fig. 10).

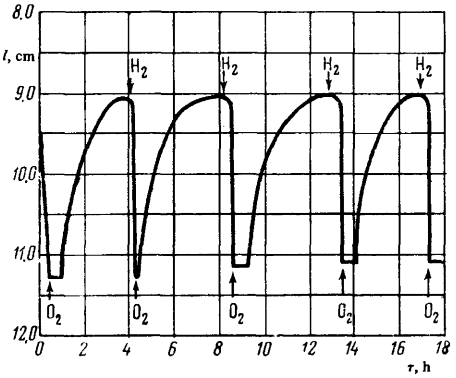


Figure 10. Variation of the length of a poly(vinyl alcohol) fibre on reversible oxidation–reduction in the presence of Cu^{2+} ions.

Kuhn's system has no analogies in the chemistry of low-molecular-weight compounds and is a striking example of the influence of the chain structure on the reactivity of the complex-forming molecule. We may note that Kuhn's system imitates the redox reactions of DNA complexes, for example with Fe^{2+} or Cu^{2+}, where the reduction of central atoms causes a weakening of the bonds between the complementary chains and its oxidation gives rise to the stabilisation of the two-tier conformation of DNA.[111]

All the findings described in this last section show that chemical reactions already known for low-molecular-weight analogues can be achieved on polymeric coordinated and non-coordinated ligands. At the same time the characteristics of the chemical reactions of macromolecules due to their polymeric nature are fairly remarkable, the effect of the polymeric chain on the reactivity of polymeric compounds of this type being most striking.
